After cataract surgery the patient usually has little or no pain but may have some scratchiness or blurriness in the operative eye. Mild analgesics are usually enough to relieve any pain. If the pain is intense, the patient should notify the HCP because this may indicate hemorrhage, infection, or increased IOP. A nursing care plan for the patient after eye surgery (eNursing Care Plan 20.1) is available on the website for this chapter.

Ambulatory Care

Patients with cataracts who have surgery remain in the surgical facility for only a few hours. The patient and caregiver are responsible for almost all postoperative care. Give them written and verbal instructions before discharge. Include the caregiver in the instructions because some patients may have difficulty with self-care activities, especially if the vision in the unoperated eye is poor. Table 20.9 outlines patient and caregiver teaching after eye surgery.

Most patients have little visual impairment after surgery. IOL implants provide immediate visual improvement. Many patients achieve a usable level of visual acuity within a few days after surgery.

TABLE 20.9 Patient & Caregiver TeachingAfter Eye Surgery

Include the following information in the teaching plan for the patient and caregiver after eye surgery:

- Proper hygiene and eye care techniques to ensure that medications, dressings, and/or surgical wound is not contaminated during eye care
- Signs and symptoms of infection (e.g., increased or purulent drainage, increased redness, any decrease in visual acuity) and when and how to report these to allow for early recognition and treatment of possible infection
- Importance of following restrictions on head positioning, bending, coughing, and Valsalva maneuver to optimize visual outcomes and prevent increased IOP
- How to instill eye medications using aseptic techniques and adherence with prescribed eye medication routine to prevent infection
- How to take pain medication and report pain not relieved by medication
- Importance of continued follow-up as recommended to maximize potential visual outcomes

A few patients may have significant visual impairment after surgery. These include patients who do not have an IOL implanted at the time of surgery, those who need several weeks to achieve a usable level of visual acuity after surgery, or those with poor vision in their unoperated eye. For those patients, the time between surgery and receiving glasses or contacts can be a period of significant visual disability. Suggest ways the patient and caregiver can modify activities and the environment to maintain an adequate level of safe functioning. Suggestions may include getting help with steps, removing area rugs and other potential obstacles, preparing meals for freezing before surgery, or obtaining audio books for diversion until visual acuity improves.

If a patch is used, tell patients that they will not have depth perception until the patch is removed. This makes special measures to avoid falls or other injuries necessary. The patient with significant visual impairment in the unoperated eye needs more help while the

operative eye is patched. Some patients may need 1 or 2 weeks for the visual acuity in the operated eye to reach an adequate level for most visual needs. These patients need special assistance until the vision improves.

Evaluation

The overall expected outcomes are that the patient after cataract surgery will:

- Have improved vision
- Be better able to take care of self
- Have minimal to no pain
- Be optimistic about expected outcomes

Gerontologic Considerations: Cataracts

Most patients with cataracts are older. When the older patient is visually impaired, even temporarily, the patient may have a loss of independence, lack of control over her or his life, and a significant change in self-perception. Societal devaluation of the older adult complicates these experiences. The older patient often needs emotional support and encouragement, as well as specific suggestions to allow a maximum level of independent function. Assure the older patient that cataract surgery can be done safely and comfortably with minimal sedation.

Retinopathy

Retinopathy is a process of microvascular damage to the retina. It can develop slowly or rapidly and lead to blurred vision and progressive vision loss. Retinopathy occurs most often in adults with diabetes or hypertension.

Diabetic retinopathy is a common complication of diabetes, especially in patients with long-standing uncontrolled disease.[13] *Nonproliferative*

retinopathy is the most common form of diabetic retinopathy. It is characterized by capillary microaneurysms, retinal swelling, and hard exudates. Macular edema represents a worsening of the retinopathy as plasma leaks from macular blood vessels. As capillary walls weaken, they can rupture, leading to intraretinal "dot or blot" hemorrhaging (Fig. 20.13). A severe loss in central vision can result. As the disease advances, *proliferative retinopathy* may occur. New blood vessels grow, but they are abnormal, fragile, and predisposed to leak, thus causing severe vision loss. (Diagnosis and treatment of diabetic retinopathy are discussed in Chapter 48.)

Hypertensive retinopathy is caused by blockages in retinal blood vessels from hypertension. (Hypertension is discussed in Chapter 32.) These changes may not initially affect a person's vision. On a routine eye examination, retinal hemorrhages, anoxic cotton-wool spots, and macular swelling can be seen. Sustained, severe hypertension can cause sudden visual loss from swelling of the optic disc and nerve *(papilledema).* Treatment, which may be an emergency, focuses on lowering the BP. Normal vision is usually restored by treating hypertension.

Retinal Detachment

A **retinal detachment** is a separation of the sensory retina and the underlying pigment epithelium, with fluid accumulation between the 2 layers. In the patient with no other risk factors who has had a retinal detachment in one eye, the risk for detachment in the second eye is as high as 25%.[14] Most patients with an untreated, symptomatic retinal detachment become blind in the involved eye.

Etiology and Pathophysiology

Retinal detachment has many causes. The most common is a retinal break. *Retinal breaks* are an interruption in the full thickness of the retinal tissue. They can be classified as tears or holes. *Retinal holes* are atrophic retinal breaks that occur spontaneously. *Retinal tears* can

occur as the vitreous humor shrinks during aging and pulls on the retina. The retina tears when the traction force exceeds the strength of the retina. Once the retina has a break, liquid vitreous can enter the subretinal space between the sensory layer and the retinal pigment epithelium layer, causing a *rhegmatogenous* retinal detachment. Risk factors for retinal detachment are listed in Table 20.10.

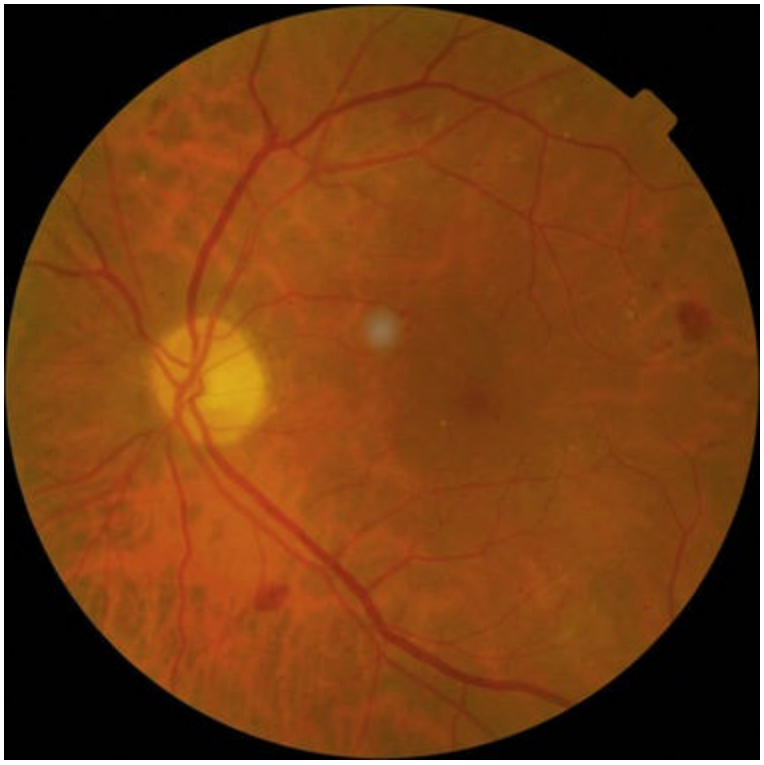

FIG. 20.13 Diabetic retinopathy. Intraretinal dot or blot hemorrhages. Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, TN.

Clinical Manifestations and Diagnostic Studies

Patients with a detaching retina describe symptoms that include *photopsia* (light flashes), floaters, and a "cobweb," "hairnet," or ring in the field of vision. Once the retina has detached, the patient describes a painless loss of peripheral or central vision, "like a curtain" coming across the field of vision.

The area of visual loss corresponds inversely to the area of detachment. For example, if the retinal detachment involves the superior retina, the defect is seen in the inferior visual field. If the detachment is small or develops slowly, the patient may not be aware of a visual problem.

Visual acuity measurements should be the first diagnostic procedure with any report of vision loss (Table 20.11). The HCP can see a retinal detachment using direct and indirect ophthalmoscopy or slit lamp microscopy in conjunction with a special lens to view the far periphery of the retina. Ultrasound may be useful in finding a retinal detachment if the retina cannot be directly visualized (e.g., when the cornea, lens, or vitreous is hazy or opaque).

TABLE 20.10 Risk Factors for Retinal Detachment

- Age
- Cataract surgery
- Eye trauma
- Family or personal history of retinal detachment
- Severe myopia

TABLE 20.11 Interprofessional CareRetinal Detachment

Diagnostic Assessment

- History and physical examination

- Visual acuity measurement
- Ophthalmoscopy (direct and indirect)
- Slit lamp microscopy
- Ultrasound if cornea, lens, or vitreous is hazy or opaque

Management

Preoperative

- Mydriatic, cycloplegic agents
- Photocoagulation of retinal break that has not progressed to detachment

Surgery

- Laser photocoagulation
- Cryopexy
- Scleral buckling procedure
- Vitrectomy
- Intravitreal bubble

Postoperative

- Topical antibiotic
- Topical corticosteroid
- Analgesia
- Mydriatics
- Positioning and activity as prescribed

Interprofessional Care

Some retinal breaks are not likely to progress to detachment. In these

situations, the HCP simply monitors the patient and teaches the patient to seek immediate evaluation if warning signs and symptoms of impending detachment occur. The goals of treatment are to re-attach the retina and seal any retinal breaks. Several techniques are used to meet these goals.

Surgical Therapy

Laser Photocoagulation and Cryopexy

These techniques seal retinal breaks by creating an inflammatory reaction that causes a chorioretinal adhesion or scar. *Laser photocoagulation* involves using an intense, precisely focused light beam to create an inflammatory reaction. The light is directed at the area of the retinal break. *Cryopexy* involves freezing (cryotherapy) the retinal break by placing a probe on the ocular surface at the location of the break. The probe is activated with compressed nitrous oxide gas that temporarily freezes the break. The freeze thaw reaction creates scarring in the area that will seal the break.

For retinal breaks accompanied by significant detachment, photocoagulation or cryopexy may be used intraoperatively in conjunction with scleral buckling. Tears or holes without accompanying retinal detachment may be treated prophylactically with laser photocoagulation or cryopexy if there is a high risk for progression to a retinal detachment. When used alone, laser photocoagulation and cryopexy therapy are outpatient procedures. They usually require topical anesthesia. The patient may have minimal adverse symptoms during or after the procedure.

Scleral Buckling

Scleral buckling is an extraocular surgical procedure that involves placing a band around the globe to move the pigment epithelium, choroid, and sclera toward the detached retina. A silicone implant is sutured against the sclera, causing the sclera to buckle inward. An encircling band may be placed over the implant if there are multiple retinal breaks, if suspected breaks cannot be found, or if there is

widespread inward traction on the retina (Fig. 20.14). If present, subretinal fluid may be drained using a small-gauge needle. This promotes contact between the retina and buckled sclera. Scleral buckling is usually done as an outpatient procedure.

Intraocular Procedures

Intraocular procedures are used on occasion. *Pneumatic retinopexy* is the intravitreal injection of a gas to form a temporary bubble in the vitreous that closes retinal breaks and provides apposition of the separated retinal layers. Because the intravitreal bubble is temporary, this technique is combined with laser photocoagulation or cryopexy. The patient with an intravitreal bubble must position the head so that the bubble is in contact with the retinal break. The patient may need to maintain this position as much as possible for up to several weeks.

Vitrectomy (surgical removal of the vitreous) may relieve traction on the retina, especially when the traction results from proliferative diabetic retinopathy. Vitrectomy may be combined with scleral buckling to provide a dual effect in relieving traction.

Postoperative Considerations

Visual prognosis varies, depending on the extent, length, and area of detachment. After surgery, the patient may be on bed rest and need special positioning to maintain proper position of an intravitreal bubble. The level of activity restriction after retinal detachment surgery varies. Verify the prescribed level of activity with the HCP and help the patient plan for any help needed related to activity restrictions.

The patient may need multiple topical medications, including antibiotics, antiinflammatory agents, or dilating agents. Give prescribed pain medications and teach the patient to take the medication as prescribed after discharge.

In most cases, retinal detachment is an urgent situation, and the patient is suddenly confronted with the need for surgery. The patient needs emotional support, especially during the immediate preoperative period when preparations for surgery can lead to more

anxiety.

The patient may go home within a few hours of surgery or may remain in the hospital for several days, depending on the surgeon and type of repair. Discharge planning and teaching are important and should begin early. Patient and caregiver teaching after eye surgery is discussed in Table 20.11. Because the patient is at increased risk for retinal detachment in the other eye, teach the patient the signs and symptoms of retinal detachment. Promote the use of proper protective eyewear to help avoid damage related to trauma.

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is the most common cause of irreversible central vision loss in people over age 60 in the United States. AMD is classified as dry (nonexudative) or wet (exudative). *Dry AMD* is the more common form, accounting for 90% of all cases. Those with dry AMD often notice that close vision tasks become harder. In dry AMD, the macular cells start to atrophy. This leads to a slowly progressive and painless vision loss.

Wet AMD is the more severe form. It accounts for most cases of AMD-related blindness. Wet AMD has a more rapid onset of vision loss. With wet AMD there is the development of abnormal blood vessels in or near the macula. Many patients with wet AMD have dry AMD first.

Etiology and Pathophysiology

AMD is related to retinal aging. Genetic factors also play a major role, and family history is a major risk factor for AMD.[15] Other risk factors include light-colored irises, high C-reactive protein levels, smoking, and hypertension.

Dry AMD starts with the abnormal accumulation of yellowish extracellular deposits called *drusen* in the retinal pigment epithelium. Over time atrophy and degeneration of macular cells occur. In wet AMD, vascular endothelial growth factor (VEGF) promotes the growth of new blood vessels in an abnormal location in the retinal epithelium. As the new blood vessels grow, they leak fluid and can bleed, causing scar tissue to gradually form.

Clinical Manifestations and Diagnostic Studies

Acute vision loss may occur from either the dry or wet forms of AMD.

The patient may have blurred and darkened vision, *scotomas* (blind spots in the visual field), and *metamorphopsia* (distortion of vision). If only one eye is affected, the patient may not notice early changes in vision.

In addition to visual acuity measurement, the primary diagnostic procedure is ophthalmoscopy. The HCP looks for drusen and other fundus changes associated with AMD. The Amsler grid test may help define the involved area. It provides a baseline for future comparison (Fig. 20.15). Fundus photography and IV angiography with fluorescein and/or indocyanine green dyes may help to further determine the extent and type of AMD. Retinal anatomy can be analyzed using optical coherence tomography (OCT) or scanning laser ophthalmoscopy.

Interprofessional Care

Visual prognosis varies greatly. Limited treatment options for patients with wet AMD include medications that are injected directly into the vitreous cavity. Ranibizumab (Lucentis), bevacizumab (Avastin), aflibercept (Eylea), and pegaptanib (Macugen) inhibit VEGF. This helps slow vision loss by stopping new vessels from forming.[15] Side effects can include blurred vision, eye irritation, eye pain, and photosensitivity. Injections are given at 4- to 6-week intervals, depending on treatment response. Disease stability is determined by OCT, which looks at pathology in the macula. The findings determine the need for continued intravitreal injections.

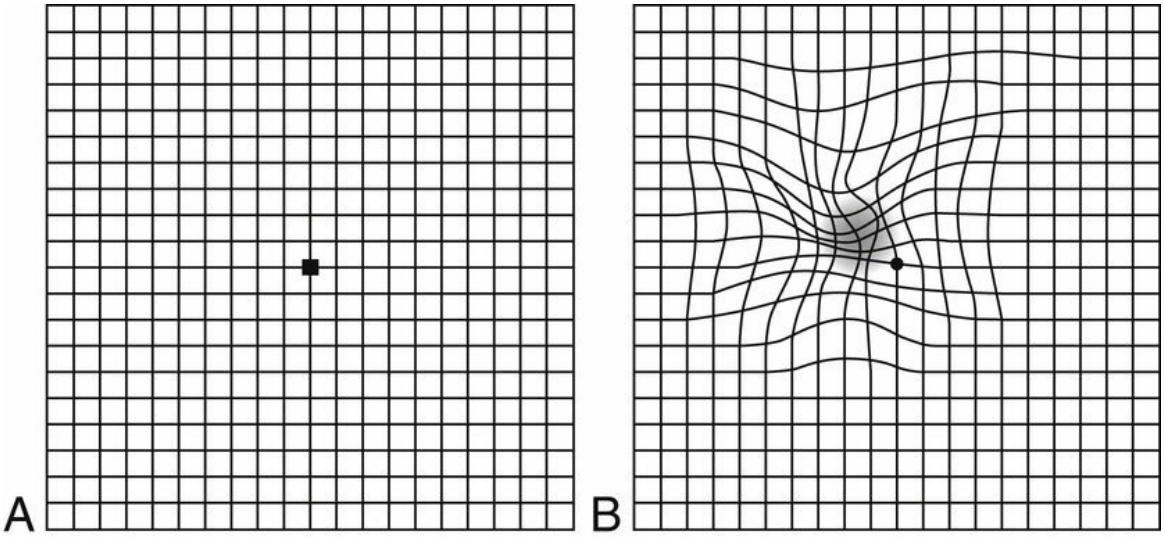

FIG. 20.15 Amsler grid. **A,** Normal grid. **B,** Abnormal grid as seen by person with macular degeneration.

Photodynamic therapy (PDT) uses verteporfin (Visudyne) IV and a "cold" laser to excite the dye. The PDT procedure is used in wet AMD to damage the abnormal blood vessels. Verteporfin is a photosensitizing drug that becomes active when exposed to the low-level laser light wave. Until the drug is completely excreted by the body, it can be activated by exposure to sunlight or other high-intensity light, such as halogen. Have patients avoid direct exposure to sunlight and other intense forms of light for 5 days after treatment. Exposure of the skin to sunlight could activate the drug in that area, causing a chemical burn.

Nutritional factors may play a role in the progression of AMD. Dietary supplements of vitamin C, vitamin E, beta-carotene, and zinc decrease the progression of AMD. Lutein/zeaxanthin supplements may help some patients. Teach the patient to eat dark green, leafy vegetables containing lutein (e.g., kale and spinach) and fatty fish at least twice a week.[16] Smoking cessation may help in halting the progression of dry AMD to a more advanced stage.

The management of the patient with visual impairment discussed on p. 359 is appropriate for the patient with AMD. Many patients with low-vision assistive devices can continue reading and keep a license to drive during the daytime and at lowered speeds. The permanent loss

of central vision has significant psychosocial implications for nursing care. Avoid giving the impression that "nothing can be done" about the problem when caring for the patient with AMD. Although therapy may not recover lost vision, much can be done to augment the remaining vision.

Glaucoma

Glaucoma is a group of disorders characterized by increased IOP and its' consequences, optic nerve atrophy, and peripheral visual field loss. Glaucoma is the second leading cause of permanent blindness in the United States and the leading cause of blindness among blacks.[3,17] Many people with glaucoma are unaware of their condition. The incidence of glaucoma increases with age. Blindness from glaucoma is largely preventable with early detection and proper treatment. Genetic factors play a role in some types of glaucoma.[17]

Etiology and Pathophysiology

A proper balance between the rate of aqueous production (*inflow*) and the rate of aqueous reabsorption (*outflow*) is essential to maintain the IOP within normal limits. We call the place where the outflow occurs the *angle* because it is the angle where the iris meets the cornea. When the rate of inflow is greater than the rate of outflow, IOP can increase above the normal limits. If IOP stays increased, permanent vision loss may occur.

Primary open-angle glaucoma (POAG) is the most common type of glaucoma. In POAG the outflow of aqueous humor is decreased in the trabecular meshwork. The drainage channels become clogged, like a clogged kitchen sink. Damage to the optic nerve can then result.

Angle-closure glaucoma (ACG) is due to a reduction in the outflow of aqueous humor that results from angle closure. Usually, this is caused by the lens bulging forward because of the aging process. Angle closure may also occur because of pupil dilation in the patient with anatomically narrow angles. Acute angle-closure glaucoma (AACG)

may be precipitated by situations in which the pupil stays partially dilated long enough to cause an acute and significant rise in the IOP. This may occur because of drug-induced mydriasis, emotional excitement, or darkness. Drug-induced mydriasis may occur from topical eye preparations or many systemic medications (both prescription and OTC). Check medication records before giving medications to the patient with ACG. Teach the patient not to take any mydriatic medications.

Clinical Manifestations

POAG develops slowly and without symptoms of pain or pressure. The patient usually does not notice the gradual visual field loss until peripheral vision has been severely compromised. Eventually, the patient with untreated glaucoma has "tunnel vision," with only a small center visual field. All peripheral vision is absent.

AACG causes definite symptoms, including sudden, severe pain in or around the eye. The patient often has nausea and vomiting. Visual symptoms include seeing colored halos around lights, blurred vision, and ocular redness.

Manifestations of subacute or chronic ACG appear more gradually. The patient who had a previous, unrecognized episode of subacute ACG may report blurred vision, seeing colored halos around lights, ocular redness, or eye or brow pain.

Diagnostic Studies

IOP is usually increased in glaucoma (normal is 10 to 21 mm Hg). In the patient with increased pressures, the measurements are repeated over time to verify the elevation. In POAG, IOP is usually between 22- and 32-mm Hg. In AACG, IOP may be more than 50 mm Hg.

In POAG, slit lamp microscopy reveals a normal angle. In ACG, there may be a markedly narrow or flat anterior chamber angle, an edematous cornea, a fixed and moderately dilated pupil, and ciliary injection (hyperemia of the ciliary blood vessels produces a red color).

Measures of peripheral and central vision provide more diagnostic

information. While central acuity may remain 20/20 even in the presence of severe peripheral visual field loss, visual field perimetry may reveal subtle changes in the peripheral vision early in the disease process, long before actual scotomas develop. In ACG, central visual acuity is reduced if the patient has corneal edema, and the visual fields may be markedly decreased. As glaucoma progresses, *optic disc cupping* may be one of the first signs of chronic POAG. The optic disc becomes wider, deeper, and paler (light gray or white), which is visible with direct or indirect ophthalmoscopy (Fig. 20.16).

Interprofessional Care

The primary focus of glaucoma therapy is to keep the IOP low enough to prevent the patient from developing optic nerve damage. Therapy varies with the type of glaucoma. The diagnostic and interprofessional care of glaucoma is outlined in Table 20.12.

Chronic Open-Angle Glaucoma

Drug therapy is the initial treatment in POAG (Table 20.13). The patient must understand that continued treatment and supervision are needed because the drugs control, but do not cure, glaucoma. Many patients with glaucoma have systemic illnesses or take systemic medications that may affect their therapy. The patient using a β-adrenergic blocking glaucoma agent may have an additive effect if a systemic β-adrenergic blocking drug is also being taken. All β-adrenergic blocking glaucoma agents are contraindicated in the patient with bradycardia, heart block greater than first-degree heart block, cardiogenic shock, and heart failure. The noncardioselective β-adrenergic blocking glaucoma agents are contraindicated in the patient with chronic obstructive pulmonary disease (COPD) or asthma. The hyperosmolar agents may precipitate heart failure or pulmonary edema in the susceptible patient. The patient on high-dose aspirin therapy should not take carbonic anhydrase inhibitors. The α-adrenergic agonists can cause tachycardia or hypertension. This may have profound consequences in the older patient.

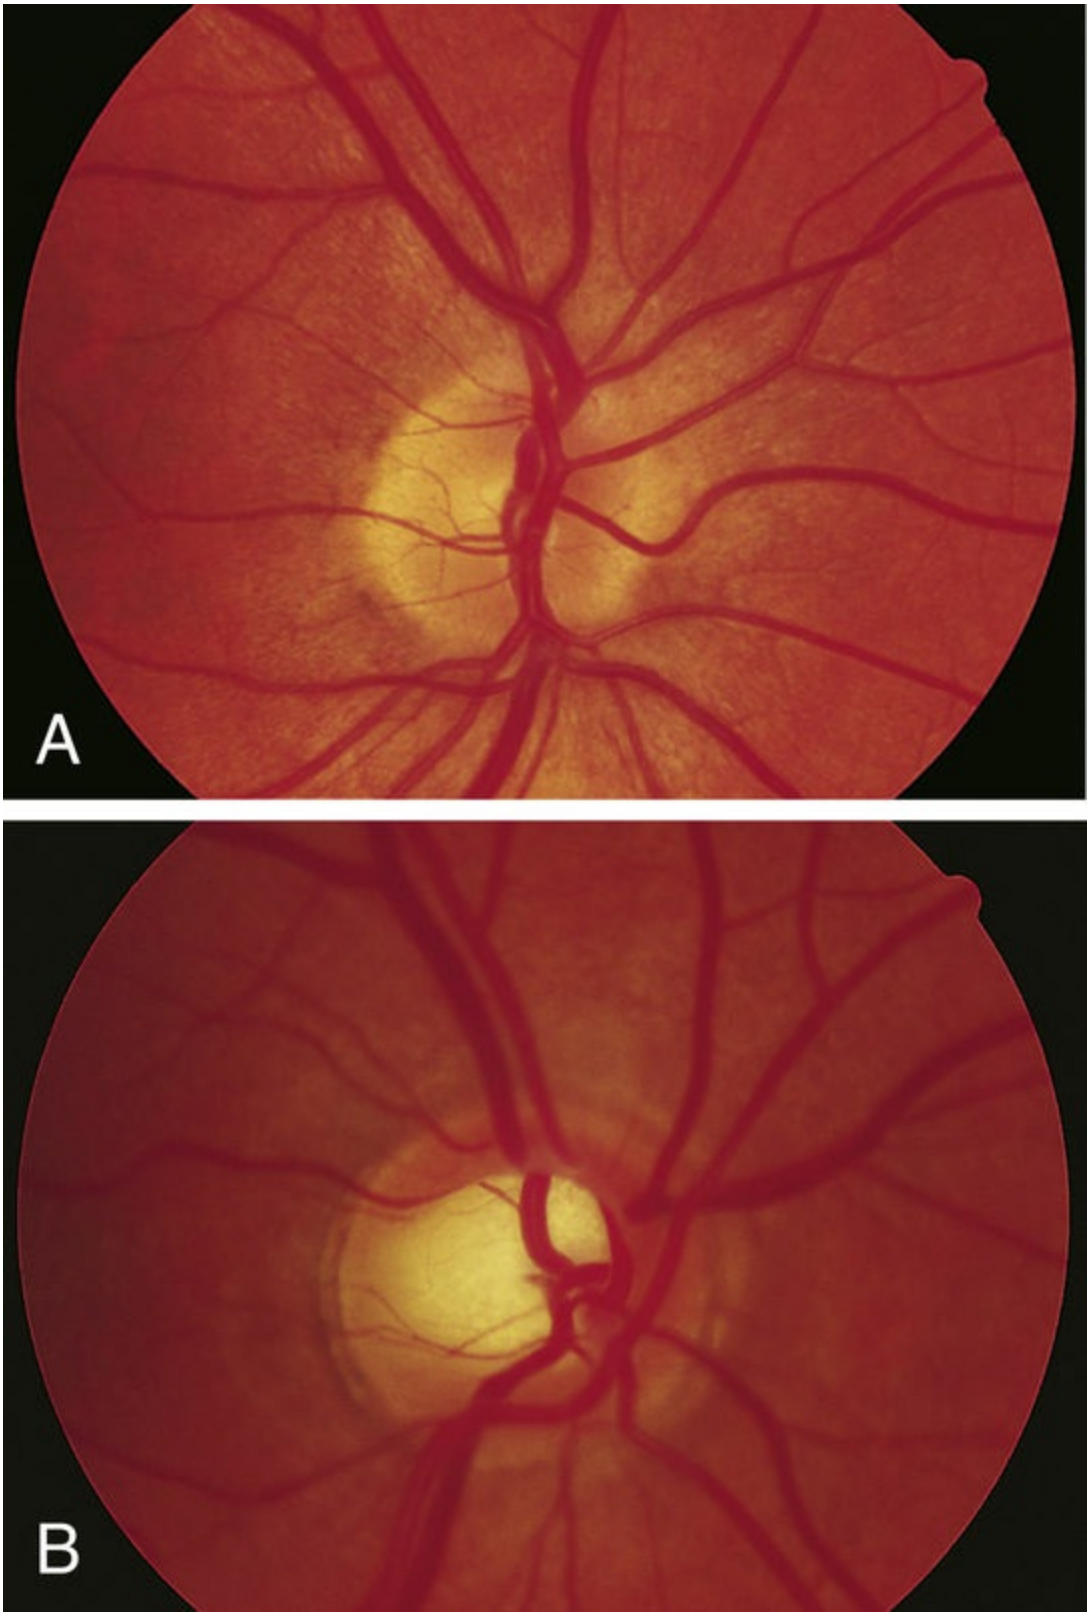

FIG. 20.16 **A,** In the normal eye the optic cup is pink with little cupping. **B,** In glaucoma the optic cup is bleached and optic cupping is present. (Note the appearance of the retinal vessels, which travel over

the edge of the optic cup and appear to dip into it.)

Diagnostic Assessment

- History and physical examination
- Visual acuity measurement
- Tonometry
- Ophthalmoscopy (direct and indirect)
- Slit lamp microscopy
- Gonioscopy
- Visual field perimetry

Management

Chronic Open-Angle Glaucoma

Drug Therapy (Table 20.13)

- β-Adrenergic blockers
- α-Adrenergic agonists
- Cholinergic agents (miotics)
- Carbonic anhydrase inhibitors

Surgical Therapy

- Argon laser trabeculoplasty (ALT)
- Trabeculectomy with or without filtering implant

Acute Angle-Closure Glaucoma

- Topical cholinergic agent
- Hyperosmotic agent
- Laser peripheral iridotomy
- Surgical iridectomy

TABLE 20.13 Drug TherapyAcute and Chronic Glaucoma

Drug	Action	Side Effects	Nursing Considerations
α-Adrenergic Agonists			
apraclonidine (Iopidine), brimonidine (Alphagan)	↓ Aqueous humor production	Ocular redness, irregular heart rate	Topical drops Used to control or prevent acute postlaser IOP rise (used before and immediately after ALT and iridotomy, Nd:YAG laser capsulotomy) Teach patient at risk for systemic reactions to occlude puncta
α- and β-Adrenergic Agonists			
dipivefrin (Propine)	Converted to epinephrine inside the eye aqueous humor production, enhances outflow facility	Ocular discomfort and redness, tachycardia, hypertension	Topical drops Contraindicated in patient with narrow-angle glaucoma Teach punctal occlusion if patient at risk for systemic reactions
epinephrine	Same as dipivefrin	Same as dipivefrin, but can be more pronounced	Topical drops Same as dipivefrin
β-Adrenergic Blockers			
betaxolol (Betoptic)	β_1 cardioselective ↓ IOP, ↓ aqueous humor production	Transient discomfort Systemic reactions rarely reported but include bradycardia, heart block, pulmonary distress, headache, depression	Topical drugs Contraindicated in patient with bradycardia, cardiogenic shock, or heart failure Systemic absorption can have additive effect with systemic β_1-blocking agents
levobunolol (Betagan) timolol maleate (Timoptic, Istalol)	β_1 and β_2 noncardioselective blockers ↓ IOP, ↓ aqueous humor production	Transient ocular discomfort, blurred vision, photophobia, bradycardia, decreased BP, bronchospasm, headache, depression	Topical drops Same as betaxolol Contraindicated in patients with asthma or COPD
Carbonic Anhydrase Inhibitors			
Systemic			
acetazolamide (Diamox) dichlorphenamide (Daranide) methazolamide	↓ Aqueous humor production	Paresthesias, especially "tingling" in extremities, hearing problems or tinnitus, loss of appetite, taste changes, GI problems, drowsiness, confusion	Oral nonbacteriostatic sulfonamides Anaphylaxis and other sulfa-type allergic reactions may occur in patient allergic to sulfa Diuretic effect can ↓ electrolyte levels Do not give to patient on high-dose aspirin therapy
Topical			
brinzolamide (Azopt) dorzolamide (Trusopt)	↓ Aqueous humor production	Transient stinging, blurred vision, redness	Anaphylaxis and other sulfa-type allergic reactions may occur in patient allergic to sulfa
Cholinergic Agents (Miotics)			
carbachol (Miostat, Isopto Carbachol)	Parasympathomimetic Stimulates iris sphincter contraction, causing miosis and opening of trabecular meshwork, facilitating aqueous outflow Partially inhibits cholinesterase	Transient ocular discomfort, headache, blurred vision, decreased adaptation to the dark, syncope, salivation, dysrhythmias, vomiting, diarrhea, hypotension	Topical drops Caution patient about ↓ visual acuity caused by miosis, particularly in dim light
pilocarpine (Isopto Carpine, Pilocar)	Parasympathomimetic Stimulates iris sphincter contraction, causing miosis and opening of trabecular meshwork, facilitating aqueous humor outflow	Same as carbachol	Topical drops Same as carbachol
Prostaglandin Agonists			
bimatoprost (Lumigan) latanoprost (Xalatan) tafluprost (Zioptan) travoprost	↓ Outflow of aqueous humor between the uvea and sclera and the usual exit through the trabecular meshwork	Increased brown iris pigmentation, ocular discomfort and redness, dryness, itching, and foreign body sensation	Topical drops Teach patient to only administer 1drop per day Have patient remove contact lens 15 min before instilling

ALT, Argon laser trabeculoplasty; *Nd:YAG,* neodymium-doped yttrium aluminum garnet

(laser).

Argon laser trabeculoplasty (ALT) is a noninvasive way to lower IOP when medications are not successful or when the patient either cannot or will not use the drug therapy as recommended. ALT is an outpatient procedure that uses topical anesthetic. The laser stimulates scarring and contraction of the trabecular meshwork, which opens the outflow channels. ALT reduces IOP most of the time. The patient uses topical corticosteroids for 3 to 5 days after the procedure. The most common complication is an acute rise in IOP. The HCP examines the patient at 1 week and again at 4 to 6 weeks after surgery.

Filtration surgery, also called a *trabeculectomy*, may be used if medical management and laser therapy are not successful.

Acute Angle-Closure Glaucoma

AACG is an ocular emergency that needs immediate intervention. Miotics (Table 20.13) and oral or IV hyperosmotic agents, including glycerin liquid (Ophthalgan), isosorbide solution (Ismotic), and mannitol solution (Osmitrol), are usually successful in immediately lowering IOP. A laser peripheral iridotomy or surgical iridectomy is necessary for long-term treatment and prevention of more episodes. These procedures allow the aqueous humor to flow through a newly created opening in the iris and into normal outflow channels. A procedure may be done on the other eye as a precaution because many patients often have an acute attack in the other eye.

Drug Alert

Miotics

- Warn patients about decreased visual acuity, especially in dim light.

Nursing Management: Glaucoma

Nursing Assessment

Because glaucoma is a chronic condition requiring long-term management, assess the patient's ability to understand and adhere to the therapy plan. Assess the patient's psychologic reaction to the diagnosis of a potentially sight-threatening chronic disorder. Include the patient's caregiver in the assessment process because the chronic nature of this disorder affects them too. For example, caregivers may become the eyedrop administrator if the patient is unwilling or unable.

Nursing Diagnoses

Nursing diagnoses for the patient with glaucoma include:

- Risk for injury
- Acute pain

Planning

The overall goals are that the patient with glaucoma will (1) have no progression of visual impairment, (2) follow the treatment plan, and (3) have no complications.

Nursing Implementation

Health Promotion

Loss of vision because of glaucoma is a preventable problem. Teach the patient and caregiver about the risk for glaucoma and that it increases with age. Stress the importance of early detection and treatment in preventing visual impairment. A comprehensive eye examination is important in identifying people with glaucoma or those at risk for developing glaucoma. The current recommendation is for an eye examination every 2 to 4 years for people between ages 40

and 64 years, and every 1 to 2 years for people age 65 years or older. Blacks in every age category should have one more often because of the increased incidence and more aggressive course of glaucoma.[17]

Acute Care

Acute nursing interventions are directed primarily toward the patient with AACG and the surgical patient. The patient with AACG needs medication immediately to lower the IOP. Most surgeries for glaucoma are outpatient procedures. Provide care to relieve any discomfort related to the procedure. Patient and caregiver teaching after eye surgery is discussed in Table 20.9.

Ambulatory Care

Because of the chronic nature of glaucoma, teach the patient to follow the therapy plan and follow-up recommendations prescribed by the HCP. Provide accurate information about the disease process and treatment options, including the reason for each option. In addition, the patient needs information about the purpose, frequency, and technique for administering antiglaucoma drugs. Encourage adherence by helping the patient set up a medication administration schedule and advocating a change in therapy if the patient reports unacceptable side effects.

Evaluation

The overall expected outcomes are that the patient with glaucoma will:

- Have no further loss of vision
- Adhere to the recommended therapy
- Safely function within own environment
- Have relief from pain associated with the disease and surgery

Intraocular Inflammation and Infection

The term *uveitis* is used to describe inflammation of the uveal tract, retina, vitreous body, or optic nerve. Inflammation may be caused by bacteria, viruses, fungi, or parasites. *Cytomegalovirus retinitis* (CMV retinitis) is an opportunistic infection that occurs in patients with acquired immunodeficiency syndrome (AIDS) and in other immunosuppressed patients. The cause of sterile intraocular inflammation includes autoimmune disorders, AIDS, cancer, or disorders associated with systemic diseases, such as inflammatory bowel disease. Pain and photophobia are common symptoms.

Endophthalmitis is an extensive intraocular inflammation of the vitreous cavity. Bacteria, viruses, fungi, or parasites can induce this serious inflammatory response. The mechanism of infection may be endogenous, in which the infecting agent arrives at the eye through the bloodstream, or exogenous, in which the infecting agent is introduced through a surgical wound or a penetrating injury. Although rare, endophthalmitis is a devastating complication of intraocular surgery or penetrating ocular injury. It can lead to irreversible blindness within hours or days. Manifestations include ocular pain, photophobia, decreased visual acuity, headaches, reddened and swollen conjunctiva, and corneal edema.

Treatment depends on the underlying cause. Intraocular infections require antimicrobial agents. They may be delivered topically, subconjunctivally, intravitreally, systemically, or in some combination. Inflammatory responses require antiinflammatory medications (e.g., corticosteroids). The patient with intraocular inflammation is usually uncomfortable and may be noticeably anxious and frightened. Provide accurate information and emotional support to the patient and caregiver. In severe cases, enucleation may be needed. When the patient has lost visual function or even the entire eye, the patient will grieve the loss. Your role includes helping the patient through the grieving process.

Ocular Tumors

Benign and cancerous tumors can occur in many areas of the eye,

including the conjunctiva, retina, and orbit.[18] Eyelid cancers include basal cell and squamous cell cancers (see Chapter 23).

Uveal melanoma is a cancer of the iris, choroid, or ciliary body. It more often occurs in light-skinned people with light eye color, who are over age 60, and have chronic UV exposure.[19] Uveal melanoma can arise from preexisting nevi in the eye. Tumors may be asymptomatic or associated with vision loss. This depends on their size and location and presence of hemorrhage and retinal detachment. As with other cancers, cancer stage and cell type are important variables in the prognosis. Diagnostic testing may include ultrasound, MRI, and fine-needle aspiration biopsy. Uveal melanoma often appears as a dome-shaped, well-circumscribed, solid brown to golden pigment in the iris, choroid, or ciliary body (Fig. 20.17).

Depending on the status of the involved eye, treatment options can include enucleation, radiation therapy (brachytherapy), external beam radiation, transpupillary photocoagulation, eye wall resection, and eye removal. Many patients do not lose their eye. Some may have good vision after treatment in the affected eye.

Enucleation

Enucleation is the removal of the eye. The primary reason for enucleation is a blind, painful eye. This may result from glaucoma, infection, or trauma. Enucleation may be used to treat ocular cancer. The surgical procedure includes severing the extraocular muscles close to their insertion on the globe, inserting an implant to maintain the intraorbital anatomy, and suturing the ends of the muscles over the implant. The conjunctiva covers the joined muscles, and a clear conformer is placed over the conjunctiva until the permanent prosthesis is fitted. A pressure dressing helps prevent bleeding.

FIG. 20.17 Uveal melanoma. A large tumor in the choroid, the most common location in the eye for melanoma.
Courtesy Cory J. Bosanko, OD, FAAO, Eye Centers of Tennessee, Crossville, TN.

After surgery, observe the patient for signs of complications, including excess bleeding or swelling, increased pain, displacement of the implant, and fever. Patient teaching should include the instillation of topical ointments or drops and wound cleansing. Teach the patient how to insert the conformer into the socket in case it falls out. The loss of an eye is often devastating, even when enucleation occurs after a lengthy period of painful blindness. Recognize the patient's emotional response and provide support to the patient and caregivers.

About 6 weeks after surgery, the wound is sufficiently healed for the permanent prosthesis. An ocularist fits the prosthesis and designs it to match the remaining eye. Teach the patient how to remove, cleanse, and insert the prosthesis. Special polishing is needed periodically to remove dried protein secretions.

Ocular Manifestations of Systemic

Diseases

Many systemic diseases have significant ocular manifestations. Ocular signs and symptoms may be the first finding or complaint in the patient with a systemic disease. One example is the patient with undiagnosed diabetes who seeks eye care for blurred vision. A careful history and examination can reveal that the underlying cause of the blurred vision is lens swelling from hyperglycemia. Another example is the patient who seeks care for a conjunctival lesion. AIDS may be diagnosed based on the presence of a conjunctival Kaposi sarcoma (KS).

Case Study

Glaucoma and Diabetic Retinopathy

© Kevin Peterson/Stockbyte/Thinkstock.

Patient Profile

J.K. is a 68-yr-old black woman with a history of osteoarthritis and type 2 diabetes for the past 15 years. She now has diabetic

retinopathy. She returns to the eye clinic with her daughter for continued care of primary open-angle glaucoma (POAG) and reexamination for changes in diabetic retinopathy. Her current drug therapy for POAG includes topical timolol maleate 0.5% extended (Timoptic-XE) once daily in both eyes (OU) and latanoprost (Xalatan) 0.005% OU daily at bedtime. At her last examination, she had microaneurysms and hard exudates of the retina.

Subjective Data

- She can no longer read the newspaper and reports that medication labels are difficult to read.
- States she is not always successful in getting the eyedrops instilled because her hands are gnarled and painful from osteoarthritis.

Objective Data

- Distant and near visual acuity are stable at 20/60 (OD) and 20/50 (OS). This is a reduction from 20/40 (OU) at her last visit.
- Intraocular pressure (IOP) stable at 20 mm Hg (OU).
- There is a new scotoma on visual field testing in the OS.
- Fluorescein angiography reveals diabetic macular edema OU.

Interprofessional Care

- Brimonidine 0.15% (OS) 15 min before and immediately after argon laser trabeculoplasty (ALT)
- Argon laser (OU) to seal leaking microaneurysms from macular edema
- Check IOP 1 hr after ALT
- Continue previous glaucoma drop regimen
- Follow-up examination for in 2 wk for possible ALT of OD

Discussion Questions

1. Explain the cause of the new scotoma.
2. Why is ALT an appropriate therapy for J.K.?
3. What is the purpose of the eyedrops before and immediately after ALT?
4. What is the cause of the vision loss from diabetic retinopathy?
5. Priority Decision: Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
6. ***Priority Decision:*** What are the priority nursing interventions for J.K.?
7. ***Patient-Centered Care:*** What are the priority topics that should be discussed in discharge teaching with J.K.?
8. ***Evidence-Based Practice:*** J.K. wants to know if her glaucoma is related to her diabetes. How would you respond to her question?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In a patient who has a hemorrhage in the posterior cavity of the eye, the nurse knows that blood is accumulating
   a. in the aqueous humor.
   b. between the lens and retina.
   c. between the cornea and lens.
   d. in the space between the iris and lens.
2. Increased intraocular pressure may occur because of

a. edema of the corneal stroma.
b. dilation of the retinal arterioles.
c. blockage of the lacrimal canals and ducts.
d. increased aqueous humor production by the ciliary process.

3. Ask patients using eyedrops to treat their glaucoma about
a. use of corrective lenses.
b. their usual sleep pattern.
c. a history of heart or lung disease.
d. sensitivity to opioids or depressants.

4. Always assess the patient with an eye problem for
a. visual acuity.
b. pupillary reactions.
c. intraocular pressure.
d. confrontation visual fields.

5. When examining the patient's eyes, which finding would be of *most* concern to the nurse?
a. Intraocular pressure of 16 mm/Hg
b. Slightly yellowish cast of the sclera
c. Outward turning of the lower lid margin
d. Small, white nodule on the upper lid margin

6. Presbyopia occurs in older people because
a. the eyeball elongates.
b. the lens becomes inflexible.
c. the corneal curvature becomes irregular.
d. light rays are focusing in front of the retina.

7. Before injecting fluorescein for angiography, it is important for the nurse to *(select all that apply)*
   a. obtain an emesis basin.
   b. ask if the patient is fatigued.
   c. administer a topical anesthetic.
   d. inform patient that skin may turn yellow.
   e. assess for allergies to iodine-based contrast media.
8. A patient says she was diagnosed with astigmatism. When she asks what that is, what is the best explanation the nurse can give to the patient?
   a. "It happens because the lens of the eye is absent."
   b. "People with astigmatism have abnormally long eyeballs."
   c. "The cornea of the eye is uneven or irregular with astigmatism."
   d. "Astigmatism occurs because the eye muscles weaken with age."
9. Which intervention would be part of the plan of care for a patient who has new vision loss?
   a. Allow the patient to express feelings of grief and anger.
   b. Have the UAP perform all self-care activities for the patient.
   c. Address any family present first when discussing care concerns.
   d. Speak loudly and clearly, addressing the patient with each contact.
10. Which patient behaviors would the nurse promote for

healthy eyes *(select all that apply)*?

a. Protective sunglasses when bicycling

b. Taking part in a smoking cessation program

c. Supplementing diet intake of vitamin C and beta-carotene

d. Washing hands thoroughly before putting in or taking out contact lenses

e. A woman avoiding pregnancy for 4 weeks after receiving MMR immunization

11. The *most* important intervention for the patient with epidemic keratoconjunctivitis is

a. cleansing the affected area with baby shampoo.

b. monitoring spread of infection to the opposing eye.

c. regular instillation of artificial tears to the affected eye.

d. teaching the patient and caregivers good hygiene techniques.

12. What should be included in the discharge teaching for the patient who had cataract surgery *(select all that apply)*?

a. Eye discomfort is often relieved with mild analgesics.

b. A decline in visual acuity is common for the first week.

c. Stay on bed rest and limit activity for the first few days.

d. Notify the provider if an increase in redness or drainage occurs.

e. Following activity restrictions is essential to reduce intraocular pressure.

1. b, 2. d, 3. c, 4. a, 5. d, 6. b, 7. a, d, 8. c, 9. a, 10. a, b, c, d, 11. d, 12. a, d, e

Assessment and Management

Auditory Problems

Mariann M. Harding

LEARNING OUTCOMES

1. Describe the structures and functions of the auditory system.
2. Obtain significant subjective and objective assessment data related to the auditory system from a patient.
3. Perform a physical assessment of the auditory system using the appropriate techniques.
4. Distinguish normal from common abnormal findings of a physical assessment of the auditory system.
5. Link the age-related changes in the auditory system to differences in assessment findings.
6. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the auditory system.
7. Explain the pathophysiology, clinical manifestations, and nursing and interprofessional management of common ear problems.
8. Compare the common causes, management, and rehabilitative potential of conductive and sensorineural hearing loss.
9. Explain the use, care, and patient teaching related to assistive

devices for ear problems.
10. Describe measures used to assist the patient in adapting to decreased hearing.

Coping
Functional Ability
Infection
Sensory Perception

Auditory System

Hearing is a complex process that allows us to interact with the environment. It is the basis for social interaction and communication. Having a hearing impairment can lead to major challenges that can negatively affect well-being. In the adult, difficulties with related concepts, including functional ability and cognition, may be present with hearing loss. This chapter presents an overview of auditory function and discusses care when problems occur.

Structures and Functions of Auditory System

The auditory system is composed of the peripheral auditory system and central auditory system. The peripheral auditory system includes the structures of the ear itself: external, middle, and inner ear (Fig. 21.1). This system is involved with the reception and perception of sound. The inner ear functions in hearing and balance.

The central auditory system integrates and assigns meaning to what one hears. This system includes the vestibulocochlear nerve (cranial nerve [CN] VIII) and auditory cortex of the brain. The brain and its pathways transmit and process sound and sensations that maintain a person's equilibrium.

The role of the external and middle part of the ear is to conduct and amplify sound waves from the environment. This part of sound conduction is termed *air conduction.* Problems in these two parts of the ear may cause *conductive hearing loss,* resulting in a decrease in sound intensity and/or a distortion in sound.[1]

Disturbances in equilibrium can impair coordination, balance, and orientation. Damage to or an abnormality of the inner ear or along the nerve pathways results in *sensorineural hearing loss.* In addition to causing distortion or faintness of sound, sensorineural hearing loss may affect the ability to understand speech or cause complete hearing loss. Impairment within the auditory pathways of the brain causes

central hearing loss. This type of hearing loss causes difficulty in understanding the meaning of words the person heard. Types of hearing loss are discussed later in this chapter on pp. 387-389.

External Ear

The external ear consists of the *auricle* (pinna), external auditory canal, and *tympanic membrane (TM).* The auricle is composed of cartilage and connective tissue covered with epithelium, which also lines the external auditory canal (Fig. 21.1). The external auditory canal is a slightly S-shaped tube about 1 inch (2.5 cm) in length in the adult. The lining of the proximal one third of the canal contains fine hairs (cilia), sebaceous (oil) glands, and ceruminous (wax) glands. The oil and wax lubricate the ear canal, keep it free from debris, and kill bacteria. Thin epithelium lines the distal two thirds of the canal. It is over bone and very sensitive.

The function of the external ear and canal is to collect and transmit sound waves to the TM, or eardrum. The TM is a shiny, translucent, pearl-gray membrane. It is made up of epithelial cells, connective tissue, and mucous membrane. It serves as a partition and transmits sounds between the external auditory canal and middle ear.

Middle Ear

The middle ear cavity is an air space in the temporal bone. Mucous membrane lines the middle ear and is continuous from the nasal pharynx via the eustachian (auditory) tube. The eustachian tube equalizes atmospheric air pressure between the middle ear and throat. This allows the TM to move freely. It is normally closed, opening only with yawning, swallowing, and chewing. Blockage of the tube can occur with allergies, nasopharyngeal infections, or enlarged adenoids. A tube that stays open is called *patulous.* When this occurs, *autophony,* or hearing your own voice, may be present.

The middle ear contains the *ossicles,* the 3 smallest bones in the body: *malleus, incus,* and *stapes.* Vibrations of the TM cause the ossicles to move and transmit sound waves to the oval window. The superior

part of the middle ear is the *epitympanum,* or the attic. It also communicates with air cells within the mastoid bone. The mastoid is the posterior part of the temporal bone. The facial nerve (CN VII) traverses above the oval window of the middle ear. The thin, bony covering of the facial nerve can become damaged by chronic ear infection, skull fracture, or trauma during ear surgery. Problems may occur related to voluntary facial movements, eyelid closure, and taste discrimination. Permanent damage to the facial nerve can result.

Inner Ear

The inner ear consists of 3 spaces in the temporal bone, assembled in a system called the bony labyrinth. The space is filled with watery fluid called perilymph. Within the perilymph is the membranous labyrinth. It follows the shape of the bony labyrinth and holds a thicker fluid called *endolymph*.

The inner ear holds the functional organs for hearing and balance. The receptor organ for hearing is the *cochlea,* a coiled structure that contains the *organ of Corti.* Its tiny hair cells respond to stimulation of select portions of the basilar membrane according to pitch. This stimulus is converted into an electrochemical impulse. It is transmitted by the acoustic part of the vestibulocochlear nerve (CN VIII) to the temporal lobe of the brain to process and interpret the sound.

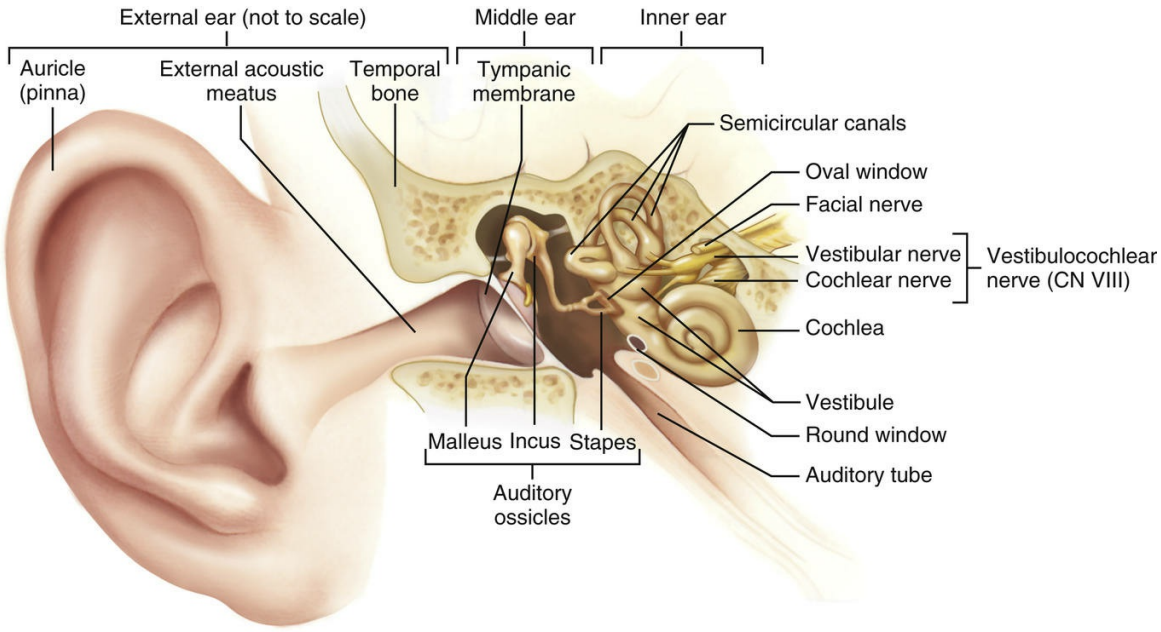

FIG. 21.1 External, middle, and inner ear.
Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.

Three *semicircular canals* and the *vestibule* make up the organ of balance. The semicircular canals sit at right angles to each other. Structures in each canal and the vestibule generate nerve impulses in response to our movements. The vestibule is beside the oval window between the semicircular canals and the cochlea. Nerves from receptors in the vestibule join those from the semicircular canals to form the vestibular nerve, which joins with the cochlear nerve to form the *vestibulocochlear nerve,* or CN VIII.

Transmission of Sound

Sound waves travel by air (air conduction) and are picked up by the auricles and auditory canal. Sound waves strike the TM, causing it to vibrate. The central part of the TM is connected to the malleus, which then starts to vibrate. The malleus transmits the vibration to the incus and then the stapes. As the stapes moves back and forth, it pushes the membrane of the oval window in and out. Movement of the oval window makes waves in the perilymph.

Once sound waves are transmitted to the liquid medium of the

inner ear, the vibration is picked up by the tiny sensory hair cells of the cochlea, which initiate nerve impulses. These impulses are carried by nerve fibers to the main branch of the acoustic portion of CN VIII and then to the brain. The bones of the skull can also transmit sound directly to the inner ear (bone conduction).

Gerontologic Considerations: Effects of Aging on Auditory System

Presbycusis, or hearing loss due to aging, is the third most common health issue in older adults, after arthritis and heart disease.[2] Sound transmission is diminished by calcification of the ossicles. **Tinnitus**, or ringing in the ears, may accompany the hearing loss that results from the aging process. Cerumen glands atrophy, causing cerumen (earwax) to be much drier. The hair in the ear becomes thicker and coarser, entrapping the hard, dry cerumen in the canal. Accumulation of dry cerumen in the external canal can interfere with the transmission of sound. A decline in balance results from atrophy of vestibular structures in the inner ear, slowing of motor responses, and musculoskeletal limitations.

Age-related changes in the auditory system and differences in assessment findings are outlined in Table 21.1.

Case Study

Patient Introduction

© iStock.com/EyeMark.

R.S. is a 57-yr-old woman who comes to the emergency department with extreme dizziness. R.S. states that she is so dizzy she “can’t do anything but lie down.” She also reports feeling like her right ear is

"plugged" and is having ringing in that ear.

Discussion Questions

1. What are the possible causes of R.M.'s hearing and balance problems?
2. Is her condition stable or an emergency?
3. What assessment questions will you ask her?

You will learn more about R.S. and her condition as you read this chapter.

(See p. 380 for more information on R.S.)

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

Assessment of Auditory System

Assessment of the auditory system should include assessment of hearing and equilibrium because the auditory and *vestibular* (balance) systems are closely related. It is often hard to separate symptoms related to these two systems. Help the patient describe symptoms and problems to determine the source of the problems. Health history questions to ask a patient with an auditory problem are listed in Table 21.2.

Problems with balance may manifest as vertigo or nystagmus. **Vertigo** is a sense that the person or objects around the person are moving or spinning. It is usually stimulated by head movement. *Dizziness* is a sensation of being off-balance that occurs when standing or walking. **Nystagmus** is an abnormal eye movement that may be seen as a twitching of the eyeball or described by the patient as a blurring of vision with head or eye movement.

At first, try to determine symptoms that are related to balance and separate them from those related to hearing loss or tinnitus. The symptoms can be combined later in the assessment to help make a diagnosis and care plan for the patient.

Subjective Data

Important Health Information

Past Health History

Many ear problems result from childhood illnesses or problems of adjacent organs. This makes a careful assessment of past health problems is important.

Ask the patient about previous ear problems, especially during childhood. Record the (1) frequency of acute middle ear infections (otitis media); (2) surgical procedures (e.g., myringotomy); (3) perforations of the eardrum; (4) drainage; and (5) history of mumps, measles, or scarlet fever. Assess for systemic conditions, including hypertension, rheumatoid arthritis, and inflammatory bowel disease, that are associated with hearing loss.[3] Document head injury because it may result in hearing loss. Information about food and environmental allergies is important because they can cause the eustachian tube to become edematous and prevent aeration of the middle ear.

TABLE 21.1 Gerontologic Assessment DifferencesAuditory System

Changes	Differences in Assessment Findings
External Ear	
Increased hair growth	Visible hair, especially in men
Loss of elasticity in cartilage	Collapsed ear canal
Thicker, drier cerumen	Impacted cerumen, potential hearing loss
Middle Ear	
Atrophic changes of tympanic membrane	Conductive hearing loss
Inner Ear	
Hair cell degeneration, neuron degeneration in auditory nerve and central pathways, reduced blood supply to cochlea, calcification of ossicles	Presbycusis, diminished sensitivity to high-pitched sounds, impaired speech reception, tinnitus
Less effective vestibular apparatus in semicircular canals	Alterations in balance and body orientation
Brain	
Decline in ability to filter out unwanted and unnecessary sound	Difficulty hearing in a noisy environment, heightened sensitivity to loud sounds

Record symptoms such as vertigo, tinnitus, and hearing loss in the patient's words. Ask for specific details of the sensations and situations that may cause them or make them worse. Information about family members with hearing loss and type of hearing loss is important. Some congenital hearing loss is hereditary. The age of onset of presbycusis also follows a familial pattern.

Medications

Obtain information about present or past use of ototoxic drugs (cause damage to CN VIII). These include aspirin, some antibiotics (aminoglycosides, erythromycin, vancomycin), loop diuretics, nonsteroidal antiinflammatory drugs (NSAIDs), antimalarial agents, and certain chemotherapy drugs (e.g., bleomycin, cyclophosphamide, cisplatin). Ask about hearing and balance problems, such as hearing loss, tinnitus, and vertigo, in patients receiving these drugs. For many, the hearing loss may be reversible if treatment is stopped. Chemicals used in industry (e.g., toluene, carbon disulfide, mercury) may damage the inner ear.

Surgery or Other Treatments

Document previous hospitalizations for ear surgery, including myringotomy (ventilation holes placed in the TM with or without tubes), tympanoplasty (surgical repair of TM), tonsillectomy, and adenoidectomy. Record the use of and satisfaction with a hearing aid. Note any problems with impacted cerumen.

Functional Health Patterns

Hearing and balance problems can affect all aspects of a person's life. To assess the impact of hearing loss, ask health history questions based on a functional health patterns approach (Table 21.2).

Health Perception–Health Management Pattern

Note the onset of hearing loss, whether sudden or gradual, and who noted the onset (e.g., patient, family, significant others). Gradual

hearing losses are often noted by those who communicate with the patient. Sudden losses and those worsened by other condition are often reported by the patient.

Assess the patient for personal measures used to preserve hearing. The use of protective ear covers or earplugs is good practice for people in high-noise environments. Document if the patient is a swimmer and the frequency and duration of swimming and use of ear protection. Note the type of water (pool, lake, ocean) in which the swimming takes place to help identify contact with contaminated water. Assess for the placement of any item in the ear, including hearing aids, which can cause trauma to the canal and TM.

Nutritional-Metabolic Pattern

Alcohol, sodium, and dietary supplements affect the amount of endolymph in the inner ear system. Patients with Ménière's disease may notice some improvement in their symptoms with alcohol restriction and a low-sodium diet. Note changes in symptoms with food intake. Ask the patient about any ear pain (otalgia) or discomfort associated with chewing or swallowing. These symptoms are often associated with middle ear problems.

TABLE 21.2 Health HistoryAuditory System

Health Perception–Health Management

Hearing

- Have you had a change in your hearing?* If yes, how does this change affect your daily life?
- Do you use any devices to improve your hearing (e.g., hearing aid, special volume control, headphones for television or stereo)?*
- How do you protect your hearing?
- Do you have any allergies that result in ear problems?*

Equilibrium

- When did the dizziness or spinning sensation first occur?
- Does this sensation occur when you first stand up, when you are lying down, or both?
- Have you ever fallen because of the dizziness?*
- Can you drive or walk alone? If no, elaborate.
- Are there any times of the day when your symptoms are worse?*

Tinnitus

- How long have you experienced ringing in your ears? Has it changed?* Describe the ringing (e.g., buzzing, ringing, roaring). Do you also have a feeling of fullness or pressure?*
- When does it bother you the most?
- What things have you tried that help or have not helped?
- What medications are you taking?

Nutritional-Metabolic

- Do you notice any differences in symptoms with changes in diet? *
- Does your ear problem cause nausea that interferes with your food intake?*
- Does chewing or swallowing cause you any ear discomfort?*

Elimination

- Does straining during a bowel movement cause ear pain?*

Activity-Exercise

- Do you need help with certain activities (e.g., lifting, bending, climbing stairs, driving, speaking) because of symptoms?*

Sleep-Rest

- Is your sleep disturbed by noises or ringing in the ears or by a sensation of spinning?*

Cognitive-Perceptual

- Do you experience ear pain?* What relieves the pain? What makes it worse? Does the pain affect your hearing or balance?
- Have you noticed any problem with communicating or understanding what people are saying?*

Self-Perception–Self-Concept

- Have changes in your hearing affected how you feel about yourself or your feeling of independence?*

Role-Relationship

- What effect has your ear problem had on your work, family, or social life?
- Are you able to recognize the effects of your ear problems on your life?*

Sexuality-Reproductive

- Has your ear problem caused a change in your sex life?*

Coping–Stress Tolerance

- Do you consider your ear problem a source of stress?*
- How do you cope when you are experiencing symptoms?

Value-Belief

- Do you have a conflict between what your health care provider would like you to do and what you believe you should do?

---

* If yes, describe.

Assessment of clenching or grinding of the teeth helps distinguish problems of the ear from referred pain of the temporomandibular joint (TMJ). Ask about dental problems and dentures.

Elimination Pattern

Elimination patterns are of interest in the patient with perilymph fistula and after surgical procedures. Frequent constipation or straining with bowel or bladder elimination may interfere with healing or repair of a perilymph fistula. After middle ear surgery (stapedectomy) the patient needs to prevent increased intracranial (and consequent inner ear) pressure associated with straining during bowel movements. Stool softeners may be needed after surgery for the patient who reports chronic problems with constipation.

Activity-Exercise Pattern

A review of the patient's activity-exercise pattern is essential when assessing for balance problems. Ask the patient about the onset,

duration, and frequency of symptoms. Identify activities that relieve or worsen symptoms and how they relate to the time of the day. For example, patients with Ménière's disease are less able to compensate for environmental input as the day progresses.

Sleep-Rest Pattern

Ask the patient with chronic tinnitus about sleep problems. Find out if the patient has tried anything to minimize the tinnitus (e.g., having fan on, using white noise devices). Assess for snoring. It can be caused by swelling or hypertrophy of tissue in the nasopharynx. This excess tissue can impair eustachian tube function and cause the sensation of ear fullness or pain.

Cognitive-Perceptual Pattern

Pain is associated with some ear problems, particularly those involving the middle ear and auditory canal. If pain is present, ask the patient to describe the pain, presence of drainage *(otorrhea),* history of teeth grinding, and treatments used for relief. Note the effect on the pain level when you move the auricle or palpate the tragus.

Note the patient's ability to pay attention and follow directions. Problems with these tasks may be an early indicator of hearing loss. The patient may not recognize a gradual hearing loss. Ask caregivers if they have noted any change in the patient's hearing.

Self-Perception–Self-Concept Pattern

Ask the patient to describe how the ear problem has affected his or her personal life and feelings about himself or herself. Hearing loss and chronic vertigo are particularly distressing for the patient. Hearing loss can result in embarrassing social situations that affect the patient's self-concept. People may think a patient with chronic vertigo is intoxicated. Sensitively question the patient about such situations. Clarify the symptom history with the patient and consider an evaluation with a hearing specialist.

Role-Relationship Pattern

Ask the patient about the effect that an ear problem or vertigo has had on family life, work responsibilities, and social relationships. Hearing loss can result in strained relationships and misunderstandings.

Ask about employment or contact with environments that have excessive noise levels, such as work with jet engines and machinery and electronically amplified music. Document the use of preventive devices worn in noisy environments. Many jobs rely on the ability to hear accurately and respond appropriately. If a hearing loss is present, gather detailed information on the effect this has on the patient's job. The unpredictability of vertigo attacks can have devastating effects on all aspects of life. Ordinary activities, such as driving, cooking, and work, that require balance all have an element of danger.

Sexuality-Reproductive Pattern

Determine whether hearing loss or vertigo has interfered with having a satisfactory sex life. Although intimacy does not depend on the ability to hear, hearing loss can interfere with establishing or maintaining a relationship.

Coping–Stress Tolerance Pattern

Ask the patient about his or her usual coping style, stress management strategies, and available support. If the patient seems unable to manage the situation, outside intervention may be needed. Denial is a common response to a hearing problem and should be assessed.

Value-Belief Pattern

Ask the patient about any conflicts produced by the problem or treatment related to values or beliefs. Make every effort to resolve the problem so that the patient does not have added stress. Ask about the use of home remedies such as hot oil in the ear.

Case Study

Subjective Data

© iStock.com/EyeMark.

A focused subjective assessment of R.S. revealed the following information:

- ***PMH:*** History of mild osteoarthritis. Hysterectomy 5 years ago. Last saw health care provider 6 months ago.
- ***Medications:*** Multivitamin 1 PO daily, ASA 81 mg PO daily, ibuprofen 200 mg PO every 6 hours as needed.
- ***Health Perception–Health Management:*** She says last night she felt like she had the start of a cold. The symptoms were present this morning when she woke up. She tried to clear her ear by blowing her nose and could not use that ear to talk on the phone. Had excellent hearing until today. Denies any syncope. Does not have allergies.
- ***Nutritional-Metabolic:*** States she is nauseous but has not vomited. Has only had a few sips of water since the symptoms started.
- ***Activity-Exercise:*** Dizziness worse when standing. It is still present when lying down but is less. Her husband drove her to the emergency room since she was unable to drive. Normally walks 1 to 2 miles 5 times a week and attends yoga class 2 times a week.
- ***Cognitive-Perceptual:*** Denies any ear pain, headache.
- ***Coping–Stress Tolerance:*** Concerned she is having a stroke.

Discussion Questions

1. Which subjective assessment findings concern you most?
2. Based on the subjective assessment findings, what should you include in the physical assessment? For what would you be looking?

You will learn more about the physical assessment of the auditory

system in the next section.
(See p. 381 for more information on R.S.)

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

Objective Data

Physical Examination

During the interview to obtain a health history, obtain objective data about the patient's ability to hear. Look for cues that a patient cannot hear (Table 21.3). Record these observations. This is important because the patient is often unaware of hearing loss or does not admit to changes in hearing until moderate losses have occurred.

A normal assessment of the auditory system is shown in Table 21.4. Age-related changes of the auditory system and differences in assessment findings are found in Table 21.1.

TABLE 21.3 Indicators of Possible Hearing Loss

- Does not respond to or understand oral communication
- Has excessively loud or soft speech
- Answers questions inappropriately
- Tilts head, leans forward when listening
- Constantly needs to clarify conversation
- States other people mumble all the time
- Increases the volume of radio or TV
- Difficulty hearing over the phone

TABLE 21.4 Normal Physical Assessment of Auditory System

- Ears symmetric in location and shape
- Auricles and tragus nontender, without lesions
- Canal clear, tympanic membrane intact, landmarks and light reflex intact

- Able to hear low whisper at 30 cm. Weber test results, no lateralization. Rinne test results AC > BC

AC, Air conduction; *BC,* bone conduction.

A *focused assessment* is used to evaluate the status of previously identified auditory problems and monitor for signs of new problems. A focused assessment of the auditory system is presented in the box below.

Focused Assessment

Auditory System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Changes in hearing	Y	N
Ear pain	Y	N
Ear drainage	Y	N
Tinnitus	Y	N

Objective: Physical Examination

Inspect

Alignment and position of ears on head	✓

Size, shape, symmetry, color, and skin intactness	✓
External auditory meatus for discharge or lesions	✓

Assess

Hearing based on ability to respond to conversation, respond to a whisper, or hear a ticking watch	✓

External Ear

Inspect and palpate the external ear before examining the external canal and tympanum. Observe the auricle, preauricular area, and mastoid area for symmetry, color of skin, swelling, redness, and lesions. Then palpate the auricle and mastoid areas for tenderness and nodules. Grasping the auricle or pressing on the tragus may cause pain, especially if the external ear or canal is inflamed.

External Auditory Canal and Tympanum

Before inserting an otoscope, inspect the canal opening for patency, palpate the tragus, and gently move the auricle to check for discomfort. Select a speculum slightly smaller than the size of the ear canal. Tip the patient's head to the opposite shoulder. Grasp the top of the auricle and gently pull up and backward to straighten the canal. Hold the otoscope while stabilizing it with your fingers on the patient's cheek, and then insert it slowly. A pneumatic otoscope creates negative pressure to pull at the TM and is helpful in confirming TM retraction or fluid behind the membrane. A tight seal of the speculum is essential during this step of the examination. Observe the canal for size and shape and the color, amount, and type of cerumen. Be careful when clearing the canal of cerumen. Damage can occur to the middle ear if the TM is perforated.

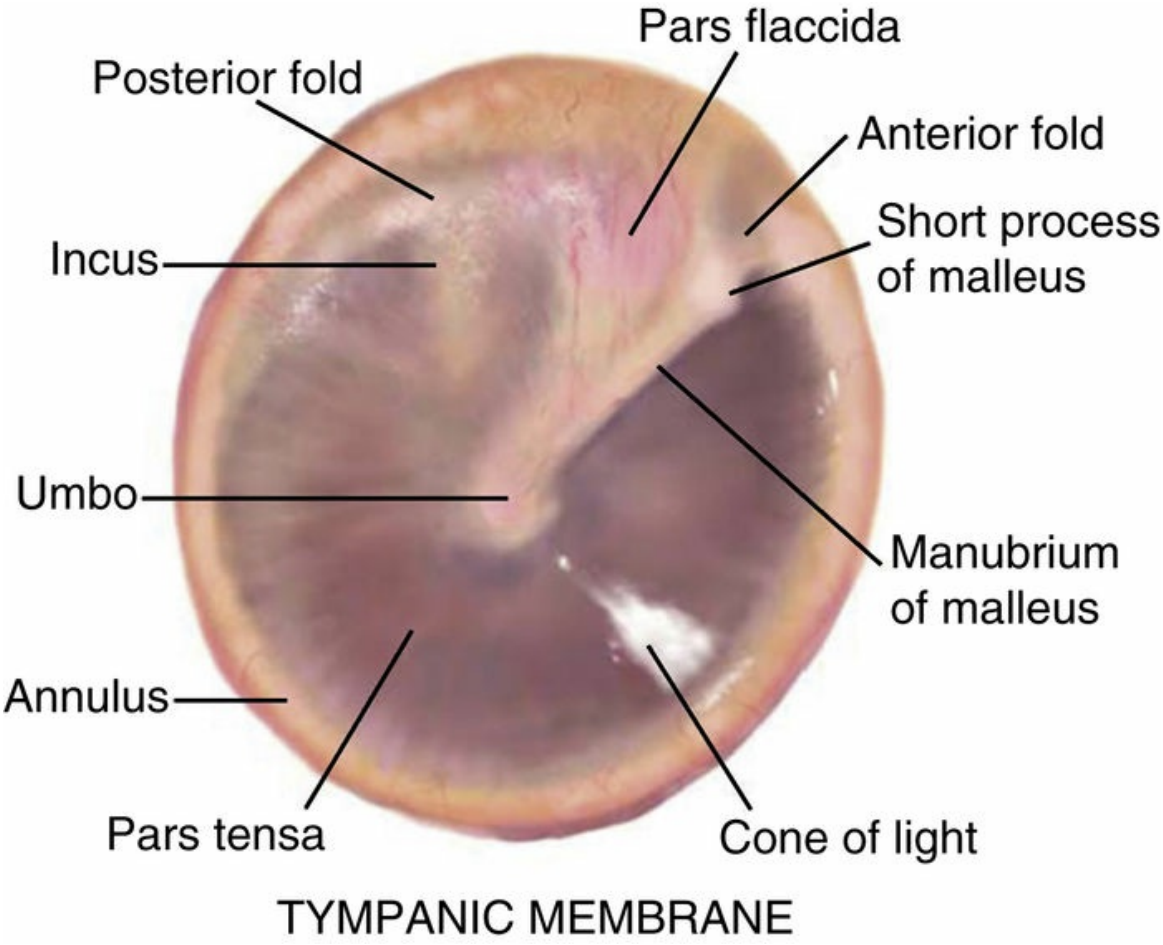

FIG. 21.2 Normal tympanic membrane.
From Jarvis C: *Physical examination and health assessment,* ed 7, St Louis, 2015, Elsevier.

Inspect the TM for color, fluid behind the membrane, landmarks, contour, and intactness (Fig. 21.2). The TM is normally pearl gray, white, or pink; shiny; and translucent. The handle (manubrium) of the malleus and its short process (umbo) should be visible through the membrane. The position and dome (concave) shape of the TM cause the light from the otoscope to reflect in a cone shape with crisp edges. If the TM is bulging or retracted, the edges of the light reflex will be fuzzy (diffuse) and may spread over the TM. The middle and inner ear cannot be examined with the otoscope.

Table 21.5 summarizes assessment abnormalities of the auditory system.

Case Study

Objective Data: Physical Examination

© iStock.com/EyeMark.

Physical examination findings of R.S. were as follows:

- Neurologic and otoscopic examinations normal

- Unable to hear whisper on the right at 30 cm
- Vision normal. PERRLA without nystagmus
- Gait unsteady. No motor weakness
- Skin pale, warm, and dry
- Heart rate 84 beats/min, temperature 97.4° F (36.3° C)

Discussion Questions

1. What physical assessment findings concern you most?
2. What diagnostic studies might you expect to be ordered?

As you continue to read this chapter, consider diagnostic studies that you would expect being performed for R.S.

(See p. 382 for more information on R.S.)

Answers available *at* http://evolve.elsevier.com/Lewis/medsurg.

TABLE 21.5 Assessment AbnormalitiesAuditory System

Finding	Description	Possible Etiology and Significance
External Ear and Canal		
Sebaceous cyst behind ear	Usually within skin, possible presence of black dot (opening to sebaceous gland)	Removal or incision and drainage if painful
Tophi	Hard nodules in the helix or antihelix consisting of uric acid crystals	Associated with gout, metabolic disorder. Further diagnosis needed
Impacted cerumen	Wax that has not normally been excreted from the ear. No visualization of eardrum	Decreased hearing possible, pain, sensation of fullness in auditory canal, removal necessary before otoscopic examination
Discharge in canal	Infection of external ear, usually painful	Swimmer's ear, infection of external ear. Possibly caused by ruptured eardrum and otitis media
Swelling of pinna, pain	Infection of glands of skin, hematoma caused by trauma	Aspiration (for hematoma)
Scaling or lesions	Change in usual appearance of skin	Seborrheic dermatitis, actinic keratosis, basal or squamous cell carcinoma
Exostosis	Bony growth extending into canal causing narrowing of canal	Possible interference with visualizing tympanum. Usually asymptomatic
Tympanum		
Retracted eardrum	Appearance of shorter, more horizontal malleus. Absent or bent cone of light	Vacuum in middle ear, blockage of eustachian tube, negative pressure in middle ear
Hairline fluid level, yellow-amber bubbles above fluid level	Caused by transudate of blood and serum, meniscus of fluid producing hairline appearance	Serous otitis media
Bulging red or blue eardrum, lack of landmarks	Fluid-filled middle ear, pus, blood	Acute otitis media, perforation possible
Perforation of eardrum (Fig. 21.3)	Previous perforations of the eardrum that have failed to heal. Thin, transparent layer of epithelium surrounding eardrum	Chronic otitis media, mastoiditis, drainage
Recruitment	Perception that sounds are getting too loud too fast	Sensorineural hearing loss. Hearing aid hard to use

Diagnostic Studies of Auditory System

Table 21.6 describes common diagnostic studies used to assess the auditory system.

Audiometry

Audiometry is beneficial as a screening test for hearing acuity and as a diagnostic test to determine the degree and type of hearing loss. The most common test performed by the audiologist is pure-tone audiometry. The audiometer produces pure tones at varying intensities to which the patient can respond. Sound is characterized by the number of vibrations or cycles that occur each second. Hertz (Hz) is the unit of measurement used to classify the frequency of a tone. The higher the frequency is, the higher the pitch.

Hearing loss can affect certain sound frequencies. The specific pattern produced on the audiogram by these losses can help in diagnosing the type of hearing loss. The intensity or strength of a

sound wave is expressed in terms of decibels (dB), ranging from 0 to 110 dB. The intensity of a sound needed to make any frequency barely audible to the average normal ear is 0 dB. Threshold refers to the signal level at which pure tones are detected (pure-tone thresholds) or the signal level at which the patient correctly hears 50% of the signals (speech detection thresholds).

Normal speech is around 40 to 65 dB; a soft whisper is 20 dB. Normally, a child and a young adult can hear frequencies from about 16 to 20,000 Hz, but hearing is most sensitive between 500 and 4000 Hz. This is similar to normal speech frequencies. A 40- to 45-dB loss in these frequencies causes moderate difficulty in hearing normal speech. A hearing aid may be helpful because it makes sound information louder but not clearer. A hearing aid may not be helpful to the patient who has problems with discrimination of sounds or sound information because the consonants are still not heard well enough to make speech understandable.

Specialized Tests

More sophisticated tests are available to determine the cause of certain hearing losses (Table 21.6). CT scan and MRI can detect lesions such as a tumor of the auditory nerve.

Case Study

Objective Data: Diagnostic Studies

© iStock.com/EyeMark.

The Weber's test shows lateralization to the left. An audiogram confirms low-frequency, sensorineural hearing loss with normal speech discrimination. An MRI of the head is normal.

Discussion Questions

1. Are these the diagnostic studies that you expected to be ordered?
2. Which diagnostic study results are of most concern to you?

(See p. 393 for more information on R.S.)

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

TABLE 21.6 Diagnostic StudiesAuditory System

Study	Description, Purpose, and Nursing Responsibility
Auditory	
Audiometry	*Pure-tone audiometry* quantifies hearing loss. Sounds are presented through earphones in soundproof room. Patient responds when sound is heard. Response is recorded on an audiogram. Purpose is to determine patient's hearing range in terms of decibels (dB) and Hertz (Hz) for diagnosing hearing loss. Tinnitus can cause inconsistent results. *Speech audiometry* includes speech reception threshold (measure of intensity at which speech is recognized) and word recognition score (ability to discriminate among various speech sounds).
Auditory brainstem response (ABR)	Study measures electrical peaks along auditory pathway of inner ear to brain and provides diagnostic information related to acoustic neuromas, brainstem problems, and stroke.
Auditory evoked potential (AEP)	Procedure is like an electroencephalogram (see Chapter 55 and Table 55.10). Electrodes are placed typically at vertex, mastoid process, and forehead. A computer is used to isolate auditory from other electrical activity of brain. Patient should avoid loud noises for 24 hours before the test.
Electrocochleography	Test records electrical activity in cochlea and auditory nerve. Electrode placed on or through the eardrum. Used to assess and monitor patients with dizziness.
Tympanometry	Used to check middle ear and mobility of eardrum. A probe is placed snugly into external ear canal, and positive and negative pressures are applied. Measurements are made of movement of eardrum.
Tuning Fork Tests	
Rinne test	Compares hearing by bone conduction (BC) and air conduction (AC). Stem of vibrating tuning fork held against mastoid bone (for BC of sound) and time noted. When the sound is no longer perceived behind the ear (BC of sound), time is noted once again and the still-vibrating fork is moved close to the pinna (AC of sound). Have the patient report when the sound next to the ear canal (AC) is no longer heard and note time. Normally, sound is heard twice as long in front of the ear as it is on the bone. With conductive hearing loss, the relationship is reversed; BC is longer than AC. With sensorineural hearing loss, both AC and BC are reduced, but AC remains longer.
Weber test	Stem of vibrating tuning fork is placed on midline of skull or forehead. Patient asked to indicate where the sound is heard best. In normal auditory function, the patient perceives a midline tone and the sound is heard equally in both ears. If a patient has conductive hearing loss in one ear, the sound will be heard louder (lateralizes) in that ear. If sensorineural loss is present, the sound is louder (lateralizes) in the normal (unaffected) ear.
Vestibular Tests	
Electronystagmography (ENG)	Used to diagnose diseases of vestibular system such as dizziness and balance disorders. Electrodes are placed near patient's eyes, and eye movement (nystagmus) is recorded on graph during specific eye movements and when ear is irrigated. Caloric test may be part of testing to measure responses to warm and cold water circulated into the ear canal. Have patient eat a light meal before test to avoid nausea. Observe patient for vomiting. Ensure patient safety.
Posturography	Balance test that can isolate one semicircular canal from others to determine site of lesion. Test is done in a boxlike device in which floor moves in response to a correction in balance by patient. Tell patient that test may be uncomfortable. Test can be stopped at any time at patient's request.
Rotary chair testing	Evaluates peripheral vestibular system. Patient is seated in a chair driven by a motor under computer control. Test is usually done in the dark. Tell patient to eat light meal before test to avoid nausea. Observe patient for vomiting. Ensure patient safety.

Auditory Problems: External Ear and Canal

External Otitis

The skin of the external ear and canal is subject to the same problems as skin anywhere on the body. **External otitis** involves inflammation or infection of the epithelium of the auricle and ear canal. Swimming may change the flora of the external canal because of chemicals and contaminated water. This can result in an infection often referred to as "swimmer's ear." Trauma from picking the ear or using sharp objects (e.g., hairpins) often causes the initial break in the skin. Piercing of cartilage in the upper part of the auricle also places the patient at higher risk for infection.

Infections and skin conditions may cause external otitis. Bacteria or fungi may be the cause. *Pseudomonas aeruginosa* is the most common bacterial cause. Fungi, especially *Candida albicans* and *Aspergillus,* thrive in warm, moist climates. The warm, dark environment of the ear canal provides a good growth medium for microorganisms.

Malignant external otitis is a serious infection caused by *P. aeruginosa.* It occurs mainly in older patients with diabetes. The infection, which can spread from the external ear to the parotid gland and temporal bone (osteomyelitis), is usually treated with antibiotics.

Ear pain *(otalgia)* is one of the first signs of external otitis. Even in mild cases, the patient may have significant discomfort with chewing, moving the auricle, or pressing on the tragus. Swelling of the ear canal can muffle hearing. There may be serosanguineous (blood-tinged fluid) or purulent (white to green thick fluid) drainage. Fever occurs when the infection spreads to surrounding tissue.

Nursing and Interprofessional Management: External Otitis

External otitis is diagnosed by otoscopic examination of the ear canal. Take care to avoid pain when pulling on the pinna to straighten out the canal or when inserting the otoscope speculum. The eardrum may be hard to see due to swelling in the canal. Culture and sensitivity studies of the drainage may be done. Moist heat, mild analgesics, and topical anesthetic drops usually control the pain. Topical treatments may include antibiotics for infection and corticosteroids for inflammation. If the surrounding tissue is involved, systemic antibiotics are used. Improvement should occur in 48 hours. The patient needs to adhere to the prescribed therapy for 7 to 14 days for complete resolution.

TABLE 21.7 Patient & Caregiver TeachingPrevention of External Otitis

Include the following instructions when teaching the patient and caregiver:

1. Do not put anything in your ear canal unless requested by your health care provider.
2. Report itching if it becomes a problem.
3. Earwax is normal.
    - It lubricates and protects the canal.
    - Report chronic excess cerumen if it impairs your hearing.
4. Keep your ears as dry as possible.
    - Use earplugs if you are prone to swimmer's ear.
    - Turn your head to each side for 30 seconds at a time to help water run out of the ears.
    - Do not dry with cotton-tipped applicators.
    - A hair dryer set to low and held at least 6 inches from the ear can speed water evaporation.

Wash hands before and after applying eardrops (otic drops). The drops should be at room temperature. Cold drops can cause vertigo

due to stimulation of the semicircular canals, and heated drops can burn the tympanum. The tip of the dropper should not touch the ear during application to prevent contamination of the entire bottle of drops. Position the ear so that the drops can run into the canal. The patient should stay in this position for 2 minutes to allow the drops to spread. Sometimes you can place the drops onto a wick of cotton, then place the wick in the canal. Tell the patient not to push the cotton farther into the ear. Careful handling and disposal of material saturated with drainage are important. Teach the patient ways to reduce the risk for external otitis (Table 21.7).

Cerumen and Foreign Bodies in External Ear Canal

Impacted cerumen (earwax) can cause discomfort and decreased hearing. Other symptoms include tinnitus and vertigo. Remove an impaction by irrigating the canal with body-temperature solutions to soften the earwax. Special syringes may be used. These vary from a simple bulb syringe to special irrigating equipment. Place the patient in a sitting position with an emesis basin under the ear. Pull the auricle up and back, and direct the flow of solution above or below the impaction. Do not completely occlude the ear canal with the syringe tip. If irrigation does not remove the wax, use mild lubricant drops to soften the earwax. The HCP may need to remove severe impactions.

Attempts to remove a foreign object from the ear may result in pushing it farther into the canal. Vegetable matter in the ear tends to swell. This can create a secondary inflammation, making removal more difficult. Mineral oil or lidocaine drops can be used to kill an insect before removal under microscope guidance. The HCP should remove impacted objects.

Cleanse ears with a washcloth and finger. Avoid using cotton-tipped applicators. Penetration of the middle ear by a cotton-tipped applicator can cause serious injury to the TM and ossicles. Their use

can also cause earwax to become impacted against the TM and impair hearing.

Trauma

Trauma to the external ear can cause injury to the subcutaneous tissue and result in a hematoma. If a hematoma is not aspirated, inflammation of the membranes of the ear cartilage (perichondritis) can result. Blows to the ear can cause conductive hearing loss if the ossicles in the middle ear are damaged or the TM is perforated. Head trauma that injures the temporal lobe of the cerebral cortex can impair the ability to understand the meaning of sounds.

Malignancy of External Ear

Skin cancers are the only common cancers of the ear. Precancerous actinic keratoses, rough sandpaper-like lesions on the upper border of the auricle, are associated with chronic sun exposure. They are often treated with liquid nitrogen. Cancers in the external ear canal include basal cell carcinoma in the pinna and squamous cell carcinoma in the ear canal. If left untreated, they can invade underlying tissue. Teach the patient about the dangers of sun exposure and the importance of using hats and sunscreen when outdoors. See Chapter 23 for more about skin cancer.

Middle Ear and Mastoid

Otitis Media

Acute Otitis Media

Acute otitis media is an infection of the tympanum, ossicles, and space of the middle ear. Swelling of the auditory tube from colds or allergies can trap bacteria, causing a middle ear infection. Pressure from the inflammation pushes on the TM, causing it to become red, bulging,

and painful. Acute otitis media is usually a childhood disease. In children the auditory tube that normally drains fluid and mucus from the middle ear is shorter and narrower, and its position is flatter than in adults. Infection can be due to viruses or bacteria. Pain, fever, malaise, drainage, and reduced hearing are signs and symptoms of infection. Referred pain from the TMJ, teeth, gums, sinuses, or throat can also cause ear pain.

Oral antibiotics and eardrops are used if an infection is present. Surgical intervention is reserved for the patient who does not respond to medical treatment. A *myringotomy* involves an incision in the tympanum to release the increased pressure and exudate from the middle ear. A tympanostomy tube may be used short- or long-term for ventilation of the ear. Prompt treatment of an episode of acute otitis media can help prevent spontaneous perforation of the TM. If allergies are a causative factor, the patient may receive antihistamines and a nasal corticosteroid spray.

Otitis Media With Effusion

Otitis media with effusion is an inflammation of the middle ear with a collection of fluid in the middle ear space. The fluid may be thin, mucoid, or purulent. If the auditory tube does not open and allow equalization of atmospheric pressure, negative pressure within the middle ear pulls fluid from surrounding tissues. This problem commonly follows upper respiratory tract or chronic sinus infections, barotrauma (caused by pressure change), or otitis media.

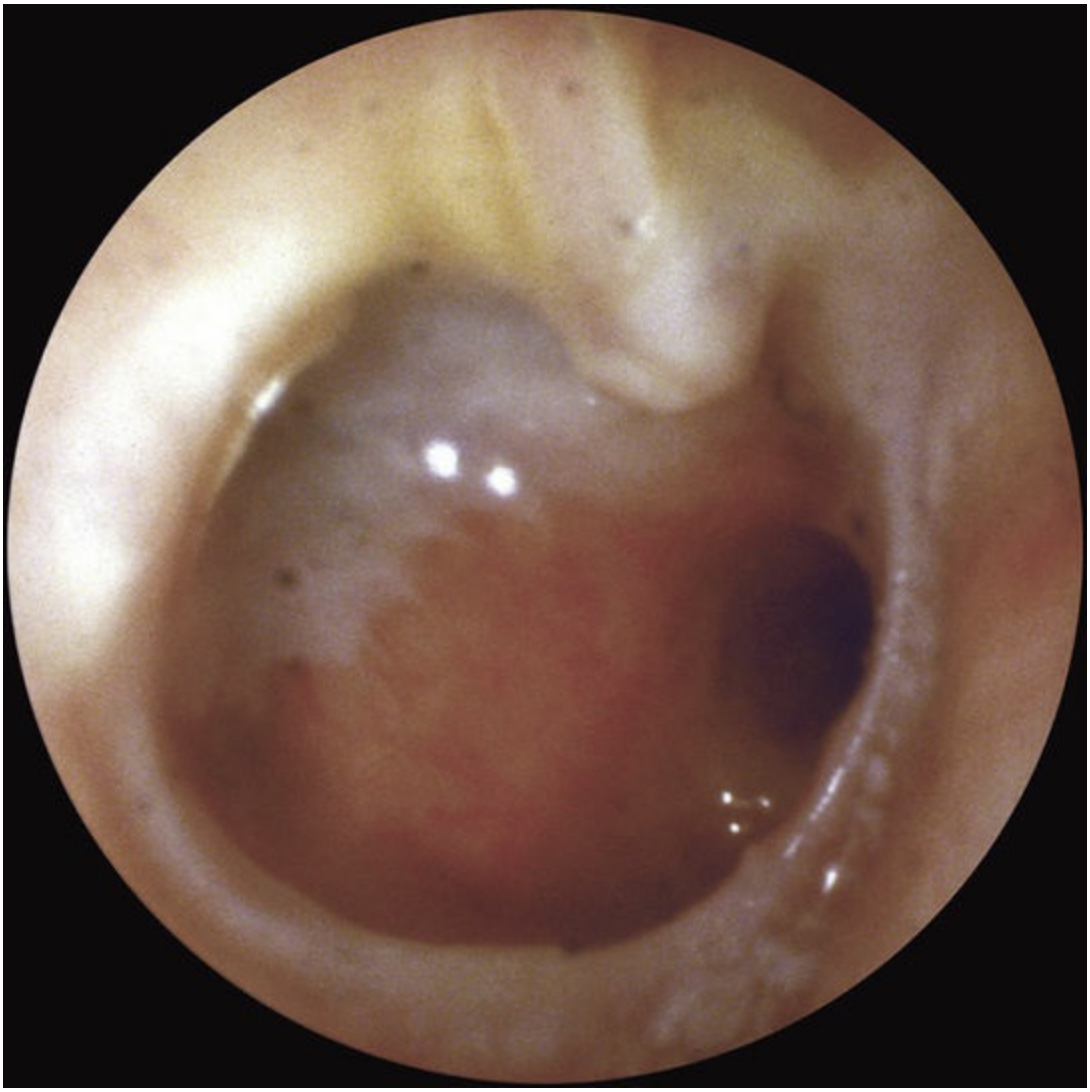

FIG. 21.3 Perforation of the tympanic membrane (TM).
From Flint P, Haughey B, Lund V, Niparko JK, eds: *Cummings otolaryngology: Head and neck surgery,* ed 5, St Louis, 2010, Mosby.

Symptoms include a feeling of fullness of the ear, a "plugged" feeling or popping, and decreased hearing. The patient does not have pain, fever, or discharge from the ear. It is common to have otitis media with effusion for weeks to months after an episode of acute otitis media. It usually resolves without treatment but may recur.

Chronic Otitis Media and Mastoiditis

Repeated attacks of otitis media may lead to chronic otitis media, especially in adults who have a history of recurrent otitis media in

childhood. Because the mucous membrane of the middle ear is continuous with the air cells of the mastoid bone, both can be involved in the chronic infectious process.

Chronic otitis media is characterized by a purulent exudate and inflammation that can involve the ossicles, auditory tube, and mastoid bone. It is often painless. Hearing loss, nausea, and episodes of dizziness can occur. Hearing loss is a complication from inflammatory destruction of the ossicles, a TM perforation, or accumulation of fluid in the middle ear space. A mass of epithelial cells and cholesterol in the middle ear *(cholesteatoma)* may develop. The cholesteatoma enlarges and can destroy the adjacent bones. Unless removed surgically, it can cause extensive damage to the ossicles and impair hearing.

Otoscopic examination of the TM may reveal changes in color and mobility or a perforation (Fig. 21.3). Culture and sensitivity tests of the drainage are necessary to identify the organisms involved so the patient may receive the appropriate antibiotic therapy. The audiogram may show a hearing loss as great as 50 to 60 dB if the ossicles have been damaged or separated. Sinus x-rays, MRI, or a CT scan of the temporal bone can assess for bone destruction and the presence of a mass.

Nursing and Interprofessional Management: Chronic Otitis Media

The goals of treatment are to clear the middle ear of infection, repair any perforations, and preserve hearing (Table 21.8). Otic and systemic (oral and IV) antibiotic therapy is started based on the culture and sensitivity results. In many cases of chronic otitis media, antibiotic resistance is present. The patient may need to have frequent evacuation of drainage and debris in an outpatient setting.

TABLE 21.8 Interprofessional CareChronic Otitis Media

Diagnostic Assessment

- History and physical examination
- Otoscopic examination
- Culture and sensitivity of middle ear drainage
- Mastoid x-ray

Management

- Ear irrigations
- Otic, oral, or parenteral antibiotics
- Analgesics
- Antiemetics
- Surgery
    - Tympanoplasty
    - Mastoidectomy

TABLE 21.9 Patient & Caregiver TeachingAfter Ear Surgery

Include the following information in the teaching plan for the patient and caregiver after ear surgery.

1. Sleep on your back or the unoperated ear for 1 week.
2. Avoid air travel and sun exposure for 6 weeks.
3. If you need to cough or sneeze, keep your mouth open.
4. Blow your nose gently, without blocking either nostril.
5. Do not shampoo your hair for 5 days. Wear a shower cap when bathing.

6. No swimming. Keep your ear dry for 6 weeks.
7. You may resume strenuous activity and contact sports in 1 month.
8. Change your ear dressing daily as prescribed.
9. Report excess drainage or severe dizziness to the health care provider.

Often chronic TM perforations do not heal with conservative treatment, and surgery is necessary. *Tympanoplasty (myringoplasty)* involves reconstruction of the TM and/or the ossicles. A *mastoidectomy* is often performed with a tympanoplasty to remove infected portions of the mastoid bone. Removal of tissue stops at the middle ear structures that appear capable of conducting sound. Sudden pressure changes in the ear and postoperative infections can disrupt healing or cause facial nerve paralysis.

Expect impaired hearing during the postoperative period if there is packing in the ear. A cotton ball dressing is used if an incision was made through the external auditory canal. Teach the patient to change the cotton packing as needed (Table 21.9). If a postauricular (behind the ear) incision was used and a drain is in place, place a dressing over that area. Then, place a soft outer dressing over the top of that dressing. This will prevent putting pressure on the auricle. Monitor the tightness of the outer dressing to prevent tissue necrosis and assess the amount and type of drainage. Keep the suture line dry.

Otosclerosis

Otosclerosis is a hereditary autosomal dominant disease. It is the most common cause of hearing loss in young adults. Spongy bone develops from the bony labyrinth, preventing movement of the footplate of the stapes in the oval window. This reduces the transmission of vibrations to the inner ear fluids and results in conductive hearing loss. Although otosclerosis is typically bilateral, one ear may show faster progression of hearing loss. The patient is often unaware of the problem until the loss becomes so severe that

communication is difficult.

TABLE 21.10 Interprofessional CareOtosclerosis

Diagnostic Assessment

- History and physical examination
- Otoscopic examination
- Rinne test
- Weber test
- Audiometry
- Tympanometry

Management

- Hearing aid
- Surgery (stapedectomy or stapes prosthesis)
- Drug therapy
    - Calcium carbonate
    - Sodium fluoride with vitamin D

Otoscopic examination may reveal a reddish blush of the tympanum (Schwartz's sign) caused by the vascular and bony changes within the middle ear. Tuning fork tests (e.g., Rinne) and an audiogram show good hearing by bone conduction with poor hearing by air conduction (air-bone gap) (Table 21.6). Usually a difference of at least 20 to 25 dB between air and bone conduction levels of hearing occurs with otosclerosis.

The hearing loss associated with otosclerosis may be stabilized by giving oral sodium fluoride with vitamin D and calcium carbonate. These medications slow bone resorption and promote the calcification of bony lesions. Amplifying sound with a hearing aid can be effective

because inner ear function is normal.

Interprofessional care of otosclerosis is outlined in Table 21.10. Microdrill or laser surgical treatment involves opening the footplate (stapedotomy) or replacing the stapes with a metal or Teflon substitute (prosthesis). These procedures are usually done with the patient under conscious sedation. The ear with poorer hearing is repaired first. The other ear may be operated on within a year. Immediately after surgery the patient often reports a significant improvement in hearing in the operative ear. Because blood and fluid accumulates in the middle ear during the postoperative period, the hearing level decreases initially, but it improves gradually with healing.

Nursing management of the patient undergoing surgery to correct otosclerosis is like that of the patient having a tympanoplasty. Place a cotton ball in the ear canal and cover the ear with a small dressing. The patient may have dizziness, nausea, and vomiting because of stimulation of the labyrinth during surgery. Disturbing the perilymph fluid can cause nystagmus. Teach the patient to avoid sudden movements that may bring on or worsen vertigo and actions that increase inner ear pressure, such as coughing, sneezing, lifting, bending, and straining during bowel movements.

Inner Ear Problems

Three manifestations that indicate disease of the inner ear are vertigo, sensorineural hearing loss, and tinnitus. Symptoms of vertigo arise from the vestibular labyrinth, while hearing loss and tinnitus arise from the auditory labyrinth. There is an overlap between manifestations of inner ear problems and central nervous system (CNS) disorders.

Ménière's Disease

Ménière's disease is a progressive disorder leading to an accumulation of endolymph in the membranous labyrinth. Although

it usually affects only one ear, it can affect both. The cause is unknown. Genetic and environmental factors may play a role. Symptoms usually begin between 30 and 60 years of age. Women are more likely to be affected.[4]

The excess fluid and resulting pressure lead to hearing and balance problems, including episodic vertigo, tinnitus, and ear pressure or fullness. Progressive hearing loss occurs over time. The patient has significant disability because of sudden, severe attacks of vertigo with nausea, vomiting, and sweating. A sense of fullness in the ear, increasing tinnitus, and muffled hearing may precede an attack. The patient may have the feeling of being pulled to the ground ("drop attacks"). Some patients report feeling like they are whirling in space. Attacks may last hours or days and may occur several times a year. The clinical course of the disease is highly variable.

Nursing and Interprofessional Management: Ménière's Disease

Interprofessional care of Ménière's disease (Table 21.11) includes diagnostic tests to rule out other causes of the symptoms, including CNS disease. Results that suggest Ménière's disease include low-frequency sensorineural hearing loss on audiogram, 2 or more spontaneous episodes of vertigo, and abnormal vestibular tests.[5] A glycerol test may aid in diagnosis. The patient receives an oral dose of glycerol, followed by serial audiograms over 3 hours. Improvement in hearing or speech discrimination supports a diagnosis of Ménière's disease. This is attributed to the osmotic effect of glycerol pulling fluid from the inner ear.

No cure exists for Ménière's disease. Treatments aim to reduce the number and severity of vertigo attacks. During an acute attack, corticosteroids, antihistamines (e.g., diphenhydramine), anticholinergics (e.g., atropine), and benzodiazepines (e.g., lorazepam [Ativan]) can decrease the abnormal sensation and lessen nausea and vomiting.[4] Acute vertigo is treated symptomatically with bed rest,

sedation, and antiemetics (e.g., prochlorperazine) or antivertigo drugs (e.g., meclizine) for motion sickness. Management between attacks may include diuretics, corticosteroids, a low-sodium diet, and stress reduction. Over time, most patients respond to the medications but must learn to live with the unpredictability of the attacks and the loss of hearing.

Frequent and incapacitating attacks are indications for surgical intervention. Decompression of the endolymphatic sac and shunting can reduce the pressure on the cochlear hair cells and prevent further damage and hearing loss. If relief is not achieved, a vestibular nerve section (cutting the nerve) may be done. When involvement is unilateral, surgical ablation of the labyrinth, resulting in the loss of vestibular and hearing cochlear function, is an option. Some patients with severe attacks of vertigo have shown improvement with the injection of gentamicin through the TM. This results in inner ear damage and a reduction in endolymph production.

TABLE 21.11 Interprofessional CareMénière's Disease

Diagnostic Assessment

- History and physical examination
- Studies (including speech discrimination, tone decay)
- Vestibular tests (including caloric test, positional test)
- Electronystagmography
- Glycerol test

Management

Acute Care

Drug Therapy

- Anticholinergics
- Antihistamines
- Antiemetics
- Benzodiazepines
- Corticosteroids

Surgical Therapy

- Endolymphatic sac decompression
- Endolymphatic shunt
- Labyrinthectomy
- Vestibular nerve section

Ambulatory Care

- Diuretics
- Corticosteroids
- Dietary restriction of sodium, caffeine, nicotine, and alcohol
- Stress reduction techniques

Plan nursing interventions to minimize vertigo and provide patient safety. During an acute attack, keep the patient in a quiet, darkened room in a comfortable position. Teach the patient to avoid sudden head movements and position changes and to close the eyes until vertigo stops. Avoid fluorescent or flickering lights and television as they may worsen symptoms. Make an emesis basin available because vomiting is common. To minimize the risk for falling, keep the side rails up and the bed in a low position when the patient is in bed. Teach the patient to call for help when getting out of bed. Give medications and fluids parenterally. Monitor intake and output. When the attack subsides, help the patient with ambulation because unsteadiness may remain.

Discharge teaching should emphasize ways to protect the patient from injury between attacks. Review with the patient the need to sit or lie down at the onset of any dizziness. Discuss home safety and measures to decrease fall risk. Teach the need to avoid swimming under water, using ladders, and being on high places until vertigo is under control. Encourage the patient to practice any balance therapy exercises daily.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo (BPPV) is a common cause of vertigo. About 50% of the cases of vertigo may be due to BPPV. In BPPV, free-floating debris in the semicircular canal causes vertigo with specific head movements, such as getting out of bed, rolling over in bed, and sitting up from lying down. The debris ("ear rocks") is composed of small crystals of calcium carbonate that come from the utricle in the inner ear. The utricle may have been injured by head trauma, infection, or degeneration from the aging process. However, for many patients, we do not know the cause.

Symptoms of BPPV include nystagmus, vertigo, light-headedness, loss of balance, and nausea. There is no hearing loss, and symptoms tend to be intermittent. The symptoms of BPPV may be confused with those of Ménière's disease. Diagnosis is based on the results of auditory and vestibular tests.

Although BPPV is bothersome, it is rarely serious unless a person falls. The Epley maneuver, or canalith repositioning procedure, is effective in providing symptom relief for many patients. This maneuver moves ear debris from areas in the inner ear that cause symptoms and into less sensitive areas where they do not cause these problems. It does not change the presence of debris but changes the location. A trained HCP can teach the patient how to perform the maneuver (Fig. 21.4).

Acoustic Neuroma

An **acoustic neuroma** is a unilateral benign tumor that occurs where the vestibulocochlear nerve (CN VIII) enters the internal auditory canal. Early diagnosis is important because the tumor can compress the trigeminal and facial nerves and arteries within the internal auditory canal. Symptoms usually begin between 40 and 60 years of age.

Early symptoms are associated with CN VIII compression and destruction. They include unilateral, progressive, sensorineural hearing loss; reduced touch sensation in the posterior ear canal; unilateral tinnitus; and mild, intermittent vertigo. Diagnostic tests include neurologic, audiometric, and vestibular tests; CT scans; and MRI.

Surgery to remove small tumors can preserve hearing and vestibular function. Large tumors (larger than 3 cm) and the surgery to remove them can leave the patient with permanent hearing loss and facial paralysis. Stereotactic radiosurgery may slow tumor growth and preserve the facial nerve. Teach the patient to report any clear, colorless discharge from the nose. This may be cerebrospinal fluid (CSF), which increases the risk for infection. Follow-up care after surgery is important to monitor hearing and for tumor recurrence.

Hearing Loss and Deafness

Hearing disorders are a common cause of disability. Age is the strongest predictor of hearing impairment. In the United States, about 25% of those 65 to 74 and 50% of those 75 and older have hearing loss.[6] Causes of hearing loss are shown in Fig. 21.5.

Types of Hearing Loss

Conductive Hearing Loss

Conductive hearing loss occurs when conditions in the outer or middle ear impair the transmission of sound through air to the inner ear. Common causes of conductive hearing loss in adults include impacted cerumen, otitis media with effusion, TM perforation, otosclerosis, and

narrowing of the external auditory canal.[1]

The audiogram shows better hearing through bone than through air (air-bone gap). The patient often speaks softly because hearing his or her own voice (which is conducted by bone) seems loud. This patient hears better in a noisy environment. The first step is to identify and treat the cause if possible. If correction of the cause is not possible, a hearing aid may help if the loss is greater than 40 to 50 dB.

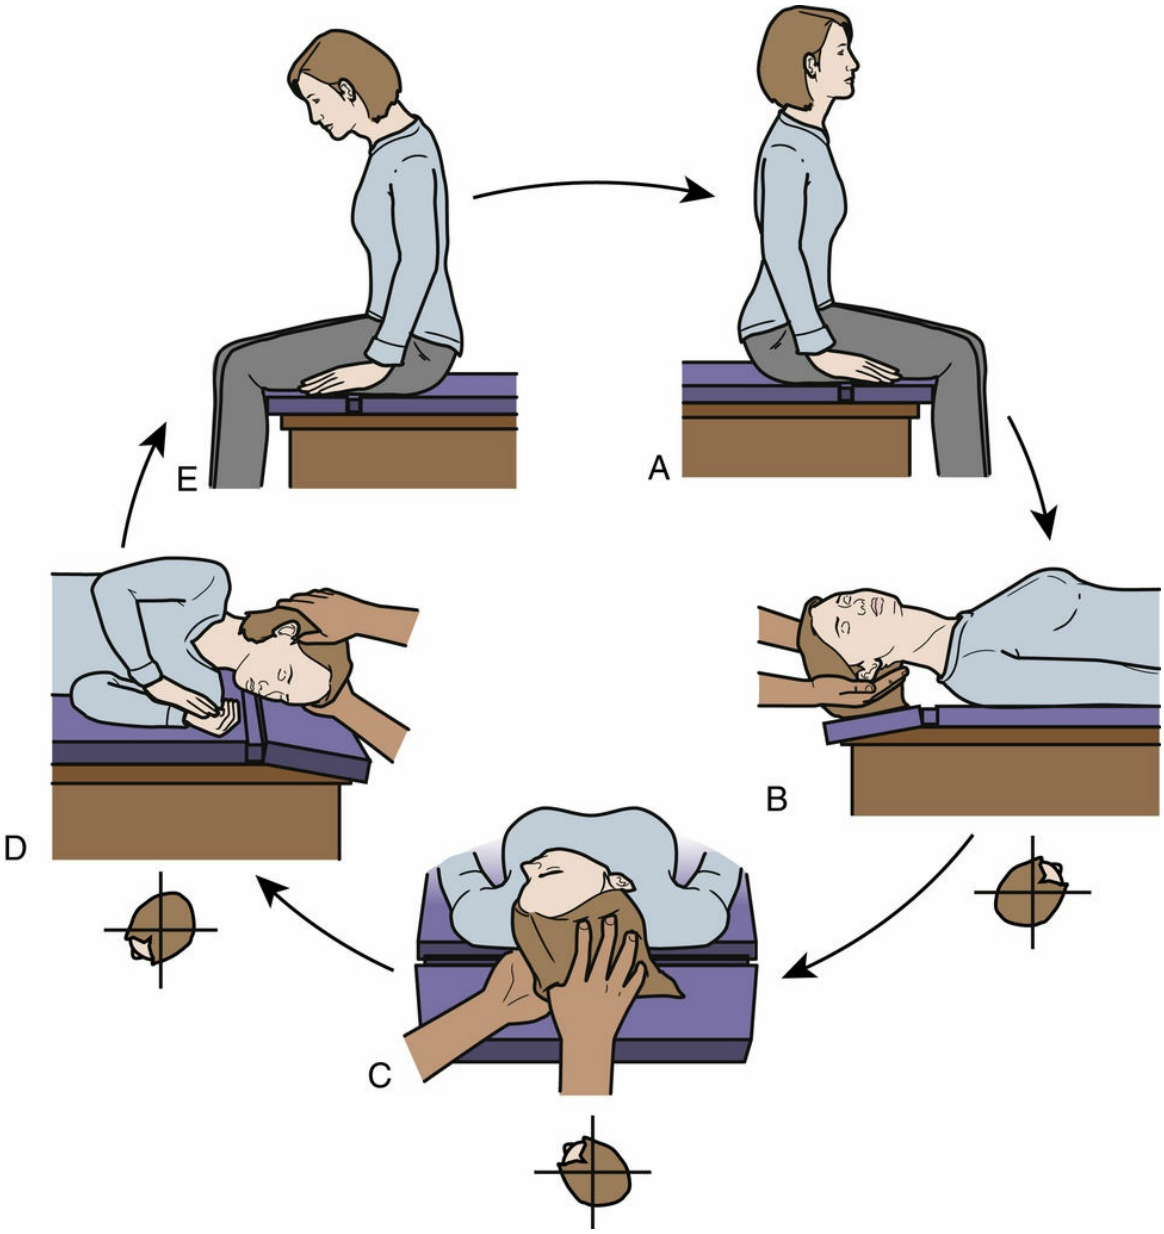

FIG. 21.4 Epley maneuver.

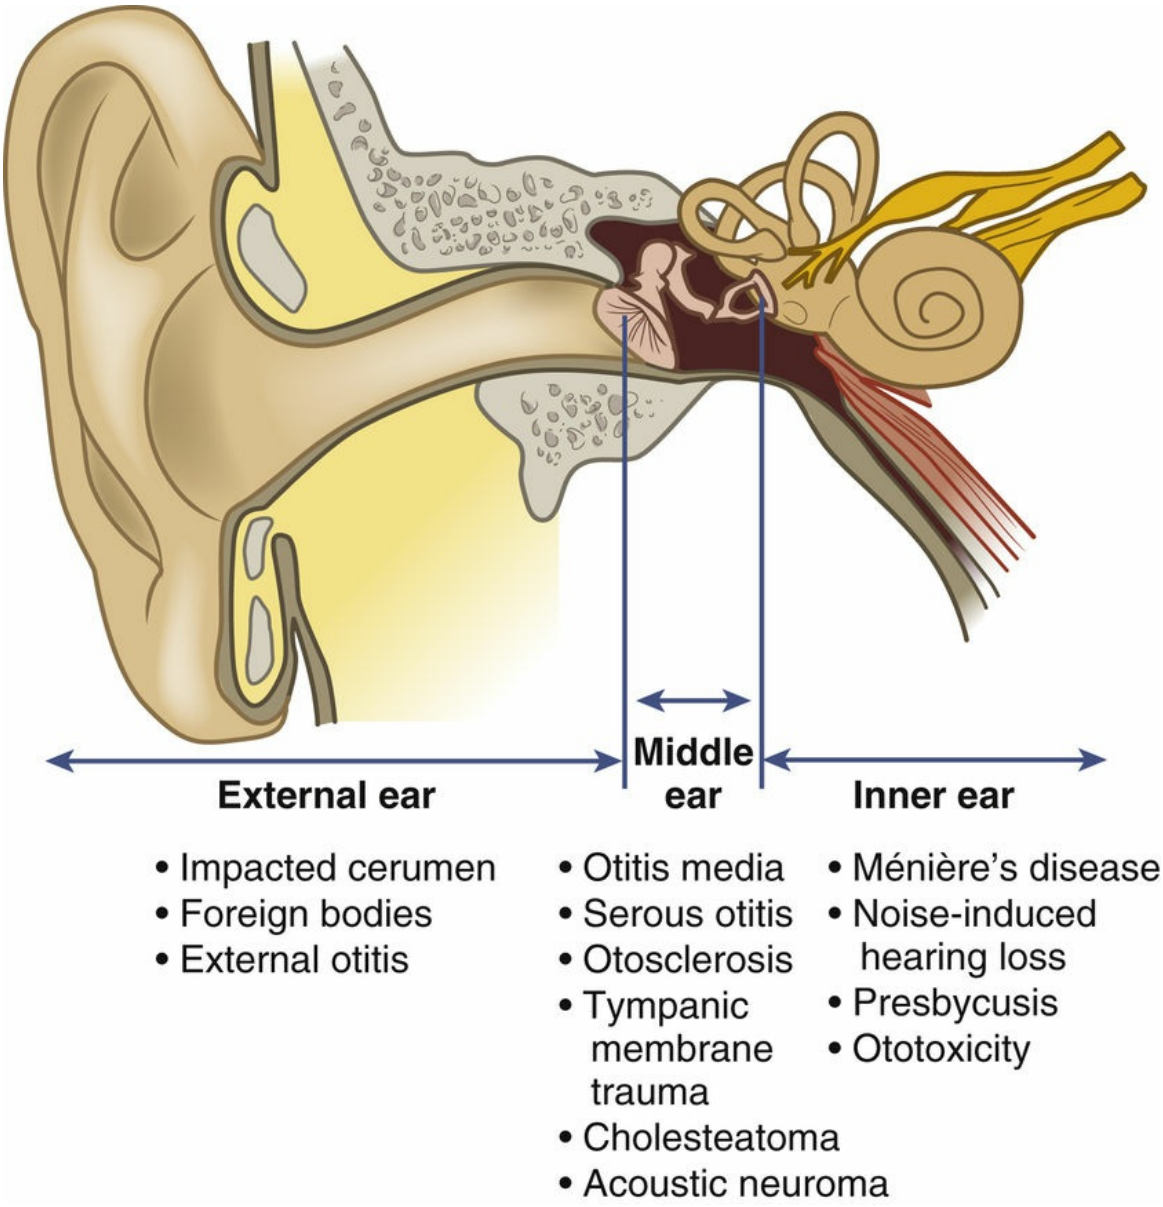

FIG. 21.5 Causes of hearing loss.

Sensorineural Hearing Loss

Sensorineural hearing loss is caused by impairment of function of the inner ear or the vestibulocochlear nerve (CN VIII). Congenital and hereditary factors, noise exposure, aging (presbycusis), Ménière's disease, trauma, and ototoxicity can cause sensorineural hearing loss. The main problems are the ability to hear sound but not to understand speech and the lack of understanding of the problem by others. The

ability to hear high-pitched sounds (including consonants) diminishes. Sounds become muffled and hard to understand. An audiogram shows a loss in decibel levels of the 4000-Hz range and eventually the 2000-Hz range. A hearing aid may help some patients, but it only makes sounds and speech louder, not clearer.

Mixed Hearing Loss

Mixed hearing loss occurs due to a combination of conductive and sensorineural causes. Careful evaluation is needed if corrective surgery for conductive loss is planned because the sensorineural hearing loss will still be present.

Central and Functional Hearing Loss

Central hearing loss involves an inability to interpret sound, including speech, because of a problem in the brain (CNS). A careful history is helpful because there are usually cases of deafness in the family. Refer the patient to a qualified hearing and speech service if indicated.

An emotional or a psychologic factor can cause functional hearing loss. The patient does not seem to hear or respond to pure-tone subjective hearing tests, but no physical reason for hearing loss can be found. Psychologic counseling may help.

Genetic Link

Heredity hearing loss is labeled non-syndromic or syndromic. Most persons have *non-syndromic hearing impairment,* in which hearing loss is the only primary problem. *GJB2* gene mutations are one of the most common causes of non-syndromic hearing loss. These result in changes in the production of the protein Connexin 26, which has a role in the cochlear function. Other genetic mutations increase the risk for ototoxicity or result in malformations of structures in the middle and/or inner ear. *Syndromic hearing impairment* is associated with other clinical abnormalities, such as malformations of the external ear or problems involving other organs. There are more than 400 syndromes that include hearing loss.

Classification of Hearing Loss

Hearing loss can be classified by the decibel level or loss as recorded on the audiogram. Normal hearing is in the 0- to 15-dB range. Most people with a hearing loss of 90 decibels or greater have been deaf since birth (congenitally deaf). Table 21.12 describes the levels of hearing loss.

Clinical Manifestations

Common early signs of hearing loss are answering questions inappropriately and not responding when not looking at the speaker (Table 21.3). Other behaviors that suggest hearing loss include straining to hear, cupping the hand around the ear, reading lips, and an increased sensitivity to slight increases in noise level. Often the patient is unaware of minimal hearing loss. Family and friends who get tired of repeating or talking loudly are often the first to notice the hearing loss. Pressure exerted by significant others is a significant factor in whether the patient seeks help for hearing impairment.

Sudden hearing loss, or sudden deafness, occurs as an unexplained, rapid loss of hearing (usually in one ear) either at once or over several days. It is a medical emergency, and the patient should see an HCP at once.

Tinnitus and Hearing Loss

Tinnitus is the perception of *sound* in the ears where no external source is present. It is "ringing in the ears" or "head noise" (see www.ata.org). Tinnitus is sometimes the first symptom of hearing loss, especially in older adults. It may be soft or loud, high pitched or low pitched.

Often, tinnitus occurs because of noise exposure. It also can be a drug side effect. More than 200 drugs are known to cause tinnitus.

Nursing and Interprofessional

Management: Hearing Loss and Deafness

Deafness is often called the "unseen handicap" because you may not realize the difficulty in communication with a deaf person until you begin a conversation with that person. You need to confirm a deaf person's understanding of health teaching. Descriptive visual aids can be helpful. If the significantly hearing-impaired person uses sign language to communicate, the Americans with Disabilities Act requires providing an interpreter when presenting significant information, such as for patient consent or discharge teaching.[7]

TABLE 21.12 Classification of Hearing Loss

Decibel (dB) Loss	Meaning
0–15	Normal hearing
16–25	Slight hearing loss
26–40	Mild impairment
41–55	Moderate impairment
56–70	Moderately severe impairment
71–90	Severe impairment
>90	Profound deafness

Interference in communication and interaction with others can be the source of many problems for the patient and caregiver. Often the patient refuses to admit or may be unaware of impaired hearing. Irritability is common because the patient must concentrate so hard to understand speech. The loss of clarity of speech in the patient with sensorineural hearing loss is most frustrating. The patient may hear what is said but not understand it. Withdrawal, depression, and accelerated cognitive decline are often associated with advancing

hearing loss.[8]

Check Your Practice

Your newly assigned 68-yr-old female patient is being discharged today following a hip replacement. Before going to her room, you prepared the materials and information for her discharge. You sit down by her bed and start talking with her. She shakes her head and says, "No, no." You are perplexed until she flashes a bracelet that says *I am deaf*.

- How will you proceed?

Health Promotion

Environmental Noise Control

Noise is the most preventable cause of hearing loss. Fig. 21.6 lists the levels of environmental noise generated by common indoor and outdoor sounds. Sudden severe loud noise (acoustic trauma) and chronic exposure to loud noise (noise-induced hearing loss) can damage hearing. Acoustic trauma causes hearing loss by destroying the hair cells of the organ of Corti. Sensorineural hearing loss from increased and prolonged environmental noise, such as amplified sound, is occurring in young adults at an increasing rate. Amplified music (e.g., on smartphones) should not exceed 50% of maximum volume. Ear protection should be worn when firing a gun and during other recreational pursuits with high noise levels. Health teaching about avoiding continued exposure to noise levels greater than 70 dB is essential.

In work environments known to have high noise levels (more than 85 dB), people should wear ear protection. Occupational Safety and Health Administration (OSHA) standards mandate ear protection for workers in environments where the noise levels consistently exceed 85 dB. Periodic audiometric screening should be part of the health

maintenance policies of industry. This provides baseline data on hearing to measure subsequent hearing loss.

Employees should take part in hearing conservation programs in work environments. Such programs should include noise exposure analysis, provision for control of noise exposure (hearing protectors), measurements of hearing, and employee-employer notification and education. Encourage young adults to keep amplified music at a reasonable level and limit their exposure time. Hearing loss caused by noise is not reversible

Promoting Population Health

Promoting Healthy Hearing

- Wear ear protection during recreational and work activities involving high noise levels.
- Monitor your audio level and how long you use personal listening devices.
- Avoid exposure to excessively loud noise whenever possible.
- Undergo audiometric screening to detect hearing loss before it progresses.
- Avoid injury from cotton-tipped applicators and other cleaning materials.

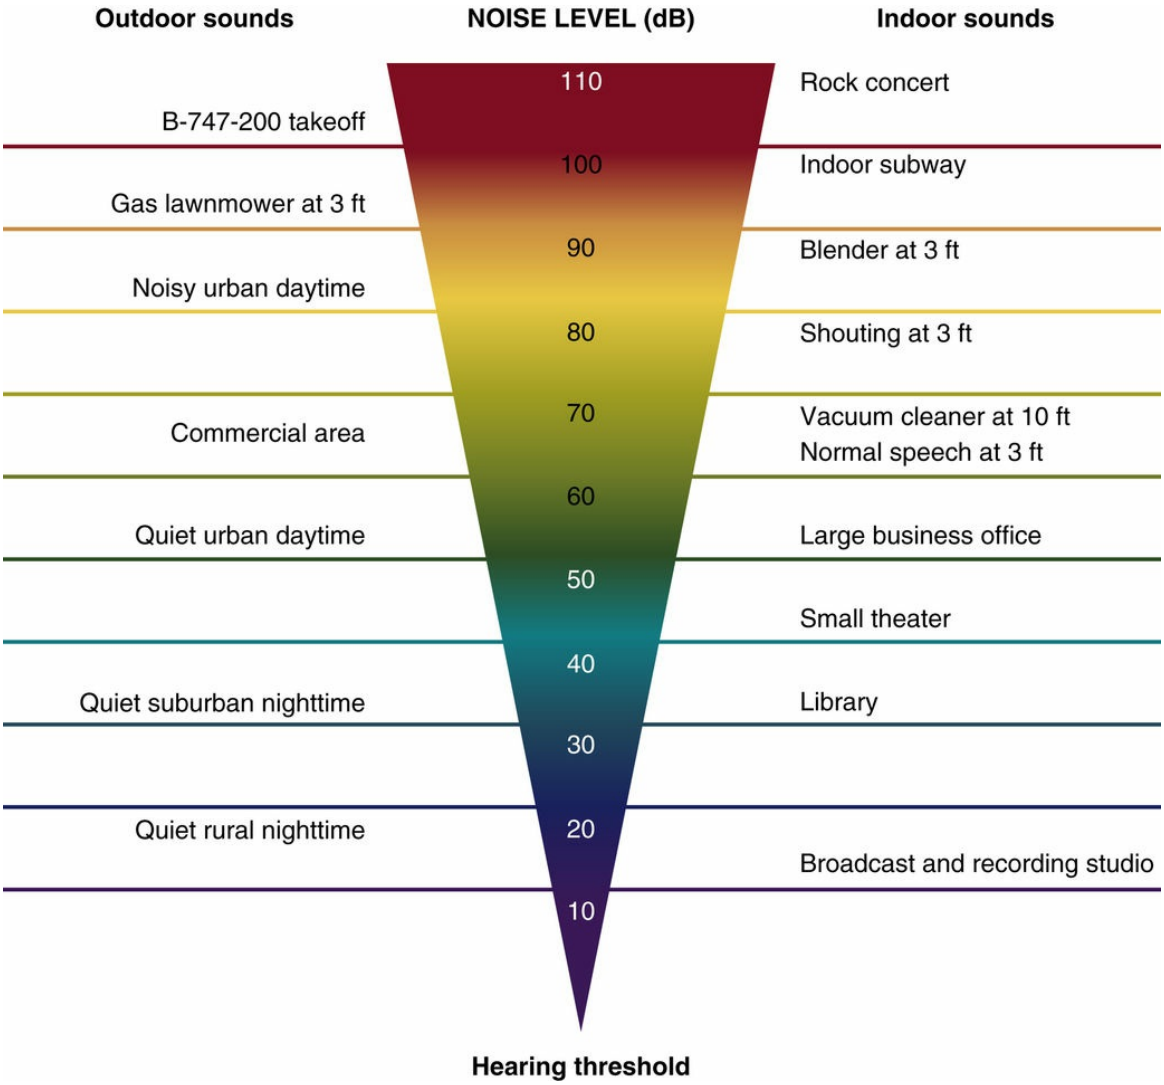

FIG. 21.6 Range of common environmental sounds.

Immunizations

Various viruses can cause deafness because of fetal damage and malformations affecting the ear. Promote childhood and adult immunizations, including the measles, mumps, and rubella (MMR) vaccine. Rubella infection during the first 8 weeks of pregnancy is associated with a high incidence of congenital rubella syndrome, which causes sensorineural deafness. Women of childbearing age should be tested for antibodies to these viral diseases. Women should avoid pregnancy for at least 3 months after being immunized. Immunization must be delayed if a woman is pregnant. Women who

are susceptible to rubella can be vaccinated safely during the postpartum period.

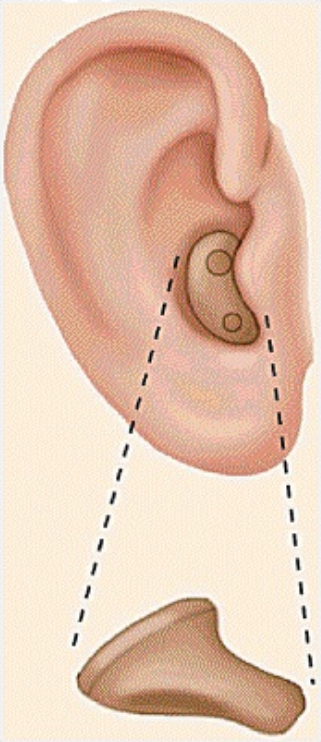
Ototoxic Substances

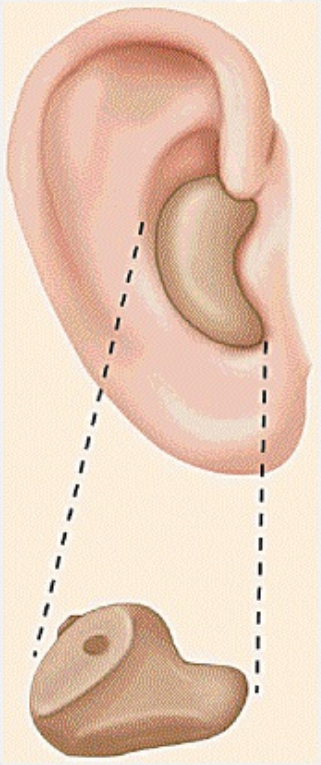
Monitor the patient who is receiving ototoxic drugs or exposed to ototoxic agents for signs and symptoms of ototoxicity, including tinnitus, diminished hearing, and balance problems. If these symptoms develop, stopping the drug may prevent further damage and allow the symptoms to disappear.

Assistive Devices and Techniques

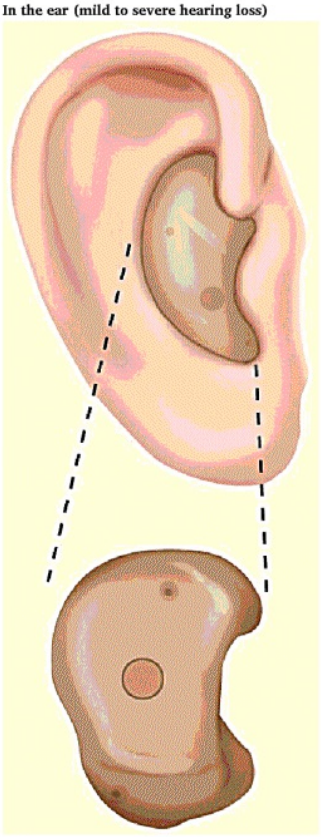
Hearing Aids

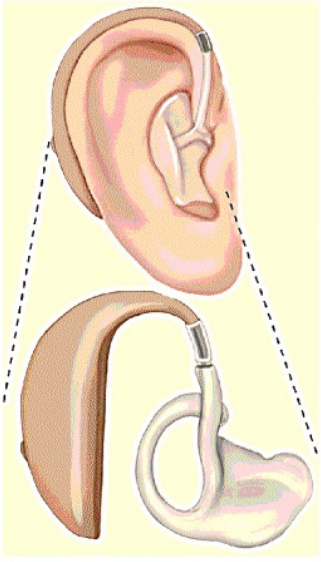
The patient with a suspected hearing loss should have a hearing assessment by a qualified audiologist. If a hearing aid is needed, it should be fitted by an audiologist or a speech and hearing specialist. Many types of hearing aids are available, each with advantages and disadvantages (Table 21.13). The conventional hearing aid serves as a simple amplifier. For the patient with bilateral hearing impairment, binaural hearing aids offer the best sound lateralization and speech discrimination.





The goal of hearing aid therapy is improved hearing with consistent use. Patients who are motivated and optimistic about using a hearing aid are more successful users. Determine the patient's readiness for hearing aid therapy, including acknowledgment of a hearing problem, the patient's feelings about wearing a hearing aid, the degree to which the hearing loss affects life, and any difficulties the patient has manipulating small objects such as putting a battery in a hearing aid.





Initially, use of a hearing aid should be restricted to quiet situations in the home. The patient must first adjust to voices (including the patient's own voice) and household sounds. The patient should try increasing and decreasing the volume as situations require. As the patient adjusts to the increase in sounds and background noise, they can progress to situations in which several people will be talking at once. Next, the environment is expanded to the outdoors and then a

shopping mall or grocery store. Adjustment to different environments occurs gradually, depending on the patient.

When a hearing aid is not being worn, it should be placed in a dry, cool area where it will not be inadvertently damaged or lost. The battery should be disconnected or removed when not in use. Battery life averages 1 week, depending on the hearing aid, battery, and amount of use. Advise patients to buy only a month's supply at a time. Ear molds should be cleaned weekly or as needed. Toothpicks or pipe cleaners can easily clear a clogged ear tip.

TABLE 21.13 Types of Hearing Aids

Type	Advantages	Disadvantages
Completely in the canal (mild to moderate hearing loss) 	Smallest and least visible aid. Protected from sounds such as wind noise	Costly. No space for add-ons such as directional microphones or volume controls. Small, short-lived batteries
In the canal (mild to severe hearing loss) 	More powerful than aids completely in the canal. Has adjustable features such as noise reduction	Small size of aid with added features may be hard to use for patients with visual loss or arthritis

Type	Advantages	Disadvantages
In the ear (mild to severe hearing loss) 	Powerful amplification. Inserts and adjusts easily. Longer lasting batteries	Visible. May pick up wind noise readily
Behind the ear (all types of hearing loss) 	Most powerful aid. Adjusts easily. Longest battery life	Largest, most visible aid. Newer models may be smaller and less obvious

An *implantable hearing device* or aid is available to patients who cannot or will not use traditional hearing aids or cochlear implants.

Implanted hearing devices amplify sound and transmit the sound vibrations through the ear. The device does not have visible external components. There are 2 types of implantable hearing devices: fully implantable and partially implantable. Fully implantable devices are placed surgically, and nothing is visible externally. Partially implanted devices have an internal device that is implanted surgically and an external device that is worn behind or in the ear.

Speech Reading

Speech reading, or *lip reading,* can be helpful in increasing communication. It allows for about 40% understanding of the spoken word. The patient uses visual cues associated with speech, such as gestures and facial expressions, to help clarify the spoken message. In speech reading, many words look alike to the patient (e.g., rabbit, woman). Help the patient by using and teaching verbal and nonverbal communication techniques as described in Table 21.14.

TABLE 21.14 Communicating With Patients With Hearing Impairment

Nonverbal Aids

- Draw attention with hand movements.
- Have speaker's face in good light.
- Avoid light behind the speaker.
- Maintain eye contact.
- Avoid covering mouth or face with hands.
- Avoid chewing, eating, smoking while talking.
- Remove background noise.
- Move close to better ear.

Verbal Aids

- Speak normally and slowly. Do not shout.
- Do not exaggerate facial expressions.
- Do not overenunciate.
- Use simple sentences.
- Rephrase sentence. Use different words.
- Write name or difficult words.
- Speak in normal voice directly into better ear.

Sign Language

Sign language is a form of communication for people with profound hearing impairment. It involves gestures and facial features such as eyebrow motion and lip-mouth movements. Sign language is not universal. American Sign Language (ASL) is used in the United States and the English-speaking parts of Canada.

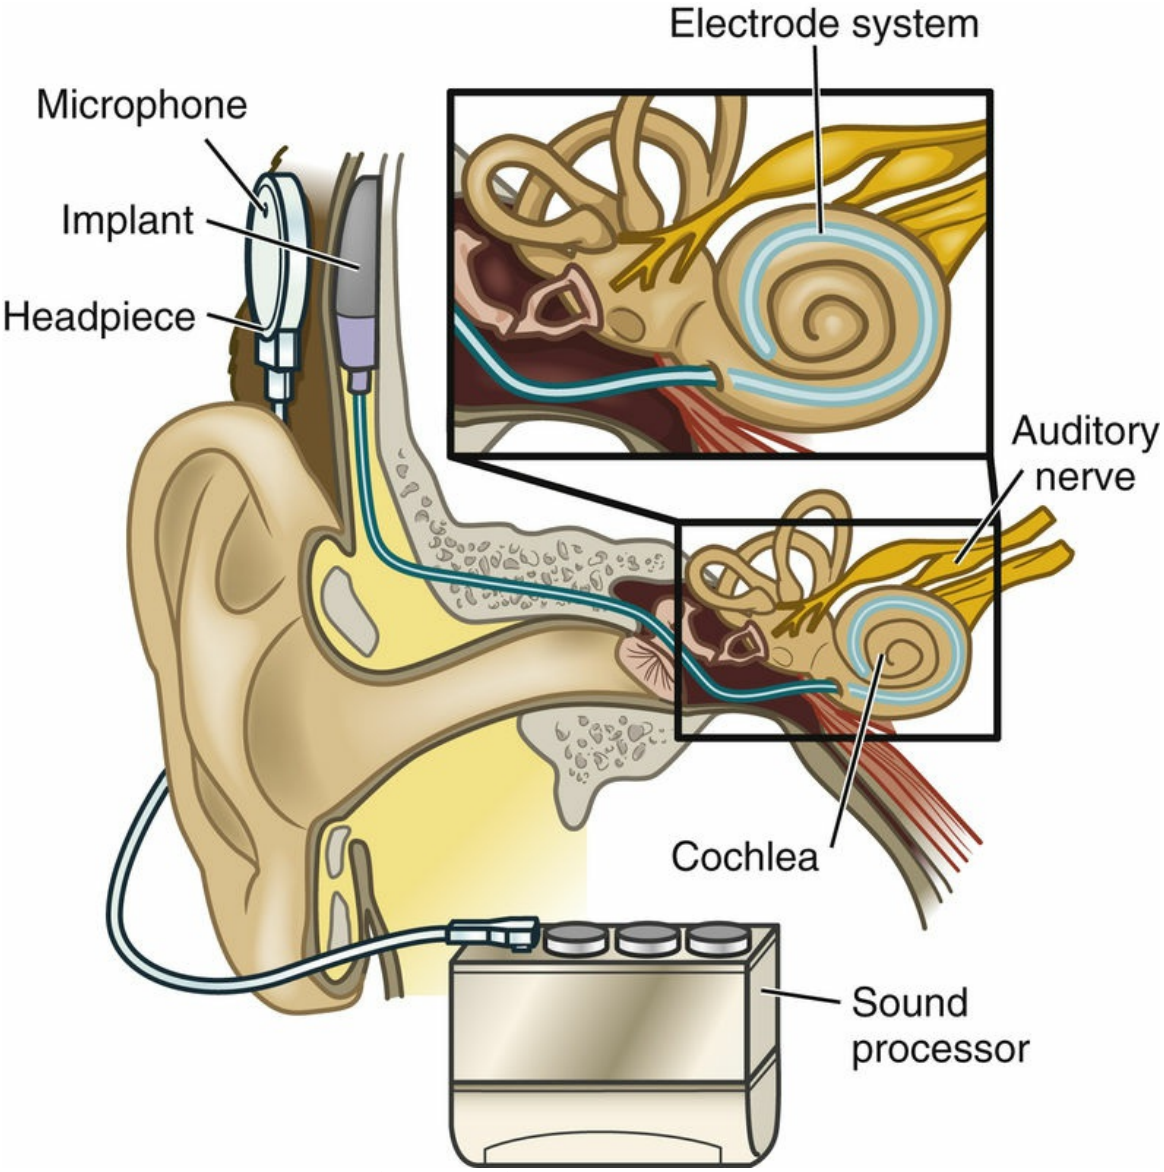


FIG. 21.7 Cochlear implant.

Cochlear Implant

A *cochlear implant* may be used for some people with severe to profound sensorineural hearing loss in one or both ears.[9] The implant bypasses damaged or missing portions of the ear and directly activates cranial nerve VIII. The ideal candidate is one who has become deaf after acquiring speech and language. The system consists of (1) an external microphone placed behind the ear, (2) a speech processor, (3) a transmitter implanted under the skin that changes

sounds into electrical impulses, and (4) electrodes placed within the cochlea that stimulate the auditory nerves in the ear (Fig. 21.7). The electrodes are inserted as far as possible into the cochlea. Cochlear implants send information that covers the entire range of sound frequencies. For patients with conductive and mixed hearing loss, the cochlear Baha system may be surgically implanted. The system works through direct bone conduction and integrates with the skull bone over time.

Extensive training and rehabilitation are essential to receive the most benefit from these implants. Besides providing sound to a person who heard none, cochlear implants improve lip-reading ability, allow self-monitoring of the loudness of speech, improve the sense of security, and decrease feelings of isolation.

Assistive Listening Devices

Many devices are available to help the hearing-impaired person. Direct amplification devices, amplified telephone receivers, alerting systems that flash when activated by sound, an infrared system for amplifying the sound of the television, and a combination FM receiver and hearing aid may be options based on patient needs. People with profound deafness may be aided by text-telephone alerting systems that flash when activated by sound, closed captioning on television, and a specially trained dog. The dogs are trained to alert their owners to specific sounds within the environment, thus increasing the person's safety and independence.

TABLE 21.15 Classification of Presbycusis

Type	Hearing Change and Prognosis
Cochlear	
Stiffening of basilar membrane, which interferes with sound transmission in the cochlea	Hearing loss increases from low to high frequencies. Speech discrimination affected with higher frequency losses. Helped by appropriate forms of amplification
Metabolic	
Atrophy of blood vessels in wall of cochlea with interruption of essential nutrient supply	Uniform loss for all frequencies accompanied by recruitment. Good response to hearing aid
Neural	
Degenerative changes in cochlea and spinal ganglion	Loss of speech discrimination. Amplification alone not sufficient
Sensory	
Atrophy of auditory nerve. Loss of sensory hair cells	Loss of high-pitched sounds. Little effect on speech understanding. Good response to sound amplification

Gerontologic Considerations: Hearing Loss

Presbycusis, hearing loss associated with aging, includes the loss of peripheral auditory sensitivity, a decline in word recognition ability, and associated psychologic and communication issues. Because consonants (high-frequency sounds) help us recognize spoken words, the older person with presbycusis has a decreased ability to understand speech. Vowels are heard, but one cannot distinguish consonants in the high-frequency range. This may lead to confusion and embarrassment because of the difference in what was said and what was heard.

Degenerative changes in the inner ear cause presbycusis. Noise exposure is thought to be a common factor. Table 21.15 describes the classification of specific causes and associated hearing changes of presbycusis. Often a person may have more than one type of presbycusis. The prognosis for hearing depends on the cause of the loss. Sound amplification with the right device is often helpful in improving the understanding of speech. In other situations, an audiologic rehabilitation program can be valuable.

The older adult is often reluctant to use a hearing aid for sound amplification. Reasons cited most often include cost, appearance, insufficient knowledge about hearing aids, amplification of competing noise, and unrealistic expectations. Most hearing aids and batteries are small, and neuromuscular changes such as stiff fingers, enlarged joints, and decreased sensory perception often make the care and handling of a hearing aid frustrating for an older person. Some older adults may also tend to accept their losses as part of getting older and

believe there is no need for improvement.

Case Study

Ménière's Disease

© iStock.com/EyeMark.

Patient Profile

While R.S. is in the emergency department, she starts violently vomiting. She tells you that any movement is making her feel like she

is “spinning like crazy.” The HCP decides to admit her under observation with plans to administer an intratympanic injection of dexamethasone.

Objective Data

- Skin pale, extremely diaphoretic
- Heart rate 112 beats/min, respirations 22 breaths/min, BP 100/64

Interprofessional Care

- 1000 mg sodium diet as tolerated
- Ondansetron 2 mg IV now
- Lorazepam 1 mg IV every 6 hours
- Meclizine 25 mg PO every 6 hours
- Electronystagmogram and glycerol test
- Dextrose 5% with 0.45% NaCl at 75 mL/hr

Discussion Questions

1. Explain the etiology of Ménière’s disease.
2. What clinical manifestations of Ménière’s disease does R.S. exhibit?
3. Give the rationale for each treatment measure ordered.
4. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses?
5. ***Priority Decision:*** What are the priority nursing interventions for R.S.?
6. ***Delegation Decision:*** Identify interventions for R.S. that can be delegated to unlicensed assistive personnel (UAP).
7. ***Safety:*** Identify an area of risk for injury to R.S. What actions will you take to ensure patient safety?
8. ***Patient-Centered Care:*** What teaching will you provide so R.S.

can successfully self-manage her condition after discharge?

9. ***Quality Improvement:*** What outcomes would indicate interprofessional care was effective?

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In a patient with vertigo, the parts of the ear most likely involved are the *(select all that apply)*
   a. cochlea.
   b. ossicles.
   c. vestibule.
   d. semicircular canals.
   e. tympanic membrane.
2. A patient reports tinnitus and balance problems. The medication that may be responsible is
   a. digoxin.
   b. warfarin.
   c. furosemide.
   d. acetaminophen.
3. What assessment technique should the nurse use to assess an adult patient's tympanic membrane?
   a. Have the patient tilt the head toward the nurse.
   b. Stabilize the otoscope with your fingers on the patient's cheek.

c. Pull the auricle down and back to straighten the auditory canal.

d. Use a speculum slightly larger than the size of the patient's ear canal.

4. A normal finding the nurse would expect when assessing hearing would be

a. absent cone of light.

b. bluish purple tympanic membrane.

c. fluid level at hairline in the tympanum.

d. midline tone heard equally in both ears.

5. Common age-related changes in the auditory system include *(select all that apply)*

a. drier cerumen.

b. tinnitus in both ears.

c. auditory nerve degeneration.

d. atrophy of the tympanic membrane.

e. greater ability to hear high-pitched sounds.

6. The nurse teaches a patient scheduled for an electronystagmography that the test involves

a. measuring ear drum movement in response to pressure.

b. recording eye movements associated with ear irrigation.

c. placing an electrode on the eardrum and assessing for dizziness.

d. wearing headphones and determining which sounds can be heard.

7. Care of the patient experiencing an acute attack of Ménière's disease includes *(select all that apply)*

a. giving antiemetics as needed.
b. implementing fall precautions.
c. keeping the room dark and quiet.
d. placing the patient on NPO status.
e. ambulating in the hall independently.

8. The patient who has a conductive hearing loss
a. hears better in a noisy environment.
b. hears sound but does not understand speech.
c. often speaks loudly because his or her own voice seems low.
d. has clearer sound with a hearing aid if the loss is less than 30 dB.

9. Teach the patient who is newly fitted with bilateral hearing aids to *(select all that apply)*
a. replace the batteries monthly.
b. clean the ear molds weekly or as needed.
c. clean ears with cotton-tipped applicators daily.
d. disconnect or remove the batteries when not in use.
e. initially restrict usage to quiet listening in the home.

10. Which strategies would *best* aid the nurse communicate with a patient who has a hearing loss *(select all that apply)*?
a. Overenunciate speech.
b. Speak normally and slowly.
c. Exaggerate facial expressions.
d. Raise the voice to a higher pitch.
e. Write out names or difficult words.

1. c, d, 2. c, 3. b, 4. d, 5. a, b, c, d, 6. b, 7. a, b, c, 8. a, 9. b, d, e, 10. b, e

Assessment

Integumentary System

Mariann M. Harding

LEARNING OUTCOMES

1. Describe the structures and functions of the integumentary system.
2. Link the age-related changes in the integumentary system to differences in assessment findings.
3. Obtain significant subjective and objective data related to the integumentary system from a patient.
4. Compare the critical components for describing primary and secondary lesions.
5. Perform a physical assessment of the integumentary system using appropriate techniques.
6. Specify the structural and assessment differences in light- and dark-skinned persons.
7. Distinguish normal from common abnormal findings of a physical assessment of the integumentary system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the integumentary system.

Conceptual Focus

Health Promotion
Tissue Integrity

The integumentary system is the largest organ of the body. It is composed of the skin, hair, nails, and certain glands. The skin has 2 major layers: epidermis (outer layer) and dermis (inner layer). The subcutaneous tissue (layer) lies under the dermis (Fig. 22.1). The skin is as complex as any organ, but, unlike the others, it is readily visible.

Being able to see and touch the skin helps you assess your patients. You can see abnormalities, understand their significance, and intervene early.

Structures and Functions of Skin and Appendages

Structures

Epidermis

The **epidermis**, the outer layer of the skin, is relatively thin, ranging from 0.05 mm on the eyelids to 0.1 mm on the soles.[1] There are no lymphatic or vascular structures in the epidermis. It is supported by passive circulation from the dermis.

The epidermis is divided into 5 distinct but interrelated layers. Two of the layers are the stratum corneum (the surface layer) and the stratum germinativum (deepest, basal layer) (Fig. 22.1).

Most epithelial cells are keratinocytes (90%). The remaining cells are melanocytes, Langerhans' cells, and Merkel cells.

Keratinocytes form in the basal layer. Initially, they are undifferentiated and shaped like columns. As they mature (keratinize), they move to the surface, where they flatten and die to form the outer skin layer (stratum corneum). Keratinocytes make a fibrous protein, keratin, which is vital to the skin's protective barrier function. The upward movement of keratinocytes from the basal layer to the outermost levels of the stratum corneum takes about 14 days. The keratinocytes stay there for another 14 days, allowing the epidermis to regenerate every 28 days. Thus each month you have a new layer of skin.

Many skin problems result from changes in this cell cycle. If dead cells slough off too rapidly, the skin appears thin and eroded. If new cells form faster than you shed old cells, the skin becomes scaly and thickened. Failure of the epidermis to function normally occurs with skin cancer and psoriasis (discussed in Chapter 23).

Melanocytes are found in the deep, basal layer. They contain melanin, a pigment that gives color to the skin and hair and protects the body from damaging ultraviolet (UV) sunlight. Sunlight and hormones stimulate the melanosome (within the melanocyte) to increase the production of melanin. People of all races have similar numbers of melanocytes. In darker skin, the melanosomes are larger and more numerous, thus producing more melanin.[2] This increased melanin forms a natural sun shield for dark skin and results in a decreased incidence of skin cancer. The distribution of melanocytes varies from one area of the body to another. For example, the face has more melanocytes than the abdomen.

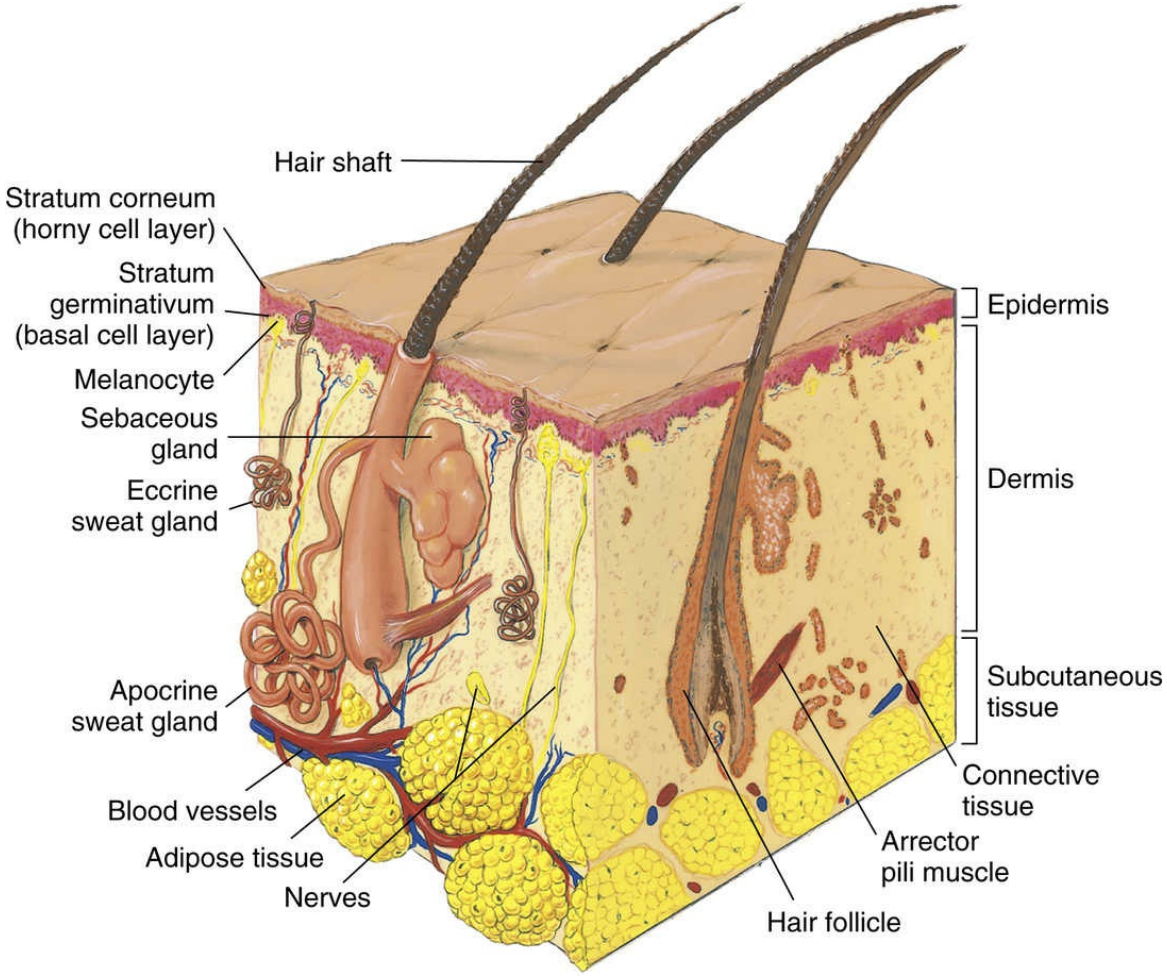

FIG. 22.1 Microscopic view of the skin in longitudinal section. From Jarvis C: *Physical examination and health assessment,* ed 6, St Louis, 2012, Saunders.

Langerhans' cells are a type of dendritic cell (discussed in Chapter 13 on p. 191). They are immunocompetent cells that recognize antigens. When they are depleted, the skin cannot initiate an immune response. The Langerhans' cells in bioengineered skin grafts have been removed to prevent graft rejection. In skin diseases such as psoriasis and sarcoidosis, there are decreased numbers of Langerhans' cells. *Merkel cells* are found in the basal layer and are involved in the sensation of light touch. We use them when feeling the texture of an object and figuring out what it is.

The basement membrane zone is between the epidermis and dermis. This structure provides for the (1) exchange of fluids between the epidermis and dermis and (2) structural support for the epidermis.

The basement membrane helps to secure the two layers together. Inflammation and separation of the epidermal and dermal layers result in the blisters seen with problems such as burns, full-thickness wounds, and mechanical trauma.

Dermis

The **dermis** is the connective tissue below the epidermis. Dermal thickness ranges from 0.3 mm on the eyelid to 3.0 mm on the back.[1] The dermis is very vascular, containing many blood vessels. It also contains nerves, lymphatic vessels, hair follicles, sebaceous glands, and specialized cells such as mast cells and macrophages that protect the body from external stimuli.

The dermis is made of 3 types of connective tissue: collagen, elastic fibers, and reticular fibers. Collagen forms the greatest part of the dermis. It gives the skin toughness and strength. The primary cell type in the dermis is the *fibroblast,* which makes collagen and elastin. Collagen is critical in wound healing.

The dermis has 2 layers: upper thin papillary layer and a deeper, thicker reticular layer. The papillary layer is arranged haphazardly in ridges, or papillae, which extend into the outer epidermal layer. These elevated surface ridges form fingerprints and footprints. The reticular layer forms the bulk of the dermis. It is made up of thick collagen bundles arranged parallel to the skin's surface.

Subcutaneous Tissue

The subcutaneous tissue lies below the dermis. It is made of loose connective tissue and fat cells that provide insulation, cushioning, temperature regulation, and energy storage. The subcutaneous tissue attaches the skin to underlying tissues, such as muscle and bone. The distribution pattern of subcutaneous tissue varies with gender, heredity, age, and nutritional status.

Skin Appendages

Skin appendages include the hair, nails, and glands (sebaceous,

apocrine, and eccrine). These appendages are epidermal extensions that have their roots in the dermis. These structures receive nutrients, electrolytes, and fluids from the dermis. Hair and nails form from specialized keratin. Systemic diseases can affect the condition and health of both hair and nails.

Hair grows on most of the body except for the lips, palms of the hands, interdigital spaces, portions of the genitalia, and soles of the feet. The density and pattern of distribution varies depending on age, sex, and race. Hair color is a result of heredity and determined by the type and amount of melanin in the hair shaft. Hair grows about 1 cm per month. People lose about 100 hairs each day.[3] Baldness, or *alopecia,* results when we do not replace lost hair.

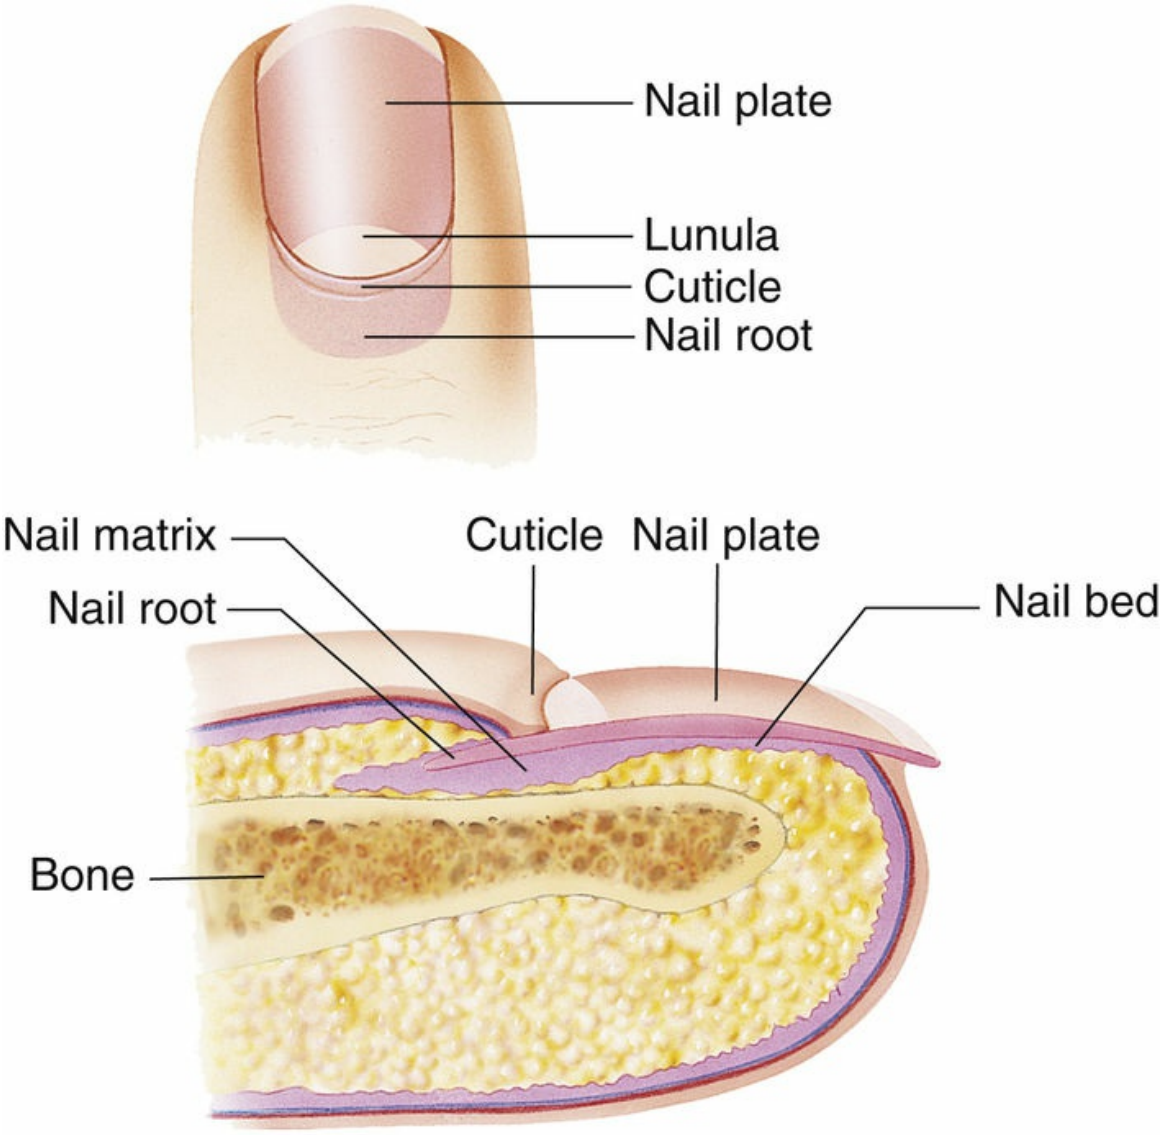

FIG. 22.2 Structure of a nail.
From Patton KT, Thibodeau GA, Douglas M: *Essentials of anatomy and physiology,* St Louis, 2014, Mosby.

Nails are made of heavily keratinized cells. The part of the nail that you can see is the nail body. The rest is the nail root. A fold of skin hides most of the nail root. The cuticle borders this skinfold. Nail growth begins in the nail root. The part of the nail root you can see is the *lunula*. This white, crescent-shaped area is the site of mitosis and nail growth (Fig. 22.2). Under the nail is an area of epidermis called the *nail bed.* The nail bed has many blood vessels. Nails grow slowly, but continuously. Fingernails grow much faster than toenails, at a rate

of 0.5 to 2 mm per week.[1] It takes 3 to 6 months to replace a fingernail. A toenail may take 12 months or longer to replace. Nail color ranges from pink to yellow or brown depending on skin color. Color and texture variations in nails may be normal or represent an abnormal condition. Pigmented longitudinal bands *(melanonychia striata)* occur in the nail bed in 90% or more of people with dark skin[4] (Fig. 22.3).

There are 2 major types of glands in the skin: sebaceous and sweat (apocrine and eccrine) glands. **Sebaceous glands** secrete *sebum,* which is emptied into the hair follicles. Sebum waterproofs and lubricates the skin and promotes the absorption of fat-soluble substances. Sebum is somewhat bacteriostatic and fungistatic. These glands depend on sex hormones, particularly testosterone, to regulate sebum secretion and production. Actual production varies depending on age, sex, and testosterone and estrogen levels. Sebaceous glands are present on all areas of the skin except the palms and soles and dorsum of the feet. These glands are most abundant on the face, scalp, upper chest, and back.

The *apocrine sweat glands* are mainly found in the axillary, genital, and breast areas. They are always connected to a hair follicle. These glands enlarge and become active at puberty because of reproductive hormones. They secrete a thick milky substance that is naturally odorless. Odor occurs when skin surface bacteria alter the secretions.

The *eccrine sweat glands* are found on most of the body, except the lips, ear canals, nail beds, labia minora, glans penis, and prepuce. One square inch of skin has about 3000 eccrine sweat glands. Their main function is to cool the body by evaporation, excrete waste products, and moisturize surface cells. Sweat is a transparent watery solution composed of salts, ammonia, urea, and other wastes. In extreme situations, the body can make 2 to 4 L of sweat per hour or up to 12 liters in 24 hours. Heat, certain mental stimuli, and ingestion of hot, spicy foods stimulate sweat secretion.

FIG. 22.3 Pigmented nail bands normally seen with dark skin color. From Ball J, Dains J, Flynn J, et al: *Seidel's guide to physical examination,* ed 8, St Louis, 2014, Mosby.

Functions of Integumentary System

The skin's main function is to protect the underlying body tissues by serving as a barrier to the external environment. The skin acts as a barrier against invasion by bacteria and viruses and prevents excess water loss. The fat in the subcutaneous layer insulates the body and provides protection from trauma. Melanin screens and absorbs UV radiation.

The skin with its nerve endings and special receptors collects sensory information from environmental stimuli. These highly specialized nerve endings give information to the brain related to pain, heat and cold, touch, pressure, and vibration.

The skin controls heat regulation by responding to changes in internal and external temperature with vasoconstriction or vasodilation. The skin's excretory function and heat regulation are related. We lose between 600 and 900 mL of water daily through

insensible water loss (invisible vaporization from the lungs and skin), which helps regulate body temperature. Sebum and sweat lubricate the skin surface. Endogenous synthesis of vitamin D, which is critical to calcium and phosphorus balance, occurs in the epidermis. Vitamin D is made in the epidermis when UV light acts on vitamin D precursor cells.

Gerontologic Considerations: Effects of Aging on Integumentary System

Many skin changes are associated with aging. Depending on a person's view of self, the normal, visible effects of aging on the skin and hair may have a profound psychologic effect. Having a youthful look may affect a person's self-image. The appearance of the signs of aging can be a threat to self-concept. Other changes in skin structure related to normal changes with aging can pose serious risk. Age-related changes of the integumentary system and differences in assessment findings are listed in Table 22.1.

Chronic UV exposure is the major contributor to the photoaging and wrinkling of skin.[5] Sun damage to the skin is cumulative (Fig. 22.4). The wrinkling of sun-exposed areas such as the face and hands is more marked than that of a sun-shielded area, such as the buttocks. A photoaged person is more susceptible to skin cancers because UV exposure decreases the ability to repair cellular damage. Chronic UV exposure from tanning beds causes the same damage as UV from the sun. Other factors that influence skin aging include diabetes, smoking, and alcohol use.

TABLE 22.1 Gerontologic Assessment DifferencesIntegumentary System

Changes	Differences in Assessment Findings
Skin	
Decreased subcutaneous fat, muscle laxity, degeneration of elastic fibers, collagen stiffening	Increased wrinkling, sagging breasts and abdomen, redundant flesh around eyes, slowness of skin to flatten when pinched (tenting)
Decreased extracellular water, surface lipids, and sebaceous gland activity	Dry, flaking skin with possible signs of excoriation caused by scratching
Decreased activity of apocrine and sebaceous glands	Dry skin with minimal to no perspiration, skin color uneven
Increased capillary fragility and permeability	Bruising
Increased focal melanocytes in basal layer with pigment accumulation	Solar lentigines on face and back of hands
Diminished blood supply	Decrease in rosy appearance of skin and mucous membranes. Skin cool to touch. Diminished awareness of pain, touch, temperature, peripheral vibration
Decreased proliferative capacity	Delayed wound healing
Decreased immunocompetence	Increase in neoplasms
Hair	
Decreased melanin and melanocytes	Gray or white hair
Decreased oil	Dry, coarse hair. Scaly scalp
Decreased hair density	Thinning and hair loss
Cumulative androgen effect; decreasing estrogen levels	Facial hirsutism, baldness
Nails	
Decreased peripheral blood supply	Thick, brittle nails with diminished growth
Increased keratin	Longitudinal ridging
Decreased circulation	Prolonged return of blood to nails on blanching

The junction between the dermis and epidermis flattens. This causes the two layers to lose their tight bond. Skin tears and other trauma become common as the epidermis slides separately from the dermis. Collagen fibers stiffen, elastic fibers degenerate, and the amount of subcutaneous tissue decreases. These changes, with the added effects of gravity, lead to wrinkling. Fewer free fatty acids in the epidermis results in dry, scaly, itchy skin. Dryness, combined with trauma caused by scratching, increases the risk for fissures (cracks) in the skin and secondary infections. Decreased subcutaneous fat increases the risk for traumatic injury, hypothermia, and skin shearing, which may lead to pressure ulcers.

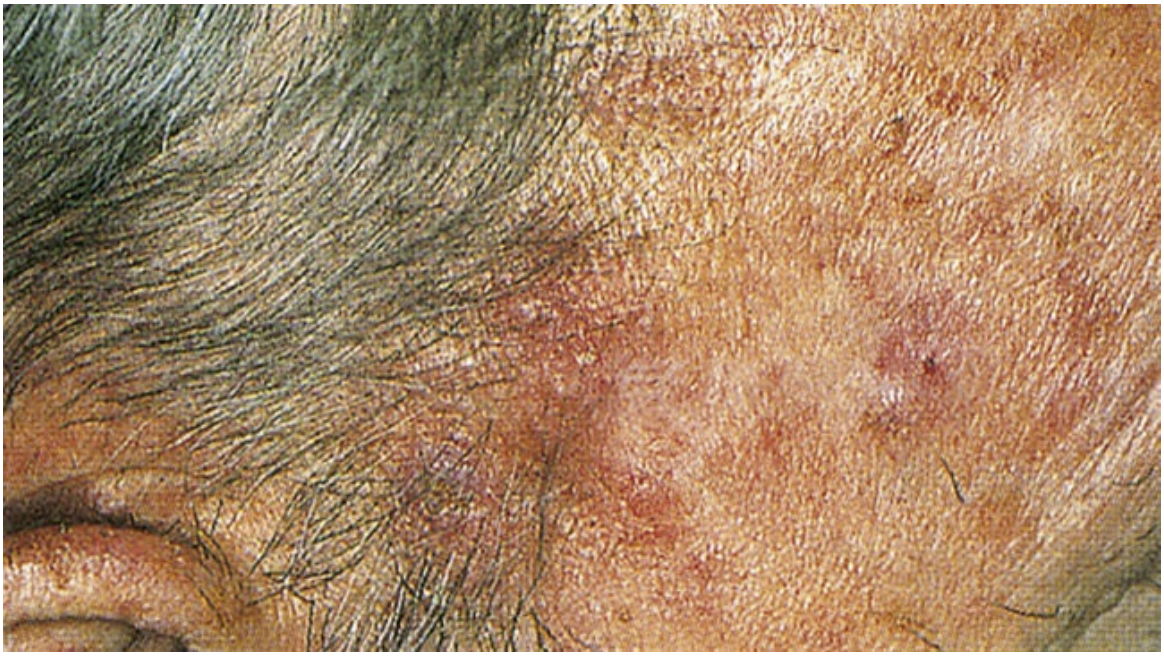

FIG. 22.4 Photoaging. Irregular pigmentation and keratoses occur on sun-damaged skin on forehead.
From Gawkrodger D, Ardern-Jones MR: *Dermatology,* ed 5, Edinburgh, 2012, Churchill Livingstone.

Fewer melanocytes are present, and with decreased levels of melanin, hair color fades. Hormonal and vitamin deficiencies can cause dry, thin hair and alopecia. The growth rate of the hair and nails decreases because of atrophy. The nail plate thins, and nails become brittle and more prone to splitting and yellowing. Nails, especially the toenails, may thicken with age. With aging, the apocrine and eccrine sweat glands atrophy, causing dry skin and decreased body odor.

Benign neoplasms related to the aging process can occur. These growths include seborrheic keratoses, vascular lesions such as cherry angiomas, and skin tags. *Actinic keratoses* appear on areas of chronic sun exposure, especially in the person who has a fair complexion and light eyes (blue, green, or hazel). These premalignant cutaneous lesions place a person at increased risk for squamous cell and basal cell carcinomas.

Assessment of Integumentary System

The general skin assessment begins with your first contact with the

patient and continues throughout the examination. As you are meeting your patient for the first time, take a moment to note the overall condition of the patient's skin and hair. You will assess specific areas of the skin when examining other body systems, unless the chief complaint is a skin problem. Record a general statement about the skin's physical condition (Table 22.2). In addition, ask the health history questions presented in Table 22.3 when you note a skin problem.

Case Study

Patient Introduction

© iStockphoto/Thinkstock.

D.A. is a 74-yr-old woman who comes to the medical clinic with concerns related to various “spots” on her face. She says they have been there for a while and she thought they were just “age spots.” She became concerned after her friend was diagnosed with a malignant melanoma.

Discussion Questions

1. Which type of assessment should you perform: comprehensive, focused, or emergency?

2. What are the possible causes of D.A.'s facial lesions?
3. What questions would you ask D.A. to determine the possible causes?

You will learn more about D.A. and her condition as you read this chapter.

(See p. 401 for more information on D.A.)

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

TABLE 22.2 Normal Physical Assessment of Integumentary System

Skin	• Evenly pigmented. No petechiae, purpura, lesions, or excoriations • Warm, good turgor
Nails	• Pink, oval, adhere to nail bed with 160-degree angle
Hair	• Shiny and full; amount and distribution appropriate for age and gender • No flaking of scalp, forehead, or pinna

Subjective Data

Perform the interview using a sensitive and nonjudgmental attitude. The problem may be the result of poor hygiene or unhealthful behaviors. Some problems are highly visible and affect the patient's body image and self-concept. A thorough health history yields information about possible causes and the effect of the problem on the person's life.

Important Health Information

Past Health History

Past health history reveals previous trauma, surgery, or disease that involves the skin. Many diseases have skin manifestations (Table 22.4). Determine if the patient has noticed any problems such as

jaundice (liver disease), delayed wound healing (diabetes), cyanosis (respiratory, cardiovascular disorder), or pallor (anemia). Obtain specific information related to food sensitivities, pet or drug allergies, and skin reactions to insect bites and stings. Note any history of chronic or unprotected exposure to UV light, including tanning bed use and radiation treatments.

Medications

A thorough medication history is important. Ask the patient about skin-related problems that occurred because of taking a medication. Many hormones, antibiotics, corticosteroids, and antimetabolites have side effects that manifest in the skin. Medications may contain fragrances and preservatives that can cause skin reactions. Document the use of medications specifically used to treat a primary skin problem, such as acne, or a secondary skin problem, such as itching. Record the drug's name, length of use, method of application, and effectiveness.

Surgery or Other Treatments

Determine if any surgical procedures, including cosmetic surgery, were done on the skin. Record any biopsy results. Note any treatments specific for a skin problem (e.g., phototherapy) or for a health problem (e.g., radiation therapy). Document any treatments undergone primarily for cosmetic purposes, such as tanning booth use, laser resurfacing, or cosmetic "peels."

Functional Health Patterns

Health Perception–Health Management Pattern

Ask the patient about health practices, such as self-care habits related to daily hygiene. Document the frequency of use and sun protection factor (SPF) of sunscreen products. Assess the use of personal care products (e.g., shampoos, moisturizing agents, cosmetics), including brand name, quantity, and frequency. Record a description of any

current skin problem, including onset, symptoms, course, and treatment. Note any medications used for treating hair loss.

Obtain information about the family history of any skin diseases, including congenital and familial diseases (e.g., alopecia, psoriasis) and systemic diseases with skin manifestations (e.g., diabetes, thyroid disease, cardiovascular diseases, immune disorders). Note any family and personal history of skin cancer, particularly melanoma.

TABLE 22.3 Health HistoryIntegumentary System

Health Perception–Health Management

- Describe your daily hygiene practices.
- What skin products are you now using?
- Describe any current skin condition, including onset, course, and treatment (if any).

Nutritional-Metabolic

- Describe any changes in the condition of your skin, hair, nails, and mucous membranes.
- Have you noticed any recent changes in the way sores or wounds heal?*
- Have you had any weight loss or dietary changes?*

Elimination

- Have you noticed recent changes in your skin related to excess sweating, dryness, or swelling?*

Activity-Exercise

- Do your leisure or work activities involve using any chemicals that might irritate your skin?*
- Do you do anything to protect yourself from the sun?*

Sleep-Rest

- Does your skin condition keep you awake or awaken you from sleep?*

Cognitive-Perceptual

- Do you have any unusual sensations of heat, cold, or touch?*
- Do you have any pain associated with your skin condition?*
- Do you have any joint pain?*

Self-Perception–Self-Concept

- How does your skin condition make you feel about yourself?

Role-Relationship

- Has your skin condition changed your relationships with others?*
- Have you changed your lifestyle because of your skin condition?*

Sexuality-Reproductive

- Has your skin condition changed your intimate relationships

with others?*

- Has your birth control method (if used) caused a skin problem?*

Coping–Stress Tolerance

- Are you aware of any situation or stressor that changes your skin condition?*
- Do you think that stress plays a role in your skin condition?*
- How do you handle stress?

Value-Belief

- Are there any cultural beliefs that influence your thinking or feelings about your skin condition?*
- Are there any treatment options that you would be opposed to using?

---

* If yes, describe.

Genetic Risk Alert

- The primary risk factor leading to skin cancer and melanoma is environmental exposure to UV radiation. UV radiation damages DNA, causing an error in the genetic code and resulting in abnormal skin cells.[6]
- Inherited genetic factors can increase skin cancer risk. A person has an increased risk for developing melanoma if they have a first-degree relative (e.g., parent, full sibling) who had a melanoma.

- People with a fair complexion (light-colored skin that easily freckles, red or blond hair, and blue or light-colored eyes) have an increased risk for skin cancer.

TABLE 22.4 Diseases With Skin Manifestations

Systemic Problem	Skin Manifestations
Endocrine	
Addison's disease	Loss of body hair (especially axillary), generalized hyperpigmentation (accentuated in folds)
Androgen deficiency	Development of sparse hair. Marked reduction in sebum production
Androgen excess	Enlarged facial pores, male sex characteristics, acne, acceleration of coarse hair growth
Diabetes	Erythematous plaques of shins, delayed wound healing, neuropathy, acanthosis nigricans (velvety, dark skin on the neck and in skin folds)
Glucocorticoid excess (Cushing syndrome)	Atrophy, striae, epidermal thinning, telangiectasia, acne. Decreased subcutaneous fat over extremities. Thin, loose dermis. Impaired wound healing. Increased vascular fragility. Mild hirsutism. Excess collection of fat over clavicles, back of neck, abdomen, and face
Hypoparathyroidism	Opaque, brittle nails with transverse ridges. Coarse, sparse hair with patchy alopecia
Hypothyroidism	Cold, dry, pale to yellow skin. Generalized nonpitting edema. Dry, coarse, brittle hair. Brittle, slow-growing nails
Hyperpituitarism (acromegaly)	Coarsened skin, deepened lines. Increased oiliness and sweating, acne. Increased number of nevi, hyperpigmentation; hypertrichosis (excess hair growth)
Hyperthyroidism	Increased sweating, warm skin with persistent flush, thin nails, alopecia. Fine, soft hair
Reproductive Organs	
Paget's disease	Eczematous patch of nipple and areola
Primary syphilis	Chancre
Secondary syphilis	Generalized skin lesions, alopecia
Tertiary syphilis	Gummas
Gastrointestinal	
Cystic fibrosis	Abnormal sweat gland function
Deficiency of essential fatty acids	Scaly skin
Inflammatory bowel disease	Mouth ulcers, erythema nodosum
Liver disease and biliary tract obstruction	Jaundice, itching, pigmentary abnormalities, changes in nails and hair, spider angiomas, telangiectasia
Malabsorption syndrome	Acquired ichthyosis (dry, scaly skin)
Musculoskeletal and Connective Tissue	
Dermatomyositis	Edema; purplish-red upper eyelids; scaly, macular erythema over knuckles
Scleroderma	Leathery hardening and stiffness of skin
Systemic lupus erythematosus	Discoid lesions, maculopapular semiconfluent rash (butterfly rash), alopecia, mouth ulcers
Metabolic	
Nicotinic acid (niacin) deficiency	Redness of exposed areas of skin of hand or foot, face, or neck; infected dermatitis
Vitamin B_1 (thiamine) deficiency	Edema, redness of soles of feet
Vitamin B_2 (riboflavin) deficiency	Red fissures at corner of mouth, glossitis
Vitamin C deficiency	Petechiae, purpura, bleeding gums
Immune	
HIV infection	Kaposi sarcoma, eosinophilic folliculitis
Hodgkin's lymphoma	Pruritus, sensitive skin
Non-Hodgkin's lymphoma	Papules, nodules, plaques, pruritus
Cardiovascular	
Rheumatic heart disease	Petechiae, urticaria, nodules, erythema
Peripheral vascular disease	Loss of hair on hands and feet. Delayed capillary filling. Dependent rubor (redness), pain
Thromboangiitis obliterans (Buerger's disease)	Pallor or cyanosis, gangrene, ulceration
Venous ulcers	Leathery, brownish skin on lower leg; pruritus, concave lesion with edema. Scar tissue with healing
Respiratory	
Inadequate oxygenation due to respiratory disease	Cyanosis
Hematologic	

Systemic Problem	Skin Manifestations
Anemia	Pallor, hyperpigmentation, pale mucous membranes, hair loss, nail dystrophy
Clotting disorders	Purpura, petechiae, ecchymosis
Renal	
Chronic kidney disease	Dry skin, pruritus, uremic frost, pallor, bruises
Neurologic	
Chronic sensory polyneuropathies Spinal cord trauma	Trophic changes in skin resulting from sensory denervation, pressure ulcers, anesthesia, paresthesias

Nutritional-Metabolic Pattern

Ask the patient about the condition of skin, hair, nails, and mucous membranes and whether they notice any changes related to diet. A diet history reveals the adequacy of nutrients essential to healthy skin and wound healing such as vitamins A, D, E, and C; dietary fat; and protein. Note any food allergies that cause a skin reaction. Ask obese patients if they have areas of chafing or a rash in **intertriginous** areas, where skin surfaces overlap and rub on each other (e.g., below the breasts, axillae, and groin). Skin in these areas is predisposed to skin tags *(acrochordons)* and candidiasis (yeast), intertrigo (bacteria, fungi, yeast), and erythrasma (bacteria) infections. Note any excess or absent sweating. Ask the patient about poor or delayed wound healing.

Elimination Pattern

Ask the patient about skin conditions, such as dehydration, edema, and **pruritus** (itching), which can indicate changes in fluid balance. If urinary or fecal incontinence is a problem, ask about the condition of the skin in the anal and perineal areas.

Activity-Exercise Pattern

Obtain information about environmental hazards in relation to hobbies and recreational activities, including exposure to known carcinogens, chemical irritants, and allergens. Ask the patient if any changes occur in the skin during exercise or other activities.

Sleep-Rest Pattern

Ask the patient about changes in sleep patterns caused by a skin condition. For example, pruritus can be distressing and interfere with normal sleep. Poor sleep and resulting tiredness can be reflected in a patient's face by dark circles under the eyes and a decreased firmness in the facial skin.

Cognitive-Perceptual Pattern

Determine the patient's perception of the sensations of heat, cold, pain, and touch. Note any discomfort associated with a skin condition, especially when observed in intact skin, or any reports of unusual skin sensations. Patients with neuropathy may describe numbness, tingling, or crawling sensations in their arms or legs. Ask about joint pain. Assess the mobility of the joints, since the patient's skin condition may cause changes in mobility.

Self-Perception–Self-Concept Pattern

Assess any feelings related to the patient's skin condition such as sadness, anxiety, despair, or altered body image. These feelings can occur with classic signs of aging or visible skin problems such as acne, rosacea, and psoriasis, which alter physical appearance.

Role-Relationship Pattern

Determine how the patient's skin condition affects relationships with family members, peers, and work associates. Ask the patient about the effect of environmental factors on the skin, such as occupational exposure to irritants, sun, and unusually cold or unhygienic conditions. Contact dermatitis caused by allergens and irritants is a common problem associated with occupation.

Sexuality-Reproductive Pattern

Tactfully assess the effect of the patient's skin condition on sexual activity. Note the reproductive status of the female patient relative to possible therapeutic interventions. For example, isotretinoin, used to treat acne, and topical fluorouracil, used to treat actinic keratoses, are

teratogenic drugs that may cause abnormal fetal development. Pregnant women or women who could become pregnant should not use them.

Coping–Stress Tolerance Pattern

Assess the role that stress may play in creating or worsening the skin condition. Ask the patient what coping strategies are used to manage the skin condition.

Value-Belief Pattern

Ask about cultural or religious beliefs that could influence the patient's self-image as related to the skin condition. Assess values and beliefs that may influence or limit the choice of treatment options.

Case Study

Subjective Data

© iStockphoto/Thinkstock.

A focused subjective assessment of D.A. reveals the following:

- ***PMH:*** Negative except for an appendectomy at age 16.
- ***Medications:*** None at present. NKA.
- ***Health Perception–Health Management:*** Washes her face with a skin cleanser in the morning and nighttime. After cleansing, she applies a moisturizer with SPF 15. She has used these facial products for the past 3 years since she first started noticing small age spots appearing. Before that, she just used soap and water.

- ***Nutritional:*** D.A. reports that her skin seems to be drier as she ages but otherwise no changes besides the "age spots" or "whatever they are." Denies any changes in the way cuts or sores heal. No weight loss. Does not take any supplemental vitamins or minerals.
- ***Elimination:*** Although skin is a little dry, D.A. does not perceive it to be excessively dry. Denies excess sweating or any swelling.
- ***Activity-Exercise:*** Loves to garden and go for walks outdoors. Reports a history of frequent, sometimes severe, sunburns as a child. No use of sunscreen growing up but does remember her mother making her wear T-shirts over her bathing suits to help prevent sunburn. Has used sunscreen for the past 20 years when outdoors. Reapplies as needed.
- ***Cognitive-Perceptual:*** Denies any pain or discomfort associated with skin lesions.
- ***Coping–Stress Tolerance:*** Fearful that she might have skin cancer.

Discussion Questions

1. Which subjective assessment findings are of most concern to you?
2. What should you include in the physical assessment? What specific characteristics of the skin lesions would you be looking for?

You will learn more about the physical examination of the skin in the next section.

(See p. 406 for more information on D.A.)

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

Objective Data

Physical Examination

A physical examination of the skin begins with a systematic, general

inspection and then a more specific assessment of problem areas. A normal range of differences exists in the skin, hair, and nails. Your assessment should note normal skin changes related to age, genetic factors, and environmental exposures from other changes. Look for changes in the color of the skin, turgor, temperature, dryness, thickness, and vascularity. General principles when assessing the skin are:

- Have a private examination room of moderate temperature with good lighting; a room with exposure to daylight is preferred.
- Ensure that the patient is comfortable and in a dressing gown that allows easy access to all skin areas.
- Perform a general inspection and then a lesion-specific examination.
- Use the metric system when taking measurements.
- Use the right terminology when reporting or documenting.

Clinical Photography

Photographs are an adjunct to documentation and promote communication among the interprofessional team. They are used to assess and monitor skin conditions and determine if the condition has improved or declined with treatment. They can be used to track moles and precancerous lesions and detect any changes early. Follow clinical agency protocol for obtaining a patient's consent to photograph lesions.

Inspection

Inspect the skin for general color and pigmentation, vascularity, bruising, and lesions or discolorations. The critical factor in assessment of skin color is change. A skin color that is normal for one patient can be a sign of a pathologic condition in another patient. The skin color depends on the amount of melanin (brown), carotene (yellow), oxyhemoglobin (red), and reduced hemoglobin (bluish red)

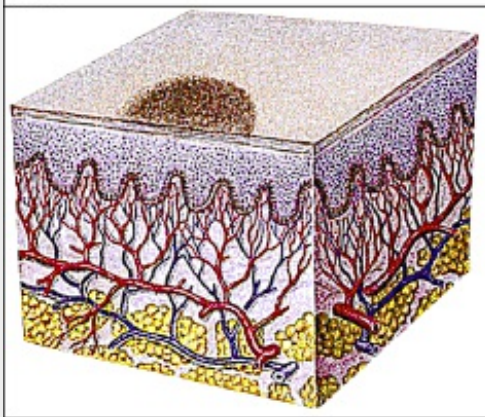
present at a particular time. The most reliable areas to assess erythema, cyanosis, pallor, and jaundice are the areas of least pigmentation, such as the sclera, conjunctivae, nail beds, lips, and buccal mucosa. The true skin color is best seen in photo-protected areas such as the buttocks. Activity, sun (UV) exposure, emotions, cigarette smoking, and edema, as well as respiratory, renal, cardiovascular, and hepatic disorders, can all directly affect skin color.

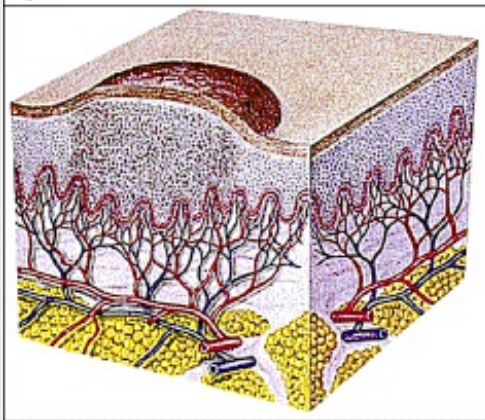
In your general inspection, note the presence of body art such as piercings and tattoos. The nose, ears, eyebrows, lips, navel, and nipples are common sites of piercing. Examine tattoos and needle-track marks and note the location and characteristics of the surrounding skin area. Tattoo pigments deposited in the skin may cause itching, pain, and sensitivity for several weeks after the tattoo is placed.

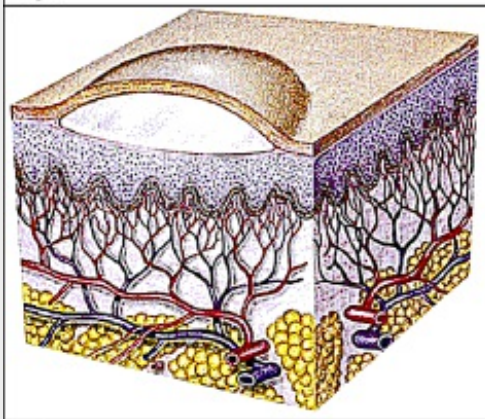
Examine the skin for problems related to vascularity, including bruising and vascular and purpuric lesions such as *angioma* (benign tumor of blood or lymph vessels), *petechiae* (tiny, flat, purplish red pinpoint lesions on skin), *ecchymosis* (bruise larger than petechiae), or *purpura* (purple colored spots and patches characterized by ecchymosis or other small hemorrhages). Note the reaction to direct pressure on the lesion. If a lesion blanches on direct pressure and then refills, the redness is due to dilated blood vessels. If the discoloration stays, it is the result of subcutaneous or intradermal bleeding or a nonvascular lesion. Note any pattern of bruising such as discoloration in the shape of the hand or fingers or bruises at different stages of resolution. These may indicate other health problems or abuse and need further investigation.

Record the color, size, height, distribution, location, and shape of any lesions. Lesions may be primary or secondary lesions. *Primary skin lesions* develop on previously unaltered skin. The common characteristics of primary skin lesions are shown in Table 22.5. *Secondary skin lesions* are lesions that change with time or occur because of scratching or infection. Secondary skin lesions are shown in Table 22.6.

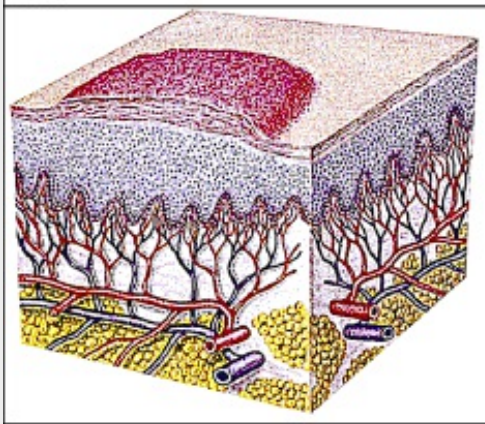
Skin lesions are usually described in terms related to the lesions'

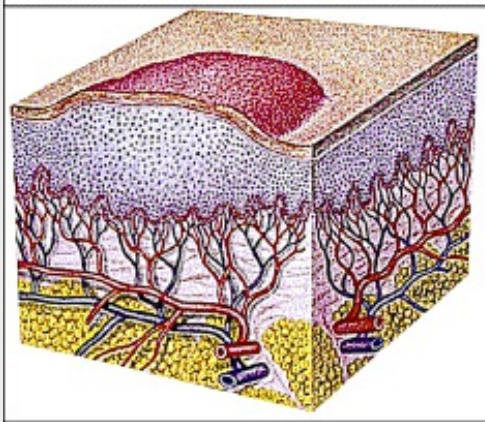


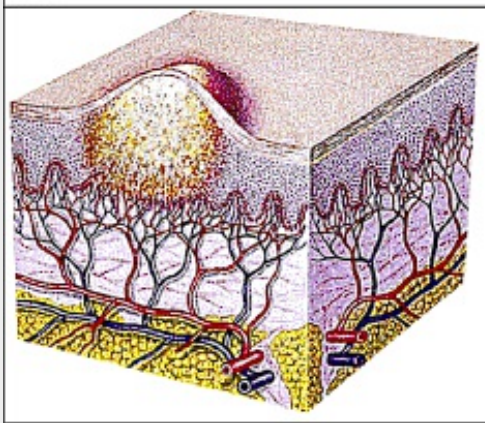




configuration (solitary or pattern in relation to other lesions) and distribution (arrangement of lesions over an area of skin) (Table 22.7). Note any unusual odors. Skin sites with lesions, such as rashes, may be colonized with yeast or bacteria, which can be associated with distinctive odors in areas where skin rubs together (Fig. 22.5).





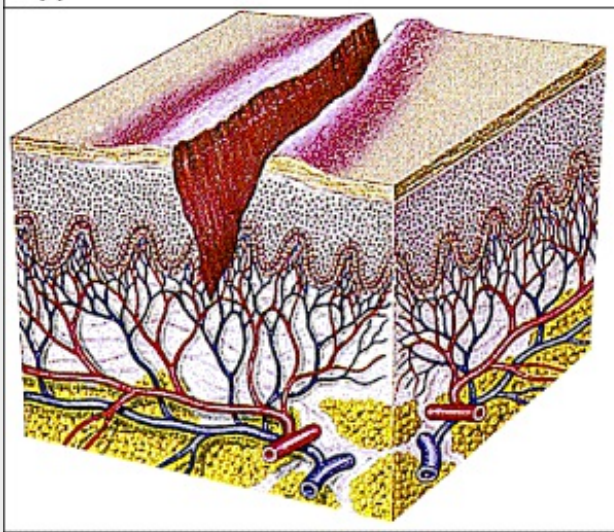


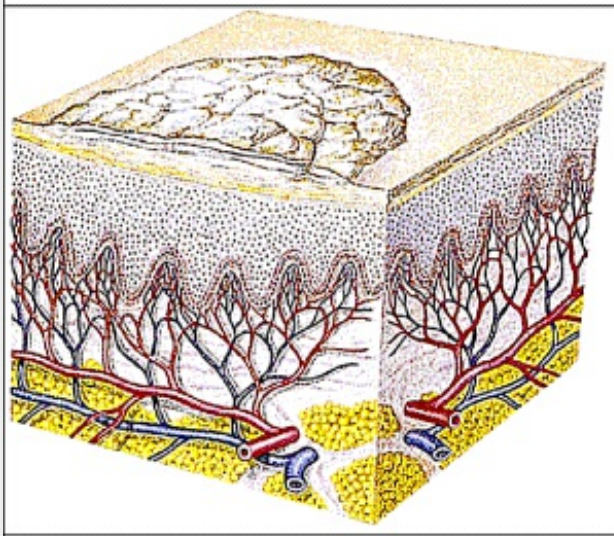
Inspect all body hair. Note the distribution, texture, and quantity of hair. Changes in the normal distribution of body hair and growth may indicate an endocrine or vascular disorder. Carefully inspect the nails, including nail shape, thickness, curvature, and surface. Note any grooves, pitting, ridges, or detachment from nail bed. Changes in nail smoothness or thickness can occur with anemia, psoriasis, thyroid problems, decreased vascular circulation, and some infections.

Palpation

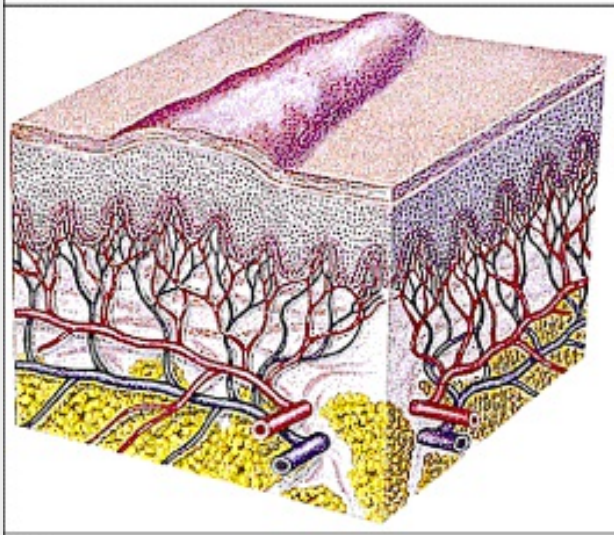
Palpate the skin to obtain information about temperature, turgor, moisture, and texture. Use the back of your hand to gauge skin temperature. The skin should be warm, not hot. Skin temperature increases when blood flow to the dermis increases. A localized temperature increase occurs with burns and local inflammation. A generalized increase occurs when a person has a fever. A decreased body temperature may occur when shock or other circulatory problems, chilling, or infection are present.

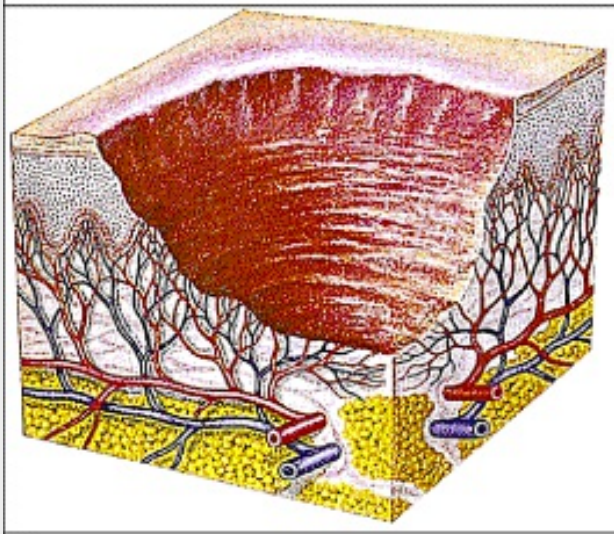
TABLE 22.5 Primary Skin Lesions

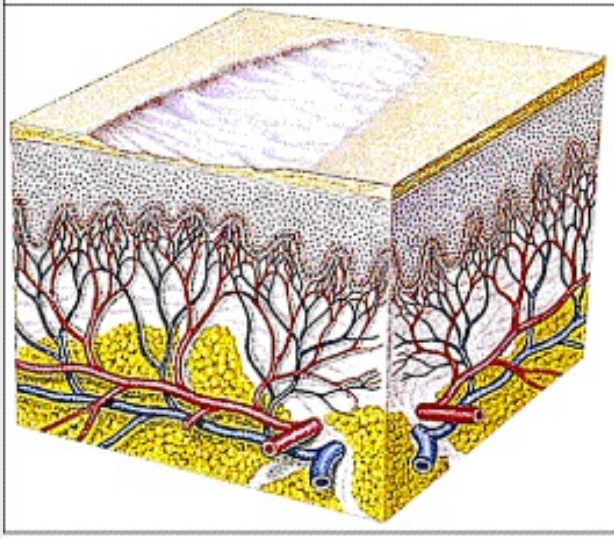




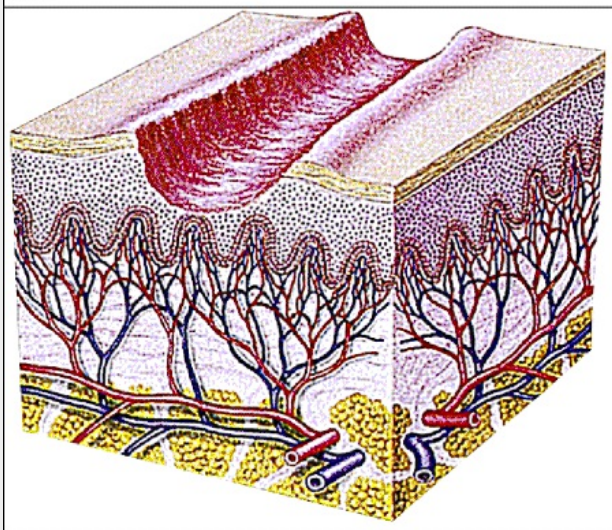
Lesion	Description
Macule 	Circumscribed, flat discoloration that is blue, red, brown, or hypopigmented. <0.5 cm in diameter. If lesion >0.5 cm, it is a patch *Examples:* freckles, petechiae, measles, flat mole (nevus), café-au-lait spots, vitiligo (complete depigmentation)
Papule 	Elevated, solid lesion. <0.5 cm in diameter. Color varies. If lesion is >0.5 cm in diameter, it is a nodule *Examples:* wart (verruca), elevated moles, lipoma, basal cell carcinoma
Plaque 	Circumscribed, elevated, superficial, solid lesion. >0.5 cm in diameter *Examples:* psoriasis, seborrheic and actinic keratoses
Pustule	Elevated, superficial lesion filled with purulent fluid *Examples:* acne, impetigo







Lesion	Description
	
Vesicle 	Circumscribed, superficial collection of serous fluid. < 0.5 cm in diameter. If lesion > 0.5 cm, it is a bulla *Examples:* varicella (chickenpox), herpes zoster (shingles), second-degree burn
Wheal 	Firm, edematous, irregularly shaped area. Size varies. May last only a few hours *Examples:* insect bite, urticaria, angioedema



Turgor refers to the elasticity of the skin. Assess turgor by gently pinching an area of skin under the clavicle or on the back of the hand. Skin with good turgor should move easily when lifted and immediately return to its original position when released. In patients with dehydration and aging, a loss of turgor occurs and can cause

tenting of the skin.

TABLE 22.6 Secondary Skin Lesions

Lesion	Description
Atrophy 	Depression in skin resulting from thinning of the epidermis or dermis *Examples:* aged skin, striae
Excoriation 	Area in which epidermis is missing, exposing the dermis *Examples:* abrasion, scratch
Fissure	Linear crack or break from the epidermis to the dermis. Dry or moist *Examples:* athlete's foot, chapping, eczema

Lesion	Description
	
Scale 	Excess, dead epidermal cells made by abnormal keratinization and shedding *Examples:* flaking of skin after a drug reaction or sunburn
Scar 	Abnormal formation of connective tissue that replaces normal skin *Examples:* surgical incision, healed wound

Lesion	Description
Ulcer 	Loss of the epidermis and dermis. Crater-like, irregular shape. Heals with scarring *Examples:* pressure ulcer, chancre

Skin moisture (dampness or dryness of the skin) increases in areas where skin rubs together. Skin moisture varies with environmental temperature, muscular activity, body weight, and body temperature. The skin should be intact with no flaking, scaling, or cracking. Skin generally becomes drier with increasing age.

TABLE 22.7 Lesion Distribution Terminology

Term	Description
Annular	Circular, begins in center and spreads to periphery (e.g., tinea corporis [ringworm])
Asymmetric	Unilateral distribution
Confluent	Merging together (e.g., urticaria [hives])
Discrete	Distinct individual lesions that are separate (e.g., acne)
Gyrate	Twisted, coiled spiral, snakelike
Grouped	Clusters of lesions (e.g., vesicles of contact dermatitis)
Localized	Clearly defined, limited areas of involvement (confined to one area)
Polycyclic	Annular lesions grow together (e.g., psoriasis)
Solitary	Single lesion

Symmetric	Bilateral distribution
Zosteriform	Linear arrangement along a dermatome area (e.g., herpes zoster)

Texture refers to the fineness or coarseness of the skin. The skin should feel smooth and firm with the surface evenly thin in most areas. Thickened callus areas are normal on the soles and palms and relate to weight bearing. Increased skin thickness is often work related and the result of excess pressure. Excess calluses on the soles of patients with neuropathy or diabetes predispose them to developing lesions.

Use a *focused assessment* to evaluate the status of previously identified skin problems and to monitor for signs of new problems. A focused assessment of the skin is presented in the following box. Assessment abnormalities of the skin are described in Table 22.8.

Focused Assessment

Integumentary System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Hair loss (unusual or rapid)	Y	N
Changes in skin (e.g., lesions, bruising)	Y	N
Nail discoloration	Y	N

Objective: Diagnostic

Check the following for results and critical values.

Biopsy results	✓
Albumin	✓

Objective: Physical Examination
Inspect

Skin for color, integrity, scars, lesions, signs of breakdown	✓
Facial and body hair for distribution, color, quantity, hygiene	✓
Nails for shape, contour, color, thickness, cleanliness	✓
Dressings, if present	✓

Palpate

Skin for temperature, texture, moisture, thickness, turgor, mobility	✓

FIG. 22.5 Intertrigo. Rash in body folds with *Candida* infection. From Graham-Brown R, Bourke J, Cunliffe T: *Dermatology: Fundamentals of practice,* Edinburgh, 2008, Mosby.

Assessment of Dark Skin

The structures of dark skin are no different from those of lighter skin, but they are often harder to assess (Table 22.9). Color is easiest to assess in areas where the epidermis is thin, and pigmentation is not influenced by sun exposure, such as the lips, mucous membranes, nail beds, and protected areas (e.g., buttocks). Palmar and plantar surfaces are lighter than other skin areas in darker skinned persons. Rashes are often harder to see and may have to be palpated. Wrinkling is less apparent in those with dark skin.

Persons with dark skin are predisposed to certain skin and hair conditions. **Keloid** is an overgrowth of collagenous tissue at the site of a skin injury (e.g., ear piercing) (Fig. 22.6). *Vitiligo* is total loss of pigment in the affected area (Fig. 22.7). In *dermatosis papulosa nigra,* the person has small, pigmented wart-like papules, often on the face (Fig. 22.8). *Nevus of Ota* is a slate-gray or blue-gray birthmark found on the forehead and face around the eye area. It may involve the sclera. *Traction alopecia* may be the result of trauma from hair rollers or from tight braiding of the hair (Fig. 22.9). The hair loss may be temporary or permanent. *Pseudofolliculitis* is an inflammatory response to ingrown hairs that occurs after shaving too closely in the beard area. The ingrown hairs result in pustules and papules.

TABLE 22.8 Assessment AbnormalitiesIntegumentary System

Finding	Description	Possible Etiology and Significance
Alopecia	Loss of hair (localized or general)	Heredity, friction, rubbing, traction, trauma, stress, infection, inflammation, chemotherapy, pregnancy, emotional shock, tinea capitis, immunologic factors
Angioma	Tumor consisting of blood or lymph vessels	Normal increase in incidence with aging, liver disease, pregnancy, varicose veins
	Yellow discoloration of skin, no	Vegetables containing carotene (e.g.,

Carotenemia (carotenosis)	yellowing of sclerae, most noticeable on palms and soles	carrots, squash), hypothyroidism
Comedo (acne lesion)	Enlarged hair follicle plugged with sebum, bacteria, and skin cells; can be open (blackhead) or closed (whitehead)	Heredity, certain drugs, hormonal changes with puberty and pregnancy
Cyanosis	Slightly bluish gray or dark purple discoloration of the skin and mucous membranes caused by excess amounts of reduced hemoglobin in capillaries	Cardiorespiratory problems, vasoconstriction, asphyxiation, anemia, leukemia, and cancers
Cyst	Sac containing fluid or semisolid material	Obstruction of a duct or gland, parasitic infection
Ecchymosis	Large, bruise-like lesion caused by collection of extravascular blood in dermis and subcutaneous tissue	Trauma, bleeding disorders
Erythema	Redness occurring in patches of variable size and shape	Heat, certain drugs, alcohol, ultraviolet rays, any problem that causes dilation of blood vessels in the skin
Hematoma	Extravasation of blood of enough size to cause visible swelling	Trauma, bleeding disorders
Hirsutism	Male distribution of hair in women	Abnormality of ovaries or adrenal glands, decrease in estrogen level, familial trait
Hypopigmentation	Loss of pigmentation resulting in lighter patches than the normal skin	Chemical agents, nutritional factors, burns, inflammation, infection
Intertrigo	Dermatitis of overlying surfaces of the skin (Fig. 22.5)	Moisture, irritation, obesity; may be complicated by *Candida* infection
Jaundice	Yellow (in white patients) or yellowish brown (in dark-skinned patients) discoloration of the skin, best seen in the sclera, secondary to increased bilirubin in the blood	Liver disease, red blood cell hemolysis, pancreatic cancer, common bile duct obstruction
Keloid	Hypertrophied scar beyond wound margins (Fig. 22.6)	Predisposition more common in dark-skinned persons
Lichenification	Thickening of the skin with accentuated normal skin markings	Repeated scratching, rubbing, and irritation usually because of pruritus or neurosis
Mole (nevus)	Benign overgrowth of melanocytes	Defects of development; excess numbers and large, irregular moles; often familial
Petechiae	Pinpoint, discrete deposits of blood <1–2 mm in the extravascular tissues and visible through the skin or mucous membrane	Inflammation, marked vasodilation, blood vessel trauma, blood dyscrasia that results in bleeding tendencies (e.g., thrombocytopenia)
Telangiectasia	Visibly dilated, superficial, cutaneous small blood vessels, commonly found on face and thighs	Aging, acne, sun exposure, alcohol, liver failure, corticosteroids, radiation, certain systemic diseases, skin tumors
	Failure of skin to return immediately	Aging, dehydration, cachexia

Tenting	to normal position after gentle pinching	
Varicosity	Increased prominence of superficial veins	Interruption of venous return (e.g., from tumor, incompetent valves, inflammation), commonly found on lower legs with aging
Vitiligo	Complete absence of melanin (pigment) resulting in chalky white patch (Fig. 22.7)	Autoimmune, familial, thyroid disease

TABLE 22.9 Nursing AssessmentAssessment Variations in Light- and Dark-Skinned Persons

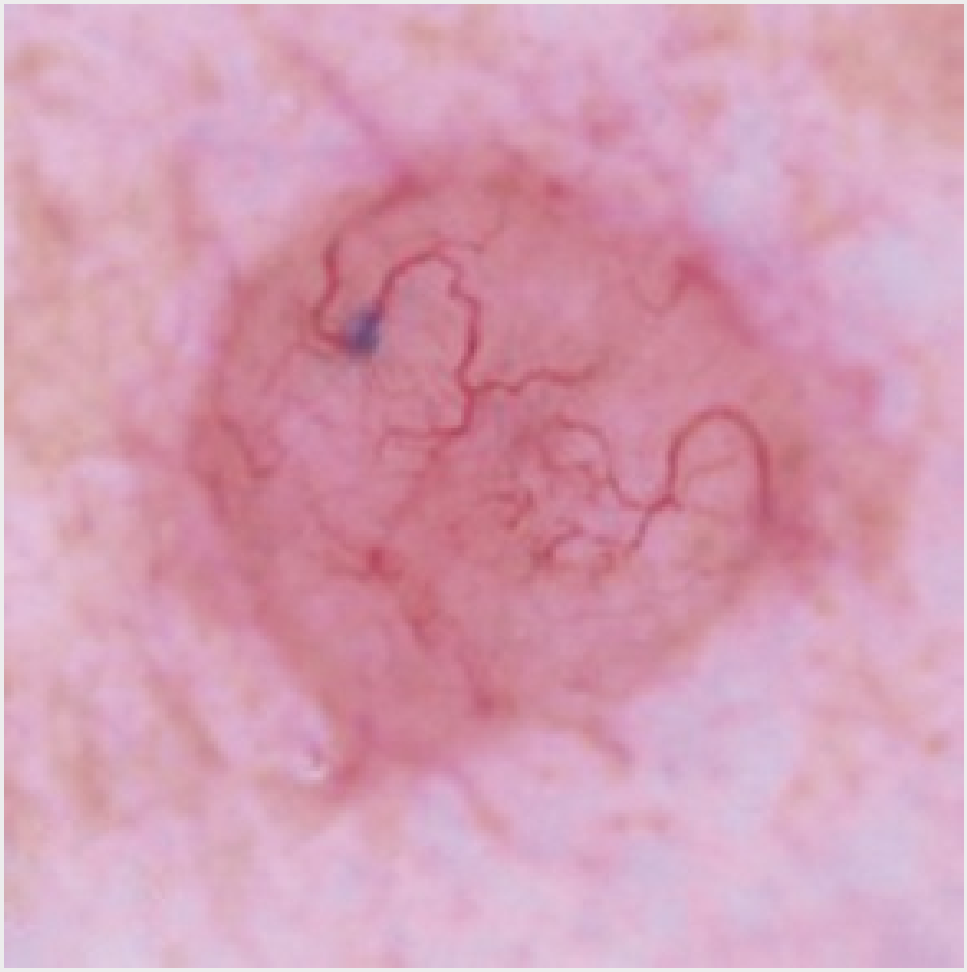
Light Skin	Dark Skin
Cyanosis	
Grayish blue tone, especially in nail beds, earlobes, lips, mucous membranes, palms, and soles	Ashen or gray color most easily seen in the conjunctiva of the eye, mucous membranes, and nail beds
Ecchymosis	
Dark red, purple, yellow, or green color, depending on age of bruise	Purple to brownish black. Hard to see unless occurring in an area of light pigmentation
Erythema	
Reddish tone, possibly accompanied by increased skin temperature secondary to localized inflammation	Deeper brown or purple skin tone with evidence of increased skin temperature secondary to inflammation
Jaundice	
Yellowish color of skin, sclera, fingernails, palms, and oral mucosa	Yellowish green color most obviously seen in sclera of eye (do not confuse with yellow eye pigmentation, which may be seen in dark-skinned patients), palms, and soles
Pallor	
Pale skin color that may appear white or ashen; also seen on lips, nail beds, and mucous membranes	Lack of underlying red tone in brown or black skin. In lighter dark-skinned persons, yellowish brown skin. In darker dark-skinned persons, ashen or gray skin
Petechiae	
Lesions appearing as small, reddish purple pinpoints, best seen on abdomen and buttocks	Hard to see. May be seen in the buccal mucosa of the mouth or conjunctiva of the eye
Rash	
May be seen and felt with light palpation	Not easily seen. May be felt with light palpation
Scar	
Generally heals, showing narrow scar line	Higher incidence of keloid development, resulting in a thickened, raised scar (Fig. 22.6)

FIG. 22.6 Keloid. Hypertrophic scarring after skin injury, which is more common in dark-skinned persons.
From Kliegman RM et al: *Nelson textbook of pediatrics,* Philadelphia, 2011, Saunders.

FIG. 22.7 Vitiligo. Total loss of pigment in the affected area. From Graham-Brown R, Bourke J, Cunliffe T: *Dermatology: Fundamentals of practice,* Edinburgh, 2008, Mosby.

FIG. 22.8 Dermatosis papulosa nigra. Small, pigmented wart-like papules, often on the face.
From James W, Berger T, Elston D: *Andrews' diseases of the skin,* ed 12, Edinburgh, 2016, Elsevier.

FIG. 22.9 Traction alopecia. Hair loss in scalp because of prolonged tension from hair rollers, braiding, or straightening combs.
From Ahanogbe I, Gavino A: Evaluation and management of the hair loss patient in the primary care setting, *Prim Care* 42:569, 2015.



Because of the darkness of the skin in some people, color may not be a reliable indicator of systemic conditions (e.g., flushed skin with fever). Cyanosis may be hard to detect because a normal bluish hue occurs in dark-skinned people. Dark skin rarely shows a blanch response, making it harder to identify pressure injuries.

Case Study

Objective Data: Physical Examination

© iStockphoto/Thinkstock.

Cheek lesion. From Bolognia JL, Schaffer JV, Duncan KO, et al: *Dermatology essentials,* Philadelphia, 2014, Saunders.

- Physical examination findings of D.A.'s skin are as follows:
    - Complexion fair. Wrinkles around eyes, above upper lip, and on sides of cheeks bilaterally. Normal skin temperature and turgor.
    - Lesions: on upper right forehead measuring 2 × 3 mm; on left forehead near hairline measuring 1 × 2 mm; and on left lower cheek measuring 2 × 2.5 mm.
    - The lesions are slightly erythematous but do not blanch with direct pressure. Borders are distinct. The lesions on the forehead have minimal elevation noted on palpation. The lesion on the cheek is slightly elevated.

- No other skin lesions noted on rest of body.

Discussion Questions

1. Which physical assessment findings are of most concern to you?
2. What diagnostic studies do you think may be ordered for D.A.?

You will learn more about diagnostic studies related to the skin in the next section.

(See p. 407 for more information on D.A.)

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

Diagnostic Studies of Integumentary System

Table 22.10 presents common diagnostic studies used for the integumentary system. The main diagnostic techniques related to skin problems are inspection of an individual lesion and a careful history related to the problem. If a definitive diagnosis cannot be made by these techniques, other tests may be needed. With *dermatoscopy*, the HCP uses a lighted instrument with optical magnification to see skin structures and colors not visible with the naked eye.[7] These hand-held screening devices (e.g., MelaFind) can help the HCP determine if a lesion should be biopsied.

Biopsy is one of the most common diagnostic tests used to evaluate a skin lesion. A biopsy is needed when cancer is suspected or a specific diagnosis is questionable. Techniques include punch, incisional, excisional, and shave biopsies. The method used depends on factors such as the site of the biopsy, cosmetic result desired, and type of tissue needed.

Other diagnostic procedures include stains and cultures for fungal, bacterial, and viral infections. Direct immunofluorescence is a special diagnostic technique used on biopsy specimens. It may be needed in

certain conditions such as bullous diseases and systemic lupus erythematosus. Indirect immunofluorescence is done on blood samples.

Case Study

Objective Data: Diagnostic Studies

© iStockphoto/Thinkstock.

The HCP examines the lesion via dermatoscopy and uses a Wood's lamp to rule out a fungal infection. The HCP suspects basal cell carcinoma.

Discussion Questions

1. Are these the diagnostic tests you expected the HCP to perform?
2. What, if any, other diagnostic studies would you expect to be ordered for D.A.?
3. What are the interprofessional team's priorities for D.A. at this time?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

TABLE 22.10 Diagnostic Studies Integumentary System

Study	Description and Purpose	Nursing Responsibility
Biopsy		
Excisional	Used when good cosmetic results and/or entire lesion removal desired. Skin closed with subcutaneous and skin sutures.	*Before:* Verify that consent form is signed (if needed). *During:* Help with site preparation, anesthesia, procedure, and hemostasis. Properly identify specimen. *After:* Apply dressing, give postprocedure instructions to patient.
Incisional	Wedge-shaped incision made in lesion too large for excisional biopsy. Useful when specimen needed is larger than shave or punch biopsy.	
Punch	Special punch biopsy instrument of appropriate size used. Instrument rotated to appropriate level to include dermis and some fat. Suturing depends on size and site. Provides full-thickness skin for diagnostic purposes.	
Shave	Single-edged razor blade used to shave off superficial lesions or small sample of a large lesion. Provides thin specimen for diagnostic purposes.	

Table Continued

Study	Description and Purpose	Nursing Responsibility
Microscopic Tests		
Culture	Test identifies fungal, bacterial, and viral organisms. For *fungi,* scraping or swab of skin performed. For *bacteria,* material obtained from intact pustules, bullae, or abscesses. For *viruses,* vesicle or bulla and exudate taken from base of lesion.	*Before*: Teach patient the purpose of test. *During*: Properly identify specimen. Follow instructions for storing specimen if not immediately sent to laboratory.
Immunofluorescence studies	Some skin diseases have specific, abnormal antibody proteins that can be identified by fluorescence studies. Can examine both skin tissue and serum.	*Before*: Teach patient the purpose of test. *During*: Help obtain specimen. For punch biopsy, place specimen in special fixative (e.g., Michel's) and not formalin.
Mineral oil slides	To check for infestations, place scrapings on slide with mineral oil and view microscopically.	*Before*: Teach patient the purpose of test. *During*: Prepare slide.
Potassium hydroxide (KOH)	Hair, scales, or nails examined for superficial fungal infection. Put specimen on glass slide and add 10%–20% concentration of KOH.	*Before*: Teach patient the purpose of test. *During*: Prepare slide.
Tzanck test (Wright's and Giemsa's stain)	Fluid and cells from vesicles examined. Used to diagnose herpes infections. Specimen put on slide, stained, and examined microscopically.	*Before*: Teach patient the purpose of test. *During*: Use sterile technique for collecting fluid.
Miscellaneous		
Patch test (Fig. 22.10)	Used to assess for allergic dermatitis and photoallergic reactions. Application of allergens to the patient's skin (usually on the back) for 48 hr. Test sites examined 48 hr later for a reaction, characterized by the presence of erythema, papules, and/or vesicles. May do additional readings beyond 48 hr.	*Before*: Teach patient the purpose of test and procedure. *After*: Tell patient to leave patches in place for 48 hr. During this time it is important not to wash the area or play vigorous sports because if the adhesive tape peels off, the process will need to be repeated. Do not expose the patches to sunlight or other sources of ultraviolet (UV) light.
Wood's lamp (black light)	Examination of skin with long-wave ultraviolet light causes specific substances to fluoresce (e.g., *Pseudomonas* organisms, fungal infections, vitiligo).	*Before*: Teach patient the purpose of test and procedure. Inform patient it is not painful. *During*: Darken room.

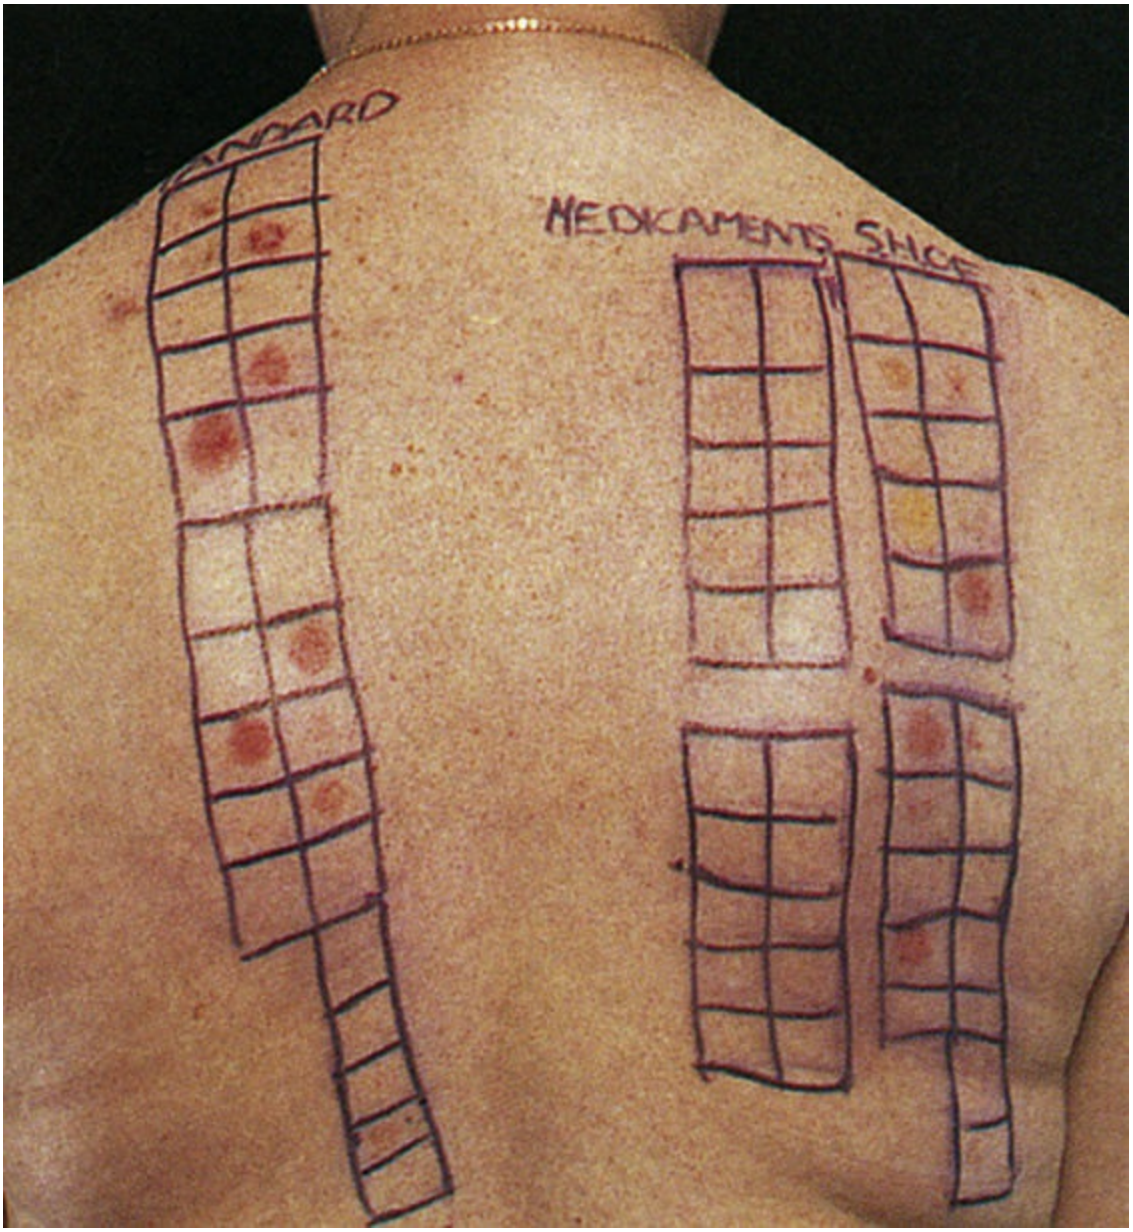


FIG. 22.10 Patch test. Results from applying possible allergens to the skin shows positive reactions in the sites labeled “standard” and “shoe.”
From Graham-Brown R, Bourke J, Cunliffe T: *Dermatology: Fundamentals of practice,* Edinburgh, 2008, Mosby.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered

outcome at the beginning of the chapter.

1. The primary function of the skin is
   a. insulation.
   b. protection.
   c. sensation.
   d. absorption.
2. Age-related changes in the hair and nails include *(select all that apply)*
   a. oily scalp.
   b. scaly scalp.
   c. thinner nails.
   d. thicker, brittle nails.
   e. longitudinal nail ridging.
3. When assessing the nutritional-metabolic pattern in relation to the skin, the nurse asks the patient about
   a. joint pain.
   b. the use of moisturizing shampoo.
   c. recent changes in wound healing.
   d. self-care habits related to daily hygiene.
4. The nurse assessed the patient's skin lesions as firm, edematous, irregularly shaped with a variable diameter. They would be called
   a. wheals.
   b. papules.
   c. pustules.
   d. plaques.

5. During the physical examination of a patient's skin, the nurse would
   a. use a flashlight in a poorly lit room.
   b. note cool, moist skin as a normal finding.
   c. pinch up a fold of skin to assess for turgor.
   d. perform a lesion-specific examination first and then a general inspection.
6. Persons with dark skin are more likely to develop
   a. keloids.
   b. wrinkles.
   c. skin rashes.
   d. skin cancer.
7. On inspection of a patient's dark skin, the nurse notes a blue-gray birthmark on the forehead and eye area. This assessment finding is called
   a. vitiligo.
   b. intertrigo.
   c. Nevus of Ota.
   d. telangiectasia.
8. Diagnostic testing is recommended for skin lesions when
   a. a health history cannot be obtained.
   b. a more definitive diagnosis is needed.
   c. percussion reveals an abnormal finding.
   d. treatment with prescribed medication has failed.

1. b, 2. b, d, e, 3. c, 4. a, 5. c, 6. a, 7. c, 8. b

Integumentary Problems

Mariann M. Harding

LEARNING OUTCOMES

1. Specify health promotion practices related to environmental hazards.
2. Explain the etiology, clinical manifestations, and interprofessional and nursing management of skin cancers.
3. Relate the etiology, clinical manifestations, and interprofessional and nursing management of bacterial, viral, and fungal skin infections.
4. Describe the etiology, clinical manifestations, and interprofessional and nursing management of infestations and insect bites.
5. Discuss the etiology, clinical manifestations, and interprofessional and nursing management of allergic skin disorders.
6. Explain the etiology, clinical manifestations, and interprofessional and nursing management related to benign skin disorders.
7. Select appropriate nursing interventions to manage the patient with a skin problem.
8. Explain the indications and nursing management related to common cosmetic procedures and skin grafts.

Conceptual Focus

Cellular Regulation
Coping
Infection
Pain

Tissue Integrity

This chapter discusses common skin conditions and skin cancer. Impaired skin integrity affects many body functions. The skin reflects both physical and psychologic well-being. Having a small abrasion or cancerous lesion leaves underlying tissues unprotected from infection and chemical dangers. Lesions can be painful because the skin has many sensory nerve endings. Skin conditions are often highly visible, potentially affecting body image and causing distress.

Environmental Hazards

Sun exposure comes with serious risk and results in permanent sun damage. Sunlight is made up of visible light and ultraviolet (UV) light. There are two types of UV light: UVA and UVB. Specific wavelengths (Table 23.1-anchor>) have different effects on the skin. UVA light is responsible for tanning, UVB for sunburn. The damage caused by UV rays is cumulative. It results in degenerative changes in the dermis and premature aging (e.g., loss of elasticity, thinning, wrinkling, abnormal dryness). Prolonged and repeated sun exposure increases risk for actinic keratosis, basal and squamous cell cancers, and melanoma.

Patient teaching on sun protection is important. People often do not understand the serious risks of sun exposure. Following sun safety guidelines beginning early in life can help avoid the damaging effects of the sun and prevent the formation of skin cancer later in life. Fair-skinned persons and those with light-colored eyes should be especially cautious about excess sun exposure. They have less melanin and thus less natural protection.

Teach the patient ways to avoid the damaging effects of the sun. This includes wearing protective clothing, including sunglasses, a large-brimmed hat, and a darker colored, long-sleeved shirt of a tightly woven fabric or carrying an umbrella. The greatest risk is with midday sun, between the hours of 10:00 am and 2:00 pm, regardless of the latitude. This is when 80% of UV rays occur. Even on overcast

days, serious sunburn can occur because up to 80% of the sun's UV rays can penetrate the clouds. Warn people of the dangers of tanning booths and sun lamps, which emit UVA. Tanning booths increase the risk for sunburn, cataracts, and skin cancer.[1]

Sunscreens can filter both UVA and UVB wavelengths. The two types of topical sunscreens are chemical and physical. Chemical sunscreens are light creams or lotions designed to absorb or filter UV light, resulting in decreased UV light penetration. Physical sunscreens are thick, opaque, heavy creams that reflect UV radiation. Regular sunscreen use decreases the risk for developing melanoma.

The U.S. Food and Drug Administration (FDA) rates sunscreen products on their **sun protection factor (SPF)**. The SPF measures the effectiveness of a sunscreen in filtering and absorbing UV radiation. All sunscreen labels in the United States must say which rays they protect against. Products labeled with "broad spectrum" block both UVA and UVB.[2] Sunscreens with broad spectrum labeling must have an SPF of at least 15. Sunscreens with an SPF of 15 or more filter 92% of the UVB rays and make sunburn unlikely when applied appropriately.

People need to select the right sunscreen for their needs. The general recommendation is that everyone should use daily sunscreen with a minimum SPF of 15. Teach patients to look for the term *broad spectrum* on sunscreen packaging. Those who have a history of skin cancer or problems with sun sensitivity should use a product with an SPF of at least 30. Sunscreens should be applied 20 to 30 minutes before going outdoors, even in cloudy weather. The SPF value of all sunscreens decreases with time. Sunscreen should be reapplied every 2 hours. You should apply 1 ounce per total body application. The ears, toes, and lips also need sunscreen. Sunscreens are not "waterproof" and must be reapplied after swimming.

TABLE 23.1 Wavelengths of Sun and Effects on Skin

Wavelength	Effect
Long (ultraviolet A [UVA])	Can produce elastic tissue damage and actinic skin damage Contributes to formation of skin cancer
Middle (ultraviolet B [UVB])	Causes sunburn and cumulative effect of sun damage Major factor in development of skin cancer
Short (ultraviolet C [UVC])	Blocked by the atmosphere and does not reach earth

TABLE 23.2 Drug TherapyDrugs That May Cause Photosensitivity

Categories	Examples
Antidepressants	amitriptyline, doxepin, venlafaxine
Antidysrhythmics	quinidine, amiodarone (Cordarone)
Antihistamines	diphenhydramine, chlorpheniramine, clemastine, cetirizine (Zyrtec)
Antimicrobials	tetracycline, sulfamethoxazole, azithromycin (Zithromax), ciprofloxacin (Cipro)
Antifungals	griseofulvin, ketoconazole
Antipsychotics	chlorpromazine, haloperidol
Chemotherapy	methotrexate, dacarbazine, fluorouracil
Diuretics	furosemide (Lasix), hydrochlorothiazide
Hypoglycemics	tolbutamide, glipizide (Glucotrol), glyburide
Nonsteroidal antiinflammatory drugs	diclofenac (Voltaren), piroxicam (Feldene), sulindac

Evidence-Based Practice

Tanning Booths and Skin Cancer

You are a nurse working in a dermatology clinic. D.F., a 30-yr-old woman with fair skin and blue eyes, is completing her health history before her annual skin screening. She says she regularly visits an indoor tanning salon every other week. She tells you that being tan

makes her feel "healthier and prettier."

Making Clinical Decisions

Best Available Evidence. There is a strong link between exposure to UVA from indoor tanning booth use and increased risk for skin cancer (melanoma and nonmelanoma). Melanoma causes less than 5% of skin cancers yet accounts for almost 75% of skin cancer deaths. Melanoma risk increases with the number of years, hours, and sessions of indoor tanning independent of outdoor exposure.

Clinician Expertise. You note that D.F. has the following skin cancer risk factors: fair skin, blue eyes, frequent use of tanning booths.

Patient Preferences and Values. After listening, D.F. tells you that she will consider reducing the frequency of her visits—going only when she has an important event to attend.

Implications for Nursing Practice

1. How would you respond to D.F. given the information that she has provided to you?
2. What resources can help address her view that a "tan looks healthy?"
3. What sun safety guidelines should she follow when outdoors to prevent skin cancer?

Reference for Evidence

Gershenwald J.E, Halpern A.C, Sondak V.K. Melanoma prevention: avoiding indoor tanning and minimizing overexposure to the sun. *JAMA*. 2016;316(18):1913.

Certain drugs potentiate the sun's effects, even with brief exposure. The chemicals in these drugs absorb light when exposed to natural sunlight and release energy that harms cells and tissues. Common photosensitizing drugs are shown in Table 23.2-anchor>. The manifestations of drug-induced photosensitivity (Fig. 23.1-anchor>) are like those of a sunburn. These include swelling, erythema, vesicles, and papular, plaquelike lesions. Assess the photosensitivity of each individual drug. Teach patients who are taking these drugs about their photosensitizing effect and the need to protect the skin from photosensitivity reactions by using sunscreen products.

Teach patients to self-examine their skin monthly. They should have a periodic professional assessment of areas that are hard to see. The cornerstone of skin examination is the ABCDE rule. Examine skin lesions for ***A****symmetry,* ***B****order* irregularity, ***C****olor* change and variation, ***D****iameter* of 6 mm or more, and ***E****volving* in appearance (Fig. 23.2-anchor>). Emphasize that a persistent skin lesion that does not heal and lesions once flat and now raised, once small and recently growing, or changing in appearance are warning signs. Patients should consult their HCP at once if any lesions or moles show any clinical signs (ABCDEs).

Skin Cancer

Skin cancer is the most commonly diagnosed cancer.[3] Skin cancers are either nonmelanoma or melanoma. The fact that skin lesions are so visible increases the chance of early detection and diagnosis. This can often lead to a highly favorable prognosis.

FIG. 23.1 Intense eruption in areas exposed to sunlight after patient started on hydrochlorothiazide.
From Habif TP: *Clinical dermatology: A color guide to diagnosis and therapy*, ed 5, St Louis, 2011, Mosby.

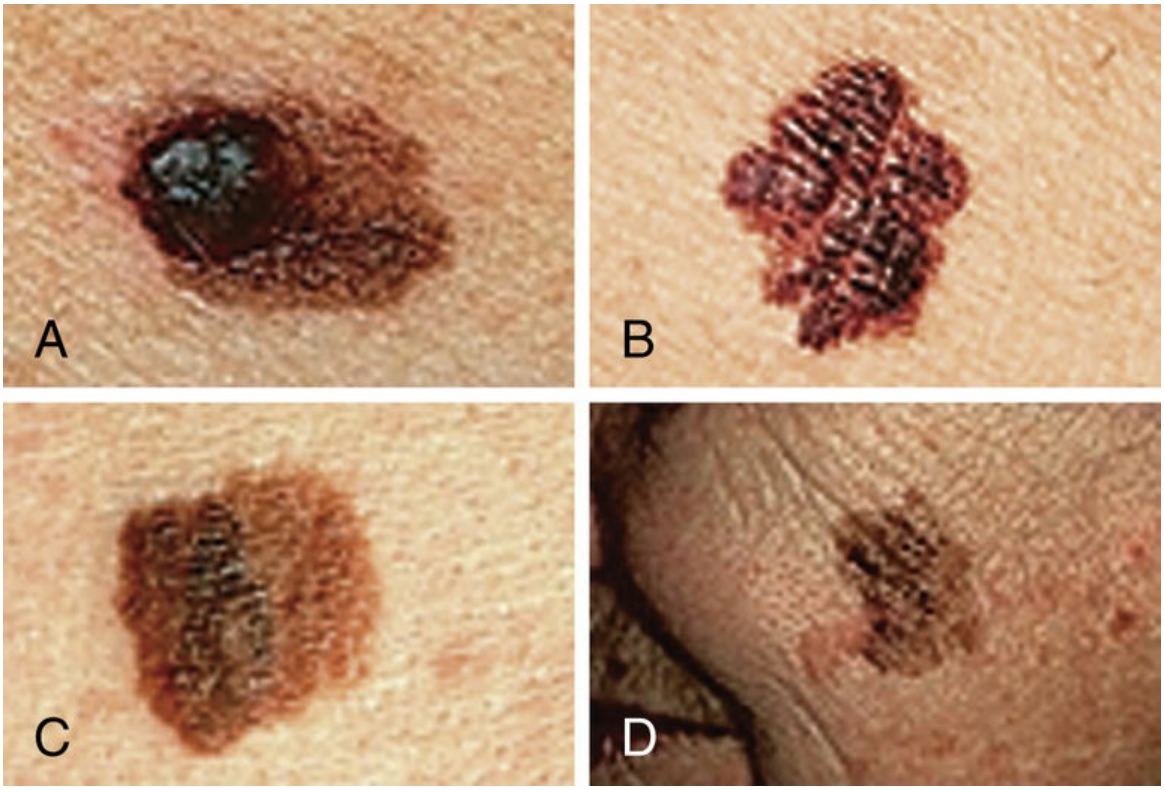

FIG. 23.2 The ABCDEs of melanoma. **A,** Asymmetry: one half unlike the other half. **B,** Border irregularity: edges are ragged, notched, or blurred. **C,** Color: varied pigmentation; shades of tan, brown, and black. **D,** Diameter: greater than 6 mm (diameter of a pencil eraser). **E,** (not pictured) Evolving; changing appearance (change in shape, size, color, or other characteristic noted over time).
From The Skin Cancer Foundation, New York, NY.

Risk Factors

Risk factors for skin cancer include (1) having fair skin, blond or red hair with blue eye color; (2) history of outdoor sunbathing; (3) living near the equator or at high altitudes; (4) family or personal history of skin cancer; (5) having an outdoor occupation; (6) spending a lot of time in outdoor recreation activities; and (7) indoor tanning.[4] The Fitzpatrick Classification of Skin Type can help you determine a person's skin complexion and how likely the person is to get skin cancer (Table 23.3-anchor>). Patients treated with oral methoxsalen (psoralen) and psoralen plus ultraviolet A radiation (PUVA) have a higher risk.

TABLE 23.3 Fitzpatrick Classification of Skin Type

Skin Type	Skin Color	Characteristics
I	White, freckles, very fair. Red or blond hair. Blue eyes	Always burns, never tans
II	White, fair. Red or blond hair. Blue, hazel, or green eyes	Usually burns, tans with difficulty
III	Cream white, fair. Any eye or hair color	Sometimes mild burn, gradually tan
IV	Brown, typical Mediterranean skin	Rarely burns, tans with ease
V	Deep brown, Middle Eastern skin types	Very rarely burns, tans very easily
VI	Black	Never burns, tans very easily

Promoting Health Equity

Skin Problems

- Blacks, Asians, and Hispanics have a lower incidence of skin cancer than whites.
- Melanoma can occur in dark-skinned persons but often goes unrecognized until the advanced stages.
- Blacks and Asians are more likely to develop a keloid at the site of an injury.
- Skin cancer outcomes are poorer for ethnic minorities, those of low socioeconomic status, and the uninsured.

Dark-skinned persons are less susceptible to skin cancer because of their increased melanin, which acts like a sunscreen. However, there is still a risk, and they need to wear sunscreen. They often have melanomas on areas with less melanin, such as the palms, soles,

mucous membranes, and under the nails. Since it is common for people with dark skin to have pigmented, longitudinal bands on their nails, assess and follow any nail discoloration.

Nonmelanoma Skin Cancer

Nonmelanoma skin cancers (basal cell and squamous cell cancers) are the most common forms of skin cancer. More than 5.4 million new cases are diagnosed each year.[3] Nonmelanoma skin cancers do not develop from melanocytes. They develop in the basement membrane of the skin. Although there are few deaths from nonmelanoma skin cancer, they have the potential for severe local destruction, permanent disfigurement, and disability.

Nonmelanoma skin cancers usually develop in sun-exposed areas, such as the face, head, neck, back of the hands, and arms. The most common causative factor is sun exposure. There are some differences between basal and squamous cell cancers. Squamous cell cancers usually occur on the head and neck where there is the highest degree of UV radiation. Basal cell cancers do not follow that pattern and may occur in sun-protected areas.

Actinic Keratosis

Actinic keratosis (AK), also known as *solar keratosis,* is the most common precancerous skin lesion. They affect most of the older white population. Sun exposure is a key factor. AKs appear most often on skin that has been exposed to the sun or to artificial UV light. They may spontaneously resolve if a person reduces exposure to sunlight.

The clinical appearance of AK can be highly varied. The typical lesion is an irregularly shaped, flat, slightly erythematous papule with indistinct borders and an overlying hard keratotic scale or horn (Table 23.4-anchor>). Because AK is impossible to distinguish from squamous cell cancer, treatment should be aggressive. Nonsurgical procedures are the first-line treatment. Any lesion that persists should be evaluated for a biopsy.

TABLE 23.4 Premalignant and Malignant Conditions of the Skin

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Actinic Keratosis		
• **Actinic (sun) damage** • **Premalignant skin lesions** • **Common in older whites** • **Increase in number with age**	• Flat or elevated, dry, hyperkeratotic scaly papule. Often multiple • May be rough or wartlike • Rough adherent scale on red base, which returns when removed • Often on erythematous sun-exposed area	• Cryosurgery. Topical application of fluorouracil, imiquimod (Aldara) or diclofenac (Solaraze), chemical peels, laser resurfacing, photodynamic therapy • Recurrence possible even with adequate treatment
Atypical or Dysplastic Nevi		
• **Morphologically between common acquired nevi and melanoma** • **May be precursor of melanoma**	• Often >5 mm. Irregular border, possibly notched. Frequently multiple • Varying colors of tan, brown, black, red, or pink within single mole • Central part often raised with flat edges • Most common site on back, but possible in uncommon mole sites such as scalp or buttocks (Fig. 23.5)	• Increased risk for melanoma • Careful monitoring of those with a familial tendency to melanoma or dysplastic nevi • Excisional biopsy for suspicious lesions
Basal Cell Carcinoma		
• **Change in basal cells. No maturation or normal keratinization** • **Continuing division of basal cells and formation of enlarging mass** • **Related to excessive sun exposure, genetic skin type, x-ray radiation, scars, and some types of nevi**	*Nodular and ulcerative:* • Small, slowly enlarging papule • Borders semitranslucent or "pearly" with overlying telangiectasia • Erosion, ulceration, and depression of center • Normal skin markings lost (Fig. 23.3) *Superficial:* • Erythematous, pearly, sharply defined, barely elevated plaques	• Surgical excision, electrodessication and curettage, cryosurgery, radiation therapy, laser therapy, and photodynamic therapy • Vismodegib (Erivedge) or sonidegib (Odomzo) for metastatic or recurrent locally invasive lesions • Fluorouracil and imiquimod for superficial lesions • Slow-growing tumor that invades local tissue • Metastasis rare, 90% cure rate with primary lesions
Cutaneous T-Cell Lymphoma		
• **Origins in skin. Localized chronic, slowly progressing disease** • **Possibly related to environmental toxins and chemical exposure** • **Mycosis fungoides (MF) is most common form** • **Sézary syndrome is an advanced form of MF** • **Prevalence twice as high in men as in women**	• Classic presentation involves 3 stages: patch (early), plaque, and tumor (advanced) • History of persistent macular eruption followed by gradual appearance of indurated erythematous plaques on trunk • Appears similar to psoriasis • Pruritus, lymphadenopathy	• Treatment usually controls symptoms but is not curative • Skin-directed treatment includes phototherapy with ultraviolet light, radiation therapy, corticosteroids, and topical nitrogen mustard, imiquimod, or retinoids • Interferon, systemic chemotherapy, extracorporeal photopheresis, romidepsin (Istodax), denileukin diftitox (Ontak), and vorinostat (Zolinza) for progressive disease • Disease course is unpredictable. 10% will have progressive disease
Melanoma		
• **Neoplastic growth of melanocytes anywhere on skin, eyes, or mucous membranes** • **Classification according to major histologic mode of spread** • **Potential invasion and widespread metastases**	• Irregular color, surface, and border • Variegated color, including red, white, blue, black, gray, brown • Flat or elevated. Eroded or ulcerated • Often <1 cm in size • Most common sites in males are back, then chest. In females are legs, then back (Fig. 23.2)	• Surgical excision and possible sentinel lymph node evaluation • Adjuvant therapy after surgery if lesion >1.5 mm in depth • Correlation between survival rate and depth of invasion • Poor prognosis unless diagnosed and treated early • Spreading by local extension, regional lymphatic vessels, and bloodstream
Squamous Cell Carcinoma		
• **Frequent occurrence on previously damaged skin (e.g., from sun, radiation, scar)** • **Malignant tumor of squamous cell of epidermis. Invasion of dermis, surrounding skin**	• Most common on sun-exposed areas such as face and hands • *Superficial:* Thin, scaly erythematous plaque without invasion into the dermis • *Early:* Firm nodules with indistinct borders, scaling, and ulceration • *Late:* Covering of lesion with scale or horn from keratinization, ulceration	• Surgical excision, cryosurgery, radiation therapy, electrosurgery, laser therapy, and photodynamic therapy • Untreated lesion may metastasize to regional lymph nodes and distant organs • Fluorouracil and imiquimod for noninvasive SCC • Chemotherapy for metastatic lesions • High cure rate with early detection and treatment

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is a locally invasive cancer arising from epidermal basal cells. It is the most common type of skin cancer but the least deadly. BCC usually occurs in middle-aged to older adults. Most BCCs occur in the head and neck area (e.g., sun-exposed), followed by the trunk and extremities.[5]

Manifestations are described in Table 23.4. Some BCCs are pigmented, with curled borders and an opaque appearance. They may be hard to distinguish from melanoma. A tissue biopsy is needed to confirm the diagnosis. BCCs rarely metastasize (Fig. 23.3-anchor>). However, untreated BCC may result in massive tissue destruction. Treatment depends on the tumor location and histologic type, size, history of recurrence, and patient characteristics (Table 23.4).

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is a cancer arising from keratinizing epidermal cells. SCC can be aggressive and has the potential to metastasize. It may lead to death if not treated early and correctly. SCC often occurs at the base of an actinic keratosis or another lesion. The main risk factors are sun exposure and immunosuppression after organ transplantation.[6] Pipe, cigar, and cigarette smoking contribute to the formation of SCC on the mouth and lips. The manifestations of SCC are described in Table 23.4. A biopsy should always be done when a lesion is suspected to be SCC.

Melanoma

Melanoma is a tumor arising from melanocytes, the cells that make melanin. It causes most skin cancer deaths. Unlike most cancers whose incidence is stable or decreasing, the incidence of melanoma is steadily rising.[1] More than 87,000 new cases are diagnosed every year in the United States and almost 10,000 people will die from the

disease.[3] Melanoma can metastasize to any organ, including the brain and heart.

A combination of environmental and genetic factors is likely involved in the development of melanoma. UV radiation from the sun is the main cause of melanoma. Artificial sources of UV radiation, such as sunlamps and tanning booths, also play a role. UV radiation damages the deoxyribonucleic acid (DNA) in skin cells, causing "misspellings" (mutations) in their genetic code. This alters the cells. Although anyone can develop melanoma, the risk is greatest for people who have red or blond hair, blue or light-colored eyes, and light-colored skin that freckles easily. These people have less melanin and thus less protection from UV radiation. The use of immunosuppressive drugs and a history of dysplastic nevi also increase risk.

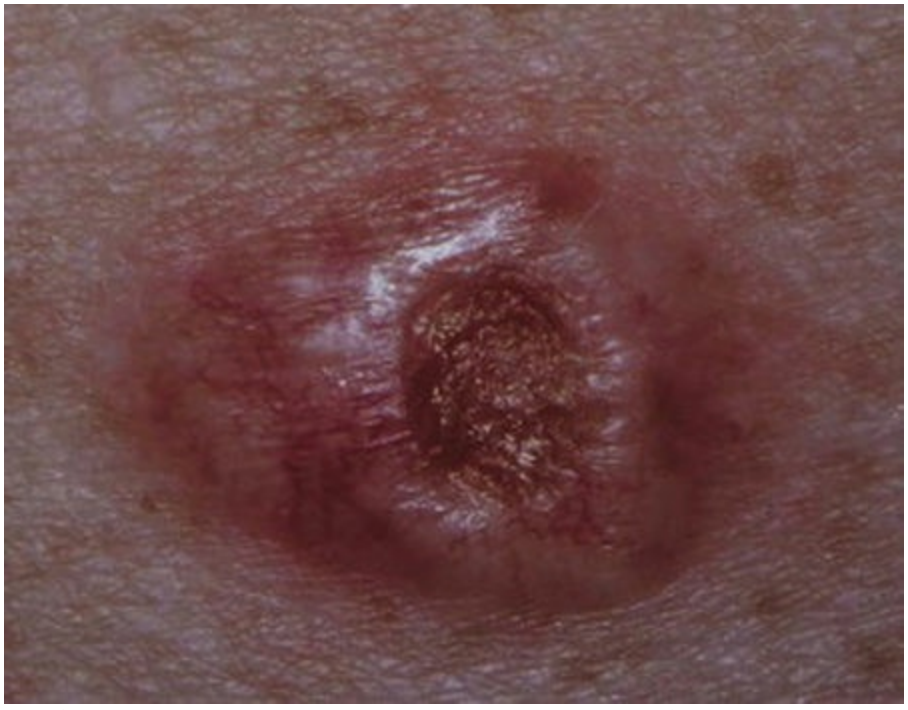

FIG. 23.3 Basal cell carcinoma. Rolled, well-defined border and central erosion.
From Goldman L, Schafer A: *Goldman-Cecil medicine*, ed 25, Philadelphia, 2016, Saunders.

A person may have a genetic predisposition toward getting melanoma. Of those with melanoma, 5% to 10% have a first-degree relative (e.g., parent, full sibling) who had melanoma.[4] This risk increases significantly if multiple relatives have had melanoma. Mutated genes have been found in some families who have a high familial incidence of melanoma.

Cutaneous melanoma begins in the skin. There are 4 subtypes of melanoma: (1) superficial spreading melanoma, (2) nodular melanoma, (3) lentigo maligna melanoma, and (4) acral lentiginous melanoma.

Clinical Manifestations

Melanoma often occurs on the lower legs in women and on the trunk and head in men. About one fourth of melanomas occur in existing nevi or moles. About 20% occur in dysplastic nevi. Rarely, it occurs in the mouth, intestines, and eyes.

The cornerstone of skin examination is the ABCDE rule (Fig. 23.2). Because most melanoma cells continue to produce melanin, melanoma tumors are often deep brown or black (Table 23.4). Lesions showing any sudden or progressive change in the ABCDE rule need evaluated.

Interprofessional Care

One of the first steps in diagnosing a suspicious lesion is dermoscopic examination. Dermoscopy can help the HCP decide if a lesion should be biopsied. Biopsy is a critical tool for determining the type of lesion. A biopsy should be done using an excisional biopsy technique. Shave biopsy, shave excision, or electrocauterization should not be done because these techniques do not measure the depth of the lesion.

The most important prognostic factor is tumor thickness at the time of diagnosis. We use 2 methods to determine thickness. The *Breslow measurement* indicates the depth of the tumor in millimeters (Fig. 23.4-anchor>). The *Clark level* indicates the depth of invasion of the tumor; the higher the number, the deeper the melanoma.

Treatment depends on the site of the original tumor and the stage of the cancer. Melanoma staging (stages 0 to IV) is based on tumor size (thickness), nodal involvement, and metastasis. In stage 0, melanoma is confined to one place (in situ) in the epidermis. Melanoma is nearly 100% curable by excision if diagnosed at stage 0. Unfortunately, those with deep tumors or disease that has already spread to lymph nodes often develop metastases. The 5-year survival rate for those with advanced disease is less than 10%.[7]

The initial treatment of melanoma is wide surgical excision. Melanoma that has spread to the lymph nodes or nearby sites usually requires additional (adjuvant) therapy with combinations of immunotherapy, targeted therapy, chemotherapy, and/or radiation therapy.

Immunotherapy can include cytokines (α-interferon, interleukin-2), PD-1 inhibitors, and CTLA-4 inhibitors. Cytokines enhance the production of many immune system cells, including T cells and B cells. Drugs that block PD-1 or CTLA-4 boost the immune response against melanoma cells.[7] PD-1 inhibitors include nivolumab (Opdivo) and pembrolizumab (Keytruda). They block PD-1, a protein on T cells that keeps T cells from attacking other cells in the body. Ipilimumab (Yervoy) blocks the action of CTLA-4, another protein that normally suppresses the action of T cells.

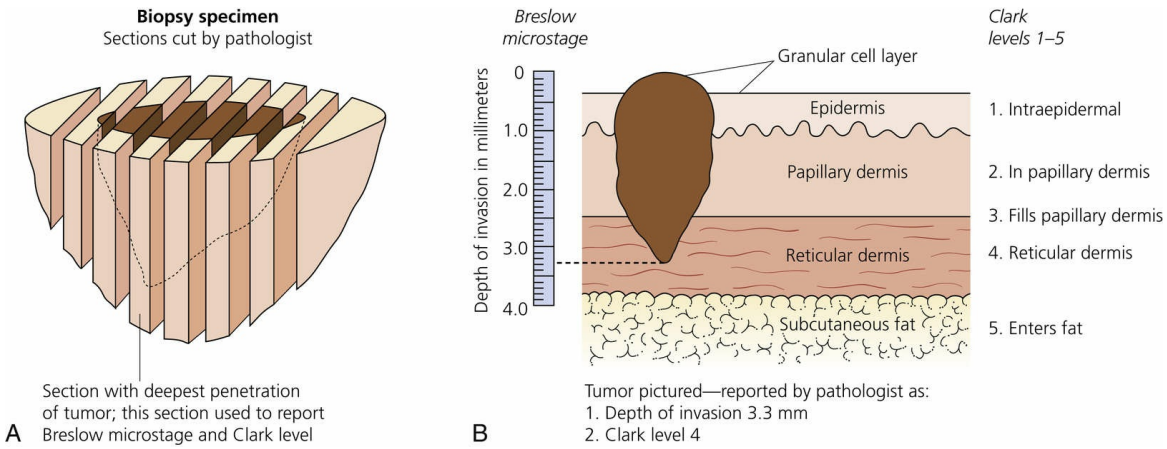

FIG. 23.4 **A,** Breslow measurement of tumor thickness. **B,** Clark level, showing tumor invasion.

From Habif TP: *Clinical dermatology: A color guide to diagnosis and therapy,* ed 6, St Louis, 2016, Mosby.

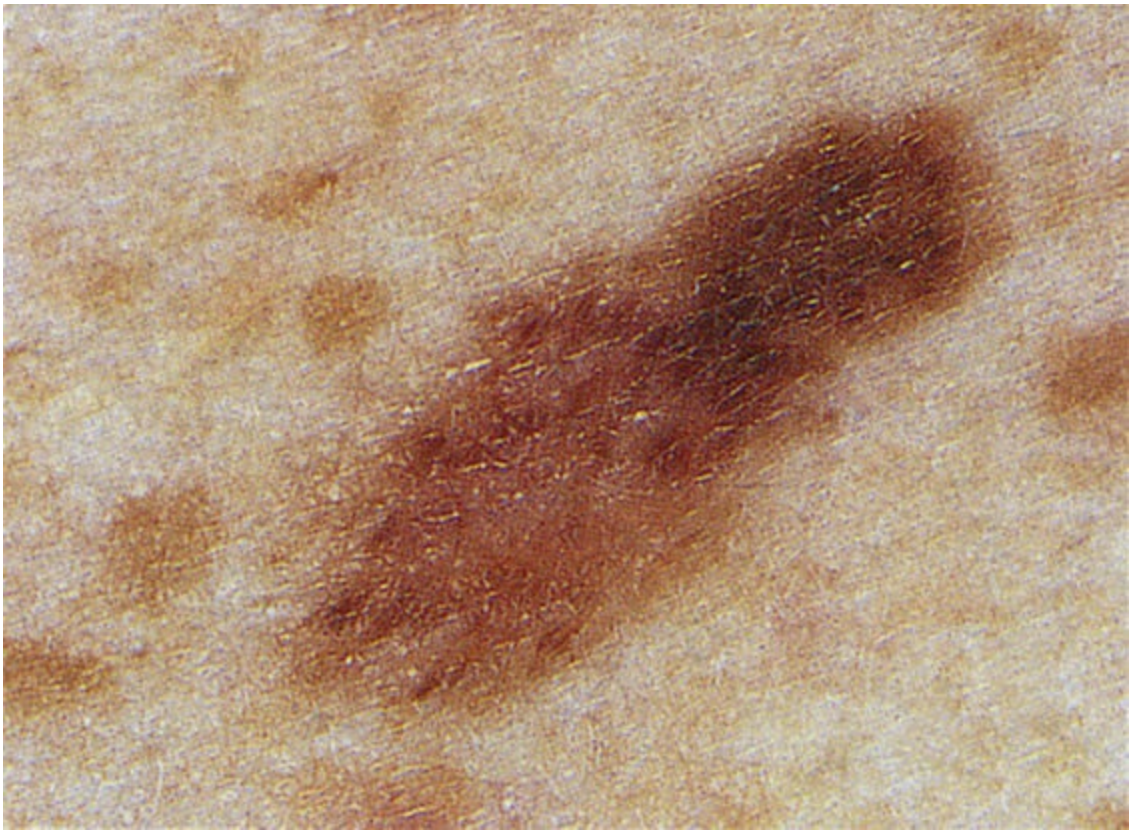

FIG. 23.5 Dysplastic nevus. Irregular border and color.
From Graham-Brown R, Bourke J, Cunliffe T: *Dermatology: Fundamentals of practice,* Edinburgh, 2008, Mosby.

Targeted therapy for melanoma includes BRAF and MEK inhibitors. About half of all melanomas have mutations in the *BRAF* gene, which makes an altered BRAF protein that signals melanoma cells to proliferate. Vemurafenib (Zelboraf), dabrafenib (Tafinlar), trametinib (Mekinist), and cobimetinib (Cotellic) are drugs that target BRAF mutations.[7]

Chemotherapy is not as effective for melanoma as it is for most other cancers. It is usually used only with advanced disease. Drugs used includes dacarbazine, temozolomide, cisplatin, paclitaxel, carboplatin, and vincristine.[3] Radiation therapy has a role in treating

lymph node and brain metastases.

Atypical or Dysplastic Nevus

Dysplastic nevi (DN), or atypical moles, are nevi that are larger than usual (greater than 5 mm across) with irregular borders and various shades of color (Fig. 23.5-anchor>). DN may have the same ABCDE characteristics as melanoma, but they are less pronounced. About 5% of the white population have DN.[8] Those with DN have an increased risk for developing melanoma in a mole or elsewhere on the body. The more DN a person has, the higher the risk. Those with 10 or more DN have 12 times the risk for developing melanoma.

Check Your Practice

You are working in an HCP office, and your next patient is a 78-yr-old white man. He is worried about the many "brown" spots on his face and arms. He tells you that they probably happened because he worked outside in construction most of his life.

- How do you distinguish among an age spot (lentigo), normal mole, and melanoma?
- What risk factors would you assess for in a patient with a suspected cancerous lesion?

Skin Infections and Infestations

Bacterial Infections

The skin provides an ideal environment for bacterial growth with an abundant supply of nutrients, water, and warm temperature. Bacterial infection occurs when the balance between the host and microorganisms is changed. This can occur as a primary infection after a break in the skin. Or, a secondary infection can occur in already

damaged skin or as a sign of a systemic disease (Table 23.5-anchor>). Predisposing factors include the presence of excess moisture, obesity, having atopic dermatitis, systemic corticosteroid and antibiotic use, and having a chronic disease, such as diabetes.

Staphylococcus aureus and group A β-hemolytic streptococci are the major types of bacteria responsible for primary and secondary skin infections. Streptococci cause impetigo, erysipelas, cellulitis, and lymphangitis. *S. aureus* causes impetigo, folliculitis, cellulitis, and furuncles (Fig. 23.6-anchor>). When an infection is present, the resulting drainage is infectious. Good skin hygiene and infection control practices are necessary to prevent the spread of the infection.

Viral Infections

Like viral infections anywhere in the body, viral infections of the skin are hard to treat. When a virus infects a cell, a skin lesion may develop. Lesions can also result from an inflammatory response to viral infections. Herpes simplex, herpes zoster (Fig. 23.7-anchor>), and warts (Fig. 23.8-anchor>) are the most common viral infections affecting the skin (Table 23.6-anchor>).

TABLE 23.5 Common Bacterial Infections of the Skin

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Carbuncle		
• **Multiple, interconnecting furuncles**	• Many pustules appearing in erythematous area • Most common at nape of neck	• Incision and drainage (possibly with packing), antibiotics, meticulous care of involved skin, frequent application of warm, moist compresses • Heal slowly with scar formation
Cellulitis		
• **Inflammation of subcutaneous tissues** • **May be a primary infection or secondary complication** • **Often following break in skin** • ***Staphylococcus aureus* and streptococci usual causative agents** • **Deep inflammation of subcutaneous tissue from enzymes produced by bacteria**	• Hot, tender, erythematous, and edematous area with diffuse borders • Chills, malaise, and fever (Fig. 23.6)	*Topical:* • Moist heat, immobilization, and elevation Systemic: • Systemic antibiotic therapy • Hospitalization if severe for IV antibiotic therapy (vancomycin, linezolid, ceftaroline fosamil, daptomycin) based on culture and sensitivity • Progression to gangrene possible if untreated
Erysipelas		
• **Superficial cellulitis primarily involving the dermis** • **Group A β-hemolytic streptococci**	• Red, hot, sharply demarcated plaque that is indurated and painful • Bacteremia possible • Most common on face and extremities • Toxic signs: fever, ↑ WBC count, headache, malaise	• Systemic antibiotics, usually penicillin • Hospitalization often needed
Folliculitis		
• **Usually staphylococci** • **Present in areas subjected to friction, moisture, rubbing, or oil** • **Increased incidence in patients with diabetes mellitus**	• Small pustule at hair follicle opening with minimal erythema • Development of crusting • Most common on scalp, beard, extremities in men • Tender to touch	• Antistaphylococcal soap (e.g., Hibiclens, Lever 2000, Dial) and water cleansing • Topical antibiotics (e.g., mupirocin) • Warm compresses of water or aluminum acetate solution • Usually heals without scarring • If lesions extensive and deep, possible scarring, loss of involved hair follicles, and treatment with systemic antibiotics
Furuncle		
• **Deep infection with staphylococci around hair follicle** • **Often associated with severe acne or seborrheic dermatitis**	• Tender erythematous area around hair follicle that is painful • Draining pus and core of necrotic debris on rupture • Most common on face, back of neck, axillae, breasts, buttocks, perineum, thighs	• Treatment is the same as for carbuncles
Furunculosis		
• **Increased incidence in patients who are obese, diabetic, chronically ill, or regularly exposed to moisture, pressure**	• Lesions as above • Malaise, regional adenopathy, elevated body temperature	*Topical:* • Incision and drainage of painful nodules • Warm, moist compresses to erythematous plaques • Measures to reduce surface staphylococci include antimicrobial cream to nares, armpits, and groin and antiseptic to entire skin • Meticulous personal hygiene *Systemic:* • Systemic antibiotic effective against MRSA pending culture and sensitivity results • Often recurrent with scarring
Impetigo		
• **Group A β-hemolytic streptococci, staphylococci, or combination of both** • **Associated with poor hygiene** • **Primary or secondary infection. Contagious**	• Vesiculopustular lesions that develop thick, honey-colored crust surrounded by erythema • Pruritic • Most common on face as primary infection	*Topical:* • Wound care with warm saline or aluminum acetate soaks followed by soap-and-water removal of crusts and application of topical antibiotic cream or ointment (mupirocin, retapamulin [Altabax]) • Meticulous hygiene essential *Systemic:* • Systemic antibiotics (e.g., cephalosporins, erythromycin, amoxicillin, clindamycin) for widespread infections or systemic manifestations

MRSA, Methicillin-resistant *S. aureus.*

Infestations and Insect Bites

There are many opportunities for exposure to *infestations* (harboring insects or worms) and insect bites (Table 23.7-anchor>). In many instances, an allergy to the venom plays a key role in the reaction. In other cases, the clinical manifestations are a reaction to the eggs, feces, or body parts of the invading organism. Some people react with a severe hypersensitivity (anaphylaxis), which can be life threatening. Anaphylaxis is discussed in Chapter 13.

Preventing insect bites by avoidance or using repellents is somewhat effective. Meticulous hygiene related to personal articles, clothing, bedding, and examination and care of pets, as well as careful choice of sexual partners, can reduce the incidence of infestations. Prompt, routine skin inspection is necessary in geographic areas where there is a risk for tick bite. Lyme disease, which is caused by a tick, is discussed in Chapter 64.

Fungal Infections

Because of the large number of fungi that are present everywhere, exposure to some pathologic varieties may occur. Skin, hair, and nails can become infected with fungi, including candidiasis and tinea

unguium. Common fungal infections of the skin are described in Table 23.8-anchor>. Most infections are harmless in healthy adults, but they can cause embarrassment and distress.

Fungal infections are easy to diagnose. A microscopic examination showing the appearance of hyphae (threadlike structures) in a skin scraping mounted in 10% to 20% potassium hydroxide (KOH) indicates a fungal infection. A Wood's light examination of hair infected with certain fungi will fluoresce blue to green.

Allergic Skin Problems

Patients often seek treatment for irritant or allergic dermatitis, two common types of contact dermatitis. *Irritant contact dermatitis* results from direct chemical injury to the skin. *Allergic contact dermatitis* is an antigen-specific, type IV delayed hypersensitivity response. The pathophysiology of allergic and contact dermatitis is discussed in Chapter 13. Skin problems associated with allergies and hypersensitivity reactions may present a challenge to the clinician (Table 23.9-anchor>). A careful family history and discussion of exposure to possible offending agents can provide valuable data. Patch testing can help determine possible causative agents (see Fig. 22.10). The best treatment of allergic dermatitis is to avoid known irritants. The extreme pruritus and its potential for chronicity make it a frustrating problem for you and the patient, especially if we cannot determine the offending agent.

Cutaneous Drug Reactions

Stevens Johnson syndrome (SJS) and *toxic epidermal necrolysis* (TEN) are rare, life-threatening diseases. They are violent immune responses that often occur as a severe adverse reaction to either a medication or, more rarely, an infection. The result is the acute destruction of the epithelium of the skin and mucous membranes. SJS, SJS-TEN overlap, and TEN represent a spectrum of disease severity. SJS involves less than 10% of total body surface area, TEN involves more than 30% of

total body surface area, and SJS-TEN overlap involves 10% to 29% of total body surface area.[8]

SJS/TEN typically occur 4 to 21 days after starting use of the offending drug. Systemic symptoms, including fever, cough, headache, anorexia, myalgia, and nausea, precede skin and mucous membrane findings by 1 to 3 days. Skin involvement starts as an erythematous, macular rash with purpuric centers. Over a period of hours to days, the rash merges to form blisters with sheet-like epidermal detachment (Fig. 23.9-anchor>). The lesions usually start on the palms, soles, and trunk, then spread to the face and extremities. They are extremely painful. Most people have mucosal lesions in the eye, mouth, and genital areas.

TABLE 23.6 Common Viral Infections of the Skin

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Herpes Simplex Virus (HSV) Types 1 and 2		
• **Oral or genital HSV infections serotyped as either HSV-1 or HSV-2** • **Both are recurrent lifelong viral infections** • **Worsened by sunlight, trauma, menses, stress, and systemic infection** • **Contagious to those not previously infected** • **Transmitted by respiratory droplets or virus-containing fluid (e.g., saliva, cervical secretions)** • **Infection in one area readily transmitted to another site by contact**	*First episode:* • Symptoms occurring 2 days to 2 weeks after contact • Painful local reaction • Single or grouped vesicles on erythematous base • Systemic symptoms (e.g., fever, malaise) possible or no symptoms possible *Recurrent:* • Recurrence in similar spot • Characteristic grouped vesicles on erythematous base	• Symptomatic • Soothing, moist compresses. Petroleum jelly to lesions • Scarring not usual result • Antiviral agents such as acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex) • Vaccine not currently available, but is being researched, for HSV-1 or HSV-2
Herpes Zoster (Shingles)		
• **Activation of the varicella-zoster virus** • **Incidence increases with age** • **Potentially contagious to anyone who has not had varicella or who is immunosuppressed**	• Linear distribution along a dermatome of grouped vesicles and pustules on erythematous base resembling chickenpox (Fig. 23.7) • Usually unilateral on trunk, face, and lumbosacral areas • Burning, pain, and neuralgia preceding outbreak • Mild to severe pain during outbreak	*Topical:* • Wet compresses, silver sulfadiazine (Silvadene) to ruptured vesicles *Systemic:* • Antiviral agents (e.g., acyclovir, famciclovir, valacyclovir) within 72 hr to prevent postherpetic neuralgia • Analgesia. Mild sedation at bedtime • Gabapentin (Neurontin) to treat postherpetic neuralgia • Usually heals without complications, but scarring and postherpetic neuralgia possible • Vaccine (Zostavax) to prevent shingles one-time dose for adults ≥ 60 yr
Plantar Warts		
• **Caused by human papillomavirus (HPV)**	• Wart on bottom surface of foot, growing inward because of pressure of walking or standing (Fig. 23.8) • Painful when pressure applied • Interrupted skin markings • Cone shaped with black dots (thrombosed vessels) when wart removed	• Topical immunotherapy (imiquimod), cryosurgery, salicylic acid, duct tape
Verruca Vulgaris		
• **Caused by HPV** • **May disappear spontaneously in 1-2 yr** • **Mildly contagious by autoinoculation** • **Specific response dependent on body part affected** • **Prevalence greater in youth and immunosuppressed**	• Circumscribed, hypertrophic, flesh-colored papule limited to epidermis • Painful on lateral compression	• Multiple treatments, including surgery using blunt dissection with scissors or curette • Liquid nitrogen therapy • Blistering agent (cantharidin) • Keratolytic agent (salicylic acid) • CO_2 laser destruction

TABLE 23.7 Common Infestations and Insect Bites

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Bedbugs		
• **Cimicidae species** • **Feeding periodic, usually at night** • **Present in furniture, walls during day**	• Wheal surrounded by vivid flare • Firm urticaria transforming into persistent lesion • Severe pruritus • Often grouped in threes appearing on uncovered parts of body	• Lesions usually require no treatment • Severe itching may require use of antihistamines or topical corticosteroids
Bees and Wasps		
• **Hymenoptera species**	• Intense, burning, local pain • Swelling and itching • Severe hypersensitivity may lead to anaphylaxis	• Cool compresses • Local application of antipruritic lotion • Antihistamines if indicated • Usually uneventful recovery

Table Continued

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Pediculosis (Head Lice, Body Lice, Pubic Lice)		
• ***Pediculus humanus* var. capitis, *Pediculus humanus* var. corporis, *Phthirus pubis*** • **Obligate parasites that suck blood, leave excrement and eggs on skin and hair, live in seams of clothing (if body lice) and in hair as nits. Transmission of pubic lice often by sexual contact**	• Minute, red, noninflammatory • Points flush with skin. Progression to papular wheal-like lesions • Pruritus • Secondary excoriation, especially parallel linear excoriations in intrascapular region • Nits and eggs are firmly attached to hair shaft in head and body	• γ-Benzene hexachloride or pyrethrins to treat various parts of body • Spinosad (Natroba) topical suspension 0.9% to treat scalp and hair • Screen and treat close contacts (e.g., bed partners and playmates) as needed • Do not share head gear
Scabies		
• ***Sarcoptes scabiei*** • **Mite penetrates stratum corneum, deposits eggs** • **Allergic reaction to eggs, feces, mite parts** • **Transmission by direct physical contact, sometimes by shared personal items** • **Rarely seen in dark-skinned people**	• Severe itching, especially at night, usually not on face • Presence of burrows, especially in interdigital webs, flexor surface of wrists, genitalia, and anterior axillary folds • Erythematous papules (may be crusted), possible vesiculation, interdigital web crusting	• 5% permethrin topical lotion, 1 overnight application with second application 1 wk later, may yield 95% eradication • Treat all family members, treat environment with plastic covering for 5 days, launder all clothes and linen with bleach • Treat sexual partner • Antibiotics, if secondary infections present • Possible residual pruritus up to 4 wk after treatment • Recurrence possible if inadequately treated
Ticks		
• ***Borrelia burgdorferi* (spirochete transmitted by ticks in certain areas) causes Lyme disease** • **Endemic areas include Northeast, Mid-Atlantic states, parts of Midwest and West (see Chapter 64)**	• Spreading, ringlike rash 3–4 wk after bite (see Fig. 64.7) • Rash common in groin, buttocks, axillae, trunk, and upper arms and legs • Warm, itchy, or painful rash • Flu-like symptoms • Cardiac, arthritic, and neurologic manifestations possible • Unreliable laboratory test	• Oral antibiotics, such as doxycycline • IV antibiotics for arthritic, neurologic, and cardiac symptoms • Rest and healthy diet • Most patients recover

TABLE 23.8 Common Fungal Infections of the Skin and Nails

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Candidiasis		
• **Caused by *Candida albicans*** • **Also known as moniliasis** • **50% of adults symptom-free carriers** • **Appears in warm, moist areas such as groin area, oral mucosa, and submammary folds** • **Immunosuppression (e.g., from HIV infection, chemotherapy, radiation, and organ transplantation) allows yeast to become pathogenic**	*Mouth:* White, cheesy plaque, resembles milk curds *Vagina:* Vaginitis with red, edematous, painful vaginal wall, white patches. Vaginal discharge. Pruritus. Pain on urination and intercourse *Skin:* Diffuse papular erythematous rash with pinpoint satellite lesions around edges of affected area	• Azole antifungals (e.g., fluconazole, ketoconazole) or other specific medication such as vaginal suppository or oral lozenge • Sexual abstinence or use of condom • Skin hygiene to keep area clean and dry • Powder is effective on nonmucosal surfaces of skin to prevent recurrence
Tinea Corporis		
• **Various dermatophytes, commonly called *ringworm*** • Typical annular (ringlike) scaly appearance, well-defined margins • Erythematous		• Cool compresses • Topical antifungals for isolated patches. Creams or solutions of miconazole, ketoconazole, clotrimazole, butenafine
Tinea Cruris		
• **Various dermatophytes** • **Commonly called *jock itch*** • Well-defined scaly plaque in groin area • Does not affect mucous membranes		• Topical antifungal cream or solution
Tinea Pedis		
• **Various dermatophytes** • **Commonly called *athlete's foot*** • Interdigital scaling and maceration • Scaly plantar surfaces sometimes with erythema and blistering • May be pruritic and painful		• Topical antifungal cream, gel, solution, spray, or powder
Tinea Unguium (Onychomycosis)		
• **Various dermatophytes** • **Incidence increases with age**	• Only few nails on one hand may be affected. Toenails more commonly affected • Scaliness under distal nail plate • Brittle, thickened, broken, or crumbling nails with yellowish discoloration	• Oral antifungal (terbinafine [Lamisil], itraconazole [Sporanox]) • Topical antifungal cream or solution (minimal effectiveness) if unable to tolerate systemic treatment • Thinning of toenails if needed • Nail avulsion (removal) is an option

TABLE 23.9 Common Allergic Conditions of the Skin

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Allergic Contact Dermatitis		
• **Type IV delayed hypersensitivity response (see Chapter 13)** • **Absorbed agent acts as antigen** • **Sensitization occurs after one or more exposures** • **Appearance of lesions 2–7 days after contact with allergen**	• Red papules and plaques • Sharply circumscribed with occasional vesicles (see Fig. 13.10) • Usually pruritic • Area of dermatitis often takes shape of causative agent (e.g., metal allergy and bandlike dermatitis on ring finger).	• Topical or oral corticosteroids, antihistamines • Skin lubrication • Elimination of contact allergen • Avoidance of irritating affected area • Systemic corticosteroids if sensitivity severe
Atopic Dermatitis		
• **Type 1 hypersensitivity response (see Chapter 13)** • **Genetically influenced, chronic, relapsing disease** • **Exaggerated by a skin response to environmental allergens** • **Associated with allergic rhinitis and asthma**	• Multiple presentations, including acute, subacute, and chronic stages. All are pruritic • *Acute stage:* Bright erythema, oozing vesicles, with extreme pruritus (see Fig. 13.8) • *Subacute stage:* Scaly, light red to red-brown plaques • *Chronic stage:* Thickened skin with accentuation of skin markings (lichenification), possible hypopigmentation, or hyperpigmentation. Dry skin. Common in antecubital and popliteal space	• Lubrication of dry skin • Topical immunomodulators (pimecrolimus [Elidel], tacrolimus [Protopic]) • Reduction of stress reduces flares • Corticosteroids, phototherapy for severe inflammation and pruritus • Antibiotics for secondary infection as needed
Drug Reaction		
• **May be caused by any drug that acts as antigen and causes hypersensitivity reaction** • **Certain drugs (e.g., penicillin) more likely to cause reactions** • **Not all reactions are allergic, some are intolerance (e.g., gastric upset)**	• Rash of any morphology • Often red, macular and papular, semiconfluent, generalized rash with abrupt onset • Appearance as late as 14 days after cessation of drug. May be pruritic • Some reactions may be life threatening requiring immediate and intensive care	• Withdrawal of drug if possible • Antihistamines, topical or systemic corticosteroids may be necessary depending on severity of symptoms
Urticaria		
• **Usually allergic phenomenon** • **Erythema and edema in upper dermis resulting from a local increase in permeability of capillaries (usually from histamine release)**	• Spontaneously occurring, raised or irregularly shaped wheals, varying size, usually multiple • A single lesion usually resolves in 24 hr • Can occur anywhere on the body	• Removal of triggering agent, if known • Oral antihistamine therapy • Possibly systemic corticosteroids

Identifying and stopping the offending drug(s) is the most important action in caring for a patient with SJS/TEN. The most common drugs involved include sulfonamides, carbamazepine, nonsteroidal antiinflammatory drugs, lamotrigine, allopurinol, phenytoin, and phenobarbital.[8] Immunotherapy may play a role in slowing disease progression and promoting skin repair.

The patient receives supportive care, often in an intensive care unit. Interventions focus on airway management, preserving renal function, maintaining fluid and electrolyte balance, and pain control. Fluid replacement is given to maintain urine output. Proper wound care helps prevent infection and promote healing. Dressing with petrolatum gauze or other nonadhesive material provides a barrier and offers moisture to help the skin repair. Because of painful oral lesions, most patients need parenteral or enteral nutrition to meet nutrition and caloric demands. Apply eyedrops, lubricating ointment, and antibiotic drops to those with conjunctivitis.

Benign Skin Problems

Although the list of benign skin problems is extensive, some of the most commonly seen and distressing ones include acne vulgaris (Fig. 23.10-anchor>), psoriasis, and seborrheic keratoses. Benign problems are outlined in Table 23.10-anchor>.

Psoriasis is a chronic autoimmune disease. It is fairly common, affecting about 7.5 million Americans.[9] Men and women develop psoriasis at equal rates. The rate is highest in whites (3.6%).[10] It usually develops in those 15 to 35 years old. One third of people with psoriasis have at least one relative with the disease. It is associated with metabolic syndrome, heart disease, and type 2 diabetes. Up to 40% of people with psoriasis also have psoriatic arthritis. Psoriatic arthritis is discussed in Chapter 64.

The diagnosis of plaque psoriasis, the most common form, is based on the skin's appearance (Fig. 23.11-anchor>). Lesions are distinct and appear as red, scaling papules that merge to form plaques. The affected area is normally rounded, with adherent silver scales that bleed easily when removed. Plaques are common on the knees, elbows, scalp, hands, feet, and lower back.[9] They are often pruritic and may be painful. Clinical presentation varies. While most have mild disease, some have psoriasis on much of their skin surface.

Treatment is tailored to meet a person's needs. This varies depending on the location of lesions, severity, patient preferences, and comorbidities. Goals range from improved quality of life to complete disease resolution. Psoriasis for most is more emotionally than physically disabling. It erodes the self-image. The person may be self-conscious and withdraws from social contacts.[8] Quality of life can diminish as people avoid activities. Depression is common.

Drug Alert

Isotretinoin (Accutane)

- Used to treat acne (Table 23.10)
- Can cause serious damage to fetus

- Contraindicated in women who are pregnant or want to become pregnant
- Cannot donate blood during treatment and for 1 month after treatment ends
- May cause depression and suicidal ideation

Interprofessional Care: Skin Problems

Diagnostic Studies

A careful history is of prime importance in diagnosing skin problems. The HCP must be skilled at detecting any evidence that could lead to the cause of many different skin problems. After a careful history and physical examination, inspect individual lesions. The history, physical examination, and diagnostic test results guide therapy.

Interprofessional Therapy

Many different treatment methods are used in dermatology. Advances in this field have brought relief to many previously chronic, untreatable conditions. Many of the specific therapeutic treatments require specialized equipment. They are usually used by a dermatologist or specially trained nurse.

Phototherapy

Ultraviolet light (UVL) therapy is a part of treating many skin problems, including psoriasis, cutaneous T-cell lymphoma, atopic dermatitis, vitiligo, and pruritus. Light sources available include broadband UVB, narrowband UVB, and long-wave UV (UVA1). One form of phototherapy combines the use of the photosensitizing drug methoxsalen with UVA light (PUVA). With PUVA, patients receive methoxsalen and then are exposed to UVA.

Treatments are generally given 2 to 3 times a week. Side effects include nausea, itching, and erythema. Taking methoxsalen with food and milk may reduce nausea. Caution patients about the hazards of

using methoxsalen and concurrent exposure to UV rays from sunlight or artificial UVL during therapy. Because of the risk for cataracts, patients receiving PUVA need to wear prescription goggles that block 100% of UVL. Teach patients to wear the eyewear for 24 hours after taking the medication when outdoors or near a bright window because UVA penetrates glass. Perform frequent skin assessments on all patients receiving phototherapy. The immunosuppressive effects of PUVA increase the risk for SCC, BCC, and melanoma.

Photodynamic therapy is a special type of phototherapy used to treat actinic keratosis and some skin cancers. This therapy uses a photosensitizing agent in a different way than other phototherapy treatments. The patient receives the photosensitizing agent IV or topically, depending on the area treated. Time is allowed for the drug to be absorbed by the target cells. Light is then applied to the area, causing the drug to react with oxygen. This starts a reaction that kills the cells.[11]

Check Your Practice

You are working in a dermatology clinic preparing a 64-yr-old woman for phototherapy to treat multiple actinic keratoses on her nose and both cheeks. She says the first lesion appeared a few years ago. She then started to worry about all the time she spent in her garden without sunscreen. She thought the lesions were just "age spots" and was unconcerned until a few started to grow and periodically bleed.

- What teaching will you do to get her ready for the procedure and to take care of herself after the procedure?

Radiation Therapy

The use of radiation therapy to treat BCC and SCC varies. The best candidates are those with lesions in challenging locations, such as the ear, nose, scalp, neck, and shin; those who may have trouble with

wound healing; or those with medical comorbidities who cannot undergo surgery.[12] Use is limited in those with melanoma to palliative pain control or treating brain metastases.

TABLE 23.10 Common Benign Conditions of the Skin

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
Acne Vulgaris		
• **Inflammatory disorder of sebaceous glands** • **More common in teenagers** • **May begin and persist into adulthood** • **Flare can occur with use of corticosteroids and androgen-dominant birth control pills and before menses.**	• Noninflammatory lesions, including open comedones (blackheads) and closed comedones (whiteheads) • Inflammatory lesions, including papules and pustules • Most common on face, neck, and upper back (Fig. 23.10)	*Topical:* • Mechanical removal of multiple lesions with comedo extractor • Topical benzoyl peroxide, retinoids, or antimicrobials (clindamycin, erythromycin) *Systemic:* • Systemic antibiotics • Use of isotretinoin (Accutane) for severe nodulocystic acne may provide lasting remission. Pregnancy tests, monitor liver function, cholesterol, triglycerides, and for depression • Aim of treatment to suppress new lesions and minimize scarring • Spontaneous remission possible • Often improvement with exposure to sun
Acrochordons (Skin Tags)		
• **Common after midlife** • **Appearance on neck, axillae, and upper trunk secondary to mechanical friction or redundant skin (associated with obesity)**	• Small, skin-colored, soft, pedunculated papules • May become irritated	• No treatment medically necessary • Surgical removal when needed. Usually just snipping without anesthesia
Lentigo		
• **Increased number of normal melanocytes in basal layer of epidermis from sun exposure and aging** • **Also called "liver spots" or "age spots"**	• Hyperpigmented, brown to black macule or patch (flat lesion) on sun-exposed areas	• Evaluate carefully for progression • Treatment only for cosmetic purposes: liquid nitrogen, laser resurfacing • May recur • Biopsy when suspicious of melanoma
Lipoma		
• **Benign tumor of adipose tissue, often encapsulated** • **Most common in 40- to 60-yr-old age group**	• Rubbery, compressible, round mass of adipose tissue • Single or multiple • Variable in size, may be extremely large • Most common on trunk, back of neck, and forearms	• Usually no treatment • Biopsy to distinguish from liposarcoma • Excision usual treatment (when indicated)
Nevi (Moles)		
• **Grouping of normal cells derived from melanocyte-like precursor cells**	• Hyperpigmented areas that vary in form and color • Flat, slightly elevated, verrucoid, polypoid, dome-shaped, sessile, or papillomatous • Preservation of normal skin markings • Hair growth possible	• No treatment necessary except for cosmetic reasons • Skin biopsy for suspicious nevi
Psoriasis		
• **Autoimmune chronic dermatitis that involves extremely rapid turnover of epidermal cells** • **Family predisposition** • **Usually develops before age 40**	• Sharply demarcated silvery scaling plaques on reddish skin often on the scalp, elbows, knees, palms, soles, and fingernails (Fig. 23.11) • Itching, burning, pain • Localized or general, intermittent or continuous • Symptoms vary in intensity from mild to severe	• Goal to reduce inflammation and suppress rapid turnover of epidermal cells. No cure, but control is possible *Topical treatments:* • Corticosteroids, tazarotene, calcipotriene, anthralin, calcineurin inhibitors (tacrolimus) • Intralesional injection of corticosteroids for chronic plaques *Systemic treatments:* • Natural or artificial UVB. PUVA (UVA with topical or systemic photosensitizer [psoralen]) • Traditional and oral therapies: antimetabolite (methotrexate), retinoid (acitretin), apremilast (Otezla), immunosuppressant (cyclosporine) • Biologic therapies: adalimumab (Humira), etanercept (Enbrel), infliximab (Remicade), ustekinumab (Stelara), brodalumab (Siliq), certolizumab pegol (Cimzia), secukinumab (Cosentyx), golimumab (Simponi), guselkumab (Tremfya), ixekizumab (Taltz) for moderate to severe plaque disease
Seborrheic Keratoses		

Etiology and Pathophysiology	Clinical Manifestations	Treatment and Prognosis
• **Benign, familial, exact etiology unknown** • **Usually occur after age 40, increase in number with age**	• Irregularly round or oval, often verrucous papules or plaques • Well-defined shape, appearance of being stuck on • Increase in pigmentation with time • Usually multiple, may be itchy	• Removal by curettage or cryosurgery for cosmetic reasons or to eliminate source of irritation • Biopsy if unable to distinguish from melanoma

Radiation therapy requires multiple visits to a radiology

department. It can produce permanent hair loss *(alopecia)* of the irradiated areas. Other adverse effects, depending on anatomic location and dose of radiation delivered, include telangiectasia, atrophy, hyperpigmentation, depigmentation, ulceration, hearing loss, ocular damage, atrophy, and mucositis. Careful shielding is necessary to prevent ocular lens damage if the irradiated area is around the eyes. See Chapter 15 for more on radiation therapy.

Total-body skin irradiation is one treatment for cutaneous T-cell lymphoma. Treatment follows a lengthy course and causes premature aging of the skin. Patients have varying degrees of permanent alopecia and radiation dermatitis with a transient loss of sweat gland function.

Laser Technology

Laser treatment is expanding rapidly as an efficient surgical tool for many types of skin problems (Table 23.11-anchor>). Depending on the type of laser and the wavelength, lasers serve a wide variety of functions. Lasers can make measurable, repeatable, consistent zones of tissue damage. They can cut, coagulate, and vaporize tissue to some degree. Laser light does not accumulate in body cells and cannot cause cumulative cellular changes or damage. With less damage to surrounding tissue, there is a decreased risk for scarring.

The surgical use of laser energy requires a focusing device to produce a small, high-density spot of energy. Several types of lasers are available. The CO_2 laser, the most common, has many applications as a vaporizing and cutting tool for most tissues. The argon laser emits light that is primarily absorbed by hemoglobin. It helps in the treatment of vascular and other pigmented lesions. Other, less common lasers include copper and gold vapors and neodymium:yttrium-aluminum-garnet (Nd:YAG). Those who work with laser equipment must be familiar with facility policies and procedures on laser safety.

Drug Therapy

Antibiotics

Several topical and systemic antibiotics are used to treat skin problems. Sometimes they are used concurrently. Many common systemic antibiotics are not used topically because of the danger of allergic contact dermatitis. Common OTC topical antibiotics include bacitracin-neomycin-polymyxin (Neosporin), bacitracin, and polymyxin B. Some HCPs do not recommend Neosporin because of the risk for allergic contact dermatitis. Prescription topical antibiotics include (1) mupirocin (for superficial *Staphylococcus* infections such as impetigo), (2) gentamicin (used for *Staphylococcus* and many gram-negative organisms), and (3) erythromycin (used for gram-positive cocci [staphylococci and streptococci] and gram-negative cocci and bacilli). Metronidazole is a common therapy for rosacea. Topical erythromycin and clindamycin are options for acne vulgaris.

- Resurfacing of skin
- Rosacea
- Skin lesions
- Tattoo removal
- Vascular lesions
- Warts

- Wrinkles

Systemic infections require systemic antibiotics. They have a role in treating acne vulgaris and bacterial infections, such as erysipelas, cellulitis, abscesses, and certain wound infections. Frequently used oral drugs include penicillin, erythromycin, doxycycline, clindamycin, and linezolid. Vancomycin is the drug of choice for severe infections.[13] Give patients drug-specific instructions on the proper technique of taking or applying antibiotics.

Corticosteroids

Corticosteroids are effective in treating a wide variety of skin problems. They can be used topically, intralesionally, or systemically. Topical corticosteroids have local antiinflammatory and antipruritic effects. Since corticosteroids may alter the manifestations, try to diagnose a skin problem before applying a corticosteroid preparation.

The potency of a preparation depends on the concentration of active drug. With prolonged use, high-potency corticosteroids can cause adrenal suppression, especially if a large surface area is covered and occlusive dressings are used. Other side effects include skin atrophy from impaired cell mitosis, capillary fragility, rosacea eruptions, severe exacerbations of acne vulgaris, and bruising. In general, atrophy does not occur until a corticosteroid has been in use for 2 to 3 weeks. If drug use is stopped at the first sign of atrophy, recovery usually occurs in several weeks. Rebound dermatitis can occur when therapy is stopped. Tapering the use of high-potency topical corticosteroids when improvement is noted reduces the risk.

Low-potency corticosteroids such as hydrocortisone act more slowly. However, they can be used for a longer time without producing serious side effects. Low-potency corticosteroids are safe to use on the face and areas where skin may touch or rub together, such as the axillae and groin.

The most potent delivery system for a topical corticosteroid is an ointment form. Apply creams and ointments in thin layers and slowly massage into the site 1 to 3 times a day.

Intralesional corticosteroids are injected directly into or just beneath the lesion. This method provides a reservoir of medication with an effect lasting several weeks to months. Intralesional injection is common in the treatment of psoriasis, alopecia areata (patchy hair loss), cystic acne, hypertrophic scars, and keloids. Triamcinolone acetonide (Kenalog) is the most common drug used for intralesional injection.

Systemic corticosteroids can have remarkable results in the treatment of skin conditions. However, they often have undesirable systemic effects (see Chapter 49). Corticosteroids are helpful in short-term therapy for acute conditions such as contact dermatitis caused by poison ivy. Long-term therapy is reserved for those with severe disease such as bullous (blistering) disorders.

Antihistamines

Oral antihistamines are helpful in treating urticaria, angioedema, and pruritus that can occur in problems such as atopic dermatitis, allergic dermatitis, and other allergic cutaneous reactions. Several antihistamines may be tried before getting an acceptable effect. Antihistamines with sedative effects, such as hydroxyzine and diphenhydramine, may be better for pruritic conditions because the tranquilizing and sedative effects offer symptomatic relief. Warn the patient about sedative effects, a problem when driving or using heavy machinery. Antihistamines, such as loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec), bind to peripheral histamine receptors, giving antihistamine action without sedation. They are not effective for controlling pruritus. Use any antihistamines with caution in older adults because of their long half-life and anticholinergic effects.

Topical Fluorouracil

Fluorouracil is a topical cytotoxic agent with selective toxicity for sun-damaged cells. It is used to treat precancerous lesions (especially AK) and some skin cancers. Patient adherence is a consideration in the use of fluorouracil. The medication produces erythema, burning, and

pruritus within 3 to 5 days. Painful, eroded areas over the damaged skin occur within 1 to 3 weeks, depending on skin thickness at the site. Reduce redness and pruritus by applying a low-potency topical corticosteroid 20 minutes after. There are 5 strengths (0.5%, 1%, 2%, 4%, and 5%). Treatment must continue with applications 1 or 2 times a day for 2 to 4 weeks. Healing may take up to 4 weeks after the medication is stopped.[8]

Adherence to therapy depends on your teaching. Tell the patient that they will look worse before they look better. Teach about the effect of the medication. Because fluorouracil is a photosensitizing drug, tell the patient to avoid sunlight during treatment. After treatment, skin should be smooth and free of AK. AK may recur in treated areas, and multiple courses of therapy may be necessary over the years for those with severely sun-damaged skin.

Immunomodulators

Topical immunomodulators, such as pimecrolimus (Elidel) and tacrolimus (Protopic), are used to treat atopic dermatitis, psoriasis, and rosacea.[14] They work by suppressing an overreactive immune system. The side effects are minimal and may include a transient burning or feeling of heat at the application site. Use may increase the risk for skin cancer and precancerous lesions.

The topical immunomodulator imiquimod (Aldara) is used to treat external genital warts, AK, and superficial BCC. It stimulates the production of α-interferon and other cytokines to enhance cell-mediated immunity. It boosts the immune response only where applied and is safe for transplant patients. Most patients using this cream experience skin reactions, including redness, swelling, blistering, peeling, itching, and burning. Dosing varies depending on the type of lesion treated and the strength of medication prescribed.[8]

Diagnostic and Surgical Therapy

Skin Scraping

Scraping with a scalpel blade can yield a sample of surface cells (stratum corneum) for microscopic inspection and diagnosis. The most common tests of skin scrapings are mineral oil examination for scabies and 10% to 20% potassium hydroxide (KOH) for fungus.

Electrodessication and Electrocoagulation

Electrical energy can be converted to heat with the tip of an electrode. The heat burns and destroys tissue. The major uses of these therapies are coagulation of bleeding vessels to obtain hemostasis and destruction of small *telangiectasias* (dilation of groups of superficial capillaries and venules). *Electrodessication* usually involves more superficial destruction. It uses a monopolar electrode. *Electrocoagulation* uses a bipolar electrode. It has a deeper effect, with better hemostasis, but an increased chance of scarring. While minor electrosurgery on patients with a pacemaker poses minimal risk, the electrical energy can affect both pacemakers and internal defibrillators.

Curettage

Curettage is the removal and scooping away of tissue using an instrument called a *curette.* A curette looks like a small spoon with very sharp edges. Although a curette is not usually strong enough to cut normal skin, it can remove many types of small, soft skin tumors and superficial lesions, such as warts, AK, seborrheic keratosis, and small BCCs and SCCs. The area to be curetted is anesthetized before the procedure. The HCP removes the lesion and then cauterizes the skin. The removed tissue is usually sent for biopsy. A dressing may be applied, and you will need to teach the patient wound care. A small scar and hypopigmentation can result.

Punch Biopsy

Punch biopsy is a common procedure used to obtain a tissue sample for histologic study or to remove small lesions (Fig. 23.12-anchor>). The procedure is simple. The HCP marks the biopsy area and then

anesthetizes it so that the anesthetic will not obscure the landmarks. The HCP rotates the punch into the skin and removes a small cylinder of skin. Hemostasis is achieved with pressure or absorbable gelatin (Gelfoam) packing. Sites of 4 mm or larger are usually closed with sutures. Punch biopsies are not done below the knee if other sites are available. Circulatory changes can make evaluating the tissue sample more difficult.

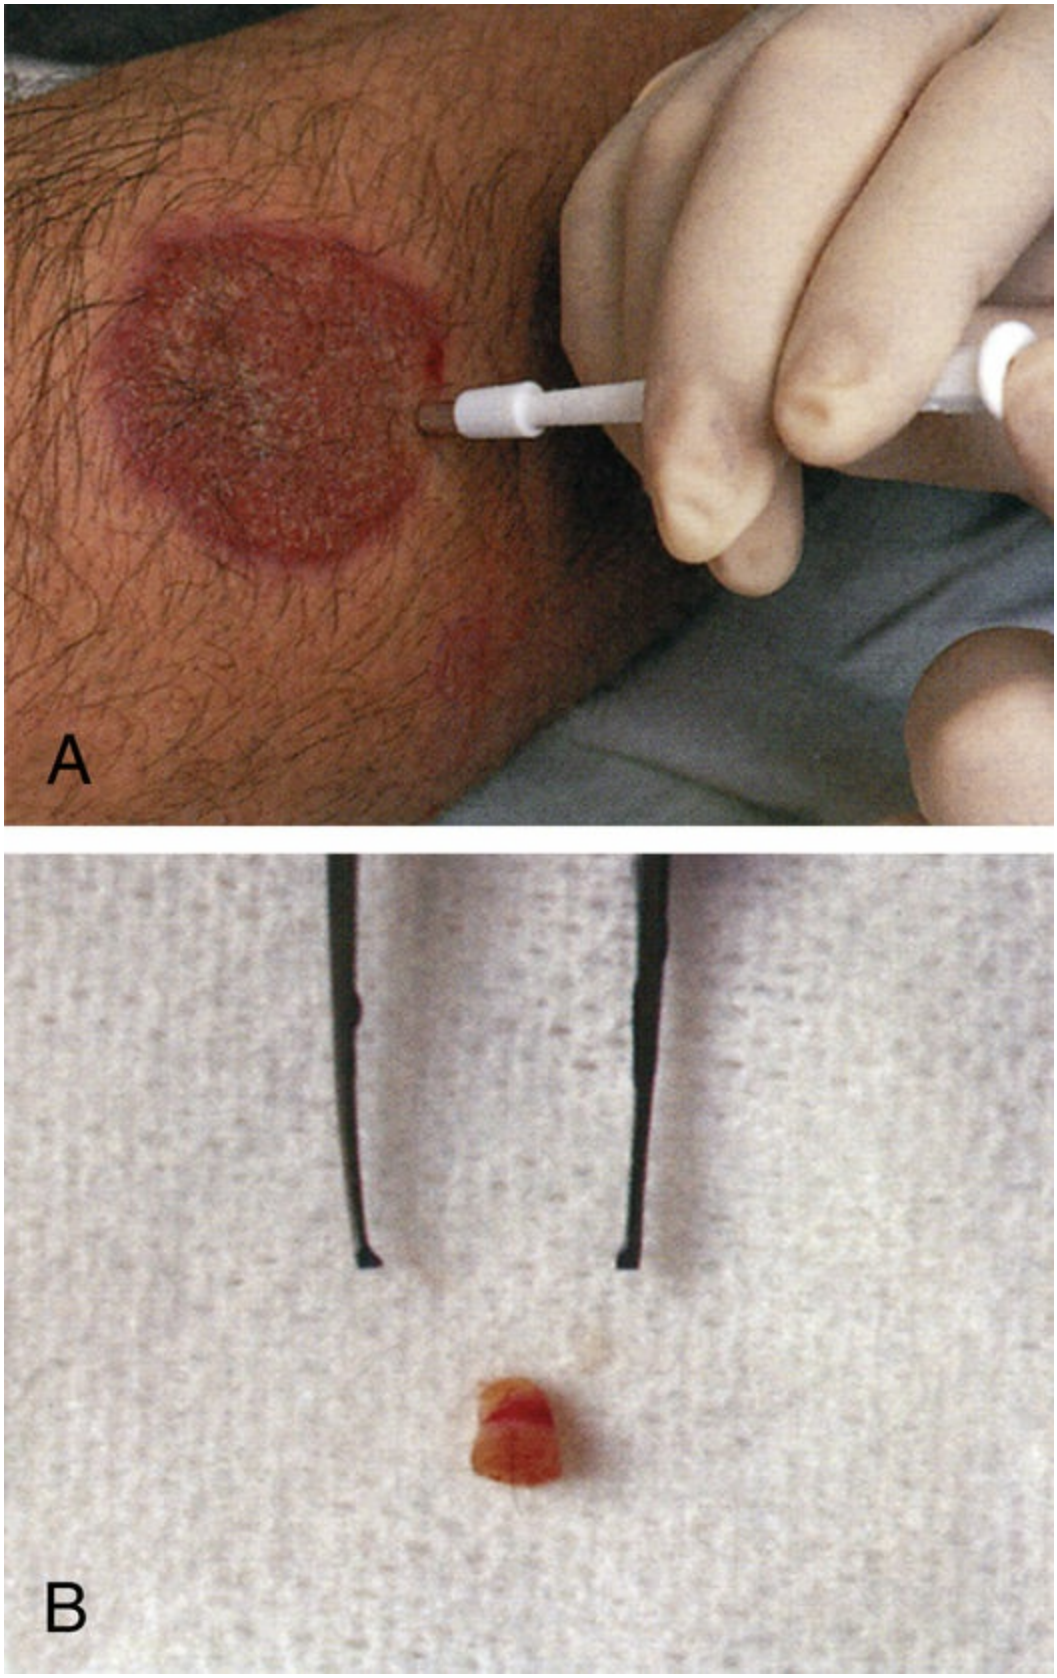

FIG. 23.12 Punch biopsy. **A,** Removal of skin for diagnostic purposes.

B, Specimen obtained.
From Graham-Brown R, Bourke J, Cunliffe T: *Dermatology: Fundamentals of practice,* Edinburgh, 2008, Mosby.

Cryosurgery

Cryosurgery is the use of subfreezing temperatures to destroy epidermal lesions. Cryosurgery is used to treat common and genital warts, cutaneous tags, thin seborrheic keratoses, lentigines, AK, BCC, and SCC. Topical liquid nitrogen is the agent most commonly used for cryosurgery.[12] Damage occurs in treated tissue because of intracellular ice formation. It causes the cell to rupture during thaw, leading to cell death and necrosis. The degree of damage depends on the rate of cooling and the minimum temperature achieved.

Liquid nitrogen is applied topically (directly onto the lesion) with a direct spray or contact probe. Tell patients that they will feel a painful, stinging cold sensation. The lesion first becomes swollen and red, and it may blister. A scab forms and falls off in 1 to 3 weeks. The skin lesion sloughs along with the scab. Growth of new skin follows.

The size of an affected area may limit the use of cryotherapy. Other disadvantages include the potential for harming adjacent healthy tissue and the low temperature of liquid nitrogen destroying melanocytes, leaving an area of hypopigmentation resembling a scar.

Excision

Excision is an option if the lesion involves the dermis. Complete closure of the excised area usually results in a good cosmetic result.

A specific type of excision is *Mohs surgery,* which is the microscopically controlled removal of a skin cancer. In this procedure, the HCP removes tissue sections in thin horizontal layers. All the specimen's margins are examined to see if any cancer cells remain (Fig. 23.13-anchor>). Any residual tumor not removed by the first surgical excision is removed in serial excisions performed the same day. Benefits of Mohs surgery are that it preserves normal tissue, produces the smallest possible wound, and can completely remove the cancer. Although it can be a lengthy procedure, it is done in an

outpatient setting using local anesthesia.

Nursing Management: Skin Problems

Ambulatory Care

Skin problems are not usually a primary reason for hospitalization. Nevertheless, many hospitalized patients have skin problems that need nursing intervention and patient education. Nursing interventions for skin conditions fall into broad categories. They apply to many problems in both inpatient and outpatient settings. A nursing care plan for the patient with chronic skin lesions (eNursing Care Plan 23.1) is available on the website for this chapter.

In your general teaching with the patient, stress the duration of the treatment and the need to follow package directions. Skin problems may be slow to resolve. Tell the patient to follow package directions when using OTC drugs. If the package insert says its use should not exceed 7 days, patients should heed this warning. Teach the patient to stop self-care and seek the help of an HCP if any systemic signs of inflammation or extensions of the skin problem (e.g., an increasing number of lesions, increased erythema, increased swelling) develop.

Wet Compresses

For superficial skin problems that involve inflammation, itching, and infection, wet compresses are commonly used. They are appropriate for damaged, oozing skin. Wet compresses are a good way to remove crusts and scabs that are adhering to the wound surface. They provide comfort and treatment of conditions such as poison ivy, insect bites, and skin infections.

It is important to understand how to do a wet compress correctly. Unless there is a concern about water quality, tap water at room temperature is the best choice. If drinkable water is not available, use filtered, bottled, or sterile water. Depending on the problem, additives may be used. Common solutions include (1) saline, (2) Burow's

solution (Domeboro powder [aluminum acetate; calcium acetate]), (3) acetic acid (vinegar), and (4) silver nitrate.[8] The temperature of the fluid should be tepid. However, when an antiinflammatory effect is desired, the fluid should be cool.

The material you select for the compress should be 4 to 8 layers thick and slightly larger than the area that you are treating. Use gauze or any clean material (e.g., thin cotton sheeting, thermal underwear, tube socks). Ingenuity is sometimes needed when covering odd-shaped body parts. Do not use gauze sponges with fillers (abdominal pads). They will retain too much solution, and fibers can be left in the wound if the skin is open. Place the prescribed compress material into fresh solution and squeeze out excess fluid. Your goal is a wet compress—not damp but not dripping.

Wet compresses are applied continuously or intermittently. When used continuously, remove the compress and replace with a new one as needed. Do not add solution to a compress. This can change the fluid's concentration and damage the skin. They can be placed intermittently, for 10 to 30 minutes, several times a day. Careful monitoring of the skin is important. If the skin appears *macerated* (softens and turns white), stop the compresses for 2 to 3 days. Change and wash daily any material used repeatedly throughout the day. Protect the patient from discomfort and chilling. A water-resistant pad will help protect the mattress, linens, and furniture.

Baths

Baths are an appropriate intervention when large areas of the body need treatment. Baths may be relaxing and will help decrease itching. Agents such as colloidal oatmeal (Aveeno) and sodium bicarbonate can be added directly to bath water. Fill the tub with tepid water to cover the affected areas. Depending on the severity of the problem and the patient's discomfort, have the patient soak for 15 to 20 minutes 3 or 4 times a day. Stress to the patient not to rub the skin dry with a towel but gently pat to prevent increased irritation and inflammation. Avoid adding oils as their use increases the risk for falls. To sustain the hydrating effect, apply cream, ointment emollients

(moisturizers), or other prescribed topical agents after the bath. This helps seal the moisture in the hydrated cells and increases the absorption of any topical agents.

Hygienic Practices

The patient's skin type, lifestyle, culture, age, and gender influence hygienic practices. The normal acidity of the skin and perspiration protect against bacterial overgrowth. Most soaps are alkaline and neutralize the skin surface, leading to a loss of protection. Using mild, moisturizing soaps and lipid-free cleansers and avoiding hot water and vigorous scrubbing can noticeably decrease local skin irritation and inflammation. Skin piercings in which jewelry has been inserted can be cared for with antibacterial soaps that do not contain sulfites.

In general, skin and hair must be washed often enough to remove excess oil and excretions and to prevent odor. Older persons should avoid harsh soaps and shampoos and frequent bathing because of the dryness of their skin and scalp. Using moisturizers right after a bath or shower (while the skin is still damp) seals in the moisture.

Topical Medications

Topical medications are commonly used to treat skin problems. The effectiveness of topical therapy depends on which base the medication is prepared in. Table 23.12-anchor> summarizes the common agents used as bases for topical preparations and their therapeutic considerations. The base selected depends on the properties needed.

Creams are very versatile and most commonly prescribed. Ointments are more lubricating than creams and offer enhanced potency of the active ingredient. They may be too occlusive for conditions with lots of exudate or in body creases. Gels work well on the scalp, where other compounds may mat the hair, and for acute exudative conditions such as poison ivy. Lotions are also fine for the scalp but may cause stinging and drying when used in skinfolds. Pastes are good for protecting the skin but are messy. A limited number of foams are available.

TABLE 23.12 Drug TherapyCommon Bases for Topical Medications

Agent	Therapeutic Considerations
Cream	Emulsions of oil and water. Most common base for topical medications. Lubrication and protection
Gel	Nongreasy combination of propylene glycol and water. May contain alcohol
Lotion	Emulsions of water, alcohol, and/or oil. Cooling and drying. Some leave residual powder film after evaporation of water. Useful in subacute pruritic eruptions
Ointment	Oil with differing amounts of water added in suspension. Lubrication and prevention of dehydration. Petrolatum most common
Paste	Mixture of powder and ointment, used when drying effect necessary because moisture is absorbed
Powder	Promotion of dryness. Lubricates skinfold areas to prevent irritation. Base for antifungal preparations. Protect patient from inhaling

Apply topical medications as directed. Proper administration will yield best results and avoid waste. Some are very costly. As a rule, apply topical medication in a thin film to clean skin and spread evenly in a downward motion in the direction of hair growth. Thick creams will spread easier if the skin is still damp. If you are using a secondary dressing, you can apply the medication directly onto a dressing. Teach the patient and caregiver proper dosing, application technique, expected results, and common reactions.

Occlusion with a plastic wrap is an effective way to increase the absorption of topical corticosteroids or simple emollients. The plastic wrap traps perspiration against the outer layer of the epidermis. Applying preparations to moist skin increases absorption 10-fold. Use tape or stretch wraps to keep the plastic wrap in place. For conditions on the feet or lower legs, the patient can wear socks over the plastic wrap. Wraps applied multiple times daily are kept in place for 2 to 8 hours. Some patients choose to use the occlusion technique at bedtime. Occlusion is not appropriate in areas prone to infection, such as skin creases.

Control of Pruritus

Many conditions cause *pruritus* (itching). This includes dry skin, almost any physical or chemical stimulus to the skin (such as drugs or insects), and any scaling skin disorder. The itch sensation is carried by the same nonmyelinated nerve fibers as pain and temperature. The patient will have pain rather than an itch if the epidermis is damaged or absent. It is important to figure out if itching preceded a skin lesion. Itching can lead to scratching that results in an excoriated and inflamed lesion.

Certain circumstances make itching worse. Teach the patient ways to help break the itch/scratch cycle. A cool environment may cause vasoconstriction and decrease itching. Hydration, wet compresses, and moisturizers (including antipruritic lotions) are normally helpful. Apply wet compresses for 30 to 60 minutes, pat the skin dry, and apply a lubricant or medication. Topical and injectable corticosteroids are sometimes used. Topically applied menthol, camphor, or phenol numb itch receptors. Systemic antihistamines may give relief. The main side effect of most antihistamines is sedation. This may be desirable because pruritus is often worse at night and can interfere with sleep. Adequate rest increases the patient's ability to tolerate itching, thereby decreasing skin damage from the resultant scratching. Have the patient avoid anything that causes vasodilation, such as heat or rubbing. Dry skin lowers the itch threshold and increases the itch sensation.

Lichenification is a thickening of epidermis with exaggerated markings resembling a washboard. It is caused by chronic scratching or rubbing of the skin. Lichenification is often associated with atopic dermatoses and other pruritic conditions. Although any area of the body may be affected, the hands, forearms, shins, and nape of the neck are common sites. Scratching may become a habit. Persistent scratching can cause excoriations. Treating the cause of the itching is the key to preventing lichenification.

Prevention of Spread

Although most skin problems are not contagious, infection control

precautions indicate wearing gloves when working with any open wounds or lesions with drainage. Not all infected drainage is purulent. Careful hand washing and properly disposing of soiled dressings are the best means of preventing the spread of infections or infestations. The most common contagious lesions include impetigo, streptococcal infections, staphylococcal infections (e.g., methicillin-resistant *S. aureus* [MRSA]), fungal infections, primary chancre, scabies, and pediculosis.

Prevention of Secondary Infections

Open skin lesions are susceptible to invasion by other viral, bacterial, or fungal organisms. Meticulous hygiene, hand washing, and dressing changes are important to minimize the potential for secondary infections. Warn the patient about scratching lesions, which can cause excoriations and create a portal of entry for pathogens. Trim the patient's nails short to minimize trauma from scratching.

Specific Skin Care

You are often in a position to teach patients skin care after simple surgical procedures, such as skin biopsy, excision, and cryosurgery. In general, your teaching should include dressing changes, use of topical antibiotics, and the signs and symptoms of infection. After a skin procedure, cleanse any oozing wound with a saline solution twice daily or as ordered by the HCP. Potable (safe, drinking water) is a safe alternative in some situations. Apply antibiotic or plain petrolatum ointment with a secondary dressing that is both absorbent and nonadherent.

Wounds that are kept moist and covered heal more rapidly and with less scarring. The initial crust that forms should be left undisturbed as a protective coating for the damaged skin beneath it. Healing crusts that have been moisturized and protected will separate naturally from healed epidermis.

A sutured wound may be covered with a variety of dressings. Sutures are generally removed in 4 to 14 days, depending on the placement site. Sometimes alternating sutures are removed after the

third day. Incision lines may need daily cleansing, usually with plain water. If necessary, a topical antibiotic is applied and the wound either is covered with a dry dressing or left open to air. The patient may have some swelling and discomfort in the first 24 hours. Intermittent application of cold (ice packs) over the surgical dressing may reduce edema. Mild analgesics, such as acetaminophen, should control discomfort. Teach the patient how to distinguish normal inflammation from an infection. A slight red border during the first few days after a procedure is normal. Signs and symptoms of infection include redness that persists longer than a week or extends beyond a 1-cm border, a fever above 101° F, increased pain, pronounced swelling, and purulent drainage. If these occur, they should be reported to the HCP at once.

Nursing Management

Skin Conditions

- Assess patient's skin for acute and chronic skin problems.
- Assess patient's risk factors for skin problems.
- Document skin condition and risk factor assessment and develop a plan of care.
- Determine whether patient is taking drugs that increase photosensitivity.
- Teach about risks associated with sun exposure and methods for decreasing exposure to the sun.
- Administer prescribed therapies such as dressings and oral or topical medications.
- Teach about therapies used for skin disorders, including dressings, baths, and oral or topical medications used on an outpatient basis.
- Evaluate treatment for effectiveness and any adverse effects.

Psychologic Effects of Chronic Skin Problems

Emotional stress can occur for those who suffer from chronic skin problems, such as psoriasis, atopic dermatitis, or acne. The sequelae of chronic skin problems could result in social and employment problems with subsequent financial implications, a poor self-image, problems with sexuality, and increasing and progressive frustration. The usual lack of systemic illness coupled with the visibility of the skin lesions often presents a real problem to the patient.

Help the patient follow the prescribed regimen. Allow the patient to verbalize the "Why me?" question, even though there is no ready answer. Refer the patient to dermatology support groups. Many are listed on the American Academy of Dermatology website (*www.aad.org*). These groups are extremely helpful with patient support and education.

The location of lesions and scars is the determining factor with respect to their cosmetic implications. Facial scars are the most damaging psychologically because they are so visible. Creative use of cosmetics can do much to mask lesions and scarring. Consider individual sensitivity to product ingredients when selecting cosmetics. Oil-free, hypoallergenic cosmetics are available and may be beneficial for the allergic patient. Rehabilitative cosmetics are available to help camouflage and deemphasize such lesions as *vitiligo* (loss of pigmentation), *melasma* (tan to brown patches on the face), or healed postoperative wound sites. These commercially available products are opaque, smudge resistant, and water resistant.

Cosmetic Procedures

A vast array of cosmetic procedures is available, including chemical peels, toxin injections, fillers, laser surgery, breast enlargement and reduction (see Chapter 51), face-lift, eyelid-lift, and liposuction. Common cosmetic topical procedures are outlined in Table 23.13-anchor>. Other types of cosmetic procedures include the injection of botulinum toxin (Botox), deoxycholic acid (Kybella), calcium hydroxylapatite (Radiesse), collagen (Zyplast), and hyaluronic acid

fillers (e.g., Restylane, Perlane, Juvéderm).[15] Transitory side effects may occur, such as mild redness, pain, swelling, and bruising. Uncommon side effects from cosmetic procedures include allergic reaction, infection, grayish skin discoloration, or lumps at the injection sites. Tell the patient that the procedure will need repeating at prescribed intervals to maintain the desired appearance.

The reasons for undergoing these procedures are as varied as the techniques. The most common reason that people incur the discomfort and financial expense (most are not covered by health insurance) of a cosmetic procedure is to improve their body image. If they feel better about themselves after having cosmetic procedures, they often act more confident and self-assured. Often social position and economic considerations are part of the decision. Increased longevity is providing a larger population to whom cosmetic procedures are appealing.

Regardless of the patient's reasons for seeking a cosmetic procedure, maintain a supportive, nonjudgmental attitude. If the patient wishes to change or enhance a body feature perceived as unattractive and has realistic expectations about the outcome, you should support this decision.

Elective Surgery

Laser Surgery

Laser surgery is used to treat congenital and acquired vascular lesions (cherry angiomas, spider leg veins, hemangiomas, port wine stains, and tattoo removal) and for skin resurfacing and hair removal. Lasers can reduce scarring and fine wrinkles around the lips or eyes and remove facial lesions (Table 23.11). Swelling, redness, and bruising are common after treatment. The treated areas usually are kept moist with ointment or occlusive dressings for the first few days. The patient must protect treated skin from the sun.

TABLE 23.13 Common Cosmetic Topical Procedures

Tretinoin (Retin-A, Renova)	Chemical Peels (e.g., Beta-Hydroxy Acid, Jessner's Peel, TCA)	Microdermabrasion	α-Hydroxy Acids (e.g., Glycolic Acid, Lactic Acid)
Indications			
Improves appearance of photodamaged skin, especially fine wrinkling. Reduces actinic keratoses	Improves appearance of photodamaged skin, acne scarring, actinic and seborrheic keratoses	Smoothes appearance of photodamaged and wrinkled skin, acne scarring	Smoothes appearance of photodamaged and wrinkled skin, acne scarring
Description			
Initially applied every 2–3 days. Treatment stopped if severe inflammation occurs. Maximum response in 8–12 mo	Solution applied in varying amounts to the skin, causing a controlled burn with a loss of melanin	Epidermis and top dermal layer removed by applying aluminum oxide or baking soda crystals. Re-epithelialization of abraded surface then occurs	Low concentrations (<10%) in many skin care products consumers can apply to the skin. Higher concentrations (50%–70%) applied only by an HCP
Side Effects			
Erythema, swelling, flaking, pigmentation changes. Teratogenic. Increases phototoxicity if taking other photosensitive drugs	Moderate swelling and crusting for 1 wk. Redness for 6–8 wk. Pink tone possible for several mo. Photosensitivity	Light pink tone that resolves within 24 hr. Photosensitivity	Photosensitivity, slight irritation at lower concentrations, severe redness, oozing, and flaking skin possible with higher concentrations
Patient Teaching			
Apply at night since preparation is inactivated by light. Apply emollients, use sunscreen, use sun avoidance measures, avoid using abrasive or drying facial cleansers for severe sensitivity (e.g., excess irritation)	Use sunscreen. Avoid sun for 6 mo to prevent hyperpigmentation	Generous application of emollients and sunscreen	Use sunscreen and sun avoidance measures

FIG. 23.14 Face-lift. **A,** Preoperative. **B,** Postoperative.
From Cuzalina A, Copty TV, Khan H: *Current therapy in oral and maxillofacial surgery,* St Louis, 2012, Elsevier.

Face-Lift

A face-lift *(rhytidectomy)* is the lifting and repositioning of the lower two thirds of the face and neck to improve appearance (Fig. 23.14-anchor>). Indications for this procedure include:

- Redundant soft tissue or scarring resulting from disease (e.g., acne scarring)
- Asymmetric redundancy of soft tissues (e.g., facial palsy)
- Redundant soft tissue resulting from trauma
- Preauricular lesions
- Redundant soft tissues resulting from *solar elastosis* (sagging of the skin from sun damage), changes in body weight, and the effects of gravity
- Restoration of body image

The surgical approach and lines of incisions vary according to the desired correction and the position of the hairline. Eyelid-lifts *(blepharoplasty)* can remove redundant tissue and possibly improve the field of vision. Preventing hematoma formation is the most important postoperative consideration. Ice packs are usually applied for the first 24 to 48 hours to reduce swelling and decrease the possibility of hematoma formation. Usually the pain is minimal. Antibiotics are used at the HCP's discretion. Complications can occur if the person smokes or is involved in vigorous exercise.

Liposuction

Liposuction is a technique for removing subcutaneous fat to improve facial and body contours. Although not a substitute for diet and exercise, it can be successful in removing areas of fat from almost any body area that is resistant to other techniques.

Liposuction is relatively free of complications. Possible contraindications include the use of anticoagulants, uncontrolled hypertension, diabetes, and poor cardiovascular status. Those under

40 years of age with good skin elasticity are the best candidates. However, patients over 40 can be treated successfully.

The procedure is usually done on an outpatient basis under local anesthesia. One or more sessions may be needed, depending on the size of the area. The HCP inserts a blunt-tipped cannula through a small incision and pushes into the fat to break it loose from the fibrous stroma. Multiple repeated thrusts disrupt the fat and create tunnels. The loosened fat is removed with a powerful suction. Afterward, firm pressure is applied to the wounds until drainage stops.[16] It may take several months for the results to be evident.

Nursing Management: Cosmetic Surgery

Many cosmetic surgical procedures are done in well-equipped day-surgery units or in dermatologist or plastic surgeon in-office surgery suites.

Preoperative Management

A major consideration before surgery relates to informed consent and realistic expectations of what cosmetic surgery can accomplish. Although the HCP should provide this information, reinforce it and answer questions and concerns. For instance, a face-lift has little or no effect on deep wrinkling of the forehead and temples, deep nasolabial grooves, or vertical lip wrinkles. Before-and-after treatment photographs of similar cases are often useful in helping the patient to set realistic expectations.

Your teaching plan should include the timeframe for healing. Explain the oozing, crusting stage of an abrasive procedure so the patient can plan time off from work if necessary. Since wound healing may not be complete for 1 year, the patient should not expect complete results at once. The final result is affected by the patient's age, general state of health, and skin type and the extent (severity) of

the condition being treated. Efforts should be made to correct or control any existing health problem before the procedure.

Postoperative Management

Most cosmetic procedures are not extremely painful. Usually, mild analgesics are enough to keep the patient comfortable. Although infection is not a common problem after cosmetic surgery, assess the sites for signs of infection. Teach the patient signs and symptoms of infection. Stress that it is important to report them at once so that treatment can be started.

If the surgery involved a change in the skin's circulation, as in a face-lift, carefully monitor for adequate circulation. Warm, pink skin that blanches on pressure shows that adequate circulation is present in the surgical area. Supportive, compressive dressings and ice packs may be necessary early in the postoperative period.

Skin Grafts

Uses

Skin grafts may be necessary to protect underlying structures or to reconstruct areas for cosmetic or functional purposes. They may be used to facilitate rapid closure and minimize complications. Ideally, wounds heal by primary intention. However, large wounds, surgically created wounds, trauma, and chronic wounds can result in extensive tissue destruction, making healing by primary intention impossible. In these cases, skin grafting may be necessary to close the defect. Improved surgical techniques make it possible to graft skin, bone, cartilage, fat, fascia, muscles, and nerves. For cosmetically pleasing results, the color, thickness, texture, and hair-growing nature of skin used for grafting should match the recipient site. See Chapter 24 for a discussion of skin grafting for patients with burn injuries.

Types

The two types of traditional skin grafts are free grafts and skin flaps. Free grafts are classified according to how they supply blood to the grafted skin. One method is to transfer the graft (epidermis and part or all the dermis) to the recipient site from the donor site. The *autograft* (from the patient's own body) or *isograft* (from an identical twin) revascularizes and becomes fixed to the new site. The other method of free skin grafting is by *reconstructive microsurgery.* With the use of an operating microscope, the HCP establishes circulation immediately in the graft by connecting blood vessels in the skin flap to vessels in the recipient site.

Skin flaps involve moving a section of skin and subcutaneous tissue from one part of the body to another without terminating the vascular attachment *(pedicle).* Skin flaps are used to cover wounds with a poor vascular bed, provide padding when needed, and cover wounds over cartilage and bone. The patient may need intermediate flap placement if the recipient site is far removed from the donor site. For instance, a skin flap from the thigh to the head would require an intermediate graft. The flap is advanced to the recipient site when circulation is well established at the intermediate site. The patient's needs and the type of defect determine the type of flap and the route of transfer.

Soft tissue expansion is a technique for providing skin (1) for resurfacing of a defect, such as a burn scar; (2) for removal of a disfiguring mark (e.g., a tattoo); or (3) as a preliminary step in breast reconstruction. A subcutaneous tissue expander of a proper size and shape is placed under the skin, usually as an outpatient procedure. Weekly expansion with saline solution can be done in a health care setting or by the patient at home. This expansion procedure is repeated until the skin reaches the size needed for the repair. This may take from several weeks to 3 to 4 months. Once enough skin is available, the old incision is opened, the expander is removed, and the soft tissue is ready to be used as an advancement flap. The tissue expander next to a defect has the primary tissue characteristics, such as color and texture.

Engineered skin substitutes (e.g., Apligraf, Dermagraft, Integra) are gaining popularity. There are several available, each with its own

indications and benefits. Some are two-layered membranes with both dermal and epidermal components. Others are only one layer. The skin is engineered from neonatal foreskins and cadavers. Skin substitutes do not contain structures such as blood vessels, hair follicles, sweat glands, or cells such as melanocytes, Langerhans cells, macrophages, and lymphocytes.[17] Engineered skin grafts have an extended shelf life. Some are cryopreserved, others shipped overnight as they are needed. Advantages include ready availability, the avoidance of a donor site, application in outpatient settings, minimal scarring, and less pain.

Case Study

Melanoma and Dysplastic Nevi

© Dimedrol68/iStock/Think stock.

Patient Profile

G.L. is a 48-yr-old white, fair-skinned man who is a long-distance truck driver. In his leisure time, he enjoys swimming. He comes to the clinic because of a changing lesion on his left arm.

Subjective Data

- History of a basal cell cancer (BCC) on his left ear in the last 4 years

- Father treated for metastatic melanoma in the last 2 years
- First noted the lesion 1 month ago when it started changing size
- Anxious that removing the lesion will require extensive, disfiguring surgery

Objective Data
Physical Examination

- Has a 4-mm lesion, deep brown, scalloped with vaguely defined borders
- 5 dysplastic nevi found on back

Diagnostic Studies

- Excisional biopsy confirmed superficial spreading melanoma.
- Sentinel node biopsy results were negative.
- Diagnostic tests indicate melanoma stage I.

Discussion Questions

1. What risk factors for melanoma does he have?
2. What are the usual clinical manifestations associated with melanoma?
3. What is the prognosis for a patient with this stage of melanoma?
4. What treatment options are available for him?
5. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
6. ***Patient-Centered Care:*** How would you help G.L. deal with his anxiety over the treatment outcomes?
7. ***Priority Decision:*** What is the priority of care for G.L.?
8. ***Safety:*** What would you include in his patient teaching plan to address future sun exposure?

9. ***Evidence-Based Practice:*** G.L. wants to know whether regularly applying sunscreen will reduce his risk for developing a second melanoma. How would you reply?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge To Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which safe sun practices would the nurse include in the teaching plan for a patient who has photosensitivity *(select all that apply)*?
   a. Wear protective clothing.
   b. Apply sunscreen liberally and often.
   c. Emphasize the short-term use of a tanning booth.
   d. Avoid exposure to the sun, especially during midday.
   e. Wear any sunscreen as long as it is bought at a drugstore.
2. When teaching a patient with melanoma about this disorder, the nurse recognizes that the patient's prognosis is *most* dependent on
   a. the thickness of the lesion.
   b. the degree of asymmetry in the lesion.
   c. the amount of ulceration in the lesion.
   d. how much the lesion has spread superficially.
3. The nurse determines that a patient with which disorder is *most* at risk for spreading the disease?

a. Tinea pedis

b. Impetigo on the face

c. Candidiasis of the nails

d. Psoriasis on the palms and soles

4. A mother and her two children have been diagnosed with pediculosis corporis at a health care center. An appropriate measure to treat this condition is

a. applying pyrethrins to the body.

b. topical application of griseofulvin.

c. moist compresses applied frequently.

d. administration of systemic antibiotics.

5. A common site for the lesions associated with atopic dermatitis is the

a. buttocks.

b. temporal area.

c. antecubital space.

d. plantar surface of the feet.

6. During the assessment of a patient, you note an area of red, sharply defined plaques covered with silvery scales that are mildly itchy on the patient's knees and elbows. You would describe this finding as

a. lentigo.

b. psoriasis.

c. actinic keratosis.

d. seborrheic keratosis.

7. In teaching a patient who is using topical corticosteroids to treat acute dermatitis, the nurse should tell the patient that

(select all that apply)

a. the cream form is the most efficient system of delivery.

b. short-term use of topical corticosteroids usually does not cause systemic side effects.

c. use a glove to apply small amounts of creams or ointments to prevent further infection.

d. abruptly stopping the use of topical corticosteroids may cause the dermatitis to reappear.

e. systemic side effects from topical corticosteroids are likely if the patient is malnourished.

8. Important patient teaching after a chemical peel includes

a. avoidance of sun exposure.

b. application of firm bandages.

c. limitation of vigorous exercise.

d. use of moist heat to relieve discomfort.

1. a, b, d, 2. a, 3. b, 4. a, 5. c, 6. b, 7. b, d, 8. a.

Burns

Cecilia Bidigare

LEARNING OUTCOMES

1. Relate the causes of burns to the prevention strategies for burn injuries.
2. Distinguish between partial-thickness and full-thickness burns.
3. Apply tools used to determine the severity of burns.
4. Compare the pathophysiology, clinical manifestations, complications, and interprofessional care throughout the 3 burn phases.
5. Compare the fluid and electrolyte shifts during the emergent and acute burn phases.
6. Outline the nutritional needs of the burn patient throughout the 3 burn phases.
7. Compare the various burn wound care techniques and surgical options for partial-thickness and full-thickness burn wounds.
8. Prioritize nursing interventions in the management of the burn patient's physiologic and psychosocial needs.
9. Examine the various physiologic and psychosocial aspects of burn rehabilitation.
10. Develop a plan of care to prepare the burn patient and caregiver for discharge.

Conceptual Focus

Coping
Fluids and Electrolytes
Infection
Nutrition
Pain
Perfusion

Tissue Integrity

The focus of this chapter is the care of patients who have a burn injury. A **burn** is an injury to the skin or other tissues of the body caused by heat, chemicals, electric current, or radiation. The resulting effects on tissue integrity are influenced by the temperature and type of burning agent, duration of contact, and type of tissue that is injured. The location of the injury, associated injuries, and age and general health of the patient influence the seriousness of the injury.

The patient with a burn injury may have a multitude of problems. There may be difficulty maintaining an airway and adequate circulation, affecting perfusion. Fluid and electrolyte imbalances are common. We must give attention to preventing malnutrition and infection. The patient often has fear, anger, guilt, and depression. The patient may have body image concerns, especially with facial and hand burns; anxiety about future therapy and surgery; and frustrations with ongoing pain.

An estimated 486,000 Americans seek medical care each year for burns.[1] Around 40,000 people are hospitalized, 60% receiving care in specialized burn centers. About 3275 Americans die annually as a direct result of their injuries. The highest fatality rates occur in children ages 4 years and younger and adults over age 65. Worldwide, over 11 million people need medical attention annually for burn injuries and about 180,000 die.[2] Although burn incidence in the United States has decreased over the past 20 years, international burn injuries still occur too often, mainly to those living in low- and middle-income counties. Most burn accidents are preventable. The focus of burn prevention has shifted from blaming victims to educating people in vulnerable communities to identify hazards and provide first aid.

Coordinated national prevention programs in higher income countries have focused on child-resistant lighters, tap water anti-scald devices, stricter building codes, having smoke detectors, and fire and burn safety education curriculums for schools.[3] As a nurse, you can advocate for and teach about burn risk-reduction strategies in the home and at work (Tables 24.1 and 24.2).

TABLE 24.1 Common Sources of Burn Injury

Home Hazards

Bathroom and Kitchen

- Hot water heaters set at 120°F (60°C) or higher
- Microwaved food
- Steam, hot grease or liquids from cooking

General Household

- Carelessness with cigarettes, matches, candles
- Heat lamps
- Fireplaces (e.g., gas, wood)
- Flammables (e.g., starter fluid, gasoline, kerosene)
- Frayed or defective wiring
- Multiple extension cords per outlet
- Open space heaters
- Outdoor grills (e.g., propane, charcoal)
- Radiators (e.g., home, automobile)

Occupational Hazards

- Cement
- Chemicals
- Combustible fuels
- Electricity from power lines
- Fertilizers, pesticides
- Hot metals

- Sparks from live electric sources
- Steam pipes
- Tar

TABLE 24.2 Promoting Population HealthStrategies to Reduce Burn Injury

Chemical

- Store chemicals safely in approved containers and label clearly.
- Ensure safety of workers handling chemicals (education, protective eyewear, gloves, masks, clothing).

Electrical

- Avoid or repair frayed wiring.
- Avoid outdoor activities during electrical (i.e., lightning) storms.
- Ensure electrical power source is shut off before beginning repairs.
- Wear protective eyewear and gloves when making electrical repairs.

Flame or Contact

- Never smoke in bed.
- Use "child-resistant" lighters.
- Hold regular home fire exit drills.
- Never leave hot oil unattended while cooking.
- Never use gasoline or other flammable liquids to start a fire.
- Never leave candles unattended or near open windows or

curtains.
- Consider a flame-retardant smoking apron for older or “at-risk” people.
- Exercise caution when microwaving food and beverages as they can get very hot.

Inhalation

- Install smoke and carbon monoxide detectors and change batteries annually (if appropriate).

Scald

- Use “anti-scald” devices with showerhead or faucet fixtures.
- Lower hot water temperature to the “lowest point” or 120°F (49°C).
- After running bath water, check temperature with back of hand or bath thermometer.
- Supervise bathing with small children, older adults, or anyone with impaired physical movement, physical sensation, or judgment.

Types of Burn Injury

Thermal Burns

Thermal burns, caused by flame, flash, scald, or contact with hot objects, are the most common type of burn injury (Fig. 24.1). The severity of the injury depends on the temperature of the burning agent and duration of contact time. Scald injuries often occur in bathrooms and kitchens. Flash, flame, or contact burns can occur while cooking, smoking, or burning leaves in the backyard.

Chemical Burns

Chemical burns are the result of contact with acids, alkalis, and organic compounds. In addition to skin damage, eyes can be injured if splashed. Acids are found in the home and at work. They include hydrochloric, oxalic, and hydrofluoric acid. Alkali burns can be more difficult to manage than acid burns since alkalis adhere to tissue, causing protein hydrolysis and melting. Alkalis are found in cement, oven and drain cleaners, and heavy industrial cleansers.[4] Organic compounds, including phenols (chemical disinfectants) and petroleum products (creosote and gasoline), produce contact burns and systemic toxicity.

Smoke and Inhalation Injury

Smoke and inhalation injuries from breathing noxious chemicals or hot air can damage the respiratory tract. Three types of smoke and inhalation injuries can occur: upper airway injury, lower airway injury, and metabolic asphyxiation. Smoke inhalation injuries are a major predictor of mortality in burn patients. Rapid initial and ongoing assessment is critical. Airway compromise and pulmonary edema can quickly develop within hours of injury.[5]

FIG. 24.1 Types of burn injury. **A,** Superficial, partial-thickness scald

burn to thigh. **B,** Deep, partial-thickness flame burn to hand. **C,** Full-thickness flame burn to posterior chest and arm.
Courtesy Judy Knighton, Toronto, Canada.

Metabolic Asphyxiation

Most deaths at a fire scene are the result of inhaling certain smoke elements, primarily carbon monoxide (CO) or hydrogen cyanide. Oxygen delivery to or consumption by tissues is impaired, resulting in hypoxia. Death may occur if **carboxyhemoglobin** (i.e., hemoglobin combined with CO) blood levels are greater than 20%. CO and hydrogen cyanide poisoning may occur in the absence of burn injury to the skin.

Upper Airway Injury

Upper airway injury results from an inhalation injury to the mouth, oropharynx, and/or larynx. The injury may be caused by thermal burns or the inhalation of hot air, steam, or smoke. Mucosal burns of the oropharynx and larynx are manifested by redness, blistering, and edema (Table 24.3). The swelling can be massive and the onset rapid. Burns to the neck and chest may make breathing more difficult because of the burn eschar, which becomes tight and constricting. Edema from facial and neck burns can be lethal, as can internal pressure from edema narrowing the airway. Obstruction can occur quickly, presenting a true airway emergency.

Lower Airway Injury

An inhalation injury to the trachea, bronchioles, and alveoli is usually caused by breathing in toxic chemicals or smoke. Tissue damage is related to the duration of exposure to toxic fumes or smoke. Manifestations of lower airway lung injury are outlined in Table 24.3. Carefully assess the patient for facial burns, singed nasal hair, hoarseness, painful swallowing, darkened oral and nasal membranes, carbonaceous sputum, history of being burned in an enclosed space, and clothing burns around the neck and chest. Pulmonary edema may

not appear until 12 to 48 hours after the burn. Then it may manifest as acute respiratory distress syndrome (ARDS) (see Chapter 67).

Electrical Burns

Electrical burns result from intense heat generated from an electric current. Direct damage to nerves and vessels, causing tissue anoxia and death, can occur. The severity of an electrical injury depends on the amount of voltage, tissue resistance, current pathways, surface area in contact with the current, and length of time that the current flow was sustained (Fig. 24.2). Tissue densities offer various amounts of resistance to electric current. For example, fat and bone offer the most resistance. Nerves and blood vessels offer the least resistance. Current that passes through vital organs (e.g., brain, heart, kidneys) produces more life-threatening sequelae than that which passes through other tissues. In addition, electric sparks may ignite the patient's clothing, causing a flash injury.

TABLE 24.3 Manifestations of Burn-Related Lung Injury

Upper Airway

- Blisters, edema
- Copious secretions
- Difficulty swallowing
- Hoarseness
- Stridor
- Substernal and intercostal retractions
- Total airway obstruction

Lower Airway

- High degree of suspicion if patient was trapped in a fire in an enclosed space or clothing caught fire
- Altered mental status
- Carbonaceous sputum
- Dyspnea
- Facial burns or singed nasal or facial hair
- Hoarseness
- Wheezing

As with inhalation injury, perform a rapid assessment of the patient with an electrical injury. Transfer to a burn center is indicated. The severity of an electrical injury can be hard to determine since most of the damage is below the skin.

Determining the electric current contact points and history of the injury may help reveal the likely path of the current and potential areas of injury. Contact with electric current can cause muscle contractions strong enough to fracture the long bones and vertebrae. Another reason to suspect long bone or spinal fractures is a fall resulting from the electrical injury. For this reason, consider cervical spine injury for all patients with electrical burns. Continue cervical spine immobilization during transport and diagnostic testing until injury is ruled out.

Electrical injury puts the patient at risk for dysrhythmias or cardiac arrest, severe metabolic acidosis, and myoglobinuria.[6] The electric shock can cause immediate heart standstill or ventricular fibrillation. Delayed dysrhythmias or arrest can occur without warning during the first 24 hours after injury. Whenever massive muscle and blood vessel damage occurs, myoglobin from injured muscle and hemoglobin from damaged red blood cells (RBCs) are released into the circulation. The myoglobin travels to the kidneys and can block the renal tubules. This can result in acute tubular necrosis (ATN) and acute kidney injury (see Chapter 46).

FIG. 24.2 Electrical injury produces heat coagulation of blood supply

and contact area as electric current passes through the skin. **A,** Back and buttock *(arrows)*. **B,** Leg *(arrow)*.

Cold Thermal Injury

Cold thermal injury, or frostbite, is discussed in Chapter 68.

Classification of Burn Injury

The treatment of burns is related to the severity of the injury.[7] Severity is determined by (1) depth of burn, (2) extent of burn calculated in percent of total body surface area (TBSA), (3) location of burn, and (4) age of the patient, preburn medical history, and circumstances or complicating factors. The American Burn Association (ABA) uses referral criteria to determine which burn injuries should be treated in burn centers (Table 24.4).[8] Patients with minor burn injuries can be managed in community hospitals.

TABLE 24.4 Burn Center Referral Criteria

Burn injuries that should be referred to a burn center include the following:

1. Partial thickness burns greater than 10% total body surface area (TBSA)
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints
3. Third-degree burns in any age-group
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
8. Any patient with burns and concomitant trauma (e.g., fractures)

in which the burn injury poses the greatest risk for morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit. Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols

9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will need special social, emotional, or rehabilitative intervention

Source: American Burn Association: Guidelines for the operation of burn centers. Retrieved from *http://ameriburn.org/wp-content/uploads/2017/05/burncenterreferralcriteria.pdf*.

Depth of Burn

Burn injury involves the destruction of the integumentary system. Table 24.5 compares the various burn classifications according to the depth of the burn injury. One system defines an injury by degrees as first, second, third, or fourth degree. The ABA recommends a more precise definition and classifies burns according to depth of skin destruction: **partial-thickness burns** and **full-thickness burns** (Fig. 24.3). If significant damage occurs to the dermis (i.e., a full-thickness burn), not enough skin cells remain to regenerate new skin. A permanent, alternative source of skin must be found.

Extent of Burn

Two common tools for determining the TBSA affected or the extent of a burn wound are the *Lund-Browder chart* (Fig. 24.4, *A*) and the *Rule of Nines* (Fig. 24.4, *B*). First-degree burns, equivalent to a sunburn, are not included when calculating TBSA. The Lund-Browder chart is considered more accurate because it considers the patient's age in

proportion to relative body-area size. The Rule of Nines is often used for initial assessment of a burn patient because it is easy to remember. For irregular- or odd-shaped burns, the patient's hand (including the fingers) is 1% TBSA. Other tools include the *Sage Burn Diagram,* a free, Web-based tool for estimating TBSA burned (*www.sagediagram.com*). There are mobile applications (e.g., 3D Burn Report, Mersey Burns) that can estimate the percent of burn and fluid resuscitation needs.[9]

Location of Burn

The location of the burn injury influences the severity. Burns to the face and neck and circumferential burns to the chest or back may interfere with breathing because of obstruction from edema or leathery, devitalized burn tissue *(eschar).* These burns may indicate possible smoke or inhalation injury.

Burns to the hands, feet, joints, and eyes are of concern because they make self-care difficult and may jeopardize future function. Burns to the hands and feet are challenging to manage because of superficial vascular and nerve supply systems that must be protected while the burn wounds are healing.

Burns of the ears and nose are at risk for infection as the skin is very thin and the underlying cartilage may be exposed. Burns to the buttocks or perineum are at high risk for infection from urine or feces contamination. Circumferential burns to the extremities can cause circulation problems distal to the burn, with possible nerve damage to the affected extremity. Patients may develop compartment syndrome (see Chapter 62) from deep damage to muscles.

TABLE 24.5 Classification of Burn Injury Depth

Classification	Appearance	Possible Cause	Structures Involved
Partial-Thickness Skin Destruction			
Superficial (first-degree) burn	Erythema, blanching on pressure, pain and mild swelling, no vesicles or blisters (although after 24 hr skin may blister and peel)	Quick heat flash Superficial sunburn	Superficial epidermal damage with hyperemia. Tactile and pain sensation intact
Deep (second-degree) burn	Fluid-filled vesicles that are red, shiny, wet (if vesicles have ruptured). Severe pain caused by nerve injury. Mild to moderate edema	Chemicals Contact burns Electric current Flame Flash Scald Tar, cement	Epidermis and dermis involved to varying depths. Skin elements, from which epithelial regeneration occurs, remain viable
Full-Thickness Skin Destruction			
Third- and fourth-degree burns	Dry, waxy white, leathery, or hard skin. Visible thrombosed vessels. Insensitivity to pain because of nerve destruction. Possible involvement of muscles, tendons, and bones	Chemical Electric current Flame Scald Tar, cement	All skin elements and local nerve endings destroyed. Coagulation necrosis present. Surgical intervention required for healing

Patient Risk Factors

Any patient with preexisting heart, lung, or kidney disease has a poorer prognosis for recovery because of the increased demands placed on the body by a burn injury. The patient with diabetes or peripheral vascular disease is at high risk for delayed healing, especially with foot and leg burns.[10] General physical weakness from any chronic disease, including alcohol or drug use and malnutrition, makes it challenging for the patient to fully recover from a burn injury. The burn patient who has fractures, head injuries, or other trauma has a more difficult recovery.

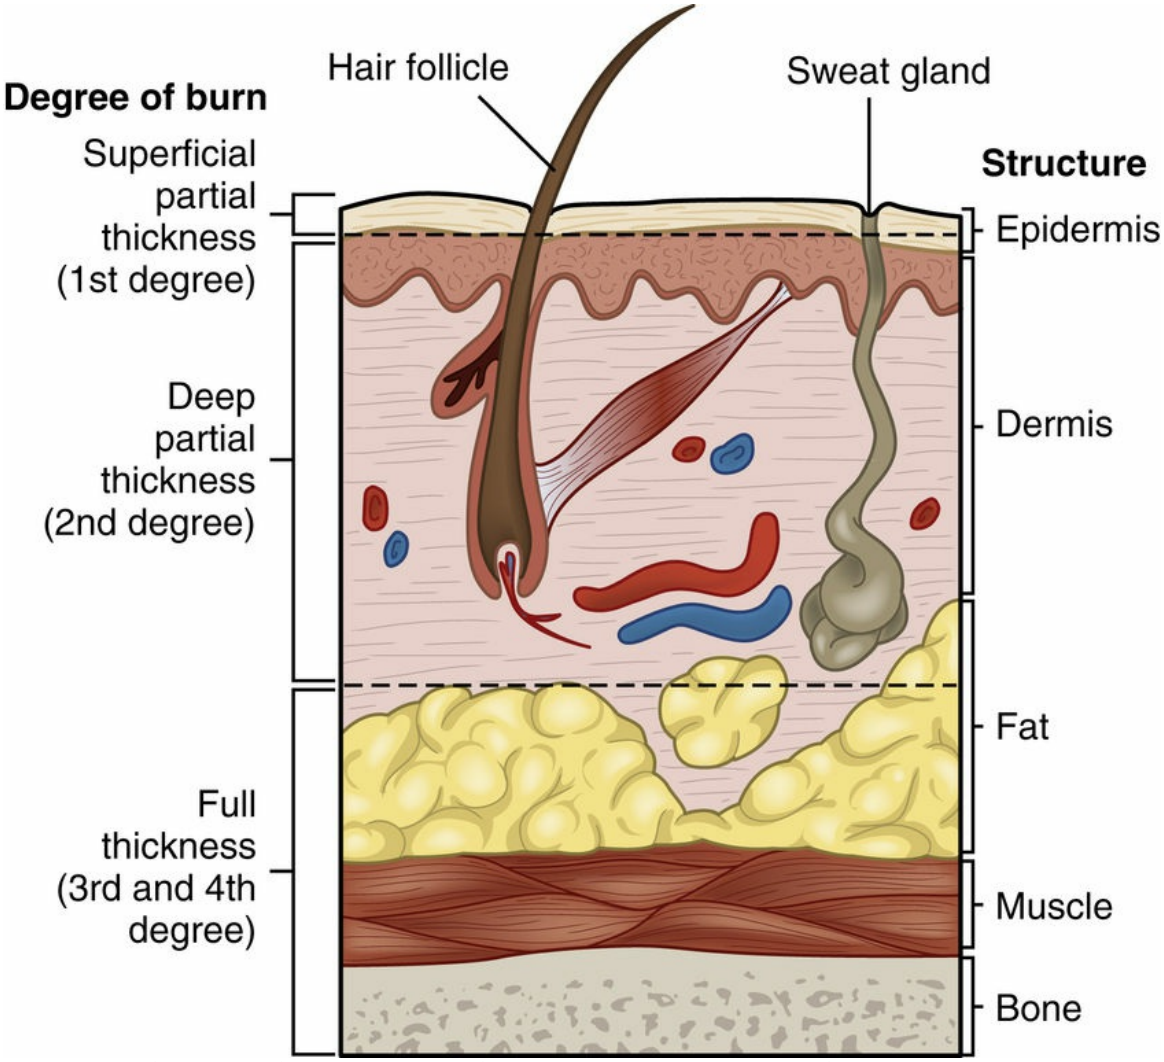

FIG. 24.3 Cross section of skin showing the depth of burn and structures involved.

Prehospital and Emergency Care

At the scene of the injury, priority is given to removing the person from the source of the burn and stopping the burning process. Rescuers must protect themselves from being injured. In the case of electrical and chemical injuries, initial care involves removing the patient from contact with the electrical or chemical source.

Small thermal burns (10% or less of TBSA) should be covered with a clean, cool, tap water–dampened towel for the patient's comfort and protection until medical care is available. Cooling of the injured area

(if small) within 1 minute helps minimize the depth of the injury. If the burn is large (greater than 10% TBSA) or an electrical or inhalation burn is suspected, and the patient is unresponsive, first focus your attention on CAB:

- *Circulation:* Check for presence of pulses and elevate the burned limb(s) above the heart to decrease pain and swelling.
- *Airway:* Check for patency, soot around nares and on the tongue, singed nasal hair, darkened oral or nasal membranes.
- *Breathing:* Check for adequacy of ventilation.

If the patient is responsive, your priorities would follow the order of the ABCs: airway, breathing, and circulation.

To prevent hypothermia, cool large burns for no more than 10 minutes. Do not immerse the burned body part in cool water because it may cause extensive heat loss. Never cover a burn with ice, since this can cause hypothermia and vasoconstriction of blood vessels, thus further reducing blood flow to the injury. Gently remove as much burned clothing as possible to prevent further tissue damage. Leave adherent clothing in place until the patient is transferred to a hospital. Wrap the patient in a dry, clean sheet or blanket to prevent further contamination of the wound and provide warmth.

Chemical burns are best treated by quickly removing any chemical particles or powder from the skin. Remove all clothing containing the chemical because the burning process continues while the chemical is in contact with the skin. Flush the affected area with copious amounts of water to irrigate the skin from 20 minutes to 2 hours after exposure. Tap water is acceptable for flushing eyes exposed to chemicals. Tissue destruction may continue for up to 72 hours after contact with some chemicals.

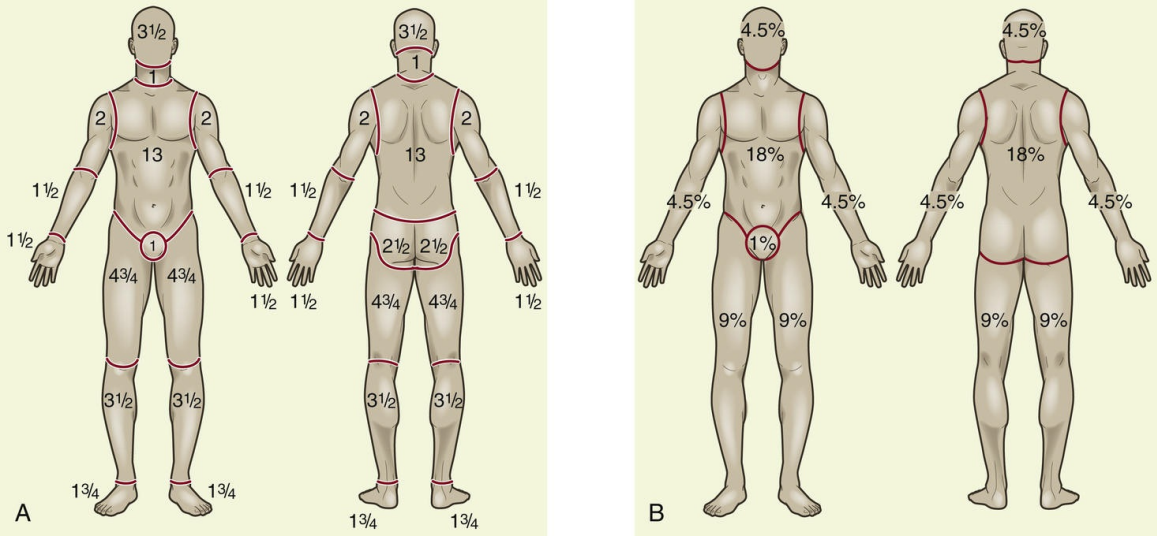

FIG. 24.4 **A,** Lund-Browder chart. By convention, areas of partial-thickness injury are colored in *blue* and areas of full-thickness injury in *red.* Superficial partial-thickness burns are not calculated. **B,** Rule of Nines chart.

Watch patients with inhalation injuries closely for signs of respiratory distress. These patients need to be treated quickly and efficiently if they are to survive. If CO poisoning is suspected, treat the patient with 100% humidified O_2. Patients who have both burns and an inhalation injury must be transferred to the nearest burn center.

Always remember that the burn patient may have sustained other injuries that could take priority over the burn itself. Persons involved in the prehospital phase of burn care must fully share the circumstances of the injury to emergency department (ED) staff. This is especially important if the patient was trapped in a closed space, exposed to hazardous chemicals or electricity, or had a possible traumatic injury (e.g., fall).

Prehospital and emergency care are outlined in tables that describe thermal burns (Table 24.6), inhalation injury (Table 24.7), electrical burns (Table 24.8), and chemical burns (Table 24.9).

Phases of Burn Management

Burn management can be organized chronologically into 3 phases: emergent (resuscitative), acute (wound healing), and rehabilitative

(restorative). Overlap in care does exist. For example, the emergent phase begins at the time of the burn injury, and care often begins prehospital or in the ED. Wound care is the primary focus of the acute phase, but wound care takes place in both the emergent and rehabilitation phases. Planning for rehabilitation begins on the day of the burn injury or admission to the burn center. Formal rehabilitation begins as soon as functional assessments can be done.

Emergent Phase

The *emergent (resuscitative) phase* is the time needed to resolve the immediate, life-threatening problems resulting from the burn injury. This phase usually lasts up to 72 hours from the time the burn occurred. The main concerns are the onset of hypovolemic shock and edema formation. The emergent phase ends when fluid mobilization and diuresis begin.

Pathophysiology

Fluid and Electrolyte Shifts

The greatest initial threat to a patient with a major burn is hypovolemic shock (Fig. 24.5). It is caused by a massive shift of fluids out of the blood vessels because of increased capillary permeability and can begin as early as 20 minutes after the burn. As the capillary walls become more permeable, water, sodium, and plasma proteins (especially albumin) move into the interstitial spaces and other surrounding tissue. The colloidal osmotic pressure decreases with progressive loss of protein from the vascular space. This results in more fluid shifting out of the vascular space into the interstitial spaces (Fig. 24.6).

TABLE 24.6 Emergency ManagementBurns

Etiology	Assessment Findings	Interventions
• **Flash flame** • **Hot liquids or solids** • **Hot surface** • **Open flame** • **Steam** • **Ultraviolet rays**	**Partial-Thickness (superficial; first-degree) Burn** • Blanching with pressure • Minimal edema • Moderate to severe tenderness • Pain • Redness **Partial-Thickness (deep; second-degree) Burn** • Blanching with pressure • Hypersensitive to touch or air • Moderate to severe pain • Moist blebs, blisters • Mottled white, pink to cherry-red **Full-Thickness (third- and fourth-degree) Burns** • Absence of pain with severe pain in surrounding tissues • Dry, leathery eschar • Impaired sensation when touched • Lack of blanching with pressure • Strong burn odor • Waxy white, dark brown, or charred appearance	**Initial** • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Assess for inhalation injury. • Provide supplemental O_2 as needed. • Anticipate endotracheal intubation and mechanical ventilation with circumferential full-thickness burns to the neck and chest or large TBSA burns. • Monitor vital signs, level of consciousness, respiratory status, O_2 saturation, and heart rhythm. • Remove nonadherent clothing, shoes, watches, jewelry, glasses or contact lenses (if face was exposed). • Cover any concurrent thermal burns with dry dressings or clean sheet. • Establish IV access with 2 large-bore catheters if burn >15% TBSA. • Begin fluid replacement. • Insert indwelling urinary catheter if burn >15% TBSA. • Elevate burned limbs above heart to decrease edema. • Give IV analgesia and assess effectiveness frequently. • Identify and treat other associated injuries (e.g., fractures, head injury). **Ongoing Monitoring** • Monitor airway, breathing, and circulation. • Monitor vital signs, O_2 saturation, heart rhythm, and level of consciousness. • Monitor pain level. • Monitor urine output.

TBSA, Total body surface area.

TABLE 24.7 Emergency ManagementInhalation Injury

Etiology	Assessment Findings	Interventions
• **Exposure of respiratory tract to intense heat or flames** • **Inhalation of noxious chemicals, smoke, or CO** • **Occurs with being trapped in an enclosed space, being in an explosion, or having clothing catch fire**	• Altered mental status, including confusion, coma • Carbonaceous sputum • Cherry-red skin color (CO levels >20%) • Coughing • Darkened oral or nasal membranes • Decreased O_2 saturation • Difficulty swallowing • Dysrhythmias • Increasing hoarseness • Irritation of upper airways or burning pain in throat or chest • Productive cough with black, gray, or bloody sputum • Rapid, shallow respirations • Restlessness, anxiety • Singed nasal or facial hair • Smoky breath	**Initial** • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Assess for concurrent thermal burn. • Provide 100% humidified O_2. • Anticipate endotracheal intubation and mechanical ventilation with significant inhalation injury. • Monitor vital signs, level of consciousness, O_2 saturation, and heart rhythm. • Obtain arterial blood gas, carboxyhemoglobin levels, and chest x-ray. • Remove nonadherent clothing, jewelry, glasses, or contact lenses (if face was exposed). • Establish IV access with 2 large-bore catheters if burn >15% TBSA. • Begin fluid replacement. • Insert indwelling urinary catheter if burn >15% TBSA. • Elevate burned limb(s) above heart to decrease edema. • Give IV analgesia and assess effectiveness frequently. • Identify and treat other associated injuries (e.g., fractures, pneumothorax, head injury). • Cover concurrent burned areas with dry dressings or clean sheet. • Anticipate need for fiberoptic bronchoscopy or intubation. **Ongoing Monitoring** • Monitor airway, breathing, and circulation. • Monitor vital signs, O_2 saturation, heart rhythm, and level of consciousness. • Monitor pain level. • Monitor urine output.

CO, Carbon monoxide; *TBSA,* total body surface area.

TABLE 24.8 Emergency ManagementElectrical Burns

Etiology	Assessment Findings	Interventions
• **Defibrillator** • **Electric wires** • **Lightning** • **Utility wires**	• Burn odor • Cardiac arrest • Depth and extent of wound difficult to see • Assume injury greater than what is seen • Decreased peripheral circulation in injured extremity • Dysrhythmias • Fractures or dislocations from force of current • Impaired touch sensation • Leathery, white, or charred skin • Location of contact points • Loss of consciousness • Minimal or absent pain • Neck or head injury if fall occurred • Thermal burns if clothing ignites	**Initial** • Remove patient from electrical source while protecting rescuer. • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Provide supplemental O_2 as needed. • Monitor vital signs, heart rhythm, level of consciousness, respiratory status, and O_2 saturation. • Remove nonadherent clothing, shoes, watches, jewelry, glasses or contact lenses (if face was exposed). • Cover burned areas with dry dressings or clean sheet. • Establish IV access with 2 large-bore catheters if burn >15% TBSA. • Begin fluid replacement. • Identify entrance and exit wounds. • Obtain arterial blood gas to assess acid-base balance. • Insert indwelling urinary catheter if burn >15% TBSA. • Elevate burned limb(s) above heart to decrease edema. • Give IV analgesia and assess effectiveness frequently. • Identify and treat other associated injuries (e.g., fractures, head injury, thermal burns). **Ongoing Monitoring** • Monitor airway, breathing, and circulation. • Monitor vital signs, O_2 saturation, heart rhythm, level of consciousness, and neurovascular status of injured limbs. • Monitor pain level. • Monitor urine output. • Monitor urine for development of myoglobinuria from muscle breakdown and hemoglobinuria from RBC breakdown. • Anticipate possible administration of $NaHCO_3$ to alkalinize the urine and maintain serum pH >6.0.

$NaHCO_3$, Sodium bicarbonate; *TBSA,* total body surface area.

TABLE 24.9 Emergency ManagementChemical Burns

Etiology	Assessment Findings	Interventions
• **Acids** • **Alkalis** • **Organic compounds**	• Burning • Decreased muscle coordination (if organophosphate) • Discoloration of injured skin • Edema of surrounding tissue • Localized pain • Paralysis, redness, swelling of injured tissue • Respiratory distress if chemical inhaled • Tissue destruction continuing for up to 72 hr	**Initial** • If unresponsive, assess circulation, airway, and breathing before decontamination procedures. • If responsive, monitor airway, breathing, and circulation. • Provide supplemental O_2 as needed. • Brush dry chemical from skin before irrigation. • Remove nonadherent clothing, shoes, watches, jewelry, glasses or contact lenses (if face was exposed). • Flush chemical from wound and surrounding area with copious amounts of saline solution or water. • For chemical burn of the eye(s), flush from inner to outer corner of eye with water or lactated Ringer's (if available). • Cover burned areas with dry dressings or clean sheet. • Establish IV access with 2 large-bore catheters if burn >15% TBSA. • Begin fluid replacement. • Insert indwelling urinary catheter if burn >15% TBSA. • Elevate burned limb(s) above heart to decrease edema. • Give IV analgesia and assess effectiveness frequently. • Contact poison control center. **Ongoing Monitoring** • Monitor airway if exposed to chemicals. • Monitor pain level. • Monitor urine output. • Consider systemic impact of identified chemical. Monitor and treat accordingly. • Monitor pH of eye if exposed to chemicals.

TBSA, Total body surface area.

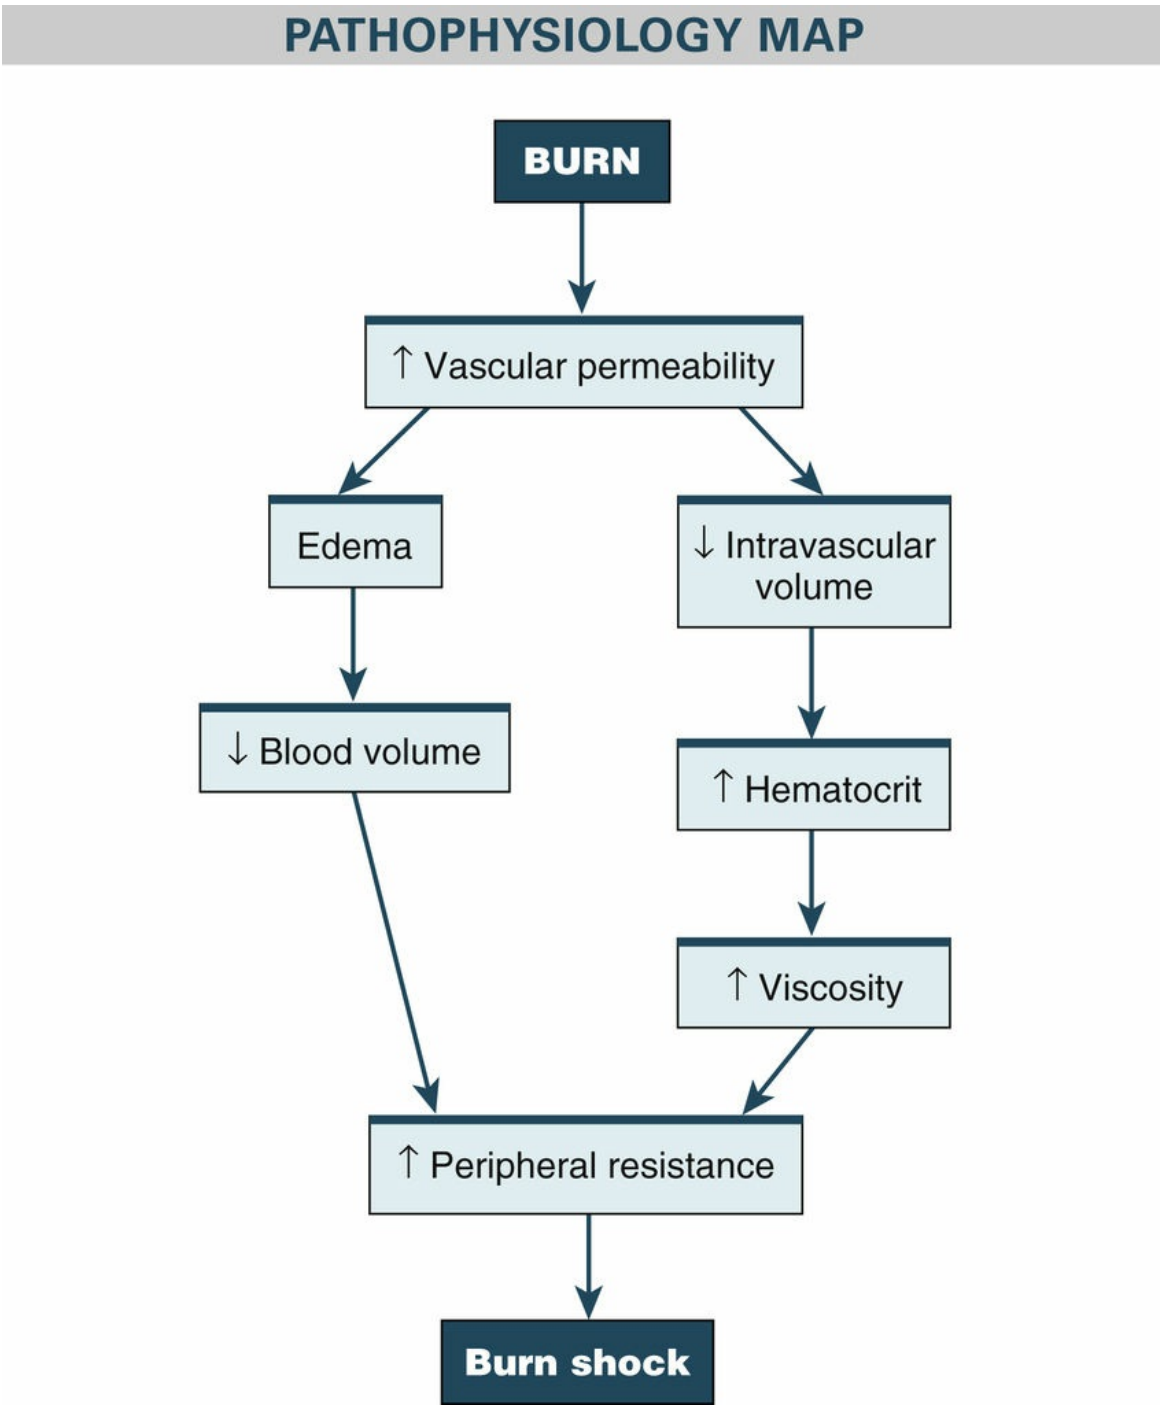

FIG. 24.5 At the time of major burn injury, there is increased capillary permeability. All fluid components of the blood begin to leak into the interstitium, causing edema and a decreased blood volume. Hematocrit increases, and the blood becomes more viscous. The combination of decreased blood volume and increased viscosity produces increased peripheral resistance. Burn shock, a type of hypovolemic shock, rapidly ensues and, if not corrected, can result in death.

FIG. 24.6 **A,** Facial edema before fluid resuscitation. **B,** Facial edema after 24 hours.
Courtesy Judy Knighton, Toronto, Canada.

Fluid moves to areas that normally have minimal to no fluid, a phenomenon termed *third spacing.* Examples of third spacing in burn injury are exudate and blister formation, as well as edema in unburned areas.

Other sources of fluid loss are insensible losses by evaporation from large, denuded body surfaces and the lungs. The normal insensible loss of 30 to 50 mL/hr is higher in the severely burned patient. The net result of the fluid shifts and losses is termed *intravascular volume depletion.* Signs of hypovolemic shock include decreased BP and increased heart rate. If hypovolemic shock is not corrected, refractory shock and death may result. (Shock is discussed in Chapter 66.)

The circulatory system is affected by the hemolysis of RBCs from

circulating factors (e.g., oxygen free radicals) released at the time of the burn and the direct insult of the burn injury. Thrombosis in the capillaries of burned tissue causes loss of more circulating RBCs. A high hematocrit is often caused by hemoconcentration due to fluid loss. After fluid balance is restored, the hematocrit levels return to normal.

Major electrolyte shifts of sodium and potassium occur during this phase. A potassium shift develops first because injured cells and hemolyzed RBCs release potassium into the circulation. Sodium rapidly moves to the interstitial spaces and stays there until edema formation ends (Fig. 24.7).

Toward the end of the emergent phase, capillary membrane permeability is restored if fluid replacement is adequate. Interstitial fluid gradually returns to the vascular space (Fig. 24.7). Diuresis occurs, and the urine has a low specific gravity.

Inflammation and Healing

Burn injury to tissues and vessels causes coagulation necrosis. Neutrophils and monocytes accumulate at the site of injury. Fibroblasts and newly formed collagen fibrils appear and begin wound repair within the first 6 to 12 hours after injury. (The inflammatory response is discussed in Chapter 11.)

Immunologic Changes

A burn injury challenges the body's immune system. The skin barrier to invading organisms is destroyed. Bone marrow depression occurs and circulating levels of immunoglobulins decrease. Defects occur in the function of white blood cells (WBCs). The inflammatory cytokine cascade, triggered by tissue damage, impairs the function of lymphocytes, monocytes, and neutrophils. Thus the patient is at a greater risk for infection.

Clinical Manifestations

The patient with severe burns is likely to be in shock from

hypovolemia. Often the areas of full-thickness and deep partial-thickness burns are at first painless because the nerve endings have been destroyed. Superficial to moderate partial-thickness burns are very painful. Blisters, filled with fluid and protein, are common in partial-thickness burns. The patient with a larger burn may develop a paralytic ileus, with absent or decreased bowel sounds. Shivering may occur because of chilling that is caused by heat loss, anxiety, or pain.

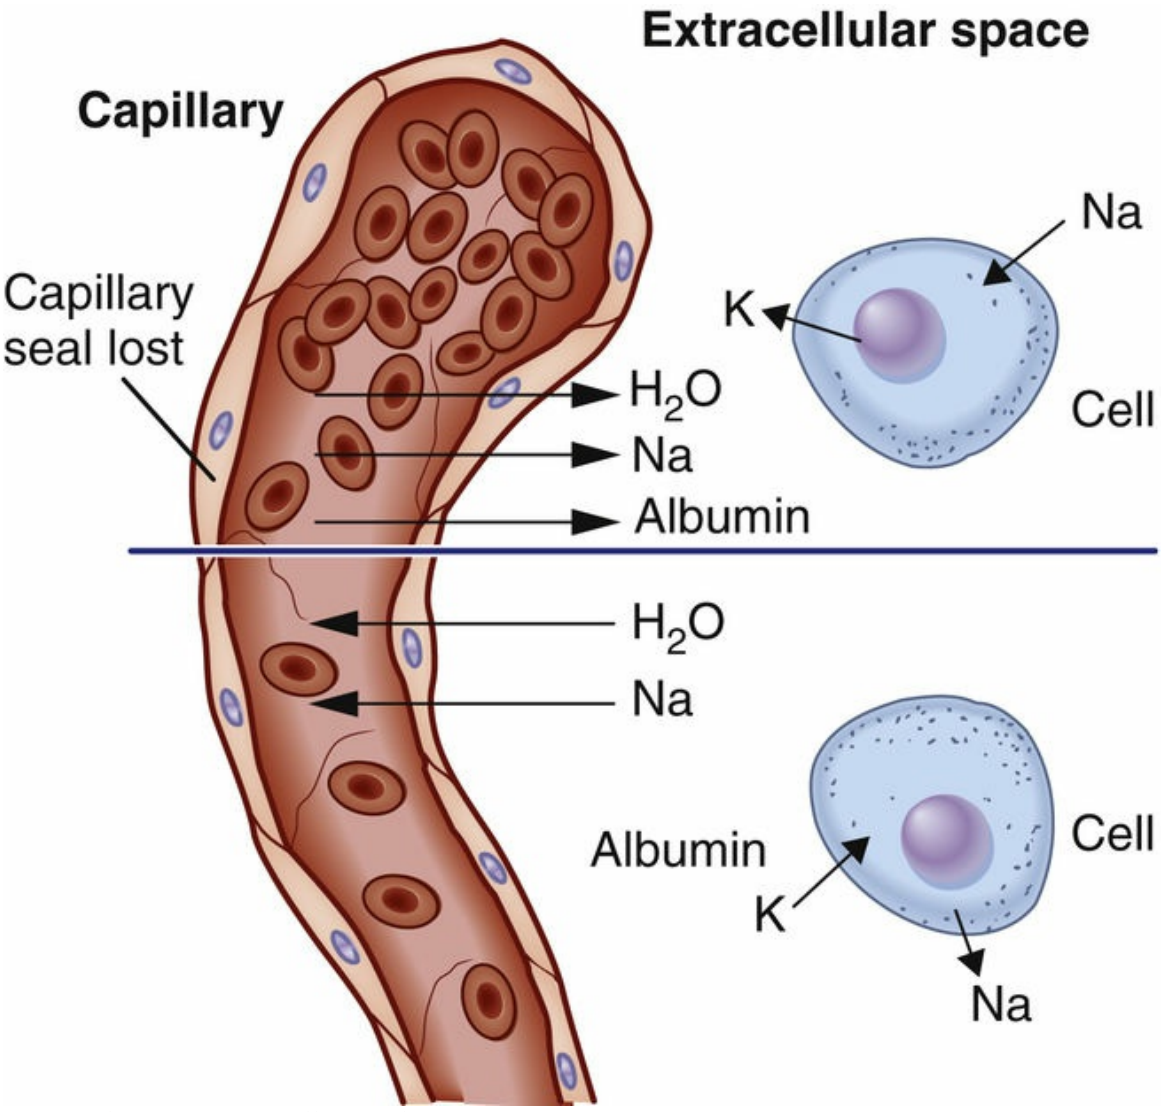

FIG. 24.7 The effects of burn shock are shown above the *purple line.* As the capillary seal is lost, interstitial edema develops. Cellular integrity is altered, with sodium *(Na)* moving into the cell in abnormal amounts and potassium *(K)* leaving the cell. The shifts after the

resolution of burn shock are shown below the *blue line.* The water and sodium move back into the circulating volume through the capillary. Albumin stays in the interstitium. Potassium is transported into the cell and sodium is transported out as the cellular integrity returns.

The patient may be alert and able to answer questions shortly after admission or until intubated (if there is respiratory compromise). Patients are often frightened and need your calm reassurances. Give simple explanations of what to expect as you provide care. Unconsciousness or altered mental status in a burn patient usually results from hypoxia associated with smoke inhalation. Other possibilities include head trauma, substance use, or excess amounts of sedation or pain medication.

Complications

The three major organ systems most susceptible to complications during the emergent phase of burn injury are the cardiovascular, respiratory, and urinary systems.

Cardiovascular System

Cardiovascular complications include dysrhythmias and hypovolemic shock. These, if untreated, may progress to irreversible shock. Circulation to the extremities can be severely impaired by deep circumferential burns and subsequent edema formation, which act like a tourniquet. If untreated, ischemia, paresthesia, and necrosis can occur. An **escharotomy** (an incision through the full-thickness eschar) is often done to restore circulation to compromised extremities or improve chest expansion (Fig. 24.8).

Initially, blood viscosity increases because of the fluid loss. Microcirculation is impaired because of the damage to skin structures that contain small capillary systems. This results in a phenomenon termed *sludging.* Sludging is corrected by adequate fluid replacement.

Burn patients are at an increased risk for venous thromboembolism (VTE) if 1 or more of the following conditions are present: advanced age, obesity, extensive or lower extremity burns, concomitant lower

extremity trauma, and prolonged immobility. VTE prophylaxis with anticoagulant drugs should be started, unless contraindicated.[11]

Respiratory System

The respiratory system is vulnerable to 2 types of injury: (1) upper airway burns and (2) lower airway injury (Table 24.3). Upper airway distress may occur with or without smoke inhalation, and airway injury at either level may occur in the absence of burn injury to the skin. (Smoke and inhalation injuries are discussed earlier in this chapter on pp. 432-433.)

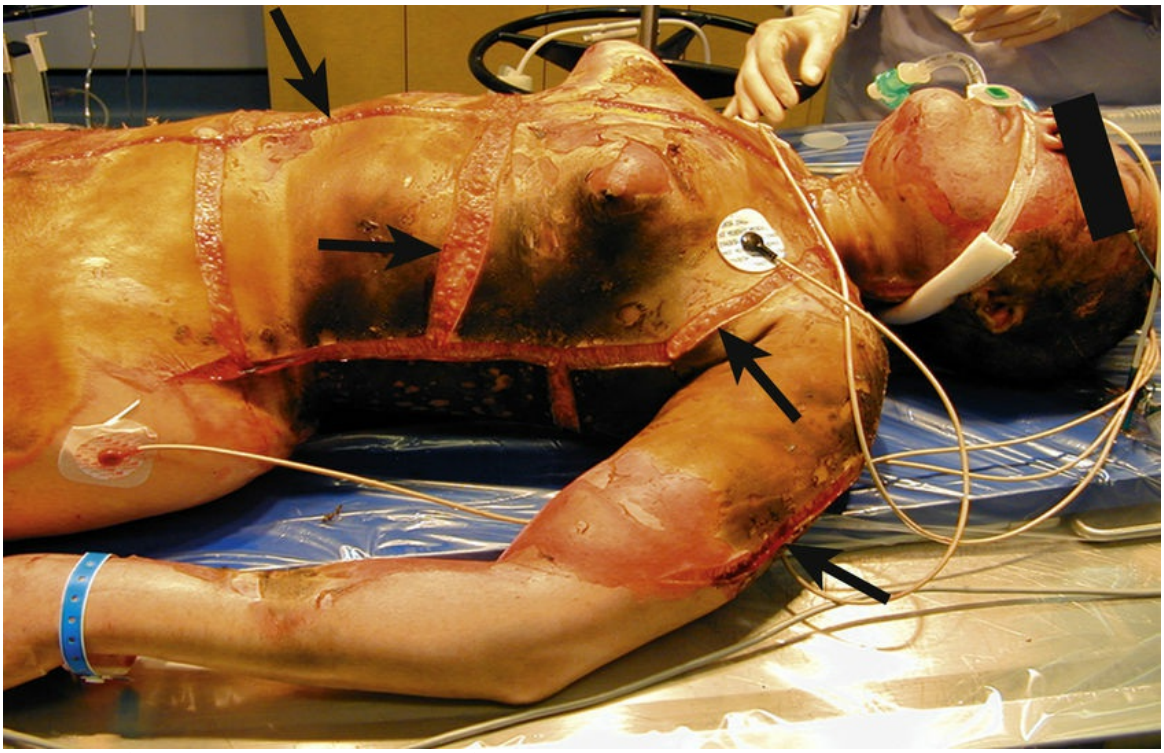

FIG. 24.8 Escharotomies of the anterior and lateral chest and arm (indicated by *arrows*).
Courtesy Judy Knighton, Toronto, Canada.

The patient may need a fiberoptic bronchoscopy and carboxyhemoglobin blood levels to confirm a suspected inhalation injury. Look in the prehospital and ED notes to see if the patient was exposed to smoke or fumes. Examine any sputum for carbon. Watch

for signs of respiratory distress, such as increased agitation, anxiety, restlessness, or a change in the rate or character of the patient's breathing, as symptoms may not be present at first.

In general, there is no correlation between the percentage TBSA burn (% TBSA) and the severity of inhalation injury. In a patient with inhalation injury, a chest x-ray may appear normal on admission, but changes can occur over the next 24 to 48 hours. Arterial blood gas (ABG) values may be within the normal range on admission and change over time.

Other Cardiopulmonary Problems

Patients with preexisting heart disease (e.g., myocardial infarction) or lung disease (e.g., chronic obstructive pulmonary disease [COPD]) are at an increased risk for complications. If fluid replacement is too vigorous, watch for early signs of heart failure or pulmonary edema. Invasive measures (e.g., hemodynamic monitoring) may be needed to monitor fluid resuscitation.

Patients with preexisting lung disease are more likely to develop a respiratory infection. Pneumonia, a common complication of major burns, is the leading cause of death in patients with an inhalation injury.[12]

Urinary System

The most common complication of the urinary system in the emergent phase is ATN. If your patient becomes hypovolemic, blood flow to the kidneys is decreased, causing renal ischemia. If this continues, acute kidney injury may develop.

With full-thickness and major electrical burns, myoglobin (from muscle cell breakdown) and hemoglobin (from RBC breakdown) are released into the bloodstream and block renal tubules. Carefully monitor the adequacy of fluid replacement because this can reverse the obstruction of the tubules.

Nursing and Interprofessional

Management: Emergent Phase

In the emergent phase, the patient's survival depends on rapid and thorough assessment and appropriate interventions. Usually the HCP and you make an initial assessment of the depth and extent of the burn and coordinate the actions of others on the health care team. In a community hospital, determine whether the patient needs inpatient or outpatient care. In the case of inpatient care, decide whether the patient stays at the hospital or must be transferred to a burn center (Table 24.4). Care mainly focuses on airway management, fluid therapy, and wound care (Table 24.10). Patients can improve or worsen, unpredictably.

Although physical therapy (PT) and occupational therapy (OT) are important in both the acute and rehabilitation phases, proper positioning and splinting begin on the day of admission. Emotional support and teaching of patients and caregivers begin on admission. A nursing care plan for the patient with burn injury (eNursing Care Plan 24.1) is available on the website for this chapter.

Informatics in Practice

Staff Training Using Gaming

- Preparing burn center staff for a mass casualty incident involving burn victims is essential.
- Interactive, video game–based training modules simulate real-life emergency events surrounding a mass casualty burn incident.
- Critical skills for triage and initial resuscitation (emergent phase) for multiple victims can be practiced.[13]

Airway Management

Airway management often involves early endotracheal (preferably

orotracheal) intubation.[14] Early intubation removes the need for emergency tracheostomy after respiratory problems have become apparent. In general, the patient with burns to the face and neck needs intubation within 1 to 2 hours after injury. Intubation is discussed in Chapter 65.

After intubation, the patient is placed on ventilatory support, with settings based on ABG results. Extubation may occur when the edema resolves. This is usually 3 to 6 days after burn injury unless severe inhalation injury exists. Chest escharotomy may be needed to relieve respiratory distress with circumferential, full-thickness burns of the neck and chest (Fig. 24.8).

A fiberoptic bronchoscopy should be done to assess the lower airway within 6 to 12 hours after injury if smoke inhalation is suspected. When intubation is not done, treatment of inhalation injury includes giving 100% humidified O_2. Place the patient in a high Fowler's position, unless contraindicated (e.g., spinal injury). Encourage deep breathing and coughing every hour. Reposition the patient every 1 to 2 hours. Provide suctioning and chest physiotherapy.

If severe respiratory distress (e.g., hoarseness, shortness of breath) develops, intubation and mechanical ventilation are started. Positive end-expiratory pressure (PEEP) may be used to prevent collapse of the alveoli and progressive respiratory failure (see Chapters 65 and 67). Bronchodilators may be given to treat severe bronchospasm. CO poisoning is treated by giving 100% O_2 until carboxyhemoglobin levels return to normal.

Safety Alert

Pulse CO Oximetry Monitoring

- Standard pulse oximetry (SpO_2) does not distinguish oxyhemoglobin from carboxyhemoglobin.

- A patient with CO poisoning will have normal SpO_2 readings despite high carboxyhemoglobin levels.
- For patients with suspected or confirmed CO poisoning, use a pulse CO oximetry (SpCO) device.

Fluid Therapy

Obtaining IV access is critical for fluid resuscitation and drug administration. At least 2 large-bore IVs must be in place for patients with burns that are 15% TBSA or more. It is critical to obtain IV access that can handle large volumes of fluid. For patients with burns greater than 30% TBSA, consider a central line for fluid and drug administration and blood sampling (central lines are discussed in Chapter 16). An arterial line is often placed if frequent ABGs or invasive BP monitoring is needed.

Assess the extent of the burn wound using a standardized tool (Fig. 24.4). Then use a standardized formula to estimate the patient's fluid resuscitation needs. Fluid replacement is achieved with crystalloid solutions (usually lactated Ringer's), colloids (albumin), or a combination of the two. IV saline is usually started during the prehospital phase.

TABLE 24.10 Interprofessional CareBurn Injury

Emergent Phase	Acute Phase	Rehabilitation Phase
Fluid Therapy (Table 24.11) • **Assess fluid needs.** • **Begin IV fluid replacement.** • **Insert indwelling urinary catheter.** • **Monitor urine output.** **Wound Care** • **Start daily shower and wound care.** • **Debride as needed.** • **Assess extent and depth of burns.** • **Give tetanus toxoid or tetanus antitoxin.** **Pain and Anxiety** • **Assess and manage pain and anxiety.** **Physical and Occupational Therapy** • **Place patient in position that prevents contracture formation and reduces edema.** • **Assess need for splints.** **Nutritional Therapy** • **Assess nutritional needs and begin feeding patient by most appropriate route as soon as possible.** **Respiratory Therapy** • **Assess oxygenation needs.** • **Provide supplemental O_2 as needed.** • **Intubate if needed.** • **Monitor respiratory status.** **Psychosocial Care** • **Provide support to patient and caregiver during initial crisis phase.**	Fluid Therapy • Continue to replace fluids, depending on patient's clinical response. Wound Care • Continue daily shower and wound care. • Continue debridement (if needed). • Assess wound daily and adjust dressing protocols as needed. • Observe for complications (e.g., infection). Early Excision and Grafting • Provide temporary allografts. • Provide permanent autografts. • Care for donor sites. Pain and Anxiety • Continue to assess for and treat pain and anxiety. Physical and Occupational Therapy • Begin daily therapy program for maintenance of range of motion. • Assess need for splints and anticontracture positioning. • Encourage and aid patient with self-care as possible. Nutritional Therapy • Continue to assess diet to support wound healing. Respiratory Therapy • Continue to assess oxygenation needs. • Continue to monitor respiratory status. • Monitor for signs of complications (e.g., pneumonia). Psychosocial Care • Provide ongoing support, counseling, and teaching to patient and caregiver about physical and emotional aspects of care and recovery. • Begin discharge planning. Drug Therapy (Table 24.13) • Assess need for drugs (e.g., antibiotics). • Continue to monitor effectiveness and adjust dosage as needed.	• Continue to teach patient and caregiver about wound care. • Continue to encourage and aid patient in resuming self-care. • Continue to prevent or minimize contractures. • Assess risk for scarring (surgery, physical and occupational therapy, splinting, pressure garments). • Discuss possible reconstructive surgery. • Prepare for discharge home or transfer to rehabilitation hospital. • Discuss possible need for home care nursing.

The Parkland (Baxter) formula for fluid replacement is the most common formula used (Table 24.11 or *www.mdcalc.com/parkland-formula-for-burns*). Remember that all formulas are estimates. Fluids are titrated based on the patient's response (e.g., hourly urine output, vital signs). Patients with an electrical injury have greater than normal fluid needs. They generally require an osmotic diuretic (mannitol [Osmitrol]) to increase their urine output and overcome high levels of hemoglobin and myoglobin in the urine. Too much fluid and overestimation of TBSA contribute to over-resuscitation of fluids or "fluid creep."[15] For the first 24 hours, the recommendation is 2 to 4 mL lactated Ringer's/kg/%TBSA burned.[16] Colloidal solutions (e.g., 5% albumin) may be given. However, they are often not started until 12 to 24 hours postburn when capillary permeability returns to normal or near normal. After this time, the plasma stays in the vascular space and expands the circulating volume. The replacement volume is calculated based on the patient's body weight and TBSA burned (e.g.,

0.3 to 0.5 mL/kg/%TBSA burned).

Assess for the adequacy of fluid resuscitation hourly using clinical parameters. Urine output, the most often used parameter, and cardiac parameters are defined as follows:

- *Urine output:* 0.5 to 1 mL/kg/hr; 75 to 100 mL/hr for electrical burn patient with evidence of hemoglobinuria or myoglobinuria.
- *Cardiac parameters:* Mean arterial pressure (MAP) greater than 65 mm Hg, systolic BP greater than 90 mm Hg, heart rate less than 120 beats/min. MAP and BP are best measured by an arterial line. Manual BP measurement is often invalid because of edema and vasoconstriction.

Check Your Practice

You are admitting a new burn patient who weighs 72 kg and has 45% TBSA burn.

- Outline the patient's fluid requirements over the first 24 hours.

TABLE 24.11 Fluid Resuscitation Formulas

Parkland (Baxter)*

4 mL lactated Ringer's solution per kilogram (kg) of body weight per percent of total body surface area (% TBSA) burned = Total fluid requirements for first 24 hr after burn

Application

1/2 of total in first 8 hr
1/4 of total in second 8 hr
1/4 of total in third 8 hr

Example

For a 70-kg patient with a 50% TBSA burn:

$$4\ mL \times 70\ kg \times 50\ (\%TBSA)\ burned = 14,000\ mL\ in\ 24\ hr$$

1⁄2 of total in first 8 hr = 7000 mL (875 mL/hr)
1⁄4 of total in second 8 hr = 3500 mL (437 mL/hr)
1⁄4 of total in third 8 hr = 3500 mL (437 mL/hr)

American Burn Association Consensus Fluid Resuscitation

2–4 mL lactated Ringer's solution per kilogram (kg) of body weight per percent of total body surface area (% TBSA) burned = Total fluid requirements for first 24 hr after burn

Wound Care

Once a patent airway, effective circulation, and adequate fluid replacement have been achieved, priority is given to care of the burn wound. Partial-thickness burn wounds appear pink to cherry-red and are wet and shiny with serous exudate. These wounds may or may not have intact blisters; are painful when touched; and have only minor, localized sensation because nerve endings may have been destroyed in the burned dermis.

You can perform cleansing and gentle debridement (using scissors and forceps) on a shower cart (Fig. 24.9), in a regular shower, or on a patient's bed or stretcher. Extensive, surgical debridement is done in the operating room (OR) (Fig. 24.10). During **debridement**, necrotic

skin is removed. Releasing escharotomies and fasciotomies are done in the emergent phase, usually in burn centers by physicians.

Patients find the first wound care to be both physically and mentally demanding. Provide emotional support and begin to build trust during this activity. A once-daily shower and dressing change in the morning, with an evening dressing change in the patient's room, are part of the routine in many burn centers. Others opt to shower the patient on admission and then perform all other dressing changes in the patient's room. Some of the newer antimicrobial dressings can be left in place from 3 to 14 days, reducing the frequency of dressing changes.

Infection can cause further tissue injury and possible sepsis. The source of infection in burn wounds is likely the patient's own flora, mostly from the skin, respiratory, and gastrointestinal (GI) systems.

Two approaches to burn wound treatment are (1) the open method and (2) the use of multiple dressing changes (closed method). In the *open method* the patient's burn is covered with a topical antimicrobial and has no dressing over the wound. This approach is usually limited to the care of facial burns. In the *multiple dressing change,* or *closed method,* sterile gauze dressings are impregnated with or laid over a topical antimicrobial (Fig. 24.11). These dressings are changed from every 12 hours to once every 14 days depending on the product. Most burn centers use the closed technique.

FIG. 24.11 Application of silver sulfadiazine cream to saline-moistened gauze.
Courtesy Judy Knighton, Toronto, Canada.

When the patient's open burn wounds are exposed, always wear personal protective equipment (PPE) (e.g., disposable hats, masks, gowns, gloves). When removing contaminated dressings and washing wounds, use nonsterile, disposable gloves. Use sterile gloves when applying ointments and sterile dressings. In addition, prevent shivering by keeping the room warm (around 85°F [29.4°C]). Before leaving one patient, remove your PPE and wash your hands. Don new PPE before you treat another patient.

TABLE 24.12 Skin Grafts Used for Burn Injury

Graft Type	Source and Description	Coverage
Allograft (or homograft) (same species)	Cadaveric skin	Temporary (3 days to 2 wk)
Autografts		
Autograft	Patient's own skin	Permanent
Cultured epithelial autograft (CEA)–Epicel	Patient's own skin cell cultures	Permanent
Dermal Substitutes		
AlloDerm	Acellular dermal matrix derived from donated human skin	Permanent
Apligraf	Donated neonatal foreskin fibroblasts and keratinocytes in bovine collagen gel	Permanent
Biobrane	Semipermeable silicone membrane bonded to nylon fabric	Temporary (10–21 days)
Integra	Biodegradable dermal layer made of bovine collagen and glycosaminoglycan bonded to silicone membrane	Permanent
Matriderm	Bovine collagen and elastin matrix	Permanent
OrCel	Donated neonatal foreskin fibroblasts and keratinocytes in bovine collagen sponge	Permanent
Xenograft (or heterograft) (different species)	Porcine skin	Temporary (3 days to 2 wk)

Permanent skin coverage is the primary goal for burn wound care. There is rarely enough unburned skin in the major (greater than 50% TBSA) burn patient for immediate skin grafting. In this situation, temporary wound closure methods are needed. *Allograft (homograft) skin* (from skin donor cadavers) is used, along with newer biosynthetic options. Treatment approaches vary among burn centers (Table 24.12).

Other Care Measures

Certain parts of the body (e.g., face, eyes, hands, arms, ears, perineum) need vigilant nursing care. The face is highly vascular and can become very swollen. It is often covered with ointments and gauze but not wrapped to limit pressure on delicate facial structures. An eye exam should occur soon after admission for all patients with facial burns. Periorbital edema can temporarily prevent eye opening and is often frightening for the patient. Always check that the patient's eyelashes are not turned inward toward the eyeball. Provide assurance that the swelling is not permanent. Instill methylcellulose drops or artificial tears into the eyes for moisture and comfort. Apply antibiotic eye ointment for corneal burns or edema as ordered.

Keep the ears free from pressure because of their poor vascularization and tendency to become infected. Do not use pillows for the patient with ear burns. The pressure on the cartilage may cause

chondritis. Also, the ear may stick to the pillowcase, causing pain and bleeding. Raise the patient's head using a rolled towel placed under the shoulders, being careful to avoid pressure necrosis. Follow the same strategy for the patient with neck burns to hyperextend the neck and prevent neck contracture.

Extend burned hands and arms and raise them on pillows or plastic-covered foam wedges to reduce edema. Ask the physical therapist (PT) and the HCP if splints should be applied to burned hands and feet to keep them in positions of function. Remove the splints often and inspect the skin and bony prominences to avoid areas of pressure from inappropriate or prolonged application. Elastic wraps may reduce edema.

Keep your patient's perineum as clean and dry as possible after each voiding or bowel movement. In addition to monitoring hourly urine outputs, an indwelling catheter prevents urine contamination of the perineal area. Regular once- or twice-daily perineal care is essential. Assess the need for an indwelling urinary catheter daily. Remove when it is no longer needed to limit the risk for a urinary tract infection. If your patient has frequent, loose stools, consider using a fecal diversion device.

Perform laboratory tests to monitor fluid and electrolyte balance. Draw ABGs to assess adequacy of ventilation and oxygenation in patients with suspected or confirmed inhalation or electrical injury.

Work with PT to perform range-of-motion (ROM) exercises during dressing changes and throughout the day. Movement aids the shift of the interstitial fluid back into the vascular bed. Active and passive exercise also maintains function and prevents skin and joint contractures. It may reassure the patient that movement is still possible.

Drug Therapy

Analgesics and Sedatives

Promote the use of analgesics for the patient's comfort. Early in the postburn period, IV pain medications should be given because (1)

onset of action is fastest with this route; (2) oral drugs have a slower onset of action and are not as effective when GI function is slowed or impaired because of shock or paralytic ileus; and (3) IM injections are not absorbed well in burned or edematous areas, causing pooling of drugs in the tissues. Consequently, when fluid mobilization starts, the patient could be inadvertently overdosed from the interstitial accumulation of previous IM drugs.

Common drugs used for pain control are listed in Table 24.13. Opioids are the drug of choice for severe pain. When given appropriately, these drugs should provide adequate pain relief. Evaluate the pain management plan often since the patient's needs may change and tolerance to drugs may develop over time. Remember that the patient's pain level may not directly correlate with the extent and depth of burn. Analgesic needs vary from one patient to another. Consider a multimodal approach to pain control. Sedatives/hypnotics and antidepressants can be given with analgesics to control the anxiety, insomnia, or depression that patients may have (Table 24.13).

Tetanus Immunization

All burn patients routinely receive tetanus toxoid because of the risk for anaerobic burn wound contamination. If the patient has not received an active immunization within 10 years before the burn injury, tetanus immunoglobulin should be considered. (Tetanus immunization is discussed in Table 68.6.)

TABLE 24.13 Drug TherapyBurns

Drugs	Purpose
Analgesics	
morphine **sustained-release morphine (MS Contin)** **hydromorphone (Dilaudid)** **sustained-release hydromorphone (Dilaudid CR)** **fentanyl (Sublimaze)** **oxycodone and acetaminophen (Percocet)** **nonsteroidal antiinflammatory (e.g., ketorolac)** **adjuvant analgesics (e.g., gabapentin [Neurontin])**	Relieve pain
Anticoagulants	
enoxaparin (Lovenox) **heparin**	Prevent venous thromboembolism
Antidepressants	
citalopram (Celexa) **sertraline (Zoloft)**	Reduce depression, improve mood
Gastrointestinal Support	
aluminum hydroxide and magnesium hydroxide (Maalox) **calcium carbonate and magnesium carbonate (Mylanta)**	Neutralize stomach acid
esomeprazole (Nexium) **ranitidine (Zantac)**	Decrease stomach acid and risk for Curling's ulcer
nystatin	Prevent overgrowth of *Candida albicans* in oral mucosa
Nutritional Support	
Minerals: zinc, iron (ferrous sulfate)	Promote cell integrity and hemoglobin formation
Vitamins A, C, E, and multivitamins	Promote wound healing
Sedatives/Hypnotics	
lorazepam (Ativan)	Reduce anxiety
midazolam (Versed)	Provide short-acting amnesic effects
zolpidem (Ambien)	Promote sleep

Antimicrobial Agents

After the wound is cleansed, topical antimicrobial agents may be applied (Fig. 24.11) and covered with a light dressing. Systemic antibiotics are not routinely used to control burn wound flora because the burn eschar has little or no blood supply, so little antibiotic is delivered to the wound. In addition, the routine use of systemic antibiotics increases the chance of developing multidrug-resistant organisms. Some topical burn agents penetrate the eschar and inhibit bacterial invasion of the wound. Silver-impregnated dressings can be left in place from 3 to 14 days, depending on the patient's clinical situation and the product. Silver sulfadiazine (Silvadene) and mafenide acetate (Sulfamylon) creams are also used.[17]

Safety Alert

Drug Allergy Check

- Check the patient for any allergies to sulfa since many burn antimicrobial creams contain sulfa.

Sepsis is a leading cause of death in the patient with major burns and may lead to multiple organ dysfunction syndrome (see Chapter 66). Systemic antibiotic therapy is started when the diagnosis of sepsis is made or when some other source of infection is identified (e.g., pneumonia).

Fungal infections may develop in the patient's mucous membranes (mouth and genitalia) because of systemic antibiotic therapy and low resistance. The offending organism is usually *Candida albicans.* Oral infection is treated with nystatin (Mycostatin) mouthwash. When a normal diet is resumed, yogurt or *Lactobacillus* (Lactinex) may be given to reintroduce the normal intestinal flora that was destroyed by antibiotic therapy.

Venous Thromboembolism Prophylaxis

Burn patients are at risk for VTE. If there are no contraindications, it is recommended that low-molecular-weight heparin (enoxaparin) or low-dose unfractionated heparin be started as soon as it is considered safe. For burn patients who have a high bleeding risk, VTE prophylaxis with intermittent pneumatic compression devices and/or graduated compression stockings is used until the bleeding risk decreases and heparin can be started (Table 24.13). (VTE prophylaxis is discussed in Chapter 37.)

Nutritional Therapy

Once fluid replacement needs have been addressed, nutrition takes priority in the initial emergent phase. Early and aggressive nutritional support within several hours of the burn injury can decrease

complications and mortality, optimize burn wound healing, and minimize the negative effects of hypermetabolism and catabolism.[18] Nonintubated patients with a burn of less than 20% TBSA will usually be able to eat enough to meet their nutritional needs.

Intubated patients and those with larger burns need more support. Enteral feedings have almost entirely replaced parenteral feeding. Early enteral feeding, usually with smaller bore tubes, preserves GI function, increases intestinal blood flow, and promotes optimal conditions for wound healing. In general, begin the feedings slowly at a rate of 20 to 40 mL/hr and increase to the goal rate within 24 to 48 hours. If a large nasogastric tube is used, gastric residuals should be checked to rule out delayed gastric emptying. Assess bowel sounds every 8 hours.

A *hypermetabolic state* proportional to the size of the wound occurs after a major burn injury. Resting metabolic expenditure may be increased by 50% to 100% above normal in patients with major burns. Core temperature is increased. Catecholamines, which stimulate catabolism and heat production, are increased. Massive catabolism can occur and is characterized by protein breakdown and increased gluconeogenesis.

Failure to supply adequate calories and protein leads to malnutrition and delayed healing. Calorie-containing nutritional supplements are often given to meet the caloric needs.[19] Protein powder can be added to food and liquids. Supplemental vitamins may be started in the emergent phase, with iron supplements often given in the acute phase (Table 24.13).

Acute Phase

The *acute phase* of burn care begins with the mobilization of extracellular fluid and subsequent diuresis. It ends when partial-thickness wounds are healed or full-thickness burns are covered by skin grafts. This may take weeks or months.

Pathophysiology

A healing burn injury causes many pathophysiologic changes in the body. Diuresis from fluid mobilization occurs, and the patient is less edematous. Bowel sounds return. The depth of the burn wounds may be more apparent as they "declare" themselves as partial or full thickness. The patient may now become more aware of the enormity of the situation and will benefit from emotional support and information.

Some healing begins as WBCs surround the burn wound and phagocytosis occurs. Necrotic tissue begins to slough. Fibroblasts lay down matrices of the collagen precursors that eventually form granulation tissue. A partial-thickness burn will heal, from both the wound edges and the dermal bed below, if kept free from infection and *desiccation* (dryness). However, full-thickness burn wounds, unless extremely small, must have the burn eschar surgically removed (excised) and skin grafts applied to heal. In some cases, healing time and length of hospitalization are decreased by early excision and grafting.

Clinical Manifestations

Partial-thickness wounds form eschar, which begins separating soon after injury. Once the eschar is removed, re-epithelialization begins at the wound margins and appears as red or pink scar tissue. Epithelial buds, from the hair follicles and glands in the dermal bed, eventually close the wound. Healing is spontaneous and usually occurs within 10 to 21 days.

Margins of full-thickness eschar take longer to separate. As a result, full-thickness burn wounds require surgical debridement and skin grafting to heal.

Laboratory Values

Because the body is trying to reestablish fluid and electrolyte balance in the initial acute phase, it is important to follow serum electrolyte

levels closely.

Sodium

Hyponatremia can develop from excess GI suction and diarrhea. Manifestations include headache, irritability, confusion, vomiting, seizures, and even coma. The patient may develop, *dilutional hyponatremia,* called *water intoxication,* from excess water intake. To avoid this condition, offer the patient fluids other than water, such as juice or nutritional supplements.

Hypernatremia may occur after successful fluid resuscitation if large amounts of hypertonic solutions were used. Hypernatremia also may be caused by tube feedings or inappropriate fluid administration. Manifestations include changes in mental status, ranging from drowsiness, restlessness, confusion, and lethargy to seizures and coma. Sodium restrictions may be applied to IV fluids and enteral or oral feedings until levels return to safe limits.

Potassium

Hyperkalemia may occur if the patient has renal failure, adrenocortical insufficiency, or massive deep muscle injury (e.g., electrical burn). Large amounts of potassium are released from damaged cells. Dysrhythmias and arrest can occur with high potassium levels. The patient may have confusion, tetany, muscle cramps, paresthesias, and weakness.

Hypokalemia occurs with vomiting, diarrhea, prolonged GI suction, and IV therapy without potassium supplementation. Potassium is also lost through the patient's burn wounds. Besides dysrhythmias, the patient may have muscle weakness, paresthesia, decreased GI motility, and decreased reflexes (see Chapter 16).

Complications

Infection

A burn injury destroys the body's first line of defense, the skin. The burn wound is now colonized with the person's own organisms that

were on the skin before the burn. The WBCs have functional defects, and the patient is immunosuppressed for many months after the burn injury.

If the levels of bacteria between the eschar and viable wound bed rise to greater than 10^5 per gram of tissue, the patient has a burn wound infection. Infection can convert partial-thickness burns to full-thickness wounds. Wound infections may be treated with systemic and local antibiotics based on wound culture and sensitivity results.

Localized inflammation, induration, and sometimes pus can be seen at the burn wound margins. Watch for signs and symptoms of infection, including hypothermia or hyperthermia, increased heart and respiratory rate, decreased BP, and decreased urine output. The patient may have mild confusion, chills, malaise, and loss of appetite. The WBC count is between 10,000/μL (10×10^9/L) and 20,000/μL (20×10^9/L).

The causative organisms of sepsis are usually gram-negative bacteria (e.g., *Pseudomonas, Proteus*), putting the patient at further risk for septic shock. If sepsis is suspected, obtain cultures from all possible sources, including the burn wound, blood, urine, sputum, oropharynx and perineal regions, and IV site. A lactate level is collected. Treatment begins with a bolus of normal saline IV and antibiotics.[20] Antibiotic therapy may be continued or changed based on the culture and sensitivity results. At this stage, the patient's condition is considered critical. Close monitoring of vital signs and mental status is needed.

Cardiovascular and Respiratory Systems

The same cardiovascular and respiratory complications present in the emergent phase continue into the acute phase of care. In addition, new problems might arise, requiring prompt intervention.

Neurologic System

Neurologically, the patient probably has no physical symptoms, unless severe hypoxia from respiratory injuries or complications from

electrical injuries occur. Probable causes of neurologic complications include electrolyte imbalance, stress, cerebral edema, sepsis, sleep problems, and the use of analgesics and antianxiety drugs.

Some patients may have certain behaviors that are not completely understood. The patient may become extremely disoriented, withdraw or become combative, hallucinate, or have frequent nightmare-like episodes. Delirium is more acute at night and occurs more often in the older patient. Start appropriate nursing interventions to prevent delirium and use a screening tool to diagnose delirium (see Table 59.18). Orient and reassure a patient who is confused or agitated. This state is usually transient, lasting from a day or two to several weeks, but complications and sequelae can last for years and be serious.

Musculoskeletal System

The musculoskeletal system is particularly prone to complications during the acute phase. The involvement of both PT and OT is vitally important. As the burns begin to heal and scar tissue forms, the skin is less supple and pliant. ROM may be limited, and skin and joint contractures can occur. Because of pain, the patient prefers a flexed position for comfort. Have the patient stretch and move the burned body parts as much as possible. Consult with PT or OT about proper positioning and splinting to prevent or reduce contracture formation.

Gastrointestinal System

The GI system may develop complications during this phase. Sepsis can cause paralytic ileus. Diarrhea may result from the use of enteral feedings or antibiotics. Constipation can occur as a side effect of opioids, decreased mobility, and a low-fiber diet. *Curling's ulcer* is a type of gastroduodenal ulcer characterized by diffuse superficial lesions (including mucosal erosion). It is caused by a generalized stress response to decreased blood flow to the GI tract. The patient has increased gastric acid secretion.

Aim to prevent Curling's ulcer by feeding the patient as soon as possible after the burn injury. Antacids, H_2-histamine blockers (e.g.,

ranitidine), and proton pump inhibitors (e.g., omeprazole) are used prophylactically to neutralize stomach acids and inhibit histamine and the secretion of hydrochloric acid (Table 24.13). Patients with major burns may have occult blood in their stools during the acute phase and require close monitoring for bleeding.

Endocrine System

Watch for transient increases in the patient's blood glucose levels because of stress-mediated cortisol and catecholamine release. There is an increased mobilization of glycogen stores and gluconeogenesis. Subsequently, glucose is produced, along with an increase in insulin production. However, insulin's effectiveness is decreased because of relative insulin insensitivity. This results in a high blood glucose level. Hyperglycemia also may be caused by the increased caloric intake needed to meet some patients' metabolic requirements. When hyperglycemia occurs, check blood glucose levels and give insulin as ordered. Point-of-care testing of glucose can be done, but serum glucose testing is more accurate. As the patient's metabolic demands are met and less stress is placed on the entire system, this stress-induced condition is reversed.

Nursing and Interprofessional Management: Acute Phase

The major therapeutic interventions in the acute phase are (1) wound care, (2) excision and grafting, (3) pain management, (4) PT and OT, and (5) nutritional therapy.

Wound Care

The goals of wound care are to (1) prevent infection by cleansing and debriding the area of necrotic tissue that would promote bacterial growth and (2) promote wound re-epithelialization and/or successful skin grafting.

Wound care consists of ongoing observation, assessment, cleansing, debridement, and dressing reapplication. Nonsurgical debridement, dressing changes, topical antimicrobial therapy, graft care, and donor site care are done as often as needed, depending on the topical cream or dressing ordered. Enzymatic debriding agents made of natural ingredients, such as collagenase, may be used for *enzymatic debridement* of burn wounds, which speeds up the removal of dead tissue from the healthy wound bed.

Cleanse wounds with soap and water or normal saline-moistened gauze to gently remove the old antimicrobial agent and any loose necrotic tissue, scabs, or dried blood. During the debridement phase, cover the wound with topical antimicrobial creams (e.g., silver sulfadiazine) or silver-impregnated dressings. When the partial-thickness burn wounds have been fully debrided, a protective, coarse or fine-meshed, greasy-based (paraffin, petrolatum) gauze dressing is applied to protect the re-epithelializing keratinocytes as they resurface and close the open wound bed.

If grafting is done, protect the skin graft (discussed later) with the same greasy gauze dressings next to the graft, followed by saline-moistened middle dressing and dry gauze outer dressings. With facial grafts, the unmeshed sheet graft is left open, so it is possible for *blebs* (serosanguineous exudate) to form between the graft and recipient bed. Blebs prevent the graft from permanently attaching to the wound bed. The evacuation of blebs is best done by aspiration with a tuberculin syringe and only by those trained in this specialized skill. (Dressings are discussed in Table 11.9.)

Excision and Grafting

Management of full-thickness burn wounds involves early removal (surgical excision) of the necrotic tissue, followed by application of split-thickness autograft skin.[21] This approach has improved the management and survival rate of burn patients. In the past, patients with major burns had low rates of survival because healing and wound coverage took so long that the patient usually died of sepsis or

malnutrition.

Many patients, especially those with major burns, are taken to the OR for wound excision on day 1 or 2 (emergent phase). The wounds are covered with a biologic dressing or allograft for temporary coverage until permanent grafting can occur (Table 24.12).

During the procedure of **excision and grafting**, devitalized tissue (eschar) is excised down to the subcutaneous tissue or fascia, depending on the degree of injury. Surgical excision can result in massive blood loss. To decrease surgical blood loss, topical application of epinephrine or thrombin, injection of saline and epinephrine, application of extremity tourniquets, or application of a fibrin sealant (Artiss) is used.

Once hemostasis has been achieved, a graft is then placed on clean, viable tissue to achieve good adherence. Whenever possible, the freshly excised wound is covered with *autograft* (the person's own) skin (Table 24.12). Recently, fibrin sealant has been used to attach skin grafts to the wound bed. Grafts also can be stapled or sutured into place (Fig. 24.12, *A*). Negative pressure wound therapy dressings are often placed on top of skin grafts to optimize adherence of the graft to the excised wound bed.[22] A temporary allograft can be used to test the suitability of the recipient site to accept a graft. The allograft is then removed several days later in the OR and an autograft applied.

With early excision, function is restored, and scar tissue formation is minimized. Clots between the graft and wound keep the graft from adhering to the wound. Outer occlusive dressings apply just enough pressure to promote adherence of the graft to the wound bed and help control bleeding. Protect the grafted area from shearing, friction, and pressure. Facial, neck, and hand burns require skilled nursing care to identify and manage clots quickly for the best functional and aesthetic outcomes.

Donor skin is taken from the patient for grafting by means of a *dermatome,* which removes a thin split-thickness layer of skin from an unburned site (Fig. 24.12, *B*). The donor skin can be meshed to allow for greater wound coverage, or it may be applied as an unmeshed sheet for a better cosmetic result when grafting the face, neck, and

hands. The donor site now becomes a new open wound.

The goals of donor site care are to promote rapid, moist wound healing; decrease pain at the site; and prevent infection. The choices of dressings for donor sites include transparent dressings (e.g., OpSite), xenograft, silver sulfadiazine, silver-impregnated dressings, calcium alginate, and hydrophilic foam dressings (Fig. 24.12, *C*). Nursing care of the donor site is specific to the dressing used. Several of the newer dressings decrease healing time, which allows earlier reharvesting of skin at the same site. The average healing time for a donor site is 10 to 14 days (Fig. 24.12, *D*).

Cultured Epithelial Autografts

In the patient with large body burns, only a limited amount of unburned skin may be available as donor sites for grafting, and some of that skin may not be suitable for harvesting. **Cultured epithelial autograft (CEA)** is a method of getting permanent skin from a person with limited skin available for harvesting. CEA is grown from biopsy samples obtained from the patient's unburned skin. This procedure is done in suitable patients in some burn centers as soon as possible. The specimens are sent to a commercial laboratory, where the biopsied keratinocytes are grown in a culture medium containing epidermal growth factor. After about 18 to 25 days, the keratinocytes have expanded up to 10,000 times and form sheets that we can use as skin grafts. The cultured skin is returned to the burn center, where it is placed on the patient's excised burn wounds (Fig. 24.13, *A*). CEA grafts generally form a seamless, smooth replacement skin tissue (Fig. 24.13, *B*). Problems related to CEA include a poor graft take because of thin epidermal skin, graft loss during healing, infection, and contracture development.

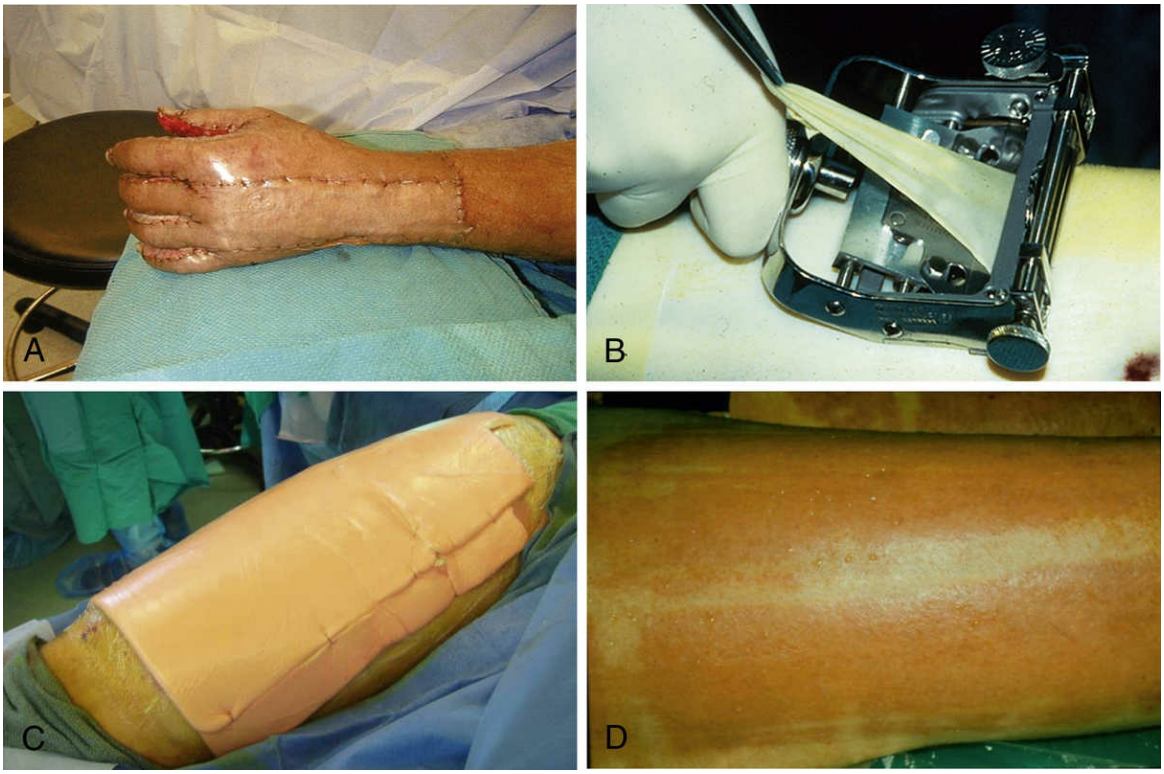

FIG. 24.12 **A,** Freshly applied split-thickness sheet skin graft to the hand. **B,** Split-thickness skin graft is harvested from a patient's thigh using a dermatome. **C,** Donor site is covered with a hydrophilic foam dressing after harvesting. **D,** Healed donor site.

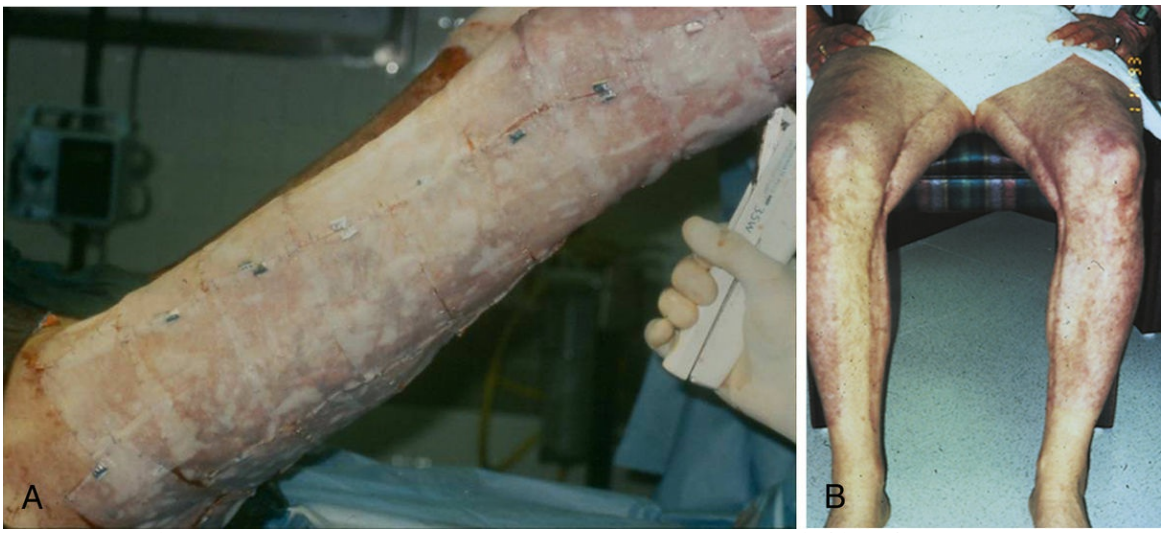

FIG. 24.13 Patient with cultured epithelial autograft (CEA). **A,** Intraoperative application of CEA. **B,** Appearance of healed CEA.

Dermal Substitutes

Dermal substitutes act as a synthetic dermis and are covered by skin graft.[23] The Integra artificial skin dermal regeneration template is an example of a skin replacement system. As with CEA, it is used in the treatment of life-threatening full-thickness or deep partial-thickness burn wounds when a conventional autograft is not available or advisable, as in older or high anesthetic-risk patients. It also has been successfully used in reconstructive burn surgery procedures. It must be applied within a few days postburn for greatest success.

Integra artificial skin has a bilayer membrane composed of acellular dermis and silicone. The wound is excised, the bilayer membrane is placed dermal layer down, and the wound is wrapped with dressings in the OR. The dermal layer functions as a biodegradable template that induces organized regeneration of new dermis by the body. The silicone layer stays intact for 3 weeks as the dermal layer degrades, and epidermal autografts become available. At this point, the silicone is removed during a second surgery and replaced by the patient's own epidermal autografts.

Another dermal replacement is AlloDerm, a cryopreserved allogenic dermis. Human allograft dermis, harvested from cadavers, is decellularized to make it immunogenic and then freeze-dried. Once thawed, AlloDerm is rehydrated in normal saline immediately before placement on a freshly excised wound.

Pain Management

Many aspects of burn care cause pain. Eliminating all pain is difficult, but most patients will have acceptable levels of relative comfort if they receive adequate analgesia. To provide effective pain management, you must understand both the physiologic and psychologic aspects of pain. Pain management is discussed in Chapter 8.

Burn patients have 2 kinds of pain: (1) *continuous, background pain* that might be present throughout the day and night; and (2) *treatment-induced pain* associated with dressing changes, ambulation, and

rehabilitation activities. The first line of pain treatment is drugs (Table 24.13). With background pain, frequent IV administration of an opioid (e.g., hydromorphone [Dilaudid]) provides a steady, therapeutic level of the drug. If tolerating food, slow-release, twice-daily opioids (e.g., morphine [MS Contin]) can be used. Patient-controlled analgesia (PCA) is used in some burn centers, with varying degrees of success. Anxiolytics (e.g., lorazepam [Ativan], midazolam) and adjuvant analgesics (e.g., gabapentin [Neurontin], pregabalin [Lyrica]), can enhance opioids. The use of these drugs can help reduce the opioid dosage and undesirable side effects.

Breakthrough doses of analgesia must be available regardless of the regimen used. Additional doses of opioids are usually given. For treatment-induced pain, premedicate with an analgesic, and possibly an anxiolytic, via the IV or oral route. For patients with an IV, a short-acting analgesic is often used.

Check Your Practice

Your patient with a burn injury is ordered fentanyl (Sublimaze) before a dressing change. The patient has multiple IV lines, and you are not sure which line to use to insert the drug. You know that mixing up IV lines can lead to serious drug errors.

- How would you determine which IV line to use to give the drug?

Some pain can be managed using nondrug strategies. Relaxation breathing, guided imagery, hypnosis, biofeedback, computerized gaming, and music therapy can help patients cope with pain (see Chapter 6).[24]

Remember, the more control the patient has in managing pain, the more successful the chosen strategies will be. Active participation in asking for time-outs and scheduling treatments and rest periods can help the patient manage feelings of anticipatory pain.

Physical and Occupational Therapy

Continuous PT throughout burn recovery is imperative if the patient is to regain and maintain muscle strength and optimal joint function. A good time for exercise is during dressing changes, when bulky dressings are removed and patients are medicated for pain. Passive and active ROM should be performed on all joints. PT and OT may join the nurse and patient during dressing changes. Ensure that the patient with neck burns continues to sleep without pillows or with the head hanging slightly over the top of the mattress to encourage hyperextension.

Maintain the OT schedule for wearing custom-fitted splints, which are designed to keep joints in functional position. Check the splints often to ensure an optimal fit, with no undue pressure that may lead to skin breakdown or nerve damage.

Nutritional Therapy

The goal of nutritional therapy during the acute burn phase is to provide adequate calories and protein to promote healing. When the wounds are still open, the burn patient is in a hypermetabolic and catabolic state.

The patient may benefit from an antioxidant protocol, which includes selenium, vitamin E, acetylcysteine, ascorbic acid, zinc, and a multivitamin. Meeting daily caloric requirements is crucial and should start within the first 1 to 2 days postburn. The daily estimated caloric needs must be regularly calculated by a dietitian and readjusted as the patient's condition changes (e.g., wound healing improves, sepsis develops). Monitor laboratory values (e.g., albumin, prealbumin, total protein, transferrin) on a regular basis.

If the patient is on mechanical ventilation or unable to eat enough calories by mouth, a small-bore feeding tube is placed, and enteral feedings are started. When the patient is extubated, contact the speech pathologist for a swallowing assessment before an oral diet is started. Encourage the patient to eat high-protein, high-carbohydrate foods to meet caloric goals. Ask caregivers to bring in favorite foods from

home. Appetite is usually reduced, and you will need to reinforce whatever steps are taken to achieve adequate intake. Ideally, weight loss should not be more than 10% of preburn weight. Record the patient's daily caloric intake using calorie count sheets, which are reviewed by the dietitian. Weigh your patient weekly to evaluate progress.

Rehabilitation Phase

The formal *rehabilitation phase* begins when the patient's wounds have nearly healed and they are engaging in some level of self-care. This may happen as early as 2 weeks or as long as 7 to 8 months after a major burn injury. Goals for the patient now are to (1) work toward resuming a functional role in society and (2) rehabilitate from any functional and cosmetic postburn reconstructive surgery that may be needed.

Pathophysiologic Changes and Clinical Manifestations

Burn wounds heal by either spontaneous re-epithelialization or skin grafting. Layers of keratinocytes begin rebuilding the tissue structure destroyed by the burn injury. Collagen fibers, present in the new scar tissue, help with healing and add strength to weakened areas. The new skin appears flat and pink. In about 4 to 6 weeks, the area becomes raised and hyperemic. If adequate ROM is not started, the new tissue will shorten, causing a **contracture**. Mature healing is reached in about 12 months, when suppleness has returned and the pink or red color has faded to a slightly lighter hue than the surrounding unburned tissue.

Tell patients who have more heavily pigmented skin that it will take longer for it to regain its color because many of the melanocytes have been destroyed. Often, the skin does not regain its original color, though this is impossible to predict. Provide teaching and emotional support to help the patient with grieving about these changes to his or

her body. Cosmetic camouflage, the implantation of pigment within the skin, can help even out unequal skin tones and improve the patient's overall appearance and self-image.

Scarring has 2 characteristics: discoloration and contour. The discoloration of scars fades somewhat with time. However, scar tissue tends to develop altered contours. That is, it is no longer flat or slightly raised but becomes elevated and enlarged above the original burned area. Some burn care providers think that pressure can eventually help keep a scar flat. Gentle pressure is maintained on the healed burn with custom-fitted pressure garments and clear, thermoplastic face masks. Pressure garments and masks should never be worn over unhealed wounds. Once a wearing schedule has been set, they are removed only for short periods while bathing. Pressure garments are worn up to 23 hours a day for as long as 12 to 18 months.

The patient typically reports discomfort from itching where healing is occurring. Teach your patient about the application of water-based moisturizers and selective, short-term use of oral antihistamines (e.g., hydroxyzine [Atarax]) to help reduce the itching. Massage, cooling, emollients, gabapentin, antidepressants, and anesthetic creams also may help.[25]

As "old" epithelium is replaced by new cells, flaking occurs. The newly formed skin is extremely sensitive to trauma. Blisters and skin tears are likely to develop from slight pressure or friction. These newly healed areas can be hypersensitive or hyposensitive to cold, heat, and touch. Grafted areas are more likely to be hyposensitive until peripheral nerve regeneration occurs. Have patients protect healed burn areas from direct sunlight for about 3 months to prevent hyperpigmentation and sunburn injury. Tell them to always wear sunscreen when outside.

Complications

The most common complications during the rehabilitation phase are skin and joint contractures and hypertrophic scarring.[26] A *joint*

contracture (an abnormal condition of a joint characterized by flexion and fixation) develops because of the shortening of scar tissue in the flexor tissues of a joint. Areas that are most susceptible to skin and joint contractures include the anterior and lateral neck areas, axillae, antecubital fossae, fingers, groin areas, popliteal fossae, knees, and ankles (Fig. 24.14). Some areas encompass major joints. Not only does the skin over these areas develop contractures, but the underlying tissues, such as the ligaments and tendons, tend to shorten during the healing process.

Carefully watch the patient for these potential problems. Encourage proper positioning, splinting, and exercise to minimize this complication. Tell the patient to continue with these strategies until the skin matures at around 1-year post healing. Rehabilitative therapy is aimed at the extension of body parts because the flexors are stronger than the extensors. Burned legs first may be wrapped with elastic (e.g., tensor, ACE) bandages to assist with circulation to leg-graft and donor sites before ambulation. Burned arms can be wrapped with a layer of tubular elastic gauze (e.g., Tubigrip). This interim pressure prevents blister formation, promotes venous return, and decreases pain and itchiness. Once the skin is completely healed and less fragile, custom-fitted pressure garments replace the elastic bandages and tubular gauze.

FIG. 24.14 Neck contracture.

Nursing and Interprofessional Management: Rehabilitation Phase

During the rehabilitation phase, encourage both the patient and caregiver to take part in care. Since the patient may go home with unhealed wounds, teach your patient and caregiver the skills for wound care. Before discharge, have them show you the proper dressing change. In addition, make sure they know when to contact the burn team (e.g., signs of infection, increased pain) and the need to keep outpatient visits to ensure good wound healing.

If needed, arrange home care nursing to assist with care. The newly discharged patient will need to know how to gently remove the dressings in the shower once daily, if a nonadherent, greasy gauze dressing is used or twice daily if a topical, antimicrobial cream is ordered. Teach that showering, not bathing, with mild soap and warm water keeps the wounds clean.

Give advice on scar management, moisturizing, and sun protection. Suggest using water-based creams that penetrate the dermis (e.g., Vaseline Intensive Rescue) on healed areas to keep the skin supple and moisturized. This will decrease itching and flaking. Sometimes antihistamines are used at bedtime if itching persists.

Base ongoing pain management and nutritional needs on individual patient status. Continue to encourage the patient to perform the PT and OT routines. Encourage and reassure the patient to maintain morale, particularly once the patient realizes that recovery can be slow. Rehabilitation may have to be a primary focus for at least the next 6 to 12 months.

Postburn reconstructive surgery is often done after a major burn. The need for further surgery is reviewed at the outpatient burn clinic appointments after discharge.

Gerontologic Considerations: Burns

The older patient presents many challenges for the burn team.[27] The normal aging process puts the patient at risk for injury because of unsteady gait, limited eyesight, and decreased hearing. As people age, skin becomes drier and more wrinkled. Older adults have thinning of the dermal layer, a loss of elastic fibers, a reduction in subcutaneous adipose tissue, and a decrease in vascularity. As a result, the thinner dermis, with reduced blood flow, sustains deeper burns with poorer rates of healing.

Once injured, the older adult has more complications in the emergent and acute phases of burn resuscitation because of preexisting co-morbidities. For example, older patients with diabetes, heart failure, or COPD have morbidity and mortality rates exceeding

those of healthy, younger patients. In older patients, pneumonia is a frequent complication, burn wounds and donor sites take longer to heal, and surgical procedures are not well tolerated. Weaning from a ventilator can be a challenge. Although usually self-limiting, delirium, if it develops, may be distressing.[28] It usually takes longer for these patients to rehabilitate to the point at which they can safely return home. For some, a return home to independent living may not be possible. As the population ages, developing strategies to prevent burn injuries in older adults is a priority.

Emotional/Psychologic Needs of Patients and Caregivers

Patients and caregivers have many emotional/psychologic needs during the often lengthy, unpredictable, and complex course of care. You have an important supportive and counseling role as patients struggle to get their lives back on track.

To manage the enormous range of emotional responses that the burn patient may have, assess the circumstances of the burn (e.g., cause, people involved), family relationships, and previous ways of coping with stress. At any time, the patient may have a variety of emotions, such as fear, anxiety, anger, guilt, and depression (Table 24.14).

Burn survivors often have thoughts and feelings that are frightening and disturbing, such as guilt about the burn incident, reliving the burn experience, fear of dying, concern about future therapy and surgery, frustrations with ongoing discomfort and treatment, and hopelessness about the future. During recovery, as more independence is expected from the patient, new fears may occur: “Can I really do this?” “Am I a desirable person?” “How can I go outside looking like this?” These challenges confront patients throughout their recovery and often for years to come.

A burn injury may adversely affect the person’s self-esteem. Some may fear the loss of relationships because of perceived or actual

physical disfigurement. In a society that values physical beauty, changes in body image can result in psychologic distress.

Open and frequent communication among the patient, caregivers, close friends, and burn team members is essential. Because of the tremendous psychologic impact of a burn injury, be particularly sensitive to the patient's emotions and concerns. Encourage the patient to discuss fears about loss of life as they once knew it, loss of function, temporary or permanent deformity and disfigurement, return to work and home life, and financial burdens resulting from a long and costly hospitalization and rehabilitation.[29]

TABLE 24.14 Common Emotional Responses

Emotion	Possible Verbal Expression
Anger	• Why did this happen to me? • The nurses enjoy hurting me. • I hope the person who did this to me dies.
Anxiety	• I feel out of control. • What's going to happen to me? • When will I look normal again?
Depression	• It is no use going on like this. • I do not care what happens to me. • I wish people would leave me alone.
Fear	• Will I die? • What will happen next? • Will I be disfigured? • Will my family and friends still love me?
Guilt	• If only I had been more careful. • I'm being punished because I did something wrong.
Hopefulness	• What do I need to do to survive this injury emotionally and return to my life/family/friends? • What am I meant to learn from this injury?

Encourage appropriate independence and an eventual return to preburn activities, such as school or work. Peer counseling and informal interactions with other burn survivors may bring comfort and help to restore confidence. Reassure patients that their feelings during this period of adjustment are a normal reaction to an extraordinary life event. Their frustration and impatience are to be expected as they work to establish a new life. Help patients in

adapting to a realistic, yet positive appraisal of their specific situation, emphasizing what they *can* do instead of what they *cannot* do.

Caregivers may share some or all these challenges and feelings. At times, they may feel helpless or too exhausted to help their loved one. Continued support from trusted and familiar burn team members is essential. Helping caregivers assist with aspects of the patient's care helps them to reconnect with their loved one and eases the transition home. Many burn survivors and their caregivers remark on the powerful learning experience of the burn and a renewed appreciation of life, despite the ongoing challenges of a prolonged recovery. You must acknowledge that their feelings are real and common. Most burn survivors speak of a real satisfaction with their postburn life and are more empowered as time goes on.

It is important to address individual spiritual and cultural needs because both have a role in treatment decisions and recovery. Pastoral care may be a helpful resource for the patient and caregiver. The need for support, information, and family involvement may vary among cultures. Identify what is important to your patient and caregiver and communicate that information in the patient's plan of care. Encourage the burn care team to be culturally aware of and sensitive to the patient's and caregiver's cultural needs.

The difficult issue of sexuality must be met with honesty. Acceptance of any changes in physical appearance is difficult at first for the patient and significant other. The nature of skin injury in itself can cause modifications in processing sexual stimuli.[30] Touch is an important part of sexuality, and immature scar tissue may make the sensation of touch unpleasant or may dull it. This may be only transient, but the patient and partner need to know that it is normal and receive anticipatory guidance from the burn team to avoid undue emotional strain.

Burn survivors may have preexisting mental health or substance use issues, any of which may have contributed to the burn incident.[31] The stress of the burn injury can precipitate a psychologic crisis. Assessment by a psychiatrist who can prescribe appropriate drugs, if needed, and offer counseling is often helpful. Early psychiatric

intervention is essential if the patient has been previously treated for a psychiatric illness or if the injury was a suicide attempt. Many burn patients have posttraumatic stress disorder. A history of mental health issues can influence the length of hospitalization and time needed to prepare for discharge.[31] However, it has been noted that distress and trauma symptoms can act as a catalyst for positive posttraumatic growth. Coping styles and social support assist in these positive changes postburn.[32]

Psychologic care typically begins in the hospital, but links to community resources must be made before discharge to ensure continuity of treatment. A referral to a psychiatrist, psychologist, psychiatric advanced practice nurse (APN), mental health counselor, or social worker should be discussed if concerns are raised at burn clinic follow-up.

Caregiver and patient support groups may be beneficial in meeting the patient's and caregiver's emotional needs at any phase of the recovery process. Speaking with others who have had burn trauma can be beneficial, both in terms of confirming that the patient's feelings are normal and in sharing helpful advice. The Phoenix Society (*www.phoenix-society.org*) is an international, highly respected burn survivors' support group. For many years the society has offered valuable support and resources (e.g., annual World Burn Congress conference) to burn survivors, caregivers, and burn team staff.

Special Needs of Nurses

Warm, trusting, and mutually satisfying relationships often develop between burn patients and nursing staff during hospitalization and the long-term rehabilitation period. Sometimes the bond can be so strong that the patient has difficulty separating from the hospital and staff. The frequency and intensity of family contact can be rewarding as well as draining to you. You may find it difficult to cope with the deformities caused by the burn injury, odors, unpleasant sight of the wound, and reality of the pain that accompanies the burn and its treatment. Do not hesitate to seek help from co-workers, a manager, or

the employee assistance program should you feel the need.

In time, you will come to know that the specialized burn care you provide makes a critical difference in helping patients not only survive but also cope with and triumph over an intense and complex injury.

Ongoing support services or critical incident stress debriefings led by a psychiatrist, psychologist, psychiatric APN, or social worker may be helpful. Peer support groups (e.g., ABA, International Society for Burn Injuries) can serve a similar purpose by helping you cope with difficult feelings experienced when caring for burn patients. Because burn nursing is physically, psychologically, and intellectually demanding, it has many challenges and inherent rewards. Attention to your own self-care is important to maintain a positive attitude and healthy work-life balance. Time with family and friends and rest and relaxation at home are essential parts of self-care and a balanced life with purpose and meaning.

Case Study

Burn Injury

© Comstock/Thinkstock.

Patient Profile

G.M., a 52-yr-old married white man, arrives at the ED with burns to

his face, neck, chest, right arm and hand, and right foot. He was burning brush on his farm when the fire went out of control. He has an 18-gauge IV with NSS running at 100 mL/hr, and he is receiving 100% humidified O_2 by mask.

Subjective Data

- Reports blurry vision and trouble swallowing
- States his burns are painful and that he is scared
- States he is a "diabetic" and has "high blood pressure"

Objective Data
Physical Examination

- Is awake, alert, and oriented, but in some distress
- Eyes are red, irritated
- Voice is hoarse; nasal hair is singed
- Face is reddened with blisters noted on the nose and forehead
- Right arm, right hand, anterior chest, neck, and right foot have shiny, bright red, wet wounds
- Is shivering

Discussion Questions

1. ***Priority Decision:*** What are the priorities of care in the prehospital setting and ED? How should his airway, breathing, and circulation be managed?
2. ***Priority Decision:*** What factors place G.M. at high risk for an inhalation injury? What priority interventions can be anticipated?
3. ***Patient-Centered Care:*** What pain medications might be considered to relieve his pain?
4. Which of the criteria for burn center referral does G.M. meet for

admission to the hospital burn unit?

5. What metabolic disturbances would be expected soon after G.M.'s admission? Explain the physiologic basis for these changes.
6. How might G.M.'s co-morbidities affect his burn care and rehabilitation?
7. ***Patient-Centered Care:*** What measures should be taken to support G.M.'s caregivers?
8. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
9. ***Evidence-Based Practice:*** What are the most effective wound care strategies to manage G.M.'s burn wounds?
10. ***Patient-Centered Care:*** Prior to discharge what teaching should be provided to G.M. and his family so they can successfully manage his care at home?
11. ***Safety:*** To ensure G.M.'s safety at home, what interventions are necessary prior to discharge?
12. ***Quality Improvement:*** What outcomes will indicate that interprofessional care was effective?

Case Study

Managing Care of Multiple Patients

You are working the day shift on a medical-surgical unit and have been assigned to care for the following 5 patients. You have 1 UAP who is assigned to work with you. There are 15 other patients on the unit being cared for by an additional 3 RNs and 3 UAP.

Patients

 © Jack Hollingsworth/Photodisc/Thinkstock.	F.M., an 81-yr-old Hispanic woman, had pneumatic retinopexy surgery yesterday to repair a partial detached retina. She has a history of type 2 diabetes, hypothyroidism, and hypertension. She is scheduled to be discharged today, but the night nurse is concerned because her BP is elevated at 150/94 mm Hg.
 © iStock.com/EyeMark.	R.S., a 57-yr-old woman, is under observation with Ménière's disease. She continues to have extreme dizziness, tinnitus, and nausea. The HCP plans to administer an intratympanic injection of dexamethasone today.
 © Stockphoto/Thinkstock.	D.A., a 74-yr-old woman, is admitted to the hospital with complaints of chest tightness and shortness of breath. Her past medical history is negative except for a recent diagnosis of basal cell carcinoma (BCC) on her face. She was scheduled to have the BCC surgically removed tomorrow. The HCP suspects D.A.'s symptoms are caused by anxiety but first needs to rule out any coronary artery disease before surgery.
 © Dimedrol68/iStock/Thinkstock.	G.L., a 48-yr-old white man, just arrived for admission. He is scheduled for surgical removal of melanoma lesions on his face at 1200. He is worried that the surgery will be disfiguring.
 © Stockphoto/Thinkstock.	D.B., a 74-yr-old white man, was admitted 3 hours ago from the ED with partial thickness burns on his chest and arms (estimated to be 6% TBSA). He was burning leaves and branches using gasoline. The pile exploded and his clothes caught fire.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide rationale.
2. ***Collaboration:*** Which tasks could you delegate to the UAP *(select all that apply)*?
    a. Obtain vital signs on F.M.
    b. Take a blood pressure reading on D.B.
    c. Perform an admission assessment on G.L.
    d. Explain planned diagnostic testing to R.S.
    e. Obtain a 12-lead electrocardiograph on D.A.
3. ***Priority Decision and Collaboration:*** When you enter D.B.'s room, he tells you he is not feeling well. He says he has a headache and his legs are "cramping up." He is also somewhat confused as he is unaware that he is in the hospital. What initial action would be *most* appropriate?
    a. Administer acetaminophen for headache relief.
    b. Have the UAP obtain a STAT capillary blood glucose reading.
    c. Notify D.B.'s health care provider of his altered level of consciousness.
    d. Ask the UAP to obtain vital signs on D.B. while you review recent laboratory results.

Case Study Progression

D.B.'s vital signs are BP 154/88 mm Hg, heart rate is 112 bpm, respirations are 18 breaths/min, and temperature is 98°F (36.8°C). His most recent laboratory results reveal a serum sodium level of 128 mEq/L (128 mmol/L). You notify his HCP, who orders a normal saline IV to infuse at 100 mL/hr.

4. D.B. complains of thirst and asks for something to drink. Which fluids would be appropriate to give him *(select all that apply)*?
    a. Gatorade

b. Tap water
c. Cola soda
d. Apple juice
e. Orange juice

5. In addition to teaching F.M. how to administer postoperative eyedrops, you will also explain
    a. position and activity restrictions.
    b. how to change the dressing on her eye.
    c. the necessity for restricting fluid intake.
    d. that protective eyewear will no longer be required.
6. When giving report to your UAP regarding your assigned patients, you are asked by the UAP if there is a significant difference between D.A. and G.L.'s skin cancers. You reply based on knowledge that
    a. basal cell carcinoma is the deadliest form of skin cancer.
    b. melanoma typically appears as red, rough patches on the skin.
    c. melanoma can metastasize to any organ, including the brain and heart.
    d. basal cell carcinoma often occurs during the second and third decades of life.
7. ***Management Decision:*** Another RN offers to help you by providing care for F.M. Which observed action by the RN would require your immediate intervention?
    a. The RN assists F.M. to lie flat on her back.
    b. The RN gives F.M. oral medication for pain.
    c. The RN assures F.M. that retinal reattachment is usually successful.
    d. The RN explains to F.M. that she is at risk for detachment in the other eye.
8. ***Priority Decision***: Which intervention has the *highest* priority for R.S.?
    a. Keeping the room dark and quiet.
    b. Placing an emesis basin at the bedside.

c. Elevating the head of the bed to the height desired.
d. Raising the side rails and having the bed in low position.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to NCLEX Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which prevention strategy would the nurse include when teaching about home fire safety?
   a. Set hot water temperature at 140°F.
   b. Use only hardwired smoke detectors.
   c. Encourage regular home fire exit drills.
   d. Do not allow older adults to cook unattended.
2. The injury that is *least* likely to result in a full-thickness burn is
   a. sunburn.
   b. scald injury.
   c. chemical burn.
   d. electrical injury.
3. When assessing a patient with a partial-thickness burn, the nurse would expect to find *(select all that apply)*
   a. blisters.
   b. exposed fascia.
   c. exposed muscles.
   d. intact nerve endings.

e. red, shiny, wet appearance.

4. A patient is admitted to the burn center with burns to his head, neck, and anterior and posterior chest after an explosion in his garage. On assessment, the nurse auscultates wheezes throughout the lung fields. On reassessment, the wheezes are gone, and the breath sounds are greatly decreased. Which action is the *most* appropriate for the nurse to take *next*?
   a. Encourage the patient to cough and auscultate the lungs again.
   b. Obtain vital signs, oxygen saturation, and a STAT arterial blood gas.
   c. Document the findings and continue to monitor the patient's breathing.
   d. Anticipate the need for endotracheal intubation and notify the provider.

5. Fluid and electrolyte shifts that occur during the early emergent phase of a burn injury include
   a. adherence of albumin to vascular walls.
   b. movement of potassium into the vascular space.
   c. movement of sodium and water into the interstitial space.
   d. hemolysis of red blood cells from large volumes of rapidly administered fluid.

6. To maintain a positive nitrogen balance in a major burn, the patient must
   a. eat a high-protein, high-carbohydrate diet.
   b. increase normal caloric intake by about four times.

c. eat at least 1500 calories/day in small, frequent meals.

d. eat a gluten-free diet for the chemical effect on nitrogen balance.

7. A patient has 25% TBSA burn from a car fire. His wounds have been debrided and covered with a silver-impregnated dressing. The nurse's *priority* intervention for wound care would be to

a. reapply a new dressing without disturbing the wound bed.

b. observe the wound for signs of infection during dressing changes.

c. apply cool compresses for pain relief in between dressing changes.

d. wash the wound aggressively with soap and water three times a day.

8. Pain management for the burn patient is *most* effective when *(select all that apply)*

a. a pain rating tool is used to monitor the patient's level of pain.

b. painful dressing changes are delayed until the patient's pain is completely relieved.

c. the patient is informed about and has some control over the management of the pain.

d. a multimodal approach is used (e.g., sustained-release and short-acting opioids, NSAIDs, adjuvant analgesics).

e. nonpharmacologic therapies (e.g., music therapy, distraction) replace opioids in the rehabilitation phase of a burn injury.

9. A therapeutic measure used to prevent hypertrophic scarring during the rehabilitation phase of burn recovery is
   a. applying pressure garments.
   b. repositioning the patient every 2 hours.
   c. performing active ROM at least every 4 hours.
   d. massaging the new tissue with water-based moisturizers.

10. A patient is recovering from second- and third-degree burns over 30% of his body, and the burn care team is planning for discharge. The *first* action the nurse should take when meeting with the patient would be to
   a. arrange a return-to-clinic appointment and prescription for pain medications.
   b. teach the patient and the caregiver proper wound care to be performed at home.
   c. review the patient's current health care status and readiness for discharge to home.
   d. give the patient written information and websites for information for burn survivors.

1. c, 2. a, 3. a, d, e, 4. d, 5. c, 6. a, 7. b, 8. a, c, d, 9. a, 10. c

Problems of Oxygenation: Ventilation

OUTLINE

25. Assessment: Respiratory System

26. Upper Respiratory Problems

27. Lower Respiratory Problems

28. Obstructive Pulmonary Diseases

25

Assessment

Respiratory System

Eugene Mondor

LEARNING OUTCOMES

1. Distinguish the structures and functions of the upper respiratory tract, lower respiratory tract, and chest wall.
2. Describe the process that initiates and controls inspiration and expiration.
3. Describe the process of oxygenation and ventilation.
4. Identify the respiratory defense mechanisms.
5. Describe the significance of arterial blood gas values in relation to respiratory function.
6. Relate the signs and symptoms of inadequate oxygenation to physical assessment findings.
7. Link age-related changes of the respiratory system to key differences in assessment findings.
8. Obtain significant subjective and objective assessment data related to the respiratory system.
9. Perform a physical assessment of the respiratory system using the appropriate techniques.
10. Distinguish normal from common abnormal findings in a

physical assessment of a patient's respiratory system.

11. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the respiratory system.

Conceptual Focus

Functional Ability
Gas Exchange

The primary purpose of the respiratory system is gas exchange. This involves the transfer of oxygen (O_2) and carbon dioxide (CO_2) between the atmosphere and blood. While adequate perfusion is needed to distribute O_2 to the body tissues, adequate oxygenation depends on a healthy, functioning respiratory system.

Structures and Functions of Respiratory System

The respiratory system is divided into 2 parts: the upper respiratory tract and the lower respiratory tract (Fig. 25.1).

Upper Respiratory Tract

The *upper respiratory tract* includes the nose, mouth, pharynx, epiglottis, larynx, and trachea. Air enters the respiratory tract through the nose. The nose is made of bone and cartilage. It is divided into 2 nares by the nasal septum. The inside of the nose is shaped into 3 passages by projections called *turbinates.* The turbinates increase the surface area of the nasal mucosa that warms and moistens the air as it enters the nose. The internal nose opens directly into the sinuses. The nasal cavity connects with the pharynx. It is a tubular passageway that is subdivided into 3 parts: the *nasopharynx, oropharynx,* and *laryngopharynx*.

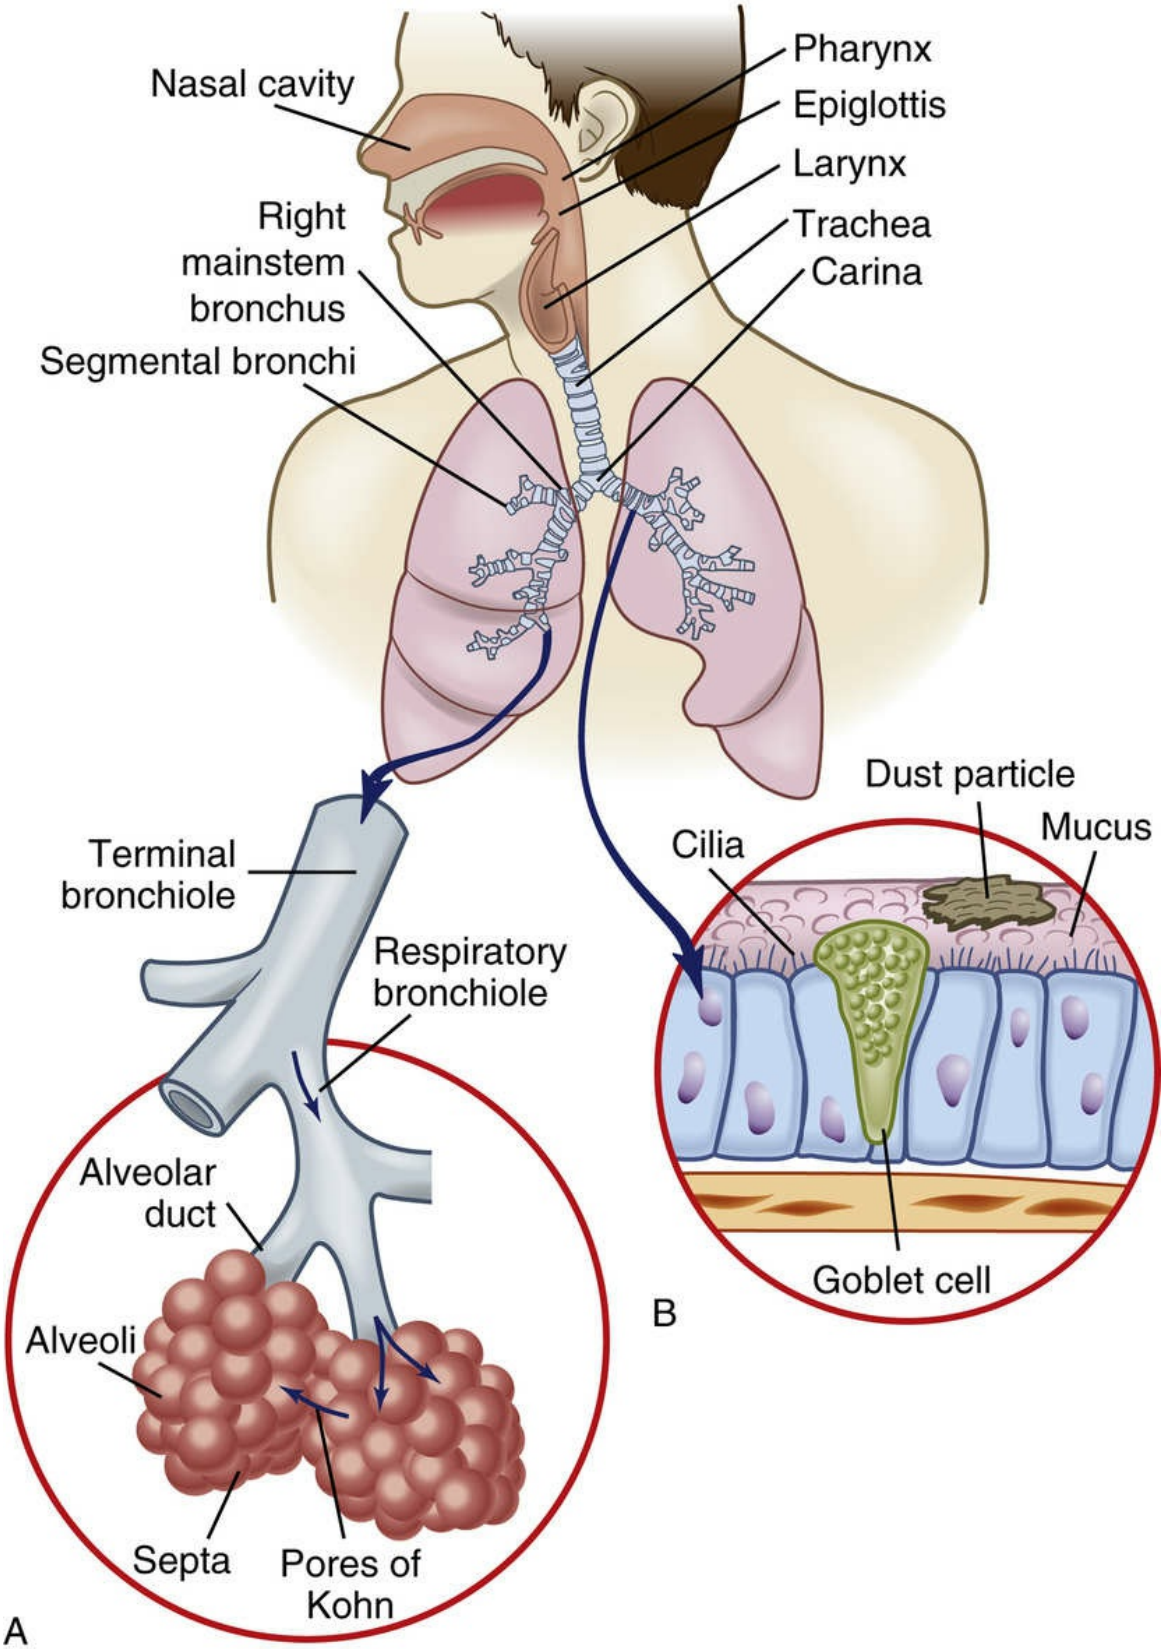

FIG. 25.1 Structures of the respiratory tract. **A,** Pulmonary functional

unit. **B,** Ciliated mucous membrane.

The nose functions to protect the lower airway by warming and humidifying air and filtering small particles before air enters the lungs. The olfactory nerve, found within the mucosa of the upper part of the nasal cavity, is responsible for the sense of smell.[1]

Air moves through the oropharynx to the laryngopharynx. It then travels through the epiglottis to the larynx before moving into the trachea. The *epiglottis* is a small flap behind the tongue that closes over the larynx during swallowing. This prevents solids and liquids from entering the lungs. The vocal cords are in the larynx. Air passes through the glottis (the opening between the vocal cords) and into the trachea.

The trachea is a cylindrical tube about 5 in (10 to 12 cm) long and 1 in (1.5 to 2.5 cm) in diameter. U-Shaped cartilages keep the trachea open but allow the adjacent esophagus to expand for swallowing. The trachea bifurcates into the right and left mainstem bronchi at a point called the *carina.* The carina is located at the *angle of Louis,* which is at the level of the 4^{th} and 5^{th} thoracic vertebrae.[2] The carina is highly sensitive. Stimulation of this area during suctioning causes vigorous coughing.

Lower Respiratory Tract

Once air passes the carina, it is in the lower respiratory tract. The *lower respiratory tract* consists of the bronchi, bronchioles, alveolar ducts, and alveoli. Except for the right and left mainstem bronchi, all lower airway structures are found within the lungs. The right lung is divided into 3 lobes (upper, middle, and lower) and the left lung into 2 lobes (upper and lower) (Fig. 25.2).

The mainstem bronchi, pulmonary vessels, and nerves enter the lungs through a slit called the *hilus.* The right mainstem bronchus is shorter, wider, and straighter than the left mainstem bronchus. That is why aspiration is more likely to occur in the right lung than in the left lung.

The mainstem bronchi subdivide several times to form the lobar, segmental, and subsegmental bronchi. Further divisions form the bronchioles. The most distant bronchioles are the respiratory bronchioles. The bronchioles are encircled by smooth muscles that constrict and dilate in response to various stimuli. The terms *bronchoconstriction* and *bronchodilation* refer to a decrease or increase in the diameter of the airways caused by contraction or relaxation of these muscles. Beyond the bronchioles lie the alveolar ducts and alveoli (Fig. 25.3).

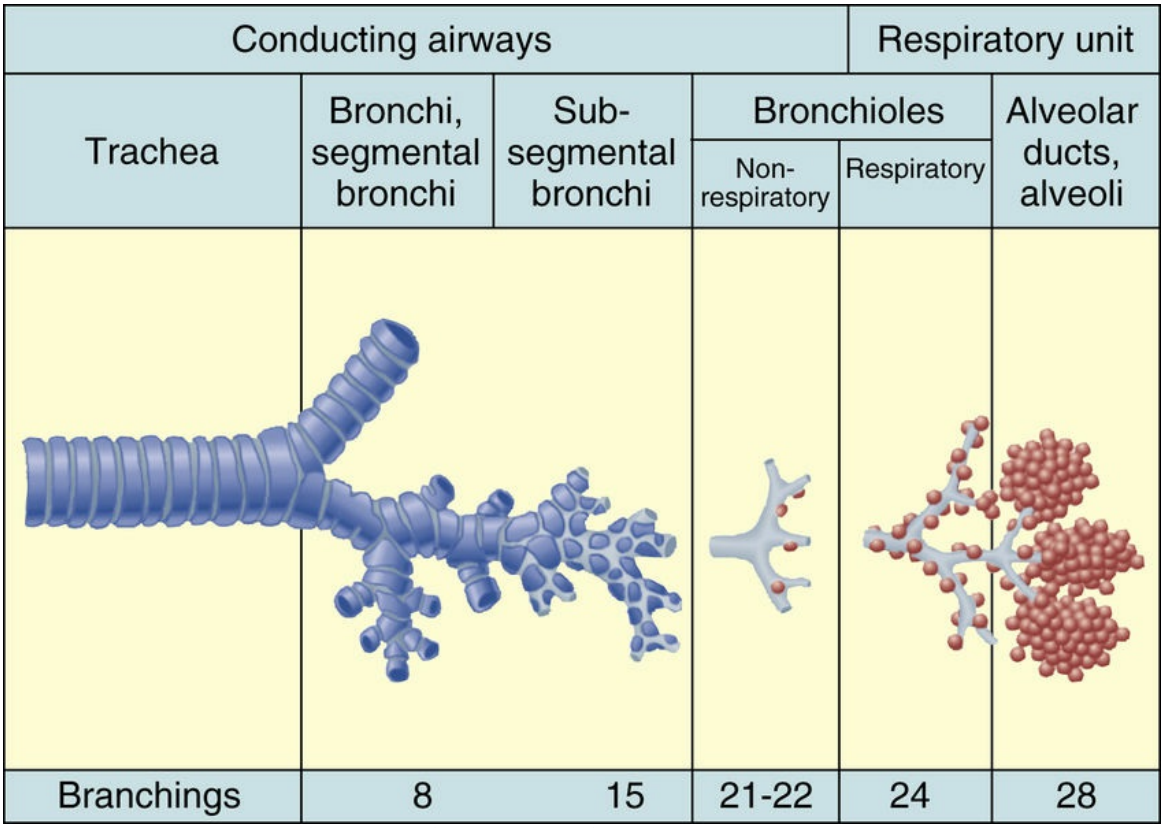

FIG. 25.3 Structures of lower airways.
Redrawn from Thompson JM, McFarland GK, Hirsch JE, et al: *Mosby's clinical nursing,* ed 5, St Louis, 2002, Mosby.

The trachea and bronchi act as a pathway to conduct gases to and from the alveoli. The volume of air in the trachea and bronchi is called the *anatomic dead space* (VD).[3] This air does not take part in gas exchange. In adults, a normal **tidal volume (V_T)**, or volume of air exchanged with each breath, is about 500 mL (in a 150-lb man). Of each 500 mL inhaled, about 150 mL is VD.

The alveoli are the terminal part of the respiratory tract (Fig. 25.3). *Alveoli* are small sacs in the lungs that are the primary site of gas exchange for O_2 and CO_2. The adult lung has over 300 million alveoli, each 0.3 mm in diameter. The alveoli are interconnected by pores of Kohn.[4] They allow movement of air from alveolus to alveolus (Fig. 25.1). Deep breathing promotes air movement through these pores and helps move mucus out of the respiratory bronchioles. Bacteria can also move through these pores, spreading infection to previously uninfected areas. Alveoli have a total volume of about 2500 mL with a

surface area for gas exchange that is about the size of a tennis court.

Gases are exchanged across the alveolar-capillary membrane, where the alveoli come in contact with pulmonary capillaries (Fig. 25.4). In conditions such as pulmonary edema, excess fluid fills the interstitial space and alveoli, markedly reducing gas exchange.

Surfactant

Because alveoli are unstable, they have a natural tendency to collapse. Alveolar cells secrete surfactant. **Surfactant** is a lipoprotein that lowers the surface tension in the alveoli.[5] It reduces the amount of pressure needed to inflate the alveoli and makes them less likely to collapse. Normally, each person takes a slightly larger breath, termed a *sigh,* after every 5 or 6 breaths. This sigh stretches the alveoli and promotes surfactant secretion.

When there is not enough surfactant, the alveoli collapse. The term *atelectasis* refers to collapsed, airless alveoli. The postoperative patient is at risk for atelectasis because of the effects of anesthesia, decreased mobility, and pain, which can alter breathing and lung expansion. In acute respiratory distress syndrome (ARDS), lack of surfactant contributes to widespread atelectasis and collapse of lung tissue (see Chapter 67).

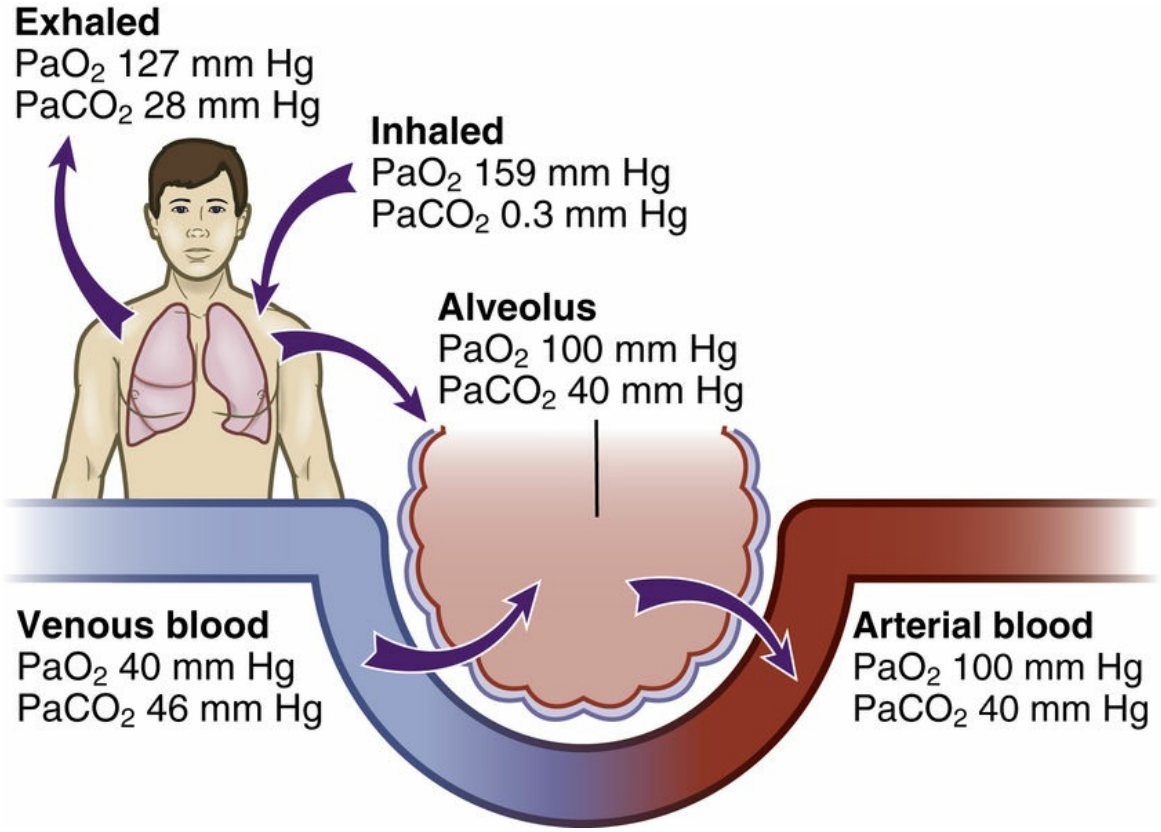

FIG. 25.4 Partial pressure of respiratory gases in normal respiration. The pressures are shown in inhaled and exhaled air from the lungs and at the level of the alveoli and pulmonary venous and arterial blood vessels.

Blood Supply

The lungs have 2 different types of circulation: pulmonary and bronchial. Pulmonary circulation provides the lungs with blood that takes part in gas exchange. The pulmonary artery receives deoxygenated blood from the right ventricle of the heart and delivers it to pulmonary capillaries that lie directly alongside the alveoli. O_2–CO_2 exchange occurs at this point. The pulmonary veins return oxygenated blood to the left atrium, which then delivers it to the left ventricle, and into systemic circulation. Venous blood is collected from capillary networks of the body and returned to the right atrium by way of the superior and inferior vena cava.

Bronchial circulation starts with the bronchial arteries, which arise from the thoracic aorta. Bronchial circulation does not take part in gas

exchange but provides O_2 to the bronchi and other lung tissues. Deoxygenated blood returns from the bronchial circulation through the azygos vein into the superior vena cava.[1]

Chest Wall

The chest wall is shaped, supported, and protected by 24 ribs (12 on each side). The thoracic cage, which consists of the ribs and sternum, protect the lungs and the heart from injury. The *mediastinum* is the space in the middle of the thoracic cavity. It contains the major organs of the chest, including the heart, aorta, and esophagus. The mediastinum physically separates the right and left lungs into 2 separate compartments.

The chest cavity is lined with a membrane called the *parietal pleura.* The lungs are lined with a membrane called the *visceral pleura*. The parietal and visceral pleurae join to form one continuous membrane. The visceral pleura does not have any sensory (pain) fibers or nerve endings. The parietal pleura has pain fibers. This is why irritation or inflammation of the parietal pleura can cause pain with each breath.

The *intrapleural space* is the space between the pleural layers. Normally this space contains 20 to 25 mL of fluid. This fluid serves 2 purposes: (1) it provides lubrication, allowing the pleural layers to slide over each other during breathing and (2) it increases unity between the pleural layers. This promotes expansion of the pleurae and lungs during inspiration.

Fluid drains from the pleural space via lymphatic circulation. Several pathologic conditions may cause the accumulation of greater amounts of fluid, termed a *pleural effusion.* Pleural fluid may accumulate because of blockage of lymphatic drainage (e.g., from cancer) or because of an imbalance between intravascular and oncotic fluid pressures, as in heart failure. Purulent pleural fluid with bacterial infection is called *empyema.*

The *diaphragm* is the major muscle of respiration. During inspiration the diaphragm contracts, moves downward, and increases intrathoracic volume. At the same time, the internal intercostals relax

and the external intercostal muscles contract. This increases the lateral and anteroposterior (AP) dimension of the chest.[6] The scalene muscles also contract on inspiration, raising the first and second ribs. This causes the size of the thoracic cavity to increase and intrathoracic pressure to decrease, pulling air into the lungs.

The diaphragm is made up of 2 hemidiaphragms, each innervated by the right and left phrenic nerves. The phrenic nerves arise from the spinal cord between C3 and C5, the 3rd and 5th cervical vertebrae. Injury to the phrenic nerve results in hemidiaphragm paralysis on the side of the injury. Complete spinal cord injuries above the level of C3 result in total diaphragm paralysis and dependence on a mechanical ventilator.

Physiology of Respiration

Oxygenation

Oxygenation refers to the process of obtaining O_2 from the atmospheric air and making it available to the organs and tissues of the body. The lungs' ability to oxygenate arterial blood adequately is evaluated by partial pressure of O_2 in arterial blood (PaO_2), arterial O_2 saturation (SaO_2), and patient assessment (Table 25.1).

O_2 is carried in the blood in 2 forms: dissolved O_2 and hemoglobin-bound O_2. The PaO_2 represents the amount of O_2 dissolved in the plasma. It is expressed in millimeters of mercury (mm Hg). The SaO_2 is the amount of O_2 bound to hemoglobin in comparison with the amount of O_2 the hemoglobin can carry. The SaO_2 is expressed as a percent. For example, if the SaO_2 is 90%, this means that 90% of hemoglobin attachments for O_2 have O_2 bound to them.

O_2 and CO_2 move back and forth across the alveolar-capillary membrane by diffusion. The overall direction of movement is from the area of higher concentration to the area of lower concentration. Thus O_2 moves from alveolar gas (atmospheric air) into the arterial blood and CO_2 from the arterial blood into the alveolar gas. Diffusion continues until equilibrium is reached.

Ventilation

Ventilation involves *inspiration,* or inhalation (movement of air into the lungs), and *expiration,* or exhalation (movement of air out of the lungs). Air moves in and out of the lungs because intrathoracic pressure changes in relation to pressure at the airway opening. Contraction of the diaphragm and external intercostal and scalene muscles increases chest dimensions, thus decreasing intrathoracic pressure. Gas flows from an area of higher pressure (atmospheric) to one of lower pressure (intrathoracic). When **dyspnea** (shortness of

breath) occurs, neck and shoulder muscles, as well as other accessory muscles of respiration, can aid the effort. Some conditions (e.g., phrenic nerve paralysis, rib fractures, neuromuscular disease) may limit diaphragm or chest wall movement. This causes the patient to breathe with smaller tidal volumes. As a result, the lungs do not fully inflate and gas exchange may be impaired.

In contrast to inspiration, expiration is passive. **Elastic recoil** is the tendency for the lungs to return to their original size after being stretched or expanded. The elasticity of lung tissue is due to the elastin fibers found in the alveolar walls and surrounding the bronchioles and capillaries. The elastic recoil of the chest wall and lungs allows the chest to passively decrease in size (volume). When intrathoracic pressure rises, air moves out of the lungs.

Exacerbations of asthma or chronic obstructive pulmonary disease (COPD) cause expiration to become an active, labored process (see Chapter 28). Abdominal, intercostal, and accessory muscles (e.g., scalene, trapezius) help expel air during labored breathing.

Compliance and Resistance

Compliance (distensibility) is a measure of the ease of expansion of the lungs. This is a product of the elasticity of the lungs and elastic recoil of the chest wall.[6] When compliance is decreased, it is harder for the lungs to inflate. This occurs with conditions that increase fluid in the lungs (e.g., pulmonary edema, ARDS, pneumonia), make lung tissue less elastic or distensible (e.g., pulmonary fibrosis, sarcoidosis), or restrict lung movement (e.g., pleural effusion). Compliance increases when there is destruction of alveolar walls and loss of tissue elasticity, as in COPD.

On the other hand, **resistance** refers to any obstacle to airflow during inspiration and/or expiration. The main factor affecting airway resistance is changes in the diameter (size) of the airways. For example, a patient with an acute asthma attack has narrowed airways, resulting in increased resistance. The presence of secretions in the bronchi also increases resistance. Secretions can partially occlude airways, making airways narrower. This makes it harder for patients

to get air into their lungs. Giving bronchodilators decreases resistance by increasing the diameter of the bronchi, promoting air entry.

Changes in compliance and/or resistance can seriously affect both oxygenation and ventilation.

Control of Respiration

Located in the brainstem, the respiratory center (the medulla) responds to chemical and mechanical signals. The medulla sends impulses to the respiratory muscles through the spinal cord and phrenic nerves.

Chemoreceptors

A **chemoreceptor** is a receptor that responds to a change in the chemical composition ($PaCO_2$ and pH) of the fluid around it. Central chemoreceptors are found in the medulla. They respond to changes in the hydrogen ion (H^+) concentration.[7] An increase in the H^+ concentration *(acidosis)* causes the medulla to increase the respiratory rate and V_T. A decrease in H^+ concentration *(alkalosis)* has the opposite effect. Changes in $PaCO_2$ regulate ventilation primarily by their effect on the pH of the cerebrospinal fluid. When the $PaCO_2$ level is increased, more CO_2 is available to combine with H_2O and form carbonic acid (H_2CO_3). This lowers the cerebrospinal fluid pH and stimulates an increase in respiratory rate. The opposite process occurs with a decrease in $PaCO_2$ level.

Peripheral chemoreceptors are found in the carotid bodies at the bifurcation of the common carotid arteries and in the aortic bodies above and below the aortic arch.[8] The peripheral chemoreceptors respond to decreases in PaO_2 and pH and to increases in $PaCO_2$. These changes also stimulate the respiratory center.

In a healthy person, an increase in $PaCO_2$ or a decrease in pH causes an immediate increase in the respiratory rate. The $PaCO_2$ does not vary more than about 3 mm Hg if lung function is normal. Conditions such as COPD change lung function and may result in

chronically elevated $PaCO_2$ levels. In these instances, the patient is not sensitive to further increases in $PaCO_2$ as a stimulus to breathe and may be maintaining ventilation largely because of a hypoxic drive from the peripheral chemoreceptors (see Chapter 28).

Mechanical Receptors

Mechanical receptors are found in the conducting upper airways, chest wall, diaphragm, and capillaries of the alveoli. They are stimulated by a variety of physiologic factors, such as irritants, muscle stretching, and alveolar wall distortion. The 3 major types of mechanical receptors are irritant, stretch, and juxtacapillary (J) receptors.[9]

Irritant receptors are found in the conducting airways. These receptors are sensitive to inhaled particles and aerosols and, when stimulated, initiate the cough reflex. Signals from stretch receptors, in the smooth muscle of the airways, aid in the control of respiration. As the lungs inflate, stretch receptors activate the inspiratory center to inhibit further lung expansion. This is called the *Hering-Breuer reflex*, and it prevents overdistention of the lungs. Stimulation of J receptors, found in the capillaries of the alveoli, occurs with increased pulmonary capillary pressure. This causes rapid, shallow respiration (tachypnea) seen in pulmonary edema.

Respiratory Defense Mechanisms

Respiratory defense mechanisms are efficient in protecting the lungs from inhaled particles, microorganisms, and toxic gases. The defense mechanisms include air filtration, mucociliary clearance system, cough reflex, reflex bronchoconstriction, and alveolar macrophages.

Filtration of Air

Nasal hairs filter inspired air. In addition, the abrupt changes in direction of airflow that occur as air moves through the nasopharynx and larynx increase air turbulence. This causes particles and bacteria to contact the mucosa lining these structures. Most large particles

(greater than 5 μm) are less dangerous because they are removed in the nasopharynx or bronchi and do not reach the alveoli.

The velocity of airflow slows greatly after it passes the larynx, facilitating the deposition of smaller particles (1 to 5 μm). They settle out the way that sand does in a river, a process termed *sedimentation.* Particles less than 1 μm in size are too small to settle in this manner and are deposited in the alveoli. An example of small particles that can build up is coal dust, which can lead to pneumoconiosis (see Chapter 27).

Mucociliary Clearance System

Below the larynx, the mucociliary clearance system, also called the *mucociliary escalator*, is responsible for the movement of mucus. Goblet cells and submucosal glands continually secrete mucus at a rate of about 100 mL/day. This mucus forms a blanket that contains the impacted particles and debris from distal lung areas (Fig. 25.1). Secretory immunoglobulin A (IgA) in the mucus helps protect against bacteria and viruses.

Cilia cover the airways from the level of the trachea to the respiratory bronchioles (Fig. 25.1). Each ciliated cell has about 200 cilia. They beat rhythmically about 1000 times per minute in the large airways, moving mucus toward the mouth. We normally swallow the mucus without noticing.

The ciliary beat is slower further down the tracheobronchial tree. As a result, we remove particles that penetrate more deeply into the airways less rapidly. Dehydration, smoking, inhalation of high O_2 concentrations, infection, and drugs, such as atropine, anesthetics, alcohol, or cocaine, impair ciliary action. Patients with COPD and cystic fibrosis often have repeated lower respiratory tract infections. These conditions are associated with destroyed cilia, resulting in impaired secretion clearance, a chronic productive cough, and chronic colonization by bacteria. These lead to frequent respiratory tract infections.

Cough Reflex

The cough is a protective reflex that clears the airway by a high-pressure, high-velocity flow of air. It is a backup for mucociliary clearance, especially when this clearance mechanism is overwhelmed or ineffective. Coughing is effective in removing secretions only above the subsegmental level (large or main airways). Secretions below this level must be moved upward by the mucociliary mechanism before we can remove them by coughing.

Reflex Bronchoconstriction

Reflex bronchoconstriction is another defense mechanism. In response to the inhalation of large amounts of irritating substances (e.g., dusts, aerosols), the bronchi constrict to prevent entry of the irritants. A person with hyperreactive airways, such as a person with asthma, may have bronchoconstriction after inhalation of triggers, such as cold air, perfume, or other strong odors.

Alveolar Macrophages

Because there are no ciliated cells below the level of the respiratory bronchioles, the primary defense mechanism at the alveolar level is alveolar macrophages. *Alveolar macrophages* rapidly phagocytize inhaled foreign particles, such as bacteria. The debris is moved to the level of the bronchioles for removal by the cilia or removed from the lungs by the lymphatic system. Particles (e.g., coal dust, silica) that cannot be adequately phagocytized tend to remain in the lungs for indefinite periods and can stimulate inflammatory responses (see Chapter 27). Because alveolar macrophage activity is impaired by cigarette smoke, the smoker who is employed in an occupation with heavy dust exposure (e.g., mining, foundries) is at an especially high risk for lung disease.

Gerontologic Considerations: Effects of Aging on Respiratory System

Age-related changes in the respiratory system can be divided into alterations in structure, defense mechanisms, and respiratory control

(Table 25.2). Structural changes include calcification of the costal cartilages, which can interfere with chest expansion. The outward curvature of the spine is marked, especially with osteoporosis, and the lumbar curve flattens. Therefore the chest may appear barrel shaped, and the older person may need to use accessory muscles to breathe. Respiratory muscle strength progressively declines after age 50. Overall, the lungs in the older adult are harder to inflate.

TABLE 25.2 Gerontologic Assessment DifferencesRespiratory System

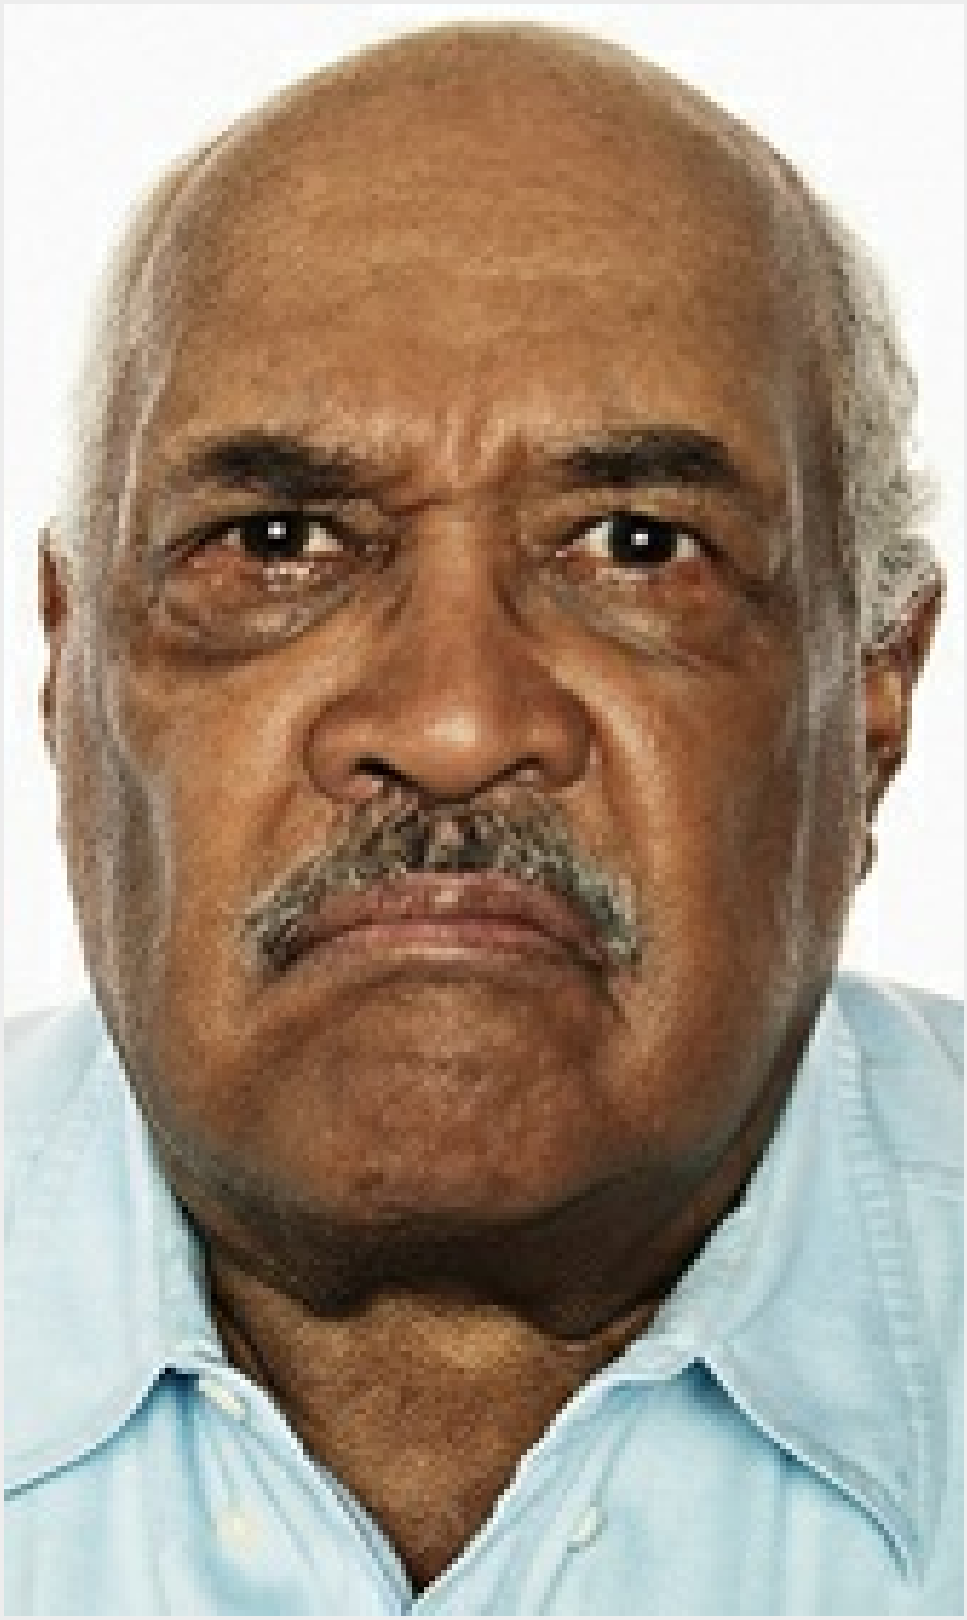
Changes	Differences in Assessment Findings
Structures	
Chest wall stiffening **Costal cartilage calcification** **↑ Anteroposterior diameter** **↓ Elastic recoil** **↓ Chest wall compliance** **↓ Functioning alveoli** **↓ Respiratory muscle strength**	Barrel chest appearance, kyphotic posture, ↓ chest wall movement, ↓ deep breathing, ↓ cough effectiveness ↓ Vital capacity, ↑ residual volume, ↑ functional residual capacity Decreased breath sounds, particularly at lung bases ↓ PaO_2 and SaO_2, normal pH and $PaCO_2$
Defense Mechanisms	
↓ Cell-mediated immunity **↓ Specific antibodies** **↓ Cilia function** **↓ Cough force** **↓ Alveolar macrophage function** **↓ Sensation in pharynx**	↓ Cough effectiveness, ↓ secretion clearance, thickened mucus ↑ Risk for upper respiratory aspiration, infection, influenza, pneumonia Respiratory infections may be more severe and last longer
Respiratory Control	
↓ Response to hypoxemia **↓ Response to hypercapnia**	Slight ↓ PaO_2 and ↑ $PaCO_2$ before respiratory rate changes ↓ Ability to maintain acid-base balance Significant hypoxemia or hypercapnia may develop from relatively small incidents Retained secretions, excessive sedation, or positioning that impairs chest expansion may substantially change PaO_2 or SpO_2 values

Within the lung, the number of functional alveoli decreases and they become less elastic. Small airways in the lung bases close earlier in expiration. Therefore more inspired air is distributed to the lung apices and ventilation is less well matched to perfusion, lowering the PaO_2. As a result, older adults have less tolerance for exertion and dyspnea can occur if their activity exceeds their normal exercise.

In older adults, *respiratory defense mechanisms* are less effective because of a decline in both cell-mediated and humoral immunity

(ability to produce antibodies). The alveolar macrophages are less effective at phagocytosis. An older patient has a less forceful cough and fewer and less functional cilia. Mucous membranes tend to be drier. Retained mucus predisposes the older adult to respiratory tract infections. Formation of secretory IgA, an important defense mechanism, is decreased. Swallowing is slower because of transit time in the pharyngeal area, and there is reduced sensation in the pharynx. Consequently, the older adult is at greater risk for aspiration.

The aging process alters respiratory control, resulting in a more gradual response to changes in blood O_2 or CO_2 level. The PaO_2 may drop to a slightly lower than normal level, and the $PaCO_2$ may rise to a level slightly higher than normal before the respiratory rate changes.



The extent of these changes in people of the same age varies greatly. For example, the older adult who has a significant smoking history, is obese, and has a chronic illness is at greater risk for adverse outcomes.

Assessment of Respiratory System

Determining a patient's needs related to the respiratory system requires an accurate health history and a thorough physical examination. A respiratory assessment can be done as part of a comprehensive physical examination or as a focused respiratory examination. Use judgment in determining whether all or part of the history and physical examination will be completed, based on your immediate assessment of the patient's degree of respiratory distress. If respiratory distress is severe, only obtain pertinent information and defer a thorough assessment until the patient's condition stabilizes.

Case Study

Patient Introduction

© Fuse/Thinkstock.

F.T. is a 70-yr-old black man who comes to the emergency department (ED) with nausea, fatigue, and increased shortness of breath, which started 3 days ago. He says that he started using his albuterol inhaler every 4 hours 2 days ago, and while it worked initially, it is no longer helping. He can walk only a few feet in his apartment before he becomes short of breath. He sleeps in a recliner in the living room. He has noticed some swelling to his hands and feet and has been having trouble urinating.

Discussion Questions

1. What are the possible causes of F.T.'s shortness of breath?
2. Does F.T. need to be admitted to the hospital or is his condition stable and he can be seen by an HCP in a few hours?
3. What questions would be a priority during the subjective assessment?

You will learn more about F.T. and his condition as you read through this assessment chapter.

(See p. 464 for more information on F.T.)

Subjective Data

Important Health Information

Past Health History

It is important to determine the frequency of upper respiratory problems (e.g., colds, sore throats, sinus problems, allergies) and whether seasonal changes influence these problems. Ask about a history of lower respiratory problems, such as asthma, COPD, pneumonia, and tuberculosis (TB).

Ask the patient with allergies about possible precipitating factors or triggers, such as medications, pollen, smoke, mold, or pet exposure. Record the characteristics and severity of the allergic reaction, such as

runny nose, wheezing, scratchy throat, or chest tightness. Determine the frequency of asthma exacerbations.

Because respiratory symptoms are often manifestations of problems that involve other body systems, it is important to ask about a history of other health problems. For example, the patient with heart problems may have dyspnea (shortness of breath) because of heart failure. The patient with human immunodeficiency virus (HIV) infection may have frequent respiratory tract infections because of compromised immune function.

TABLE 25.3 Health HistoryRespiratory System

Health Perception–Health Management

- Describe your daily activities. Have breathing problems prevented you from doing activities that you used to be able to do?* Are your breathing problems better, worse, or about the same compared with 6 months ago?
- How do your breathing problems affect your self-care abilities?
- Have you ever smoked? Do you smoke now? If so, what have you smoked? Cigarettes? Cigars? Pipes? Electronic cigarettes?
- If yes, how many cigarettes each day and for how long? Are you interested in stopping smoking? Are there aids we can tell you about that would assist your quitting? Would you be willing to come back for a visit so that we can explore your quitting? If you stopped smoking, did you do so because of your health?* How did you stop?
- Have you ever used chewing tobacco?
- Have you ever smoked street drugs?*
- Do you get the flu shot yearly? When was your last flu shot? Have you had a Pneumovax vaccination?
- What equipment helps you manage your respiratory problems?

How often do you use it? Does it help? Cause problems?
- Do you feel that your respiratory problem is getting better or worse?

Nutritional-Metabolic

- Have you recently lost weight because of trouble eating related to your respiratory problem? How much weight have you lost? Have you lost this weight voluntarily?
- Do any foods affect your breathing?* Sputum production?*

Elimination

- Does your breathing problem make it hard for you to get to the toilet?*
- Are you inactive because of shortness of breath to the point that you have incontinence?* Constipation?*

Activity-Exercise

- Are you ever short of breath during exercise?* At rest?*
- Do you get too short of breath to do the things you want to do?*
- Is your home 1 story? 2 stories? How many steps from the street to your door?
- Can you walk up a flight of steps without stopping?
- Are you able to maintain your typical activities of daily living? If not, what are you able to do independently? What do you need help with? What have you had to give up?
- What do you do when you get short of breath? Does this help? How long does it take you to recover after you have been short of breath?

Sleep-Rest

- Do breathing problems cause you to wake up during the night?*
- Can you lie flat at night? If not, how many pillows do you use?
- Do you need to sleep upright in a chair?*
- Are you or your partner aware of any snoring?
- Do you awaken in the morning feeling rested?
- Do you ever wake up in the morning with a headache?*
- Do you fall asleep easily during the day?*

Cognitive-Perceptual

- Do you have any pain associated with breathing?* On a scale from 0 to 10, with 0 being "no pain" and 10 being "the worst pain you can imagine," where would you rate your pain? Does it hurt more on inspiration?* Expiration?* Or both?*
- If you are having pain with breathing, describe the pain.
- Has the pain gotten better, worse, or stayed about the same over the past 6 months?
- Do you ever feel restless, irritable, or confused without a reason?*
- Do you have difficulty remembering things?*

Self-Perception–Self-Concept

- Describe how your respiratory problems have changed your life.
- If you use O_2, do you ever go out without bringing it with you? How often does this occur? Why?

Role-Relationship

- Has your respiratory problem caused any problems in your work, family, or social relationships?*

Sexuality-Reproductive

- Has your respiratory problem caused a change in your sexual activity?*
- Have you and your partner talked about ways to minimize your breathing problems during sexual activity?

Coping–Stress Tolerance

- On a daily/weekly basis, how often do you leave your home?
- Do you feel under any stress right now?
- Does stress influence your breathing?*
- Do you notice if your emotions have any effect on your respiratory problems?
- Are you aware of any respiratory support groups in your area?

Value-Belief

- What do you think causes/has caused your respiratory problem(s)?
- How are you feeling right now?
- Do you think the things you have been told to do for your respiratory problems help? If not, why?
- What are you looking for/expecting from the HCP today, in terms of your breathing problem(s)?

---

* If answer is “yes” to any of the above questions, ask the patient to

describe.

Medications

Take a thorough medication history, including the names of prescription and over-the-counter (OTC) medications and nonprescription (illicit) substances. Ask about the dose (if known), frequency, length of time taken, any side effects, and the reason for taking the medication. Assess for overuse of short-term bronchodilators as a key indicator of symptom control. Cough is a common side effect of angiotensin-converting enzyme (ACE) inhibitors. Encourage the patient to bring all medication bottles and any inhalers to each visit with an HCP.

If the patient is using O_2 for a breathing problem, record the fraction of inspired O_2 concentration (FIO_2), flow rate (liters per minute), method of administration, number of hours used per day, and effectiveness of the therapy. Assess safety practices, including the patient's cognitive and physical ability related to using O_2 and any metered-dose inhalers.

Surgery or Other Treatments

Find out if the patient has been hospitalized for a respiratory problem. Note the dates, therapy (including surgery), and status of the problem. Determine if the patient has ever been intubated because of a respiratory problem. Ask about the use of and response to respiratory treatments, such as a nebulizer, humidifier, airway clearance modalities (see Chapter 28), high-frequency chest wall oscillation, postural drainage, and percussion.

Functional Health Patterns

Health history questions to ask a patient with a respiratory problem are outlined in Table 25.3.

Health Perception–Health Management Pattern

Ask the patient if there has been a perceived change in health status

within the last several days, months, or years. In COPD, lung function declines slowly over many years. The patient may not notice this decline because they have been altering activity to accommodate reduced tolerance. If an upper respiratory tract infection is superimposed on a chronic problem, dyspnea and decreased exercise tolerance may occur very quickly. In asthma, symptoms may occur or worsen during exercise, in the presence of mold, or with changes in temperature or air pollution.

Explore common manifestations of respiratory problems (e.g., cough, dyspnea). Describe the course of the patient's illness, including when it began, type of symptoms, and factors that worsen or relieve these symptoms. Because of the chronic nature of respiratory problems, the patient may relate a change in symptoms (rather than the onset of new symptoms) when describing the present illness. For example, increased shortness of breath or increased purulence of sputum may suggest an acute exacerbation of COPD.

If a cough is present, assess its quality. For example, a loose-sounding cough occurs with secretions. A dry, hacking cough may mean an airway irritation or obstruction. A harsh, barky cough suggests upper airway obstruction from inhibited vocal cord movement due to subglottic edema. Assess whether the cough is strong enough to clear secretions. Note whether it is productive or nonproductive of secretions. Determine if the cough is acute or chronic (longer than 3 weeks in duration) or if it first began with an upper respiratory tract infection. The pattern and cause of the cough are determined by asking questions such as: What has been the pattern of coughing? Has it been regular or paroxysmal (i.e., sudden, periodic onset) or related to a time of day, the weather, certain activities, talking, or deep breathing? Any change over time? Do you clear your throat a lot? What have you tried to relieve the coughing? Did you try any prescription or OTC drugs?

If the patient has a productive cough, evaluate the following characteristics of sputum: amount, color, consistency, and odor. Quantify the amount of sputum per day. Note any recent increases or decreases in the amount. Sputum is normally clear or slightly whitish.

If a patient is a cigarette smoker, the sputum is usually clear to gray with occasional specks of brown. The patient with COPD may have clear, whitish, or slightly yellow sputum, especially in the morning on rising. If the patient reports any change from baseline color, suspect pulmonary complications. Note any changes in consistency of sputum to thick, thin, or frothy and pink tinged. These changes may indicate dehydration, postnasal drip or sinus drainage, or possible pulmonary edema. Normally sputum should be odorless. A foul odor or exceptionally bad breath or taste in the mouth suggests an infectious process. Ask the patient if sputum production increases or decreases with changes in position (e.g., increased with lying down) or activity.

When assessing phlegm, determine if the patient has a history of spitting or coughing up blood *(hemoptysis)*. Hemoptysis can range from a slight streaking of blood in the sputum to massive coughing up of blood. The patient may not be able to tell between hemoptysis and *hematemesis* (vomiting blood). Hemoptysis occurs with a variety of conditions such as pneumonia, TB, lung cancer, and severe bronchiectasis.

Assess for a history of any difficulty breathing. For example, *wheezes* are musical sounds that can be audible. Wheezing indicates some degree of airway obstruction, such as asthma, foreign body aspiration, and emphysema. Assess for any history of family exposure to *Mycobacterium tuberculosis.*

Genetic Risk Alert

- Respiratory problems that have a strong genetic link include cystic fibrosis, COPD from α_1-antitrypsin deficiency, and asthma.
- If people have a family history of these respiratory problems, they have a greater risk for developing them.
- Although cigarette smoking is a major risk factor for COPD, only a minority of cigarette smokers develop symptomatic disease. The risk for COPD related to cigarette smoking is genetically

related.

- Determine if there is a family history of any respiratory problems that may have genetic or familial tendencies.

Smoking is the most important risk factor for COPD and lung cancer. Ask about cigarette use and find out about the use of any tobacco products. This includes cigars, pipes, chewing tobacco, electronic cigarettes (e-cigarettes), and hookah (instrument for vaporizing and smoking flavored tobacco). Find out about exposure to secondhand smoke. Determine if the patient has tried to quit using tobacco products, including using prescription, OTC, and herbal remedies.

Discuss current and past smoking habits. Quantify smoking habits in *pack-years*. Do this by multiplying the number of cigarettes smoked per day by the number of years smoked. For example, a person who smoked 20 cigarettes per day for 15 years has a 15 pack-year history.

Assess if the patient received immunizations for influenza (flu) and pneumococcal pneumonia. Patients should receive an influenza vaccine yearly in the fall. Recommendations for pneumococcal vaccines are shown in Table 27.5.

Ask where the patient has lived and traveled. Risk factors for TB include prior residence in China, India, Africa, the former Soviet Republics, Latin America, or any developing country. Other TB risk factors include exposure to people with high rates of TB transmission, such as the homeless, injection drug users, and people with HIV infection. Risk factors for fungal lung infections include those exposed to bird and rodent feces or polluted water, those working closely with the soil, and immunocompromised patients. Ask the patient about the use of equipment to manage respiratory symptoms (e.g., home O_2 equipment, inhalers, devices for sleep apnea). Find out the type of equipment used, cleaning of the device, frequency of use, its effect, and any side effects. Have patients show you the use of their inhalers. Many patients do not use these devices correctly (see Chapter 28).

Nutritional-Metabolic Pattern

Weight loss can be a symptom of respiratory disease. Determine if weight loss was intentional, and, if not, if food intake is changed by anorexia (from medications), fatigue (from hypoxemia, increased work of breathing), or feeling full quickly (from lung hyperinflation). Anorexia, weight loss, and chronic malnutrition are common in patients with COPD, lung cancer, TB, and chronic severe infection (bronchiectasis). Assess fluid intake. Dehydration can cause sputum to thicken and obstruct the airway. Rapid weight gain from fluid retention may impair gas exchange.

Elimination Pattern

Healthy elimination habits depend on a healthy balance between activity and rest. Activity intolerance secondary to dyspnea could result in incontinence, when unable to reach a toilet when needed. Dyspnea can be the cause of limited mobility, which can cause constipation. Ask the patient with dyspnea about frequency, urgency, and elimination patterns (e.g., day vs night). People with a chronic cough, especially women, may have urinary incontinence during paroxysms of coughing.

TABLE 25.4 Dyspnea Rating ScaleModified Borg Rating Scale for Perceived Dyspnea

Rate	Description
0	Nothing at all
0.5	Very, very slight shortness of breath
1	Very mild shortness of breath
2	Mild shortness of breath
3	Mild shortness of breath or breathing difficulty
4	Somewhat severe
5	Strong or hard breathing
6	

7	Severe shortness of breath or very hard breathing
8	
9	Extremely severe
10	Shortness of breath so severe you need to stop

From Hillegass E: *Essentials of cardiopulmonary physical therapy,* ed 4, Philadelphia, 2017, Saunders.

Activity-Exercise Pattern

Determine if dyspnea limits activity. Assess whether the patient's residence (e.g., number of steps, levels) poses any problems. Ask the patient about the perceived degree of the dyspnea (Table 25.4). For example, can the patient walk up 1 flight of stairs without stopping because of dyspnea? Is dyspnea associated with any activity better, worse, or about the same in the last few days? Months? Determine if the patient has difficulty breathing in a certain position, or if dyspnea is relieved by assuming a different position (e.g., tripod position in COPD).

Discuss whether the patient can carry out activities of daily living without dyspnea or other respiratory symptoms. If unable, record the amount and type of care the patient needs. Immobility and sedentary habits are risk factors for hypoventilation leading to atelectasis or pneumonia.

Sleep-Rest Pattern

Determine if the patient wakes up at night because of pulmonary problems. The patient with asthma or COPD may awaken with chest tightness, wheezing, or coughing. This suggests a need for adjunct therapy or other medication changes. The patient with heart disease (e.g., heart failure) may sleep with the head elevated on several pillows to avoid respiratory problems brought on by lying flat *(orthopnea).* Excess weight interferes with normal ventilation and may cause sleep apnea (see Chapter 7). Extremely obese persons may hypoventilate while awake or asleep. Manifestations of sleep apnea include snoring, insomnia, abrupt awakenings, daytime drowsiness,

and early morning headaches. Night sweats may be a sign of TB.

Cognitive-Perceptual Pattern

Because hypoxia can cause neurologic symptoms, ask the patient about apprehension, restlessness, irritability, and memory changes. These can indicate inadequate cerebral oxygenation (Table 25.1). Assess the patient's cognitive ability to cooperate with treatment. Hypoxemia interferes with the ability to learn and retain information. Failure or inability to take part in needed therapy may result in worsening of respiratory problems. For this reason, teaching may be more effective if the caregiver is present during teaching sessions to provide reinforcement later.

Ask about any discomfort or pain with breathing. Explore reports of chest pain carefully to rule out heart involvement. Problems such as pleurisy, fractured ribs, and costochondritis cause chest pain. Careful assessment of the patient having pain with breathing, such as onset, exact location of the pain, and factors that make the pain better or worse, can help establish a diagnosis.

Self-Perception–Self-Concept Pattern

Dyspnea limits activity, impairs ability to fulfill normal roles, and often alters self-esteem. A patient may be reluctant to appear in public with a highly visible nasal cannula and O_2 equipment. A barrel chest, clubbed fingers, pursed-lip breathing, and frequent expectoration of sputum or throat clearing can be embarrassing and can lead to social isolation. Explore with the patient any body image concerns. Referral to a support group or pulmonary rehabilitation program may be beneficial in developing a support system and coping strategies.

Role-Relationship Pattern

Acute and chronic respiratory problems can seriously affect performance in work or other activities. Discuss the impact of medications, O_2 therapy, and special routines (e.g., pulmonary hygiene for cystic fibrosis) on the patient's family, job, and social life.

Review the nature of the patient's work and frequency and intensity of exposure to fumes, toxins, asbestos, coal, fibers, or silica. Ask whether symptoms are worse in specific situations (e.g., home vs. work environments). Hobbies, such as woodworking (sawdust) or pottery (silica), and animal exposure (allergies) can cause respiratory problems. Because of hyperreactive airways, exposure to fumes, smoke, and other chemicals may trigger an attack in the patient with asthma.

Sexuality-Reproductive Pattern

Most patients can continue to have satisfactory sexual relationships despite marked physical limitations. In a tactful manner, ask whether breathing difficulties have caused changes in sexual activity. If so, discuss positions that decrease dyspnea during sexual activity and alternative strategies for sexual fulfillment. For example, patients may need to perform good pulmonary hygiene (bronchodilators, coughing, deep breathing) before intimacy. They may need to use O_2 therapy equipment during intercourse just like they would with any strenuous physical activity.

Coping–Stress Tolerance Pattern

Dyspnea causes anxiety, and anxiety worsens dyspnea. The result is a vicious cycle—the patient avoids activities that cause dyspnea, becoming more deconditioned and more dyspneic. The outcome is often physical and leads to social isolation. Assess how often the patient leaves home and interacts with others. Referral to a support group or pulmonary rehabilitation program may be helpful.

The chronic nature of many respiratory problems, such as COPD and asthma, can cause prolonged stress. Ask about the patient's coping strategies to manage this stress.

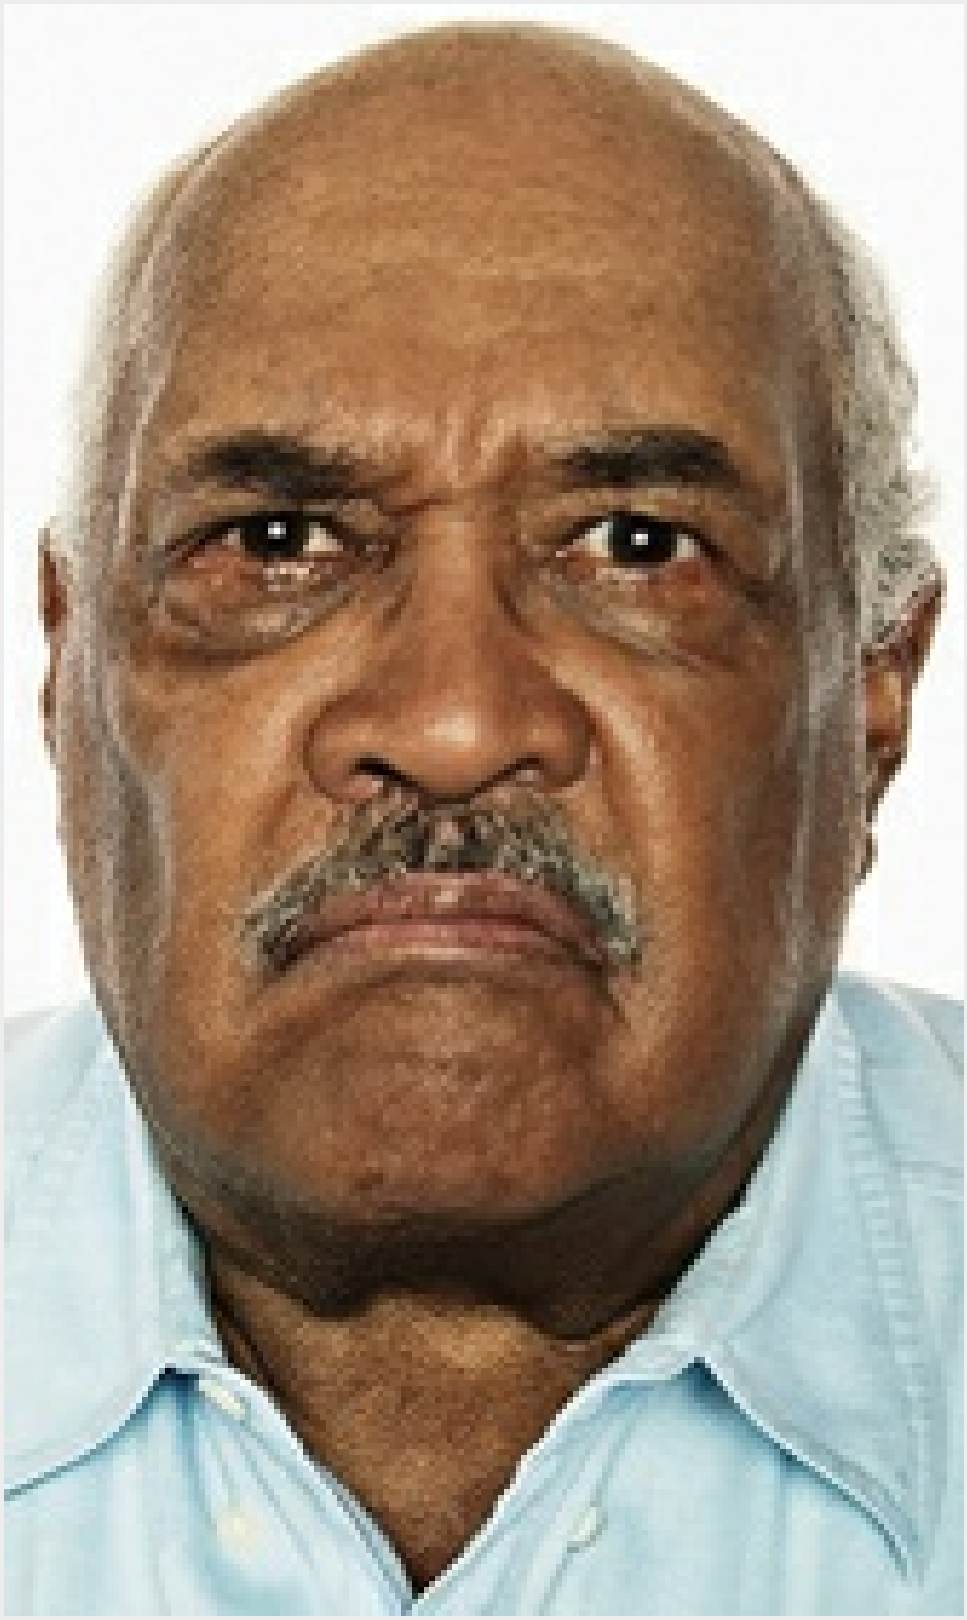
Value-Belief Pattern

Determine the patient's adherence to his or her treatment program. Explore possible reasons for lack of adherence, including conflict with

cultural beliefs, financial constraints (e.g., costs of prescriptions), or failure to understand benefit. Correct misinformation and provide up-to-date information about respiratory conditions and medication management. Including the patient and caregiver in the planning of care can improve adherence.

Objective Data

Physical Examination



Vital signs are important data to collect before examining the respiratory system.

Nose

Inspect the nose for patency, inflammation, deformities, symmetry, and discharge. Check each nare for air patency with respiration while briefly occluding the other nare. Tilt the patient's head backward and push the tip of the nose upward

Case Study

Subjective Data

© Fuse/Thinkstock.

A focused subjective assessment of F.T. revealed the following information:

PMH: COPD, hypertension, heart failure, benign prostatic hyperplasia. No history of allergies.

Medications: Metoprolol (Toprol XL) 50 mg daily PO, furosemide 20 mg PO daily, finasteride (Proscar) 5 mg/day PO, Advair inhaler (fluticasone and salmeterol) 2 puffs twice daily, and albuterol inhaler 2 puffs every 4hr PRN. Uses O_2 @ 3L/min via nasal cannula at home for the past 10 years.

Health Perception–Health Management: States he usually manages his COPD well with the Advair inhaler and occasional use of the albuterol inhaler. He thinks he caught a cold from his granddaughter last week. Increasing difficulty breathing, even with albuterol. Has a history of 30 pack-years of smoking, quitting 5 years ago.

Nutritional-Metabolic Pattern: Eating and drinking very little over past 2 to 3 days.

Elimination: Voiding small amounts of dark, concentrated urine (mostly at night).

Activity-Exercise: At present, cannot walk 100 feet without feeling short of breath. Cannot walk up 1 flight of stairs (21 steps) to get in or out of his apartment without stopping to catch his breath.

Sleep-Rest: Difficulty sleeping. Last night he slept upright in his recliner.

Cognitive-Perceptual: Denies any pain associated with shortness of breath. Feels slightly irritable because of lack of sleep.

Coping–Stress Tolerance: Does not know how he will manage to get groceries or clean his apartment. His daughter lives an hour away and has 3 children in school.

Discussion Questions

1. Of the information provided, which subjective assessment findings are of most concern to you?
2. From the information provided from F.T., what other information would you ask him about his condition (time permitting)?
3. What type of assessment would be most appropriate for F.T.: comprehensive, focused, or emergency?
4. F.T. cannot use his inhaler appropriately while he is talking with you. Is this a good time to teach him about the proper use of his inhaler?
5. What will you include in the physical assessment? What would you think will be priorities in your physical assessment?

You will learn about the physical assessment of the respiratory system in the next section.

(See p. 467 for more information on F.T.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

gently. With a nasal speculum and a good light, inspect the interior of the nose. The mucous membrane should be pink and moist, with no evidence of edema (bogginess), exudate, or bleeding. Inspect the nasal septum for deviation, perforations, and bleeding. Some septal deviation is normal in an adult. Inspect the turbinates for polyps, which are abnormal, fingerlike projections of swollen nasal mucosa. Polyps may result from long-term irritation of the mucosa (e.g., from allergies). Assess any discharge for color and consistency. Purulent and malodorous discharge could occur with a foreign body. Watery discharge could be related to allergies or from cerebrospinal fluid. Bloody discharge could be from trauma or dryness. Thick mucosal discharge could mean an infection.

Mouth and Pharynx

Using a good light source, inspect the interior of the mouth for color, lesions, masses, gum retraction, bleeding, and poor dentition. Inspect the tongue for symmetry and lesions. Observe the pharynx by

pressing a tongue blade gently against the middle of the back of the tongue. If the oropharynx is tight, have the patient yawn, since this usually allows more structures to be visible. The pharynx should be smooth and moist, with no evidence of exudate, ulcerations, swelling, or postnasal drip. Note the color, symmetry, and any enlargement of the tonsils. Stimulate the gag reflex by placing a tongue blade along the side of the pharynx, at the back of the tongue. A normal response (gagging) means that cranial nerves IX (glossopharyngeal) and X (vagus) are intact and that the airway is protected.

Neck

Inspect the neck for symmetry and tender or swollen areas. Palpate the lymph nodes while the patient is sitting erect with the neck slightly flexed. Progression of palpation is from the nodes around the ears, to the nodes at the base of the skull, and then to those under the angles of the mandible to the midline. The patient may have small, mobile, nontender nodes *(shotty nodes),* which are not a sign of a pathologic condition. Tender, hard, or fixed nodes may indicate disease. Describe the location and characteristics of any palpable nodes.

Thorax and Lungs

Picture imaginary lines on the chest to help identify abnormalities (Fig. 25.2). Describe abnormalities in terms of their location relative to these lines (e.g., 2 cm lateral from the right midclavicular line).

Chest examination is best done in a well-lit, warm room with measures taken to ensure the patient's privacy. Expose the patient's chest. Perform all physical assessment maneuvers (inspection, palpation, percussion, auscultation) on either the anterior or the posterior chest first rather than moving from anterior to posterior or vice versa with each maneuver. It is best to begin on the posterior chest, particularly with female patients, since you can obtain more information without interference from breast tissue. If the patient tires or you are interrupted, you will obtain baseline data with the most information from examining the posterior chest.

When assessing the *posterior chest,* ask the patient to lean forward with arms folded. This position moves the scapulae away from the spine, exposing more of the area you need to examine. When assessing the *anterior chest,* have the patient sit upright or position the patient supine with the head of the bed elevated to 30 degrees (semi-Fowler's position). The patient may need to lean forward for support on the bedside table to facilitate breathing.

Inspection

First, observe the patient's appearance and note any evidence of respiratory distress, such as tachypnea or use of accessory muscles. Next, determine the shape and symmetry of the chest. Chest movement should be equal on both sides, and the anterior-posterior (AP) diameter should be less than the side-to-side or transverse diameter. Normal AP ratio is 1:2. An increase in AP diameter (e.g., barrel chest) may be due to normal aging or result from lung hyperinflation. Look for abnormalities in the sternum (e.g., *pectus carinatum* [a prominent protrusion of the sternum]) and *pectus excavatum* (an indentation of the lower sternum above the xiphoid process). Note any spinal curvature. Spinal curvatures that affect breathing include kyphosis, scoliosis, and kyphoscoliosis.

Observe the respiratory rate, depth, and rhythm. The normal adult respiratory rate is 12 to 20 breaths/min. Inspiration (I) should take half as long as expiration (E) (I/E ratio = 1:2). Observe for abnormal breathing patterns, such as *Kussmaul* (rapid, deep breathing), *Cheyne-Stokes* (abnormal respirations characterized by alternating periods of apnea and deep, rapid breathing), or *Biot's* (irregular breathing with apnea every 4 to 5 cycles) respirations.

Skin color provides clues to respiratory status. Cyanosis, a late sign of hypoxemia, is best seen in light-skinned patients as a bluish tinge to the mucous membranes, lips, and palms of the hands. In dark-skinned persons, cyanosis may be seen as a gray or white discoloration in the conjunctivae or around the mouth. Causes of cyanosis include hypoxemia or decreased cardiac output. Inspect the fingers for evidence of long-standing hypoxemia, known as *clubbing.* It is an

increase in the angle between the base of the nail and the fingernail to 180 degrees or more. Clubbing usually accompanied by an increase in the depth, bulk, and sponginess of the end of the finger.

Palpation

Determine tracheal position by gently placing the index fingers on either side of the trachea just above the suprasternal notch and gently pressing backward. Normal tracheal position is midline; deviation to the left or right is abnormal. Tracheal deviation occurs away from the side of a tension pneumothorax or a neck mass, but toward the side of a pneumonectomy or lobar atelectasis.

Symmetry of chest expansion and extent of movement are determined at the level of the diaphragm. Place your hands over the lower anterior chest wall along the costal margin and move them inward until the thumbs meet at midline. Ask the patient to breathe deeply. Observe the movement of the thumbs away from each other. Normal expansion is 1 in (2.5 cm). Hand placement on the posterior side of the chest is at the level of the tenth rib. Move the thumbs until they meet over the spine (Fig. 25.5). You can check expansion anteriorly or posteriorly. It is not necessary to check both.

Normal chest movement is equal. Unequal expansion occurs when air entry is limited by conditions involving the lung (e.g., atelectasis, pneumothorax) or the chest wall (e.g., incisional pain). Equal but decreased expansion occurs in conditions that produce a hyperinflated or barrel chest or in neuromuscular diseases (e.g., amyotrophic lateral sclerosis, spinal cord lesions). Movement may be absent or unequal over a pleural effusion, an atelectasis, or a pneumothorax.

Fremitus is the vibration of the chest wall made by vocalization. You can feel tactile fremitus by placing the palmar surface of your hands against the patient's chest with the fingers hyperextended. Ask the patient to repeat a phrase, such as "boy-oh-boy," "toy boat," or "blue balloons," in a deeper, louder-than-normal voice. At the same time, move your hands from top to bottom on the patient's chest (Fig. 25.6). As you palpate, simultaneously compare vibrations (right side

vs. left side, from top to bottom). Tactile fremitus is most intense by the sternum and between the scapulae because these areas are closest to the major bronchi. Fremitus is less intense farther away from these areas.

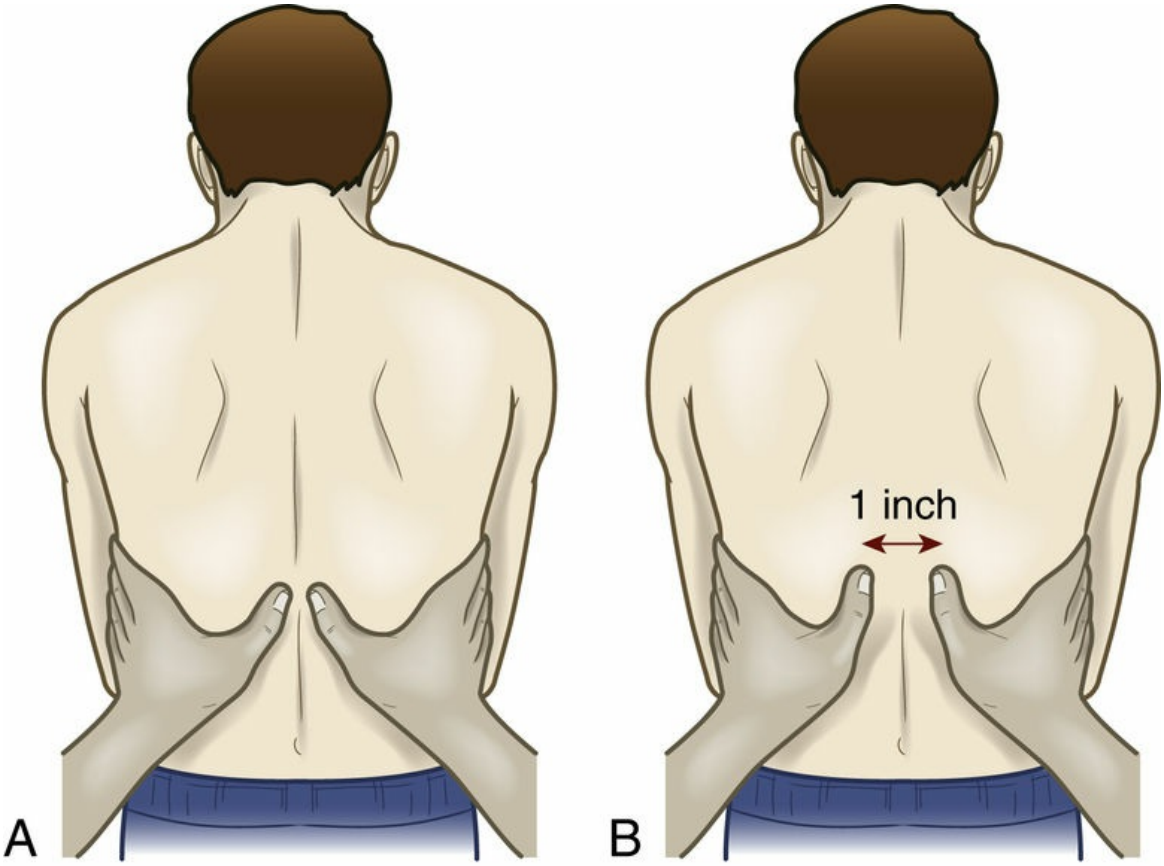


FIG. 25.5 Estimation of thoracic expansion. **A,** Exhalation. **B,** Maximal inhalation.

Note any increase, decrease, or absence of fremitus. Increased fremitus occurs when the lung becomes filled with fluid or is denser. As the patient's voice moves through a dense tissue or fluid, you can feel that the vibration is increased. This happens with pneumonia, lung tumors, thick bronchial secretions, and above a pleural effusion (the lung is compressed upward). Fremitus is decreased if the hand is farther from the lung (e.g., pleural effusion) or the lung is hyperinflated (e.g., barrel chest). Absent fremitus may occur with

pneumothorax or atelectasis. The anterior of the chest is harder to palpate for fremitus because of the large muscles and breast tissue.

Percussion

Percussion is used to assess the density or aeration of the lungs. Percussion sounds are described in Table 25.5. (The technique for percussion is described in Chapter 3 and Fig. 3.3.)

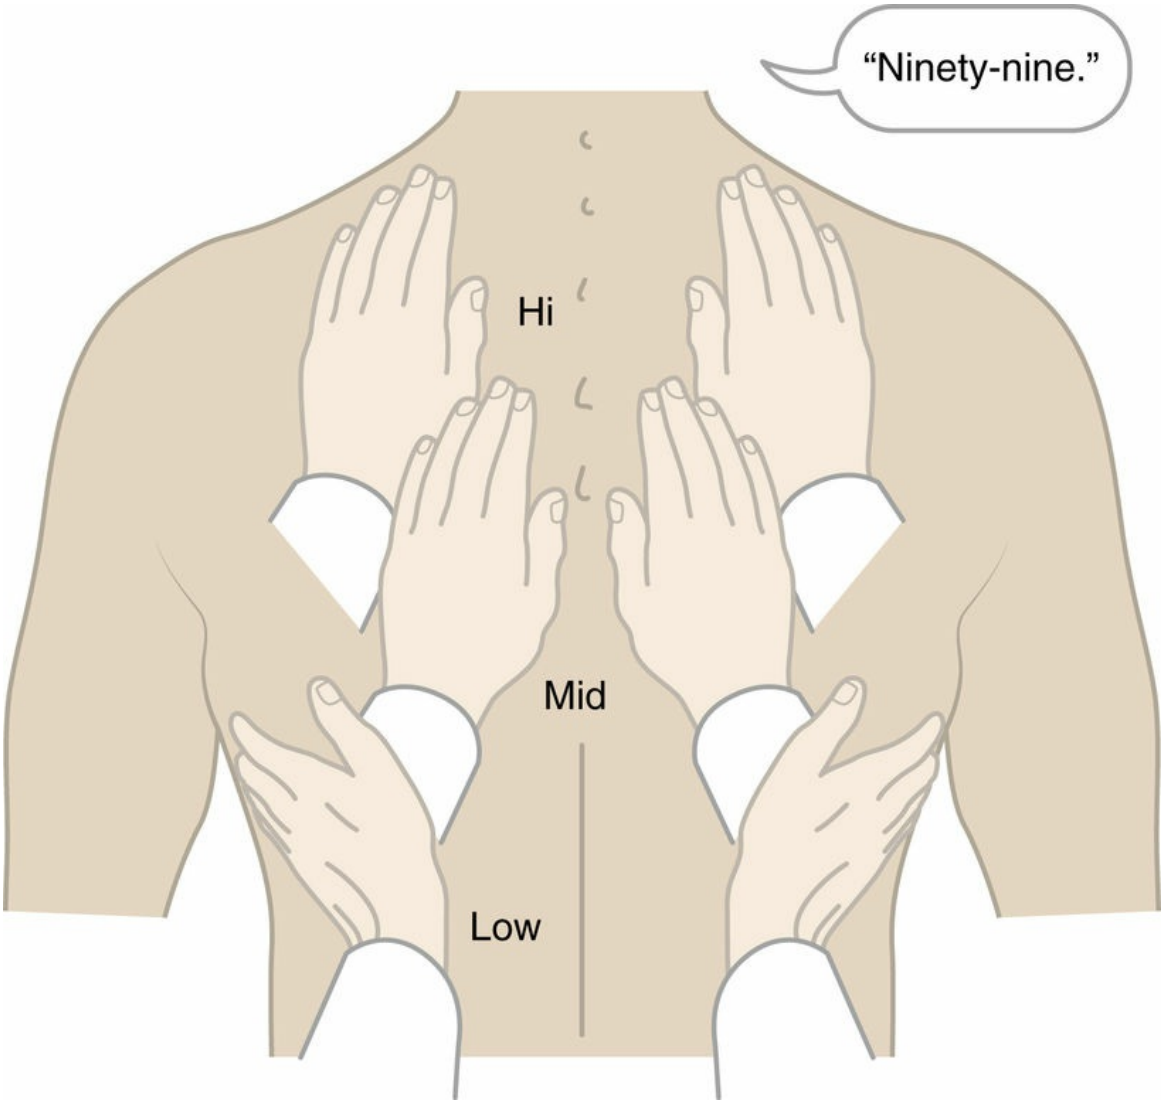

FIG. 25.6 Hand position for tactile fremitus. Place the palms of the hands in the position designated as "*low*" on the right and left sides of the chest. Compare the intensity of vibrations. Continue for all positions in each sequence.

TABLE 25.5 Percussion Sounds

Sound	Description
Dull	Sound with medium-intensity pitch and duration heard over areas of "mixed" solid and lung tissue, such as top area of liver, partially consolidated lung tissue (pneumonia), or fluid-filled pleural space
Flat	Soft, high-pitched sound of short duration heard over very dense tissue where air is not present, such as posterior chest below level of diaphragm
Hyperresonance	Loud, lower pitched sound than normal resonance heard over hyperinflated lungs, such as in chronic obstructive pulmonary disease and acute asthma
Resonance	Low-pitched sound heard over normal lungs
Tympany	Drum-like, loud, empty quality sound heard over pneumothorax

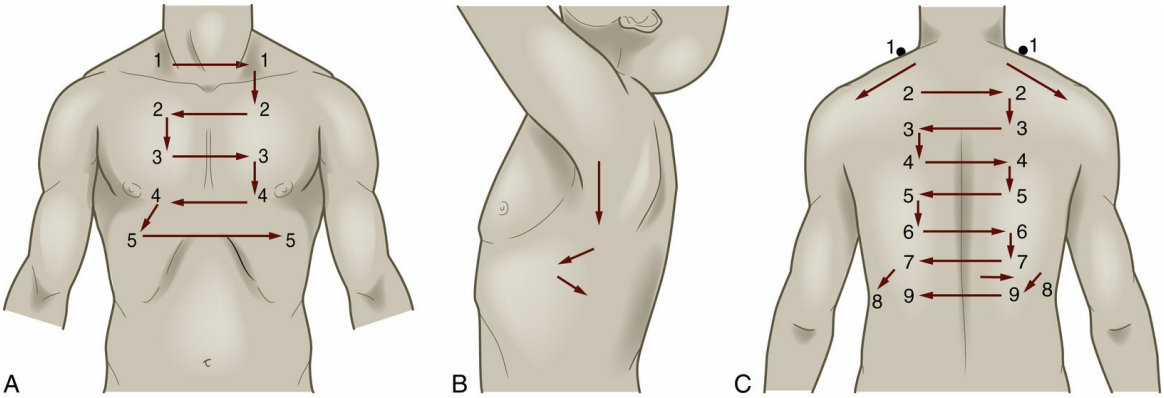

FIG. 25.7 Sequence for auscultation of the chest. **A,** Anterior sequence. **B,** Lateral sequence. **C,** Posterior sequence. Place the stethoscope at each position and listen to at least 1 complete inspiratory and expiratory cycle. Keep in mind that with a female patient the breast tissue will modify the completeness of the anterior examination.

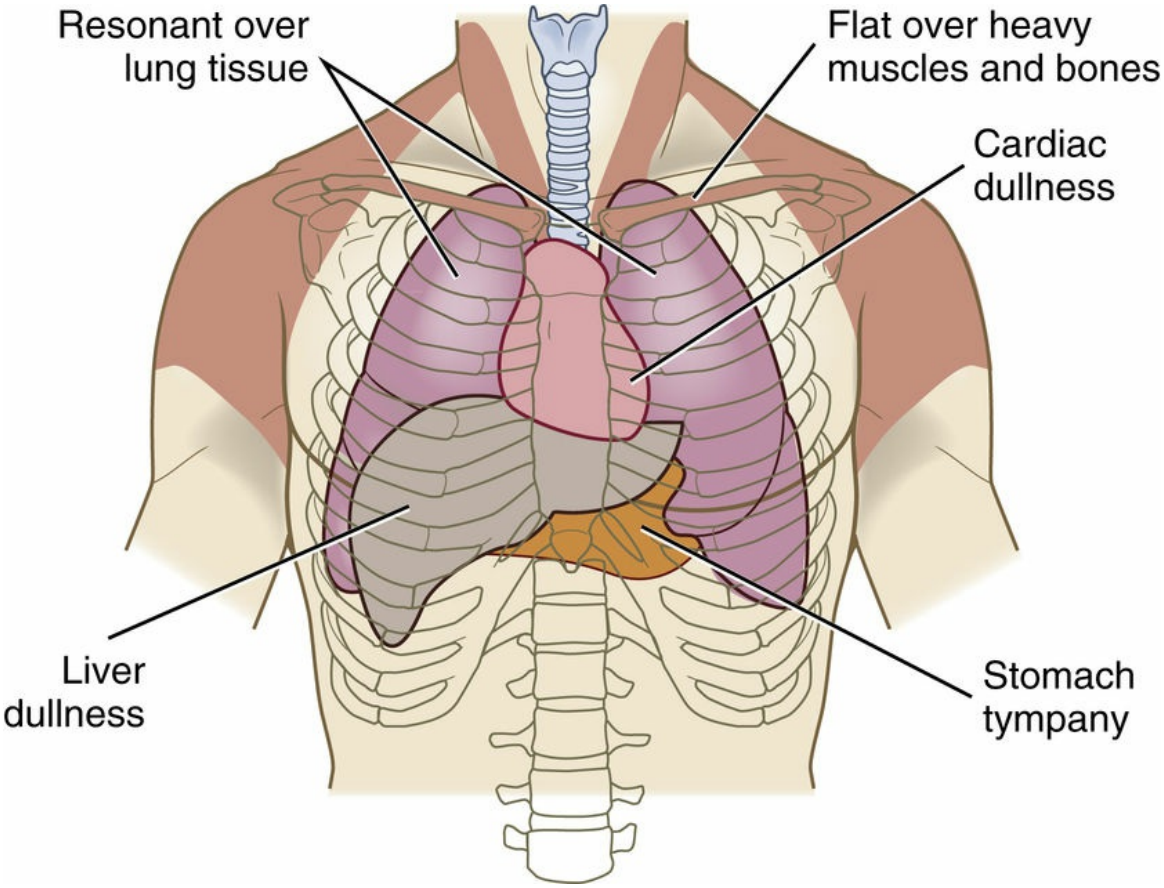

FIG. 25.8 Diagram of percussion areas and sounds on the anterior side of the chest. For percussion, tap the chest at each designated position, moving downward from side to side. Compare percussion sounds at all positions.
Redrawn from Thompson JM, McFarland GK, Hirsch JE, et al: *Mosby's clinical nursing,* ed 5, St Louis, 2002, Mosby.

The anterior chest is percussed with the patient in a semi-sitting or supine position. Starting above the clavicles, percuss downward, intercostal space by intercostal space (Fig. 25.7). The area over lung tissue should be resonant, except for the area of cardiac dullness (Fig. 25.8). To percuss the posterior chest, have the patient sit leaning forward with arms folded. The posterior chest should be resonant over lung tissue to the level of the diaphragm (Fig. 25.9).

Auscultation

During chest auscultation, have the patient breathe slowly and a little more deeply than normal through the mouth. Auscultation should proceed from the lung apices to the bases, comparing opposite areas

of the chest. If the patient is in mild respiratory distress or you think the patient will tire easily, start at the bases. Place the stethoscope over lung tissue, not over bony prominences. At each placement of the stethoscope, listen to at least 1 cycle of inspiration and expiration. Visualize the location of normal breath sounds by using a lung model (Fig. 25.10).

Lung sounds are heard anteriorly from a line drawn perpendicular from the sternum lateral to the midclavicular line. From the xiphoid process, palpate inferiorly (down) 2 ribs in the midaxillary line and around to the posterior chest. This gives you a fairly accurate and easy way to locate the lung fields. When recording the location of lung sounds, divide the anterior and posterior right lung into thirds (upper, middle, and lower) and the left lung into upper and lower areas. With practice, you will be able to identify which lobes of the lung has particular lung sounds.

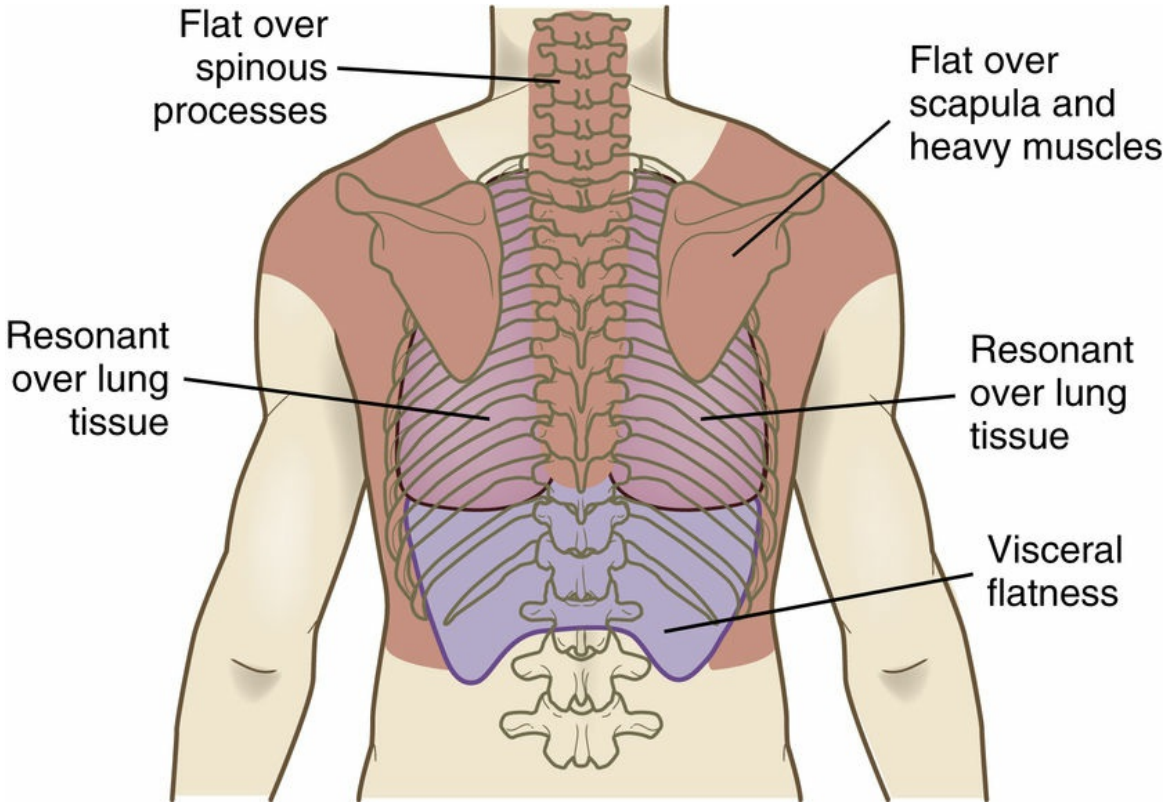

FIG. 25.9 Diagram of percussion areas and sounds on the posterior side of the chest. Percussion proceeds from the lung apices to the lung

bases while comparing sounds in opposite areas of the chest.
Redrawn from Thompson JM, McFarland GK, Hirsch JE, et al: *Mosby's clinical nursing,* ed 5, St Louis, 2002, Mosby.

The 3 normal breath sounds are bronchial, bronchovesicular, and vesicular. *Bronchial sounds* are loud, high-pitched sounds that resemble air blowing through a hollow pipe. Bronchial sounds have an inspiratory to expiratory (I/E) ratio of 2:3, with a gap between inspiration and expiration. To hear bronchial breath sounds, place the stethoscope next to the trachea in the neck. *Bronchovesicular sounds* have a medium pitch and intensity. They are best heard anteriorly between the first and second intercostal space and posteriorly between the scapulae. Bronchovesicular sounds have a 1:1 ratio, with inspiration equal to expiration. *Vesicular sounds* are relatively soft, low-pitched, gentle, rustling sounds. They are heard over all lung areas except the major bronchi. Vesicular sounds have a 3:1 ratio, with inspiration 3 times longer than expiration.

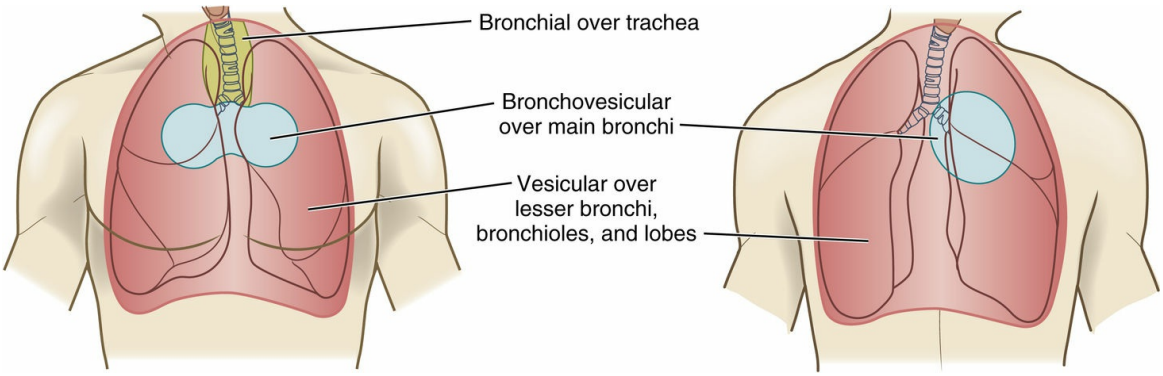

FIG. 25.10 Normal auscultatory sounds.
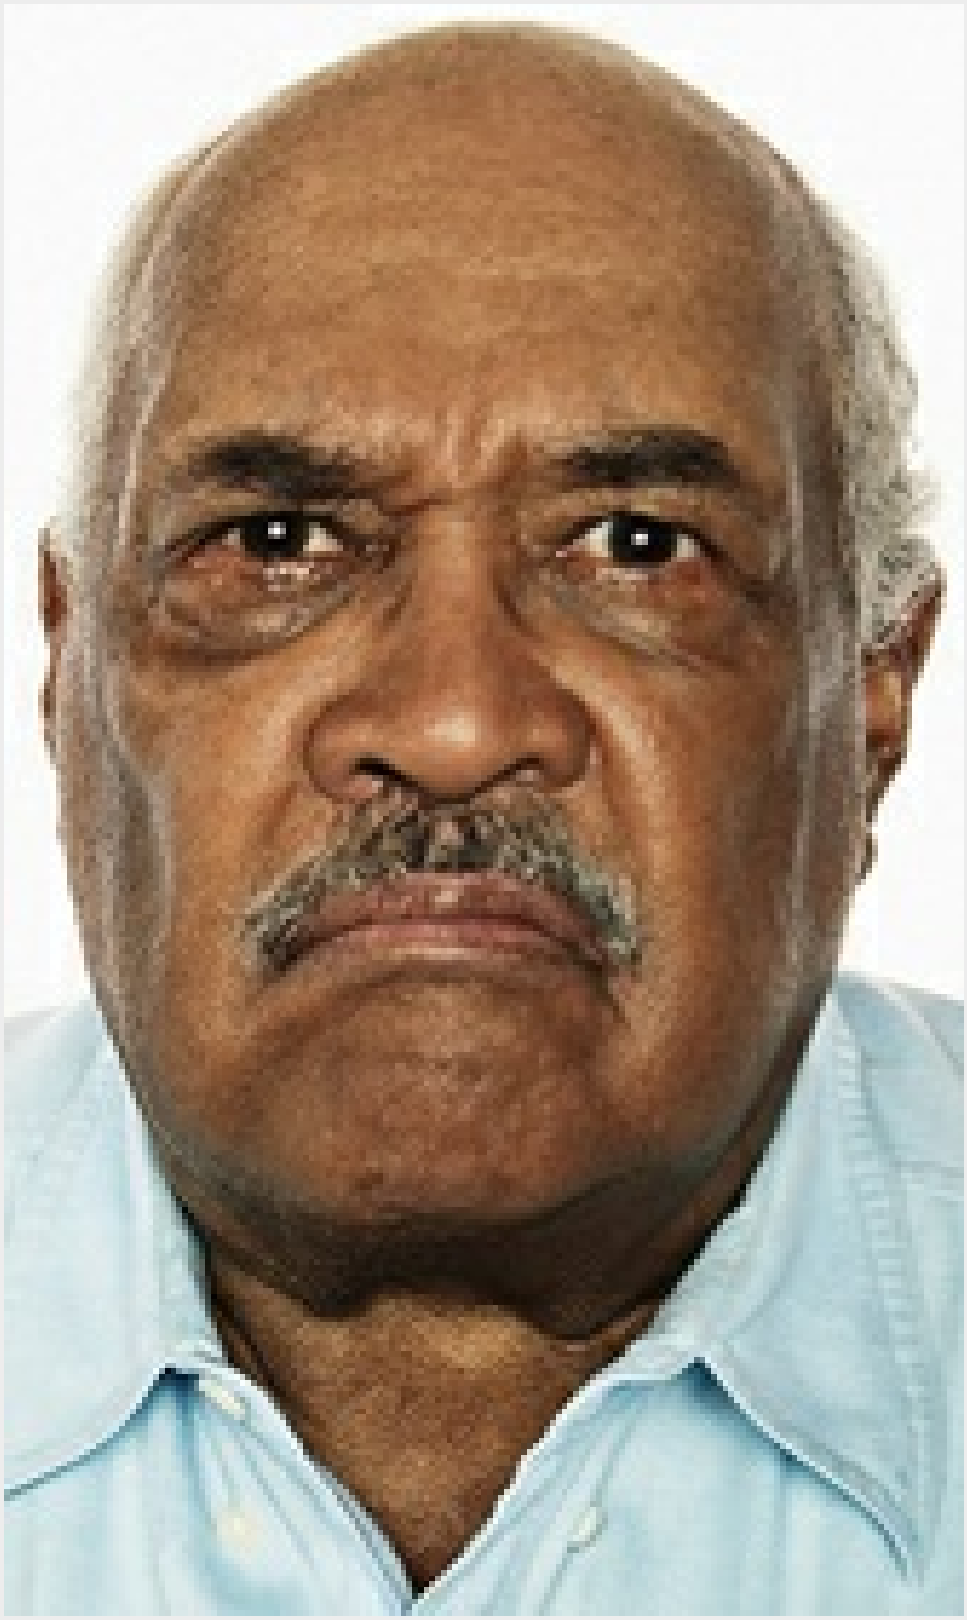
Redrawn from Beare PG, Myers JL: *Adult health nursing,* ed 3, St Louis, 1998, Mosby.



We classify breath sounds into 2 main categories: normal and abnormal (adventitious). There are a variety of terms that have been inconsistently used to describe abnormal breath sounds. **Adventitious breath sounds** include crackles (fine and coarse), wheezes, stridor, and pleural friction rub (Table 25.6). A *focused assessment* is used to evaluate the status of previously identified respiratory problems and

to monitor for signs of new problems. A focused assessment of the respiratory system is shown in the box on this page.

As you begin your assessment of lung sounds, first note the air entry, which may be adequate, slightly decreased, or decreased. Absent air entry in any part of the lung is an assessment finding that you should report at once. Next, listen for the breath sounds and the presence of normal and adventitious sounds. Are the normal breath sounds where you would expect to hear them? Focus your assessment on the characteristics of

Case Study

Objective Data: Physical Examination

© Fuse/Thinkstock.

Physical examination findings of F.T. are as follows:

Temperature: 38°C (100.4°F), apical pulse 110 (irregular), respiratory rate 30 (regular, shallow, slightly labored), BP 170/90. Sitting on edge of bed with arms resting on bedside table. Skin color normal for race with no signs of cyanosis. Using accessory muscles in neck and shoulders. Trachea midline. Barrel-shaped chest; chest expansion minimal but equal. Prolonged expiration. Slight clubbing noted. Edema: 3+ pitting edema of both lower legs and feet, bilaterally. Lungs: adequate air entry at apices bilaterally with fine crackles; decreased air entry to right middle lobe and both bases with coarse crackles. Slight expiratory wheeze heard throughout all lung fields. Cough: moist, productive, with yellow-tinged sputum.

You decide to check F.T.'s O_2 saturation (SpO_2). His SpO_2 is 87% on room air.

Discussion Questions

1. What physical assessment findings are of most concern to you?
2. Identify 3 interventions that may be implemented immediately.
3. With F.T.'s physical assessment information, what diagnostic studies would you expect to be ordered?

(See p. 475 for more information on F.T.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

any abnormal sound, including the location, pitch (e.g., high, low), duration of sound, and whether the sound is heard on inspiration, expiration, or both.

Assessment abnormalities of the thorax and lungs are outlined in Table 25.6. A record of the normal physical assessment of the respiratory system is shown in Table 25.7. Chest examination findings in common pulmonary problems are described in Table 25.8. Age-related changes in the respiratory system and assessment findings are outlined in Table 25.2.

Focused Assessment

Respiratory System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Shortness of breath	Y	N
Pain with breathing	Y	N
Cough	Y	N
Sputum production (color, quantity)	Y	N
Wheezing	Y	N

Objective: Physical Examination

Observe

Respirations: Rate, quality, and pattern	
Accessory muscle use	
Mouth or nose breathing	

Inspect

Neck for position of trachea	
Shape, symmetry, and movement of chest wall	
Skin and nails for integrity and color	

Palpate

Chest and back for abnormalities (i.e. masses)	

Auscultate

Lung sounds (anterior and posterior)	

Objective: Diagnostic

Check the following diagnostic tests for abnormal results.

Arterial blood gases	
Chest x-ray	
Hemoglobin	
Hematocrit	

TABLE 25.6 Assessment AbnormalitiesRespiratory System

Finding	Description	Common Etiology and Significance
Inspection		
Abdominal paradox	Inward (rather than normal outward) movement of abdomen during inspiration	Inefficient and ineffective breathing pattern. Nonspecific indicator of severe respiratory distress
Accessory muscle use. Intercostal retractions	Neck and shoulder muscles used to assist breathing; muscles between ribs pull in during inspiration	COPD, asthma exacerbation, secretion retention Indicates severe respiratory distress/failure, hypoxemia
↑ AP diameter	AP chest diameter equal to lateral. Slope of ribs more horizontal (90 degrees) to spine	COPD, asthma, cystic fibrosis, lung hyperinflation, advanced age
Clubbing	↑ Depth, bulk, sponginess of distal part of finger	Chronic hypoxemia, cystic fibrosis, lung cancer, bronchiectasis
Cyanosis	Bluish color of skin best seen in lips and on the palpebral conjunctiva (inside the lower eyelid)	Reflects 5–6 g of hemoglobin not bound with O_2, ↓ O_2 transfer in lungs, ↓ cardiac output. Nonspecific, unreliable indicator
Kussmaul respirations	Regular, rapid, and deep respirations Fruity odor to breath	Metabolic acidosis. Increases CO_2 excretion
Pursed-lip breathing	Exhalation through mouth with lips pursed together to slow exhalation	COPD, asthma. Suggests ↑ breathlessness Strategy taught to slow expiration, ↓ dyspnea
Splinting	Voluntary ↓ in tidal volume to ↓ pain on chest expansion	Thoracic or abdominal incision, chest trauma, pleurisy
Tachypnea	Rate >20 breaths/min	Fever, anxiety, hypoxemia, restrictive lung disease Magnitude of ↑ above normal rate reflects increased work of breathing
Tripod position. Inability to lie flat	Leaning forward with arms and elbows supported on overbed table	COPD, asthma exacerbation, pulmonary edema Indicates moderate to severe respiratory distress
Palpation		
Altered chest movement	Unequal or equal but decreased movement of 2 sides of chest with inspiration	Unequal movement caused by atelectasis, pneumothorax, pleural effusion, splinting Equal but decreased movement caused by barrel chest, restrictive disease, neuromuscular disease
Altered tactile fremitus	Increase or decrease in vibrations	↑ In pneumonia, pulmonary edema. ↓ in pleural effusion, lung hyperinflation. Absent in pneumothorax, atelectasis
Tracheal deviation	Leftward or rightward movement of trachea from normal midline position	Nonspecific indicator of change in position of mediastinal structures. Medical emergency if caused by tension pneumothorax (trachea deviates to side opposite collapsed lung)
Percussion		
Dullness	Medium-pitched sound over areas that normally make a resonant sound	↑ Density (pneumonia, large atelectasis), ↑ fluid in pleural space (pleural effusion)
Hyperresonance	Loud, lower pitched sound over areas that normally make a resonant sound	Lung hyperinflation (COPD), lung collapse (pneumothorax), air trapping (asthma)
Auscultation		
Absent breath sounds	No sound heard over entire lung or area of lung	Pneumothorax, pleural effusion, mainstem bronchi obstruction, large atelectasis, pneumonectomy, lobectomy
Bronchophony, whispered pectoriloquy	Spoken or whispered syllable more distinct than normal on auscultation	Pneumonia
Coarse crackles	Louder, discontinuous, low-pitched sounds caused by air passing through airway intermittently occluded by mucus, unstable bronchial wall. May be heard on inspiration, expiration, or both. Similar sound to blowing through straw under water	Excess fluid within the lungs, heart failure, pulmonary edema, pneumonia with severe congestion, COPD
Egophony	Spoken "E" similar to "A" on auscultation because of altered transmission of voice sounds	Pneumonia, pleural effusion
Fine crackles	Short, discontinuous, high-pitched sounds heard just before the end of inspiration. Result of rapid equalization of gas pressure when collapsed alveoli or terminal bronchioles suddenly snap open. Similar sound to that made by rolling hair between fingers	Interstitial edema (early pulmonary edema), alveolar filling (pneumonia), loss of lung volume (atelectasis), early phase of heart failure, idiopathic pulmonary fibrosis
Pleural friction rub	Creaking or grating sound from roughened, inflamed pleural surfaces rubbing together. Evident during inspiration, expiration, or both. No change with coughing. Often uncomfortable, especially on deep inspiration	Pleurisy, pneumonia, pulmonary infarct

Finding	Description	Common Etiology and Significance
Stridor	Continuous musical or crowing sound of constant pitch. Result of partial obstruction of larynx or trachea	Croup, epiglottitis, vocal cord edema after extubation, foreign body
Wheezes	Continuous high-pitched squeaking or musical sound caused by rapid vibration of bronchial walls. First evident on expiration but possibly evident on inspiration as obstruction of airway increases. May be audible without stethoscope	Bronchospasm (caused by asthma), airway obstruction (caused by foreign body, tumor), COPD

Diagnostic Studies of Respiratory System

Numerous diagnostic studies are available to assess the respiratory system. Tables 25.9 through 25.17 describe common studies. Select studies are described in more detail here.

Two methods are used to assess the efficiency of gas transfer in the lung and tissue oxygenation: (1) pulse oximetry and (2) analysis of *arterial blood gases* (ABGs) (Table 25.9). These are primarily used to assess for hypoxia. For the patient with normal or near-normal cardiac function, assessing PaO_2 or SaO_2 is usually enough to determine the level of oxygenation. With either one, we can also use CO_2 monitoring to assess for hypercapnia to determine patient's oxygenation and ventilatory status. The patient with impaired cardiac output or hemodynamic instability (e.g., altered level of consciousness, changes in heart rate and rhythm, low BP) may have inadequate tissue O_2 delivery and/or abnormal O_2 consumption. For these patients, we can evaluate a mixed venous blood gas.

Oximetry

Arterial O_2 saturation can be monitored noninvasively and continuously using a *pulse oximetry* probe on the finger, toe, ear, forehead, or bridge of the nose. The abbreviation SpO_2 is used to indicate the O_2 saturation of hemoglobin as measured by pulse oximetry. SpO_2 and heart rate are displayed on the monitor as digital readings. Normal SpO_2 values are 94% to 99% (Table 25.10).

TABLE 25.7 Normal Physical Assessment of the Respiratory System

Nose	• Symmetric with no deformities • Nasal mucosa pink, moist with no edema, exudate, blood, or polyps • Nasal septum straight (slight nasal deviation possible) • Nares patent bilaterally
Oral mucosa	• Light pink, moist, no exudate or ulcerations
Pharynx	• Smooth, moist, and pink
Neck	• Trachea midline
Chest	• AP diameter 1:2 • Respirations nonlabored at 12–20 breaths/min • Breath sounds vesicular without crackles or wheezes • Excursion equal bilaterally with no increase in tactile fremitus

In many inpatient areas, SpO_2 is assessed with each routine vital sign check. Oximetry is also used during exercise testing and when adjusting flow rates during O_2 therapy. Pulse oximetry is especially valuable in perioperative and critical care situations, in which anesthesia, sedation, or decreased consciousness may mask hypoxia. Changes in SpO_2 can be detected and treated quickly (Table 25.9).

Values obtained by pulse oximetry are less accurate if the SpO_2 is less than 70%.[10] At this level the oximeter may display a value that is ±4% of the actual value. For example, if the SpO_2 reading is 70%, the actual value can range from 66% to 74%. Pulse oximetry is inaccurate if hemoglobin variants (e.g., carboxyhemoglobin, methemoglobin) are present. Other factors that can alter the accuracy of pulse oximetry include motion, low perfusion, anemia, cold extremities, bright fluorescent lights, intravascular dyes, thick acrylic nails, and dark skin color. If there is doubt about the accuracy of the SpO_2 reading, obtain an ABG analysis to verify the values.

Arterial Blood Gases

ABGs are obtained to determine oxygenation status and acid-base

balance. ABG analysis includes measurement of the PaO_2, $PaCO_2$ (the partial pressure of CO_2 in arterial blood), acidity (pH), bicarbonate (HCO_3^-), and SaO_2. Normal values for ABGs are shown in Table 25.11.

Blood for ABG analysis can be obtained by arterial puncture or from an arterial catheter, which is usually inserted into the radial or femoral artery. Both techniques allow only intermittent analysis, but an arterial catheter permits ABG sampling without repeated arterial punctures. The normal PaO_2 decreases with advancing age. It varies in relation to the distance above sea level. At higher altitudes, the barometric pressure is lower, resulting in a lower inspired O_2 pressure and a lower PaO_2.

TABLE 25.8 Chest Examination Findings in Respiratory Problems

Problem	Inspection	Palpation	Percussion	Auscultation
Asthma exacerbation	Prolonged expiration, tripod position, pursed lips	↓ Movement	Hyperresonance	Wheezes, ↓ breath sounds ominous sign (severely decreased air movement)
Atelectasis	No change unless involves entire segment, lobe	If small, no change If large, ↓ movement, ↓ fremitus	Dull over affected area	Fine crackles (may disappear with deep breaths) Absent sounds if large
COPD	Barrel chest, cyanosis, tripod position, use of accessory muscles	↓ Movement	Hyperresonant or dull if consolidation	Crackles, wheezes, distant breath sounds
Pleural effusion	Tachypnea, use of accessory muscles	↑ Movement ↑ Fremitus above effusion Absent fremitus over effusion	Dull	Decreased or absent over effusion, egophony above effusion
Pneumonia	Tachypnea, use of accessory muscles, duskiness or cyanosis	↑ Fremitus over affected area	Dull over affected areas	*Early*: Bronchial sounds *Later*: Fine and/or coarse crackles, egophony, whispered pectoriloquy
Pulmonary edema	Tachypnea, labored respirations, cyanosis, pink-tinged sputum	↓ Movement or normal movement	Dull or normal depending on amount of fluid	Fine or coarse crackles
Pulmonary fibrosis	Tachypnea	↓ Movement	Normal	Crackles or sounds like Velcro being pulled apart

TABLE 25.9 Diagnostic Studies: Oxygenation

Study	Description and Purpose	Nursing Responsibility
Arterial blood gases (ABGs)	Arterial blood is obtained through puncture of radial or femoral artery or through arterial catheter. Done to assess acid-base balance, oxygenation/ventilation status, need for and/or change in O_2 therapy, or change in ventilator settings. See Table 25.11 for reference values.	*Before:* Indicate whether patient is using O_2 (flow rate in L/min). Avoid change in O_2 therapy or interventions (e.g., suctioning, position change) for 15 min before obtaining sample. *During:* Assist with positioning (e.g., palm up, wrist slightly hyperextended if radial artery is used). Collect blood in heparinized syringe. To ensure accurate results, expel all air bubbles. *After:* Apply pressure to radial artery for at least 5 min after specimen is obtained to prevent hematoma at the arterial puncture site. Send sample to lab promptly for analysis.
O_2 Monitoring		
Oximetry	Monitors arterial or venous O_2 saturation. Probe attaches to finger, toe, earlobe, bridge of the nose for SpO_2 monitoring or is in a pulmonary artery catheter for SvO_2 monitoring. Used for intermittent or continuous monitoring and exercise testing. *Normal SpO_2:* 94%–100% *Normal SvO_2:* 60%–80%	*During:* Apply probe. When interpreting SpO_2 and SvO_2 values, first assess patient status and presence of factors that can alter accuracy of pulse oximeter reading. For SpO_2, these include motion, low perfusion, cold extremities, bright lights, acrylic nails, dark skin color, carbon monoxide, and anemia. For SvO_2, these include change in O_2 delivery or O_2 consumption.
CO_2 Monitoring		
End-tidal CO_2 ($PetCO_2$) (capnography)	Assesses the level of CO_2 in exhaled air. Graphically displays partial pressure of CO_2. Expired gases are sampled from patient's airway and analyzed by a CO_2 sensor to measure exhaled CO_2. Sensor may be attached to an adaptor on endotracheal or tracheostomy tube. A nasal cannula with a sidestream capnometer can be used in patients without an artificial airway. Can be a diagnostic measure to detect lung disease and for monitoring patients. Normal difference between $PaCO_2$ and $PetCO_2$ is 2–5 mm Hg ($PaCO_2$: 35–45 mm Hg; $PetCO_2$: 40–50 mm Hg).	*Before:* Teach patient and caregiver about purpose of capnography monitoring, emphasizing the benefit of continuous monitoring. *During:* Make sure that sensor is properly attached. Record data per agency policy.

SvO_2, venous O_2 saturation.

TABLE 25.10 Normal and Critical Values for PaO_2 and SpO_2

PaO_2 (mm Hg)	SpO_2 (%)	Significance	Manifestations	Management
80–100	≥94	Normal value	Asymptomatic	• Routine assessment of patient
60–79	90	Mild hypoxemia	Restlessness, tachycardia, dysrhythmias, dyspnea, hypertension	• Assess patient condition as needed • Supplemental O_2 may be needed
40–59	88	Moderate hypoxemia	Confusion, lethargy, dysrhythmias, hypotension, respiratory distress, accessory muscle use	• O_2 required • Escalate level of care. Obtain critical care consult • Monitor frequently for sudden deterioration in condition
<40	75	Severe hypoxemia	Cyanosis, coma, respiratory and/or cardiac arrest possible	• High FIO_2, intubation, mechanical ventilation • Continuous patient assessment and evaluation

TABLE 25.11 Normal Arterial Blood Gas Values

Laboratory Value	Sea Level BP 760 mm Hg	1 Mile Above Sea Level BP 629 mm Hg
pH	7.35–7.45	7.35–7.45
PaO_2†	80–100 mm Hg	65–75 mm Hg
SaO_2†	>95%	>95%
$PaCO_2$	35–-45 mm Hg	35–45 mm Hg
HCO_3^-	22–26 mEq/L (mmol/L)	22–26 mEq/L (mmol/L)

BP, Barometric pressure; *HCO_3^-*, bicarbonate; *PaO_2*, partial pressure of O_2 in arterial blood; *$PaCO_2$*, partial pressure of arterial CO_2; *SaO_2*, arterial O_2 saturation.

TABLE 25.12 Normal Venous Blood Gas Values

Venous Blood Gases	
Mixed Venous Blood Gases	
pH	7.31–7.41
PvO_2	38–42 mm Hg
SvO_2	60%–80%‡
$PvCO_2$	38–55 mm Hg
HCO_3^-	22–26 mEq/L (mmol/L)

$PvCO_2$, Partial pressure of CO_2 in venous blood; *PvO_2*, partial pressure of O_2 in venous blood; *SvO_2*, venous O_2 saturation.

TABLE 25.13 Sputum Studies

Study	Description and Purpose	Nursing Responsibility
Acid-fast bacteria (AFB) smear and culture	2 different tests used to assess sputum for acid-fast bacilli (e.g., *Mycobacterium tuberculosis*). In AFB smear (a rapid test), sputum sample spread thinly on glass slide, treated with a fluorochrome stain, and examined under a microscope for AFB. Culture for AFB may take up to 6 wk.	*During:* Obtain specimen in early morning after mouth care because secretions collect during night. Have patient expectorate sputum into container after coughing deeply. If unsuccessful, try increasing oral fluid intake unless fluids are restricted. Can collect sputum in sterile container (sputum trap) during suctioning via endotracheal tube or by aspirating secretions from the trachea. If patient cannot produce specimen, bronchoscopy may be needed (Fig. 25.11). *After:* Send specimen to laboratory promptly for analysis.
Culture and sensitivity	Diagnose bacterial infection, select antibiotic, and evaluate treatment. Sputum specimen collected in a sterile container. Takes 48–72 hr for results.	
Cytology	Determines presence of abnormal cells that may indicate cancer. Single sputum specimen collected in special container with fixative solution.	
Gram stain	Sputum staining allows for classification of bacteria into gram-negative and gram-positive types. Results guide therapy until culture and sensitivity results are complete.	

TABLE 25.14 Interpreting Tuberculin Skin Testing

Types of Responses	Consider Positive in the Following Groups
Positive Reactions	
≥5-mm induration	• HIV-infected people • People who had recent contact with a person with TB disease • People with fibrotic lesions on chest x-ray consistent with prior TB • Patients with organ transplants • Immunosuppressed persons (e.g., taking the equivalent of ≥15 mg/day of prednisone for ≥1 mo)
≥10-mm induration	• Recent immigrants (<5 yr) from high-prevalence countries • Injecting drug users • Residents and employees of high-risk congregate settings • Mycobacteriology laboratory personnel • People with clinical conditions (e.g., diabetes mellitus, end-stage kidney disease) that place them at high risk
≥15-mm induration	• Any person (including those with no known risk factors for TB)

False Reactions	Possible Causes
False-negative reactions (do not react even though infected)	• Anergy, immunosuppression • Recent TB infection (within 8–10 wk of exposure) • Overwhelming TB infection • Very old TB infection (many years) • Recent live virus vaccination (e.g., measles, chickenpox)
False-positive reactions (react even though not infected)	• Nontuberculous mycobacteria (e.g., *Mycobacterium avium-intracellulare* [MAI] or *Mycobacterium avium* complex [MAC]) • Previous BCG vaccine

Source: Centers for Disease Control and Prevention: Tuberculosis (TB) fact sheet: Tuberculin skin testing. Retrieved from *www.cdc.gov/tb/publications/factsheets/testing/skintesting.htm*.

CO_2 Monitoring

CO_2 can be monitored using transcutaneous CO_2 ($PtCO_2$) and end-tidal CO_2 ($PetCO_2$) capnography. Transcutaneous measurement of CO_2 is a noninvasive method of estimating arterial pressure of CO_2 ($PaCO_2$) using an electrode placed on the skin.[11]

$PetCO_2$ is the noninvasive measurement of alveolar CO_2 during exhalation when CO_2 concentration is at its peak. It is used to monitor and assess trends in the patient's ventilatory status. Expired gases are sampled from the patient's airway and are analyzed by a CO_2 sensor that uses infrared light to measure exhaled CO_2. The sensor may be attached to an adaptor on the endotracheal tube or the tracheostomy tube. A nasal cannula with a sidestream capnometer can be used in patients without an artificial airway. Capnography is usually presented as a graph of expiratory CO_2 plotted against time.[12]

In the past, capnography was mainly used during and after surgery and in critical care units. Today's $PetCO_2$ monitors are portable and practical for use in emergency departments and on inpatient units.

Mixed Venous Blood Gases

The pulmonary artery (PA) catheter is a flow-directed catheter. When it is positioned correctly, the tip of the catheter lies in the pulmonary artery. Blood drawn from a PA catheter is called a mixed venous blood gas (SvO_2), because (1) it consists of venous blood that has returned to the right side of the heart from all parts of the body and (2) it samples blood just before blood enters the lungs to be oxygenated. Normal SvO_2 is 60% to 80%. Other normal mixed venous values are given in Table 25.12.

SvO_2 can be monitored intermittently by obtaining a blood sample from the PA catheter or continuously via a fiberoptic sensor as part of a specific central line with SpO_2 monitoring capability. Changes in SvO_2 provide an early warning of a change in cardiac output or tissue O_2 delivery. A decrease in SvO_2 suggests that less O_2 is being

delivered to the tissues or that more O_2 is being consumed.

Sputum Studies

Observe the patient's sputum for color, volume, viscosity, and presence or absence of blood. We can obtain a sputum sample by expectoration, tracheal suction, or bronchoscopy. When the patient is unable to expectorate spontaneously, sputum may be collected by inhaling an irritating aerosol, usually hypertonic saline. This is called *sputum induction*.

Specimens may be examined for culture and sensitivity to identify an infecting organism (e.g., *Mycobacterium*) or to confirm a diagnosis (e.g., cancer). Table 25.13 describes common sputum tests and specific responsibilities when obtaining samples.

TABLE 25.15 Diagnostic StudiesRespiratory System

Study	Description and Purpose	Nursing Responsibility
Radiology		
Chest x-ray	Used to screen, diagnose, and evaluate changes in respiratory system. Most common views are anteroposterior (AP) and lateral.	*Before*: Have patient undress to waist, put on gown, and remove any metal between neck and waist.
Computed tomography (CT) scan	Diagnose suspicious lesions difficult to assess (e.g., mediastinum, hilum, pleura) by conventional x-ray. Common types are helical or spiral CT (contrast medium usually used) and high-resolution CT scan (contrast medium not used). Spiral CT used to diagnose a pulmonary embolism.	*Before*: Before contrast medium used, evaluate renal function. Assess if patient is allergic to shellfish, since the contrast is iodine based. Patient may need to be NPO 4 hr prior to study. *During*: Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After*: Encourage patient to drink fluids to avoid renal problems with any contrast.
Magnetic resonance imaging (MRI)	Used for in-depth diagnosis of lesions difficult to assess by CT scan (e.g., lung apex) and for differentiating vascular from nonvascular structures. An IV contrast agent (gadolinium) may be given.	*Before*: Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function before test. Have patient remove all metal objects. Remove metallic foil patches. Contraindicated for persons with implanted metallic devices or other metal fragments unless noted to be MRI safe. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During*: Patient must lie completely still during scan.
Positron emission tomography (PET) scan	Glucose-containing nuclear tracer substance injected and taken up by metabolically active cells. Follow-up scan shows different-colored tissues based on metabolic rate. Because cancer cells have an increased uptake of glucose, "hot spots" reflecting increased glucose consumption indicate the presence of active cancer. Used to distinguish benign and cancerous lung nodules.	*Before*: Obtain IV access to inject the tracer substance. Patients should be NPO, except for water and medications, for at least 4 hr prior. Hold glucose-containing IV solutions and change to normal saline. Check blood glucose levels. The glucose level must be between 60-140 mg/dL (3.3–7.8 μmol/L) for accurate glucose metabolic activity. *During*: Patient must lie completely still during scan. *After*: Encourage fluids to excrete radioactive substance.
Pulmonary angiogram	Visualize pulmonary vasculature and locate obstruction or pathologic conditions (e.g., pulmonary embolus). Contrast medium injected through a catheter threaded into pulmonary artery or right side of heart. Series of x-rays taken after contrast medium is injected into pulmonary artery.	*Before*: Assess for allergies, especially to contrast dye. Have patient fast 6–12 hours before. Give sedative and other drugs, as ordered. *After*: Check pressure dressing site after procedure. Monitor BP, pulse, and circulation distal to injection site. Place compression device over site. Maintain IV and/or oral fluid intake.
Ventilation-perfusion (V/Q) scan	Assesses ventilation and perfusion of lungs. IV radioisotope given to assess perfusion. To assess ventilation, patient inhales a radioactive gas (xenon or krypton) that outlines alveoli. Normal scans show homogeneous radioactivity. Decreased or absent radioactivity suggests lack of perfusion or airflow. Ventilation without perfusion suggests a pulmonary embolus.	Same as for chest x-ray. *After*: No precautions needed afterward because the gas and isotope transmit radioactivity for only a brief interval.
Endoscopy		
Bronchoscopy (Fig. 25.11)	Flexible fiberoptic scope used for diagnosis, biopsy, specimen collection, or assessment of changes. It may be done to suction mucous plugs, lavage lungs, or remove foreign objects.	*Before*: Obtain signed consent. Have patient be NPO for 6–12 hr before the test. Give sedative as ordered. *After*: Keep patient NPO until gag reflex returns. Monitor for recovery from sedation. Blood-tinged mucus is not abnormal. If biopsy was done, monitor for hemorrhage and pneumothorax.
Lung biopsy	Specimens may be obtained by transbronchial or percutaneous biopsy or via transthoracic needle aspiration (TTNA), video-assisted thoracoscopic surgery (VATS), or open lung biopsy. Transbronchial biopsy and VATS can be done in the bronchoscopy suite. TTNA is done under CT guidance in radiology department. Open lung and VATS are done in the OR. Tests used to obtain specimens for laboratory analysis.	*Before*: Obtain signed consent. Same as bronchoscopy if procedure done with bronchoscope, and same as thoracotomy if open lung biopsy done. *After TTNA:* Check breath sounds q4hr for 24 hr and report any respiratory distress. Check incision site for bleeding. A chest x-ray should be done after TTNA or transbronchial biopsy to check for pneumothorax. *After VATS*: A chest tube may be placed postprocedure until lung has reexpanded. Monitor breath sounds to follow chest reexpansion. Encourage deep breathing for lung reinflation.
Mediastinoscopy	Scope inserted through a small incision in suprasternal notch and advanced into mediastinum to inspect and biopsy lymph nodes. Used to diagnose lung cancer, non-Hodgkin's lymphoma, granulomatous infections, and sarcoidosis.	*Before*: Obtain signed consent. Prepare patient for surgical intervention. Performed in OR using a general anesthetic. *After*: Monitor as for bronchoscopy.

Table Continued

Study	Description and Purpose	Nursing Responsibility
Thoracentesis (Fig. 25.12)	Used to obtain specimen of pleural fluid for diagnosis, remove pleural fluid, or instill medication. Obtain chest x-ray after procedure to check for pneumothorax.	*Before:* Explain procedure and obtain signed consent. *During:* Usually done in patient's room. Position patient upright with elbows on an overbed table and feet supported. Tell patient not to talk or cough during procedure. *After:* Observe for signs of hypoxia and pneumothorax, and verify breath sounds in all fields. Encourage deep breaths to expand lungs. Send labeled specimens to laboratory promptly for analysis.
Pulmonary Function Tests	Used to evaluate lung function. Involves use of spirometer to assess air movement as patient performs prescribed respiratory maneuvers (Tables 25.16 and 25.17).	*Before:* Avoid scheduling immediately after mealtime. Avoid administration of inhaled bronchodilator 6 hr before. Assess for respiratory distress. *During:* Assess for respiratory distress. *After:* Assess for respiratory distress. Provide rest after procedure.
Exercise Testing	Used to diagnose and determine exercise capacity. A *complete test* involves walking on a treadmill while monitoring expired O_2 and CO_2, respiratory rate, heart rate, and heart rhythm. In a *modified test* (desaturation test), only SpO_2 is monitored.	*Before:* Have patient wear comfortable shoes. *During:* Encourage patient to hold handlebars on treadmill and walk as quickly as possible.
6-Min walk test	Used to measure functional capacity and response to treatment in patients with heart or lung disease. Pulse oximetry usually monitored during walk. Distance walked measured and used to monitor progression of disease or improvement after rehabilitation.	*During:* Patient walks as far as possible during 6 min, stopping when short of breath and continuing when able. Continually assess and observe patient tolerance to test.

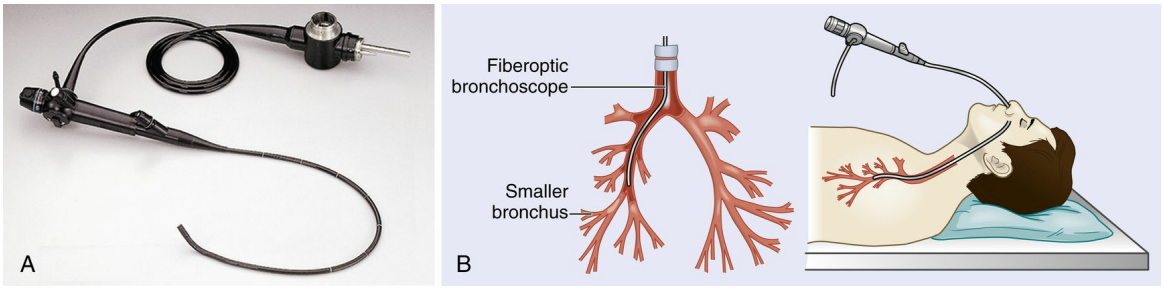


FIG. 25.11 Fiberoptic bronchoscope. **A,** The transbronchoscopic balloon-tipped catheter and the flexible fiberoptic bronchoscope. **B,** The catheter is introduced into a small airway and the balloon inflated with 1.5 to 2 mL of air to occlude the airway. Bronchoalveolar lavage is done by injecting and withdrawing 30-mL aliquots of sterile saline solution, gently aspirating after each instillation. Specimens are sent to the laboratory for analysis.
A, Courtesy Olympus America Inc, Melville, NY.

Skin Tests

Skin tests may be done to test for allergic reactions (see Chapter 13) or exposure to TB bacilli or fungi. Skin tests involve the intradermal injection of an antigen. Table 25.14 discusses how to interpret tuberculin skin testing. For example, a positive result on a TB skin test means that the patient has been exposed to the antigen. It does not

mean that the patient has TB. A negative result means either no exposure or a depression of cell-mediated immunity, which occurs in HIV infection.

Our responsibilities are similar for all skin tests. First, to prevent a false-negative reaction, be sure that the injection is intradermal and not subcutaneous. After the injection, circle the site(s) and tell the patient not to remove the marks. When charting administration of the antigen, draw a diagram of the forearm and hand, and label the injection site. The diagram is especially helpful when the patient receives more than 1 test.

When reading test results, use a good light. If an induration is present, use a marking pen to indicate the periphery on all 4 sides of the induration. As the pen touches the raised area, make a mark. Then determine the diameter of the induration in millimeters. Do not measure reddened, flat areas.

Endoscopy

Bronchoscopy

Bronchoscopy is a procedure in which the bronchi are visualized through a fiberoptic tube (Fig. 25.11). Bronchoscopy may be used for diagnostic purposes (obtain biopsy specimens) and for treatment (e.g., to remove mucous plugs, foreign bodies). Laser therapy, electrocautery, cryotherapy, and stents may be placed through a bronchoscope to achieve patency of an airway that has been partially or nearly fully obstructed by tumors (Table 25.15).

Bronchoscopy can be done in an outpatient procedure room, in a surgical suite, or at the bedside in the critical care unit or on a medical-surgical unit. The patient may be positioned supine, in low-Fowler's, or even be seated. The HCP inserts the bronchoscope through the nose or mouth. Depending on the approach, the nasopharynx or oropharynx is anesthetized with local anesthetic spray. The bronchoscope is coated with water-soluble lubricant and inserted down into the airways. Small amounts (30 mL) of sterile saline may be injected through the scope and withdrawn and

examined for cells, a technique termed *bronchoalveolar lavage* (BAL). Bronchoscopy can be done through the endotracheal tube of a mechanically ventilated patient.

Lung Biopsy

Lung biopsy may be done (1) transbronchially, (2) percutaneously or via transthoracic needle aspiration (TTNA), (3) by video-assisted thoracic surgery (VATS), or (4) as an open lung biopsy (Table 25.15). The purpose of a lung biopsy is to obtain tissue, cells, and/or fluid for evaluation. Specimens can be cultured or examined for cancer cells.

Transbronchial biopsy involves passing a forceps or needle through the bronchoscope for a specimen. A combination of transbronchial lung biopsy and BAL is used to distinguish infection and rejection in lung transplant recipients. A percutaneous or TTNA biopsy involves inserting a needle through the chest wall, usually under bedside ultrasound or CT guidance. Because of the risk for a pneumothorax, a chest x-ray is done after TTNA.

In VATS, a rigid scope with a lens is passed through a trocar placed into the pleura via 1 or 2 small incisions in the thoracic cavity. The HCP views the lesions in the pleura or peripheral lung on a monitor directly via the scope and can obtain biopsy specimens. A chest tube is kept in place until the lung expands. VATS is much less invasive than open lung biopsy. It is associated with shorter hospital stays and reduced mortality.[13] It is ideal for pleural biopsy and resecting lung nodules.

An open lung biopsy is used when other procedures cannot diagnose pulmonary disease. With the patient under anesthesia, the chest is opened with a thoracotomy incision and a biopsy specimen is obtained. Postprocedure care is the same as after thoracotomy (see Chapter 27).

Thoracentesis

Thoracentesis is the insertion of a large-bore needle through the chest wall into the pleural space to obtain specimens for diagnostic

evaluation, remove pleural fluid, or instill medication (Fig. 25.12). The patient is positioned sitting upright, leaning on an overbed table with feet supported. The skin is cleansed and a local anesthetic (lidocaine) is injected subcutaneously. A percutaneous catheter may be left in to allow further drainage of fluid (Table 25.15).

Pulmonary Function Tests

Pulmonary function tests (PFTs) measure lung volumes and airflow. The results of PFTs can diagnose pulmonary disease, monitor disease progression, assess response to bronchodilators, and evaluate disability. Airflow measurement is obtained by trained personnel using a spirometer. The patient inserts a mouthpiece, takes as deep a breath as possible, and exhales as hard, as fast, and for as long as possible. Verbal coaching is given to ensure that the patient continues blowing out until exhalation is complete.

Computer software calculates the patient's percent of predicted values, that is, how well the performance compares with an average based on age, gender, race, and height.[14] Normal values are 80% to 120% of the predicted value. Normal values for PFTs are shown in Tables 25.16 and 25.17.

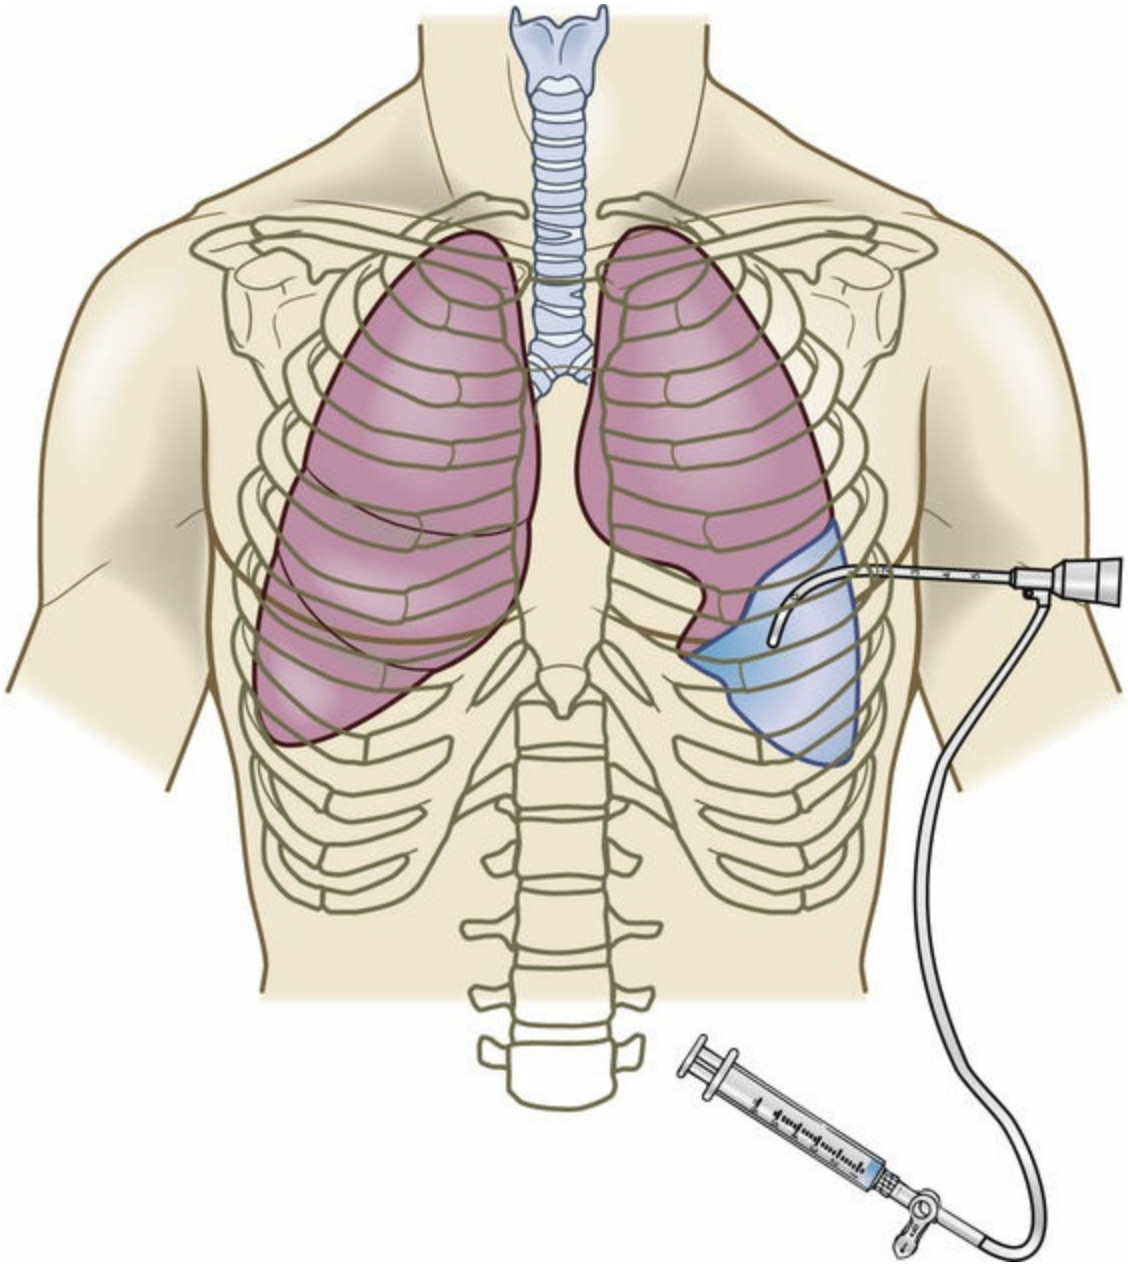

FIG. 25.12 Thoracentesis. A catheter is positioned in the pleural space to remove accumulated fluid.

TABLE 25.16 Lung Volumes and Capacities

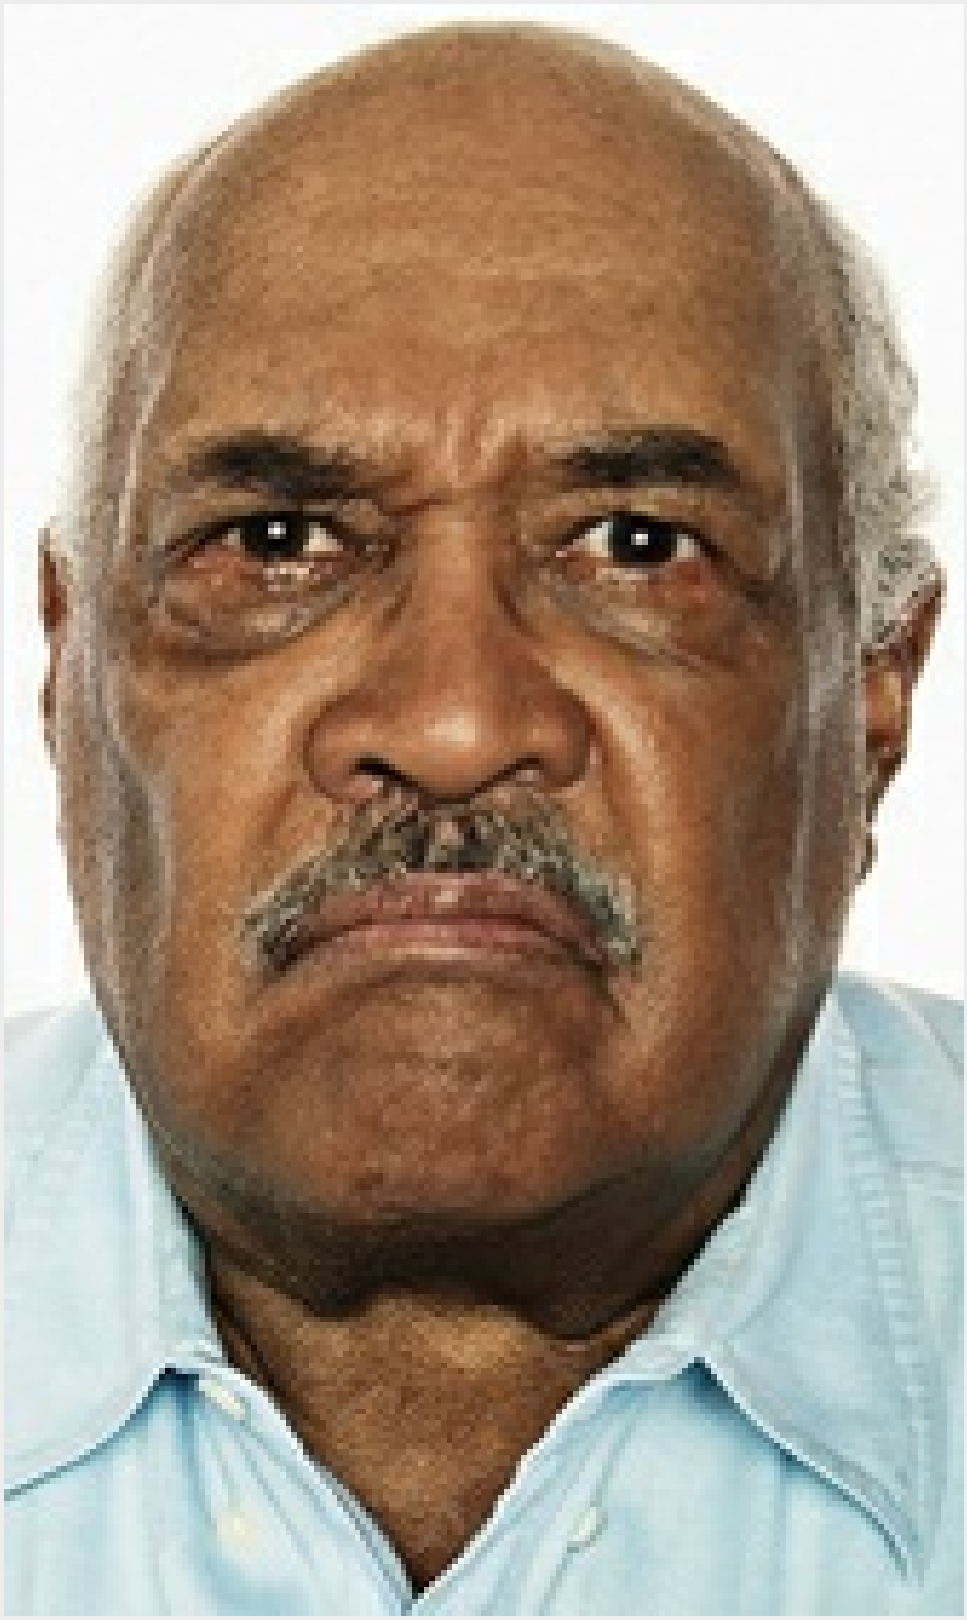
Parameter	Definitions	Normal Value*
Volumes		
Tidal volume (V_T)	Volume of air inhaled and exhaled with each breath. Only a small proportion of total capacity of lungs	0.5 L
Expiratory reserve volume (ERV)	Additional air that can be forcefully exhaled after normal exhalation is complete	1.0 L
Residual volume (RV)	Amount of air remaining in lungs after forced expiration. Air available in lungs for gas exchange between breaths	1.5 L
Inspiratory reserve volume (IRV)	Maximum volume of air that can be inhaled forcefully after normal inhalation	3.0 L
Capacities		
Total lung capacity (TLC)	Maximum volume of air that lungs can contain (TLC = IRV + V_T + ERV + RV)	6.0 L
Functional residual capacity (FRC)	Volume of air remaining in lungs at end of normal exhalation (FRC = ERV + RV). Increase or decrease possible with lung disease	2.5 L
Vital capacity (VC)	Maximum volume of air that can be exhaled after maximum inspiration (VC = IRV + V_T + ERV). Higher VC for men (generally)	4.5 L
Inspiratory capacity (IC)	Maximum volume of air that can be inhaled after normal expiration (IC = V_T + IRV)	3.5 L

* Normal values vary with patient's height, weight, age, race, and gender.

Spirometry may be done before and after giving a bronchodilator to determine the patient's response. This helps gauge the reversibility of airway obstruction (e.g., asthma). A positive bronchodilator response is an increase of greater than 200 mL or 12% in FEV_1 after administering a bronchodilator.

TABLE 25.17 Pulmonary Function Airflow

Measure	Description	Normal Value*
Forced vital capacity (FVC)	Amount of air that can be quickly and forcefully exhaled after maximum inspiration	>80% of predicted
Forced expiratory volume in first second of expiration (FEV_1)	Amount of air exhaled in first second of FVC. Grades severity of airway obstruction	>80% of predicted
FEV_1/FVC ratio	Dividing value for FEV_1 by value for FVC. Useful in differentiating obstructive and restrictive pulmonary dysfunction	*Age <50:* ≥75% of predicted *Age ≥50:* ≥70% of predicted
Forced midexpiratory flow rate ($FEF_{25\%-75\%}$)	Measurement of airflow rate in middle half of forced expiration. Early indicator of disease of small airways	*Age <50:* ≥75% of predicted *Age ≥50:* ≥70% of predicted
Maximal voluntary ventilation (MVV)	Deep breathing as rapidly as possible for specified period. Fairly nonspecific test that gives information about exercise capacity. Used in conjunction with exercise stress test	About 170 L/min
Peak expiratory flow rate (PEFR)	Maximum airflow rate during forced expiration. Aids in monitoring bronchoconstriction in asthma. Can be measured with peak flow meter	Up to 600 L/min



* Normal values vary with patient's height, age, race, and gender.

Home spirometry may be used to monitor lung function in people with asthma, cystic fibrosis, or COPD, as well as before and after lung transplantation or other thoracic surgeries. A peak flow meter is the hand-held instrument used at home. The person blows through it forcefully and quickly after taking a deep breath. Spirometry changes can warn of early lung transplant rejection or infection. Data from a peak flow meter provide important feedback to patients with asthma so that they can learn to change activities and medications in response to changes in peak expiratory flow rates.

More specific pulmonary function parameters can be directly assessed at the bedside in a high-acuity or critical care unit to determine the need for or weaning and extubation from mechanical ventilation (see Table 65.13).

Case Study

Objective Data: Diagnostic Studies

© Fuse/Thinkstock.

The HCP orders the following diagnostic studies for F.T.:

- Pulse oximetry
- Chest x-ray
- 12-lead electrocardiogram (ECG)
- CBC, basic metabolic panel (electrolytes, BUN, creatinine)
- ABGs
- Sputum for culture and sensitivity

F.T.'s SpO_2 is 87% on O_2 @ 3/L min via nasal cannula. The chest x-ray shows a slightly enlarged heart and bilateral consolidation to both lower lobes. The 12-lead ECG reveals sinus tachycardia, rate 110, with no ST segment elevation or depression and no T-wave inversion. The ABGs show compensated respiratory alkalosis with hypoxemia. The WBC is 17,350/μL and potassium 2.9 mEq/L. Sputum results are pending. F.T. is admitted to the medical nursing unit.

Discussion Questions

1. Of the diagnostic test results, is anything abnormal?
2. Which results concern you most?
3. What do you think is the cause of F.T.'s problems?
4. What patient teaching can you do with F.T. as he is waiting to be admitted to the hospital unit?
5. What is the interprofessional team's top priority for F.T. at this time?

You will learn more about the upper and lower respiratory problems and chronic obstructive pulmonary disease (COPD) in the next 3 chapters.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered learning outcome identified at the beginning of this chapter.

1. The key anatomic landmark that separates the upper respiratory tract from the lower respiratory tract is the
   a. carina.
   b. larynx.
   c. trachea.
   d. epiglottis.
2. A patient asks, "How does air get into my lungs?" The nurse bases her answer on knowledge that air moves into the lungs because of
   a. positive intrathoracic pressure.
   b. contraction of the accessory abdominal muscles.
   c. stimulation of the respiratory muscles by the chemoreceptors.
   d. a decrease in intrathoracic pressure from an increase in thoracic cavity size.
3. The nurse can *best* determine adequate arterial oxygenation of the blood by assessing
   a. heart rate.
   b. hemoglobin level.
   c. arterial oxygen partial pressure.
   d. arterial carbon dioxide partial pressure.
4. Defense mechanisms that help protect the lung from inhaled particles and microorganisms include the *(select all that apply)*
   a. cough reflex.

b. mucociliary escalator.

c. alveolar macrophages.

d. reflex bronchoconstriction.

e. alveolar capillary membrane.

5. A student nurse asks the RN what can be measured by arterial blood gas (ABG). The RN tells the student that the ABG can measure *(select all that apply)*

a. acid-base balance.

b. oxygenation status.

c. acidity of the blood.

d. bicarbonate (HCO_3^-).

e. compliance and resistance.

6. To detect early signs or symptoms of inadequate oxygenation, the nurse would examine the patient for

a. dyspnea and hypotension.

b. apprehension and restlessness.

c. cyanosis and cool, clammy skin.

d. increased urine output and diaphoresis.

7. During the respiratory assessment of an older adult, the nurse would expect to find *(select all that apply)*

a. a vigorous reflex cough.

b. increased chest expansion.

c. increased residual volume.

d. decreased lung sounds at base of lungs.

e. increased anteroposterior (AP) chest diameter.

8. When assessing subjective data related to the respiratory

health of a patient with emphysema, the nurse asks about *(select all that apply)*

a. date of last chest x-ray.

b. dyspnea during rest or exercise.

c. pulmonary function test results.

d. ability to sleep through the entire night.

e. prescription and over-the-counter medication.

9. When auscultating the chest of an older patient in mild respiratory distress, it is *best* to

a. begin listening at the apices.

b. begin listening at the lung bases.

c. begin listening on the anterior chest.

d. Ask the patient to breathe through the nose with the mouth closed.

10. Which respiratory assessment finding does the nurse interpret as abnormal?

a. Inspiratory chest expansion of 1 inch

b. Symmetric chest expansion and contraction

c. Resonance (to percussion) over the lung bases

d. Bronchial breath sounds in the lower lung fields

11. The nurse is preparing the patient for a diagnostic procedure to remove pleural fluid for analysis. The nurse would prepare the patient for which test?

a. Thoracentesis

b. Bronchoscopy

c. Pulmonary angiography

d. Sputum culture and sensitivity

1. a, 2. d, 3. c, 4. a, b, c, d, 5. a, b, c, d, 6. b, 7. c, d, e, 8. b, d, e, 9. b, 10. d, 11. a

Upper Respiratory Problems

Eugene Mondor

LEARNING OUTCOMES

1. Describe the clinical manifestations and nursing and interprofessional management of problems of the nose.
2. Discuss the clinical manifestations and nursing and interprofessional management of problems of the paranasal sinuses.
3. Describe the clinical manifestations and nursing and interprofessional management of problems of the pharynx and larynx.
4. Relate the nursing and interprofessional management of the patient who has a tracheostomy.
5. Identify the steps involved in performing tracheostomy care and suctioning a patient with a tracheostomy.
6. Outline the risk factors for and clinical manifestations of head and neck cancer.
7. Discuss the nursing and interprofessional management of patients requiring surgery for head and neck cancer.
8. Explain essential components of discharge teaching for the patient going home with a permanent tracheostomy after total laryngectomy for cancer.

Conceptual Focus

Cellular Regulation
Functional Ability
Gas Exchange
Immunity
Infection
Sensory Perception

Disorders of the upper respiratory system, including the nose, sinuses,

pharynx, and larynx, and the care of those undergoing surgery for head and neck cancers are the focus of this chapter. The primary concern with these problems is the impact on ventilation and oxygen (O_2) availability. Upper airway problems can negatively affect sleep and impair the ability to obtain and maintain nutrition. Sinus and upper respiratory tract infections, allergies, and oral problems can change the senses of both smell and taste. The patient with head and neck cancer often has depression and changes in body image and sexuality.

Problems Of Nose And Paranasal Sinuses

Deviated Septum

Deviated septum is a deflection of the normally straight nasal septum. Although up to 80% of adults may have septa that are slightly off center, the diagnosis of deviated septum is generally reserved for those whose septa are severely shifted.[1] Trauma to the nose, either at birth or later in life, is the most common cause of deviated septum.[2] Deviated septum can interfere with both airflow and sinus drainage through the narrowed passageway.

Symptoms vary depending on the degree of deviation. Minor septal deviations can range from asymptomatic to nasal congestion and frequent sinus infections. Manifestations of severe septal deviation include facial pain, nosebleeds *(epistaxis),* and obstruction to nasal breathing.

The diagnosis of deviated septum is made during physical examination with a nasal speculum. The medical management of minor septal deviation focuses on symptom control. For nasal inflammation and congestion, use saline rinses and decongestants to clear nasal passages and analgesics for pain relief. For severe septal deviation, a nasal septoplasty, done under local or general anesthetic, reconstructs and properly aligns the deviated septum.

Nasal Fracture

Nasal fracture is the most common facial fracture and the third most common fracture of any bone.[3] They often occur from blunt trauma, including fights, automobile accidents, falls, and sports injuries. Using protective sports equipment and safeguarding against falls can prevent many nasal fractures.

There is no universally accepted classification system for nasal fractures. We can classify nasal fractures according to the fracture pattern (e.g., impacted, comminuted) or based on direction of injury (e.g., lateral, frontal). *Simple fractures* may be unilateral or bilateral and typically have little or no displacement. Powerful frontal blows can cause *complex fractures,* which may involve damage to adjacent facial structures, such as the teeth or eyes. Patients with complex nasal fractures should be evaluated for injury to the cervical spine, orbital bone, or mandible.[4] Complications include airway obstruction, nosebleeds, meningeal tears causing cerebrospinal fluid (CSF) leakage, septal hematoma, and cosmetic deformity.

Diagnosis of a nasal fracture is based on health history and physical assessment. Although facial deformity with a nasal fracture is common, a nosebleed may be the only manifestation. Other manifestations include localized pain, crepitus on palpation, swelling, difficulty breathing out of the nostrils, and bruising.

Assess the patient's ability to breathe through each side of the nose. Note the presence of edema, bleeding, or hematoma. Periorbital bruising involving both eyes is called *raccoon eyes*. It suggests a basilar skull fracture (see Chapter 56). Inspect the nose internally for evidence of septal deviation, clear drainage, edema, or bleeding.

Clear or pink-tinged persistent drainage after control of bleeding suggests a possible CSF leak. Checking this fluid for glucose at the bedside to help confirm the presence of CSF is not recommended because the result is highly unreliable. If needed, send a specimen to the laboratory to determine the fluid type.

Goals of nursing management are to maintain a patent airway, reduce edema and pain, prevent complications, and provide

emotional support. The best way to maintain the airway is to keep the patient sitting upright. Apply ice to the face and nose in 10- to 20-minute intervals to help reduce edema and bleeding. Give analgesia as ordered to control pain. Acetaminophen is preferred over nonsteroidal antiinflammatory drugs (NSAIDs) or acetylsalicylic acid (ASA; aspirin) for the first 48 hours to avoid prolonging clotting time and increasing the risk for bleeding. Nasal stuffiness may be relieved with nasal decongestants, saline nasal sprays, and a humidifier. The patient should avoid hot showers and alcohol for the first 48 hours to prevent an increase in swelling. Encourage the patient to quit or decrease smoking to help tissue healing.

When a fracture is confirmed, the goals are to realign the fracture using closed or open reduction.[5] Simple fractures are often reduced with manual manipulation. With complex nasal fractures, considerable swelling of soft tissues occurs. It may be necessary to wait to repair the fracture until after the edema subsides, which may be 5 to 10 days. Antibiotics should be considered for any nasal fracture with disruption to the mucosa.

Surgical options include septoplasty and rhinoplasty. Septoplasty is done to correct a deviated septum. Patients have rhinoplasty for several reasons. Both procedures help maintain a patent airway, restore function of the nose, and help reestablish the patient's cosmetic appearance. The presence of septal hematoma increases the patient's risk for deformity and infection, which may require drainage and antibiotic therapy.

Rhinoplasty

Rhinoplasty, surgical reconstruction of the nose, is done to improve airway function when trauma or developmental deformities result in nasal obstruction or for cosmetic reasons. When caring for rhinoplasty patients before surgery, assess the patient's expectations of the surgery. Actual or perceived changes in body image (e.g., deformed or enlarged nose) can affect self-esteem and interactions with others. The HCP can use digital photographs to show patients their projected

appearance after surgery. These images can help patients decide whether to undergo rhinoplasty.

Most rhinoplasty is an outpatient procedure using regional or general anesthesia. Nasal tissue is added or removed, and the nose may be lengthened or shortened. Plastic implants are sometimes used to reshape the nose. Incisions are typically inside the nose and hidden. Sonic rhinoplasty incorporates the use of an ultrasonic device to gently aspirate bone, enabling a refined cosmetic result.[6]

After surgery, nasal packing may be inserted to apply pressure and prevent bleeding or septal hematoma formation. An external plastic splint protects and supports the new shape of the nose during the healing process. If present, nasal packing is usually removed 1 or 2 days after surgery. The splint may be left in place for 1 to 2 weeks.

Nursing Management: Nasal Surgery

Before surgery, teach patients to notify the HCP about any medications that they take at home. Aspirin-containing drugs and NSAIDs may need to be stopped for 5 days to 2 weeks preoperatively to reduce the risk for bleeding. Encourage smoking cessation to promote postoperative wound healing. During the immediate postoperative period, nursing interventions include (1) ensuring patency of the airway, (2) continuous assessment of respiratory status, (3) monitoring for airway obstruction, (4) pain management, and (5) observation of the surgical site for edema, bleeding, and signs and symptoms of infection.

Teaching is important because the patient must be able to detect complications at home. The patient typically has temporary nasal and/or facial edema and bruising. Cold compresses and elevation of the head can help minimize swelling and discomfort. Teach about activity restrictions aimed at preventing bleeding and injury (no nose blowing, swimming, heavy lifting, strenuous exercise). Sometimes swelling may be slow to resolve, delaying the achievement of a full cosmetic result for up to 1 year.

Epistaxis

Epistaxis (nosebleed) most often occurs in adults over age 50. Nosebleeds can be caused by trauma, hypertension, low humidity, upper respiratory tract infections, allergies, sinusitis, foreign bodies, chemical irritants (e.g., street drugs), overuse of decongestant nasal sprays, facial or nasal surgery, anatomic malformation, and tumors.[7] Conditions that prolong bleeding time or change platelet counts may predispose a patient to nosebleeds. Bleeding time may be prolonged if the patient takes aspirin, NSAIDs, warfarin, or other anticoagulant drugs.

About 90% of nosebleeds occur in the anterior part of the nasal cavity and are easily visualized. Anterior bleeding can be self-treated and usually stops spontaneously.

Posterior bleeding occurs more often with older adults secondary to other health problems (e.g., hypertension). Since posterior nosebleeds are closer to the throat, it is often hard to determine how much blood loss has occurred. Posterior bleeding may need medical treatment.

Interprofessional and Nursing Care

Use simple first aid measures to control nosebleeds. These include (1) place the patient in a sitting position, leaning slightly forward with head tilted forward; (2) apply direct pressure by squeezing the entire soft lower part of the nose (nostrils) together for 5 to 15 minutes; and (3) reassure and calm the patient. If bleeding does not stop within 15 minutes, seek medical assistance.

Medical management involves trying to find the location of the bleed. For anterior bleeds, a pledget (nasal tampon) impregnated with anesthetic solution (lidocaine) and/or vasoconstrictive agents (epinephrine) may be placed into the nasal cavity. Absorbable materials, such as oxidized cellulose (surgical), gelatin foam (Gelfoam), or a gelatin-thrombin combination (Floseal), are another option. Packing for anterior bleeds can stay in place for 48 to 72 hours. Silver nitrate may be used to chemically cauterize a specific bleeding point. Thermal cauterization is reserved for more severe bleeding and

may require the use of local or general anesthesia.[8]

It may be harder to find the location of a posterior bleed. Posterior bleeds often need packing. Packing with compressed nasal sponges (e.g., Merocel) or epistaxis balloons (e.g., Rapid Rhino) is preferred over the use of traditional Vaseline ribbon gauze because of the ease of placement. Packing is inserted into the nares and advanced along the floor of the nasal cavity. The sponge expands with moisture to fill the nasal cavity and tamponade bleeding. The epistaxis balloon is inflated with air to achieve the same pressure effect (Fig. 26.1). In the absence of a specific nasal device, a size 10F, 12F, or 14F Foley catheter with a 30-mL balloon may be used. A nasal sling (folded 2 × 2–inch gauze pad) may be gently taped under the nares to absorb drainage. If packing does not stop the bleeding, arterial embolization may be needed.

Nasal sponges, packing, and balloons can impair respiratory status. Closely monitor the level of consciousness, heart rate and rhythm, respiratory rate, and O_2 saturation (SpO_2) using pulse oximetry. Observe for any signs of difficulty breathing or swallowing. Because of the increased risk for complications due to location of the injury, all patients with posterior packing should be admitted to a monitored unit for close observation.

Nasal packing is painful because sufficient pressure must be applied to stop the bleeding. The patient should receive appropriate analgesia. Nasal packing predisposes patients to infection from bacteria (e.g., *Staphylococcus aureus*) present in the nasal cavity. Antibiotics effective against staphylococci may be prescribed.

Nasal packing for posterior bleeds may be left in place for 2 to 3 days. Before removal, pre-medicate the patient for pain because this procedure is uncomfortable. After packing removal, cleanse the nares gently and lubricate them with water-soluble jelly.

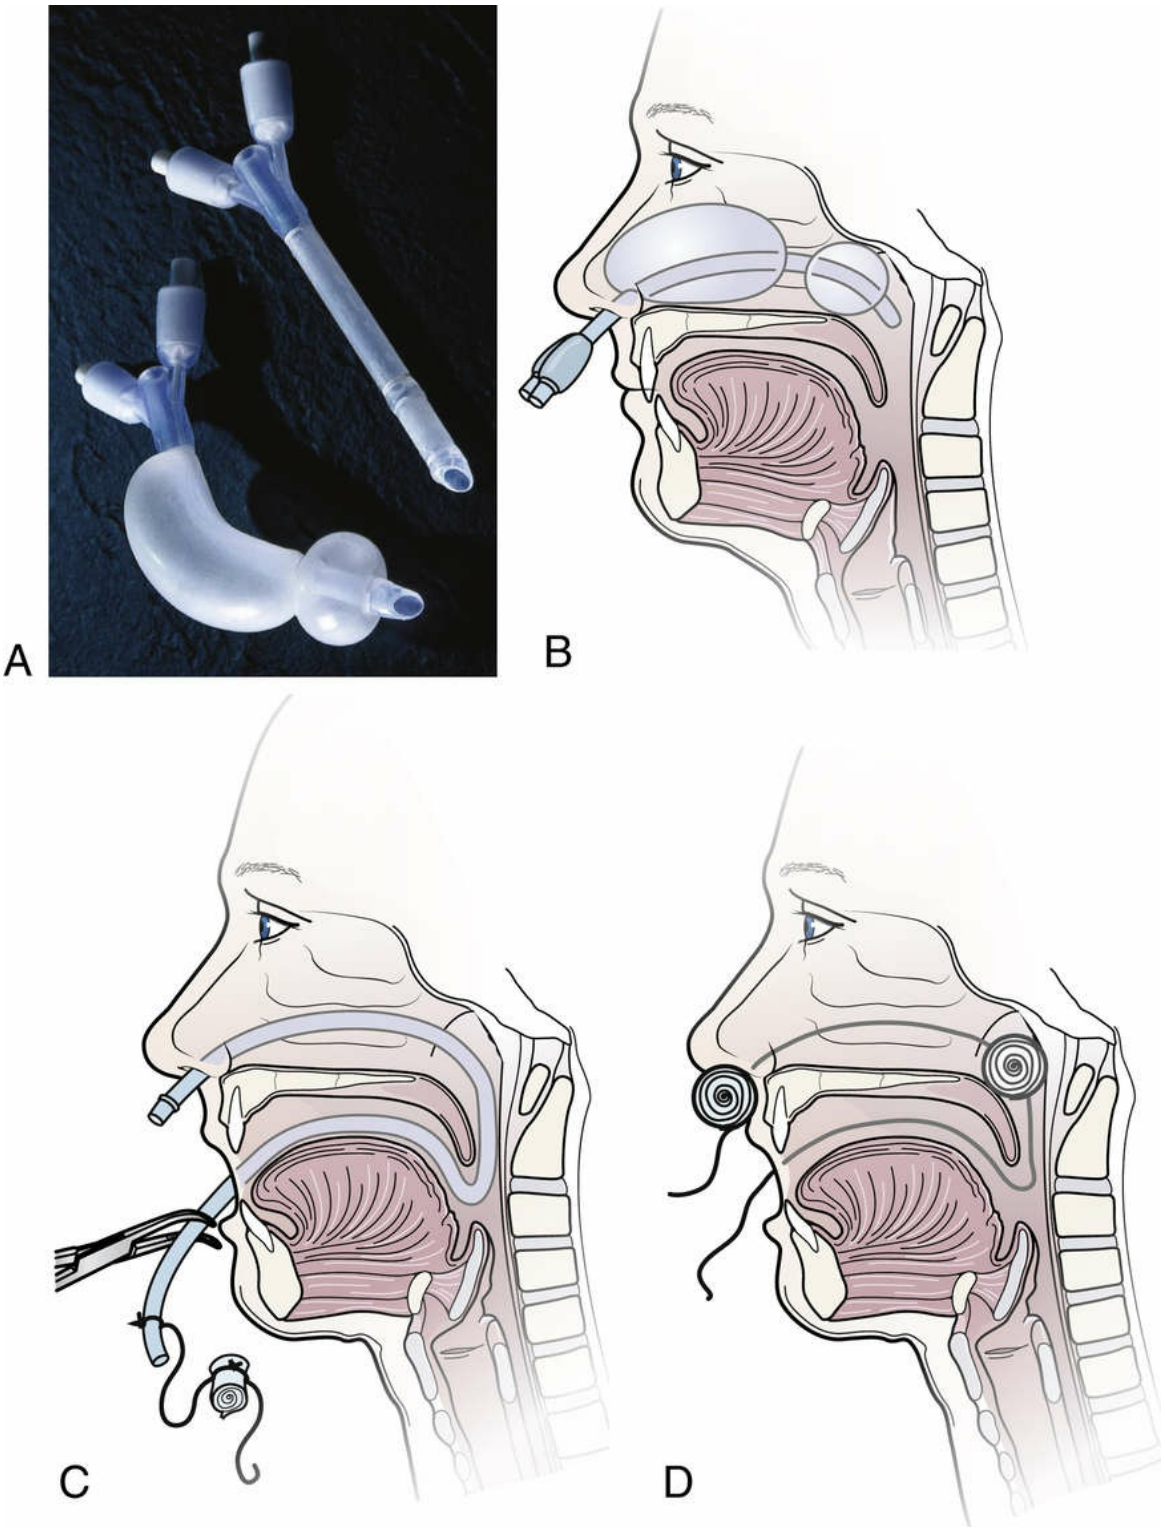

FIG. 26.1 **A,** Epistaxis balloon. The balloon is inflated after insertion. (Courtesy Boston Medical, Westborough, Mass.) **B,** Epistaxis balloon in proper position in nares. (From Roberts JR, Hedges JR: *Clinical procedures in emergency medicine,* ed 5, Philadelphia, 2009, Saunders.) **C,** Method for placing posterior nasal pack. Catheter is passed through the bleeding side of the nose and pulled out through

the mouth with a hemostat. Strings are tied to the catheter, and the pack is pulled up behind the soft palate and into the nasopharynx. **D,** Nasal pack in position in the posterior nasopharynx. Dental roll at the nose helps maintain correct position.

Before discharge teach the patient and caregiver about follow-up care. Review how to use saline nasal spray and/or a humidifier. Have the patient sneeze with the mouth open and avoid the use of aspirin-containing products or NSAIDs. Teach the patient to avoid vigorous nose blowing, engaging in strenuous activity, and lifting and straining for 4 to 6 weeks.

Allergic Rhinitis

Allergic rhinitis is inflammation of the nasal mucosa, often in response to a specific allergen. Allergic rhinitis can be classified according to the causative allergen (seasonal or perennial) or the frequency of symptoms (episodic, intermittent, or persistent). *Episodic* refers to symptoms related to sporadic exposure to allergens not typically encountered in the patient's normal environment, such as exposure to animal dander when visiting another person's home. *Intermittent* means that the symptoms are present less than 4 days a week or less than 4 weeks per year. *Persistent* means that symptoms are present more than 4 days a week and for more than 4 weeks per year.

Seasonal rhinitis usually occurs in the spring and fall. It is caused by allergy to pollens from trees, flowers, grasses, or weeds. Attacks may last for several weeks during times when pollen counts are high; then it disappears and often recurs at the same time the next year. *Perennial rhinitis* occurs year-round from exposure to environmental allergens, such as animal dander, dust mites, cockroaches, fungi, and molds. Both seasonal and perennial rhinitis can be classified as episodic, intermittent, or persistent, depending on the duration and frequency of symptoms.

Sensitization to an allergen occurs with initial allergen exposure, which results in the production of antigen-specific immunoglobulin E

(IgE) (see Fig. 13.6). After exposure, mast cells and basophils release histamine, cytokines, prostaglandins, and leukotrienes. These cause the early symptoms of sneezing, itching, rhinorrhea, and congestion.[9] 4 to 8 hours after exposure, inflammatory cells infiltrate the nasal tissues, causing and maintaining the inflammatory response. Because symptoms of rhinitis are like those of the common cold, the patient may think the condition is a continuous or repeated cold.

Clinical Manifestations

Manifestations of allergic rhinitis are sneezing; watery, itchy eyes and nose; decreased sense of smell; and thin, watery nasal discharge that can lead to a more sustained mucus production and nasal congestion. Nasal turbinates appear pale, boggy, and swollen. The turbinates may fill the air space and press against the nasal septum. The posterior ends of the turbinates can become so enlarged that they obstruct sinus aeration or drainage and result in sinusitis. With chronic exposure to allergens, the patient may develop a headache, stuffy nose, nasal congestion, and sinus pressure. Nasal polyps and postnasal drip are the most common causes of cough. The patient may report hoarseness and the need to frequently clear the throat.

Interprofessional and Nursing Care

The key step to managing allergic rhinitis is identifying and avoiding triggers of allergic reactions (Table 26.1). Teach the patient to take note when allergic reactions occur and keep a diary of activities that precipitate the reaction. Patients are often more aware of intermittent exposure to an allergen, such as pets, than they are of a more persistent exposure to allergens, such as dust mites, cockroaches, or mold. Identifying triggers is the first step toward avoiding them.

TABLE 26.1 Patient & Caregiver

TeachingAvoiding Allergens in Allergic Rhinitis

Include the following instructions when teaching a patient or caregiver about allergic rhinitis:

What to Avoid	Specific Approaches
House dust	• Focus on the bedroom. Remove carpeting. Limit furniture. • Put the pillows and mattress in airtight vinyl bags. • Limit clothing in the bedroom to items worn often. Place clothing in airtight, zipper-sealed vinyl clothes bags. • Install a high-efficiency particulate air (HEPA) filter. • Close the air-conditioning vent into room. • Use blinds rather than draperies.
House dust mites	• Wash bedding in hot water (140° F [60° C]). • Wear a mask when vacuuming. • Install a filter on the outlet port of vacuum cleaner. • Avoid sleeping or lying on upholstered furniture. • Keep house temperature and conditions cool and dry.
Mold spores	• The 3 *D*s that promote growth of mold spores are darkness, dampness, and drafts. • Ventilate closed rooms and open doors. Consider adding windows to dark rooms and keeping a small light on in closets. • Basement light with a timer that provides light several hours a day may decrease mold growth. • Avoid places where humidity is high (e.g., basements, clothes hampers, greenhouses, barns). Dehumidifiers are rarely helpful.
Pet allergens	• Remove pets from interior of home. • Clean living area thoroughly. • Do not expect instant relief. Symptoms usually do not improve significantly for 1 to 2 months after pet removal.
Pollens	• Stay inside with doors and windows closed during high-pollen season. • Install an air conditioner with an air filter. Wash filters weekly during high-pollen season. • Use your car's air conditioner "recirculation" feature (circulates air inside the car, while shutting off air coming into the vehicle from the outside). • Avoid having plants, especially in the bedroom.
Smoke	• Encourage family and friends to refrain from smoking (if possible) or to go outdoors to smoke. • Presence of a smoker will sabotage any symptom reduction program.

The goal of drug therapy is to reduce inflammation associated with allergic rhinitis, reduce nasal symptoms, minimize associated complications, and maximize quality of life. Nasal corticosteroid sprays are the first-line and most effective treatment for allergic rhinitis.[10] Appropriate oral medication options include H_1-antihistamines, decongestants, and leukotriene receptor antagonists (LTRAs). Intranasal medications include antihistamines, anticholinergics, corticosteroids, cromolyn, and decongestants (Table 26.2).[11]

TABLE 26.2 Drug TherapyRhinitis and Sinusitis

Drug	Mechanism of Action	Side Effects	Nursing Actions
Anticholinergic			
Nasal Spray **ipratropium bromide (Atrovent)**	Blocks nasal cholinergic receptors, reducing nasal secretions in the common cold and nonallergic rhinitis.	Nasal dryness and irritation, nosebleeds may occur. Does not cause systemic side effects.	• May reduce the need for other rhinitis medications.
Antihistamines			
First-Generation Agents (Oral)			
brompheniramine **chlorpheniramine (Chlor-Trimeton)** **clemastine (Tavist)** **dexchlorpheniramine** **diphenhydramine (Benadryl)**	Bind with H_1 receptors on target cells, blocking histamine release. Relieve acute symptoms of allergic response (itching, sneezing, rhinorrhea).	Cross blood-brain barrier, often causing sedation and somnolence. Can cause paradoxic stimulation (restlessness, nervousness, insomnia). Anticholinergic side effects (e.g., palpitations, dry mouth, constipation, urinary hesitancy).	• Warn patient that operating machinery and driving may be dangerous because of sedative effect. • Teach patient to report palpitations, change in heart rate, change in bowel or bladder habits. • Teach patient not to use alcohol with antihistamines because of additive depressant effect. • Rapid onset of action, no drug tolerance with prolonged use.
Second-Generation Agents (Oral)			
cetirizine (Zyrtec) **desloratadine (Clarinex)** **fexofenadine (Allegra)** **levocetirizine (Xyzal)** **loratadine (Claritin)**	Same as above.	Limited affinity for brain H_1 receptors. Cause minimal sedation, few effects on psychomotor activities or bladder function.	• Teach patient to expect few, if any, side effects. • More expensive than traditional antihistamines. • Rapid onset of action, no drug tolerance with prolonged use.
Second-Generation Agents (Intranasal)			
azelastine (Astelin) **olopatadine (Patanase)**	Blocks histamine release and reduces nasal congestion.	Headache, bitter taste, somnolence, nasal irritation.	• Longer use increases risk for rebound vasodilation, which can increase congestion.
Corticosteroids			
Nasal Spray **beclomethasone** **budesonide (Rhinocort)** **ciclesonide (Omnaris)** **flunisolide** **fluticasone (Flonase)** **fluticasone** **mometasone (Nasonex)** **triamcinolone**	Inhibits inflammatory response of allergic rhinitis. Decreases mucosal inflammation and facilitates drainage of sinuses. Systemic effects may occur with higher than recommended doses.	At recommended dose, systemic side effects unlikely due to low systemic absorption. Mild transient nasal irritation, mucosal drying, nosebleeds. In rare instances, localized fungal infection with *Candida albicans*.	• Adherence important. Teach patient to use on regular basis and not PRN. • Teach patient to clear nasal passages before use. • Reinforce that spray acts to decrease inflammation and it may take several days or 1–2 wks to achieve maximum effects. • Stop use if nasal infection develops.
Decongestants			
Oral			
pseudoephedrine (Sudafed)	Stimulates adrenergic receptors and promotes vasoconstriction of superficial vessels in the nose and reduces nasal congestion.	CNS stimulation, causing insomnia, excitation, headache, irritability, increased blood and ocular pressure, dysuria, palpitations, tachycardia.	• Tolerance variable. • Advise patient of adverse reactions. • Patient to inform HCP if preexisting cardiovascular disease, hypertension, diabetes, glaucoma, benign prostatic hyperplasia, hepatic or renal disease present before starting therapy. • Rebound nasal congestion may occur with chronic overusage.
Intranasal (Nasal Spray)			
oxymetazoline **phenylephrine**	Same as above.	Same as above.	• Teach patient that these drugs should not be used for >3 days or >3 or 4 times/day. • Rebound nasal congestion may occur. • Addiction possible.
Leukotriene Receptor Antagonists (LTRAs) and Inhibitors			
Antagonists **montelukast (Singulair)** **zafirlukast (Accolate)** ***Inhibitors*** **zileuton (Zyflo)**	Suppress leukotriene activity, thereby inhibiting airway edema, bronchoconstriction, mucus production, and inflammation (see Fig. 11.2).	Well tolerated. May cause headaches, dizziness, rash, altered liver function, GI changes. *Zafirlukast and zileuton:* Monitor PT levels if patient is taking warfarin.	• Monitor liver function tests periodically while on therapy. Stop if elevated. • Give on empty stomach. • Do not stop therapy without consulting HCP. • Do not use for acute attacks.

Drug	Mechanism of Action	Side Effects	Nursing Actions
			Table Continued

Drug	Mechanism of Action	Side Effects	Nursing Actions
Mast Cell Stabilizer			
Nasal Spray **cromolyn spray**	Suppresses release of histamine and other inflammatory mediators from mast cells.	Minimal side effects. Occasional nasal irritation.	• Reinforce that spray prevents symptoms. • Begin 1 wk before pollen season starts and use throughout pollen season. • For isolated allergy, use prophylactically before exposure to allergen. • When used to treat chronic rhinitis, antihistamine and/or nasal decongestant may be used at the same time.
Combination Cold Medications			
hydrocodone, pseudoephedrine (Rezira oral solution) **hydrocodone, chlorpheniramine, pseudoephedrine (Zutripro oral solution)**	Hydrocodone suppresses cough. Mechanism of action of chlorpheniramine and pseudoephedrine discussed above.	See individual drugs above.	• Potential for misuse with repeated use. • Avoid in patients with head injury, increased ICP, acute abdominal conditions. • Do not use at the same time, or, within 14 days of MAOI drugs. • Increased risk for sedation when used with CNS depressants and/or benzodiazepines.

PT, prothrombin time; *ICP,* intracranial pressure; *MAOI,* monoamine oxidase inhibitor.

Second-generation antihistamines are used before first-generation antihistamines because of their nonsedating effects. Teach patients taking antihistamines to have adequate fluid intake to reduce adverse symptoms. Nasal corticosteroid sprays decrease inflammation with little absorption in the systemic circulation. Therefore systemic side effects are rare. If monotherapy does not relieve symptoms, a 2-drug combination, such as an oral H_1-antihistamine and an intranasal corticosteroid, may be helpful.

Drug Alert

Antihistamines

- First-generation antihistamines (e.g., chlorpheniramine [Chlor-Trimeton]) can cause drowsiness and sedation.
- Warn patients that operating machinery and driving may be dangerous because of the sedative effect.

Drug Alert

Pseudoephedrine (Sudafed)

- Large doses may cause tachycardia and palpitations, especially in patients with heart disease.
- Overdose in those over 60 years of age may result in central nervous system depression, seizures, and hallucinations.

Immunotherapy (allergy shots) may be used when a specific, unavoidable allergen is identified, and drugs are not tolerated or are ineffective in controlling symptoms. Immunotherapy involves controlled exposure to small amounts of the known allergen through frequent (at least weekly) injections with the goal of decreasing sensitivity. Sublingual or intranasal administration of allergen immunotherapy may an option for select patients. Immunotherapy is discussed in Chapter 13.

Acute Viral Rhinopharyngitis

Acute viral rhinopharyngitis (nasopharyngitis, common cold) is an infection of the upper respiratory tract. It is the most prevalent infectious disease, with the average adult contracting 1 to 3 colds per year. More than 200 different viruses can cause a common cold. Most are caused by the coronavirus and are mild and self-limiting. Other viruses, such as human respiratory syncytial virus (RSV) and enterovirus, can cause a common cold.

The viruses are contagious. They spread by airborne droplets emitted by the infected person while breathing, talking, sneezing, or coughing. Because they can survive on inanimate objects for up to 3 days, transmission also occurs by direct hand contact. Frequency of the infection increases in winter months when people stay indoors and overcrowding is more common. Other factors that increase susceptibility include fatigue, physical and emotional stress, allergies

affecting the nose and throat, and a compromised immune status. Exercise may reduce the number of upper respiratory tract infections.

Symptoms typically begin 2 or 3 days after infection. They may include runny nose, watery eyes, nasal congestion, sneezing, cough, sore throat, fever, headache, and fatigue. Patients are contagious 1 to 2 days before symptom onset and remain contagious until symptoms have subsided. Symptoms may last 2 to 14 days, with typical recovery in 7 to 10 days.

Complementary & Alternative Therapies

Echinacea

Scientific Evidence

- Echinacea may slightly reduce the incidence of the common cold.
- Taking echinacea does not appear to reduce the duration of a common cold.

Nursing Implications

- Echinacea is considered safe when used on a short-term basis in recommended doses.
- Caution patients with autoimmune disorders or a tendency toward allergic reactions about using this herb.

Source: Retrieved from *www.nccih.nih.gov/health/echinacea/ataglance.htm*.

Complementary & Alternative Therapies

Zinc

Scientific Evidence

- Zinc is available in 2 forms: oral zinc (e.g., lozenges, tablets, syrup) and intranasal zinc (e.g., swabs, gels).
- When given within 24 hrs of onset of symptoms, zinc lozenges may reduce the duration of cold symptoms.

Nursing Implications

- Intranasal zinc can cause an irreversible loss of the sense of smell.
- Long-term zinc use, especially in high doses, can cause copper deficiency and may increase the risk for urinary tract problems and reduce immune function.
- Zinc may interact with drugs, including antibiotics and penicillamine.

Source: Retrieved from *www.nccih.nih.gov/health/zinc*.

Interprofessional and Nursing Care

Interventions are directed at relieving symptoms. Rest, oral fluids, antipyretics, and analgesics are recommended. Warm salt water gargles, ice chips, lozenges, or sprays may help ease a sore throat. Petroleum jelly soothes a raw nose. Saline nasal spray reduces nasal congestion. Antihistamine and decongestant therapy reduce postnasal drip and decreases the severity of cough, nasal obstruction, and nasal discharge. Caution patients to use intranasal decongestant sprays for no more than 3 days to prevent rebound congestion from occurring. Cough suppressants, for irritating, bothersome coughs, may be used, but may not be effective. Patients may ask about vitamin C, echinacea, and zinc products. There is inconclusive evidence to support treatment with these therapies.

Complications include acute bronchitis, sinusitis, otitis media, tonsillitis, and pneumonia. Antibiotics have no effect on viruses. They are an option only if complications are present. Refer to an HCP if there is no improvement in symptoms within 10 to 14 days.

Teach patients to recognize the manifestations of a secondary bacterial infection, such as a temperature higher than 103° F (39.4° C); tender, swollen glands; severe sinus or ear pain; or significantly worsening symptoms. Green, purulent nasal drainage during the later stages of a cold is not uncommon and not always indicative of bacterial infection. In the patient with lung disease, signs of infection include a change in consistency, color, or volume of the sputum. Because infection can progress rapidly, teach the patient with chronic respiratory disease to immediately report sputum changes, increased shortness of breath, and chest tightness.

During the cold season, teach patients with a chronic illness or a compromised immune system to avoid crowded situations and those with obvious cold symptoms. Frequent hand washing and avoiding hand-to-face contact can help prevent direct spread.

Influenza

Influenza (flu) is a highly contagious respiratory illness that causes significant morbidity and mortality. Millions of Americans (about 5% to 20% of U.S. population) contract influenza each year. The flu season begins in September and continues through April of each year, peaking between December to February. More than 310,000 people were hospitalized for flu-related complications in 2016.[12] Although the exact number of flu-related deaths is not known, it is estimated that influenza is responsible for 3000 - 49,000 deaths annually, depending on the strain.[13] Vaccination of high-risk groups may help prevent many of these deaths.

Etiology and Pathophysiology

We classify influenza viruses into 4 serotypes (A, B, C, D). Only A and

B cause significant illness in humans. Influenza A is subtyped based on the presence of 2 surface proteins: hemagglutinin (H) and neuraminidase (N). The H antigens enable the virus to enter the cell, and the N antigens facilitate cell-to-cell transmission. As a result, we name influenza A viruses according to their H and N type (e.g., H3N2).

Influenza A is the most common and most virulent flu virus. It can infect a variety of animals as well as humans. More than 100 types of influenza A are found in birds (avian flu), pigs (swine flu), horses, seals, and dogs. When the virus mutates (changes), this allows it to infect different species. When a new viral strain reaches humans, people do not have immunity and the virus can spread quickly around the globe, causing a *pandemic.* For example, type A H1N1 influenza (swine flu) emerged in 2009 and had never been seen in humans before, resulting in a worldwide pandemic. The reemergence of a viral strain that has not circulated for many years can also trigger a pandemic. *Epidemics* are more localized outbreaks, often occurring yearly, caused by variants of already circulating strains of the influenza virus.

Influenza B and C viruses only infect humans. They are not divided into subtypes. Outbreaks of influenza B can cause regional epidemics, but the disease it produces is milder than that caused by influenza A. Influenza C causes mild illness and does not cause epidemics or pandemics. Influenza D only occurs in animals.

Influenza is communicable between humans primarily through infected droplets, inhalation of aerosolized particles, and, to a lesser extent, through direct contact with contaminated surfaces. The virus has an incubation period of 1 to 4 days, with peak transmission risk starting 1 day before onset of symptoms and continuing for 5 to 7 days after a person first becomes sick.[14]

Clinical Manifestations

For some patients, it may be hard to tell between the common cold and flu (Table 26.3). The onset of flu is abrupt. There may be chills,

fever, and generalized myalgia, often accompanied by a headache, cough, sore throat, and fatigue. Assessment findings are usually minimal, with normal breath sounds on chest auscultation. In uncomplicated cases, symptoms often subside within 7 days.

Common complications include pneumonia, which can be either primary influenza [viral] pneumonia or secondary bacterial pneumonia, and ear or sinus infections. Dyspnea and diffuse crackles are signs of pulmonary complications. Some patients, especially older adults, have weakness or lethargy that may last for weeks. The patient who develops secondary bacterial pneumonia usually has gradual improvement of influenza symptoms, then worsening cough and purulent sputum. Treatment with antibiotics is usually effective if started early.

Diagnostic Studies

Influenza is often diagnosed based on the patient's health history and physical assessment and the knowledge of other cases of influenza in the community.

TABLE 26.3 Comparison of Common Cold and Influenza

Manifestations and Treatment	Common Cold (Viral Rhinitis)	Influenza
Symptom onset	Appear gradually	Abrupt onset. Within 3–6 hr
Fever	Rare	Characteristically high 102–104° F (38.9–40° C]). Lasts 3–4 days
Headache	Uncommon, but may occur	Common (can be severe)
General aches and pains	Slight	Often severe myalgia
Fatigue and weakness	Sometimes. Usually mild	Usual. Starts early and can last up to 2–3 wks

Exhaustion	Uncommon	Usual at beginning of illness
Stuffy nose	Common	Sometimes
Sneezing	Common	Sometimes
Sore throat	Common	Sometimes
Chest discomfort, cough	Common. Mild to moderate hacking cough	Common
Complications	Sinus congestion. Earache	Bronchitis, pneumonia, acute respiratory failure, ARDS. Can be life-threatening
Prevention	Hand washing. Avoid close contact with anyone who has a cold	Hand washing. Annual vaccination. Antiviral drugs. Avoid close contact with anyone who has the flu
Treatment	Temporary relief of symptoms: rest, hydration, decongestants, acetaminophen or ibuprofen for headache, aches, and pains	Antiviral drugs if given within 24–48 hrs of onset. Rest, hydration, acetaminophen or ibuprofen for headache, aches, and pains

Adapted from CDC Centers for Disease Control and Prevention. Retrieved from *www.cdc.gov/flu/about/qa/coldflu.htm*.

TABLE 26.4 Types of Influenza Immunization

Trivalent (TIV) or Quadrivalent (QIV) Inactivated Influenza Vaccine	Live Attenuated Influenza Vaccine (LSIV)
Trivalent: Protects against 3 different types of influenza virus (2-type A; 1-type B) *Quadrivalent:* Protects against 4 different types of influenza virus (2-type A; 2-type B)	Made from weakened influenza virus
Given by injection	Given as an intranasal spray into both nostrils
Approved for use in people ≥6 mo of age	Approved for healthy people ages 2–49 yrs • Children 2–8 yrs and have not had influenza vaccine before need 2 doses (second dose 4 weeks after first dose) • Children >9 yrs need 1 dose
Should NOT be used in: • Infants <6 mo in age • Serious allergy/reaction to previous influenza vaccine • Guillain-Barré syndrome diagnosed within previous 6 wks	Should NOT be used in: • Children <2 yrs or adults >50 yrs • Pregnant women or women who plan to become pregnant
Can be used in people at increased risk: • People of any age with chronic medical conditions • Residents of nursing homes and long-term care facilities • People who are immunocompromised • Pregnant women	Prior to receiving the vaccination, please inform your HCP if you or the person you are caring for have any of the following: • Immunodeficiency • Children or adolescents receiving aspirin or other salicylates • Medical conditions that increase the risk for complications from influenza (chronic heart, lung, liver, kidney, or CNS disorders) diabetes; hemoglobinopathies) • HCPs of high-risk patients because of risk for viral transmission from vaccine (should not care for high-risk patients for 7 days after vaccination)
Most common side effects are injection site reactions, such as pain, redness, and swelling	Adverse effects are rare. When effects do occur, may resemble mild flu with runny nose, nasal congestion, cough, and headache

Viral cultures, once considered the gold standard for diagnosing influenza, have decreased in popularity with the emergence of other rapid testing methods. We can obtain a viral culture from a throat swab, nasopharyngeal swab, expectorated sputum, ET tube sample, or bronchoscopy (bronchial wash). A viral culture can identify which virus (A, B, or another respiratory virus) and which viral strains are present.

Rapid influenza diagnostic tests (RIDTs) can help in the diagnosis by detecting the virus in secretions from the respiratory tract. Depending on the method, the test may be completed in the HCP's office with results available in as little as 5 minutes. The test can help distinguish influenza from other viral and bacterial infections with similar manifestations that may be serious but are treated differently. RIDTs are best used within the first 48 hours of the onset of symptoms. The main disadvantages of the rapid flu test are that it will miss some cases or occasionally be positive when a person does not actually have the flu. Always evaluate test results considering the patient's clinical condition.

Interprofessional and Nursing Care

The most effective strategy for managing influenza is prevention. Two types of flu vaccines are available: inactivated and live attenuated (Table 26.4). Receiving a flu vaccine results in the production of antibodies against the viruses in the vaccine.

The influenza vaccine is changed on a yearly basis, depending on the virus strains the Centers for Disease Control and Prevention (CDC) determines as being most likely to cause illness in the upcoming flu season. The best time to receive the vaccine is in September or October (before flu exposure) because it takes 2 weeks for full protection to occur. However, the vaccine can be given at any time during the flu season.

Safety Alert

Influenza Vaccination

- Advocate for vaccination of all people older than 6 months of age, especially those at high risk (e.g., health care workers, residents of long-term care facilities).
- Give high priority to groups, such as health care workers, who can transmit influenza to high-risk persons.

Vaccinating healthy people decreases the incidence and risk for transmitting influenza to those who have less ability to cope with the effects of this illness. Many people do not get receive the vaccination despite the obvious benefits. Current vaccines are highly purified, and reactions are extremely rare. Soreness at the injection site is the most reported adverse effect. Contraindications are a history of severe allergic reactions to previous flu vaccine. Patients with anaphylactic hypersensitivity to eggs should discuss the vaccine with their HCP, as alternatives for vaccinating patients with egg allergies are now available.

The primary nursing goals are relief of symptoms and prevention of secondary infection. Unless the patient with influenza is at high risk or complications develop, supportive therapy is often all the patient needs. Rest, hydration, analgesics, and antipyretics can provide symptom relief. Older adults and those with a chronic illness may need hospitalization.

There are several antiviral medications we can use to treat shorten the duration of influenza symptoms and reduce the risk for complications. Zanamivir (Relenza), oseltamivir (Tamiflu), and peramivir (Rapivab) are neuraminidase inhibitors that prevent the virus from being released and spreading to other cells. [15] Zanamivir is given using an inhaler, oseltamivir is available as an oral capsule, and peramivir is given IV. The newest drug is baloxavir marboxil

(Xofluza). It is a PA endonuclease inhibitor that works by inhibiting viral replication. Patients receive 1 oral dose. Do not give Xofluza with dairy products or calcium-fortified drinks.

Treatment with antiviral medication should be started as soon as possible in hospitalized patients with influenza, those with severe or complicated illness, or those at high risk for complications. For maximum benefit in the treatment of influenza, therapy should begin within 2 days of the onset of symptoms, but it can be started later based on clinical judgment.

Sinusitis

Sinusitis affects 1 in every 7 adults. It develops when inflammation or swelling of the mucosa blocks the openings (ostia) in the sinuses, through which mucus drains into the nose (Fig. 26.2). *Rhinosinusitis,* which may accompany sinusitis, is concurrent inflammation or infection of the nasal mucosa. Nasal polyps, foreign bodies, deviated septa, or tumors can cause obstruction of mucus drainage. Secretions that accumulate behind the blocked ostia provide a rich medium for growth of bacteria, viruses, and fungi, all of which may cause infection.

Viral sinusitis may follow an upper respiratory tract infection in which the virus penetrates the mucous membrane and decreases ciliary function. Viral infections usually resolve without treatment in less than 14 days. If symptoms worsen after 3 to 5 days or last for longer than 10 days, a secondary bacterial infection may be present. Only 5% to 10% of patients with viral sinusitis develop a bacterial infection and need antibiotic therapy.

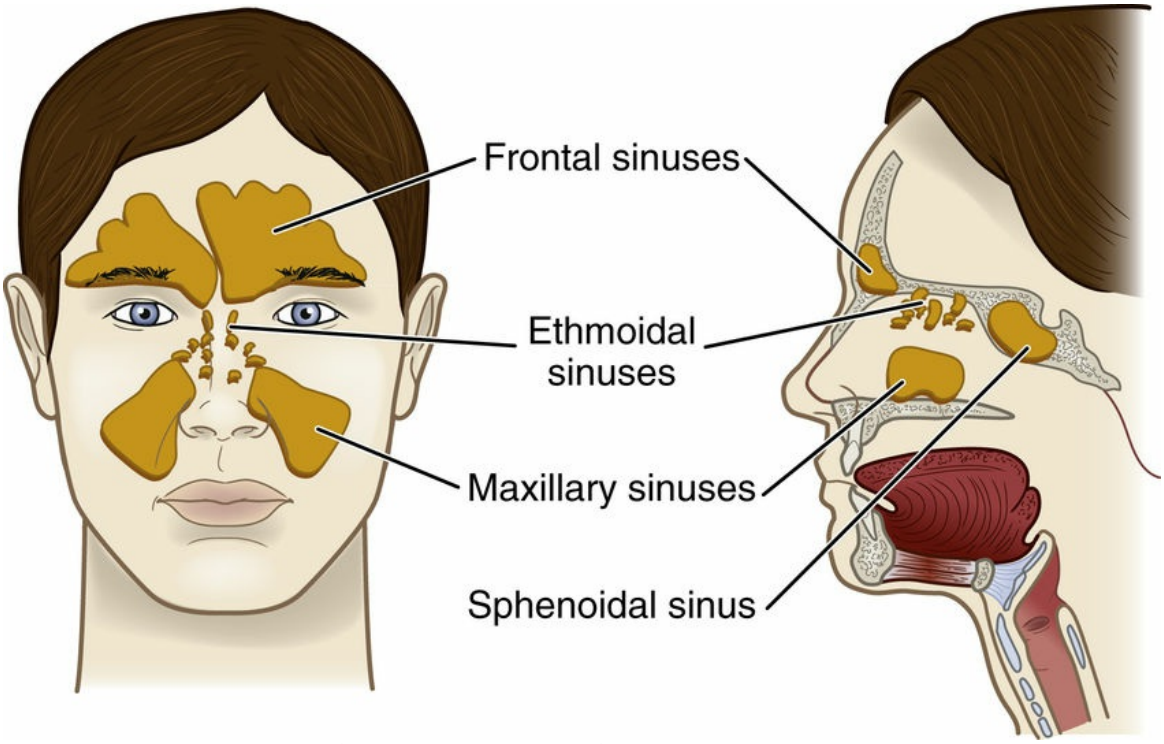

FIG. 26.2 Location of the sinuses.

Streptococcus pneumoniae, Haemophilus influenzae, and *Moraxella catarrhalis* are the most common causes of bacterial sinusitis.[7] Fungal sinusitis is uncommon. It usually occurs in patients who are debilitated or immunocompromised.

Sinusitis can be classified as acute, subacute, or chronic.[16] *Acute sinusitis* typically begins within 1 week of an upper respiratory tract infection and lasts less than 4 weeks. *Subacute sinusitis* is present when symptoms progress over 4 to 12 weeks. *Chronic sinusitis* (lasting longer than 12 weeks) is a persistent infection usually associated with allergies and nasal polyps. Chronic sinusitis generally results from repeated episodes of acute sinusitis that result in irreversible loss of the normal ciliated epithelium lining the sinus cavity.

Clinical Manifestations

Acute sinusitis causes significant pain over the affected sinus, purulent nasal drainage, nasal obstruction, congestion, fever, and malaise. The patient may appear acutely ill. Inspect the nasal mucosa

and palpate the paranasal sinuses for pain. Findings that indicate acute sinusitis include edematous mucosa, discolored purulent nasal drainage, enlarged turbinates, tenderness over the involved frontal and/or maxillary sinuses, and *halitosis* (bad breath). Recurrent headaches are common and may change in intensity with position changes or when secretions drain.

The symptoms of chronic sinusitis are often nonspecific. The patient is rarely febrile. The patient may have facial or dental pain, nasal congestion, and increased drainage. Severe pain and purulent drainage are often absent. Some symptoms mimic those seen with allergies. X-rays or CT scan of the sinuses may help confirm the diagnosis. CT scans may show the sinuses are filled with fluid or a thickened mucous membrane. Nasal endoscopy with a flexible scope may be used to examine the sinuses, obtain a specimen for culture, and restore normal drainage.

As many as 50% of patients with moderate to severe asthma have chronic sinusitis. The exact link between these diseases is unclear. Postnasal drip associated with sinusitis may trigger asthma by stimulating bronchoconstriction. Gastroesophageal reflux disease (GERD) and smoking may increase the risk for a person with asthma developing sinusitis. Appropriate treatment of sinusitis often causes a reduction in asthma symptoms.

Interprofessional and Nursing Care

If allergies are the precipitating cause of sinusitis, teach the patient ways to reduce sinus inflammation and infection, including environmental control of allergens and appropriate drug therapy (see allergic rhinitis discussed earlier in this chapter).

Initial treatment for acute sinusitis focuses on symptom relief. Medications include oral or topical decongestants to promote drainage, intranasal corticosteroids to decrease inflammation, analgesics to relieve pain, and saline nasal spray to relieve congestion. Teach patients using topical decongestants to use the medication for no longer than 4 to 5 days to prevent rebound congestion caused by vasodilation. Saline irrigation of the nasal cavity can rinse nasal

passages, promote drainage, and decrease inflammation. Saline nasal spray is available over the counter.

If symptoms worsen or last longer than 1 week, antibiotic therapy may be prescribed. Amoxicillin is the first-line drug of choice. It is taken for 10 to 14 days to prevent the formation of antibiotic-resistant organisms.[17] If symptoms do not resolve, the antibiotic should be changed to amoxicillin with clavulanate, a fluoroquinolone, or a 2nd or 3rd generation cephalosporin.

With chronic sinusitis, mixed bacterial flora is often present and infections are hard to eliminate. Broad-spectrum antibiotics may be used for 4 to 6 weeks. Patient and caregiver teaching for acute and chronic sinusitis is shown in Table 26.5.

Medical therapy may not relieve the symptoms of some patients with persistent, recurrent, or chronic sinus illnesses. These patients may need nasal endoscopic surgery to relieve blockage caused by hypertrophy or septal deviation. This is usually done as an outpatient procedure using local anesthesia. Propel, a self-expanding implant, can be placed directly in the sinus during surgery. Propel helps maintain patency to the sinus cavity after surgery and provide local corticosteroid delivery directly to the sinus lining before dissolving after 30 days.

TABLE 26.5 Patient & Caregiver TeachingAcute or Chronic Sinusitis

Include the following instructions when teaching the patient and caregiver about management of sinusitis:

1. Get plenty of rest to help body fight infection and promote recovery.
2. Keep well hydrated by drinking 6 to 8 glasses of water per day to loosen secretions.
3. Take hot showers. Use a steam inhaler (15-minute vaporization of boiled water), bedside humidifier, or nasal saline spray to

promote secretion drainage.

4. Apply warm, damp towels around nose, cheeks, and eyes to ease facial pain.
5. Sleep with head elevated to help sinuses drain and reduce congestion.
6. Report a temperature of 100.4° F (38° C) or higher, which indicates infection.
7. Follow prescribed medication plan:
    - Take analgesics to relieve pain.
    - Take decongestants/expectorants to relieve swelling.
    - Take antibiotics (as prescribed) for infection. Be sure to take entire prescription and report continued symptoms or a change in symptoms.
    - Use nasal sprays to relieve congestion.
8. Perform nasal saline washes once or twice a day to wash sinuses.
9. Do not smoke and avoid exposure to smoke (will irritate and will worsen symptoms).
10. If allergies predispose to sinusitis, follow instructions about environmental control, drug therapy, and immunotherapy to reduce the inflammation and prevent sinus infection.

Obstruction of Nose and Sinuses

Nasal Polyps

Nasal polyps are soft, painless, benign (noncancerous) growths that form slowly in response to repeated inflammation of the sinus or nasal mucosa. They are most common in adults over age 40 and are twice as likely to occur in men than women.[18] Polyps, which appear as chronic yellow, gray, or pink semitransparent projections in the naris, can exceed the size of a grape.

Small polyps are typically asymptomatic. Manifestations of larger polyps include nasal obstruction, nasal discharge (usually clear mucus), and speech distortion. Topical and systemic corticosteroids

are primary therapies used to shrink nasal polyps. Endoscopic or laser surgery can remove nasal polyps, but recurrence is common.

Foreign Bodies

A variety of foreign bodies may potentially lodge in the upper respiratory tract of adults, but these are rare occurrences. Some situations may be the result of trauma or found in patients with mental illness. Foreign bodies may be inorganic or organic. Inorganic foreign bodies, such as plastic or metal objects, may cause no symptoms and be incidentally discovered on routine examination. Organic foreign bodies, such as food, may cause a local inflammatory reaction and nasal discharge, which may become purulent and foul smelling if the object stays in the nasal cavity for an extended time. Foreign bodies can cause pain, difficulty breathing, and nasal bleeding.

Foreign bodies should be removed from the nose through the route of entry. Sneezing or blowing the nose with the opposite nostril closed may be effective in removing the foreign object. Avoid irrigating the nose or pushing the object backward, since these could cause aspiration and airway obstruction. If sneezing or blowing the nose does not remove the object, consult an HCP.

Problems of Pharynx

Acute Pharyngitis

Acute ***pharyngitis*** is an acute inflammation of the pharyngeal walls. It may include the tonsils, palate, and uvula. It can be caused by a viral, bacterial, or fungal infection. Viral pharyngitis accounts for about 90% of cases. Bacterial pharyngitis ("strep throat") usually results from group A β-hemolytic streptococci and accounts for 5% to 10% of cases.

Fungal pharyngitis, such as candidiasis, can develop with the prolonged use of antibiotics or inhaled corticosteroids. It can also occur in immunosuppressed patients, especially those with human

immunodeficiency virus (HIV) infection. Other causes of pharyngitis include dry air, smoking, GERD, allergy and postnasal drip, ET intubation, chemical fumes, and cancer.

Clinical Manifestations

Symptoms of acute pharyngitis range in severity from a "scratchy" throat to pain so severe that swallowing is difficult. Because both viral and streptococcal infections appear as a red and edematous pharynx (with or without patchy exudates), it may be hard to distinguish between them.

Four classic manifestations present in bacterial pharyngitis include: (1) fever greater than 100.4° F (38° C); (2) anterior cervical lymph node enlargement; (3) tonsillar or pharyngeal exudate; and (4) absence of cough.[19] However, appearance is not always diagnostic. When 2 or 3 of these criteria are present, a rapid antigen detection test and/or a throat culture can help establish the cause and direct treatment. White, irregular patches on the oropharynx suggest fungal infection with *Candida albicans.*

Interprofessional and Nursing Care

The goals of nursing management are infection control, symptom relief, and prevention of secondary complications.

For viral pharyngitis, antibiotics are not recommended. For bacterial pharyngitis caused by group A β-hemolytic streptococci, penicillin is the drug of choice. This antibiotic must be taken several times a day for a full 10 days to prevent complications, such as rheumatic fever. For patients allergic to penicillin, erythromycin and clindamycin are appropriate substitutes.[20] Other antibiotics, such as azithromycin (Zithromax) or a 1st generation cephalosporin, are options. Most people with streptococcal infections are contagious until they have been on antibiotics for 24 to 48 hours. Repeat throat cultures after antibiotic therapy are not required.

Candida infections are treated with nystatin, an antifungal antibiotic. Teach patients to swish the preparation in their mouths for as long as

possible before swallowing it. Treatment should continue until symptoms are gone. Patients taking inhaled corticosteroids are at risk for infection with *Candida* organisms. Thoroughly rinsing the mouth with water after using corticosteroids can prevent this infection.

Teach patients to use ibuprofen or acetaminophen for pain relief. Encourage the patient to increase fluid intake. For symptom relief, have patients to gargle with warm salt water (½ tsp of salt in 8 oz of water); drink warm or cold liquids; and suck on popsicles, hard candies, or throat lozenges. Cool, bland liquids and gelatin will not irritate the pharynx. Citrus juices are often irritating. Encourage the patient to use a cool mist vaporizer or humidifier.

Peritonsillar Abscess

Peritonsillar abscess is a complication of tonsillitis. It is most often caused by group A β-hemolytic streptococci. The abscess causes pain, swelling, and blockage of the throat (when severe), threatening airway patency. The patient may have a high fever, chills, leukocytosis, difficulty swallowing, and a muffled voice. Treatment consists of IV antibiotic therapy and needle aspiration or incision and drainage of the abscess. In some cases an emergency tonsillectomy is done or an elective tonsillectomy is scheduled after the infection has subsided.

Problems of Larynx and Trachea

Laryngeal Polyps

Laryngeal polyps develop on the vocal cords from vocal abuse (e.g., excessive talking, singing) or irritation (e.g., intubation, cigarette smoking). The most common sign is hoarseness. Polyps are treated conservatively with voice rest and adequate hydration. Large polyps may cause dysphagia, dyspnea, and stridor and may need surgically removed. Polyps are usually benign but may be removed because they can become cancerous.

Acute Laryngitis

Acute **laryngitis** is swelling and inflammation of the voice box (larynx). A virus (e.g., flu, common cold) is the most common cause. Other causes include inflammatory or infectious conditions of the upper respiratory tract (e.g., tonsillitis, acute bronchitis), overuse of one's voice (e.g., yelling loudly at a concert or a sporting event), exposure to smoke-filled environments, or chemical inhalation.

The classic hallmark signs of acute laryngitis include a tingling or burning sensation at the back of the throat, a persistent need to clear the throat, and hoarseness, which may be accompanied by complete loss of voice. The patient may have a low-grade fever, persistent cough, or feeling of fullness in the throat. Symptoms will appear suddenly, increase in severity over 2 to 3 days, then gradually subside over the next 7 to 10 days as the condition improves. It usually resolves within 21 days.

Diagnosis of acute laryngitis is made based on the history, clinical presentation, and changes in voice. Treatment for acute laryngitis is supportive. The patient is strongly encouraged to limit use of the larynx. This includes no talking or singing, which realistically is almost impossible to do. Patients will want to whisper when communicating but whispering places increased strain on the vocal cords that may worsen the pain. Acetaminophen, cough suppressants, throat lozenges, and use of a humidifier are helpful for throat discomfort.

Have the patient increase fluid intake. They should avoid caffeine and alcohol, which may worsen a sore throat. Encourage smoking cessation. If a bacterial cause is known, such as acute bronchitis or tonsillitis, antibiotics should help resolve the condition. If symptoms last longer than 3 weeks, patients should return to their HCP for further investigation and treatment.

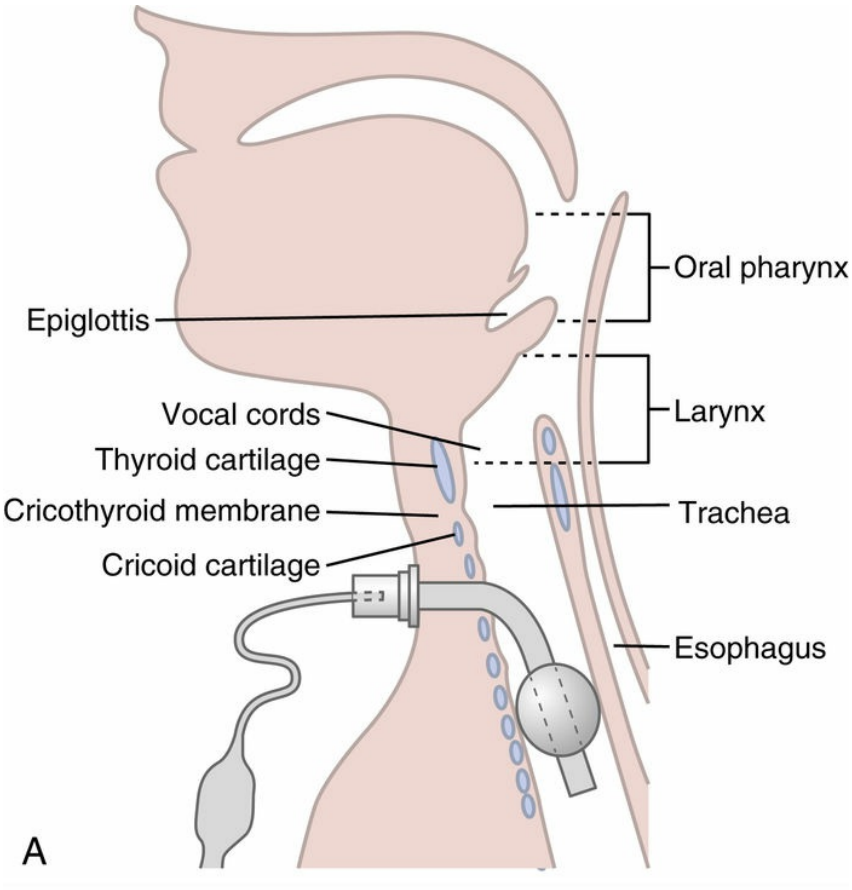
Airway Obstruction

Acute airway obstruction is a medical emergency. Airway obstruction

can be caused by aspiration of food or a foreign body, allergic reactions, edema and inflammation caused by infections or burns, peritonsillar or retropharyngeal abscesses, cancer, laryngeal or tracheal stenosis, and trauma.

Airway obstruction may be partial or complete. The presentation of an airway obstruction often depends on the cause of the obstruction and/or location of the blockage. For example, objects lodged within the larynx may cause voice hoarseness or complete airway obstruction. Tracheal obstruction may produce wheezing. Objects lodged within the lower respiratory system (e.g., bronchus) may produce a cough or decreased air entry on the affected side.

Manifestations include choking, stridor, use of accessory muscles, suprasternal and intercostal retractions, flaring nostrils, wheezing, restlessness, tachycardia, cyanosis, and change in level of consciousness.[21] Prompt assessment and treatment are essential because partial obstruction may quickly progress to complete obstruction. Complete airway obstruction can result in permanent brain damage or death if not corrected within 3 to 5 minutes.



Your immediate priority is to ensure the patient has a patent airway. Interventions to reestablish a patent airway include the obstructed airway (Heimlich) maneuver (see Appendix A), cricothyroidotomy, ET intubation, or tracheostomy. Unexplained partial airway obstruction or recurrent symptoms indicate the need for more tests, including a chest x-ray, laryngoscopy, and rigid bronchoscopy.

Tracheostomy

A **tracheostomy** is a surgically created stoma (opening) in the anterior part of the trachea (Fig. 26.3, *A*). A tracheostomy may be done to (1) establish a patent airway, (2) bypass an upper airway obstruction, (3) facilitate removal of secretions, (4) permit long-term mechanical ventilation, and (5) assist with weaning from mechanical ventilation.[22]

The tracheostomy tube is shorter in length and slightly wider in diameter than an ET tube. This makes it easier to keep the tube clean

and facilitates better oral and bronchial hygiene. A tracheostomy (compared to an ET tube) may increase patient comfort because no tube is present in the mouth. There is also less risk for long-term damage to vocal cords.

FIG. 26.3 Tracheostomy tube. **A,** Placement of a tracheostomy tube. **B,** Parts of a tracheostomy tube.

A variety of tracheostomy tubes are available to meet specific patient needs (Table 26.6). All tracheostomy tubes have a faceplate, or *flange,* which rests against the neck, and an *obturator,* which is used to help insert the tube. Many tracheostomy tubes have an *outer cannula* (which keeps the airway patent), and an *inner cannula* (which can be disposable or nondisposable and removed for cleaning) (Fig. 26.3).

Cuffed and *uncuffed* tracheostomy tubes are available. A tracheostomy tube with an inflated cuff (balloon) is used the most, especially if the patient needs mechanical ventilation. The cuff, inflated via the *balloon inflation port* on the tracheostomy tube, ensures the patient receives the volume of air delivered by the ventilator, and helps decrease the risk for aspiration. Cuffless tubes are primarily used for patients with longer term tracheostomies, when mechanical ventilation is not required and the risk for aspiration has decreased. They make talking and eating easier.

The outer and/or inner cannula may be *fenestrated* or *non-fenestrated*. A *fenestrated tube* has an opening (a hole) on the dorsal surface of the tube. This tube promotes spontaneous breathing. For example, with the use of a cuffed, fenestrated tracheostomy tube, when the cuff is deflated and the inner cannula removed, air can pass from the lungs up through the opening in the tracheostomy tube through the vocal cords and larynx, into the upper airway, and out the mouth and nose. This allows the patient to breathe spontaneously and speak with the tracheostomy tube in place. When the cuff is reinflated and the inner cannula reinserted, air cannot pass from the lungs through the vocal cords.

Most patients who need mechanical ventilation first have an ET tube, because we can quickly insert one an emergency. Care of the patient with an ET tube is discussed in Chapter 65. When swelling, trauma, or upper airway obstruction prevents ET intubation, an emergent **surgical cricothyroidotomy** (also known as a cricothyrotomy) is needed. This procedure, which can be completed in minutes, involves making an incision through the skin and

cricothyroid membrane on the anterior surface of the neck.

Most surgical tracheostomies are done in the operating room using general anesthesia. The HCP makes a horizontal incision on the anterior part of the trachea. After inserting the tracheostomy tube, the HCP sutures the incision and applies a sterile dressing.

A newer surgical technique is the *percutaneous tracheostomy*. Using local anesthesia, sedation, and under video-assisted guidance, the ET tube is withdrawn up to the level of the glottis. A needle is placed between the second and third tracheal rings, into the middle of the trachea. A dilator is then placed over the top of the needle. The HCP makes the opening progressively larger (with increasingly larger dilators) until the hole is big enough for insertion of the tracheostomy tube. Percutaneous tracheostomy approaches have less risk for bleeding and fewer postoperative complications.[23] Both surgical and percutaneous tracheostomies may be done at the patient's bedside in the emergency department or ICU.

Nursing Management: Tracheostomy

Acute Care

Before the tracheostomy procedure (and time permitting), explain the purpose of the procedure to both the patient and caregiver. If the patient is having the tracheostomy in the operating room, follow all hospital policies and procedures for preparing the patient for surgery (see care of the preoperative patient in Chapter 17).

TABLE 26.6 Nursing Management of Tracheostomies

Tube and Characteristics	Nursing Management
Tracheostomy tube with cuff and pilot balloon (Fig. 26.3, *B*) **When properly inflated, low-pressure, high-volume cuff distributes cuff pressure over large area, minimizing pressure on tracheal wall.**	**Procedure for cuff inflation** • Mechanically ventilated patient: • *Minimal occlusion volume (MOV) technique* recommended. Place stethoscope over lateral neck (beside trachea). Inflate cuff by slowly injecting air into the cuff until no leak (sound) is heard at peak inspiratory pressure (end of ventilator inspiration). • *Minimal leak technique (MLT).* Involves inflating the cuff to minimal occlusion pressure and then withdrawing 0.1–0.5 mL of air. No longer recommended due to risk for silent aspiration. • *Spontaneously breathing patient:* Inflate cuff by slowly injecting air into the cuff until no sound is heard after deep breath or during inhalation with bag-valve-mask. If using MLT, remove 0.1–0.5 mL of air while maintaining seal. MLT should not be used if there is risk for aspiration. • *Immediately after cuff inflation (both groups):* Verify pressure is within accepted range (20–30 cm H_2O, 15–22 mmHg) with a manometer. Record cuff pressure and volume of air used for cuff inflation in chart. **Care of patients with an inflated cuff:** • Monitor and record cuff pressure q8hr. Cuff pressure should be 20–30 cm H_2O (15–22 mm Hg) to allow adequate tracheal capillary perfusion. If needed, remove or add air to the pilot tubing using a syringe and stopcock. Afterward, verify cuff pressure is within accepted range with manometer. • Report inability to keep the cuff inflated or need to use progressively larger volumes of air to keep cuff inflated. Potential causes include tracheal dilation at the cuff site or a crack or slow leak in the housing of the 1-way inflation valve. If the leak is due to tracheal dilation, the HCP may cannulate the patient with a larger tube.
Fenestrated tracheostomy tube (Shiley, Portex) with cuff, inner cannula, and decannulation plug (Fig. 26.6) **When nonfenestrated inner cannula is removed, cuff deflated, and decannulation plug inserted, air flows around tube, through fenestration in outer cannula, and up over vocal cords. Patient can then speak. A fenestrated inner cannula can be used to facilitate cleaning.**	• If possible, assess risk for aspiration before removing inner cannula. A speech pathologist may be able to assist if available. Deflate cuff. Note coughing. • *Never* insert decannulation plug in tracheostomy tube until cuff is deflated and nonfenestrated inner cannula removed. Otherwise, patient will be prevented from breathing (no air inflow). This will precipitate a respiratory arrest. • Assess for signs of dyspnea and/or respiratory distress when a fenestrated cannula is first used. If this occurs, remove the cap, insert a nonfenestrated inner cannula, reinflate the cuff, and notify the HCP. • A nonfenestrated inner cannula must be used to suction patient to prevent tracheal damage from suction catheter passing through fenestrated openings. • Cuff management as described above.
Talking tracheostomy tube (Portex with cuff, 2 external tubings) **Has 2 tubings, one leading to cuff and second to opening above the cuff. When port is connected to air source, air flows out of opening and up over the vocal cords.**	• Patient must be awake, alert, and hemodynamically stable. • Must be able to tolerate cuff deflation and exhale around the tracheostomy tube. • When patient desires to speak, deflate cuff, and connect port to compressed air (or O_2). Be certain to identify correct tubing. If gas enters the cuff, it will overinflate and rupture, requiring an emergency tube change. Use lowest flow (typically 4–6 L/min) that results in speech. Patient may not tolerate high flows. • Give O_2 via tracheal collar or O_2 adaptor on speaking valve. • Observe for any signs of dyspnea and/or respiratory distress. • Disconnect flow when patient does not want to speak to prevent mucosal dehydration. • Cuff management as described above.
Tracheostomy tube (Bivona Fome-Cuf) with foam-filled cuff **Cuff is filled with plastic foam. Before insertion, cuff is deflated. After insertion, cuff self-inflates. Pilot tubing is not capped. Does not require cuff pressure monitoring. Patient cannot speak with this tube.**	• Before insertion, withdraw all air from the cuff using a 20-mL syringe. Cap pilot balloon tubing to prevent reentry of air. • After tracheostomy is inserted, remove cap from pilot tubing, allowing cuff to passively reinflate. Cuff is always inflated on this tube. • Do not inject air into tubing or cap pilot balloon tubing while it is in patient. Air will flow in and out in response to pressure changes (head turning). Place tag on tubing to alert staff not to cap or inflate cuff. • Tube tends to collect moisture and secretions while patient is on the ventilator. • Deflate cuff daily via pilot balloon to evaluate integrity of cuff. Assess ability to easily deflate cuff. Difficulty deflating cuff indicates a need for tube change. If aspirate returns with air, cuff is no longer intact. • Tube can be used for up to 1 month in patients on home mechanical ventilation. • Good choice for patients who need an inflated cuff at home, since teaching about cuff pressure is simplified.

If the procedure is being done at the patient's bedside, ensure all appropriate personnel, including respiratory therapist, are present.

Emergency resuscitation equipment, including a bag-valve-mask (BVM), should be readily available and functional.

Record vital signs, including heart rate, respiratory rate and rhythm, BP, and SpO_2. Ensure an existing IV line is patent and that bedside suction is working. Help assemble and set up all necessary equipment. Position the patient supine. Give analgesia and sedation as ordered by the HCP, ensuring correct identification of times and dosages. Monitor patient response to analgesia and/or sedatives. Observe patient's tolerance to the procedure.

Immediately after the procedure, the tracheostomy cuff (balloon) is inflated. We use several different methods to confirm tracheostomy tube placement: (1) auscultation of the patient's chest for air entry, (2) end-tidal CO_2 capnography, and (3) passage of a suction catheter through the tracheostomy tube. After placement is confirmed, the ET tube (if present) is removed. The tracheostomy tube is sutured and secured in place with cotton tracheostomy ties, tracheostomy tapes, or Velcro straps.

TABLE 26.7 Complications of Tracheostomy

Closely monitor patients with a tracheostomy for the following potential complications:

- Air leak
- Airway obstruction
- Altered body image
- Aspiration
- Bleeding
- Fistula formation
- Impaired cough
- Infection: wound or respiratory tract
- Subcutaneous emphysema

- Tracheal necrosis
- Tracheal stenosis
- Tube displacement

Monitor and record the patient's heart rate, respiratory rate, BP, and SpO_2. SpO_2 readings should remain stable. Note and record the mechanical ventilator settings, including mode, FIO_2, and positive end-expiratory pressure (PEEP). (Care of the patient receiving mechanical ventilation is discussed in Chapter 65.) Observe the amount of blood at the tracheostomy insertion site. Notify the HCP if bleeding persists. A chest x-ray should be obtained after the procedure. Many different complications can occur because of tracheostomy (Table 26.7). You must be aware of them, especially airway obstruction, bleeding, and infection.

There is considerable variation in the care of a patient with a new tracheostomy. In some places, it is the nurse who is primarily responsible; in others, it is a shared responsibility between nursing and respiratory therapy. You need to be familiar with your agency's policies and procedures. The following discussion highlights general guidelines when caring for a patient with a tracheostomy during the first few days after the procedure.

At a minimum, you must assess the tracheostomy site every shift. Confirm the patency of the tracheostomy tube. Observe the site for any redness, inflammation, edema, ulceration, or signs of infection. Sterile dressing changes should be done every 12 hours. Clean around the stoma with normal saline and apply a sterile pre-cut dressing around the tracheostomy tube site. You can complete dressing changes more often based on your assessment.

Because an inflated tracheostomy cuff exerts pressure on the tracheal mucosa, it is important to inflate the cuff with the least volume of air needed to obtain an airway seal. We can measure cuff inflation pressure with a hand-held cuff manometer. Monitor the pressure at least every 8 hours. Cuff inflation pressure should not exceed 20 to 25 cm H_2O. Higher pressures may compress tracheal

capillaries, limit blood flow, and predispose the patient to tracheal necrosis. The minimal occlusion volume (MOV) is one way we often use to inflate the tracheostomy cuff (Table 26.6). Routine cuff deflation is not recommended.[24]

Suction the airway via the tracheostomy tube as needed (Fig. 26.4 and Table 26.8). Try to avoid suctioning through the newly created tracheostomy in the first few hours after the procedure, as this may aggravate discomfort and promote bleeding. Suctioning may be done using sterile glove and catheter technique, or an existing in-line suction catheter. Each time the patient is suctioned, note and record the amount, color, clarity, and patient tolerance to the procedure. At first, patients should receive humidified air to compensate for the loss of the upper airway to warm and moisturize secretions. Humidification is essential to keep secretions thin and decrease formation of mucous plugs.

FIG. 26.4 Suctioning tracheostomy with closed system suction catheter.
From Potter PA, Perry AG: *Basic nursing: Essentials for practice*, ed 7,

If the inner cannula is disposable, replace as per manufacturer and agency guidelines. Clean a nondisposable inner cannula at least every shift. Cleaning removes mucus from the inside of the tube to prevent airway obstruction (Table 26.9).

Change the tracheostomy tapes after the first 24 hours and then as needed (Fig. 26.5 and Table 26.9). A 2-person technique, 1 person to stabilize the tracheostomy and the other to change the tapes, is best practice to ensure that the tracheostomy does not become accidentally dislodged during the procedure. In some places, the HCP and/or respiratory therapist may complete this task. At the end of the procedure, place 2 fingers underneath the tapes to ensure they are not too tight around the neck.

When turning and repositioning the patient, take care not to dislodge the tracheostomy tube. Because tube replacement may be difficult in the immediate postoperative period, several precautions are required, including (1) keep a replacement tube of equal or smaller size at the bedside, readily available for emergency reinsertion; (2) do not change tracheostomy tapes for at least 24 hours after the surgical procedure; and (3) if needed, the HCP performs the first tube change usually no sooner than 7 days after the tracheostomy.

If the tube is accidentally dislodged, immediately call for help. While waiting for the HCP, a respiratory therapist, or other designated individual to arrive, several options may be used (depending on your nursing scope of practice and specific agency policies and procedures). It is essential that you know and understand your role and scope of practice for care of the patient with a tracheostomy.

Immediately call for help. Quickly assess the patient's level of consciousness, ability to breathe, and the presence or absence of any respiratory distress. If respiratory distress is present, you can quickly use a hemostat to spread the opening where the tube was displaced. Insert the obturator in the replacement (spare) tracheostomy tube, lubricate with saline, and insert the tube into the stoma. Once the tube is inserted, remove the obturator at once so that air can flow through

the tube. Another option is to insert a suction catheter to allow passage of air and serve as a guide for insertion. Thread the tracheostomy tube over the catheter and remove the suction catheter. Trying to reinsert will be easier if the stoma tract is mature or older than 1 week.

TABLE 26.8 Suctioning a Tracheostomy

Assess the need for suctioning hourly. Indications include visible coughing, coarse crackles or wheezes over large airways, moist cough, increase in peak inspiratory pressure on mechanical ventilator, and restlessness or agitation. Neurologic patients may not show any signs and/or symptoms of the need to be suctioned, so suctioning once per shift (at minimum) is recommended. Do not suction routinely.

1. If suctioning is indicated, explain procedure to patient.
2. Collect necessary sterile equipment: suction catheter (no larger than half the lumen of the tracheostomy tube), sterile water, cup, and personal protective equipment (PPE). If a closed tracheal suction system is used, the catheter is enclosed in a plastic sleeve and reused (Fig. 26.4). No other equipment is needed.
3. Check suction source and regulator. Adjust suction pressure to no greater than 125 mm Hg pressure with tubing occluded.
4. Assess heart rate and rhythm, respiratory rate and SpO_2 to provide baseline for detecting changes in patient condition during suctioning.
5. Wash hands and put on PPE.
6. Use sterile technique to open package, fill cup with sterile water, put on sterile gloves, and connect catheter to suction tubing. Designate one hand as contaminated for (1) connecting and disconnecting the tubing at the suction catheter, (2) using the manual bag-valve-mask (BVM), and (3) operating the suction

control. Suction sterile water through the catheter to test the system.

7. Provide preoxygenation for a minimum of 30 seconds by (1) adjusting ventilator to deliver 100% O_2 or (2) using a reservoir-equipped BVM connected to 100% O_2. The method chosen depends on whether the patient is attached to a mechanical ventilator or has a tracheostomy tube in place but is spontaneously breathing and receiving supplemental O_2. The patient who has a long-term chronic tracheostomy and is not acutely ill may be able to tolerate suctioning without using a BVM.
8. Gently insert catheter *without suction* to the point at which the patient coughs. Do *not* insert the catheter until you meet resistance (this is the carina, and repeated trauma with suction catheter can promote bleeding). Apply suction as you slowly begin to withdraw the catheter.
9. Apply continuous suction for no more than 10 to 15 seconds.
10. Observe the patient during the suctioning procedure. Immediately stop suctioning and remove the suction catheter from the patient's trachea if the patient becomes bradycardic or hypotensive, a dysrhythmia occurs, or SpO_2 decreases to less than 90%. A vagal response may have occurred.
11. After each suction pass, wait at least 30 seconds before suctioning again. Always hyperoxygenate for at least 30 seconds (via mechanical ventilator or BVM with 5 or 6 breaths) in between each suctioning pass.
12. Repeat procedure until airway is clear. Limit insertion of suction catheter to as few times as possible. If airway is not clear after 3 suction passes, allow the patient to rest before additional suctioning.
13. Return O_2 concentration to prior setting.
14. Rinse catheter. If using the in-line suction catheter (via mechanical ventilation), ensure that normal saline used to flush out the suction catheter does not enter the patient's airway. For disposable suction catheters, dispose of catheter by wrapping it

around fingers of gloved hand and pulling glove over catheter. Discard equipment in proper waste container.
15. Suction the oropharynx or use mouth suction.
16. Reassess heart rate and rhythm and SpO_2. Auscultate to assess changes in lung sounds.
17. Record time, amount, and character of secretions and patient response to suctioning.

If the tube cannot be replaced because of tract immaturity (less than 1 week old) or other circumstances, immediately place the patient in semi-Fowler's position to decrease dyspnea. Cover the stoma with a sterile dressing and provide ventilation with the BVM over the nose and mouth. If a patient has had a total laryngectomy, there will be complete separation between the upper airway and trachea. Ventilate this patient through the tracheostomy stoma. Severe dyspnea may progress to respiratory arrest.

TABLE 26.9 Tracheostomy Care

The following are general guidelines for basic tracheostomy care. Become familiar with the specific policies and/or procedures in your agency:

1. Explain procedure to patient.
2. Use tracheostomy care kit or collect necessary sterile equipment (e.g., suction catheter, 1 pair sterile gloves, 1 pair nonsterile gloves, water basin, tracheostomy ties, tube brush or pipe cleaners, 4 × 4–inch gauze pads, sterile water or normal saline, tracheostomy dressing [optional]). NOTE: Clean rather than sterile technique is used at home.
3. Place patient in semi-Fowler's position.
4. Assemble needed materials on bedside table next to patient.
5. Wash hands. Put on PPE.
6. Auscultate chest sounds. If wheezes or coarse crackles are present, suction the patient if unable to cough up secretions

(Table 26.8). Remove soiled dressing and clean gloves.

7. Open sterile equipment, pour sterile H_2O or normal saline into 2 compartments of sterile container or 2 basins, and put on sterile gloves. NOTE: Hydrogen peroxide (3%) is only used if an infection is present. If it is used, rinse the inner cannula and skin with sterile H_2O or normal saline afterward to prevent trauma to tissue.
8. If present, unlock and remove inner cannula. Many tracheostomy tubes do not have inner cannulas. Care for these tubes includes all steps except for inner cannula care.
9. Replace a disposable inner cannula with a new cannula. With a nondisposable cannula:
    - Immerse inner cannula in sterile solution and clean inside and outside of cannula using tube brush or pipe cleaners.
    - Rinse cannula in sterile solution. Remove from solution and shake to dry.
    - Insert inner cannula into outer cannula with the curved part downward, and lock in place.
10. Remove dried secretions from stoma using 4 × 4–inch gauze pad soaked in sterile water or saline. Gently pat area around the stoma dry. Be sure to clean under the tracheostomy flange (faceplate), using cotton swabs to reach this area.
11. Place dressing around tube (Fig. 26.5). Use a pre-cut tracheostomy dressing or unlined gauze. Do not cut the gauze because threads may be inhaled or wrap around the tracheostomy tube. Change the dressing as needed. Wet dressings promote infection and stoma irritation.
12. Change tracheostomy tapes, using a 2-person change technique. Tie tracheostomy tapes securely with room for 2 fingers between tapes and skin (Fig. 26.5). To prevent accidental tube removal, secure the tracheostomy tube by gently applying pressure to the flange of the tube during the tape changes. *Do not change tracheostomy tapes for 24 hours after the tracheostomy procedure.*

13. Some patients prefer tracheostomy tapes made of Velcro, which are easier to adjust.
14. Repeat care 3 times/day and as needed.

Check Your Practice

You are caring for a patient who had a surgically created tracheostomy 6 hours ago. While suctioning the patient, he coughs, dislodging the tracheostomy tube.

- What should you do?

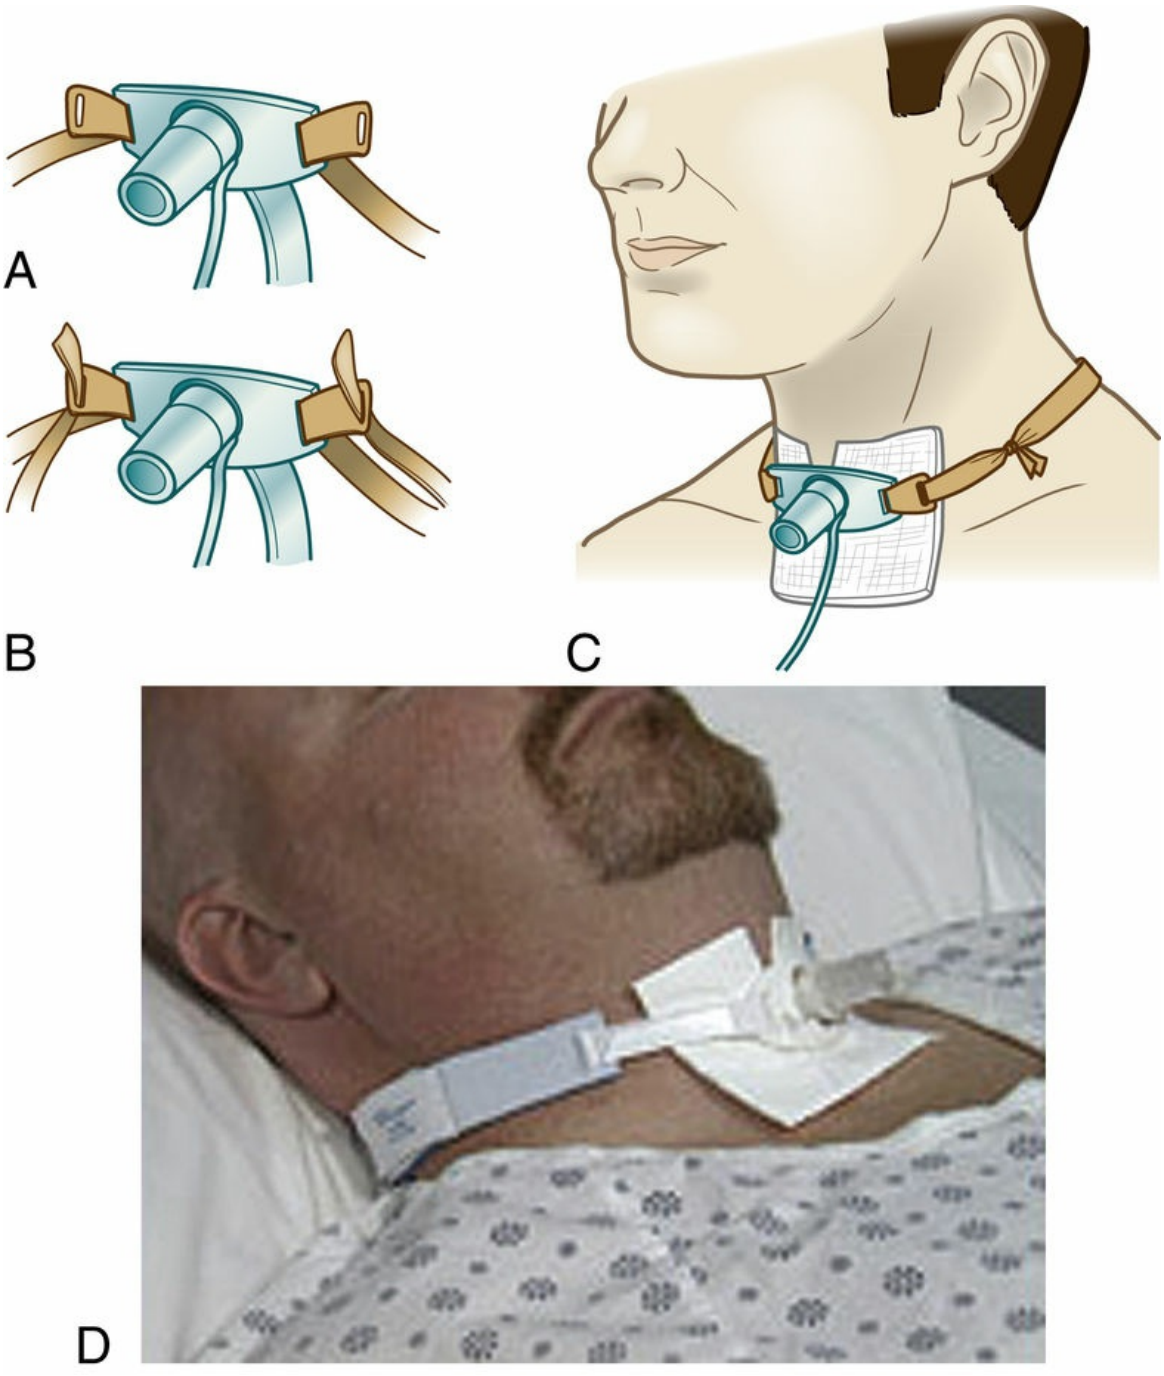

FIG. 26.5 Changing tracheostomy tapes. **A,** A slit is cut about 1 in (2.5 cm) from the end. The slit end is put into the opening of the cannula. **B,** A loop is made with the other end of the tape. **C,** The tapes are tied together with a double knot on the side of the neck. **D,** A Velcro tracheostomy tube holder.
D, Courtesy Dale Medical Products.

Chronic Care

Some patients will never be able to be weaned from mechanical ventilation and will need a tracheostomy for life. Care of the patient with a long-term tracheostomy includes all the same care as patients with a new tracheostomy. This includes observing the tracheostomy site, cleaning the inner cannula, suctioning, and changing tracheostomy tapes.

The tracheostomy tube should be changed around 1 month after the first tube change and every 1 to 3 months thereafter. When a tracheostomy has been in place for several months, the healed tract should be well formed. Changing the tracheostomy tube is important as it permits assessment of the stoma and cleaning of the tube. The patient may be taught to observe for signs and symptoms of infection and how to change the tube at home using a clean technique. Engaging patients to take part in their care may help decrease the incidence of complications, including infection, and promote an overall feeling of well-being.

Swallowing Dysfunction

An inflated tracheostomy tube cuff may result in swallowing problems by interfering with the normal function of muscles used to swallow. Therefore, for long-term tracheostomy patients, it is important to evaluate the patient's swallowing ability and risk for aspiration.

A speech therapist is often the one who assesses the patient's ability to swallow. Using different consistencies of thickened fluids, the patient is evaluated for aspiration and/or microaspiration under videofluoroscopy or with a fiberoptic endoscopy. If the patient can swallow without aspiration when the cuff is deflated, the cuff may be left deflated or a cuffless tube substituted. At this time, patients may be allowed varying levels of thickened fluids and soft foods.

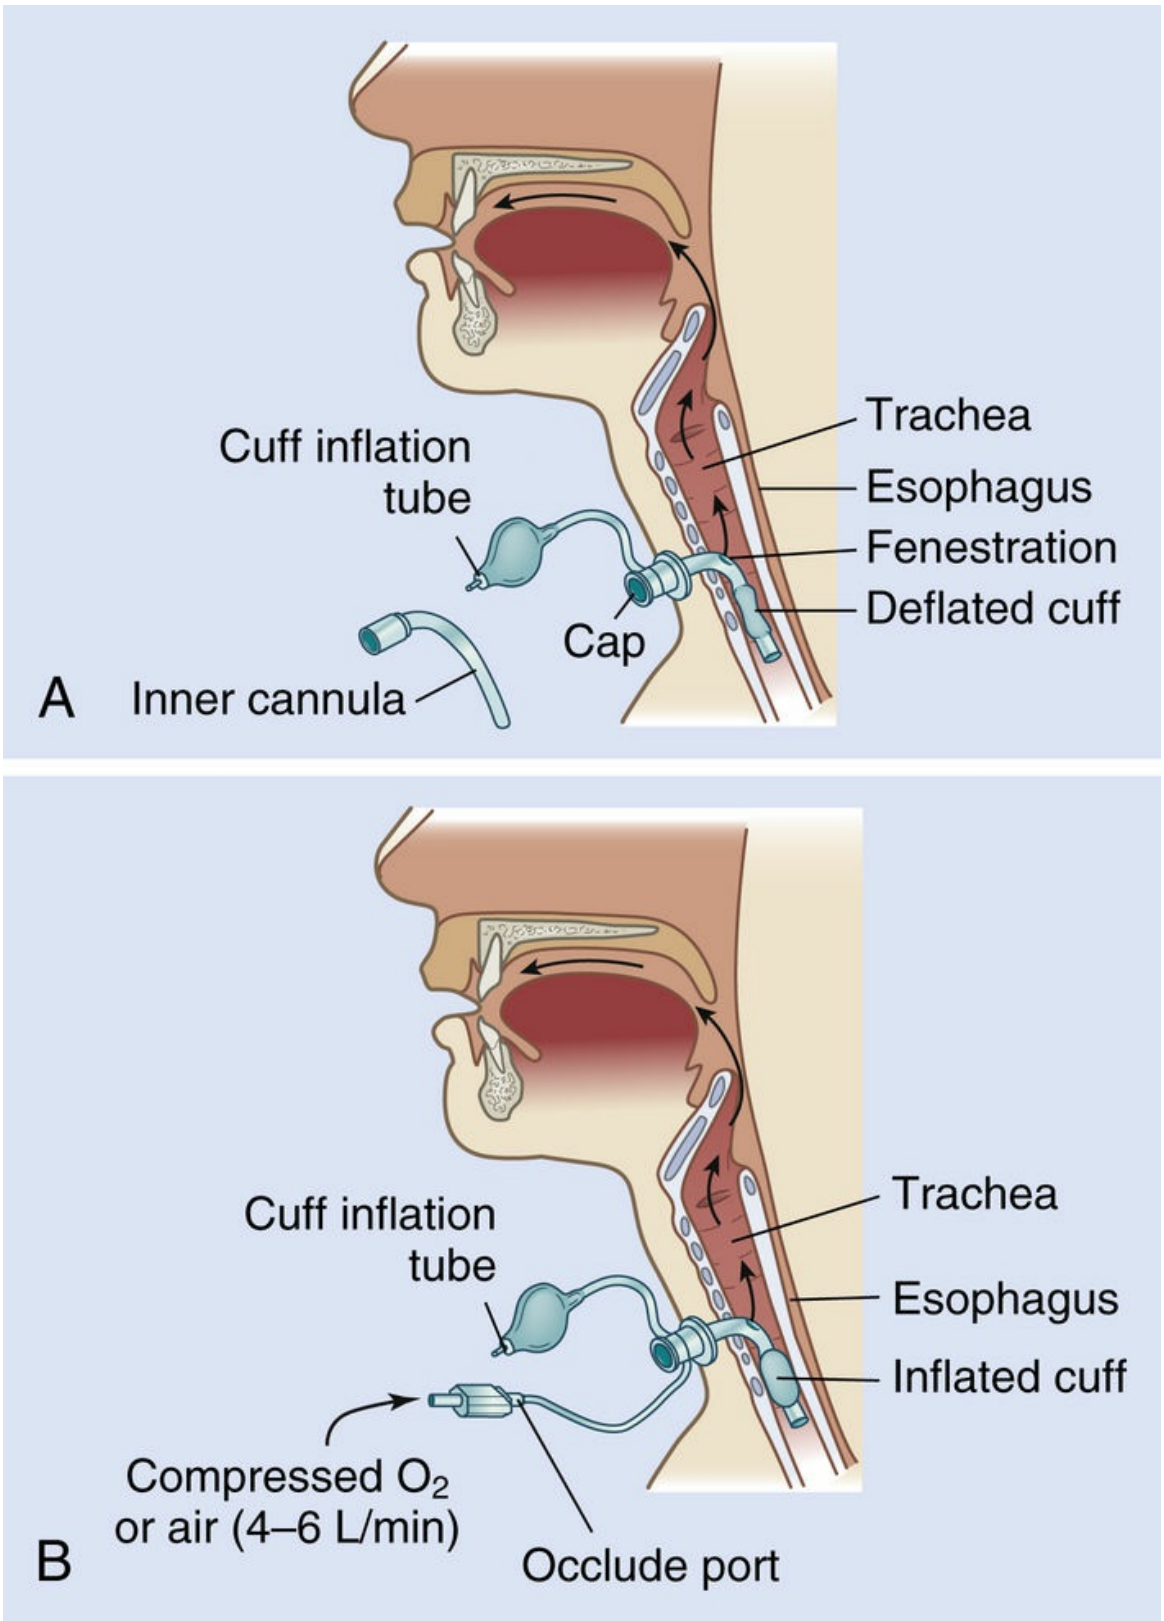

FIG. 26.6 Speaking tracheostomy tubes. **A,** Fenestrated tracheostomy tube with cuff deflated, inner cannula removed, and tracheostomy tube capped to allow air to pass over the vocal cords. **B,**

Speaking tracheostomy tube. One tube is used for cuff inflation. The second tube is connected to a source of compressed air or O_2. When the port on the second tube is occluded, air flows up over the vocal cords, allowing speech with an inflated cuff.

Speech With a Tracheostomy Tube

Several techniques promote speech in the patient with a tracheostomy. When the patient needs mechanical ventilation, provide the patient with a paper and pencil, a white board, or cellular phone for texting. A communication board with pictures of common needs is convenient for patients who may speak other languages. A visual alphabet for spelling words is useful for patients who are weak or have difficulty writing.

The spontaneously breathing patient may be able to talk with a tracheostomy. Several options are available depending upon the type of tracheostomy. For example, if the patient is at low risk for aspiration, (1) remove the inner cannula (if non-fenestrated), (2) deflate the cuff, and (3) place the cap on the tube (Fig. 26.6). When the tracheostomy cuff is deflated, exhaled air can flow upward over the vocal cords. When a fenestrated cannula is first used, frequently assess the patient for signs and symptoms of respiratory distress. If the patient is unable to tolerate the procedure, remove the cap, insert a non-fenestrated cannula, and reinflated the cuff. Monitor for improvement in patient condition.

The Passy-Muir valve is a simple device that attaches to the hub of the tracheostomy tube (Fig. 26.7). With the cuff deflated, the valve redirects airflow through the vocal cords. On inspiration, the valve on the device opens, allowing the patient to inhale. When the patient exhales, the valve closes and air flows upward around the tracheostomy and through the vocal cords. The patient exhales through the nose and mouth instead of through the tracheostomy, allowing speech. The patient may initially be able to tolerate only short periods of use until they become accustomed to exhaling through the mouth. Remove the valve immediately if there are any signs and symptoms of respiratory distress. Advocating for the use of

speaking devices may help improve self-care and increase self-esteem for the patient with a long-term tracheostomy.

FIG. 26.7 Passy-Muir speaking tracheostomy valve. The valve is placed over the hub of the tracheostomy tube after the cuff is deflated. Multiple options are available and can be used for ventilated and nonventilated patients. The 1-way valve allows air to enter the lungs during inspiration and redirects air upward over the vocal cords into the mouth during expiration.
Courtesy Passy-Muir, Irvine, CA.

Decannulation

Removal of the tracheostomy from the trachea is known as **decannulation**. Removal is possible when the primary condition for which the patient initially received a tracheostomy has been resolved. In addition, the patient needs to (1) be hemodynamically stable; (2)

have a stable, intact respiratory drive; (3) be able to adequately exchange air, and (4) independently expectorate secretions.

Immediately prior to decannulation, explain to the patient what will occur. Monitor and record vital signs. Suction the patient prior to decannulation through the tracheostomy. Clear the mouth of any oral secretions. Loosen and/or cut the tracheostomy tapes, and remove any visible sutures holding the tracheostomy in place. Most importantly, ensure that the tracheostomy cuff is deflated. Pull the tracheostomy tube outward in one smooth motion. Stop if you meet any resistance and notify the appropriate personnel immediately.

After the tracheostomy tube is removed, care involves applying a sterile occlusive dressing and monitoring the site for bleeding. The dressing must be changed if it gets soiled or wet. If necessary, close the stoma with tape strips. Monitor the patient's respiratory status and O_2 saturation for any evidence of airway compromise or difficulty breathing. Apply an alternative method of O_2 delivery (e.g., nasal prongs) if needed. Teach the patient to splint the stoma with the fingers when coughing, swallowing, or speaking. Epithelial tissue begins to form in 24 to 48 hours, and the opening closes within 4 or 5 days. Surgical intervention to close the tracheostomy is usually not needed.

Nursing Management

Suctioning and Tracheostomy Care

Suctioning and tracheostomy care are complex nursing activities. Every nurse who performs suctioning and tracheostomy care is responsible for knowing the scope of practice and policies and procedures of the agency in which they work for all health care personnel. Collaborate with respiratory therapy staff, who will play a key role in the patient's care.

For unstable patients:

- Assess for the need for suctioning.
- Suction the ET or tracheostomy tube.
- Assess for adverse effects during suctioning, such as dysrhythmias.
- Evaluate the patient's respiratory status after suctioning.
- Maintain appropriate cuff inflation pressure at 20 to 25 cm H_2O or use minimal leak technique to maintain cuff pressure.
- Assess tracheostomy site at least once per shift for any signs of inflammation or infection.
- Replace the tracheostomy tube or ventilate the patient with a bag-valve-mask device after accidental tracheostomy dislodgment if needed.
- Assess swallowing ability and risk for aspiration.
- Develop plan to avoid aspiration in a patient with a tracheostomy.
- Teach patient and caregiver about home tracheostomy care.
- Delegate care of the stable patient to the licensed practical/vocational nurse (LPN/VN):
    - Determine the need for suctioning
    - Suction the tracheostomy
    - Evaluate patient status after suctioning
    - Provide tracheostomy care using sterile technique
    - Notify the RN of any changes in the patient's respiratory status
- Oversee the UAP in providing oral care to patient with a tracheostomy.
- Collaborate with the respiratory therapist:
    - Ensure proper equipment is available for suctioning and tracheotomy care
    - Measure tracheal cuff pressures
    - Replace tracheostomy tube after accidental dislodgement
    - Assist with bronchoscopy

- Assist with decannulation

Head and Neck Cancer

Head and neck cancer is classified according to the area where it occurs. These cancers may involve the nasal cavity and paranasal sinuses, nasopharynx, oropharynx, larynx, oral cavity, and/or salivary gland. (Cancer of the oral cavity is discussed in Chapter 41.) Most head and neck cancers arise from squamous cells that line the mucosal surfaces of the head and neck.

More than 52,000 new cases of head and neck cancer are diagnosed each year in the United States.[25] Tobacco use causes 85% of head and neck cancers. Excess alcohol consumption is another major risk factor. Head and neck cancer most often occurs in people over age 50 and twice as often in men compared to women. Head and neck cancers in those younger than 50 years are often associated with human papillomavirus (HPV) infection. Other risk factors include exposure to the sun, asbestos, industrial carcinogens, marijuana use, radiation therapy to the head and neck, and poor oral hygiene.[26]

Unfortunately, most patients have locally advanced disease at the time of diagnosis. Disability from both the disease and subsequent treatment is significant because of the potential loss of voice, adverse effects from chemotherapy and/or radiation, disfigurement, and social concerns.

Clinical Manifestations

The early manifestations of head and neck cancer vary with the location of the tumor. For example, patients with pharyngeal cancer may have what feels like a lump in the throat or a sore throat that does not get better with treatment. Some have white or red patches in the mouth or a change in the quality of the voice. Hoarseness that lasts more than 2 weeks may be a symptom of early laryngeal cancer.

Other manifestations may include ear pain or ringing in the ears, swelling or lumps in the neck, constant coughing, and coughing up

blood. Swelling of the jaw can cause dentures to fit poorly or become uncomfortable. Unintentional weight loss and difficulty with chewing, swallowing, moving the tongue or jaw, and breathing are typically late symptoms. A partially or fully obstructed airway is often a late manifestation of head and neck cancer.

Diagnostic Studies

Early detection is key to patient survival. Physical assessment involves a focused assessment of the ears, nose, throat, mouth, and neck. Thoroughly examine the mouth, including the area under the tongue and dentures, with a flashlight. There may be thickening of the normally soft and pliable oral mucosa. Inspect the floor of the mouth and tongue. *Leukoplakia* (white patch) or *erythroplakia* (fiery red patch) may be present. Both leukoplakia and carcinoma in situ (localized to a defined area) may precede invasive carcinoma by many years. Palpate the lymph nodes in the neck.

If lesions are suspected, the HCP will examine upper airways may be examined using indirect pharyngoscopy and laryngoscopy (which involves using a laryngeal mirror). The larynx and vocal cords are visually inspected for lesions and tissue mobility. Typically, multiple biopsy specimens are obtained to help determine the extent of the disease. A CT scan or MRI may be done to detect local and regional spread. Positron emission tomography (PET) scanning is also used in diagnosis. The interprofessional care of head and neck cancer is outlined in Table 26.10.

TABLE 26.10 Interprofessional CareHead and Neck Cancer

Diagnostic Assessment
• History and physical examination • Indirect pharyngoscopy and laryngoscopy

- Endoscopy
- Biopsy
- Chest x-ray
- Barium swallow

Management

- Surgery
    - Vocal cord stripping
    - Laser surgery
    - Cordectomy
    - Partial or total laryngectomy
    - Pharyngectomy
    - Lymph node removal with neck dissection
    - Tracheostomy
    - Reconstructive procedures
- Radiation therapy
- Chemotherapy
- Targeted therapy
- Respiratory therapy
- Physical therapy
- Occupational therapy
- Speech therapy

Staging of Head and Neck Cancer

Head and neck cancer is staged based on the size of the tumor (T), number and location of involved lymph nodes (N), and extent of metastasis (M). This is referred to as *TNM staging*.[27] Staging is slightly different for each type of cancer. Generally, stage 0 is in situ, or confined to where it began, through stage 4, with more advanced disease. Oral cancer staging considers a patient's HPV status. TNM staging is discussed in Chapter 15.

Interprofessional Care

The choice of treatment for head and neck cancer is based on many factors. These include the location of tumor, TNM stage, patient's age and overall general health, urgency of treatment, cosmetic and functional considerations (e.g., ability to talk, swallow, chew), and patient choice. Treatment options include surgery, radiation therapy, chemotherapy, targeted therapy, or any combination of these modalities.[28]

Surgical Therapy

Surgery is often the first-line treatment option for head and neck cancers. Some patients may be treated with surgery alone. For other patients, combining surgery with radiation therapy and/or chemotherapy may be appropriate. Depending on the location and stage of cancer, surgical options include:

- *Vocal cord stripping:* Removal of outer layers of tissue on the vocal cords. This approach may be used for a biopsy or to treat some stage 0 cancers confined to the vocal cords. Vocal cord stripping rarely affects speech.
- *Laser surgery:* An endoscope with a laser is inserted down the throat, and the tumor can be vaporized or removed.
- *Cordectomy:* Removal of part or all the vocal cords. There may be changes in tone of voice. Removing part of a vocal cord may lead to a hoarse voice. If both vocal cords are removed, speech will no longer be possible.
- *Partial or total* ***laryngectomy****:* Removal of part or all the larynx. A total laryngectomy will change airflow in and out of the lungs and normal voice production will not be possible (Fig. 26.8).
- *Pharyngectomy:* Removal of part or all the throat.
- *Tracheostomy:* A tracheostomy is done to create an alternate pathway for breathing by creating a stoma in the trachea.
  Lymph node removal: Head and neck cancer sometimes spreads

to the lymph nodes. The amount of tissue and number of lymph nodes that are removed depend on how far the cancer has spread.

- *Neck dissection surgery:* There are 3 main types:
    - *Radical neck dissection:* Removal of all the tissue on the side of the neck from the mandible to the clavicle. This includes the muscle, nerve, salivary gland, and major blood vessels.
    - *Modified radical neck dissection:* This is the most common type of neck dissection for cancer. All lymph nodes are removed. Less neck tissue is taken out than in radical dissection. This surgery may spare the nerves in the neck and, sometimes, the blood vessels or muscle.
    - *Selective neck dissection:* If cancer has not spread far, fewer lymph nodes are removed. The muscle, nerve, and blood vessels in the neck may be saved.

After extensive surgery to remove head and neck cancer, reconstructive operations can help restore both the structure and function of the affected areas.

Radiation Therapy

Radiation therapy can be delivered by either external-beam therapy or internal implants (brachytherapy). Brachytherapy is a concentrated and localized method of delivering radiation that involves placing a radioactive source near or into the tumor. The goal is to deliver high doses of radiation to the target area while limiting exposure of surrounding tissues. Thin, hollow, plastic needles are inserted into the tumor area, and radioactive seeds are placed in the needles. The seeds emit continuous radiation. Radiation therapy and brachytherapy are discussed in Chapter 15.

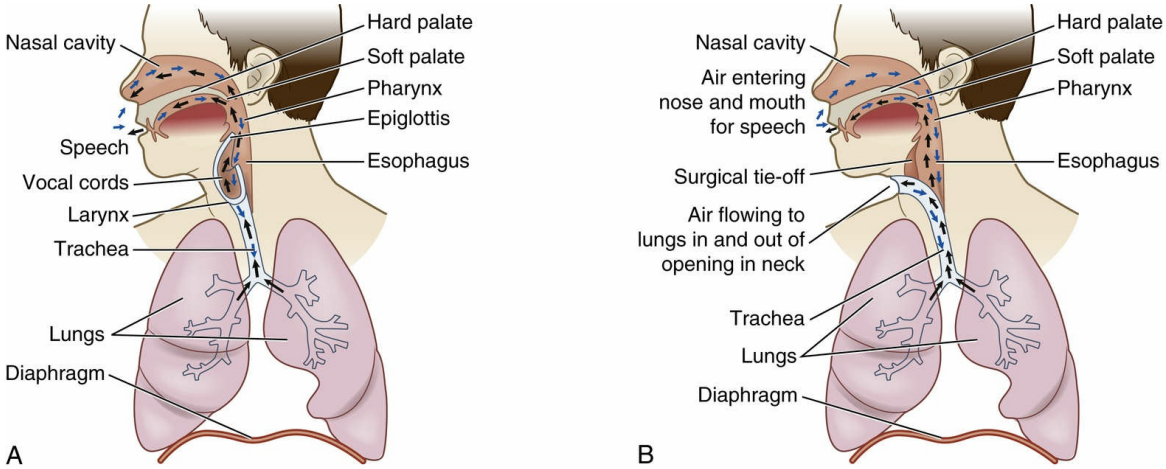

FIG. 26.8 Airflow in and out of the lungs after total laryngectomy. There is no anatomic connection between the nose, mouth, and throat. Inhaled and exhaled air enters the lungs through a surgically created stoma (hole) in the neck.

Radiation therapy is often preferred for patients with early head and neck cancer because it offers the patient good results with voice preservation. Some patients refuse surgical intervention for advanced lesions because of the extent of the procedure and potential risks involved. In this situation, radiation therapy is used as the sole treatment or in combination with chemotherapy. Other patients may opt for surgery and a combination of either radiation and/or chemotherapy treatments.

Chemotherapy and Targeted Therapy

Chemotherapy is used in combination with radiation therapy for patients with stage 3 or 4 head and neck cancers. Chemotherapy agents currently recommended include cisplatin, 5-fluorouracil, carboplatin, docetaxel (Taxotere), paclitaxel, methotrexate, and bleomycin.[29]

Cetuximab (Erbitux), a targeted therapy, is used with chemotherapy to treat patients with late-stage head and neck cancer. The drug targets epidermal growth factor receptor (EGFR), a specific protein within cancer cells, and stops the cells from growing. Targeted therapy is discussed in Chapter 15 and Table 15.13.

Nutritional Therapy

Many patients with head and neck cancer are malnourished even before treatment begins. Treatment modalities increase the risk for malnutrition. For example, after radical neck surgery, the patient may be unable to consume nutrients orally because of swelling, the location of sutures, or difficulty with swallowing. Side effects from chemotherapy and radiation therapy can impair the patient's ability to maintain adequate nutrition. Painful oral mucositis often leads to breaks in treatment if the patient is relying solely on oral intake for nutrition.

A thorough nutritional assessment and prophylactic placement of a gastrostomy tube in high-risk patients are vital to maintaining adequate nutrition. Enteral nutrition may be started before initiating treatment to obtain and maintain optimal nutritional status needed for tissue repair. (Enteral nutrition is described in Chapter 39.) Elevate the head of the bed while the patient is eating. Observe for feeding intolerance and adjust the amount, time, and/or formula if nausea, vomiting, diarrhea, or distention occurs. Teach the patient and caregiver about the enteral feedings.

Patients who are not candidates for or who refuse enteral feedings need to be monitored closely for weight loss. Antiemetics or analgesics given before meals can reduce nausea and mouth pain. Bland foods are easier for patients to tolerate. Patients can increase caloric intake by adding dry milk to foods during preparation, eating foods high in calories, and using oral supplements. It is helpful to add mild sauces and gravy to food. This adds calories and moistens food so that it is more easily swallowed. Expect swallowing problems when the patient resumes eating after surgery. The type and degree of difficulty varies depending on the surgical procedure. Videofluoroscopic swallowing studies may be used to evaluate the safety of swallowing postoperatively. When the patient can successfully swallow with low or no risk for aspiration, small amounts of thickened liquids or pureed foods may be given with the patient in high-Fowler's position. Avoid thin, watery fluids because they are hard to swallow and increase the risk for aspiration. Closely monitor

and observe for any signs or symptoms of respiratory distress and/or choking when eating resumes. Oral suctioning may be done to prevent aspiration.

Physical Therapy

After surgery for head and neck cancer, the physical therapist will help teach the patient how to use the upper extremities to assist with support and movement of the head. In the immediate postoperative period, the patient should begin an exercise program to maintain strength and movement in the shoulders and neck. Without exercise, the patient could be left with a "frozen" shoulder and limited range of neck motion. The patient should continue the exercise program after discharge to prevent future functional disabilities.

Speech Therapy

Preoperatively, a speech therapist should meet with the patient and caregiver to discuss any effect that surgery will have on the voice and potential adaptations or voice restoration options. The International Association of Laryngectomees, an association of laryngectomy patients, focuses on helping patients reestablish speech. Local groups, such as "Lost Chord" or "New Voice," often have volunteers to visit patients before surgery.

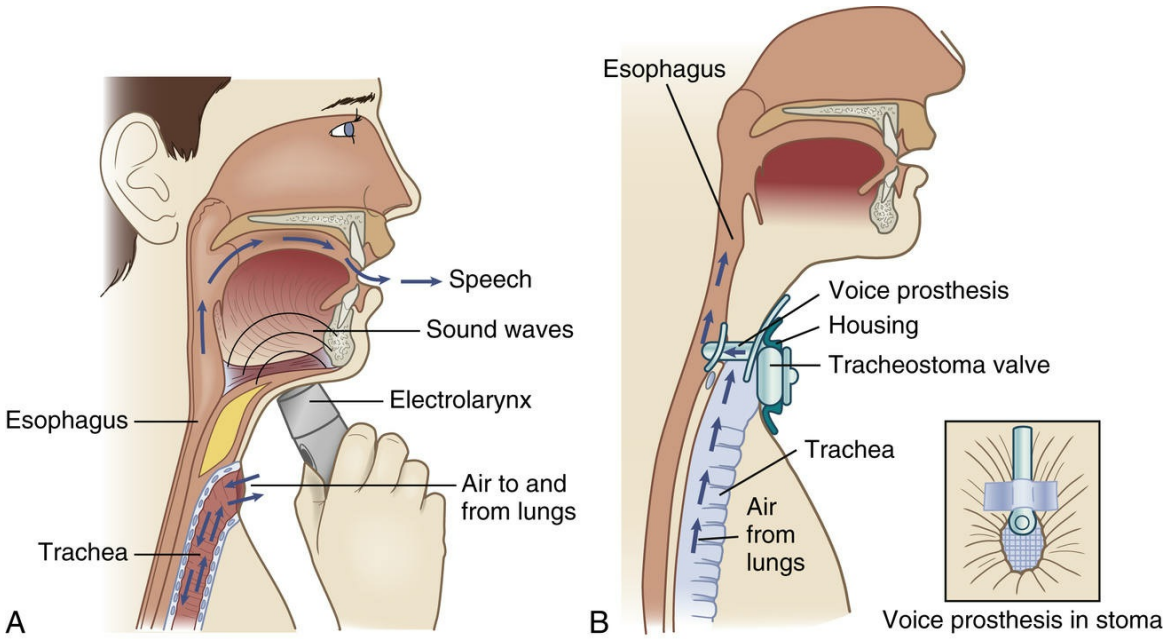

FIG. 26.9 **A,** The sound waves created by the electrolarynx allow the person to speak. **B,** The Blom-Singer voice prosthesis and valve.

Three major approaches are used to restore oral communication: (1) electrolarynx, (2) tracheoesophageal puncture (TEP) voice restoration, and (3) esophageal speech. An *electrolarynx* is a hand-held, battery-powered device that creates speech with the use of sound waves (Fig. 26.9, *A*). This option allows for speech immediately after surgery. It needs little maintenance and is easy to learn. The primary disadvantage of the electrolarynx is the mechanical sound quality, which many patients find unacceptable.

In *transesophageal puncture (TEP),* a fistula is created in the tracheoesophageal wall that diverts pulmonary air across the pharyngoesophageal mucosa for phonation when the tracheostoma is occluded. A 1-way prosthetic valve is placed in the tract. The valve prevents aspiration of food or saliva from the esophagus into the tracheostomy. To speak, the patient manually blocks the stoma with the finger. Air moves from the lungs, through the prosthesis, into the esophagus, and out the mouth. Speech is made by the air vibrating against the esophagus and is formed into words by moving the tongue and lips. A common voice prosthesis is the Blom-Singer prosthesis (Fig. 26.9, *B*). TEP offers the best speech quality with the highest degree of patient satisfaction.

Esophageal speech depends upon air that is introduced into the esophagus and then expelled past the pharyngoesophageal segment, the vibratory source for sound production. The primary disadvantages of developing esophageal speech are the length of time needed to learn the technique and the reduction in voice quality.

Nursing Management: Head and Neck Cancer

Nursing Assessment

Table 26.11 presents subjective and objective data to obtain from a person with head and neck cancer.

Nursing Diagnoses

Nursing diagnoses for the patient with head and neck cancer include:

- Impaired airway clearance
- Risk for aspiration

TABLE 26.11 Nursing AssessmentHead and Neck Cancer

Subjective Data
Important Health Information
Past health history: Positive family history; prolonged tobacco use (cigarettes, pipes, cigars, chewing tobacco, smokeless tobacco); prolonged, heavy alcohol use; poor intake of fruits and vegetables
Medications: Prolonged use of over-the-counter medication for sore throat, decongestants
Functional Health Patterns
Health perception–health management: Does not take part in preventive health measures, long history of alcohol and tobacco use

Nutritional-metabolic: Mouth ulcer that does not heal, change in fit of dentures, change in appetite, sudden or unexplained weight loss, swallowing difficulty (e.g., sensation of lump in throat, pain with swallowing, aspiration when swallowing)
Activity-exercise: Fatigue with minimal exertion
Cognitive-perceptual: Sore throat, pain on swallowing, referred ear pain

Objective Data

Respiratory

Hoarseness, change in voice quality, chronic laryngitis, nasal voice, palpable neck mass and lymph nodes (tender, hard, fixed), tracheal deviation; dyspnea, stridor (late sign)

Gastrointestinal

White (leukoplakia) or red (erythroplakia) patches inside mouth, ulceration of mucosa, asymmetric tongue, exudate in mouth or pharynx, mass or thickening of mucosa

Possible Diagnostic Findings

Mass on direct or indirect laryngoscopy; tumor on soft tissue x-ray, CT scan, or MRI; positive biopsy

- Difficulty coping
- Impaired communication

More information on nursing diagnoses and the care of the patient with head and neck cancer is presented in eNursing Care Plan 26.2 on the website for this chapter.

Planning

The overall goals are that the patient will have (1) a patent airway, (2) an acceptable body image, (3) no complications related to therapy, (4) adequate nutritional intake, (5) minimal to no pain, and (6) the ability to communicate.

Nursing Implementation

Health Promotion

Most head and neck cancers can be prevented. The development of head and neck cancer is closely related to personal habits, mainly tobacco use and excess alcohol use. Poor oral hygiene and HPV infection are also risk factors for head and neck cancer.

Include information about risk factors in health teaching. Encourage good oral hygiene. Teach patients about safe sex practices to prevent HPV infection (e.g., use condoms, encourage monogamous relationships, choose a partner who has had no or few previous partners). If cancer has been diagnosed, tobacco and alcohol cessation are still important. The chance of a cure, by any treatment modality, for a patient with head and neck cancer who continues to smoke and use alcohol is decreased. Also, the risk for a second primary cancer is significantly increased. Give patients information about smoking cessation programs and techniques for success. If needed, refer to an alcohol treatment program. Smoking cessation and treatment of alcohol use are discussed in Chapter 10.

Acute Care

Teach the patient and caregiver about the type of treatment to be performed, care needed, and reason for treatment and care. Help prepare them to deal with the psychological impact of the diagnosis of cancer, change in physical appearance, possible need for enteral feedings, and use of other communication methods because of loss of voice.

Care plans should include assessment of the patient's support system. The patient may not have someone to help after discharge or may have a job that cannot be continued, leaving the patient unemployed.

Surgical Therapy

Preoperatively assess the patient's physical and psychosocial needs. Physical preparation is the same as for any major surgery, with an emphasis on oral hygiene. Assess knowledge and understanding of the planned surgical procedure and clarify misinformation or misunderstanding as needed. When possible, include the caregiver in

preoperative teaching.

Tailor teaching to the planned surgical procedure. For example, include information about expected changes in speech after a laryngectomy. Alphabet boards, writing materials, pictorial guides, laptops, and hand signals are useful methods for communicating. Programmable speech-generating devices allow use of recorded messages that are matched with a graphic representing each message. Integration of newer technology into patient care enhances the patient's ability to communicate basic needs after surgery.

Informatics in Practice

Communication Devices for Patient With Laryngectomy

- Assisting with communication will improve a patient's quality of life after a laryngectomy.
- Use a tablet or smartphone and download a text-to-speech application. These applications allow the patient to type in text, and then a computer voice says the text aloud.
- You can teach the patient how to use a keyboard-based communication program. The patient types on a traditional keyboard and generates speech that is transmitted through hand-held speakers.

Immediately after surgery, nursing care priorities include airway management, wound care, nutrition, communication, and psychosocial issues related to body image changes. Maintaining a patent airway is essential. Inflammation in the surgical area may compress the trachea. Keep the patient in a semi-Fowler's position to decrease edema and limit tension on suture lines.

Give analgesic drugs as needed for pain control. Because patients may not be able to speak, have them nonverbally rate their pain (e.g., visual pain scale) to help assess the effectiveness of the medication.

(Pain management is discussed in Chapter 8.) Monitor vital signs frequently. Be alert for hemorrhage, as many of the structures in the head and neck area are very vascular. Pay careful attention to heart rate, blood pressure, SpO_2, and the patient's hemoglobin value.

The patient with a laryngectomy needs frequent suctioning via the tracheostomy tube. Secretions typically change in amount and consistency over time. The patient may initially have a large amount of blood-tinged secretions that gradually diminish and thicken. Maintain adequate fluid intake (IV, enteral) and humidification of inspired gases to keep secretions liquid and mucous membranes moist. Encourage deep breathing and coughing.

Pressure dressings, packing, or drainage tubes may be present, depending on the type of surgical procedure. Do not change any dressing unless you have a specific order from the HCP. If skin flaps are used, dressings are typically not present. This allows better visualization of the flap and avoids excess pressure on tissue. Skin flaps must initially be checked hourly for color and any change in size or edema. Doppler ultrasound may be used to determine the presence of a pulse, depending upon the location of the skin flap. Hemovac, Jackson-Pratt, and Penrose drains are some of the drainage devices that may be used.

Drainage may initially be bloody, then serosanguineous, and gradually decrease in volume over 24 to 48 hours. Monitor patency of drainage tubes every hour in the first few hours after surgery, then every 4 hours to ensure proper functioning. If tubing becomes obstructed, fluid will accumulate under the skin flap and predispose the patient to formation of hematomas or seromas, impair wound healing, and increase the risk for infection. After drainage tubes are removed, closely monitor the area to detect any swelling. Closely monitor incision sites for signs of infection.

The patient may have a nasogastric tube inserted during surgery to remove gastric contents via intermittent suction for the first 24 to 48 hours until peristalsis returns. Because the nasogastric tube lies close to internal incision lines, do not manipulate or move the tube. When bowel sounds return, start enteral feedings slowly and advance to

meet nutritional needs.

Radiation Therapy

Dry mouth *(xerostomia),* a frequent and annoying problem, typically occurs within a few weeks of treatment. The patient's saliva decreases in volume and becomes thick. This change may be temporary or permanent. Pilocarpine hydrochloride (Salagen) is often effective in increasing saliva production.

Check Your Practice

Your 64-yr-old male patient with oral cancer has been receiving radiation therapy for 3 weeks. He has developed xerostomia and oral mucositis. He asks if you have any suggestions to help relieve his symptoms.

- How would you respond?

Once patients can have foods or fluids by mouth, they can get symptom relief by increasing fluid intake, chewing sugarless gum or sugarless candy, using nonalcoholic mouth rinses (baking soda, glycerin solutions), and using artificial saliva. Teach patients to always carry a water bottle with them. Fluoride gels or treatments can help prevent dental deterioration caused by xerostomia.

Oral mucositis can cause irritation, ulceration, and pain. Teach the patient on oral care basics, including the use of a soft toothbrush and regular flossing. Empty fluoride gel trays, along with bite blocks, athletic mouth guards, or gauze pads, can be worn during radiation treatments. This prevents radiation scatter to the tongue and cheek from metal work in the mouth. Warm bland rinses, like those with salt and baking soda, 4 to 6 times daily may be helpful. Sucking on ice chips can also help with the pain. Patients should avoid commercial mouthwashes and hot, spicy, or acidic foods because they are irritating.

Skin over the irradiated area often becomes reddened and sensitive to touch. Teach patients to use only prescribed lotions and skin products while undergoing radiation therapy and to not use any lotions within 2 hours before treatment. Skin care for patients having radiation therapy is discussed in Chapter 15.

Fatigue is a common side effect of radiation therapy as well as chemotherapy. Encourage patients to walk 15 to 30 minutes each day since regular exercise can give them more energy. Teach patients to do activities that are most important to them and to rest during periods of low energy. Identify support systems and encourage patients to ask for help.

Stoma Care

Should the patient have a stoma after surgery, teach the patient proper care of the stoma. The patient should wash the area around the stoma daily with a moist cloth. A nasal wash spray (e.g., Alkalol) can be used every 1 to 2 hours to keep the stoma moist and prevent crusting. Dried secretions can be removed with tweezers. If a laryngectomy tube is in place, the patient must remove the entire tube at least daily and clean it in the same manner as a tracheostomy tube. The inner cannula may have to be removed and cleaned more often. A scarf or loose shirt can hide the stoma.

The patient should cover the stoma when coughing (because mucus may be expectorated) and during any activity (e.g., shaving, applying makeup) that may lead to inhalation of foreign materials. Because water can easily enter the stoma, the patient should wear a plastic collar when taking a shower. Swimming is contraindicated. Initially, humidification is given with mechanical ventilation or, after extubation, with a tracheostomy mask. After discharge, the patient can use a bedside humidifier.

Psychosocial Needs

Psychosocial care of the patient with head and neck cancer is of utmost importance. Issues concerning depression, change in body image, and sexuality are common. Although changes are discussed

before surgery, the patient may not be psychologically prepared for the extent of these changes. If the patient has a significant other, this person's reaction to the patient's altered appearance is important. Acceptance by another person can promote an improved self-image.

Depression may occur for many reasons: inability to speak because of surgical procedure and/or presence of ET or tracheostomy tube, altered physical appearance due to the surgery and edema, loss of independence and reliance upon others, and feelings of helplessness and hopelessness. Depression also may be related to concern about the prognosis.

Allow the patient and caregiver to express their feelings and emotions. Convey acceptance to help patients regain positive feelings about their body image and self-concept. Encourage participation in support groups. Information about available groups can be obtained through the local branch of the American Cancer Society. A psychiatric referral may be needed for the patient who has prolonged or severe depression.

Surgery and surgical devices such as tracheostomy and gastrostomy tubes may dramatically affect body image. Xerostomia and fatigue can physically affect sexuality. It may be hard for the patient to talk about sexual problems because of changes in communication. Help the patient and partner by allowing them to talk about their sexuality and how surgery and treatment may affect their relationship. Helping the patient see that sexuality involves much more than appearance may relieve some anxiety.

Ambulatory Care

The patient may be discharged with a tracheostomy and a nasogastric or gastrostomy feeding tube. Some patients initially need a home health care referral and assessment to evaluate the patient's or caregiver's ability to perform self-care activities. Both patient and caregiver need to learn how to manage tubes and whom to call if there are problems. Provide pictorial instructions for tracheostomy care, suctioning, stoma and skin care, and enteral feeding as appropriate. Encouraging the patient to take part in self-care is an important part of

rehabilitation.

Teach the patient the importance of wearing a Medic Alert bracelet or other identification that alerts emergency personnel of the possible changes in breathing status because of surgery. Because the patient no longer breathes through the nose, the ability to smell smoke and taste food is often lost. Teach the patient to install smoke and carbon monoxide detectors in the home. Encourage preparation of food that is colorful, attractive, and nutritious because taste may be decreased due to the loss of smell and radiation therapy. Refer to a dietitian as needed.

The patient can resume exercise, recreation, and sexual activity when able. Most patients can return to work 1 to 2 months after surgery. However, many never return to full-time employment. The changes that follow a total laryngectomy can be upsetting. Loss of speech, loss of the ability to taste and smell, inability to produce audible sounds (including laughing and weeping), and the presence of a permanent tracheal stoma that produces undesirable mucus are often overwhelming to patients.

Evaluation

Expected outcomes for the patient with head and neck cancer who is treated surgically are that the patient will:

- Have effective coughing and secretion clearance
- Swallow oral foods without aspiration
- Uses effective coping strategies
- Use techniques to effectively communicate

Case Study

Laryngeal Cancer

© iStockphoto/Thinkstock.

Patient Profile

M.R., a 69-yr-old retired baker, was admitted to the hospital for influenza. He told his HCP that he has "a cough that just won't go away," difficulty swallowing, and "a sore throat that really hasn't gotten better" over the past year. His wife passed away 6 years ago. He has 3 adult children; 1 daughter lives in the same city. He has a history of hypertension, smoking, alcohol use, gastroesophageal

reflux disease (GERD), and type 2 diabetes.

Subjective Data

- States that his symptoms worsened in the past 3 months
- Has used various cough and cold remedies over the past 6 months to relieve symptoms without relief
- Has lost weight because of decrease in appetite and difficulty swallowing
- Has smoked 3 packs of cigarettes a day for the past 50 yrs
- Consumes 4 to 6 cans of beer a day

Objective Data
Physical Examination

- *Vital signs:* Temperature 102.4° F (39.1° C), heart rate 99 beats/min (pulse strong, regular), respiratory rate 24 breaths/min (short, shallow, slightly labored), BP 176/84 (cuff), SpO_2 87% on room air
- *Inspection:* Awake and alert, appears gray, malnourished, dehydrated. Small, irregular white patches on the sides of oral cavity
- *Palpation:* Enlarged cervical nodes bilaterally (nontender)
- *Auscultation:* Adequate and clear air entry to upper lung fields; slightly decreased air entry to bases with occasional fine crackles on expiration

Diagnostic Studies

- Chest x-ray: lung fields clear
- Laryngoscopy: mass in subglottic area (requires further evaluation)
- CT scan: subglottic lesion with lymph node involvement

- Diagnosis: laryngeal cancer

Interprofessional Care

- *Surgery:* suggests a total laryngectomy
- *Oncology:* suggests radiation and chemotherapy postoperatively
- *Gastroenterology:* percutaneous gastrostomy tube preoperatively for enteral feeding
- *Dietary:* explain nutritional options with/without ET tube/tracheostomy
- *Physical therapy:* visit pre-surgery to explain postoperative exercise routine
- *Social worker:* determine social supports available postoperatively

Discussion Questions

1. What assessment information suggests that M.R. is at risk for laryngeal cancer?
2. ***Priority Decision:*** What are your priority teaching strategies for M.R. before his total laryngectomy? Postoperative teaching priorities?
3. How would you explain the gastrostomy tube to M.R.?
4. Is there anything in his history that may affect wound healing after surgery?

Progression of Case

M.R. is transferred to the clinical unit after 24 hours in ICU. He is awake, alert, but slightly confused. Vital signs are stable. BP 168/94. Large surgical dressing on neck with 3 Jackson-Pratt drains. Tracheostomy tube in place. Receiving O_2 via tracheal mask. Enteral feeding at 30 mL/hr via gastrostomy tube. Foley catheter patent, draining a moderate amount of amber urine. M.R. is picking at his

surgical drains, and when you try to reassure him, he just starts waving his hands at you.

5. ***Collaboration:*** What information would you want to know from the ICU nurse who has just transported M.R. to the clinical unit?
6. ***Priority Decision:*** Based on the assessment data presented, what are your priority nursing diagnoses? Are there any collaborative problems?
7. ***Evidence-Based Practice:*** How could you best meet M.R.'s communication needs during the first few postoperative days?
8. Four hours after transfer to the clinical unit, M.R. is tearful and is staring at the wall. What should you do?
9. ***Patient-Centered Care:*** What teaching is required to help him assume self-care after his surgery? What precautions should he take because of his stoma?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient is seen in the clinic for a nosebleed, which is controlled by placement of anterior nasal packing. During discharge teaching, the nurse teaches the patient to
   a. use aspirin for pain relief.
   b. remove the packing later that day.
   c. avoid vigorous nose blowing and strenuous activity.
   d. insert more packing into the nose if rebleeding occurs.
2. A patient with allergic rhinitis reports severe nasal

congestion; sneezing; and watery, itchy eyes and nose at various times of the year. When teaching the patient about how to control these symptoms, the nurse teaches the patient to

a. avoid all intranasal sprays and oral antihistamines.

b. limit the usage of nasal decongestant spray to 10 days.

c. use oral decongestants at bedtime to prevent symptoms during the night.

d. keep a diary of when the allergic reaction occurs and what precipitates it.

3. A patient is seen at the clinic with fever, muscle aches, sore throat with yellowish exudate, and headache. The nurse anticipates that the interprofessional management will include *(select all that apply)*

a. antiviral agents to treat influenza.

b. treatment with antibiotics starting ASAP.

c. a throat culture or rapid strep antigen test.

d. supportive care, including cool, bland liquids.

e. comprehensive history to determine possible cause.

4. The *best* method for determining the risk for aspiration in a patient with a tracheostomy is to

a. consult a speech therapist for swallowing assessment.

b. have the patient drink plain water and assess for coughing.

c. ask the patient to rate the perceived degree of swallowing difficulty.

d. assess for sputum changes 48 hours after the patient drinks small amount of blue dye.

5. Which nursing action would be of *highest priority* when suctioning a patient with a tracheostomy?
   a. Auscultating lung sounds after suctioning is complete
   b. Giving antianxiety medications 30 minutes before suctioning
   c. Instilling 5 mL of normal saline into the tracheostomy tube before suctioning
   d. Assessing the patient's oxygen saturation before, during, and after suctioning
6. When planning health care teaching to prevent or detect early head and neck cancer, which people would be the *priority* to target *(select all that apply)*?
   a. 65-year-old man who has used chewing tobacco most of his life
   b. 45-year-old rancher who uses snuff to stay awake while driving his herds of cattle
   c. 21-year-old college student who drinks beer on weekends with his fraternity brothers
   d. 78-year-old woman who has been drinking liquor since her husband died 15 years ago
   e. 22-year-old woman who has been diagnosed with human papilloma virus of the cervix
7. While in the recovery room, a patient with a total laryngectomy is suctioned and has bloody mucus with some clots. Which nursing interventions would apply? (*select all that apply*)
   a. Notify the health care provider at once.
   b. Place the patient in semi-Fowler's position.

c. Use a bag-valve-mask (BVM) and begin rescue breathing for the patient

d. Instill 10 mL of normal saline into the tracheostomy tube to loosen secretions.

e. Continue patient assessment, including O_2 saturation, respiratory rate, and breath sounds.

8. Appropriate discharge teaching for the patient with a permanent tracheostomy after a total laryngectomy for cancer would include (*select all that apply*)

a. encouraging regular exercise such as swimming.

b. washing around the stoma daily with a moist washcloth.

c. encouraging participation in postlaryngectomy support group.

d. providing pictures and "hands-on" instruction for tracheostomy care.

e. teaching how to hold breath and trying to gag to promote swallowing reflex.

1. c, 2. d, 3. c, d, e, 4. a, 5. d, 6. a, b, d, e, 7. b, e, 8. b, c, d

Lower Respiratory Problems

Eugene Mondor

LEARNING OUTCOMES

1. Compare and contrast the clinical manifestations and nursing and interprofessional management of patients with acute bronchitis and pertussis.
2. Distinguish among the types of pneumonia and their etiology.
3. Describe the pathophysiology, clinical manifestations, diagnostic studies, and interprofessional and nursing management of patients with pneumonia.
4. Describe the pathogenesis, classification, clinical manifestations, complications, diagnostic abnormalities, and interprofessional and nursing management of patients with tuberculosis.
5. Describe the causes, clinical manifestations, and nursing and interprofessional management of patients with pulmonary fungal infections.
6. Explain the pathophysiology, clinical manifestations, and nursing and interprofessional management of a patient with a lung abscess.
7. Identify the causative factors, clinical manifestations, and nursing and interprofessional management of patients with environmental lung diseases.
8. Describe the etiology, risk factors, pathophysiology, clinical manifestations, and interprofessional and nursing management of

lung cancer.

9. Compare and contrast the pathophysiology, clinical manifestations, and nursing and interprofessional management of fractured ribs, flail chest, and pneumothorax.
10. Describe the purpose, function, and nursing responsibilities related to chest tubes and chest drainage systems.
11. Explain the types of chest surgery and appropriate preoperative and postoperative care.
12. Describe the etiology, clinical manifestations, and nursing and interprofessional management of patients with restrictive lung disorders.
13. Describe the pathophysiology, clinical manifestations, and nursing and interprofessional management of pulmonary embolism, pulmonary hypertension, and cor pulmonale.
14. Discuss the use of lung transplantation as a treatment for pulmonary disorders, emphasizing nursing and interprofessional management of the postoperative lung transplant patient.

Conceptual Focus

Cellular Regulation
Clotting
Functional Ability
Gas Exchange
Infection

A variety of problems affect the lower respiratory system. This chapter discusses lower respiratory tract diseases that influence the concept of gas exchange. It focuses on infectious, environmental,

oncologic, traumatic, restrictive, and vascular problems that impair gas exchange. Gas exchange is related with multiple concepts, as a problem has profound consequences because of the need of adequate oxygenation for life.

Lower Respiratory Tract Infections

Lower respiratory tract infection is both a common and serious occurrence. It is the reason for thousands of clinic and emergency department (ED) visits and hospital admissions each year. In the United States, pneumonia and influenza cause more than 57,000 deaths annually.[1]

Acute Bronchitis

Acute bronchitis is a self-limiting inflammation of the bronchi in the lower respiratory tract. It is the reason for 10% of all clinic visits and 100 million ED visits per year.[2] Most acute bronchial infections are caused by viruses. Air pollution, dust, inhalation of chemicals, smoking, chronic sinusitis, and asthma are other triggers.

Cough, which is the most common symptom, may last for up to 3 weeks. It is the main reason for seeking medical care. Clear sputum is often present, although some patients have purulent sputum. The presence of colored (e.g., green) sputum is not a reliable indicator of bacterial infection. Other symptoms may include headache, fever, malaise, hoarseness, myalgias, dyspnea, and chest pain.

Diagnosis is based on the assessment. Assessment may reveal normal breath sounds or crackles or wheezes, usually on expiration and with exertion. *Consolidation* (which occurs when fluid accumulates in the lungs), suggestive of pneumonia, is absent with bronchitis. Chest x-rays are normal and not needed unless pneumonia or some other pulmonary disorder is suspected.

The goal of treatment is to relieve symptoms and prevent pneumonia. Treatment is supportive. It includes cough suppressants (e.g., dextromethorphan), encouraging oral fluid intake, and using a humidifier. Throat lozenges, hot tea, and honey may help relieve cough. β_2-Agonist (bronchodilator) inhalers are useful for patients with wheezes or underlying pulmonary conditions. Antibiotics are not prescribed for viral infections because they have side effects and promote antibiotic resistance. Antibiotics may be given to patients with underlying chronic conditions who have a prolonged infection associated with systemic symptoms.

Encourage patients not to smoke, to avoid secondhand smoke, and to wash their hands often. If the acute bronchitis is due to an influenza virus, treatment with antiviral drugs may be started. If patients with acute bronchitis develop a fever, have difficulty breathing, or have symptoms last longer than 4 weeks, they should see their HCP.

Pertussis

Pertussis is a highly contagious infection of the respiratory tract caused by the gram-negative bacillus *Bordetella pertussis*. The bacteria attach to the cilia of the respiratory tract and release toxins that damage the cilia, causing inflammation and swelling. The incidence of pertussis has been steadily increasing in the United States since the 1980s. The largest increase is seen in adults. We think that immunity from childhood tetanus, diphtheria, and pertussis vaccine (Tdap) vaccination may decrease over time, allowing a milder (but still contagious) infection. The Centers for Disease Control and Prevention (CDC) currently recommends that all adolescents (11 years and older) and adults who have not received a dose of Tdap receive a one-time vaccination as soon as possible.[3]

Manifestations of pertussis occur in stages. The first stage, lasting 1 to 2 weeks, manifests as a mild upper respiratory tract infection (URI) with a low-grade or no fever, runny nose, watery eyes, generalized malaise, and mild, nonproductive cough. The second stage, from the second to tenth week of infection, is characterized by paroxysms of cough. The last stage lasts 2 to 3 weeks. It is characterized by a less severe cough and weakness.

Promoting Population Health

Preventing Respiratory Diseases

- Wash hands often to prevent and avoid spreading infections.
- Avoid cigarette smoking and exposure to environmental smoke.
- Get a pneumococcal vaccine and yearly flu vaccine as directed by the HCP.
- Avoid exposure to allergens, indoor pollutants, and ambient air pollutants.

- Wear proper personal protective equipment when working in an occupation with prolonged exposure to dust, fumes, or gases.

The hallmark characteristic of pertussis is uncontrollable, violent coughing. Inspiration after each cough produces the typical "whooping" sound as the patient tries to breathe in air against an obstructed glottis. The "whoop" is often not present in teens and adults (especially those who have been vaccinated). Like acute bronchitis, the coughing is more frequent at night. Vomiting may occur with coughing. Unlike acute bronchitis, the cough with pertussis may last from 6 to 10 weeks.

In the community, diagnosis is primarily by history and examination. In the clinical setting, the CDC recommends nasopharyngeal cultures, polymerase chain reaction (PCR) of nasopharyngeal secretions, or serology testing.[4] The treatment is macrolide (erythromycin, azithromycin [Zithromax]) antibiotics to minimize symptoms and prevent spread of the disease. For the patient who cannot take macrolides, trimethoprim/sulfamethoxazole is used. The patient is infectious from the beginning of the first stage through the third week after onset of symptoms or until 5 days after antibiotic therapy has been started. Routine and droplet precautions are required for hospitalized patients. Patients should not use cough suppressants and antihistamines as they are ineffective and may induce coughing episodes. Corticosteroids and bronchodilators are also not helpful. The CDC recommends postexposure antibiotics to those who have had close contact with the patient.

Pneumonia

Pneumonia is an acute infection of the lung parenchyma. Despite remarkable progress in the development of antibiotics to treat pneumonia, pneumonia is still associated with significant morbidity and mortality. The CDC reports that pneumonia and influenza are the 8th leading cause of death in the United States.[5]

Etiology

Normally, various defense mechanisms protect the airway distal to the larynx from infection. Mechanisms that create a mechanical barrier to microorganisms entering the tracheobronchial tree include air filtration, epiglottis closure over the trachea, cough reflex, mucociliary escalator mechanism, and reflex bronchoconstriction (see Chapter 25). Immune defense mechanisms include secretion of immunoglobulins A and G and alveolar macrophages.

Pneumonia is more likely to occur when defense mechanisms become incompetent or are overwhelmed by the virulence or quantity of infectious agents. A weakened cough or epiglottal reflex may allow aspiration of oropharyngeal contents into the lungs. Tracheal intubation bypasses normal filtration processes and interferes with the cough reflex and mucociliary escalator mechanism. Air pollution, cigarette smoking, viral URIs, and normal changes that occur with aging can impair the mucociliary mechanism. Chronic diseases can suppress the immune system's ability to inhibit bacterial growth. The risk factors for pneumonia are listed in Table 27.1.

Pathogens that cause pneumonia reach the lung in 3 ways:

1. *Aspiration* of normal flora from the nasopharynx or oropharynx. Many organisms that cause pneumonia are normal inhabitants of the pharynx in healthy adults.
2. *Inhalation* of microbes present in the air. Examples include *Mycoplasma pneumoniae* and fungal pneumonias.

3. *Hematogenous spread* from a primary infection elsewhere in the body. Examples are streptococci and *Staphylococcus aureus* from infective endocarditis.

TABLE 27.1 Risk Factors for Pneumonia

- Abdominal or chest surgery
- Age >65 years
- Air pollution
- Altered consciousness: alcoholism, head injury, seizures, anesthesia, drug overdose, stroke
- Bed rest and prolonged immobility
- Chronic diseases: chronic lung and liver disease, diabetes, heart disease, cancer, chronic kidney disease
- Debilitating illness
- Exposure to bats, birds, rabbits, and farm animal droppings (excrement)
- Immunosuppressive disease and/or therapy (corticosteroids, cancer chemotherapy, HIV infection, immunosuppressive therapy after organ transplant)
- Inhalation or aspiration of noxious substances
- Intestinal and gastric feedings via nasogastric or nasointestinal tubes
- IV drug use
- Malnutrition
- Recent antibiotic therapy
- Resident of a long-term care facility
- Smoking
- Tracheal intubation (endotracheal intubation, tracheostomy)
- URI

Classifications of Pneumonia

There is no universally accepted classification system for pneumonia. Some suggest classifying pneumonia according to the causative pathogens (e.g., bacterial, viral, fungal, etc.), characteristics of the disease, or radiographic appearance on chest x-ray. The most widely recognized and effective way to classify pneumonia is as either *community-acquired* or *hospital-acquired* pneumonia. This classification helps the HCP identify the most likely cause (Table 27.2) and the choice of antimicrobial therapy.

Community-Acquired Pneumonia

Community-acquired pneumonia (CAP) is an acute infection of the lung occurring in patients who have not been hospitalized or lived in a long-term care facility within 14 days of the onset of symptoms. The decision to treat the patient at home or admit to hospital is based on several factors. These include the patient's age, vital signs, mental status, presence of co-morbid conditions, and current physiologic condition. We can use tools such as the expanded CURB-65 scale (Table 27.3) to supplement clinical judgment.

Hospital-Acquired Pneumonia

Hospital-acquired pneumonia (HAP), also known as *nosocomial pneumonia,* is pneumonia in a nonintubated patient that begins 48 hours or longer after admission to hospital and was not present at the time of admission. *Ventilator-associated pneumonia (VAP),* a type of HAP, refers to pneumonia that occurs more than 48 hours after endotracheal intubation.[6] VAP is discussed in Chapter 65. Both HAP and VAP are associated with longer hospital stays, increased associated costs, sicker patients, and increased risk for morbidity and mortality.

Once the diagnosis of CAP, HAP, or VAP is made, treatment is started based on known risk factors, early versus late onset, presentation, underlying medical conditions, hemodynamic stability, and the likely causative pathogen. *Empiric antibiotic therapy,* the

initiation of treatment before a definitive diagnosis or causative agent is confirmed, should be started as soon as pneumonia is suspected. Empiric antibiotic therapy is based on the knowledge of drugs known to be effective for the likely cause. Antibiotic therapy can be adjusted once the results of sputum cultures identify the exact pathogen.

TABLE 27.2 Organisms Causing Pneumonia

Community-Acquired Pneumonia

- *Chlamydophila pneumoniae*
- *Chlamydophila psittaci*
- *Coxiella burnettii*
- Gram-negative bacilli
- Fungi
- Influenzae
- Influenza A and B
- *Klebsiella pneumoniae*
- *Legionella pneumophila**
- MRSA*
- *Moraxella catarrhalis*
- *Mycobacterium tuberculosis*
- *Mycoplasma pneumoniae*
- Oral anaerobes (e.g., alcoholism, IV drug use)
- *Pseudomonas aeruginosa*
- Respiratory viruses
- *S. pneumoniae**

Hospital-Acquired Pneumonia

- *Acinetobacter* species†
- *Enterobacter* species
- *Escherichia coli*†
- *H. influenzae*
- *Klebsiella pneumoniae*†
- *Proteus* species
- *Pseudomonas aeruginosa*†
- *S. aureus*
- *S. pneumoniae*

---

* Most common cause of community-acquired pneumonia (CAP).
† Most common causes of hospital-acquired pneumonia (HAP).

TABLE 27.3 Assessing Pneumonia Severity Using Expanded CURB-65

The **Expanded CURB-65 scale** may be used as a supplement to clinical judgment to determine the severity of pneumonia and if patients need to be hospitalized.

Identifying the Level of Risk

Patients receive 1 point for each of the following indicators:

- **C:** Confusion (compared to baseline)
- **U:** BUN >20 mg/dL
- **R:** Respiratory rate ≥30 breaths/min
- **B:** Systolic blood pressure <90 mm Hg or diastolic blood pressure ≤60 mm Hg
- **65:** ≥Age 65 yr

- **LDH:** >230 μ/L
- **Albumin:** <3.5 g/dL
- **Platelet count:** <100 × 10^9/L

Scoring and Decision Making

Score	Perceived Risk	Location
0–2	Low	Outpatient
3–4	Intermediate	In patient
5–8	High	ICU

Source: Liu J, Xu F, Zhou H, et al: Expanded CURB-65: A new score system predicts severity of community-acquired pneumonia with superior efficiency, *Sci Rep* 6:22911, 2016.

Types of Pneumonia

There are several types of pneumonia. *Viral pneumonia* is the most common type of pneumonia. It occurs in one third of all pneumonia cases. It may be mild and self-limiting or cause potentially life-threatening problems, such as acute respiratory failure in influenza. Patients with *bacterial pneumonia* may be extremely unwell and need hospital admission. *Mycoplasma pneumonia*, which has traits of both bacteria and viruses, is often referred to as "atypical" pneumonia. It is mild and occurs in persons younger than 40 years of age. Aspiration, necrotizing, and opportunistic pneumonia deserve further attention.

Aspiration Pneumonia

Aspiration pneumonia results from the abnormal entry of material from the mouth or stomach into the trachea and lungs. Conditions that increase the risk for aspiration include decreased level of consciousness (e.g., seizure, anesthesia, head injury, stroke, alcohol intake), difficulty swallowing, and insertion of nasogastric (NG) tubes with or without enteral feeding. With loss of consciousness, the gag

and cough reflexes are depressed and aspiration is more likely to occur.

The aspirated material (food, water, vomitus, oropharyngeal secretions) triggers an inflammatory response. The most common form of aspiration pneumonia is a primary bacterial infection. Typically, the sputum culture shows more than 1 organism, including aerobes and anaerobes, since they both make up the flora of the oropharynx.

Until cultures are done and results obtained, initial antibiotic therapy is based on an assessment of probable cause, severity of illness, and patient factors (e.g., malnutrition, current use of antibiotic therapy). For patients who aspirate in hospitals, antibiotic coverage should include both gram-negative organisms and methicillin-resistant *Staphylococcus aureus* (MRSA). Aspiration of acidic gastric contents causes *chemical (noninfectious) pneumonitis,* which may not need antibiotic therapy. However, secondary bacterial infection can occur 48 to 72 hours later.

Necrotizing Pneumonia

Necrotizing pneumonia is a rare complication of bacterial lung infection. It causes the lung tissue to turn into a thick, liquid mass. In some situations, cavitation occurs. This often happens with CAP. Although we do not know the exact pathophysiologic mechanisms involved, causative organisms include *Staphylococcus, Klebsiella,* and *Streptococcus.* Lung abscesses often occur. Signs and symptoms include immediate respiratory insufficiency and/or failure, leukopenia, and bleeding into the airways.[7] Treatment includes long-term antibiotic therapy and possible surgery.

Opportunistic Pneumonia

Opportunistic pneumonia is inflammation and infection of the lower respiratory tract in immunocompromised patients. Persons at risk include those with altered immune responses. This can include people with severe protein-calorie malnutrition or immunodeficiencies (e.g., human immunodeficiency virus [HIV] infection) and those receiving

radiation therapy, chemotherapy, and any immunosuppressive therapy, including long-term corticosteroid therapy. In addition to the risk for bacterial and viral pneumonia, the immunocompromised person may develop an infection from organisms that do not normally cause disease, such as *Pneumocystis jiroveci* (formerly *carinii*) or cytomegalovirus (CMV).

P. jiroveci pneumonia (PJP) rarely occurs in the healthy person. It is the most common form of pneumonia in people with HIV disease. The onset is slow and subtle with symptoms of fever, tachypnea, tachycardia, dyspnea, nonproductive cough, and hypoxemia. The chest x-ray usually shows diffuse bilateral infiltrates. In widespread disease, the lungs have massive consolidation. PJP can be life-threatening, causing acute respiratory failure and death. Infection can spread to other organs, including the liver, bone marrow, lymph nodes, spleen, and thyroid. Bacterial and viral pneumonias first must be ruled out because of the vague presentation of PJP. Although the causative agent is fungal, PJP does not respond to antifungal agents. Treatment consists of a course of trimethoprim/sulfamethoxazole (Bactrim, Septra) either IV or orally depending on the severity of disease and the patient's response.

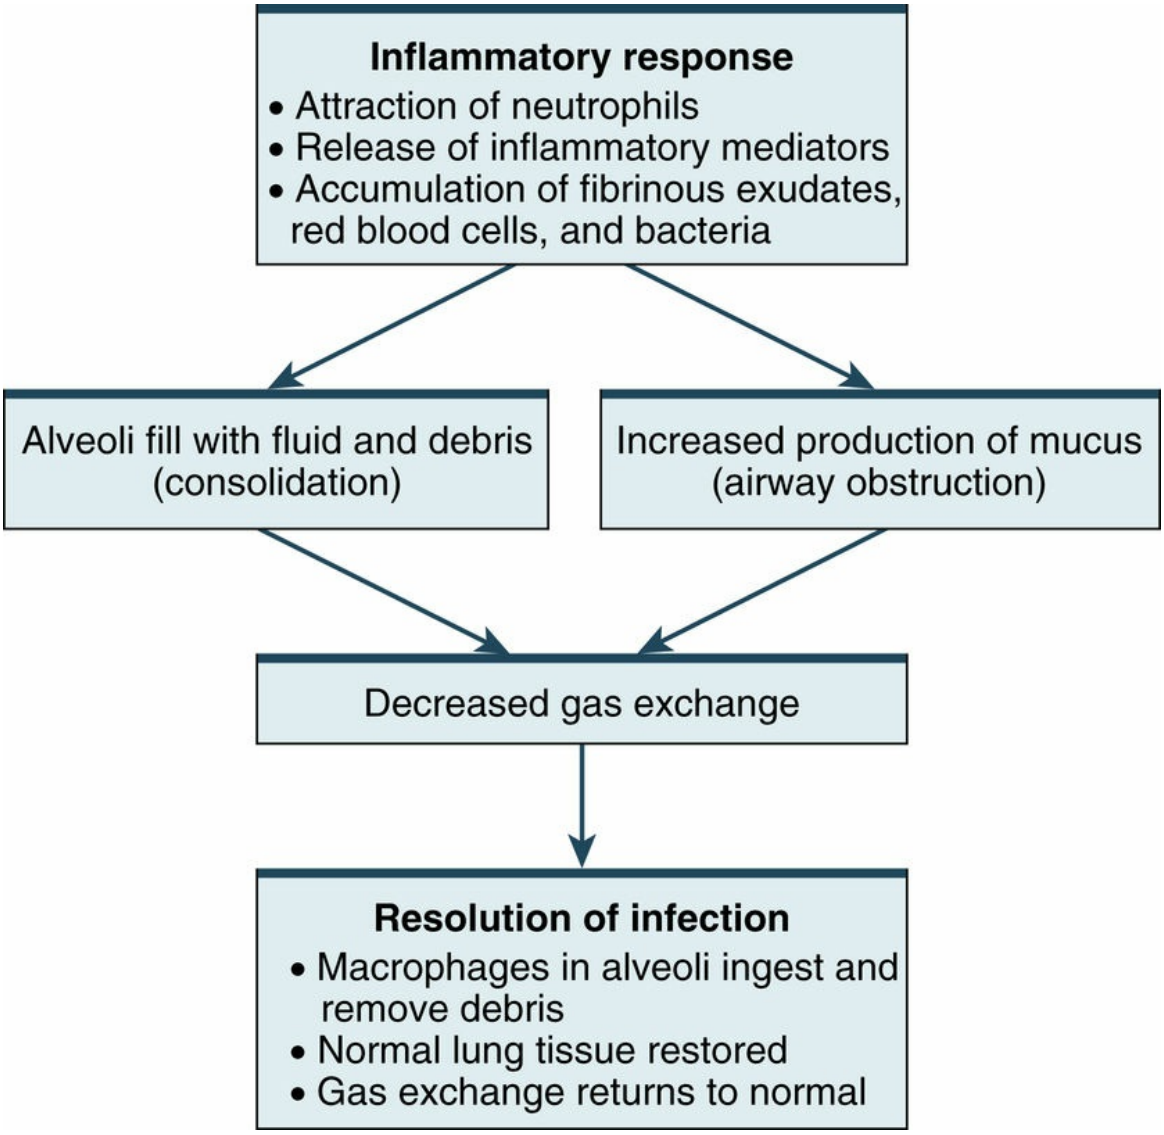

FIG. 27.1 Pathophysiologic course of pneumonia.

CMV, a herpesvirus, can cause viral pneumonia. Most CMV infections are asymptomatic or mild. Severe disease can occur in people with an impaired immune response. CMV is one of the most important life-threatening infectious complications after hematopoietic stem cell transplantation.[8] Antiviral medications (e.g., ganciclovir [Cytovene], foscarnet [Foscavir], cidofovir) and high-dose immunoglobulin are used for treatment.

Pathophysiology

Specific pathophysiologic changes related to pneumonia vary according to the offending pathogen. Almost all pathogens trigger an inflammatory response in the lungs (Fig. 27.1). Inflammation, characterized by an increase in blood flow and vascular permeability, activates neutrophils to engulf and kill the offending pathogens. As a result, the inflammatory process attracts more neutrophils, edema of the airways occurs, and fluid leaks from the capillaries and tissues into alveoli. Normal O_2 transport is affected, leading to manifestations of hypoxia (e.g., tachypnea, dyspnea, tachycardia).

Atelectasis, the absence of gas or air in 1 or more areas of the lung, may occur with pneumonia. It rarely causes any adverse effects except shortness of breath (Fig. 27.2). On the other hand, c*onsolidation,* a feature typical of bacterial pneumonia, occurs when the normally air-filled alveoli become filled with water, fluid, and/or debris (Fig. 27.3). This can potentially obstruct airflow, impair gas exchange, and cause the signs and symptoms associated with bacterial infection. Over time and with appropriate antibiotic therapy, macrophages lyse and process the debris. This allows lung tissue to recover and gas exchange to return to normal.

Clinical Manifestations

The most common presenting symptoms of pneumonia are cough, fever, chills, dyspnea, tachypnea, and pleuritic chest pain. The cough may or may not be productive. Sputum may be green, yellow, or even rust colored (bloody). Viral pneumonia may initially be seen as influenza, with respiratory symptoms appearing and/or worsening 12 to 36 hours after onset.

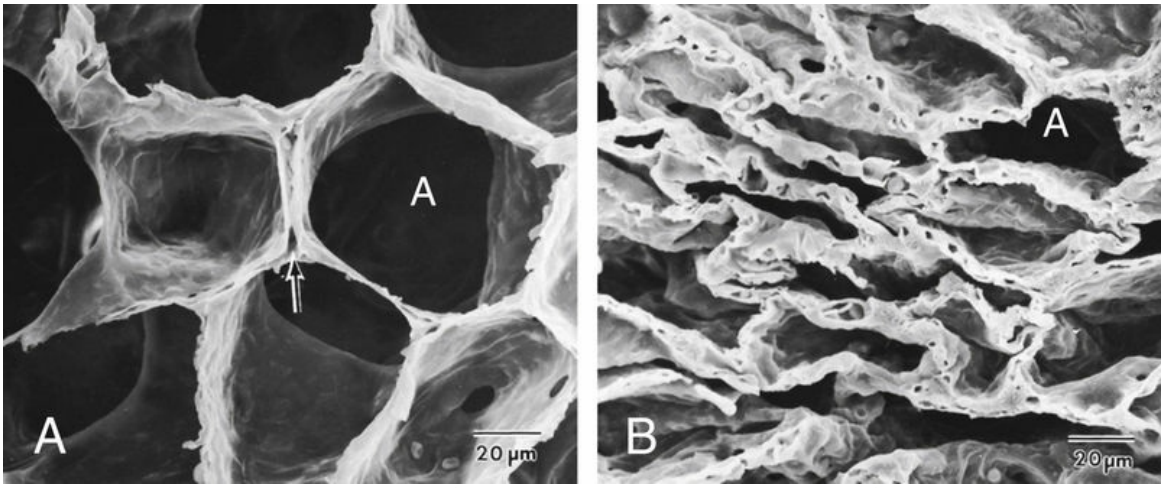

FIG. 27.2 Atelectasis. Scanning electron micrograph of lung parenchyma. **A,** Alveoli *(A)* and alveolar-capillary membrane *(arrow).* **B,** Effects of atelectasis. Alveoli *(A)* are partially or totally collapsed.

In RJ Mason, VC Broaddus, JF Murray, et al, eds: *Murray and Nadel's textbook of respiratory medicine,* ed 4, Philadelphia, 2005, Saunders.

FIG. 27.3 Chest x-ray examination of patient with acute bacterial pneumonia.
© *iStock*.com/stockdevil.

The older or debilitated patient may not have classic symptoms of pneumonia. Confusion or stupor (possibly related to hypoxia) may be the only finding. Hypothermia, rather than fever, also may be seen in the older adult. Nonspecific manifestations include diaphoresis,

anorexia, fatigue, myalgias, and headache.

On assessment, fine or coarse crackles may be auscultated over the affected region. If consolidation is present, bronchial breath sounds, egophony (an increase in the sound of the patient's voice), and increased fremitus (vibration of the chest wall made by vocalization) may be present. Patients with pleural effusion may have dullness to percussion over the affected area.

Complications

A major problem today is pneumonia caused by multidrug-resistant (MDR) pathogens. Common culprits include MRSA and gram-negative bacilli. Risk factors for MDR pneumonia include advanced age, immunosuppression, history of antibiotic use, and prolonged mechanical ventilation. Antibiotic susceptibility tests can identify MDR pathogens. The virulence of these pathogens can severely limit the available and appropriate antimicrobial therapy. MDR pathogens increase the morbidity and mortality associated with pneumonia. (See Chapter 14 for more about MDR pathogens.)

Other complications from pneumonia develop more often in older adults and those with underlying chronic diseases. These include:

- *Atelectasis*
- *Pleurisy,* an inflammation of the pleura.
- *Pleural effusion,* or fluid in the pleural space. In most cases, the effusion is sterile and is reabsorbed in 1 to 2 weeks. Sometimes, effusions require aspiration by thoracentesis.
- *Bacteremia*, bacterial infection in the blood, is more likely to occur in infections with *Streptococcus pneumoniae* and *Haemophilus influenzae.*
- *Pneumothorax* can occur when air collects in the pleural space, causing the lungs to collapse.
- *Acute respiratory failure* is one of the leading causes of death in patients with severe pneumonia. Failure occurs when pneumonia damages the lungs' ability to exchange O_2 and

CO_2 across the alveolar-capillary membrane.

- *Sepsis/septic shock* can occur when bacteria within alveoli enter the bloodstream. Severe sepsis can lead to shock and multisystem organ dysfunction syndrome (MODS) (see Chapter 66).

Lung abscess is not a common complication of pneumonia. However, it may occur with pneumonia caused by *S. aureus* and gram-negative organisms. *Empyema,* the accumulation of purulent exudate in the pleural cavity, occurs in less than 5% of cases. It requires antibiotic therapy and drainage of the exudate by a chest tube or open surgical drainage.[9] Pleurisy, pleural effusion, atelectasis, lung abscess, and pneumothorax are discussed later in this chapter.

Diagnostic Studies

The common diagnostic procedures for pneumonia are outlined in Table 27.4. History, physical examination, and chest x-ray often give enough information to make immediate decisions about early treatment. Chest x-ray often shows patterns characteristic of the infecting pathogen and is important in diagnosing pneumonia. X-ray may also show pleural effusions. A thoracentesis and/or bronchoscopy with washings may be used to obtain fluid samples from patients not responding to initial therapy.

Arterial blood gases (ABGs) may be obtained to assess for hypoxemia (partial pressure of O_2 in arterial blood [PaO_2] less than 80 mm Hg), hypercapnia (partial pressure of carbon dioxide in arterial blood [$PaCO_2$] greater than 45 mm Hg), and acidosis (pH less than 7.35). Leukocytosis occurs in most patients with bacterial pneumonia. The white blood cell (WBC) count is usually greater than 15,000/μL (15×10^9/L) with the presence of bands (immature neutrophils).

Ideally, a sputum specimen for culture and Gram stain to identify the organism is obtained before beginning antibiotic therapy. However, antibiotic administration should not be delayed if a specimen cannot be obtained. Delays in antibiotic therapy can increase

the risk for morbidity and mortality. Blood cultures are done for patients who are seriously ill.

TABLE 27.4 Interprofessional CarePneumonia

Diagnostic Assessment

- History and physical examination
- Chest x-ray
- Sputum: Gram stain, culture and sensitivity test
- Pulse oximetry or arterial blood gases (if indicated)
- CBC, white blood cell differential, and routine blood chemistries (if indicated)
- Blood cultures (if indicated)

Management

- Increased fluid intake (at least 3 L/day), IV fluids
- Balance between activity and rest
- O_2 therapy
- Physiotherapy
- VTE prophylaxis
- Critical care management, with mechanical ventilation as needed

Drug Therapy

- Appropriate antibiotic therapy (Table 27.6)
- Antipyretics
- Analgesics
- Nonsteroidal antiinflammatory drugs (if no contraindications)

Serum levels of C-reactive protein (CRP), kallistatin, and procalcitonin are currently being explored as sources of information to help distinguish pneumonia from other types of heart and respiratory failure.[10]

Interprofessional Care

Pneumococcal vaccine is used to prevent *S. pneumoniae* infection (Table 27.5). Prompt treatment with the appropriate antibiotic is essential. Antibiotics are highly effective for both bacterial and mycoplasma pneumonia. In uncomplicated cases, the patient responds to drug therapy within 48 to 72 hours. Signs of improvement include decreased temperature, improved breathing, and reduced chest discomfort. Abnormal physical findings can last more than 7 days. A repeat chest x-ray may be done in 6 to 8 weeks to assess for resolution.

Supportive measures are tailored to the patient's needs. These may include O_2 therapy to treat hypoxemia, analgesics to relieve chest pain, and antipyretics (e.g., aspirin, acetaminophen) for fever. Although cough suppressants, mucolytics, bronchodilators, and corticosteroids are often prescribed as adjunctive therapy, the use of these drugs is debatable. However, they may be prescribed for patients with underlying chronic conditions.

Tailor rest and activity to each patient's tolerance. Benefits of mobility include improved diaphragm movement and chest expansion, mobilization of secretions, and prevention of venous stasis.

Currently, no definitive treatment exists for most viral pneumonias. Care is generally supportive. In most circumstances, viral pneumonia is self-limiting and will often resolve in 3 to 4 days. Antiviral therapy may be used to treat pneumonia caused by influenza (e.g., oseltamivir, zanamivir) or a few other viruses (e.g., acyclovir [Zovirax] for herpes simplex virus).[11]

Drug Therapy

Once the pneumonia is classified, the HCP selects empiric therapy

based on the likely pathogen (Table 27.2). Table 27.6 presents the drug therapy for bacterial CAP.

For all types of pneumonia, empiric antibiotic therapy is based on whether the patient has risk factors for MDR pathogens. The prevalence and resistance patterns of MDR pathogens vary among localities and agencies. Therefore the antibiotic regimen must be adapted to local patterns of antibiotic resistance. Multiple regimens exist, but all should initially include antibiotics that are effective against both resistant gram-negative and resistant gram-positive organisms.

TABLE 27.5 Pneumococcal Vaccines

Vaccine*	Recommendations for Use
Pneumococcal conjugate vaccine (PCV13, Prevnar 13)†	• All children <2 yrs • All adults ≥65 yrs • Anyone 2–64 yrs old with certain medical conditions (e.g., sickle cell disease, asplenia, immunodeficiencies, HIV infection, chronic renal failure, leukemia, cancer, long-term immunosuppressive therapy, CSF leaks, cochlear implant[s])
Pneumococcal polysaccharide vaccine (PPSV23, Pneumovax 23)†	• All adults ≥65 yrs • Anyone 2–64 yrs old with certain long-term health problems (e.g., heart disease, lung disease, diabetes, alcoholism, cirrhosis, sickle cell disease, CSF leaks, cochlear implant) • Anyone 2–64 yrs with a disease or condition that weakens the immune system or taking drugs that lower the body's resistance to infection (e.g., HIV infection; lymphoma or leukemia; kidney failure; damaged or no spleen; multiple myeloma; receiving immunosuppressive chemotherapy, radiation therapy, or long-term corticosteroids; after organ or bone marrow transplantation) • Adults 19–64 yrs who smoke cigarettes or have asthma

* For more details on scheduling of pneumococcal vaccinations, see *www.cdc.gov/vaccines/vpd/pneumo/hcp/recommendations.html* .

† As their names imply, PCV13 and Prevnar 13 protect against 13 types of pneumococcal bacteria, and PPSV23 and Pneumovax 23 protect against 23 types of pneumococcal bacteria. The vaccinations have different mechanisms of action.

Clinical improvement usually occurs in 3 to 5 days. Patients who deteriorate or do not respond to therapy need aggressive reevaluation to assess for noninfectious causes, complications, coexisting infectious processes, or pneumonia caused by an MDR pathogen.

IV antibiotic therapy should be switched to oral therapy as soon as the patient is hemodynamically stable, is improving clinically, is able to ingest oral medication, and has a functioning gastrointestinal (GI)

tract. Stable patients do not need to be observed in the hospital and can be discharged to home on oral antibiotics. Total treatment time for patients with CAP should be a minimum of 5 days. The patient should be afebrile for 48 to 72 hours before stopping treatment. However, you need to emphasize the importance of completing the full course of antibiotic treatment. Longer treatment time may be needed if initial therapy was not active against the identified pathogen or complications occur.

Nutritional Therapy

Hydration is important in the supportive treatment of pneumonia to prevent dehydration and to thin and loosen secretions. Carefully monitor fluid intake. If the patient is an older adult, has heart failure (HF), or has a known preexisting respiratory condition, IV administration of fluids and electrolytes may be needed.

Weight loss may occur in patients with pneumonia because of increased metabolic needs and difficulty eating due to shortness of breath or nonspecific abdominal symptoms. Small, frequent meals are easier for dyspneic patients to tolerate. Offer foods high in calories and nutrients.

TABLE 27.6 Drug TherapyBacterial Community-Acquired Pneumonia

Patient Variable	Treatment Options
Outpatient	
Previously healthy **No recent antibiotic therapy in past 3 months and no risk for drug-resistant *Staphylococcus pneumoniae* (DRSP)**	Macrolide *OR* doxycycline
Co-morbidities (e.g., COPD; diabetes; chronic heart, liver, lung, or renal disease; cancer; use of antibiotics in past 3 months)	Respiratory fluoroquinolone *OR* β-Lactam plus macrolide (doxycycline may be substituted for macrolide)
Regions with ≥25% macrolide-resistant *S. pneumoniae*	Respiratory fluoroquinolone *OR* β-Lactam plus macrolide
Inpatient	
Medical unit	Respiratory fluoroquinolone *OR* β-Lactam plus macrolide
ICU **Acute respiratory failure, septic shock, intubation and mechanical ventilation**	β-Lactam plus either azithromycin or respiratory fluoroquinolone
Special Considerations	
• **Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA)**	Add vancomycin or linezolid (Zyvox)
• ***Pseudomonas* infection**	Antipneumococcal, antipseudomonal β-lactam plus either ciprofloxacin or levofloxacin *OR* Antipneumococcal, antipseudomonal β-lactam plus aminoglycoside and azithromycin *OR* Antipneumococcal, antipseudomonal β-lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone
• ***Pseudomonas* infection in patient with penicillin allergy**	Substitute aztreonam for the above β-lactam
Types of Antibiotics	
Antipneumococcal, antipseudomonal β-lactams	imipenem/cilastatin, meropenem (Merrem), cefepime (Maxipime), piperacillin/tazobactam (Zosyn)
β-Lactams	High-dose amoxicillin, amoxicillin/clavulanate (Augmentin), cefpodoxime, ceftriaxone, cefuroxime (Ceftin)
Fluoroquinolones	moxifloxacin (Avelox, Vigamox), levofloxacin, gemifloxacin (Factive)
Macrolides	erythromycin, azithromycin (Zithromax), clarithromycin (Biaxin)

Nursing Management: Pneumonia

Nursing Assessment

Table 27.7 presents subjective and objective data to obtain from a patient with pneumonia.

Nursing Diagnoses

Nursing diagnoses for the patient with pneumonia may include:

- Impaired gas exchange
- Impaired breathing
- Fluid imbalance
- Hyperthermia
- Activity intolerance

Additional information on nursing diagnoses and interventions for the patient with pneumonia is presented in eNursing Care Plan 27.1 on the website for this chapter.

TABLE 27.7 Nursing AssessmentPneumonia

Subjective Data Important Health Information
Past health history: Lung cancer, COPD, diabetes, chronic debilitating disease, malnutrition, altered consciousness, immunosuppression, exposure to chemical toxins, dust, or allergens *Medications:* Antibiotics, corticosteroids, chemotherapy, or any immunosuppressants

Surgery or other treatments: Recent abdominal or chest surgery, splenectomy, endotracheal intubation, or any surgery with general anesthesia. Enteral feedings

Functional Health Patterns

Health perception–health management: Cigarette smoking, alcohol use; recent URI, malaise
Nutritional-metabolic: Anorexia, nausea, vomiting. Chills
Activity-exercise: Prolonged bed rest or immobility. Fatigue, weakness. Dyspnea, cough (productive or nonproductive). Nasal congestion
Cognitive-perceptual: Pain with breathing, chest pain, sore throat, headache, abdominal pain, muscle aches

Objective Data
General

Fever, restlessness, or lethargy. Splinting of affected area

Respiratory

Tachypnea, pharyngitis, asymmetric chest movements or retraction, decreased excursion, nasal flaring. Use of accessory muscles (neck, abdomen). Crackles, friction rub on auscultation, dullness on percussion over consolidated areas, increased tactile fremitus on palpation. Pink, rusty, purulent, green, yellow, or white sputum (amount may be scant to copious)

Cardiovascular

Tachycardia

Neurologic

Changes in mental status, ranging from confusion to delirium

Possible Diagnostic Findings

Leukocytosis. Abnormal ABGs with ↓ or normal PaO_2, ↓ or normal $PaCO_2$, and ↑ or normal pH initially, and later ↓ PaO_2, ↑ $PaCO_2$, and ↓ pH. Positive sputum on Gram stain and culture. Patchy or diffuse infiltrates, abscesses, pleural effusion, or pneumothorax on chest x-ray

Planning

The overall goals are that the patient with pneumonia will have (1) clear breath sounds, (2) normal breathing patterns, (3) no signs of hypoxia, (4) normal chest x-ray, (5) normal WBC count, and (6) absence of complications related to pneumonia.

Nursing Implementation

Health Promotion

To reduce the risk for pneumonia, teach patients to practice good health habits, such as frequent hand washing, proper nutrition, adequate rest, regular exercise, and coughing or sneezing into the elbow rather than hands. Avoiding cigarette smoke is one of the most important health-promoting behaviors. If possible, avoid exposure to people with URIs. If a URI occurs, it requires prompt attention with supportive measures (e.g., rest, fluids). If symptoms persist for longer than 7 days, the person should seek medical care. Identifying patients at risk (Table 27.1) and taking measures to prevent pneumonia are priority interventions. Encourage those at risk for pneumonia (e.g., chronically ill, older adult) to obtain both influenza and pneumococcal vaccines (Table 27.5).

Acute Care

Although many patients with pneumonia are treated on an outpatient basis, the nursing care plan for a patient with pneumonia (eNursing Care Plan 27.1) applies to both patients at home and hospitalized patients. Essential nursing care for patients with pneumonia includes monitoring physical assessment parameters, providing treatment, and monitoring the patient's response to treatment. Prompt collection of specimens and initiation of antibiotics are critical. O_2 therapy, hydration, nutritional support, breathing exercises, early ambulation, and therapeutic positioning are part of nursing care. Working with respiratory therapy to monitor the patient's condition and with physical therapy for postural drainage and chest percussion is essential.

Place the patient with altered consciousness in positions (e.g., side-lying, upright) that will prevent or minimize the risk for aspiration. Turn and reposition patients at least every 2 hours to promote adequate lung expansion and mobilization of secretions. Encourage and assist with ambulation and positioning into a chair. In the ICU, strict adherence to all aspects of the ventilator bundle (see Table 67.8), a group of interventions aimed at reducing the risk for VAP, significantly reduces VAP.

For the patient who has difficulty swallowing and needs aid in eating, drinking, and taking medication to prevent aspiration, elevate the patient's head-of-bed to at least 30 degrees and have the patient sit up for all meals. Assess for a gag reflex before giving food or fluids. Patients who have orogastric or NG tubes are at risk for aspiration pneumonia (see Chapter 39). Although feeding tubes are small, any interruption in the integrity of the lower esophageal sphincter can allow reflux of gastric contents. To prevent aspiration, elevate the head of the bed to at least 30 degrees (see Table 39.11).

Patients with impaired mobility from any cause need help with turning and moving as well as encouragement to breathe deeply at frequent intervals. Observe the patient's skin and all pressure points for any evidence of redness or breakdown, especially the sacrum and coccyx. Treat pain to a comfort level that permits the patient to deep

breathe and cough yet remain awake and alert and achieve optimum mobility. Early mobilization, the use of an incentive spirometer, and twice-daily oral hygiene with chlorhexidine swabs significantly reduce the incidence of pneumonia in postoperative patients.[12]

Practice strict medical asepsis and adherence to infection control guidelines to reduce the incidence of health care–associated infection (HAI). Staff and visitors should wash their hands on entering and leaving the patient's room. Staff must wash or use sanitizing hand gel before and after providing care and on removing gloves. Use strict sterile aseptic technique when suctioning the patient's trachea, and use caution when handling ventilator circuits, tracheostomy tubing, and nebulizer circuits that can become contaminated from patient secretions. Avoid inappropriate use of antibiotics to prevent the development of MDR organisms.

Ambulatory Care

Teach the patient about the importance of taking every dose of the prescribed antibiotic, any drug-drug and food-drug interactions for the prescribed antibiotic, and the need for adequate rest to promote recovery. Tell the patient to drink plenty of liquids (at least 6 to 10 glasses/day, unless contraindicated) and to avoid alcohol and smoking. A cool mist humidifier or warm bath may help the patient breathe easier. Tell patients that it may be several weeks before their usual vigor and sense of well-being return. Explain that a follow-up chest x-ray may be done in 6 to 8 weeks to evaluate resolution of pneumonia. The older adult or chronically ill patient may have a prolonged period of convalescence.

Teaching should include information about available influenza and pneumococcal vaccines. Patients can receive the pneumococcal vaccine and influenza vaccine at the same time but not in the exact same location. The vaccines cannot be mixed into 1 injection.

Evaluation

The expected outcomes are that the patient with pneumonia will have:

- Effective respiratory rate, rhythm, and depth of respirations
- Lungs clear to auscultation
- Absence of infection

Tuberculosis

Tuberculosis (TB) is an infectious disease caused by *Mycobacterium tuberculosis*. It usually involves the lungs, but can infect any organ, including the brain, kidneys, and bones. About one third of the world's population are infected with TB.[13] The incidence of TB worldwide declined until the mid-1980s. We are now seeing increasing rates of TB. This is attributed to HIV disease and the emergence of drug-resistant strains of *M. tuberculosis.* TB is the leading cause of mortality in patients with HIV infection. Though the prevalence of TB in the United States has steadily declined, we do not think it is currently possible to eradicate TB in the United States.[14]

TB occurs disproportionately in the poor, underserved, and minorities. People most at risk include the homeless, residents of inner-city neighborhoods, foreign-born people, those living or working in institutions (long-term care facilities, prisons, shelters, hospitals), IV injecting drug users, overcrowded living conditions, less than optimal sanitation, and those with poor access to health care. Immunosuppression from any cause (e.g., HIV infection, cancer, long-term corticosteroid use) increases the risk for active TB infection.

Once a strain of *M. tuberculosis* develops resistance to the most potent first-line antitubercular drugs (isoniazid [INH] and rifampin [Rifadin]), it is defined as *multidrug-resistant tuberculosis (MDR-TB).*[15] Extensively drug-resistant TB (XDR-TB)

Promoting Health Equity

Tuberculosis

- Of the reported TB cases in the United States, most occur in racial and ethnic minorities.
- Asians have the highest TB rate of any ethnic group in the United

States. Hispanics and blacks have the second and third highest TB rates.

- Of all the TB cases in the United States, 66% occur in foreign-born people. This rate is 13 times higher than in U.S.-born people.
- The percent of foreign-born people with MDR-TB increased from 31% in 1993 to 90% in 2013.

Source: Centers for Disease Control and Prevention: Health disparities in TB. Retrieved from www.cdc.gov/tb/topic/populations/healthdisparities/default.htm.

occurs when the organism is also resistant to any of the fluoroquinolones plus any injectable antibiotic agent.[16] Resistance results from several problems, including incorrect prescribing, lack of public health case management, patient nonadherence to the prescribed regimen, and lack of funding for education and prevention.

Etiology and Pathophysiology

M. tuberculosis is a gram-positive, aerobic, acid-fast bacillus (AFB). It is usually spread from person to person by airborne droplets expectorated when breathing, talking, singing, sneezing, and coughing. A process of evaporation leaves small droplet nuclei, 1 to 5 μm in size, suspended in the air for minutes to hours. Another person then inhales the bacteria. Humans are the only known reservoir for TB. TB is not highly infectious, as transmission usually requires close contact and frequent or prolonged exposure. The disease cannot be spread by touching, sharing food utensils, kissing, or any other type of physical contact.

Factors that influence transmission include the (1) number of organisms expelled into the air, (2) concentration of organisms (small spaces with limited ventilation would mean higher concentration), (3) length of time of exposure, and (4) immune system of the exposed person. Once inhaled, these small droplets lodge in bronchioles and alveoli. A local inflammatory reaction occurs, and the focus of

infection is established. This is called the *Ghon lesion* or *focus*. It represents a calcified TB granuloma, the hallmark of a primary TB infection.[17] The formation of a granuloma is a defense mechanism aimed at walling off the infection and preventing further spread. Replication of the bacillus is inhibited, and the infection is stopped.

Most immunocompetent adults infected with TB can completely kill the mycobacteria. Some people have the mycobacteria in a nonreplicating dormant state. Of these persons, 5% to 10% develop active TB infection when the bacteria begin to multiply months or years later. While *M. tuberculosis* is aerophilic (O_2 loving) and has an affinity for the lungs, the infection can spread through the lymphatic system and find favorable environments for growth in other organs. These include the cerebral cortex, spine, epiphyses of the bone, liver, kidneys, lymph nodes, and adrenal glands.

Classification

Several systems can be used to classify TB. The American Thoracic Society classifies TB based on development of the disease (Table 27.8). TB also can be classified according to (1) its presentation (primary, latent, or reactivated) and (2) whether it is pulmonary or extrapulmonary.

TABLE 27.8 Classification of Tuberculosis

Class	Exposure or Infection	Description
0	No TB exposure	No TB exposure, not infected (no history of exposure, negative tuberculin skin test)
1	TB exposure, no infection	TB exposure, no evidence of infection (history of exposure, negative tuberculin skin test)
2	Latent TB infection,	TB infection without disease (positive reaction to tuberculin skin test, negative bacteriologic studies, no x-ray findings compatible with TB, no clinical evidence

	no disease	of TB)
3	TB, clinically active	TB infection with clinically active disease (positive bacteriologic studies or both a significant reaction to tuberculin skin test and clinical or x-ray evidence of current disease)
4	TB, but not clinically active	No current disease (history of previous episode of TB or abnormal, stable x-ray findings in a person with a positive reaction to tuberculin skin test. Negative bacteriologic studies if done. No clinical or x-ray evidence of current disease)
5	TB suspect	TB suspect (diagnosis pending). Person should not be in this classification for >3 mo

Source: American Thoracic Society.

Primary TB infection occurs when the bacteria are inhaled and start an inflammatory reaction. Most people mount effective immune responses to encapsulate these organisms for the rest of their lives, preventing the initial infection from progressing to disease. If the initial immune response is not adequate, the body cannot contain the organisms. As a result, the bacteria replicate and *active TB disease* results. When active disease develops within the first 2 years of infection, it is called *primary TB*. People co-infected with HIV are at greatest risk for developing active TB.

Post-primary TB, or *reactivation TB,* is defined as TB disease occurring 2 or more years after the initial infection. If the site of TB is pulmonary or laryngeal, the person is infectious and can transmit the disease to others.

Latent TB infection (LTBI) occurs in a person who does not have active TB disease (Table 27.9). People with LTBI have a positive skin test but are asymptomatic. They cannot transmit the TB bacteria to others but can develop active TB disease at some point. Immunosuppression, diabetes, poor nutrition, aging, pregnancy, stress, and chronic disease can reactivate the disease. Treatment of LTBI (discussed later in this chapter) is as important as primary TB.

Clinical Manifestations

Symptoms of pulmonary TB usually do not develop until 2 to 3 weeks after infection or reactivation. The primary manifestation is an initial

dry cough that often becomes productive with mucoid or mucopurulent sputum. Active TB disease may initially present with constitutional symptoms (e.g., fatigue, malaise, anorexia, unexplained weight loss, low-grade fevers, night sweats). Dyspnea is a late symptom that may signify considerable pulmonary disease or a pleural effusion. Hemoptysis, which occurs in less than 10% of patients with TB, is also a late symptom.

TABLE 27.9 Latent Tuberculosis Infection (LTBI) Compared to Tuberculosis Disease

LTBI	TB Disease
Has no symptoms	Has symptoms that may include: • Bad cough that lasts ≥ 3 wk • Pain in the chest • Coughing up blood or sputum • Weakness or fatigue • Weight loss, no appetite • Chills • Fever • Sweating at night
Does not feel sick	Usually feels sick
Cannot spread TB bacteria to others	May spread TB bacteria to others
Usually has a skin test or blood test result showing TB infection	Usually has a skin test or blood test result showing TB infection
Has a normal chest x-ray and a negative sputum smear	May have an abnormal chest x-ray or positive sputum smear or culture
Needs treatment for latent TB infection to prevent active TB disease	Needs treatment for active TB disease

Source: CDC: Latent TB infection and TB disease. Retrieved from *www.cdc.gov/tb/topic/basics/tbinfectiondisease.htm*.

Sometimes TB has a more acute, sudden presentation. The patient may have a high fever, chills, generalized flu-like symptoms, pleuritic pain, a productive cough, and acute respiratory failure. Auscultation of the lungs may be normal or reveal adventitious sounds, such as crackles.

Immunosuppressed (e.g., HIV-infected) people and older adults are less likely to have fever and other signs of an infection. In patients with HIV, classic manifestations of TB, such as fever, cough, and weight loss, may be wrongly attributed to PJP or other HIV-associated

opportunistic diseases. Respiratory problems in patients with HIV must be carefully investigated to determine the cause. A change in cognitive function may be the only initial presenting sign of TB in an older person.

The manifestations of extrapulmonary TB depend on the organs infected. For example, renal TB can cause dysuria and hematuria. Bone and joint TB may cause severe pain. Headaches, vomiting, and lymphadenopathy may be present with TB meningitis.

Complications

Properly treated, pulmonary TB typically heals without complications, except for scarring and residual cavitation within the lung. Significant pulmonary damage, although rare, can occur in patients who are poorly treated or who do not respond to TB treatment.

Miliary TB is widespread dissemination of the mycobacterium. The bacteria spread through the bloodstream to several distant organs. The infection is characterized by a large amount of TB bacilli and may be fatal if untreated. It can occur with primary disease or reactivation of LTBI. Manifestations slowly progress over a period of days, weeks, or even months. Symptoms vary depending on the organs that are affected. Fever, cough, and lymphadenopathy are present. Hepatomegaly and splenomegaly may occur.

Pleural TB, a specific type of extrapulmonary TB, can result from either primary disease or reactivation of a latent infection. Chest pain, fever, cough, and presence of a unilateral pleural effusion are common. A pleural effusion is caused by bacteria in the pleural space, which trigger an inflammatory reaction and a pleural exudate of protein-rich fluid. Empyema is less common than effusion but may occur from large numbers of tubercular organisms in the pleural space. Diagnosis is confirmed by AFB cultures and a pleural biopsy.

Because TB can infect organs throughout the body, various acute and long-term complications can result. TB in the spine (Pott's disease) can lead to destruction of the intervertebral disc and adjacent vertebrae. Central nervous system (CNS) TB can cause severe bacterial

meningitis. Abdominal TB can lead to peritonitis, especially in HIV-positive patients. The kidneys, adrenal glands, lymph nodes, and urogenital tract can be affected.

Diagnostic Studies

Tuberculin Skin Test

The tuberculin skin test (TST) (Mantoux test) using purified protein derivative (PPD) is the standard method to screen people for *M. tuberculosis*. The test is given by injecting 0.1 mL of PPD intradermally on the ventral surface of the forearm. The test is read by inspection and palpation 48 to 72 hours later for the presence or absence of induration. Induration, a palpable, raised, hardened area or swelling (not redness) at the injection site means the person has been exposed to TB and has developed antibodies.[18] Antibody formation occurs 2 to 12 weeks after initial exposure to the bacteria. Any indurated area present is measured and recorded in millimeters. Based on the size of the induration and the risk factors, an interpretation is made according to CDC standards for determining a positive test reaction. Because the immunocompromised patient may have a decreased response to TST, smaller induration reactions (5 mm or larger) are considered positive. See Table 25.14 for guidelines in interpreting responses to the TST.

Two-step testing with the Mantoux TST should be used for baseline or initial screening. If the initial test is positive, the person needs further evaluation for active disease. If the first test is negative, a second TST is done 1 to 3 weeks later. Some people with LTBI or who were previously infected with TB may have a false negative result with the first TST. Repeating the TST may stimulate (boost) the body's ability to react to tuberculin in future tests.[18] A positive reaction to a subsequent test could be a new infection or the result of the boosted reaction to an old infection. Two-step testing is recommended for initial testing for health care workers and for those who have a decreased response to allergens. A previously negative 2-step TST ensures that any future positive results can be accurately interpreted

as being caused by a new infection.

Interferon-γ Release Assays

Interferon-γ (INF-γ) release assays (IGRAs) are another screening tool for TB. IGRAs are blood tests that detect INF-γ release from T cells in response to *M. tuberculosis*.[19] Examples of IGRAs include QuantiFERON-TB Gold In-Tube test (QFT-GIT) and the T-SPOT.TB test. Test results are available in a few hours.

IGRAs offer several advantages over the TST in that they require only 1 patient visit, are not subject to reader bias, have no booster phenomenon, and are not affected by prior bacillus Calmette-Guérin (BCG) vaccination. The cost of an IGRA is much higher than the TST. Current guidelines suggest that both tests are viable options and that choice should be based on context and reasons for testing. Neither IGRAs nor TST can tell between LTBI and active TB infection. LTBI can only be diagnosed by excluding active TB.

TABLE 27.10 Interprofessional CarePulmonary Tuberculosis

Diagnostic Assessment

- History and physical examination
- Tuberculin skin test (TST)
- QuantiFERON-TB Gold In-Tube test (QFT-GIT) or T-SPOT.TB test
- Chest x-ray
- Bacteriologic studies
- Sputum smear for acid-fast bacilli (AFB)
- Sputum culture

Management

- Long-term treatment with antimicrobial drugs (Tables 27.11 and 27.12)
- Follow-up AFB smears, cultures, and chest x-rays
- Follow-up care, addressing needs and concerns of patient and close contacts, and involving community health care workers and social workers

Chest X-ray

Although the chest x-ray findings are important, it is not possible to make a diagnosis of TB solely on chest x-ray findings. The chest x-ray may appear normal in a patient with TB. Findings suggestive of TB include upper lobe infiltrates, cavitary infiltrates, lymph node involvement, and pleural and/or pericardial effusion. Other diseases, such as sarcoidosis, can mimic the appearance of TB.

Bacteriologic Studies

Culture is the gold standard for diagnosing TB. Three consecutive sputum specimens are needed, each collected at 8- to 24-hour intervals, with at least 1 early morning specimen. The initial test involves a microscopic examination of stained sputum smears for AFB. A definitive diagnosis of TB requires mycobacterial growth, which can take up to 6 weeks. Treatment is needed pending the culture results for patients in whom suspicion of TB is high. Samples for other suspected TB sites can be collected from gastric washings, cerebrospinal fluid (CSF), or fluid from an effusion or abscess.

Interprofessional Care

Most patients with TB are treated on an outpatient basis (Table 27.10). Many people can continue to work and maintain their lifestyles with few changes. Patients with sputum smear–positive TB are considered infectious for the first 2 weeks after starting treatment. Advise these patients to restrict visitors and avoid travel on public transportation and trips to public places. Teach them the importance of good hand

washing and oral hygiene. Hospitalization may be needed for the severely ill or debilitated.

Drug Therapy

Active TB Disease

The mainstay of TB treatment is drug therapy (Table 27.11). Promoting and monitoring adherence are critical for treatment to be successful. Because of the growing prevalence of MDR-TB, it is important to manage the patient with active TB aggressively. Drug therapy is divided into 2 phases: initial and continuation (Table 27.12). In most circumstances the treatment regimen for patients with previously untreated TB consists of a 3-month initial phase with 4 drugs (isoniazid, rifampin, pyrazinamide, and ethambutol). If drug susceptibility test results show that the bacteria are susceptible to all drugs, ethambutol may be stopped. If the patient develops a toxic reaction to the primary drugs, other drugs can be used, including rifabutin and rifapentine (Priftin). If pyrazinamide cannot be included in the initial phase (because of liver disease, pregnancy, etc.), the remaining 3 drugs are used for the initial phase.

TABLE 27.11 Drug TherapyTuberculosis

Drug	Common Side Effects
aminoglycosides **• amikacin** **• capreomycin (Capastat)** **bedaquiline (Sirturo)**	Hepatitis, GI toxicity Prolongation of QT interval Ototoxicity, nephrotoxicity Hepatotoxicity, nausea
ethambutol (Myambutol)	Headache, blurred vision, ocular toxicity (decreased red-green color discrimination)
fluoroquinolones **• levofloxacin** **• moxifloxacin (Avelox, Vigamox)**	GI problems, neurologic effects (dizziness, headache), rash
isoniazid	Hepatotoxicity, asymptomatic elevation of aminotransferases (ALT, AST) Vomiting, confusion, headaches
pyrazinamide	Hepatotoxicity, arthralgias, hyperuricemia
rifabutin (Mycobutin)	Hepatotoxicity, thrombocytopenia, neutropenia Orange discoloration of bodily fluids (sputum, urine, sweat, tears) Nausea, vomiting, loss of appetite
rifampin (Rifadin)	Hepatotoxicity, thrombocytopenia, Orange discoloration of bodily fluids (sputum, urine, sweat, tears) Anorexia, nausea, abdominal discomfort
rifapentine (Priftin)	Like those of rifampin
streptomycin	Ototoxicity, neurotoxicity, nephrotoxicity

ALT, Alanine transaminase; *AST,* aspartate aminotransferase; *MDR-TB,* multidrug resistant tuberculosis.

TABLE 27.12 Drug TherapyTuberculosis Treatment Regimens

Initial Phase	Continuation Phase
Option 1	
4-drug regimen consisting of isoniazid, rifampin, pyrazinamide, ethambutol **Given daily for 56 doses (8 wk) *OR* 5 days/wk DOT for 40 doses (8 wk)**	isoniazid, rifampin daily for 126 doses (18 wk) *OR* 5 days/wk DOT for 90 doses (18 wk)
Option 2	
4-drug regimen consisting of isoniazid, rifampin, pyrazinamide, ethambutol **Given daily for 56 doses (8 wk) *OR* 5 days/wk DOT for 40 doses (8 wk)**	isoniazid, rifampin 3 times weekly for 54 doses (18 wk)
Option 3	
4-drug regimen consisting of isoniazid, rifampin, pyrazinamide, ethambutol **Given 3 times weekly for 24 doses (8 wk)**	isoniazid, rifampin 3 times weekly for 54 doses (18 wk)
Option 4	
4-drug regimen consisting of isoniazid, rifampin, ethambutol, pyrazinamide **Given daily for 14 doses (2 wk) then twice weekly for 12 doses**	isoniazid, rifampin twice weekly for 36 doses (18 wk)

DOT, Directly observed therapy.

www.cdc.gov/tb/topic/treatment/tbdisease.htm.

Drug Alert

Isoniazid

- Alcohol may increase risk for hepatotoxicity.
- Teach patient to avoid drinking alcohol during treatment.
- Monitor for signs of hepatitis before and while taking drug.

Sensitivity testing guides the treatment for MDR-TB. MDR-TB therapy in the initial phase typically includes 5 drugs: 1or 2 first-line agents, a fluoroquinolone, an injectable antibiotic, and 1 or more second-line agents, for at least 6 months after sputum culture is negative. This is followed by at least 4 drugs, minus the injectable antibiotic, for 18 to 24 months. Two newer drugs, bedaquiline (Sirturo) and Delamanid (Deltyba), are used in combination with other drugs to treat MDR-TB and XDR-TB.

Directly observed therapy (DOT) involves providing the antitubercular drugs directly to patients and watching as they swallow the medications. To ensure adherence, it is the preferred strategy for all patients with TB, especially for those at risk for nonadherence.[20] Nonadherence is a major factor in the emergence of MDR-TB and treatment failures. Many people do not adhere to the treatment program despite understanding the disease process and value of treatment. DOT is an expensive but essential public health measure. The risk for reactivation of TB and MDR-TB is increased in patients who do not complete the full course of therapy. In many areas, the public health nurse administers DOT at a clinic site.

When DOT is not used, fixed-dose combination drugs may enhance adherence. Combinations of isoniazid and rifampin and of isoniazid, rifampin, and pyrazinamide are available to simplify therapy. The therapy for people with HIV follows the same therapy options

outlined in Table 27.12. However, alternative regimens in any HIV-infected patient that include once-weekly isoniazid plus rifapentine continuation dosing or twice-weekly isoniazid plus rifampin or rifabutin, should not be used if $CD4^+$ counts are less than 100/μL.

Teaching patients about the adverse effects of these drugs and when to seek prompt medical attention is critical. The major side effect of isoniazid, rifampin, and pyrazinamide is nonviral hepatitis. Baseline liver function tests (LFTs) are done at the start of treatment and monitored closely (e.g., every 2 to 4 weeks), especially if results are abnormal.

Latent Tuberculosis Infection

In people with LTBI, drug therapy helps prevent a TB infection from developing into active TB disease. Because a person with LTBI has fewer bacteria, treatment is much easier. Usually only 1 drug is needed. Drug therapy regimens for LTBI are outlined in Table 27.13.

The standard treatment regimen for LTBI is 9 months of daily isoniazid. It is an effective and inexpensive drug that the patient can take orally. While the 9-month regimen is more effective, adherence issues may make a 6-month regimen preferable. For patients with HIV and those with fibrotic lesions on chest x-ray, isoniazid is given for 9 months. An alternative 3-month regimen of isoniazid and rifapentine may be used for otherwise healthy patients who are not presumed to be infected with MDR bacilli. Four-month therapy with rifampin may be indicated if the patient is resistant to isoniazid. Because of severe liver injury

Ethical/Legal Dilemmas

Patient Adherence

Situation

While working at a health clinic at a homeless shelter, you discover that F.C., a 64-yr-old man with tuberculosis (TB), has not been taking

his prescribed medications. He tells you that it is hard for him to get to the clinic to obtain the medication, much less to keep on a schedule. You are concerned not only about this patient, but about the risks for the other people at the shelter, in the park, and at the meal sites where he often visits.

Ethical/Legal Points for Consideration

- Adherence is a complex issue involving a person's culture, values, and beliefs, perceived risk for disease, availability of resources, access to treatment, and perceived consequences of failure to adhere to treatment.
- Advocacy for the patient and the community obliges you to involve other members of the health care team, such as social services, to aid in obtaining resources or support for the patient to complete a course of treatment.
- Some cities and states have a stepwise legal process for managing nonadherent TB patients.[1]
- Legally the constitutional right to control one's own body may be limited by state and federal obligation to protect public health and safety. Most of these laws have provisions for the protection of constitutional rights, such as right to counsel, right to least restrictive alternative in terms of confinement setting, and right to prompt judicial review.
- The federal government and many states have provisions for quarantine, detention, and treatment. With the threats of bioterrorism and the globalization of exposure to highly lethal infectious diseases, it seems unlikely that the government's power to detain will be removed.

Discussion Questions

1. What alternatives of care can we offer to F.C.?
2. Under what circumstances, if any, are HCPs justified in

overriding a patient's autonomy or decision making?

Reference

California Department of Public Health: Plan for the detention of persistently non-adherent tuberculosis patients. Retrieved from *www.cdph.ca.gov/Programs/CID/DCDC/CDPH%20Document%20Librar SPM-CD-Plan-for-Detention-of-Persistently-Non-Adherent-TB-Patients.pdf*

and deaths, the CDC does not recommend the combination of rifampin and pyrazinamide for treatment of LTBI.

Bacille Calmette-Guérin Vaccine

Bacille Calmette-Guérin (BCG) vaccine is a live, attenuated strain of *Mycobacterium bovis*. The vaccine is given to infants in parts of the world with a high prevalence of TB. In the United States, it is typically not used because of the low risk for infection, the vaccine's variable effectiveness against adult pulmonary TB, and potential interference with TB skin test reactivity. The BCG vaccination can result in a false-positive TST. IGRA results are not affected. The BCG vaccine should be considered only for select persons who meet specific criteria (e.g., health care workers who are continually exposed to patients with MDR-TB and when infection control precautions are not successful).

TABLE 27.13 Drug TherapyLatent Tuberculosis Infection Regimens

Drugs	Duration (mo)	Interval	Minimum Doses
isoniazid	9	Daily	270
		Twice weekly*	76
isoniazid	6	Daily	180
		Twice weekly*	52
isoniazid and rifapentine	3	Once weekly*	12
rifampin	4	Daily	120

* Use directly observed therapy (DOT).

Nursing Management: Tuberculosis

Nursing Assessment

Ask the patient about a previous history of TB, chronic illness, or any immunosuppressive disease or medications. Obtain a social and occupational history to determine risk factors for transmission of TB. Assess the patient for productive cough, night sweats, fever, weight loss, pleuritic chest pain, and abnormal lung sounds. If the patient has a productive cough, early morning is the ideal time to collect sputum specimens for an AFB smear.

Nursing Diagnoses

Nursing diagnoses for the patient with TB may include:

- Impaired breathing
- Impaired airway clearance
- Risk for infection
- Lack of knowledge

Planning

The overall goals are that the patient with TB will (1) have normal pulmonary function, (2) adhere to the therapeutic regimen, (3) take appropriate measures to prevent the spread of the disease, and (4) have no recurrence of disease.

Nursing Implementation

Health Promotion

The ultimate goal is to eradicate TB worldwide. Screening programs in known risk groups are of value in detecting persons with TB. Treatment of LTBI reduces the number of TB carriers in the

community. The person with a positive TST should have a chest x-ray to assess for active TB disease. People with a diagnosis of TB must be reported to the public health authorities for identification and assessment of contacts and risk to the community.

Programs to address the social determinants of TB are needed to decrease transmission of TB. Reducing HIV infection, poverty, overcrowded living conditions, malnutrition, smoking, and drug and alcohol use can help minimize TB infection rates. Improving access to health care and education is important.

Acute Care

Patients admitted to the ED or directly to the nursing unit with respiratory symptoms should always be assessed for the possibility of TB. Those strongly suspected of having TB should (1) be placed on airborne isolation; (2) receive a medical workup, including chest x-ray, sputum smear, and culture; and (3) receive appropriate drug therapy. Airborne infection isolation is needed for the patient with pulmonary or laryngeal TB until the patient is not infectious. *Airborne infection isolation* refers to isolation of patients infected with organisms spread by the airborne route. Patients are in a single-occupancy room with negative pressure and airflow of 6 to 12 exchanges per hour.

High-efficiency particulate air (HEPA) masks are worn whenever entering the patient's room. These masks are highly effective at protecting from small droplets 5 μm or less in diameter. Several types of HEPA masks are currently available. To ensure proper mask size, health care professionals should be "fit tested" with significant changes in weight gain or loss, with any facial and/or dental changes (e.g., Botox injections), and each time there is a new brand or model of mask. Otherwise, yearly mask "fit testing" is acceptable. To be effective, the mask must be molded to fit tightly around the nose and mouth.

Teach patients to cover the nose and mouth with paper tissues every time they cough, sneeze, or produce sputum. The tissues should be thrown into a paper bag and disposed of with the trash or flushed down the toilet. Emphasize careful hand washing after handling

sputum and soiled tissues. If patients need to be out of the negative-pressure room, they must wear a standard isolation mask to prevent exposure to others. Minimize prolonged visitation to other parts of the hospital.

Identify and screen close contacts of the person with TB. Anyone testing positive for TB infection will need further evaluation and treatment for either LTBI or active TB disease.

Ambulatory Care

Patients who respond clinically are discharged home (even with positive cultures) if their household contacts have already been exposed and the patient is not posing a risk to others. A sputum specimen for AFB smear and culture should be obtained at a minimum of monthly intervals until 2 consecutive specimens are negative on culture. More frequent AFB smears may be useful to assess the early response to treatment and provide an indication of infectiousness. Negative cultures are needed to declare the patient not infectious.

Teach the patient how to minimize exposure to close contacts and household members. Homes should be well ventilated, especially the areas where the infected person spends a lot of time. While still infectious, the patient should sleep alone, spend as much time as possible outdoors, and minimize time in congregate settings or on public transportation.

It is important to teach the patient and caregiver about adherence with the prescribed regimen. Most treatment failures occur because the patient does not take the drug, stops taking it too soon, or takes it irregularly. Strategies to improve adherence include teaching and counseling, reminder systems, incentives or rewards, contracts, and DOT.

Notifying the public health department is required. The public health nurse is responsible for follow-up on household contacts and assessment of the patient for adherence. If adherence is an issue, the public health agency may be responsible for DOT. Most patients can be considered adequately treated when the therapy regimen has been

completed and there is evidence of negative cultures, overall improvement in patient condition, and improvement on chest x-ray.

Because about 5% of patients have relapses, teach the patient to recognize the symptoms that occur with recurrent TB. If these symptoms occur, the patient should seek immediate medical attention. Teach the patient about factors that could reactivate TB, such as immunosuppressive therapy, cancer, and prolonged debilitating illness. If the patient has any of these events, the HCP must be told so that TB can be closely monitored for reactivation. In some situations, it is necessary to put the patient on anti-TB therapy. Because smoking is associated with poor outcomes in TB, patients should be encouraged to quit. Provide patients with teaching and resources to help them stop smoking.

Evidence-Based Practice

Adherence to Tuberculosis Treatment Program

You are a nurse working in an outpatient health clinic with C.J., a 42-yr-old man diagnosed 2 months ago with active TB. He is on DOT. You notice C.J. has started to miss or has been late for his clinic appointments. He tells you it is hard to make his appointments as a new job requires long work hours. He asks if he needs to continue with his visits to get his drugs. He says he is "feeling better" and will take the drugs on his own.

Making Clinical Decisions

Best Available Evidence. Guidelines for effective case management of patients with TB include patient education, field/home visits, patient reminders, and incentives. TB clinic attendance and treatment completion rates are higher when patients take part in DOT compared to self-administered therapy. When appointments are missed, phone calls, Web-based videos, or home visits will engage patients, resulting in

improved clinic attendance and treatment completion.

Clinician Expertise. You know that patient-centered care includes being responsive to patients' changing needs. You know that patients may stop attending clinics and taking their drugs when feeling well again. This can lead to treatment failure, the need to restart therapy, and multidrug resistance.

Patient Preferences and Values. C.J. tells you he has a busy job and does not always remember his appointment dates. He would like to self-administer his drugs.

Implications for Nursing Practice

1. What information would you give C.J. about the importance of DOT?
2. Your clinic has interest in starting a reminder system for clinic appointments. What strategy would you recommend?
3. How will you know if C.J. is adhering to the prescribed drug treatment program?

Evaluation

The expected outcomes are that the patient with TB will have:

- Resolution of the disease
- Normal pulmonary function
- Absence of any complications
- No further transmission of TB

Atypical Mycobacteria

There are more than 30 varieties of acid-fast mycobacteria that do not cause TB but cause pulmonary disease, lymphadenitis, skin or soft tissue disease, or disseminated disease. Atypical mycobacteria are not airborne or transmitted by droplets. They can be found in tap water, soil, bird feces, and house dust.

Pulmonary symptoms include cough, shortness of breath, weight loss, fatigue, and blood-tinged sputum. People who are immunosuppressed (e.g., HIV/AIDS) or have chronic pulmonary disease are most susceptible. We cannot distinguish this type of pulmonary disease from TB clinically and radiologically. A culture is required. Treatment is similar to that for TB.

Pulmonary Fungal Infections

Pulmonary fungal pneumonia is an infectious process in the lungs caused by endemic (native and common) or opportunistic fungi (Table 27.14). *Endemic* fungal pathogens cause infection in healthy people and in immunocompromised people in certain geographic locations in the United States. For example, *Coccidioides,* which causes coccidioidomycosis, is a fungus found in the soil of dry, low-rainfall areas.[21] It is endemic in many areas of the southwestern United States. *Opportunistic* fungal infections occur in immunocompromised patients (e.g., those receiving chemotherapy, immunosuppressive drugs) and in patients with HIV and cystic fibrosis. These pulmonary fungal infections can be life-threatening.

Pulmonary fungal infections are acquired by inhaling spores. They are not transmitted from person to person. The patient does not have to be placed in isolation. The manifestations are like those of bacterial pneumonia. Skin testing, serology, and biopsy methods aid in identifying the infecting organism.

The choice of antifungal agent is made based on the pathogen identified on culture or most likely suspected. Amphotericin B is the standard therapy for treating serious systemic fungal infections. It must be given IV to achieve adequate blood and tissue levels because the GI tract does not absorb it well. Less serious infections can be treated with oral antifungals, such as ketoconazole, fluconazole (Diflucan), voriconazole (Vfend), and itraconazole (Sporanox). Effectiveness of therapy can be monitored with fungal serology titers.

Environmental Lung Diseases

Environmental or occupational lung diseases result from inhaled dust or chemicals. The extent of lung damage is influenced by the toxicity of the inhaled substance, amount and duration of exposure, and individual susceptibility. Environmentally induced lung disease includes pneumoconiosis, chemical pneumonitis, and hypersensitivity pneumonitis.

Pneumoconiosis is a general term for a group of lung diseases caused by inhalation and retention of mineral or metal dust particles. The literal meaning of *pneumoconiosis* is "dust in the lungs." We classify these diseases according to the origin of the dust (e.g., silicosis, asbestosis, berylliosis). For example, silicosis occurs from inhaling silica from sand and rock. Coal worker's pneumoconiosis (CWP), also known as *black lung,* is caused by inhaling large amounts of coal dust. It is an occupational hazard for underground coal miners. The inhaled substance is ingested by macrophages, which releases substances that cause cell injury and death. Fibrosis occurs from tissue repair after inflammation. Breathing problems become evident after many years of repeated exposure, resulting in diffuse *pulmonary fibrosis* (excess connective tissue).

Asbestos is a group of minerals composed of microscopic fibers. For many years, asbestos was used for insulation and to help fireproof buildings. When disturbed, asbestos releases tiny filament particles into the air. Once inhaled, the tiny fibers become deposited within the lung. Asbestosis is chronic inflammation of the lung, and people with repeated exposure are at a greater risk for disease. Lung cancer, either squamous cell carcinoma or adenocarcinoma, is the most frequent cancer associated with asbestos exposure. There is a lapse of at least 15 to 19 years between first exposure and development of lung cancer. Mesothelioma, both pleural and peritoneal, is associated with asbestos exposure.

Chemical pneumonitis results from exposures to toxic chemical fumes. There are 2 types of chemical pneumonitis: acute and chronic.

Acutely, there is diffuse lung injury characterized by pulmonary edema. Chronically, the clinical picture is that of *bronchiolitis obliterans* (obstruction of the bronchioles due to inflammation and fibrosis). It is usually associated with a normal chest x-ray or one that shows hyperinflation.

Hypersensitivity pneumonitis, or extrinsic allergic alveolitis, is a form of parenchymal lung disease seen when a person inhales antigens to which they are allergic. There are acute, subacute, and chronic forms. Examples include bird fancier's lung (exposure to particles in feathers and droppings of birds), and farmer's lung (inhalation of hay dust particles).

Clinical Manifestations

Symptoms of many environmental lung diseases may not occur until at least 10 to 15 years after the initial exposure to the inhaled irritant. Manifestations common to all pneumoconioses include dyspnea, cough, wheezing, and weight loss. Pulmonary function studies often show reduced vital capacity. A chest x-ray often reveals lung involvement specific to the primary problem. CT scans have been useful in detecting early lung involvement.

Cor pulmonale, a condition in which the right side of the heart fails, is a late complication, especially in conditions characterized by diffuse pulmonary fibrosis. COPD is the most common complication of environmental lung disease. Other associated disorders include acute pulmonary edema, lung cancer, mesothelioma, and TB. Appearance of these symptoms and complications are often the reason the patient seeks health care.

Interprofessional and Nursing Care

The best approach to managing environmental lung diseases is to prevent or decrease environmental and occupational exposure. Teach those at risk about the use of appropriate personal protective equipment. Wearing masks and using well-designed, effective ventilation systems are appropriate for some occupations and

household activities. Inhalation of smoke by nonsmokers has led to regulations requiring a smoke-free workplace. Periodic inspections and monitoring of workplaces by agencies such as the Occupational Safety and Health Administration (OSHA) and the National Institute for Occupational Safety and Health (NIOSH) reinforce employers' obligations to provide a safe work environment. NIOSH is responsible for workplace safety and health regulations in the United States.

Encourage regular medical check-ups. Early diagnosis is essential to halting the disease process. Strategies are directed toward preventing disease progression and monitoring, improving or controlling respiratory symptoms. They depend on the cause and severity of the condition. Strategies may include O_2 therapy, IV fluid, inhaled bronchodilators, corticosteroids, nonsteroidal antiinflammatory drugs (NSAIDs), intubation and mechanical ventilation, percussion therapy, and pulmonary rehabilitation. Patients should be immunized against pneumococcal pneumonia and influenza. Discontinuing exposure to the offending inhalant and smoking cessation may or may not be effective in stopping disease progression.

Lung Cancer

Lung cancer is the leading cause of cancer-related deaths in the United States.[23] Lung cancer accounts for 26% of all cancer deaths, more than those caused by breast and colon cancer combined. In 2019, it is estimated that 234,000 new cases of lung cancer will be diagnosed, and 154,000 Americans will die. Although lung cancer is associated with a high mortality and low cure rate, advances in medical treatment are improving the response to treatment.

Etiology

Smoking causes 80% to 90% of all lung cancers.[24] There is no safe form of tobacco or tobacco product. Smokeless tobacco, pipes and cigars, hookah and waterpipe, bidis, and kreteks all pose significant risk for lung cancer to those who use them.[25]

Tobacco smoke contains over 7000 chemicals, of which 250 are harmful. Of the harmful substances in tobacco smoke, 69 interfere with normal cell development and are linked to lung cancer. Exposure to tobacco smoke causes changes in the bronchial epithelium, which usually returns to normal with smoking cessation. The risk for lung cancer gradually decreases with smoking cessation, reaching that of nonsmokers within 10 to 15 years of quitting.

The risk for developing lung cancer is directly related to total exposure to tobacco smoke. This is measured by total number of cigarettes smoked in a lifetime, age of smoking onset, depth of inhalation, tar and nicotine content, and the use of unfiltered cigarettes. Both smokers and nonsmokers can develop lung cancer. Sidestream smoke (smoke from burning cigarettes, cigars) has the same carcinogens found in mainstream smoke (smoke inhaled and exhaled by the smoker). This exposure to secondhand smoke creates a health risk for nonsmoking adults and children.

Other common causes of lung cancer include high levels of pollution, radiation (especially radon exposure), and asbestos. Heavy

or prolonged exposure to industrial agents, such as ionizing radiation, coal dust, nickel, uranium, chromium, formaldehyde, and arsenic, can increase the risk for lung cancer, especially in smokers.[26]

Marked variations exist in a person's tendency to develop lung cancer. Differences in lung cancer incidence, risk factors, and survival exist between men and women (see Gender Differences box). Genetic, hormonal, and molecular influences may contribute to these differences.

Gender Differences

Lung Cancer

Men

- Have a 1 in 15 chance of developing lung cancer (smokers and nonsmokers)
- Diagnosed with lung cancer more than women
- Die from lung cancer more than women
- Male smokers are 10 times more likely to develop lung cancer than nonsmokers
- Lung cancer incidence and deaths are decreasing in men

Women

- Have a 1 in 17 chance of developing lung cancer (smokers and nonsmokers)
- Lung cancer incidence and deaths are increasing in women
- Develop lung cancer after fewer years of smoking than men
- Develop lung cancer at a younger age than men
- Nonsmoking women are at greater risk for developing lung cancer than nonsmoking men

- Women with lung cancer live, on the average, 12 months longer than men.

Promoting Health Equity

Lung Cancer

Blacks

- Have the highest incidence of lung cancer
- Are more likely to die from lung cancer than any other ethnic group
- Have a higher rate of lung cancer among men than in other ethnic groups

Whites

- Have the second-highest death rate from lung cancer
- Have a higher rate of lung cancer among women than in other ethnic groups

Asian/Pacific Islanders and Hispanics

- Have the lowest rates of lung cancer in both men and women

Other

- Regional variations among ethnic groups may be due to smoking prevalence or exposure to cancer-causing substances
- Cigarette use has decreased dramatically in developed countries, such as the United States and Canada

- Cigarette smoking is increasing in developing countries (e.g., nations in Africa, Asia, Latin America)

Source: Singh GK, Jemal A: Socioeconomic and racial/ethnic disparities in cancer mortality, incidence, and survival in the United States, 1950–2014, *J Environ Public Health*, 2017. Retrieved from www.doi.org/10.1155/2017/2819372.

Pathophysiology

Most primary lung tumors are believed to arise from mutated epithelial cells. The growth of mutations, which are caused by carcinogens, is influenced by various genetic factors. Once underway, tumor development is promoted by epidermal growth factor. These cells grow slowly, taking 8 to 10 years for a tumor to reach 1 cm in size, the smallest lesion detectable on x-ray. Lung cancers occur primarily in the segmental bronchi or beyond and usually occur in the upper lobes of the lungs (Fig. 27.4).

Primary lung cancers are categorized into 2 broad subtypes (Table 27.15): non–small cell lung cancer (NSCLC) (85%) and small cell lung cancer (SCLC) (15%).[27] Lung cancers metastasize primarily by direct extension and through the blood and lymph system. The common sites for metastasis are the lymph nodes, liver, brain, bones, and adrenal glands.

Paraneoplastic Syndrome

Lung cancers can cause *paraneoplastic syndrome*. Paraneoplastic syndrome may be caused by hormones, cytokines, enzymes (secreted by tumor cells) or antibodies (made by the body in response to the tumor) that destroy healthy cells. Sometimes the symptoms of paraneoplastic syndrome manifest even before the cancer is diagnosed.

Examples of paraneoplastic syndrome include hypercalcemia, syndrome of inappropriate antidiuretic hormone secretion (SIADH), adrenal hypersecretion, polycythemia, and Cushing syndrome. SCLCs

are most often associated with paraneoplastic syndrome. These conditions may stabilize with treatment of the underlying cancer. SIADH, adrenal hypersecretion, and Cushing syndrome are discussed in Chapter 49.

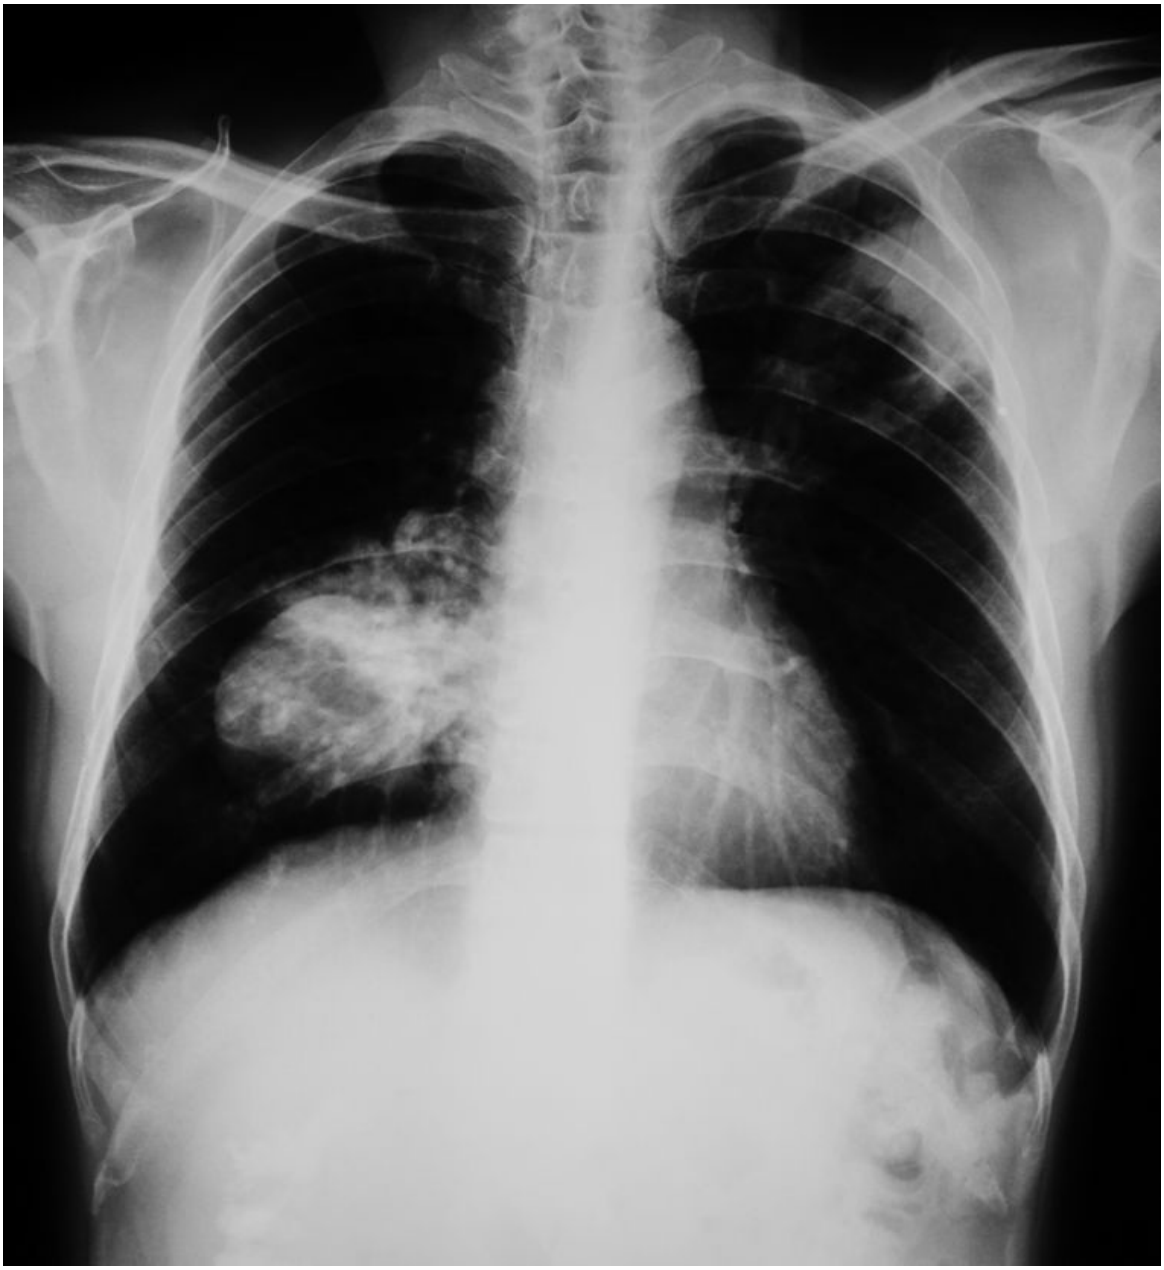

FIG. 27.4 Lung cancer lesion.
© iStock.com/Sutthaburawonk.

Clinical Manifestations

The manifestations of lung cancer are usually nonspecific and appear late in the disease process. Symptoms may be masked by a chronic cough attributed to smoking or smoking-related lung disease. Manifestations depend on the type of primary lung cancer, its location, and extent of metastatic spread. Lung cancer often presents as a lobar pneumonia that does not respond to treatment.

The most common symptom and often the one that is reported first is a persistent cough. The patient may report dyspnea or wheezing. Blood-tinged sputum may be present because of bleeding caused by the cancer. Chest pain, if present, may be localized or unilateral, ranging from mild to severe.

Later manifestations include nonspecific systemic symptoms, such as anorexia, nausea and vomiting, fatigue, and weight loss. Hoarseness may be present due to laryngeal nerve involvement. Dysphagia, unilateral paralysis of the diaphragm, and superior vena cava obstruction may occur because of intrathoracic spread of the cancer. Lymph nodes are often palpable in the neck or axillae. Mediastinal involvement may lead to pericardial effusion, cardiac tamponade, and dysrhythmias.

Diagnostic Studies

A chest x-ray is the first diagnostic test done for patients with suspected lung cancer. The x-ray may be normal or identify a lung mass or infiltrate (Fig. 27.4). Evidence of metastasis to the ribs or vertebrae and a pleural effusion may be seen on chest x-ray. CT scanning is used to further evaluate the lung mass. CT scans can identify the location and extent of masses in the chest, any mediastinal involvement, and lymph node enlargement.

Sputum cytologic studies can identify cancer cells, but sputum samples are rarely used in diagnosing lung cancer because cancer cells are not always present in the sputum. A definitive diagnosis requires a biopsy. Cells for biopsy can be obtained by CT-guided needle aspiration, bronchoscopy, mediastinoscopy, or video-assisted

thoracoscopic surgery (VATS). If a thoracentesis is done to relieve a pleural effusion, the fluid is analyzed for cancer cells.

TABLE 27.15 Types of Primary Lung Cancer

Type	Growth Rate	Characteristics	Response to Therapy
Non–Small Cell Lung Cancer (NSCLC)			
Adenocarcinoma	Moderate	• Accounts for 40% of lung cancers • Most common lung cancer in United States • Most common cancer in people who have not smoked • Found in peripheral areas of lung • Often has no manifestations until widespread metastasis is present	• Surgical resection may be tried depending on staging • Does not respond well to chemotherapy
Large cell (undifferentiated) cancer	Rapid	• Accounts for 10% of lung cancers • Composed of large cells that are anaplastic • Often arise in bronchi • Is highly metastatic via lymphatics and blood	• Surgery is not usually done because of high rate of metastases • Tumor may be radiosensitive but often recurs
Squamous cell cancer	Slow	• Accounts for 25%–30% of lung cancers • Centrally located • Causes early symptoms of nonproductive cough and hemoptysis • Does not have a strong tendency to metastasize	• Surgical resection may be tried • Adjuvant chemotherapy and radiation • Depending on the staging, life expectancy is better than for SCLC
Small Cell Lung Cancer (SCLC)			
Small cell cancer	Very rapid	• Accounts for about 10%–15% of lung cancers • Very aggressive form of lung cancer • Spreads early via lymphatics and bloodstream • Frequent metastasis to brain • Associated with endocrine problems	• Chemotherapy mainstay of treatment; more responsive to chemotherapy than NSCLC • Radiation used as adjuvant therapy and palliative measure • Overall poor prognosis

TABLE 27.16 Interprofessional CareLung Cancer

Diagnostic Assessment

- History and physical examination
- Chest x-ray
- Bronchoscopy
- Cytologic study of bronchial washings or pleural space fluid
- Transbronchial or percutaneous fine-needle aspiration
- CT scan, MRI, PET

- Mediastinoscopy
- Video-assisted thoracoscopic surgery (VATS)

Management

- Surgery (segmental or wedge resection, lobectomy, pneumonectomy)
- Radiation therapy
- Chemotherapy
- Targeted therapy and immunotherapy
- Prophylactic cranial radiation
- Bronchoscopic laser therapy
- Photodynamic therapy
- Airway stenting
- Radiofrequency ablation

Accurate assessment of lung cancer is critical for staging and determining appropriate treatment. Bone scans and CT scans of the brain, pelvis, and abdomen are used to determine if metastatic disease is present. A complete history and physical examination, CBC with differential, chemistry panel, liver function tests, and renal function tests are ordered. In some situations, pulmonary function tests will be done. MRI and/or positron emission tomography (PET) may be used to evaluate and stage lung cancer. Table 27.16 outlines the diagnostic assessment of lung cancer.

TABLE 27.17 Staging of Non–Small Cell Lung Cancer

Stages	Characteristics

0	Cells found in respiratory airway, alveoli
I	Tumor is small and localized to lung. No lymph node involvement
A	Tumor <3 cm
B	Tumor 3–4 cm and invading main airway, visceral pleura.
II	Increased tumor size, some lymph node involvement
A	Tumor 4–5 cm with invasion of main airway, visceral pleura, lymph nodes on same side of chest
B	Tumor 5–7 cm involving the bronchus and lymph nodes on same side of chest *OR* Tumor 5–7 cm with visceral and parietal pleura, diaphragm, phrenic nerve involvement
III	Increased spread of tumor
A	Tumor ≤5 cm or smaller spread to the nearby structures (chest wall, pleura, pericardium) and regional lymph nodes
B	Extensive tumor >5 cm involving heart, trachea, esophagus, mediastinum, malignant pleural effusion, contralateral lymph nodes, scalene or supraclavicular lymph nodes
C	Tumor >5 cm and more than one tumor in a different lobe of the lung
IV	Distant metastasis

Staging

Staging of NSCLC is done using the TNM staging system (see Table 15.5). Under the TNM system, cancer is grouped into 4 stages with A or B subtypes. A simplified version of staging of NSCLC is shown in Table 27.17. Patients with stages I, II, and IIIA disease may be surgical candidates. However, stage IIIB or IV disease is usually inoperable and has a poor prognosis.

Staging of SCLC by TNM has not been useful because this cancer is aggressive and is always considered systemic. The stages of SCLC are *limited* and *extensive*. *Limited* means that the tumor is only on 1 side of the chest and regional lymph nodes. *Extensive* SCLC means that the cancer extends beyond the limited stage. Most patients with SCLC have extensive disease at time of diagnosis.

Screening for Lung Cancer

The American College of Chest Physicians recommends screening for

high-risk patients.[28] Adults ages 55 to 77 with a history of smoking (30 pack-year smoking history or currently smoke) or who quit smoking but less than 15 years ago should have annual screening for lung cancer. Screening is done using low-dose CT. Several other groups have endorsed these guidelines, including the American Cancer Society.[29]

Interprofessional Care

Surgical Therapy

Surgical resection is the treatment of choice in NSCLC stages I to IIIA without mediastinal involvement. Resection gives the best chance for a cure. Factors that affect survival include the size of the primary tumor and preexisting co-morbidities. For other NSCLC stages, patients may have surgery in conjunction with radiation therapy, chemotherapy, and targeted therapy. Many NSCLCs are not resectable at the time of diagnosis.

Surgical procedures include segmental or wedge resection procedures, lobectomy (removal of 1 or more lobes of the lung), or pneumonectomy (removal of 1 entire lung). VATS may be used to treat lung cancers near the outside of the lung. Surgery is generally not done for SCLC because of its rapid growth and dissemination at the time of diagnosis.

When the tumor is considered operable, the patient's cardiopulmonary status must be evaluated to determine the ability to have surgery. Pulmonary function studies, ABGs, and anesthesia and critical care consults are often done before surgery to assess the patient's cardiopulmonary status.

Radiation Therapy

Radiation therapy may be used as treatment for both NSCLC and SCLC. Radiation therapy may be given as curative therapy, palliative therapy (to relieve symptoms), or adjuvant therapy in combination with surgery, chemotherapy, or targeted therapy.

Radiation therapy may be used as primary therapy in the person

who is unable to tolerate surgical resection because of co-morbidities. Radiation therapy relieves symptoms of dyspnea and hemoptysis from bronchial obstructive tumors and treats superior vena cava syndrome. It can treat pain from metastatic bone lesions or brain metastasis. Radiation before surgery can reduce the tumor mass before surgical resection. Complications of radiation therapy include esophagitis, skin irritation, nausea and vomiting, anorexia, and radiation pneumonitis (see Chapter 15).

Stereotactic body radiotherapy (SBRT), also called *stereotactic radiosurgery (SRS),* is a newer lung cancer treatment. It is a type of radiation therapy that uses high doses of radiation delivered to tumors outside the CNS. SBRT uses special positioning procedures and radiology techniques to deliver a higher dose of radiation to the tumor and expose only a small part of healthy lung. It does not destroy the tumor, but damages tumor DNA. Therapy is given over 1 to 3 days. SBRT provides an option for patients with early-stage lung cancers who are not surgical candidates for other medical reasons.

Chemotherapy

Chemotherapy is the main treatment for SCLC. In NSCLC, chemotherapy may be used in the treatment of nonresectable tumors or as adjuvant therapy to surgery. We use a variety of chemotherapy drugs and multidrug protocols. Chemotherapy for lung cancer typically consists of combinations of 2 of the following drugs: etoposide (VP-16), carboplatin, cisplatin, paclitaxel (Taxol), vinorelbine (Navelbine), docetaxel (Taxotere), gemcitabine (Gemzar), and pemetrexed (Alimta).

Targeted Therapy

Targeted therapy uses drugs that block the growth of molecules involved in specific aspects of tumor growth (see Chapter 15). Because this type of therapy inhibits growth rather than directly killing cancer cells, targeted therapy may be less toxic than chemotherapy. One type of targeted therapy for patients with NSCLC inhibits tyrosine kinase, an enzyme associated with speeding up molecular reactions. Tyrosine

kinase inhibitors, which block signals for growth in the cancer cells, include cetuximab (Erbitux), erlotinib (Tarceva), afatinib (Gilotrif), gefitinib (Iressa), osimertinib (Tagrisso), and necitumumab (Portrazza).

Another type of kinase inhibitor is used to treat patients with NSCLC who have an abnormal anaplastic lymphoma kinase *(ALK)* gene. Drugs in this class include crizotinib (Xalkori), brigatinib (Alunbrig), and ceritinib (Zykadia). These drugs directly inhibit the kinase protein made by the *ALK* gene that is responsible for cancer development and growth.

Another type of targeted therapy used to treat lung cancer inhibits the growth of new blood vessels (angiogenesis) by targeting vascular endothelial growth factor. Bevacizumab (Avastin) is an angiogenesis inhibitor.

Immunotherapy

Nivolumab (Opdivo), atezolizumab (Tecentriq), and pembrolizumab (Keytruda) are drugs that target PD-1, a protein on T cells that normally helps keep these cells from attacking other cells in the body. By blocking PD-1, these drugs boost the immune response against cancer cells. This can shrink some tumors or slow their growth. Nivolumab and pembrolizumab can be used in people with metastatic NSCLC whose cancer has progressed after other treatments and with tumors that express PD-1.

Other Therapies

Prophylactic Cranial Irradiation

Patients with SCLC have early metastases, especially to the CNS. Most chemotherapy does not penetrate the blood-brain barrier. As a result, after successful systemic treatment, the patient is at risk for brain metastases. Prophylactic radiation can decrease the incidence of brain metastases and may improve survival rates in patients with limited SCLC.[30]

Bronchoscopic Laser Therapy

Bronchoscopic laser therapy makes it possible to remove obstructing bronchial lesions. The laser's thermal energy is transmitted to the target tissue. It is a safe and effective treatment of endobronchial obstructions from tumors. Symptoms of airway obstruction are relieved due to thermal necrosis and shrinkage of the tumor. The procedure may be repeated as needed.

Photodynamic Therapy

Photodynamic therapy (PDT) is a form of treatment for early-stage lung cancers that uses a combination of a drug and a specific type of light. Cancer cells are killed when the drug, known as a photosynthesizer, is exposed to a specific wavelength of light. Porfimer (Photofrin) is the most used photosynthesizer. After an IV injection, it selectively concentrates in tumor cells in the esophagus and outer layers of the airways. After a set time (usually 48 hours), the tumor is exposed to laser light via bronchoscopy, activating the drug and causing cell death. Necrotic tissue is removed with bronchoscopy a few days later. This process can be repeated as needed. PDT can affect nutrient delivery to cancer cells and stimulate the immune system to attack the cancer cells.

Airway Stenting

Stents are used alone or in combination with other techniques for relief of dyspnea, cough, or respiratory insufficiency. The stent is inserted during a bronchoscopy. The advantage of an airway stent is that it supports the airway wall against collapse or external compression and can delay extension of tumor into the airway lumen. At this time, we do not know which patients will benefit most from airway stents.

Radiofrequency Ablation

Radiofrequency ablation therapy is used to treat small NSCLC lung tumors that are near the outer edge of the lungs. This therapy is an

alternative to surgery in patients who cannot or elect not to have surgery. A thin, needle-like probe is inserted through the skin into the tumor. CT scans are used to guide placement. An electric current is then passed through the probe, which heats and destroys tumor cells. Local anesthesia is used for this outpatient procedure.

Nursing Management: Lung Cancer

Nursing Assessment

It is important to determine the patient and caregiver's understanding of the current medical condition, diagnostic tests (those completed as well as those planned), diagnosis or potential diagnosis, treatment options, and prognosis. Assess the patient's level of anxiety and support provided by the patient's significant others. Subjective and objective data that should be obtained from a patient with lung cancer are described in Table 27.18.

Nursing Diagnoses

Nursing diagnoses for the patient with lung cancer may include:

- Impaired airway clearance
- Impaired breathing
- Impaired gas exchange
- Anxiety

Planning

The overall goals are that the patient with lung cancer will have (1) adequate airway clearance, (2) effective breathing patterns, (3) adequate oxygenation of tissues, (4) minimal to no discomfort, and (5) a realistic outlook about treatment and prognosis.

Nursing Implementation

Health Promotion

The best way to halt the epidemic of lung cancer is to prevent people from smoking, help smokers stop smoking, and decrease exposure to environmental pollutants. Because most smokers start in the teenage

years, prevention of teen smoking has the most significant role in reducing the incidence of lung cancer. A wealth of material is available to the smoker who is interested in smoking cessation. (See Chapter 10.)

Modeling healthy behavior by not smoking, promoting smoking cessation programs, and actively supporting education and policy changes related to smoking are important nursing activities. Many changes have occurred because of the recognition that secondhand smoke is a health hazard. Laws prohibit smoking in most public places and limit public smoking to designated areas. Most hospital environments are now completely smoke free, prohibiting smoking by employees and patients. A new trend is for hospitals to refuse employment to anyone testing positive for nicotine.

TABLE 27.18 Nursing AssessmentLung Cancer

Subjective Data

Important Health Information

Past health history: Exposure to secondhand smoke, airborne carcinogens (e.g., asbestos, radon, hydrocarbons), or other pollutants. Urban living environment. Chronic lung disease (e.g., TB, COPD, bronchiectasis). History of cancer.

Medications: Cough medicines, bronchodilators, expectorants, or other respiratory medications

Functional Health Patterns

Health perception–health management: Smoking history, including what was smoked, amount per day, and number of years. Family history of lung cancer. Frequent respiratory tract infections

Nutritional-metabolic: Anorexia, nausea, vomiting, weight loss,

dysphagia (late). *Activity-exercise:* Fatigue. Persistent cough (productive or nonproductive). Dyspnea at rest or with exertion, hemoptysis (late symptom)

Cognitive-perceptual: Chest pain or tightness, shoulder and arm pain, headache, bone pain (late symptom)

Objective Data

General

Fever, nose and/or throat infection, neck and axillary lymphadenopathy, paraneoplastic syndrome (e.g., syndrome of inappropriate ADH secretion)

Integumentary

Edema of neck and face (superior vena cava syndrome), digital clubbing. Jaundice (liver metastasis).

Respiratory

Wheezing, hoarseness, stridor, dyspnea on exertion (unilateral diaphragm paralysis), pleural effusions (late signs)

Cardiovascular

Pericardial effusion, cardiac tamponade, dysrhythmias (late signs)

Neurologic

Confusion, disorientation, unsteady gait (brain metastasis)

Musculoskeletal

Pathologic fractures, muscle wasting (late)

Possible Diagnostic Findings

Observance of lesion on chest x-ray, CT scan, or PET scan. MRI findings of vertebral, spinal cord, or mediastinal invasion. Positive sputum or bronchial washings for cytologic studies. Positive fiberoptic bronchoscopy and biopsy findings

ADH, Antidiuretic hormone; *PET,* positron emission tomography.

Acute Care

Care of the patient with lung cancer initially involves support and reassurance during diagnostic evaluation. It is important to recognize the multiple stressors that occur when someone receives a lung cancer diagnosis. The stress response is a normal and adaptive response but can become detrimental when stress is overwhelming and intense. Patients have the stress of their symptoms, including dyspnea and cough. Diagnostic and therapeutic interventions provide more stress by placing patients in unfamiliar environments with unusual and perhaps painful procedures. Emotional stressors include waiting for test results and awareness of the high mortality rate associated with lung cancer and the causal effect of cigarette smoking. Worries about role performance and ability to care for their family while undergoing cancer treatment provide further stress. Carefully assess the patient since each will have unique stressors. The insight gained will help the patient and caregiver cope with the stress of both illness and treatment.

Care of the patient undergoing chest surgery is discussed later in this chapter on pp. 529–530. Care of the patient undergoing radiation therapy and chemotherapy is discussed in Chapter 15. Individualized

care depends on the plan for treatment. Assessment and intervention in symptom management are pivotal, as is teaching the patient to recognize signs and symptoms that may indicate progression or recurrence of disease. Teach signs and symptoms to report (e.g., hemoptysis, dysphagia, chest pain, hoarseness).

Provide patient comfort, teach methods to reduce pain, monitor for side effects of prescribed drugs, foster appropriate coping strategies for both the patient and caregiver, assess smoking cessation readiness, and help the patient access resources to deal with the illness.

Check Your Practice

You are completing discharge teaching with a 72-yr-old woman who had a lobectomy for NSCLC. She tells you, "I'm not going to give up smoking my cigarettes because I am just going to die anyhow. I might as well enjoy smoking while I still can."

- How would you respond?

Ambulatory Care

Counseling patients on smoking cessation and prevention is essential in decreasing morbidity and mortality risks associated with lung cancer. Encourage the patient and family to provide a smoke-free environment. This may include smoking cessation for multiple family members. If the treatment plan includes home O_2, the teaching plan must include the safe use of O_2.

For many patients with lung cancer, little can be done to significantly prolong their lives. Radiation therapy and chemotherapy can provide palliative relief from distressing symptoms. Constant pain may become a major problem. Measures used to relieve pain are discussed in Chapter 8. Care of the patient with cancer is discussed in Chapter 15. The palliative care team should be involved as the patient and family move toward the end of life (see Chapter 9). The team can

provide information about disability, financial planning, and community resources for end-of-life care, such as hospice and home care.

Evaluation

The expected outcomes are that the patient with lung cancer will:

- Have adequate breathing patterns
- Maintain adequate oxygenation
- Have minimal to no pain
- Convey feelings openly and honestly, with a realistic attitude about prognosis

Other Types of Lung Tumors

SCLC and NSCLC account for 95% of lung tumors. The other 5% include:

- *Hamartomas,* the most common benign tumor, is a slow-growing congenital tumor composed of fibrous tissue, fat, and blood vessels.
- *Mucous gland adenoma* is a benign tumor arising in the bronchi that consists of columnar cystic spaces.
- *Mesotheliomas* are either malignant or benign and start in the visceral pleura. Malignant mesotheliomas are associated with exposure to asbestos. Benign mesotheliomas are localized lesions.

Secondary metastases from other cancers can occur. Cancer cells from another part of the body reach the lungs through the pulmonary capillaries or lymphatic network. The main cancers that spread to the lungs often start in the breast, GI, or genitourinary tract.

Chest Trauma and Thoracic Injuries

Traumatic injuries to the chest contribute to many deaths. Chest injuries range from simple rib fractures to cardiorespiratory arrest. We describe the primary mechanisms of injury responsible for chest trauma as either blunt trauma or penetrating trauma.

Blunt trauma occurs when the chest strikes or is struck by an object. The impact can cause shearing and compression of chest structures. The external injury may appear minor, but internally organs may have been severely damaged. Rib and sternal fractures can lacerate lung tissue. In a high-velocity impact, shearing forces can result in laceration or tearing of the aorta. Compression of the chest may result in contusion, crush injury, and organ rupture.

Penetrating trauma is an injury in which a foreign object impales or passes through the body tissues, creating an open wound. Examples include knife wounds, gunshot wounds, and injuries with other sharp objects. Emergency care of the patient with a chest injury is outlined in Table 27.19. The most common chest emergencies and their management are described in Table 27.20.

Fractured Ribs

Rib fractures are the most common type of chest injury from blunt trauma. Ribs 5 through 9 are most often fractured because they are the least protected by chest muscles. A fractured rib that is splintered or displaced can damage the pleura, lungs, heart, and other internal organs.

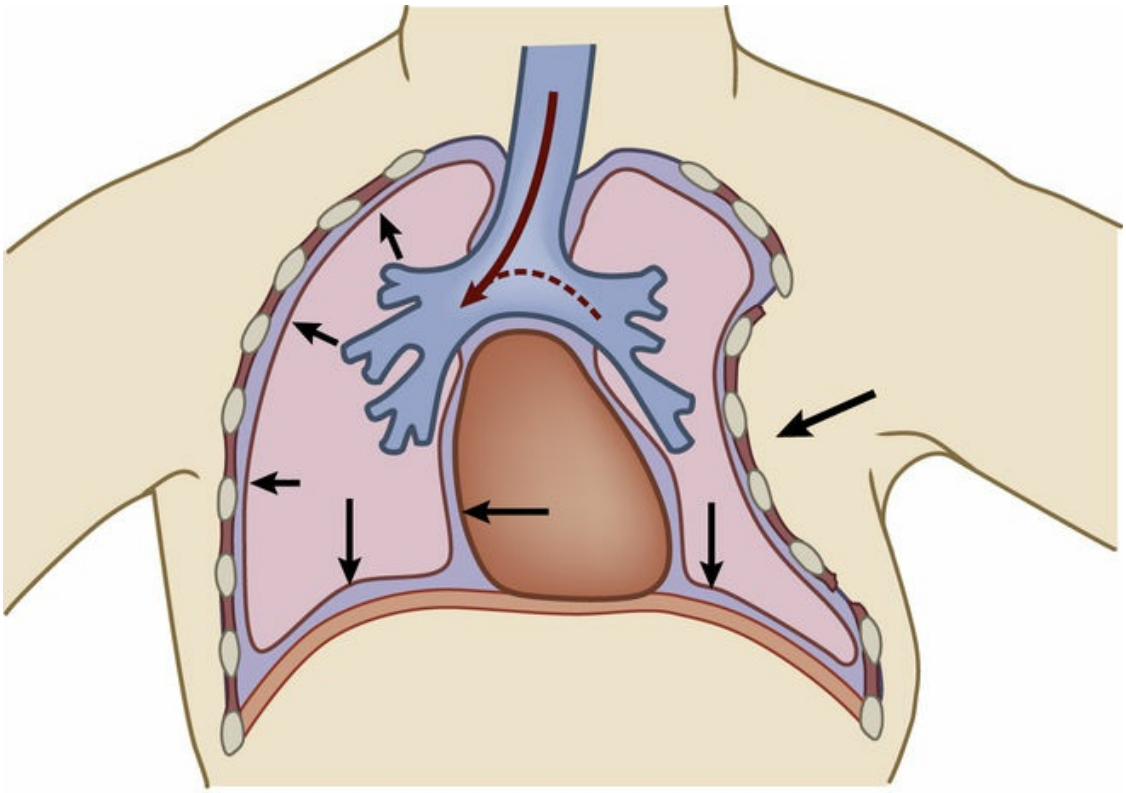
Manifestations of fractured ribs include pain at the site of injury, especially during inspiration and with coughing. The patient splints the affected area and takes shallow breaths to try to decrease the pain. Atelectasis and pneumonia may develop because of decreased chest wall movement and retained secretions.

The goal of treatment is to decrease pain so that the patient can breathe adequately and clear secretions. Strapping the chest with tape or using a thoracic binder is not recommended. These limit chest expansion and predispose the person to atelectasis. NSAIDs, opioids, and thoracic nerve blocks can be used to reduce pain and assist with deep breathing and coughing. Patient teaching should emphasize deep breathing, coughing, incentive spirometry, and appropriate use of pain medications.

TABLE 27.19 Emergency ManagementChest Trauma

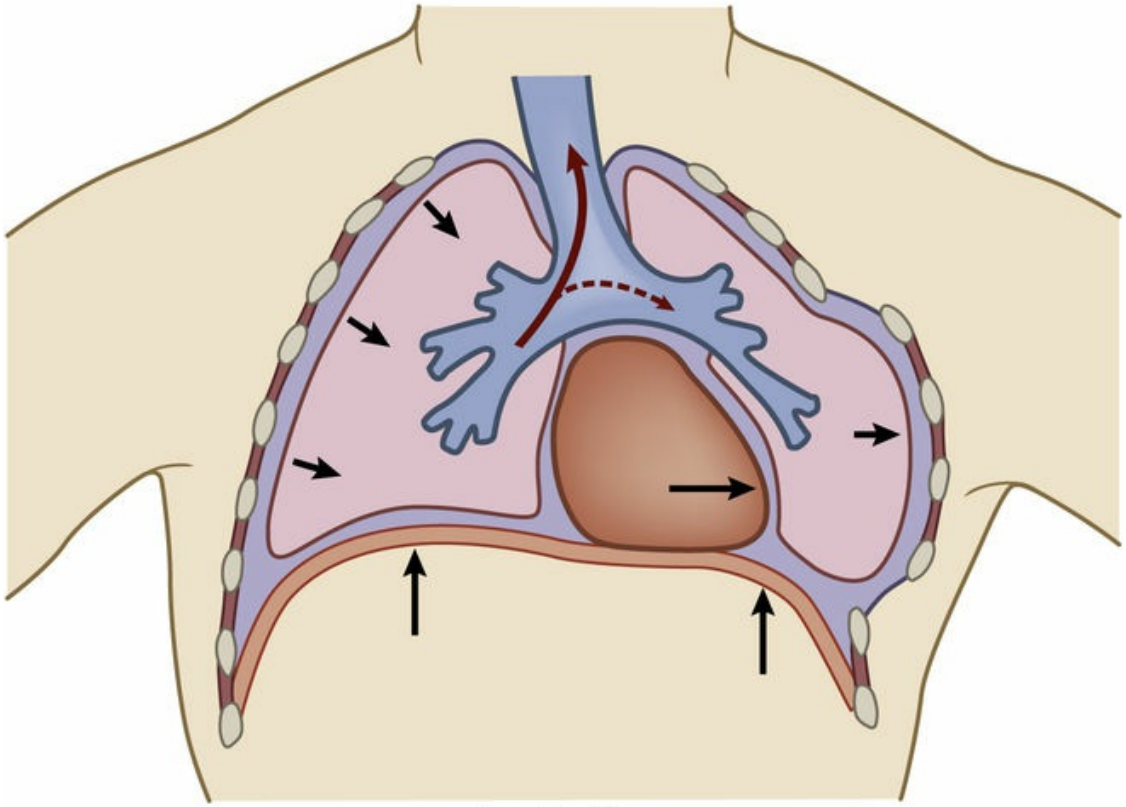
Etiology	Assessment Findings	Interventions
Blunt • **Assault with blunt object** • **Crush injury** • **Explosion** • **Fall** • **Motor vehicle collision** • **Pedestrian accident** • **Sports injury** **Penetrating** • **Arrow** • **Gunshot** • **Knife** • **Stick**	**Respiratory** • Audible air escaping from chest wound • Cough with or without hemoptysis • Cyanosis of mouth, face, nail beds, mucous membranes • Decreased breath sounds on side of injury • Decreased O_2 saturation • Dyspnea, respiratory distress • Frothy secretions • Tracheal deviation **Cardiovascular** • Asymmetric BP values in arms • Chest pain • Decreased BP • Distended neck veins • Dysrhythmias • Muffled heart sounds • Narrowed pulse pressure • Rapid, thready pulse **Surface Findings** • Abrasions • Asymmetric chest movement • Bruising • Contusions • Lacerations • Open chest wound • Subcutaneous emphysema	**Initial** • If unresponsive, immediately assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Apply high-flow O_2 to keep SpO_2 >90%. • Establish IV access with 2 large-bore catheters. Begin IV fluid resuscitation as appropriate. • Remove clothing to assess injury. • Cover sucking chest wound with nonporous dressing taped on 3 sides (vent dressing). • Stabilize impaled objects with bulky dressings. *Do not remove object.* • Assess for life-threatening injuries and treat appropriately. • Place patient in a semi-Fowler's position if breathing is easier *after* cervical spine injury has been ruled out. • Give small amounts of analgesia as needed for pain and to help with breathing. • Prepare for emergency needle decompression if tension pneumothorax or cardiac tamponade present. **Ongoing Monitoring** • Monitor level of consciousness, vital signs, O_2 saturation, cardiac rhythm, respiratory status, and urine output. • Anticipate intubation for respiratory distress. • Release vent dressing if tension pneumothorax develops after sucking chest wound is covered.

TABLE 27.20 Emergency ManagementChest Injuries



Injury and Description	Manifestations	Intervention
Cardiac Tamponade		
Blood rapidly collects in pericardial sac, compresses myocardium because pericardium does not stretch, and prevents ventricles from filling.	Muffled, distant heart sounds, hypotension, neck vein distention, increased central venous pressure	Medical emergency. Pericardiocentesis with surgical repair as appropriate.
Flail Chest		
Fracture of 2 or more adjacent ribs in 2 or more places with loss of chest wall stability (Fig. 27.5).	Paradoxical movement of chest wall, respiratory distress. May be associated hemothorax, pneumothorax, pulmonary contusion	O_2 as needed to maintain O_2 saturation, analgesia. Stabilize flail segment with positive pressure ventilation (intubation and mechanical ventilation as needed). Treat associated injuries. Possible surgical fixation.
Hemothorax		
Blood in the pleural space, may or may not occur in conjunction with pneumothorax.	Dyspnea, decreased or absent breath sounds, dullness to percussion, decreased Hgb, shock (depending on blood volume lost)	Chest tube insertion with chest drainage system. Autotransfusion of collected blood, treatment of hypovolemia as needed with IV fluid, packed red blood cells.
Pneumothorax		
Air in pleural space (Fig. 27.6).	Dyspnea, decreased movement of involved chest wall, decreased or absent breath sounds on the affected side, hyperresonance to percussion	Chest tube insertion with chest drainage system.
Tension Pneumothorax		
Air in pleural space that does not escape Increased air in the pleural space shifts organs and increases intrathoracic pressure (Fig. 27.6).	Cyanosis, air hunger, extreme agitation, subcutaneous emphysema, neck vein distention, hyperresonance to percussion, tracheal deviation away from affected side (late sign)	Medical emergency: needle decompression followed by chest tube insertion with chest drainage system.

Flail Chest



Flail chest results from the fracture of 3 or more consecutive ribs, in 2 or more separate places, causing an unstable segment (Fig. 27.5). It also can be caused by fracture of the sternum and several consecutive ribs. The resulting instability of the chest wall causes paradoxical movement during breathing. The affected (flail) area moves in the opposite direction with respect to the intact part of the chest. During inspiration, the affected part is sucked in, and during expiration, it bulges out. This paradoxical chest movement prevents adequate ventilation and increases the work of breathing. The underlying injured lung may be contused, aggravating hypoxemia.

A flail chest is usually apparent on physical examination. The patient has rapid, shallow respirations and tachycardia. Movement of the thorax is asymmetric and uncoordinated. The patient may ventilate poorly and try to splint the chest to assist with breathing. Observation of abnormal chest cavity movement, palpation for crepitus near the rib fractures, and chest x-ray all assist in the diagnosis.

Initial therapy consists of ensuring adequate ventilation and supplemental O_2 therapy. The goal is to promote lung expansion and ensure adequate oxygenation. Analgesia can help promote adequate respiration. Although many patients can be managed without mechanical ventilation, intubation and ventilation may be needed. In cases of extreme chest trauma, surgical fixation of the flail segment may be done. The lung parenchyma and fractured ribs heal with time. Some patients continue to have intercostal pain several weeks after the flail chest has resolved.

Inspiration

Expiration

FIG. 27.5 Flail chest causes paradoxical respiration. On inspiration, the flail section moves inward with mediastinal shift to the uninjured side. On expiration, the flail section bulges outward with mediastinal shift to the injured side.

Pneumothorax

A **pneumothorax** is caused by air entering the pleural cavity. Normally, negative (subatmospheric) pressure exists between the visceral pleura (surrounding the lung) and parietal pleura (lining the chest cavity), known as the *pleural space.* The pleural space has a few milliliters of lubricating fluid to reduce friction when the tissues move. When air enters this space, the change to positive pressure causes a partial or complete lung collapse (Fig. 27.6). As the volume of air in the pleural space increases, lung volume decreases.

Pneumothorax can be classified as *open* (air entering through an opening in the chest wall) or *closed* (no external wound). Penetrating trauma allows air to enter the pleural space through an opening in the chest wall (Fig. 27.6). A penetrating chest wound may be referred to as a *sucking chest wound,* since air enters the pleural space through the chest wall during inspiration. A pneumothorax should be suspected after any trauma to the chest wall.

If a pneumothorax is small, mild tachycardia and dyspnea may be the only manifestations. If the pneumothorax occupies a large area, respiratory distress may be present, including short, shallow, rapid respirations; dyspnea; air hunger; and O_2 desaturation. On auscultation, breath sounds are absent over the affected area. Time permitting, a chest x-ray will show air or fluid in the pleural space and reduction in lung volume.

Types of Pneumothorax

Spontaneous Pneumothorax

A spontaneous pneumothorax typically occurs due to the rupture of small blebs (air-filled sacs) on the surface of the lung. These blebs can occur in healthy, young people or from lung disease, such as COPD, asthma, cystic fibrosis, and pneumonia. Smoking increases the risk for bleb formation. Other risk factors include being tall and thin, male gender, family history, and previous spontaneous pneumothorax.

Iatrogenic Pneumothorax

Iatrogenic pneumothorax can occur due to laceration or puncture of the lung during medical procedures. For example, transthoracic needle aspiration, subclavian catheter insertion, pleural biopsy, and transbronchial lung biopsy all have the potential to injure the lung. Barotrauma from excessive ventilatory pressure during manual or mechanical ventilation can rupture alveoli, creating a pneumothorax. Esophageal procedures may result in a pneumothorax. For example, tearing of the esophageal wall during insertion of a gastric tube can allow air from the esophagus to enter the mediastinum and pleural space.

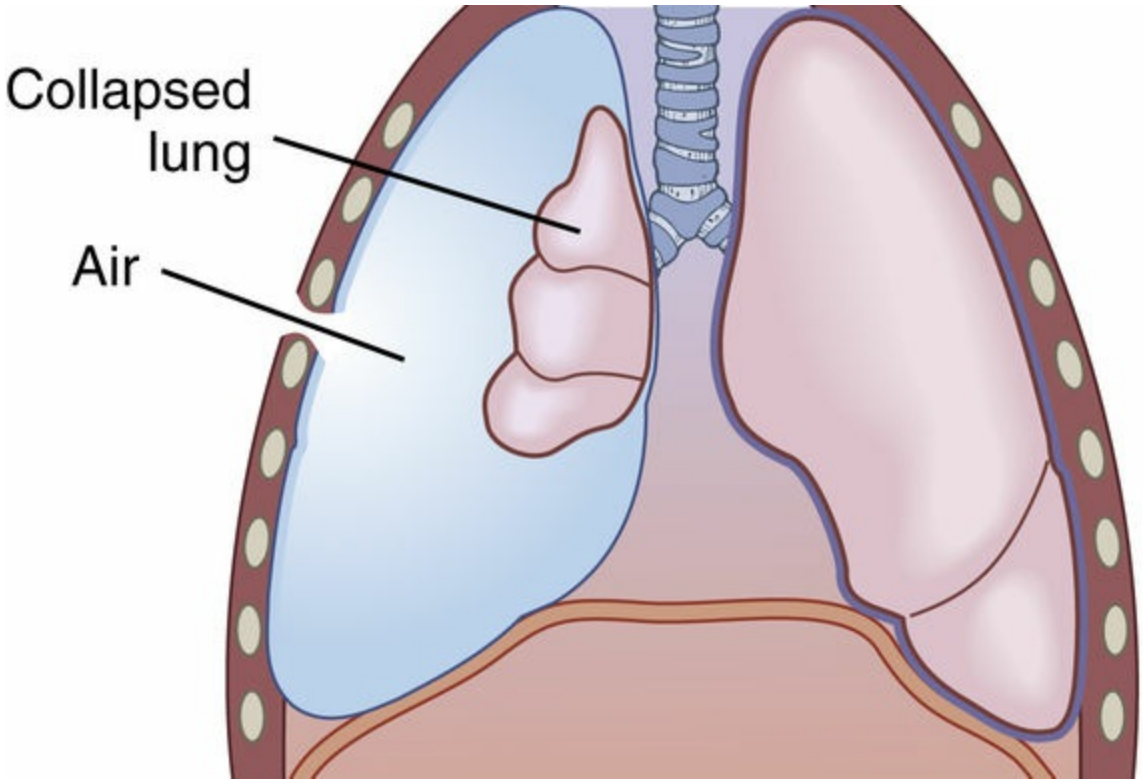


FIG. 27.6 Open pneumothorax resulting from collapse of lung due to disruption of chest wall and outside air entering.

Tension Pneumothorax

Tension pneumothorax occurs when air enters the pleural space but

cannot escape. The continued accumulation of air in the pleural space causes increasingly elevated intrapleural pressures. This results in compression of the lung on the affected side and pressure on the heart and great vessels, pushing them away from the affected side (Fig. 27.7). The mediastinum shifts toward the unaffected side, compressing the "good" lung, which further compromises oxygenation. As the pressure increases, venous return decreases and cardiac output falls.

Tension pneumothorax may result from either an open or a closed pneumothorax. In an open chest wound, a flap may act as a one-way valve. Thus air can enter on inspiration but cannot escape. Tension pneumothorax can occur with mechanical ventilation and resuscitative efforts. It can also occur if chest tubes are clamped or become blocked in a patient with a pneumothorax. Unclamping the tube or relieving the obstruction may correct this situation.

Tension pneumothorax is a medical emergency. It affects both the respiratory and cardiovascular systems. Manifestations include severe dyspnea, marked tachycardia, tracheal deviation, decreased or absent breath sounds on the affected side, neck vein distention, cyanosis, and profuse diaphoresis. If the tension in the pleural space is not relieved, the patient is likely to die from inadequate cardiac output or severe hypoxemia.

Hemothorax

Hemothorax is an accumulation of blood in the pleural space from injury to the chest wall, diaphragm, lung, blood vessels, or mediastinum. When it occurs with pneumothorax, it is called a *hemopneumothorax*. The patient with a traumatic hemothorax needs immediate insertion of a chest tube for evacuation of the blood. Recovered blood can be reinfused for a short time after the injury. (Autotransfusion is discussed in Chapter 30.)

Chylothorax

Chylothorax is the presence of lymphatic fluid in the pleural space. The thoracic duct is disrupted either traumatically or from cancer,

allowing lymphatic fluid to fill the pleural space. This milky white fluid is high in lipids. Normal lymphatic flow through the thoracic duct is 1500 to 2500 mL/day. This amount can be increased up to 10-fold after ingestion of fats. Some cases heal with conservative treatment (chest drainage, bowel rest, dietary modifications). Octreotide may reduce the flow of lymphatic fluid. Surgery (thoracic duct ligation) and pleurodesis (the artificial production of adhesions between the parietal and visceral pleura) are options for refractory cases.

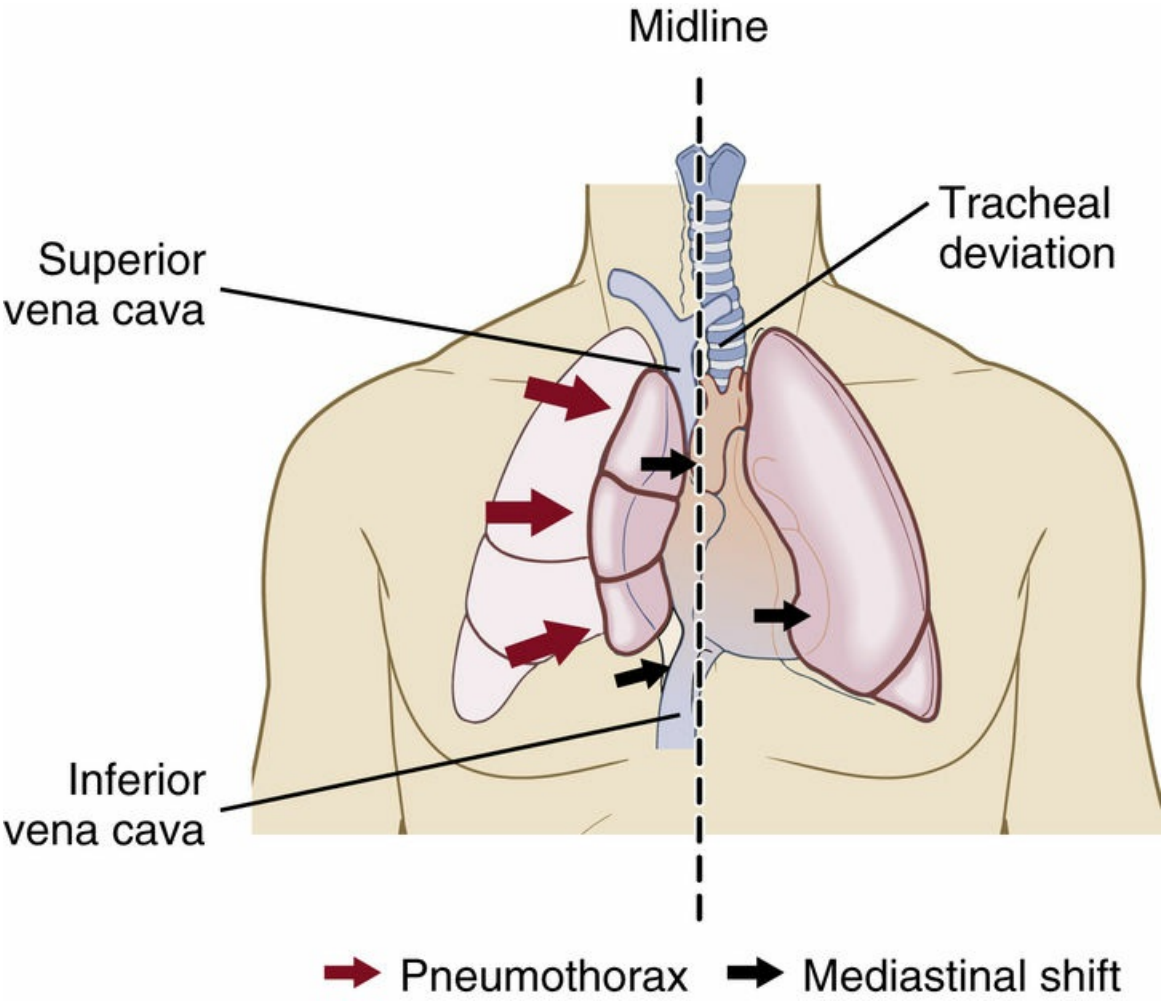

FIG. 27.7 Tension pneumothorax. As pleural pressure on the affected side increases, mediastinal displacement ensues, causing respiratory and cardiovascular compromise. Tracheal deviation is an external (but late) manifestation of the mediastinal shift.

Interprofessional Care

Treatment of a pneumothorax depends on its severity, underlying cause, and hemodynamic stability of the patient. If the patient is stable and has minimal air and/or fluid accumulated in the intrapleural space, no treatment may be needed since the condition may resolve spontaneously.

Emergency treatment consists of covering the wound with an occlusive dressing that is secured on 3 sides (vent dressing). During inspiration, as negative pressure is created in the chest, the dressing pulls against the wound, preventing air from entering the pleural space. During expiration, as the pressure rises in the pleural space, the dressing is pushed out and air escapes through the wound and from under the dressing. If the object that caused the open chest wound is still in place, do not remove it. Stabilize the impaled object with a bulky dressing. Wait until an HCP is present or arrange transport to the nearest medical facility.

The most definitive and common treatment of pneumothorax and hemothorax is to insert a chest tube and connect it to water-seal drainage. Repeated spontaneous pneumothorax may need surgical treatment with a partial pleurectomy, stapling, or pleurodesis to promote adherence of the pleurae to one another. Tension pneumothorax is a medical emergency, requiring urgent needle decompression followed by chest tube insertion to water-seal drainage.

Chest Tubes and Pleural Drainage

If enough fluid or air accumulates in the pleural space, the normally negative subatmospheric pressure becomes positive and the lungs collapse. Inserting a chest tube can drain the pleural space, reestablish negative pressure, and allow for proper lung expansion.

Chest tubes are about 20 in (51 cm) long and vary in size from 12F to 40F. The size inserted depends on the patient's condition. Large (36F to 40F) tubes are used to drain blood, medium (24F to 36F) tubes are used to drain fluid, and small (12F to 24F) tubes are used to drain air. Pigtail tubes are very small (10F to 14F) tubes with a curly end designed to keep them in place. Pigtail tubes are a safe and effective alternative to larger-bore chest tubes for treatment of pneumothorax.

Chest Tube Insertion

Insertion of a chest tube can take place in the ED, the operating room, or at the patient's bedside. Time permitting, a chest x-ray is used to confirm the affected side. The patient is positioned with the arm raised above the head on the affected side to expose the midaxillary area, the standard site for insertion. Elevate the patient's head 30 to 60 degrees, when possible, to lower the diaphragm and reduce the risk for injury.

The area is cleansed with an antiseptic solution. The HCP infiltrates the chest with a local anesthetic and makes a small incision over a rib. The chest tube is advanced up and over the top of the rib to avoid the intercostal nerves and blood vessels that are behind the rib inferiorly (Fig. 27.8). Once inserted, the HCP secures (sutures) the tube in place and closes the incision with sutures. The tube is connected to a pleural drainage system (Fig. 27.9). The wound is covered with an occlusive dressing. Most HCPs prefer to seal the wound around the chest tube with petroleum (airtight) gauze. Proper tube placement is confirmed by chest x-ray.

FIG. 27.8 Placement of chest tubes.

The insertion of a chest tube and its presence in the pleural space are painful. Monitor the patient's comfort frequently and use appropriate pain-relieving interventions.

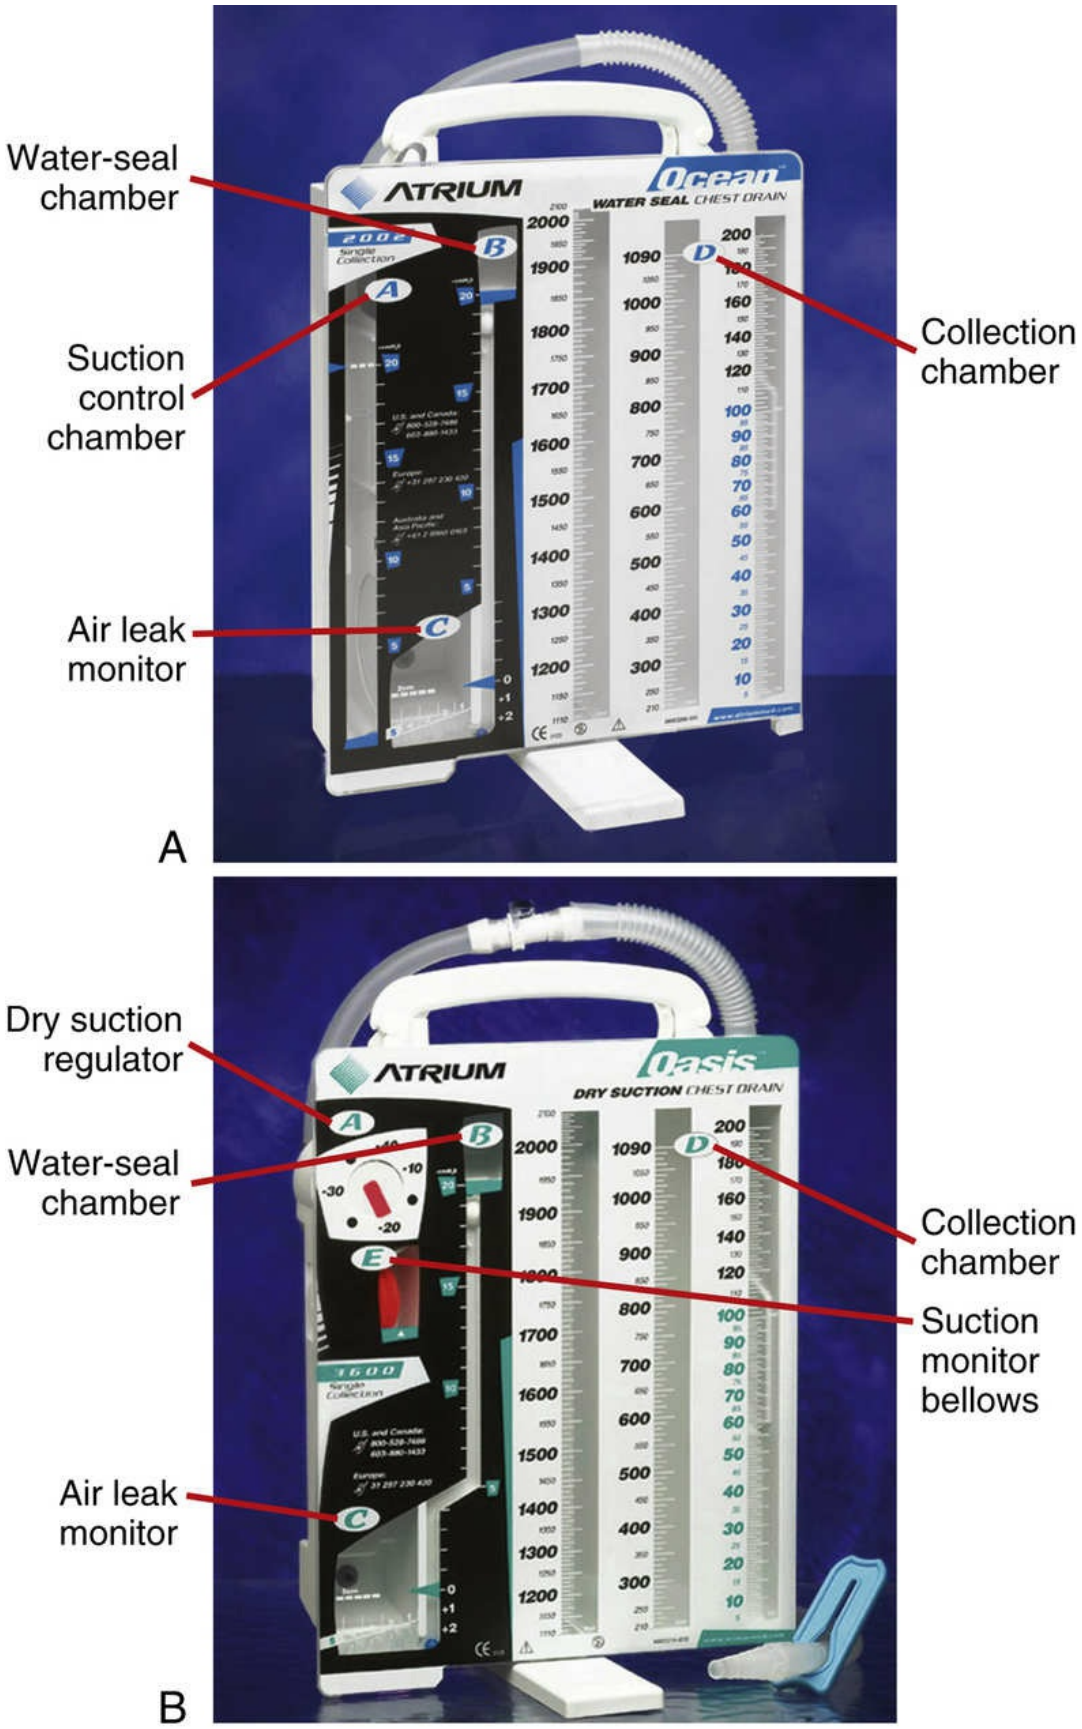
Flutter or Heimlich Valve

A flutter valve (also called the *Heimlich valve*) is used to remove air from the pleural space (Fig. 27.10). This device consists of a one-way rubber valve within a rigid plastic tube. It is attached to the external end of the chest tube. It has 2 nozzles. The inlet nozzle allows the air to pass in the valve through the chest drainage tube attached to it. The outlet nozzle allows the air to pass to the environment or a collecting device during expiration. During inspiration, when pressure in the chest decreases, the valve closes. During expiration, when intrathoracic pressure increases, the valve closes.

The flutter valve can be used for small to moderate-sized pneumothorax. It also allows for patient mobility. The smaller drainage bag can be hidden under the clothes while the patient ambulates. Drainage bags attached to the flutter valve must have a vent to the atmosphere to prevent a tension pneumothorax. This is done by simply cutting a small slit in the top of any drainage bag that does not have a built-in vent. Patients may go home with a flutter valve in place.

Pleural Drainage

A chest tube is usually attached to a drainage device or chamber to collect fluid, air, and/or blood from the chest cavity. Several different disposable chest drainage units are currently available. All drainage units have 3 basic compartments (Fig. 27.9).



Water-seal chamber
Suction control chamber
Air leak monitor
Collection chamber
ATRIUM
Ocean
WATER SEAL CHEST DRAIN

DRY SUCTION CHEST DRAIN
B

FIG. 27.9 Chest drainage unit. Both units have 3 chambers: (1) collection chamber; (2) water-seal chamber; and (3) suction control chamber. Suction control chamber requires a connection to a wall suction source that is dialed up higher than the prescribed suction for the suction to work. **A,** Water suction. This unit uses water in the suction control chamber to control the wall suction pressure. **B,** Dry suction. This unit controls wall suction by using a regulator control dial. From Atrium Medical Corporation, Hudson, NH.

The *first compartment,* or collection chamber, receives fluid and air from the pleural space. The drained fluid stays in this chamber while expelled air vents to the second compartment. The *second compartment,* the water-seal chamber, contains 2 cm of water, which acts as a one-way valve. Incoming air enters from the collection chamber and bubbles up through the water. The water prevents backflow of air into the patient. Brisk bubbling of air often occurs in this chamber when a pneumothorax is first evacuated. Intermittent bubbling during exhalation, coughing, or sneezing (when the patient's intrathoracic pressure is increased) may be seen as long as there is air in the pleural space. Eventually, as the air leak resolves and the lung becomes more fully expanded, bubbling ceases.

Normal fluctuation of the water within the water-seal chamber is called *tidaling*. This up and down movement of water in concert with respiration reflects intrapleural pressure changes during inspiration and expiration. If tidaling stops suddenly, assess the chest tube as this may signify an occluded chest tube. As the lung reexpands, tidaling gradually slows then eventually stops.

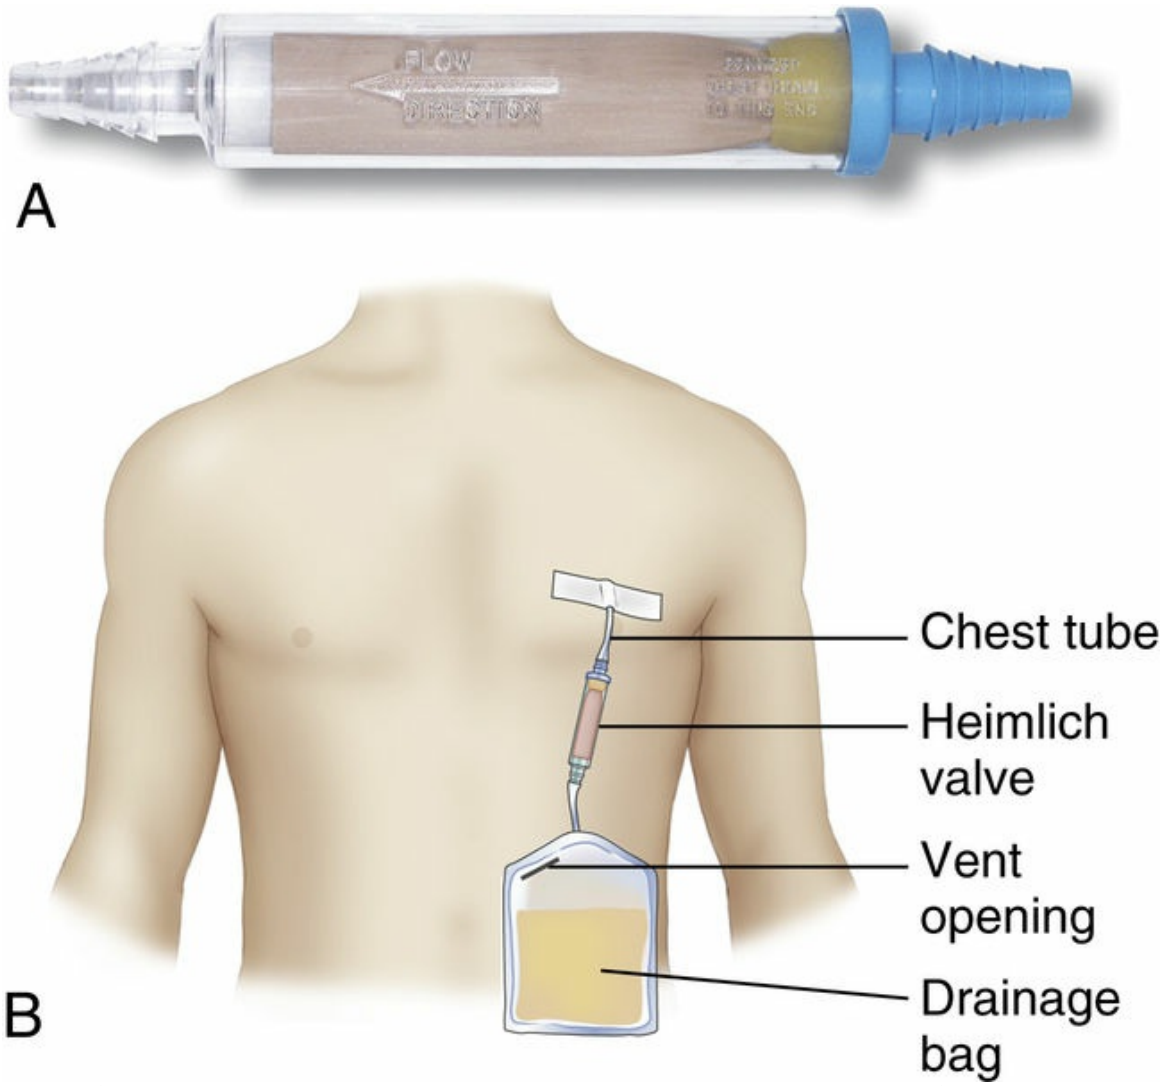

FIG. 27.10 **A,** Heimlich chest drain valve is a specially designed flutter valve that is used in place of a chest drainage unit for small uncomplicated pneumothorax with little or no drainage and no need for suction. The valve allows for escape of air but prevents the reentry of air into the pleural space. **B,** Placement of valve between chest tube and vented drainage bag, which can be worn under a person's clothes. *A,* Courtesy and © Becton, Dickinson and Company.

The *third compartment,* the suction control chamber, applies suction to the chest drainage unit. There are 2 main types of suction control: water and dry. The water suction control chamber uses a column of water to control the amount of suction from the wall regulator.

The chamber is typically filled with 20 cm of water. The amount of suction applied to the chest drainage unit is regulated by the amount of water in this chamber and not by the amount of suction applied to

the system. An increase in wall suction does not result in an increase in negative pressure to the system because any excess suction merely draws in air through the vent on top of the third chamber. The suction pressure is usually ordered to be −20 cm H_2O. Higher pressures (−40 cm H_2O) are sometimes needed to evacuate the pleural space. Lower pressure (−10 cm H_2O) may be used for frail and older patients at risk for tissue damage with higher pressures. When the negative pressure generated by the suction source exceeds the set –20 cm H_2O, air from the atmosphere enters the chamber through a vent on top of the chest drainage unit and the air bubbles up through the water, causing a suction-breaker effect. As a result, excess pressure is relieved.

To start suction, adjust (increase) the vacuum source until gentle bubbling is present in the third chamber. Excessive bubbling does not increase the amount of suction but does increase the rate of evaporation of the water and the amount of noise made by the device.

Dry suction chest drainage systems do not contain water. They often have a visual alert that shows if the suction is working. It uses either a restrictive device or a regulator to dial the desired negative pressure; this is internal in the chest drainage system. To increase the suction pressures, turn the dial on the drainage system. Increasing the vacuum source does not increase the pressure. When decreasing suction, depress the manual vent to reduce excess vacuum to the lower prescribed level.

A variety of disposable plastic chest drainage systems are available. Manufacturers include directions for set-up and use with each unit.

Informatics in Practice

Chest Drainage System

- You find yourself in a situation in which you need to set up a chest drainage system. You have not done this since simulation in nursing school.

- On the Internet, find a procedure manual or watch a video or podcast on this procedure.

Nursing Management: Chest Drainage

General guidelines for nursing care of the patient with chest tubes and water-seal drainage systems are shown in Table 27.21.

Clamping of chest tubes during transport or when the tube is accidentally disconnected is no longer advocated. The danger of rapid accumulation of air in the pleural space, causing tension pneumothorax, is far greater than that of a small amount of atmospheric air that enters the pleural space. If a chest tube becomes disconnected, the immediate priority is to reestablish the water-seal system. In some agencies, when disconnection occurs, the chest tube is immersed in sterile water to act as a water seal until a new system can be set up and chest drainage reestablished. It is important to know the unit protocol, the clinical situation (whether an air leak exists), and HCP preference before any chest tube clamping occurs.

Chest tubes may be momentarily clamped to change the drainage apparatus or to check for air leaks. Appearance of a new air leak warrants assessment of the drainage system to identify whether the air leak is coming from the patient or the system. Again, you must be familiar with the policies and procedures of your agency about specific clinical situations when you may clamp a chest tube.

Closely monitor the patient for complications associated with chest tube placement and drainage. If volumes from 1 to 1.5 L of fluid and/or blood are removed rapidly, reexpansion pulmonary edema or severe, symptomatic hypotension can occur. Subcutaneous emphysema can occur from air leaking into the tissue surrounding the chest tube insertion site. A “crackling” sensation will be felt when palpating the skin. A small amount of subcutaneous air is harmless and will be reabsorbed. However, severe subcutaneous emphysema can cause drastic swelling of the head and neck with potential airway compromise.

Meticulous sterile technique during dressing changes can reduce the incidence of infected chest tube insertion sites. Nursing care and patient teaching can minimize the risk for atelectasis and shoulder

stiffness. Encourage coughing, deep breathing, incentive spirometer use, and range-of-motion exercises. Inspect the integrity of the chest tube system. Monitor the color and amount of drainage hourly in the first few hours after chest tube insertion. Drainage greater than 200 mL in the first hour, development of subcutaneous emphysema, or any signs and symptoms of respiratory distress should be reported to the HCP at once.

Check Your Practice

You are caring for a 26-yr-old male patient who has chest injuries from a motorcycle accident. He has 2 chest tubes in place that are each attached to a chest drainage system. While turning him, you accidentally disconnect one of the chest tubes from the drainage system.

- What is your most immediate priority?

TABLE 27.21 Chest Tubes and Water-Seal Drainage

Set-Up and Insertion

1. Make sure patient is aware of the procedure and informed consent is obtained.
2. Gather equipment.
    - Thoracotomy or chest tube insertion tray
    - Chest drainage unit (CDU)
    - Chest tube
    - Bottle of sterile water
    - 1% lidocaine
    - Suction tubing and collection container

- Occlusive dressing

3. Prepare CDU.
    - *Wet suction:* Add sterile water to 2-cm mark in water-seal chamber and to 20-cm mark (or as ordered) in suction control chamber.
    - *Dry suction:* Add sterile water to the fill line of the air leak meter. Attach suction tubing and increase suction until the bellows-like float moves across the display window.
4. Position and support the patient to minimize movement during procedure.

Drainage System

1. Keep all tubing loosely coiled below chest level. Tubing should drop straight from bed or chair to drainage unit. Do not let it be compressed.
2. Keep all connections between chest tubes, drainage tubing, and the drainage collector tight, and tape all connections.
3. Observe for air fluctuations (tidaling) and bubbling in the water-seal chamber.
    - If tidaling (rising with inspiration and falling with expiration in the spontaneously breathing patient) is not seen, the drainage system is blocked, the lungs are reexpanded, or the system is attached to suction.
    - If bubbling increases, there may be an air leak in the drainage system or a leak from the patient (bronchopleural leak).
4. If the chest tube is connected to suction, disconnect from wall suction to check for tidaling.
5. Suspect a system leak when bubbling is continuous.
    - Retape tubing connections.
    - Ensure that dressing is air occlusive.
    - If leak persists, briefly clamp the chest tube at the patient's chest. If the leak stops, the air is coming from

the patient*
- If the air leak persists, briefly and methodically move the clamps down the tubing away from the patient until the air leak stops. The leak will then be present between the last 2 clamp points. If the air leak persists all the way to the drainage unit, replace the unit.*

6. High fluid levels in the water seal indicate residual negative pressure.
    - The chest system may have to be vented by using the high-negativity release valve available on the drainage system to release residual pressure from the system.
    - Do not lower water-seal column when wall suction is not operating or when patient is on gravity drainage.

Patient's Clinical Status

1. Monitor the patient's clinical status. Assess vital signs, lung sounds, and pain.
2. Assess for reaccumulation of air and fluid in the chest (↓ or absent breath sounds), significant bleeding (>100 mL/hr), infection at chest tube insertion site (drainage, erythema, fever, ↑ WBCs), or poor wound healing. Notify HCP for management plan.
3. Evaluate for subcutaneous emphysema at chest tube site.
4. Encourage the patient to breathe deeply periodically to promote lung expansion and encourage range-of-motion exercises to the shoulder on the affected side. Encourage use of incentive spirometry every hour while awake to prevent atelectasis or pneumonia.

Chest Drainage

1. Never elevate the drainage system to the level of the patient's chest because this will cause fluid to drain back into the lungs.

Change the unit if the collection chamber is full. Do not try to empty it.
2. Mark the time of measurement and the fluid level on the drainage unit according to the unit standards. Report any change in the quantity or characteristics of drainage (e.g., clear yellow to bloody) to the HCP and record the change. Notify HCP if >100 mL/hr drainage.
3. Check the position of the chest drainage container. If the drainage system is overturned and the water seal is disrupted, return it to an upright position and encourage the patient to take a few deep breaths, followed by forced exhalations and cough maneuvers.
4. If the drainage system breaks, place the distal end of the chest tubing connection in a sterile water container at a 2-cm level as an emergency water seal.
5. Position tubing so that drainage flows freely.

Monitoring Wet Versus Dry Suction Chest Drainage Systems

Suction Control Chamber in Wet Suction System

1. Keep the suction control chamber at the right water level by adding sterile water as needed to replace water lost to evaporation.
2. Keep the cover over the suction control chamber in place to prevent more rapid evaporation of water and to decrease the noise of the bubbling.
3. After filling the suction control chamber to the ordered suction amount (generally 20 cm H_2O suction), connect the suction tubing to the wall suction.
4. Dial the wall suction regulator until there is continuous gentle bubbling in the suction control chamber (generally 80 to 120 mm Hg). Vigorous bubbling is not necessary and will increase the rate of evaporation.

5. If there is no bubbling in the suction control chamber, (1) there is no suction, (2) suction is not high enough, or (3) the pleural air leak is so large that suction is not high enough to evacuate it.

Suction Control Chamber in Dry Suction System (see manufacturer's directions)

1. After connecting patient to system, turn the dial on the chest drainage system to amount ordered (generally −20 cm H_2O pressure), connect suction tubing to wall suction source, and increase the suction until the float appears in the window of the CDU.
2. If ordered to decrease suction, turn the dial down, depress the high-negativity vent, and assess for a rise in the water level of the water-seal chamber.

Chest Tube Dressings

1. Change dressing according to unit protocol and HCP preference.
2. Remove old dressing carefully. Assess the site for inflammation or infection and culture site as needed.
3. Cleanse the site according to protocol, maintaining strict sterile asepsis.
4. Redress with occlusive dressing. Some HCPs prefer the use of petroleum gauze dressing around the tube to prevent air leak. Date the dressing and document dressing change.

---

* As per agency policy and procedures.

Chest Tube Removal

Chest tubes are removed when the lungs are reexpanded and fluid drainage has ceased or is minimal. In some centers, suction is discontinued, and the chest drain is allowed to drain by gravity for 24 hours before the tube is removed. Give the patient pain medication about 30 to 60 minutes before tube removal.

Gather dressing supplies, including petroleum jelly and dry gauze dressing. Explain the procedure to the patient. In most settings, the tube is removed by the HCP or an advanced practice nurse. The suture is cut, and with the patient holding his or her breath or bearing down (Valsalva maneuver), the tube is removed. The site is immediately covered with the airtight dressing to prevent air from entering the pleural space. The pleura will seal off, and the wound usually heals in a few days. A chest x-ray is done 30 to 60 minutes after chest tube removal to evaluate for pneumothorax or fluid accumulation. Observe the wound for drainage and reinforce the dressing if needed. Monitor and record vital signs. Assess the patient for respiratory distress, which may signify a recurrence of the original problem.

Chest Surgery

Chest surgery is done for various reasons, including lung, heart, vascular, and esophageal disorders. The most common types of chest surgery are described in Table 27.22.

Surgical Procedures

Thoracotomy

A **thoracotomy** is a surgical incision into the chest to gain access to the heart, lungs, esophagus, thoracic aorta, or anterior spine. Two common approaches to a thoracotomy are the median sternotomy and lateral thoracotomy. The median sternotomy involves splitting the sternum. It is primarily used for surgery involving the heart. The lateral thoracotomy incision can be done using a posterolateral or anterolateral incision. The *posterolateral incision* is used for most surgeries involving the lung. The incision is made from front to back at the level of the 4th, 5th, or 6th intercostal space. Strong mechanical retractors are used to separate the ribs and gain access to the lung. The *anterolateral incision* is made in the 4th or 5th intercostal space from the sternal border to the midaxillary line. This procedure is often done for surgery or trauma victims, mediastinal operations, and wedge resections of the upper and middle lobes of the lung.

TABLE 27.22 Chest Surgeries

Type	Description	Indications
Decortication		
Removal or stripping of thick, fibrous membrane from visceral pleura	• Need chest tubes postoperatively	Empyema or other inflammatory process unresponsive to conservative management
Exploratory Thoracotomy		
Incision into thorax to look for injured or bleeding tissues	• Need chest tubes postoperatively	Chest trauma
Lobectomy		
Removal of 1 lobe of lung	• Most common lung surgery • Lung tissue expands to fill up space left by resected lobe • Need chest tubes postoperatively	Lung cancer, bronchiectasis, TB, advanced emphysema, benign lung tumors, fungal infections
Lung Volume Reduction Surgery		
Bronchoscopic procedure	• Used to place one-way valves in airways leading to the diseased parts of the lung • Valves let air out, but not in, thus collapsing a certain segment of lungs	Advanced emphysema, α_1-antitrypsin emphysema
Open surgical procedure	• Involves reducing lung volume by multiple wedge excisions or VATS • Removes most diseased lung tissue	Emphysema, limited NSCLC
Pneumonectomy		
Removal of entire lung	• Done when lobectomy or segmental resection will not remove all diseased lung • Fluid will gradually fill space where lung was removed • May have chest tube postoperatively • Position patient on operative side to promote expansion of remaining lung	Lung cancer (most common)
Segmental Resection		
Removal of 1 or more lung segments	• Indicated for a patient unable to handle more extensive surgery • Remaining lung tissue expands to fill space • Need chest tubes postoperatively	Lung cancer, bronchiectasis
Thoracotomy (Not Involving Lungs)		
Incision into thorax for surgery on other organs	• Postoperative care related to thoracotomy and reason for surgical procedure • Need chest tubes postoperatively	Hiatal hernia repair, open heart surgery, esophageal surgery, tracheal resection, thoracic aorta repair
Video-Assisted Thoracic Surgery		
Video-assisted technique with a rigid scope with a distal lens inserted into pleura and image shown on a monitor screen	• Allows HCP to manipulate instruments passed into pleural space through separate small intercostal incisions • Done under general anesthesia in operating room • May need chest tube postoperatively	Lung biopsy, lobectomy, resection of nodules, repair of fistulas
Wedge Resection		
Removal of small, localized lesion that occupies only part of a segment	• Most conservative approach • Done to remove small peripheral nodules or for patients unable to handle more extensive surgery • Need chest tubes postoperatively	Lung biopsy, excision of small nodules

Video-Assisted Thoracic Surgery

Video-assisted thoracoscopic surgery (VATS) is a widely used, minimally invasive surgical approach. It provides a real-time 2-dimensional video image of the inside of the chest cavity. It is used for diagnosis and treatment of diseases of the pleura, pulmonary masses and nodules, mediastinal masses, and interstitial lung disease. Through

incisions just large enough to insert the instruments, the HCP can inspect the chest cavity, biopsy suspicious areas, obtain samples of fluids for analysis, and remove tissue.

VATS is increasingly being used for patients with chest trauma. The HCP can examine, diagnose, and manage injuries in both blunt and penetrating trauma, including injuries to the diaphragm. A chest tube is placed in the pleural space through 1 or more of the incisions at the end of the procedure, secured with sutures, and connected to a drainage unit in the usual manner.

The advantages of VATS include less discomfort, faster return to normal activity level, reduced length of hospital stay, lower postoperative morbidity risk, and fewer complications.[31] Patients who have marginal respiratory reserve or are too debilitated to tolerate an open thoracotomy approach may benefit from the VATS procedure.

Preoperative Care

Assess the patient's cardiopulmonary status to determine their ability to tolerate the surgery and provide a baseline reference for postoperative care. Diagnostic studies may include chest x-ray, electrocardiogram (ECG), ABGs, pulmonary function studies, blood urea nitrogen (BUN), serum creatinine, blood glucose, serum electrolytes, prothrombin time/international normalized ratio (PT/INR), activated partial thromboplastin time (aPTT), and CBC. An anesthesia consult is usually completed.

The patient should be in the best possible health and, if applicable, stop smoking before elective surgery. Anxiety associated with anticipated surgery makes smoking cessation more difficult. Provide encouragement, support, and teaching about various methods to help stop smoking before surgery (see Chapter 10).

Teach the patient what to expect after surgery. Include the use of O_2, the chance of intubation, administration of blood and IV fluids, and the purpose and function of chest tubes. Reassure the patient that adequate medication will be used to reduce pain. Explain how to use patient-controlled analgesia (PCA), if planned. Preoperative teaching

should always include exercises for effective deep breathing and use of incentive spirometry. If the patient practices these techniques before surgery, they will be easier to perform after surgery. Show the patient how to splint the incision with a pillow to promote deep breathing. Teach and have the patient provide a return demonstration of range-of-motion exercises on the surgical side (similar to those for the mastectomy patient [see Fig. 51.8]).

The thought of losing part of a vital organ is often frightening. Reassure the patient that the lungs have a large degree of functional reserve. Even after the removal of 1 lung, enough lung tissue is left to maintain adequate oxygenation. Be available to answer the patient and caregiver's questions. Answer questions openly and honestly. Encourage the expression of concerns, feelings, and questions.

Postoperative Care

The thoracotomy incision is the most painful surgical incision for patients and one of the most difficult for nurses to manage. Pain after a thoracotomy is typically intense because respiratory muscles are cut during surgery. For most chest surgeries, chest tubes are placed in the pleural space to allow for lung reexpansion. In a pneumonectomy, chest tubes may or may not be placed in the space from which the lung was removed. Adequate pain management is a priority to prevent respiratory compromise. The use of PCA, epidural infusions, and intercostal nerve blocks allows patients to breathe deeply, cough, and move the arm and shoulder on the operative side.

Nursing care priorities in the postoperative period include assessment of respiratory function, including observation of respiratory rate and effort, breath sounds, sputum volume and color, and chest tube function and drainage. Daily chest x-rays are often ordered. Assessment of pain, monitoring of temperature, and observation of the surgical site are similar to care provided for other postoperative patients (see Chapter 19). Care after thoracotomy is presented in eNursing Care Plan 27.2 (available on the website for this chapter).

Thoracentesis

Thoracentesis is aspiration of intrapleural fluid for diagnostic and therapeutic purposes. For a thoracentesis, the patient may sit on the edge of a bed and lean forward over a bedside table. A chest x-ray or ultrasound images are used to determine the optimal puncture site. The skin is cleansed with an antiseptic solution and injected with a local anesthetic. The thoracentesis needle is inserted into the intercostal space (see Fig. 25.12). Fluid is aspirated with a syringe, or tubing is connected to the needle to allow fluid to drain into a sterile container. After the fluid is removed, the needle is withdrawn, and a bandage is applied over the insertion site.

Usually no more than 1000 to 1200 mL of pleural fluid is removed at one time. Rapid removal of a large volume can result in hypotension, hypoxemia, or reexpansion pulmonary edema. A chest x-ray may be done after the procedure to assess for complications, such as pneumothorax. During and after the procedure, monitor vital signs and pulse oximetry. Observe the patient for respiratory distress.

Restrictive Respiratory Disorders

Disorders that impair the ability of the chest wall and diaphragm to move with respiration are called *restrictive respiratory disorders.* There are 2 categories: *extrapulmonary conditions,* in which the lung tissue is normal, and *intrapulmonary conditions,* in which the cause is the lung or pleura. Examples of extrapulmonary and intrapulmonary conditions that alter respiratory functioning are listed in Table 27.23. These disorders are further described in their respective chapters.

Pulmonary function tests are the best means of distinguishing between restrictive and obstructive respiratory disorders. The hallmark characteristic of a restrictive lung disorder is a reduced total lung capacity (TLC). The hallmark characteristic of an obstructive disorder is reduced forced expiratory volume (FEV_1). Mixed obstructive and restrictive disorders sometimes occur together. For example, a patient may have both asthma (an obstructive problem) and pulmonary fibrosis (a restrictive problem).

TABLE 27.23 Common Causes of Restrictive Lung Disease

Intrapulmonary Causes

Pleural Disorders

- Pleural effusion
- Pleurisy (pleuritis)
- Pneumothorax

Parenchymal Disorders

- Acute respiratory distress syndrome (ARDS)

- Atelectasis
- Interstitial lung diseases
- Pneumonia

Extrapulmonary Causes
Central Nervous System

- Head injury, central nervous system lesion (e.g., tumor, stroke)
- Opioid and barbiturate overdose

Neuromuscular System

- Amyotrophic lateral sclerosis
- Guillain-Barré syndrome
- Muscular dystrophy
- Myasthenia gravis

Chest Wall

- Kyphoscoliosis
- Obesity-hypoventilation syndrome (Pickwickian syndrome)

Atelectasis

Atelectasis is a lung condition characterized by collapsed, airless alveoli. There may be decreased or absent breath sounds and dullness to percussion over the affected area. The most common cause of atelectasis is obstruction of the small airways with secretions. This is common in bedridden patients and in postoperative abdominal and chest surgery patients. Normally the pores of Kohn (see Fig. 25.1) provide collateral passage of air from one alveolus to another. Deep inspiration opens the pores effectively. For this reason, deep-breathing exercises, coughing, incentive spirometry, and early mobility are important to prevent atelectasis and treat the patient at risk. (The prevention and treatment of atelectasis are discussed in Chapter 19.)

Pleurisy

Pleurisy (pleuritis) is an inflammation of the pleura. It can be caused by infectious diseases, cancer, autoimmune disorders, chest trauma, GI disease, and certain medications. The inflammation usually subsides with adequate treatment of the primary disease. The pain of pleurisy is typically abrupt, sharp in onset, and worse with inspiration. The patient's breathing is shallow and rapid to avoid unnecessary movement of the pleura and chest wall. A pleural friction rub may occur. This is the sound heard over areas where inflamed visceral pleura and parietal pleura rub over one another during inspiration. This sound, like a squeaking door, is usually loudest at peak inspiration. It may be heard during exhalation as well.

Treatment of pleurisy is aimed at treating the underlying disease and providing pain relief. Teach the patient to splint the rib cage when coughing. If the pain is severe, intercostal nerve blocks may be considered.

Pleural Effusion

Types

The pleural space normally holds 5 to 15 mL of fluid that acts as a lubricant between the chest wall (parietal pleura) and lungs (visceral pleura). **Pleural effusion** is an abnormal collection of fluid in this space. It is not a disease but a sign of disease. A balance among hydrostatic pressure, oncotic pressure, and capillary membrane permeability governs movement of fluid in and out of the pleural space. Fluid accumulation can be due to increased pulmonary capillary pressure, decreased oncotic pressure, increased pleural membrane permeability, or obstruction of lymphatic flow.

We classify pleural effusions as transudative or exudative depending on the protein content. A *transudate* occurs primarily in noninflammatory conditions. It is an accumulation of protein-poor, cell-poor fluid. The fluid is clear, pale yellow. These effusions are caused by (1) increased hydrostatic pressure found in HF or (2) decreased oncotic pressure (from hypoalbuminemia) found in chronic liver or renal disease. An *exudative effusion* results from increased capillary permeability due to an inflammatory reaction. They most often occur with an infection or cancer (called a malignant effusion).

An **empyema** is the collection of purulent fluid in the pleural space. It is often caused by pneumonia, TB, lung abscess, and infected surgical wounds of the chest. Treatment options include antibiotic therapy (to eradicate the causative organism), percutaneous drainage, chest tube insertion, VATS, intrapleural fibrinolytic therapy (instilled through the chest tube) to dissolve fibrous adhesions, decortication, and open window thoracostomy.

Clinical Manifestations

Common manifestations of pleural effusion are dyspnea, cough, and occasional sharp, non-radiating chest pain that is worse on inhalation. Physical examination of the chest may show decreased movement of

the chest on the affected side, dullness to percussion, and decreased breath sounds over the affected area. A chest x-ray and CT reveal the volume and location of the effusion. Indications of an empyema include the manifestations of pleural effusion as well as fever, night sweats, cough, and weight loss.

Interprofessional Care

The management of pleural effusions is to treat the underlying cause. For example, adequate treatment of HF with diuretics and sodium restriction may result in a decreased incidence of pleural effusion. The treatment of malignant effusions is more difficult. These effusions often reoccur and reaccumulate quickly after thoracentesis.

Chemical pleurodesis is done to obliterate the pleural space and prevent reaccumulation of effusion fluid. This procedure first requires chest tube drainage of the effusion. Once the fluid is drained, a chemical slurry is instilled into the pleural space. Talc is the most effective agent for pleurodesis. Other agents that can be used include doxycycline and bleomycin. The chest tube is clamped for 8 hours while the patient is turned in different positions to allow the chemical to contact the entire pleural space. After 8 hours the chest tube is unclamped and attached to a drainage unit. Chest tubes are left in place until fluid drainage is less than 150 mL/day and no air leaks are noted. Fever and chest pain are the most common side effects associated with pleurodesis.

Interstitial Lung Diseases

Interstitial lung disease (ILD), also called *diffuse parenchymal lung disease*, refers to more than 200 lung disorders in which the tissue between the air sacs of the lungs (the interstitium) is affected by inflammation or scarring (fibrosis).[32] Most ILDs are extremely rare. Many times, the cause is unknown. Two common ILDs of unknown cause are idiopathic pulmonary fibrosis and sarcoidosis. Other ILDs are caused by inhalation of occupational and environmental toxins, certain medications, radiation therapy, connective tissue disorders, cancer, and infection. Treatment is aimed at reducing exposure to the causative agent and/or treating the underlying disease process. Although scarring is irreversible, treatment with corticosteroids and immunosuppressant drugs can minimize progression. A lung transplant may be an option for some patients.

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (IPF) is a chronic, progressive disorder characterized by chronic inflammation and formation of scar tissue in the connective tissue. Risk factors include a history of cigarette smoking and exposure to wood and metal dust. IPF affects more men than women. It typically first appears between the ages of 50 and 70 years. There is no known cure for IPF.

Manifestations include exertional dyspnea; dry, nonproductive cough; clubbing of the fingers; and inspiratory crackles. Fatigue, weakness, anorexia, and weight loss may occur as the disease progresses. Chest x-ray findings are generally nonspecific. Pulmonary function tests may be abnormal, with evidence of restriction (reduced vital capacity) and impaired gas exchange. Open lung biopsy using VATS often helps to confirm the pathology and is considered the gold standard for diagnosis.

The course of IPF is variable and the prognosis is poor. The 5-year survival rate is 30% to 50% after diagnosis. Many people diagnosed with IPF are first treated with a corticosteroid (prednisone), sometimes in combination with other drugs that suppress the immune system (e.g., methotrexate, cyclosporine). Kinase inhibitor drugs, which block multiple pathways that involved with scarring, include nintedanib (Ofev) and pirfenidone (Esbriet).

O_2 therapy and pulmonary rehabilitation should be prescribed for all patients. Lung transplantation may be an option for those who meet the criteria. (Lung transplantation is discussed later in this chapter on p. 537.)

Sarcoidosis

Sarcoidosis is a chronic, multisystem granulomatous disease of unknown cause that primarily affects the lungs. The disease may also involve the skin, eyes, liver, kidney, heart, and lymph nodes. Those at higher risk include blacks and those with a family history of sarcoidosis.

Signs and symptoms vary depending on what organs are affected. Pulmonary symptoms include dyspnea, cough, and chest pain. Many patients do not have symptoms.

Staging and treatment decisions are based on pulmonary function and disease progression. Some patients have a spontaneous remission. Treatment is aimed at suppressing the inflammatory response. Patients are followed every 3 to 6 months with pulmonary function tests, chest x-ray, and CT scan to monitor disease progression.

TABLE 27.24 Causes of Pulmonary Edema

- Acute respiratory distress syndrome (ARDS)
- Altered capillary permeability of lungs: aspiration, inhaled toxins, inflammation (e.g., pneumonia), severe hypoxia, near-drowning
- Anaphylactic (allergic) reaction
- Hypoalbuminemia: nephrotic syndrome, liver disease, nutritional disorders
- Left ventricular (heart) failure
- Lymph system cancer (e.g., non-Hodgkin's lymphoma)
- Overhydration with IV fluids
- O_2 toxicity
- Unknown causes: neurogenic condition, opioid overdose, reexpansion pulmonary edema, high altitude

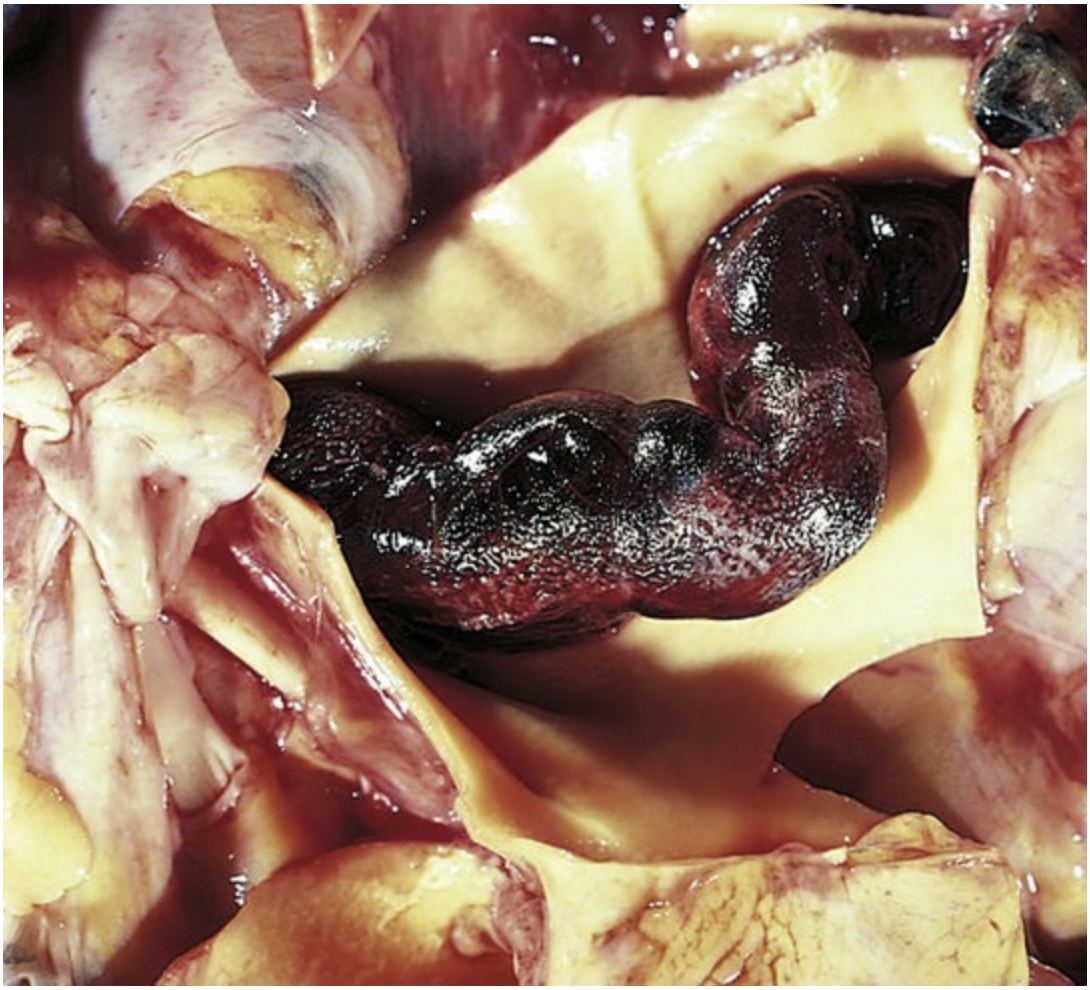

FIG. 27.11 Large embolus from the femoral vein lying in the main left and right pulmonary arteries.
From the teaching collection of the Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX. In Kumar V, Abbas AK, Aster JC, Fausto N, eds: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Vascular Lung Disorders

Pulmonary Edema

Pulmonary edema is an abnormal accumulation of fluid in the alveoli and interstitial spaces of the lungs. It is a complication of various heart and lung diseases (Table 27.24). In severe cases, pulmonary edema can be a life-threatening medical emergency. The most common cause of pulmonary edema is left-sided HF. (HF is discussed in Chapter 34.)

Pulmonary Embolism

Etiology and Pathophysiology

Pulmonary embolism (PE) is the blockage of 1 or more pulmonary arteries by a thrombus, fat or air embolus, or tumor tissue. The word *embolus* derives from a Greek word meaning "plug" or "stopper." *Emboli* are mobile clots that generally do not stop moving until they lodge at a narrowed part of the circulatory system. A PE consists of material that gains access to the venous system and then to the pulmonary circulation. The embolus travels with blood flow through ever-smaller blood vessels until it lodges and obstructs perfusion of the alveoli (Fig. 27.11). The lower lobes of the lung are most often affected.

Most PEs arise from deep vein thrombosis (DVT) in the deep veins of the legs. *Venous thromboembolism (VTE)* is the preferred term to describe the spectrum of pathologic conditions from DVT to PE (see Table 37.7). Other sites of origin of PE include femoral or iliac veins, right side of the heart (atrial fibrillation), and pelvic veins (especially after surgery or childbirth). Upper extremity DVT sometimes occurs in the presence of central venous catheters or arterial lines. These cases may resolve with the removal of the catheter. A *saddle embolus* refers to a large thrombus lodged at an arterial bifurcation.

Less common causes include fat emboli (from fractured long bones), air emboli (from improperly administered IV therapy), bacterial vegetation on heart valves, amniotic fluid, and cancer. Risk factors for PE include immobility or reduced mobility, surgery within the last 3 months (especially pelvic and lower extremity surgery), history of VTE, cancer, obesity, oral contraceptives, hormone therapy, cigarette smoking, prolonged air travel, HF, pregnancy, and clotting disorders.

Clinical Manifestations

The signs and symptoms of PE are varied and nonspecific, making diagnosis difficult. Manifestations depend on the type, size, and

extent of emboli. Small emboli may go undetected or cause vague, transient symptoms. Symptoms may begin slowly or appear suddenly. Dyspnea is the most common presenting symptom, occurring in 85% of patients with PE. Mild to moderate hypoxemia may occur. Other manifestations include tachypnea, cough, chest pain, hemoptysis, crackles, wheezing, fever, accentuation of pulmonic heart sound, tachycardia, and syncope. Massive PE may cause a sudden change in mental status, hypotension, and feelings of impending doom.

Complications

About 10% of patients with massive PE die within the first hour. Treatment with anticoagulants significantly reduces mortality.

Complications include pulmonary infarction and pulmonary hypertension. *Pulmonary infarction* (death of lung tissue) is most likely when there is: (1) occlusion of a large or medium-sized pulmonary vessel (more than 2 mm in diameter), (2) insufficient collateral blood flow from the bronchial circulation, or (3) preexisting lung disease. Infarction results in alveolar necrosis and hemorrhage. Sometimes the necrotic tissue becomes infected and an abscess may develop. Concomitant pleural effusion is frequent.

Pulmonary hypertension results from hypoxemia or from involvement of more than 50% of the area of the normal pulmonary bed. As a single event, a PE rarely causes pulmonary hypertension. Recurrent PEs gradually reduce capillary bed blood flow and eventually cause pulmonary hypertension. Dilation and hypertrophy of the right ventricle can develop due to pulmonary hypertension. Depending on the degree of pulmonary hypertension and how quickly it develops, outcomes can vary, with some patients dying within months of the diagnosis and others living for decades.

Diagnostic Studies

D-dimer is a laboratory test that measures the amount of cross-linked fibrin fragments. These fragments are the result of clot degradation

and are rarely found in healthy people. The disadvantage of D-dimer testing is that it is neither specific (many other conditions cause elevation) nor sensitive, because up to 50% of patients with a small PE have normal results. Patients with suspected PE and an elevated D-dimer level but normal venous ultrasound may need a spiral CT or lung scan.

A *spiral (helical) CT scan* (also known as CT angiography or CTA) is the most common test to diagnose PE. An IV injection of contrast media is needed to view the pulmonary blood vessels. The scanner continuously rotates around the patient while obtaining views (slices) of the pulmonary vasculature. This allows visualization of all anatomic regions of the lungs. Computer software reconstructs the data to give a 3-dimensional picture and assist in seeing PEs.

If a patient cannot have contrast media, a ventilation-perfusion (V/Q) scan is done. The V/Q scan has 2 parts. It is most accurate when both are done:

1. *Perfusion scanning* involves IV injection of a radioisotope. A scanning device images the pulmonary circulation.
2. *Ventilation scanning* involves inhalation of a radioactive gas, such as xenon. Scanning reflects the distribution of gas through the lung. The ventilation portion requires the patient's cooperation. It may not be possible to perform in the critically ill patient, especially if the patient is intubated.

ABG analysis is important but not diagnostic. The PaO_2 may be low because of inadequate oxygenation from occluded pulmonary vasculature preventing matching of perfusion to ventilation. The pH is often normal unless respiratory alkalosis develops because of prolonged hyperventilation or to compensate for lactic acidosis caused by shock. Abnormal findings may be seen on a chest x-ray (atelectasis, pleural effusion) and ECG (ST segment and T wave changes), but they are not diagnostic for PE. Serum troponin levels and b-type natriuretic peptide (BNP) levels are often increased but not diagnostic.

Interprofessional Care

To reduce mortality risk, treatment is started as soon as PE is suspected (Table 27.25). The goals are to (1) provide adequate tissue perfusion and respiratory function, (2) prevent further growth or extension of thrombi in the lower extremities, (3) prevent embolization from the upper or lower extremities to the pulmonary vascular system, and (4) prevent further recurrence of PE.

TABLE 27.25 Interprofessional CareAcute Pulmonary Embolism

Diagnostic Assessment

- History and physical examination
- Chest x-ray
- Continuous ECG monitoring
- Arterial blood gases
- Spiral (helical) CT scan
- Ventilation-perfusion (V/Q) lung scan
- D-dimer level
- Troponin level, b-natriuretic peptide level

Management

- Supplemental O_2, intubation if needed
- Monitor hemoglobin, assess patient for bleeding
- Monitor activated partial thromboplastin time and international normalized ratio levels
- Balance activity and rest
- Inferior vena cava filter

- Pulmonary embolectomy in life-threatening situation

Drug Therapy

- Fibrinolytic agent
- Unfractionated heparin IV
- Low-molecular-weight heparin (e.g., enoxaparin [Lovenox])
- Warfarin (Coumadin) for long-term therapy
- Analgesia

Immediate assessment should focus on the patient's cardiopulmonary status, which can vary according to the size and location of the PE. O_2 should be given by mask or cannula when hypoxemia is present. The concentration of FIO_2 is titrated based on ABG analysis. In some situations, endotracheal intubation and mechanical ventilation are needed to maintain adequate oxygenation and ventilation. Respiratory measures, including turning, coughing, deep breathing, and incentive spirometry, are important to help prevent or treat atelectasis. If manifestations of shock are present, IV fluids and vasopressor agents are given as needed to support circulation (see Chapter 66). If HF is present, diuretics are used (see Chapter 34). Pain from pleural irritation or reduced coronary blood flow is treated with opioids.

Drug Therapy

Immediate anticoagulation is required for patients with PE. Subcutaneous administration of low-molecular-weight heparin (LMWH) (e.g., enoxaparin [Lovenox]) or fragmin [Dalteparin] or fondaparinux) is the recommended treatment for patients with acute PE. LMWH is safer and more effective than unfractionated heparin.[33] Advantages of LMWH over unfractionated heparin include greater bioavailability, subcutaneous administration, once daily dosing, and longer duration of therapeutic effect. Monitoring the aPTT is not

necessary or useful with LMWH. Unfractionated IV heparin can be as effective but is hard to titrate to therapeutic levels.

Warfarin (Coumadin), an oral anticoagulant, should also be started at the time of diagnosis.[34] Warfarin should be given for at least 3 months and then reevaluated. Alternatives to warfarin include apixaban (Eliquis), dabigatran (Pradaxa), and edoxaban (Savaysa). Anticoagulant therapy may be contraindicated if the patient has complicating factors, such as liver problems causing changes in the clotting, overt bleeding, a history of hemorrhagic stroke, heparin-induced thrombocytopenia (HIT), or other blood dyscrasias.

Some HCPs use direct thrombin inhibitors (see Table 37.10) in the treatment of PE. Similarly, fibrinolytic agents, such as tissue plasminogen activator (tPA) or alteplase (Activase), may help dissolve the PE and the source of the thrombus in the pelvis or deep leg veins, thereby decreasing the risk for recurrent emboli. Fibrinolytic therapy is discussed in Chapter 33.

Surgical Therapy

Hemodynamically unstable patients with massive PE in whom thrombolytic therapy is contraindicated may be candidates for pulmonary embolectomy. Embolectomy, the removal of emboli, can be achieved through a diagnostic imaging (vascular catheter) or surgical approach. It can help decrease right ventricular afterload, Surgical outcomes have improved in recent years, in part due to rapid diagnosis and enhanced surgical procedures.

Percutaneous catheter embolectomy or endovascular ultrasound delivered thrombolysis are newer, moderately invasive procedures for PE. In patients who are at high risk and patients for whom anticoagulation is contraindicated, an inferior vena cava (IVC) filter may be the treatment of choice. This device, inserted percutaneously through the femoral vein, is placed at the level of the renal veins in the inferior vena cava. Once inserted, the filter expands and prevents migration of large clots into the pulmonary system. Complications associated with this device are rare but include misplacement, migration, and perforation.

Nursing Management: Pulmonary Embolism

Prevention of PE begins with prevention of DVT. Nursing measures aimed at prevention of PE are similar to those for prophylaxis of VTE (see Chapter 37). These include the use of intermittent pneumatic compression devices, early ambulation, and anticoagulant medications.

The prognosis of a patient with PE is good if therapy is started immediately. Keep the patient on bed rest in a semi-Fowler's position to facilitate breathing. Assess the patient's cardiopulmonary status with careful monitoring of vital signs, cardiac rhythm, pulse oximetry, ABGs, and lung sounds. Apply O_2 therapy as ordered. Maintain a patent IV line for medications and fluid therapy. Monitor laboratory results to ensure therapeutic ranges of INR (for warfarin) and aPTT (for IV heparin). Monitor platelet counts for thrombocytopenia and the development of HIT. Observe the patient for complications of anticoagulant and fibrinolytic therapy (e.g., bleeding, hematomas, bruising). Provide appropriate interventions related to immobility and fall precautions once the patient is permitted out of bed.

The patient may be anxious because of pain, inability to breathe, and fear of death. Carefully explain the situation and the medications. Provide emotional support and reassurance to help relieve the patient's anxiety.

Patient teaching about long-term anticoagulant therapy is essential. Anticoagulant therapy continues for at least 3 months. Patients with large or recurrent emboli may be treated indefinitely with anticoagulants. INR levels are drawn at intervals and warfarin dosage is adjusted. Some patients are monitored by nurses in an anticoagulation clinic.

Long-term management of PE is similar to that for the patient with VTE (see discussion of VTE in Chapter 37). Discharge planning is aimed at preventing worsening of the condition and avoiding

complications and recurrence. Reinforce the need for the patient to return to the HCP for regular follow-up examinations.

Pulmonary Hypertension

Pulmonary hypertension is characterized by elevated pulmonary artery pressure from an increase in resistance to blood flow through the pulmonary circulation. Normally the pulmonary circulation is characterized by low resistance and low pressure. In pulmonary hypertension the pulmonary pressures are high, with the mean pulmonary artery pressure greater than 25 mm Hg at rest (normal is 12 to 16 mm Hg) or greater than 30 mm Hg with exercise.

The World Health Organization (WHO) has identified 5 classes of pulmonary hypertension.[35] Each group is based on cause of the disorder.

Group 1: Attributed to medication, specific diseases, genetic (inherited) link, or idiopathic
Group 2: Related to left-sided HF
Group 3: Related to the lungs and hypoxemia
Group 4: Related to the cardiovascular system and thromboembolic occlusion
Group 5*:* Multifactorial (and often unclear) origins with hematologic or metabolic involvement

Pulmonary hypertension can occur as a primary disease *(idiopathic pulmonary arterial hypertension)* or as a secondary complication of a respiratory, heart, autoimmune, liver, or connective tissue disorder *(secondary pulmonary arterial hypertension).*

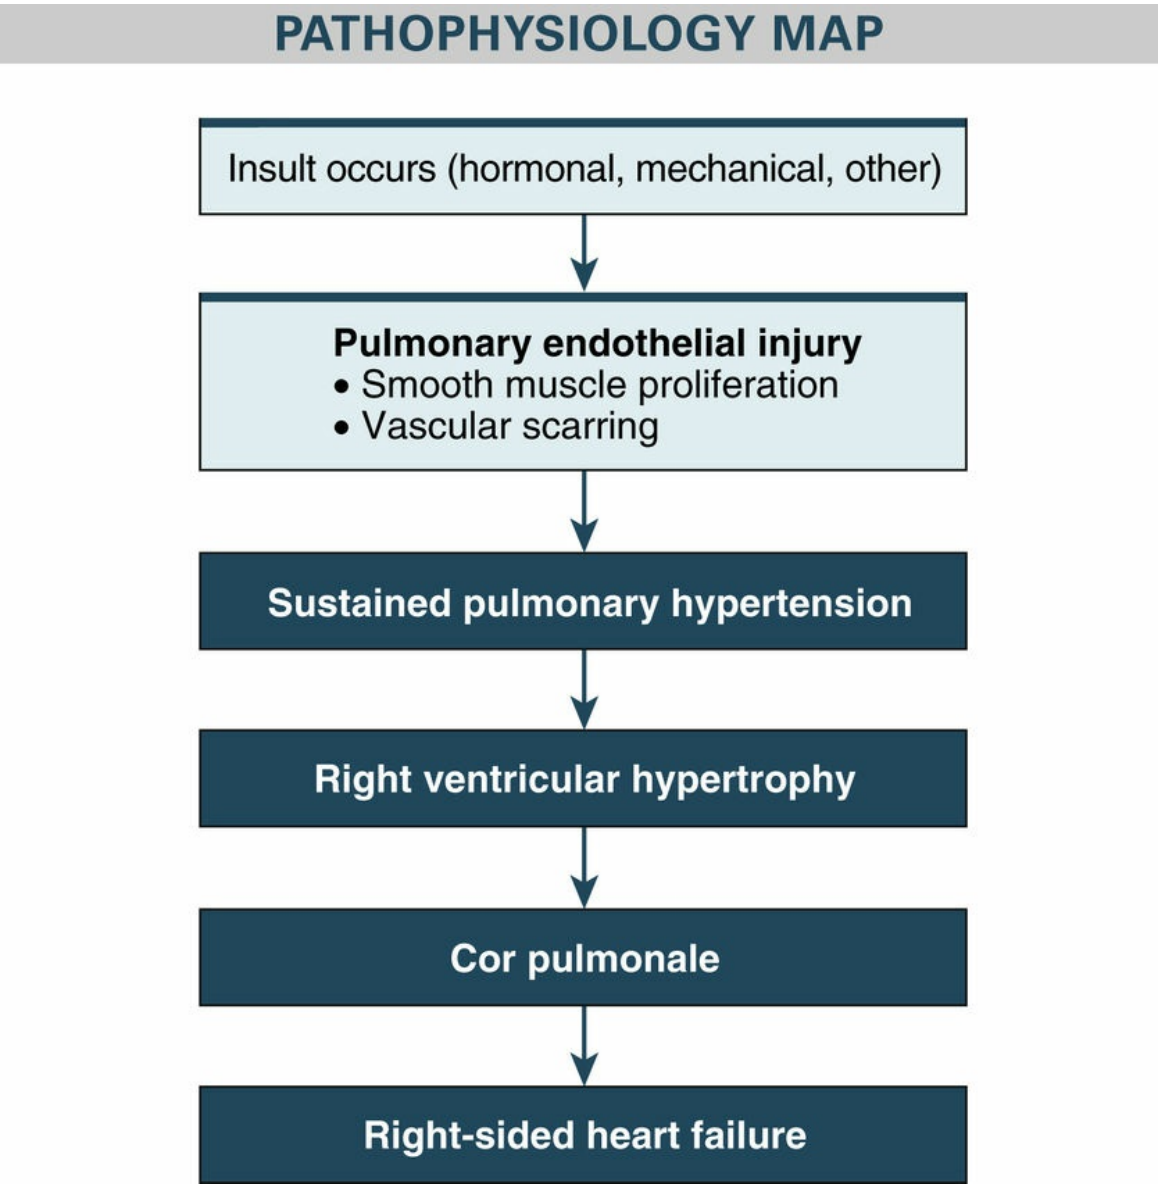

FIG. 27.12 Pathogenesis of pulmonary hypertension and cor pulmonale.

Idiopathic Pulmonary Arterial Hypertension

Idiopathic pulmonary arterial hypertension (IPAH) is pulmonary hypertension that occurs without an apparent cause. It was previously known as *primary pulmonary hypertension* (PPH). If untreated, IPAH can rapidly progress, causing right-sided HF and death within a few years. Although new drug therapy has greatly improved survival, the disease is not curable.

Etiology and Pathophysiology

The cause of IPAH is unknown. It is related to connective tissue diseases, cirrhosis, and HIV. The exact relationship between these disorders and IPAH is unclear. Similarly, the pathophysiology of IPAH is poorly understood. We think that some type of insult (e.g., hormonal, mechanical) to the pulmonary endothelium may occur, causing a cascade of events leading to vascular scarring, endothelial dysfunction, and smooth muscle proliferation (Fig. 27.12). IPAH affects females more than males.

Clinical Manifestations and Diagnostic Studies

The classic symptoms are dyspnea on exertion and fatigue. Exertional chest pain, dizziness, and syncope may occur. These are related to the inability of cardiac output to increase in response to increased O_2 demand. Abnormal heart sounds may be heard, including an S_3. Eventually, as the disease progresses, dyspnea occurs at rest. Pulmonary hypertension increases the workload of the right ventricle and causes right ventricular hypertrophy (a condition called *cor pulmonale*) and eventually HF.

Right-sided cardiac catheterization is the definitive test to diagnose any type of pulmonary hypertension. It gives an accurate measurement of pulmonary artery pressures, cardiac output, and

pulmonary vascular resistance. Confirmation of IPAH requires a thorough workup to exclude conditions that may cause secondary pulmonary hypertension. Diagnostic evaluation often includes ECG, chest x-ray, pulmonary function tests, echocardiogram, and CT scan.

The mean time between onset of symptoms and the diagnosis is about 2 years. By the time patients become symptomatic, the disease is already in the advanced stages and the pulmonary artery pressure is 2-3 times normal values.

Interprofessional and Nursing Care

Early recognition is essential to interrupt the vicious cycle responsible for progression of the disease. Encourage patients to report unexplained shortness of breath, syncope, chest discomfort, and edema of the feet and ankles to their HCP.

Although IPAH has no cure, treatment can relieve symptoms, improve quality of life, and prolong life. Drug therapy consists of agents that promote vasodilation of the pulmonary blood vessels, reduce right ventricular overload, and reverse remodeling (Table 27.26). Diuretics are used to manage peripheral edema. Anticoagulants are beneficial in pulmonary complications related to thrombus formation. Because hypoxia is a potent pulmonary vasoconstrictor, low-flow O_2 gives symptomatic relief. The goal is to keep O_2 saturation 90% or greater.

Surgical interventions include pulmonary thromboendarterectomy (PTE), in which clots are removed from the pulmonary arteries. It is a technically demanding procedure and is done only at certain centers. Atrial septostomy (AS) is a palliative procedure that involves the creation of an intraatrial right-to-left shunt to decompress the right ventricle. It is used for a select group of patients awaiting lung transplantation. Lung transplantation is an option for patients who do not respond to drug therapy and progress to severe right-sided HF. Recurrence of the disease has not been reported in persons who had a transplant.

Secondary Pulmonary Arterial Hypertension

Secondary pulmonary arterial hypertension (SPAH) occurs when another disease causes a chronic increase in pulmonary artery pressures. The specific primary disease pathology can cause anatomic or vascular changes that cause the pulmonary hypertension. SPAH can develop due to parenchymal lung disease, left ventricular dysfunction, intracardiac shunts, chronic PE, or systemic connective tissue disease.

The symptoms can reflect the underlying disease, but some are directly attributable to SPAH, including dyspnea, fatigue, lethargy, and chest pain. The initial physical findings can include right ventricular hypertrophy and signs of right-sided HF (increased pulmonic heart sound, S_4 heart sound, peripheral edema, hepatomegaly).

Diagnosis of SPAH is like that of IPAH. Treatment of SPAH consists of treating the underlying primary disorder. When irreversible pulmonary vascular damage has occurred, therapies used for IPAH are started. A PTE may offer a cure for patients with chronic pulmonary hypertension caused by PE.

Cor Pulmonale

Cor pulmonale is enlargement of the right ventricle caused by a primary disorder of the respiratory system. Almost any disorder that affects the respiratory system can cause cor pulmonale. The most common cause is COPD. Pulmonary hypertension is usually a preexisting condition in the person with cor pulmonale. Overt HF may be present. Fig. 27.12 outlines the cause and pathogenesis of pulmonary hypertension and cor pulmonale.

TABLE 27.26 Drug TherapyPulmonary Hypertension

Drug	Mechanism of Action	Considerations
Calcium Channel Blockers		
diltiazem (Cardizem, Cardizem LA, Cartia XT, Tiazac) **nifedipine (Procardia)**	• Act on vascular smooth muscle, causing dilation • Lower pulmonary artery pressure	• Only used in patients who do not have right-sided heart failure (HF) • Used at high doses in comparison to other uses of calcium channel blockers
Endothelin Receptor Antagonists		
ambrisentan (Letairis) **bosentan (Tracleer)** **macitentan (Opsumit)**	• Binds to endothelin-1 receptors and blocks the constriction of pulmonary arteries • Promotes relaxation of pulmonary arteries and decrease pulmonary artery pressure	• Given orally • For patients with New York Heart Association (NYHA) class II to IV symptoms • Hepatotoxic • Monitor liver function tests monthly
Phosphodiesterase (Type 5) Enzyme Inhibitors		
sildenafil (Revatio) **tadalafil (Adcirca)**	• Promote selective smooth muscle relaxation in lung vasculature	• Given orally • Contraindicated in patients taking nitroglycerin, since may cause refractory hypotension
Vasodilators (Inhaled)		
iloprost (Ventavis) **treprostinil (inhaled) (Tyvaso)**	• Synthetic analogs of prostacyclin (PGI_2) • Dilate systemic and pulmonary arterial vasculature	• For patients with NYHA class III or IV HF • Given 6–9 times a day using a disk inserted into a nebulizer • Can cause orthostatic hypotension. Do not give to patients with systolic BP <85 mm Hg.
Vasodilators (Parenteral)		
adenosine (Adenocard) **epoprostenol (Flolan, Veletri)** **treprostinil (Remodulin)**	• Prostacyclin analog • Promote pulmonary vasodilation and reduce pulmonary vascular resistance	• Given IV to patients who do not respond to calcium channel blockers or have NYHA class III or IV right-sided HF • Given by continuous IV (central line) or continuous subcutaneous route • Half-life of epoprostenol is short. Potential clinical deterioration from abrupt withdrawal if infusion disrupted

Clinical Manifestations and Diagnostic Studies

Manifestations are subtle and often masked by symptoms of the pulmonary condition. Common symptoms include exertional dyspnea, tachypnea, cough, and fatigue. Physical signs include evidence of right ventricular hypertrophy on ECG and an increase in intensity of S_2. Chronic hypoxemia leads to polycythemia and increased total blood volume and viscosity of the blood. Polycythemia is often present in cor pulmonale from COPD.

If HF accompanies cor pulmonale, manifestations, including peripheral edema, weight gain, distended neck veins, full, bounding pulse, and enlarged liver, may occur. We use various laboratory tests and imaging studies to confirm the diagnosis of cor pulmonale (Table 27.27).

Interprofessional and Nursing Care

Early identification is essential before changes to the heart occur that may be irreversible. Management is directed at determining the cause and treating the underlying problem (Table 27.27).

Long-term O_2 therapy, the mainstay of treatment to correct the hypoxemia, reduces vasoconstriction and pulmonary hypertension. All other interventions are tailored for each patient. If fluid, electrolyte, and/or acid-base imbalances are present, they must be corrected. Diuretics may help decrease plasma volume and reduce the workload on the heart but must be used with extreme caution. In some cases, decreases in fluid volume from diuresis can worsen heart function. Bronchodilator therapy is needed if the underlying respiratory problem is due to an obstructive disorder.

TABLE 27.27 Interprofessional CareCor Pulmonale

Diagnostic Assessment

- History and physical examination

- Arterial blood gases, SpO_2
- Serum and urine electrolytes
- b-Type natriuretic peptide (BNP)
- ECG
- Chest x-ray
- Echocardiography
- CT scan, MRI
- Cardiac catheterization

Management

- O_2 therapy
- Low-sodium diet

Drug Therapy

- Bronchodilators
- Diuretics
- Vasodilators (if indicated)
- Calcium channel blockers (if indicated)
- Inotropic agents

Other treatments may include vasodilator therapy, calcium channel blockers, anticoagulants, digitalis, and phlebotomy. All have varying degrees of success. Chronic management of cor pulmonale from COPD is like that described for COPD (see Chapter 28).

Lung Transplantation

Lung transplantation has become an important alternative option for patients with end-stage lung disease. Unfortunately, the limiting factor for this therapy is the lack of donors. A variety of pulmonary disorders are potentially treatable with lung transplantation (Table 27.28). Better patient selection criteria, improvements in surgical techniques, enhanced methods of immunosuppression, and excellent postoperative care have resulted in improved survival rates.

Preoperative Care

Patients being considered for lung transplantation need to undergo extensive evaluation. Absolute contraindications for lung transplant include cancer within past 2 years (some types of skin cancer are excluded), chronic active hepatitis B or C, HIV, untreatable advanced dysfunction of another major organ system (e.g., liver or renal failure), current smoker, poor nutritional status, poor rehabilitation potential, and significant psychosocial problems. The patient and family must be able to cope with a complex postoperative regimen (e.g., strict adherence to immunosuppressive therapy, continuous monitoring for early signs of infection, prompt reporting of manifestations of infection). Many transplant centers require preoperative outpatient pulmonary rehabilitation to maximize physical conditioning.

In the United States, the United Network for Organ Sharing (UNOS) is a private, non-profit organization that works with the federal government to manage organ transplantation. UNOS designates recipients of donor lungs based on a lung allocation score (LAS). The LAS helps to prioritize waiting list recipients based on the urgency of need and expected posttransplant survival expectations.

Patients who are accepted as transplant candidates must always carry a pager in case a donor organ becomes available. They must be prepared to be at their transplant center at a moment's notice. Patients may be encouraged to limit their travel within a certain geographic

region to facilitate rapid transportation to a transplant center.

TABLE 27.28 Common Indications for Lung Transplantation

- α_1-Antitrypsin deficiency
- Chronic obstructive pulmonary disease (COPD)
- Cystic fibrosis
- Idiopathic pulmonary arterial hypertension
- Idiopathic pulmonary fibrosis

Surgical Procedure

Four types of transplant procedures are available: single-lung transplantation, bilateral lung transplantation, heart-lung transplantation, and transplantation of lobes from a living-related donor.

Single-lung transplantation involves a thoracotomy incision on the side of the chest. The opposite lung is ventilated while the diseased lung is excised and the donor lung implanted. Three anastomoses are done: bronchus, pulmonary artery, and pulmonary veins. In *bilateral lung transplantation,* the incision is made across the sternum and the donor lungs are implanted separately. A median sternotomy incision is used for a *heart-lung transplant* procedure. *Lobar transplantation* from living donors is reserved for those who urgently need transplantation and are unlikely to survive until a donor becomes available. Most of these recipients are patients with cystic fibrosis, and donors are their parents or relatives. Once anastomosis is complete, the lung is gently reinflated, perfusion is reestablished, chest tubes are inserted, and the surgical incision is closed.

Postoperative Care

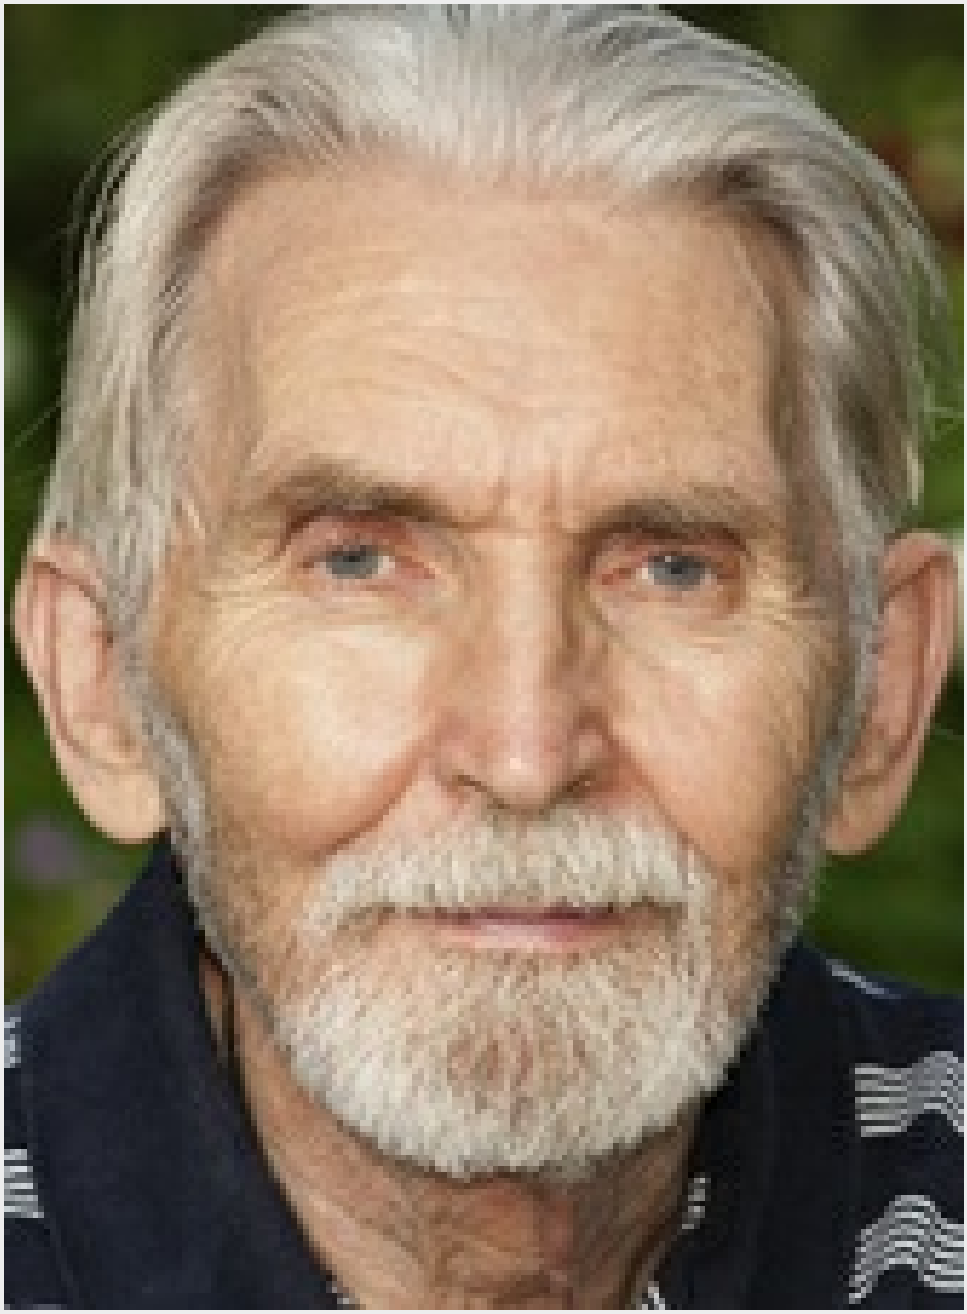
Early postoperative care often includes ventilatory support, hemodynamic management, IV fluid therapy, immunosuppression, nutritional support, detection of early rejection, and prevention or treatment of complications, including infection. Once hemodynamic stability has been achieved, the patient is often transferred from the ICU to a high-acuity observation or surgical unit. Maintaining accurate fluid balance is vital after surgery.

Lung transplant recipients are at high risk for multiple complications. Infections are the leading cause of death at all time points after lung transplant. Bacterial bronchitis and pneumonia are the most common infections. CMV, fungi, viruses, and mycobacteria are also causative agents. Noninfectious issues may include VTE, diaphragmatic dysfunction, and cancer.

Immunosuppressive therapy usually includes a 3-drug regimen of tacrolimus, mycophenolate mofetil (CellCept), and prednisone. The mechanisms of action of these drugs are discussed in Table 13.17 and Fig. 13.13.) Drug levels are monitored on a regular basis. Lung transplant recipients usually receive higher levels of immunosuppressive therapy than other organ recipients.

Acute rejection is fairly common in lung transplantation. It typically occurs in the first 5 to 10 days after surgery. Signs of rejection include low-grade fever, fatigue, dyspnea, dry cough, and O_2 desaturation. Accurate diagnosis of rejection is by transtracheal biopsy. Treatment consists of high doses of IV corticosteroids for 3 days, followed by high doses of oral prednisone. In patients with persistent or recurrent acute rejection, antilymphocyte therapy may be useful.

Bronchiolitis obliterans (BOS) is a manifestation of chronic rejection in lung transplant patients. BOS is characterized by airflow obstruction that progresses over time. The onset is often subacute, with gradual development of exertional dyspnea, nonproductive cough, wheezing, and/or low-grade fever. Airway obstruction is not responsive to bronchodilators and corticosteroid therapy. Although not proven effective, additional immunosuppressive agents may be used to treat chronic rejection. Because acute rejection is a major risk factor for BOS,



preventing acute rejection is key to decreasing the incidence of chronic rejection.

Before discharge, the patient needs to be able to perform self-care activities, including medication management and activities of daily living, and to know when to call the transplant team. Patients are taught pulmonary clearance measures, including aerosolized bronchodilators, chest physiotherapy, and deep-breathing and coughing techniques, to help minimize complications. Home spirometry is useful in monitoring trends in lung function. Teach patients to keep medication logs, laboratory results, and spirometry records. Patients are placed in an outpatient rehabilitation program to improve physical endurance.

After discharge, the transplant team follows patients for transplant-related issues. Patients return to their HCP for health maintenance and routine illnesses. As transplant procedures become more frequent, transplant patients will return to hospitals for other routine procedures. Coordination of care among the transplant team, inpatient team, and primary care team is essential for ongoing successful management of these patients. (Organ transplantation, histocompatibility, rejection, and immunosuppressive therapy are discussed in Chapter 13.)

Case Study

Pneumonia and Lung Cancer

(© iStockphoto/Thinkstock.)

Patient Profile

J.H. is a 52-yr-old white man who comes to the ED with shortness of breath. He has not seen an HCP for many years.

Subjective Data

- Has a 38 pack-year history of cigarette smoking
- Has had 25-lb weight loss despite a normal appetite in the past few months
- Admits to a "smoker's cough" for the past 2 to 3 years; recently coughing up blood
- Is married and the father of 3 adult children

Objective Data
Physical Examination

- Thin, pale man who looks older than stated age
- Height 6 ft (182.9 cm); weight 135 lb (61.2 kg)
- Intermittently confused and anxious
- Lung auscultation reveals coarse crackles on left side that clear with cough; right side has decreased breath sounds
- Chest wall has limited excursion on right side
- Vital signs: temperature 102.6° F (39.2° C), heart rate 120, respiratory rate 36, BP 98/54; short, shallow respirations

Diagnostic Studies

- Arterial blood gases: pH 7.51, PaO_2 62 mm Hg, $PaCO_2$ 30 mm Hg, HCO_3^- 22 mEq/L, O_2 saturation 88% (room air)
- Chest x-ray: consolidation of the right lung, especially in the base with mass around right bronchus; pleural effusion on the right side
- Bronchoscopy with biopsy of mass: small cell lung cancer

Interprofessional Care

- Diagnosis: pneumonia with small cell lung cancer

- Follow-up with patient and family to consider treatment options

Discussion Questions

1. How would you classify J.H.'s pneumonia? Why is this important?
2. What is your analysis of J.H.'s arterial blood gas results?
3. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
4. ***Priority Decision:*** What are the priority nursing interventions for J.H.?
5. ***Collaboration:*** Identify activities that can be delegated to unlicensed assistive personnel (UAP).
6. ***Patient-Centered Care:*** You are planning a meeting with J.H. and his family to discuss their needs. The HCP tells you that J.H. is terminally ill. Who will you include in this meeting?
7. ***Evidence-Based Practice:*** J.H.'s children tell you that they are worried they will get lung cancer, since their father has it and they grew up around his secondhand smoke. They want to know what kind of screening is available for them. How will you respond?

- What is the goal if radiation therapy is used for J.H.?
- ***Patient-Centered Care:*** What issues should be addressed in your teaching of J.H. and his wife as you prepare him for discharge and care at home?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Lung Abscess

Etiology and Pathophysiology

A **lung abscess** is necrosis of lung tissue. It typically results from bacteria aspirated from the oral cavity in patients with periodontal disease. They can also result from IV drug use, cancer, pulmonary emboli, TB, and various parasitic and fungal diseases. The abscess usually develops slowly, beginning with an enlarging area of infection that becomes necrotic and eventually forms a cavity filled with purulent material. Abscesses usually contain more than 1 type of microbe, most often reflecting the anaerobic flora of the mouth.

The area of the lung most often affected due to aspiration is the posterior segment of the upper lobes. The abscess may erode into the bronchial system, causing the production of foul-smelling or sour-tasting sputum. It may grow toward the pleura and cause pleuritic pain. Multiple small abscesses, sometimes referred to as *necrotizing pneumonia,* can occur within the lung.

TABLE 27.14 Fungal Infections of the Lung

Infection	Organism
Endemic Fungal Infections	
Blastomycosis	*Blastomyces dermatitidis*
Coccidioidomycosis	*Coccidioides immitis*
Histoplasmosis	*Histoplasma capsulatum*
Opportunistic Fungal Infections	
Aspergillosis	*Aspergillus niger, Aspergillus fumigatus*
Candidiasis	*Candida albicans*
Cryptococcosis	*Cryptococcus neoformans*

Clinical Manifestations and Complications

Manifestations usually occur slowly over a period of weeks to months,

especially if anaerobic organisms are the cause. Symptoms of abscess caused by aerobic bacteria develop more acutely and resemble bacterial pneumonia. The most common is cough-producing purulent sputum (often dark brown) that is foul smelling and foul tasting. Hemoptysis is common, especially when an abscess ruptures into a bronchus. Other manifestations include fever, chills, prostration, night sweats, pleuritic pain, dyspnea, anorexia, and weight loss.

Lung assessment reveals dullness to percussion and decreased breath sounds on auscultation over the involved segment of lung. Bronchial breath sounds may be transmitted to the periphery if the communicating bronchus becomes patent and the segment begins to drain. Crackles may be present in the later stages as the abscess drains.

The infection can spread through the bloodstream and cause several possible complications. Pulmonary abscess, bronchopleural fistula, bronchiectasis, and empyema from perforation of the abscess into the pleural cavity can occur.[22]

Diagnostic Studies

A chest x-ray is often the only test needed to diagnose a lung abscess. The presence of a single cavitary lesion with an air-fluid level and local infiltrate confirms the diagnosis. CT scanning may be helpful if the cavitation is not clear on chest x-ray. If there is drainage via the bronchus, sputum will contain the microorganisms that are present in the abscess. However, expectorated sputum samples are contaminated with oral flora, making it hard to determine the responsible organism(s).

Bronchoscopy may be used to (1) avoid oropharyngeal contamination, (2) collect a specimen if drainage is delayed, or (3) investigate for an underlying cancer. Pleural fluid and blood cultures may be useful to identify the offending organisms. Although nonspecific, an elevated neutrophil count from a complete blood count (CBC) may indicate an infectious process. Necrotic pulmonary lesions also can be caused by lung infarction, pulmonary embolism,

and sarcoidosis.

Interprofessional and Nursing Care

Monitor the patient's vital signs, level of consciousness, and respiratory status for any signs of hypoxemia. Note any signs and symptoms of respiratory distress. Apply O_2 as needed. IV antibiotic therapy should be started as soon as possible. Clindamycin is first-line therapy for its effectiveness against *Staphylococcus* and anaerobic organisms. Parenteral antibiotics are switched to oral antibiotics once the patient shows clinical and chest x-ray signs of improvement.

Because of the need for prolonged antibiotic therapy, the patient must be aware of the importance of continuing the medication for the prescribed period. To avoid the risk for a secondary or worsening infection, all antibiotics should be taken as directed for the entire prescribed period. Sometimes the patient is asked to return periodically during the course of antibiotic therapy for repeat cultures and sensitivity tests to ensure that the infecting organism is not becoming resistant to the antibiotic. When antibiotic therapy is complete, the patient is reevaluated.

Teach the patient how to cough effectively (see Table 28.21). Chest physiotherapy and postural drainage are not recommended because they may promote movement of microorganisms into other bronchi, extending infection. Rest, optimal nutrition, and adequate fluid intake are supportive measures to promote recovery. If dentition is poor and dental hygiene is not adequate, encourage the patient to obtain dental care. Collaborate with the social worker to evaluate available options for dental care if the patient has limited resources.

If the patient does not adequately respond to antibiotic treatment, percutaneous drainage of the abscess may be done. A small catheter, guided by CT or ultrasound, may be placed to drain the abscess. Surgery is sometimes done when reinfection of a large cavitary lesion occurs, when an empyema develops, or to establish a diagnosis when there is evidence of an underlying problem, such as cancer. The usual procedure in such cases is a lobectomy. A pneumonectomy may be

needed for multiple abscesses.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. When caring for a patient with acute bronchitis, the nurse will *prioritize* interventions by
   a. auscultating lung sounds.
   b. encouraging fluid restriction.
   c. administering antibiotic therapy.
   d. teaching the patient to avoid cough suppressants.
2. Which patients have the greatest risk for aspiration pneumonia? *(select all that apply)*
   a. Patient with seizures
   b. Patient with head injury
   c. Patient who had thoracic surgery
   d. Patient who had a myocardial infarction
   e. Patient who is receiving nasogastric tube feeding
3. An appropriate nursing intervention to assist a patient with pneumonia manage thick secretions and fatigue would be to
   a. perform postural drainage every hour.
   b. provide analgesics as ordered to promote patient comfort.
   c. administer O_2 as prescribed to maintain optimal O_2 levels.
   d. teach the patient how to cough effectively and expectorate secretions.

4. A patient with TB has been admitted to the hospital and is placed on airborne precautions and in an isolation room. What should the nurse teach the patient? *(select all that apply)*
   a. Expect routine TB testing to evaluate the infection.
   b. No visitors will be allowed while in airborne isolation.
   c. Adherence to precautions includes coughing into a paper tissue.
   d. Take all medications for full length of time to prevent multidrug-resistant TB.
   e. Wear a standard isolation mask if leaving the airborne infection isolation room.
5. A patient has been receiving high-dose corticosteroids and broad-spectrum antibiotics for treatment of an infection after a traumatic injury. The nurse plans care for the patient knowing that the patient is most susceptible to
   a. candidiasis.
   b. cryptococcosis.
   c. histoplasmosis.
   d. coccidioidomycosis.
6. When caring for a patient with a lung abscess, what is the nurse's *priority* intervention?
   a. Postural drainage
   b. Antibiotic administration
   c. Obtaining a sputum specimen
   d. Patient teaching about home care
7. You are caring for patients exposed to a chlorine leak from

a local factory. The nurse would closely monitor these patients for

a. pulmonary edema.

b. anaphylactic shock.

c. respiratory alkalosis.

d. acute tubular necrosis.

8. The nurse receives an order for a patient with lung cancer to receive influenza vaccine and pneumococcal vaccines. The nurse will

a. call the health care provider to question the order.

b. give both vaccines at the same time in different arms.

c. give the pneumococcal vaccine and obtain a nasal influenza vaccine.

d. give the flu shot and tell the patient to come back in 1 week to have the pneumococcal vaccine.

9. The nurse identifies a flail chest in a trauma patient when

a. multiple rib fractures are determined by x-ray.

b. a tracheal deviation to the unaffected side is present.

c. paradoxical chest movement occurs during respiration.

d. there is decreased movement of the involved chest wall.

10. The nurse notes tidaling of the water level in the water-seal chamber in a patient with closed chest tube drainage. The nurse should

a. continue to monitor the patient.

b. check all connections for a leak in the system.

c. lower the drainage collector further from the chest.

d. clamp the tubing at a distal point away from the patient.

11. After a pneumonectomy, an appropriate nursing intervention is

a. monitoring chest tube drainage and functioning.

b. positioning the patient on the unaffected side or back.

c. doing range-of-motion exercises on the affected upper limb.

d. auscultating frequently for lung sounds on the affected side.

12. A *priority* nursing intervention for a patient who has just undergone a chemical pleurodesis for recurrent pleural effusion is

a. giving ordered analgesia.

b. monitoring chest tube drainage.

c. sending pleural fluid for laboratory analysis.

d. monitoring the patient's level of consciousness.

13. When planning care for a patient at risk for pulmonary embolism, the nurse *prioritizes*

a. maintaining the patient on bed rest.

b. using intermittent pneumatic compression devices.

c. encouraging the patient to cough and deep breathe.

d. teaching the patient how to use the incentive spirometer.

14. Which statement(s) describe(s) the management of a patient following lung transplantation *(select all that apply)*?

a. High doses of O_2 are administered around the clock.

b. Using a home spirometer will help to monitor lung function.

c. Immunosuppressant therapy usually involves a 3-drug

regimen.

d. Most patients have an acute rejection episode within the first 2 days.

e. A lung biopsy is done using a transtracheal method if rejection is suspected.

1. a, 2. a, b, e, 3. d, 4. c, d, e, 5. a, 6. b, 7. a, 8. b, 9. c, 10. a, 11. c, 12. a, 13. b, 14. b, c, e

Obstructive Pulmonary Diseases

Eugene Mondor

LEARNING OUTCOMES

1. Describe the etiology, pathophysiology, and clinical manifestations of asthma.
2. Explain the difference between an acute asthma exacerbation and status asthmaticus.
3. Describe the interprofessional and nursing management of the patient with asthma.
4. Identify the classifications of drugs used in the treatment of asthma and chronic obstructive pulmonary disease (COPD).
5. Describe the etiology, pathophysiology, clinical manifestations, and interprofessional care of the patient with COPD.
6. Relate the indications for O_2 therapy, methods of delivery, and complications of O_2 administration.
7. Explain the nursing management of the patient with COPD.
8. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with cystic fibrosis.
9. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with bronchiectasis.

Cenceptual Focus

Fatigue
Functional Ability
Gas Exchange
Infection
Self-Management

Imagine needing to consciously think about every breath that you take each minute, each hour, and every day of your life. You are tired and weak and have not been sleeping well. Your appetite is poor. The stress of living with these symptoms makes you feel anxious and depressed. You have been absent from work and are having some financial problems. Many people with obstructive lung disease have this experience.

The obstructive pulmonary diseases are the most common chronic lung diseases. They are characterized by increased resistance to airflow because of airway obstruction or airway narrowing. There are 4 major types of obstructive lung disease: asthma, chronic obstructive pulmonary disease (COPD), cystic fibrosis (CF), and bronchiectasis.

Asthma causes inflammation with variable degrees of airflow obstruction. Between acute exacerbations, or attacks, the patient with asthma is often asymptomatic with normal lung function. On the other hand, in COPD there is progressive limitation in airflow that is not fully reversible. The limitation in expiratory airflow in COPD is generally more constant day-to-day and worsens over time. Emphysema and chronic bronchitis are 2 related respiratory conditions often responsible for COPD.[1]

The pathophysiology of asthma and the response to therapy differs from COPD. However, patients with asthma who have less responsive airflow obstruction are hard to tell from COPD patients. In fact, some patients share features of both asthma and COPD. This is known as asthma-COPD overlap syndrome.[2] It is characterized by significantly worse respiratory signs and symptoms, an increased number of hospitalizations, and a much poorer quality of life than asthma or COPD alone.[3]

CF is an inherited genetic disorder. It produces airway obstruction because of changes in exocrine glandular secretions, resulting in increased mucus production. There are about 30,000 people in the United States living with CF, with 52.7% being adults.[4]

Bronchiectasis is characterized by dilated bronchioles, making it hard to clear secretions. It most often results from poorly treated or untreated pulmonary infections, immune system problems, or genetic

factors.

Promoting Health Equity

Obstructive Pulmonary Diseases

Asthma

- Asthma prevalence rates are 38% higher among blacks than whites.
- Hispanics, especially those from Puerto Rico, have higher rates of asthma and age-adjusted death rates than all other racial and ethnic subgroups.
- Black females have the highest mortality rates from asthma.

COPD

- Whites have the highest incidence of COPD despite higher rates of smoking among other ethnic groups.
- Hispanics have lower death rates from COPD than other ethnic groups.

Cystic Fibrosis

- Whites have the highest incidence of CF.
- CF is uncommon among blacks, Hispanics, and Asian Americans.

Asthma

Asthma is a heterogenous disease characterized by bronchial hyperreactivity with reversible expiratory airflow limitation. Signs and symptoms can be variable. They often include episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night or in the early morning. These episodes are associated with widespread, variable airflow obstruction that is usually reversible, either spontaneously or with treatment. The clinical course of asthma is unpredictable, ranging from periods of adequate control to attacks with poor control of symptoms.

Asthma affects around 20.4 million adult Americans.[5] It is a major public health concern, with more than 1.7 million emergency department (ED) visits each year.[5] After a long period of an increasing incidence of asthma, the mortality and use of health care services for asthma have decreased over the past 10 years. Unfortunately, more than 3600 people still die each year from asthma.[5]

Gender Differences

Asthma

Men

- Before puberty, more boys are affected than girls.

Women

- In adulthood, women are much more likely to be affected than men.
- Women who present to the ED are more likely to need

hospitalization than men.
- Mortality is higher in women than in men.

Risk Factors for Asthma and Triggers of Asthma Attacks

Risk factors for asthma and triggers of asthma attacks can be related to the patient (e.g., genetic factors) or the environment (e.g., pollen) (Table 28.1). Important factors and triggers are discussed in this section.

Nose and Sinus Problems

Most patients with asthma have a history of allergic rhinitis. Treatment of allergic rhinitis usually improves the symptoms of asthma. Acute and chronic sinusitis, especially bacterial rhinosinusitis, may worsen asthma. Patients with asthma often have chronic sinus problems that cause inflammation of the mucous membranes and can trigger an asthma attack. Sinusitis must be treated and large nasal polyps removed for an asthma patient to have good control. (Sinusitis is discussed in Chapter 27.)

TABLE 28.1 Triggers of Asthma Attacks

Air Pollutants
• Aerosol sprays • Cigarette smoke • Exhaust fumes • Oxidants • Perfumes • Sulfur dioxides

Allergen Inhalation

- Animal dander (e.g., cats, mice, guinea pigs)
- Cockroaches
- House dust mite
- Molds
- Pollens

Drugs

- Aspirin
- β-Adrenergic blockers
- Nonsteroidal antiinflammatory drugs

Food Additives

- Beer, wine, dried fruit, shrimp, processed potatoes
- Monosodium glutamate
- Sulfites (bisulfites and metabisulfites)
- Tartrazine

Occupational Exposure

- Agriculture, farming
- Industrial chemicals and plastics
- Laundry detergents
- Metal salts
- Paints, solvents
- Wood and vegetable dusts

Viral or Bacterial Infection

- Sinusitis, allergic rhinitis
- Viral URI

Other Factors

- Exercise and cold, dry air
- Gastroesophageal reflux disease (GERD)
- Hormones, menses
- Stress

Respiratory Tract Infections

Respiratory tract infections are often a major trigger of an acute asthma attack. Acute infection can decrease the diameter of the airways and induce airway hyperresponsiveness. Viral-induced changes in epithelial cells, the accumulation of inflammatory cells, edema of airway walls, and exposure of airway nerve endings contribute to altered respiratory function. These changes may exacerbate asthma.

Allergens

Allergens cause varying degrees of allergic reactions in susceptible persons. Indoor and outdoor allergens, such as cockroaches, furry animals, fungi, pollen, and molds, can trigger asthma attacks. However, their role in the actual development of asthma is not as clear.[6]

Cigarette Smoke

The Centers for Disease Control and Prevention (CDC) estimates that 21% of asthma patients smoke.[7] In a person with asthma, smoking is associated with a faster decline of lung function, increased disease

severity, more frequent visits to the HCP, and a decreased response to treatment. The smoke exhaled by a smoker, known as secondhand smoke, is also a risk factor.

Air Pollutants

Various air pollutants, such as wood smoke or vehicle exhaust, can trigger asthma attacks. In heavily industrialized or densely populated areas, climate conditions often lead to concentrated pollution in the atmosphere, especially with thermal inversions and stagnant air masses. News sources report ozone alert days. Patients with breathing problems should minimize outdoor activity during these times.

Occupational Factors

Occupational asthma is the most common job-related respiratory disorder. These irritants cause a change in the responsiveness of the airways. However, the development of symptoms may not occur until the patient has had months to years of exposure. These agents are diverse and include wood dusts, laundry detergents, metal salts, chemicals, paints, solvents, and plastics. Often, people with occupational asthma give a history of arriving at work feeling well but gradually develop symptoms, which may become progressively worse, by the end of the day.

Exercise

Asthma that is induced or worse during physical exertion is called exercise-induced asthma (EIA) or exercise-induced bronchospasm (EIB). Typically, symptoms of EIA are pronounced during activities in which there is exposure to cold, dry air. For example, swimming in an indoor heated pool is less likely to cause symptoms than downhill skiing. Airway obstruction may occur due to changes in the airway mucosa caused by hyperventilation during exercise, with either cooling or rewarming of air and capillary leakage in the airway wall. EIB occurs after vigorous exercise, not during it (e.g., jogging, aerobics, walking briskly, climbing stairs).

Drugs and Food Additives

Some people with asthma have what we call the *asthma triad:* nasal polyps, asthma, and sensitivity to aspirin and nonsteroidal antiinflammatory drugs (NSAIDs). Some persons with asthma who use salicylic acid (e.g., aspirin) or NSAIDs develop wheezing within 2 hours. In addition, there is usually profound rhinorrhea, congestion, tearing, and even angioedema. Avoiding salicylic acid and NSAIDs is required. Teach the patient to read labels. Salicylic acid is in many OTC drugs and some foods, beverages, and flavorings. Under the care of an allergist, daily administration of the drug can desensitize some patients.

β-Adrenergic blockers in oral form (e.g., metoprolol [Toprol-XL]) or topical eye drops (e.g., timolol [Timoptic]) may trigger an asthma attack because they can cause bronchospasm. Angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril) may cause a dry, hacking cough in susceptible persons, making asthma symptoms worse. Asthma attacks can occur after the use of sulfite-containing preservatives found in topical ophthalmic solutions, IV corticosteroids, and some inhaled bronchodilator solutions.

Food and drug additives that may trigger asthma in the susceptible person are tartrazine (yellow dye no. 5) and sulfiting agents. They are widely used as preservatives and sanitizing agents. Sulfiting agents are in fruits, beer, and wine. They are used in salad bars to protect vegetables from oxidation. Food allergies triggering asthma reactions in adults are rare. Avoidance diets are not recommended until testing has proven an allergy is present.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is more common in people with asthma than in the general population. GERD can worsen asthma symptoms because reflux may trigger bronchoconstriction and cause aspiration. Asthma drugs may worsen GERD symptoms. β_2-Agonists used to treat asthma (especially when given orally) relax the lower esophageal sphincter. This allows stomach contents to reflux into the esophagus and be aspirated into the lungs. Effective treatment

for GERD can improve nocturnal asthma control, improve quality of life, and prevent asthma symptoms in some patients. (GERD is discussed in Chapter 41.)

Genetics

Asthma has an inherited component, but the genetics are complex. Numerous genes may be involved in the development of asthma. They are likely responsible for varying responses among patients to different types of asthma drugs. Atopy, the genetic predisposition to develop an allergic (immunoglobulin E [IgE]–mediated) response to common allergens, is a major risk factor for asthma.

Immune Response

The *hygiene hypothesis* suggests that a newborn baby's immune system must be conditioned so that it will function properly during infancy and the rest of life. People who have a lower incidence of asthma were exposed to certain infections early in life, used fewer antibiotics, were around other children (e.g., siblings, day care), or lived in rural settings or with pets. People for whom these factors are not present in childhood have a higher incidence of asthma.

Psychological Factors

Asthma is not a psychosomatic disease. However, many people with asthma report that symptoms worsen with stress. An asthma attack caused by any triggering event can produce panic, stress, and anxiety. These emotions, and other psychological factors, can cause bronchoconstriction through stimulation of the cholinergic reflex pathways. Extreme behavioral expressions (e.g., crying, laughing, anger, fear) can lead to hyperventilation and hypocapnia, which can cause airway narrowing.

Pathophysiology

The main pathophysiologic process in asthma is persistent but variable inflammation of the airways. Airflow is limited because

inflammation results in bronchoconstriction, airway hyperresponsiveness (hyperreactivity), and edema of the airways. Exposure to allergens or irritants initiates the inflammatory cascade (Fig. 28.1). A variety of inflammatory cells are involved, including mast cells, macrophages, eosinophils, neutrophils, T and B lymphocytes, and epithelial cells of the airways.

As the inflammatory process begins, mast cells (found beneath the basement membrane of the bronchial wall) degranulate and release multiple inflammatory mediators (Fig. 28.2). IgE antibodies are linked to mast cells, and the allergen cross-links the IgE. As a result, inflammatory mediators, such as leukotrienes, histamine, cytokines, prostaglandins, and nitric oxide, are released. Inflammatory mediators have effects on the (1) blood vessels, causing vasodilation and increasing capillary permeability (runny nose); (2) nerve cells, causing itching; (3) smooth muscle cells, causing bronchial spasms and airway narrowing; and (4) goblet cells, causing mucus production (Fig. 28.3). This whole process is sometimes referred to as the *early-phase response* in asthma. Clinically, it occurs within 30 to 60 minutes after exposure to an allergen or irritant.

Symptoms can recur 4 to 6 hours after the early response because of the influx of many inflammatory cells, which are set in motion by the initial response. At this later time, the patient may develop symptoms again or worsening of symptoms. This is called the *late-phase response*. It occurs in about 50% of people with asthma. In the late-phase response, more inflammatory cells are recruited and activated, with continuing inflammation of the airways. Thus bronchoconstriction with symptoms lasts for 24 hours or more. Corticosteroids are effective in treating inflammation in this phase.

Chronic inflammation may cause structural changes in the bronchial wall, known as *remodeling.* A progressive loss of lung function occurs that therapy cannot fully reverse. The changes in structure may include fibrosis of the subepithelium, hypertrophy of the smooth muscle of the airways, mucus hypersecretion, continued inflammation, and *angiogenesis* (proliferation of new blood vessels).[8] We think remodeling explains why some persons have persistent

asthma and limited response to therapy.

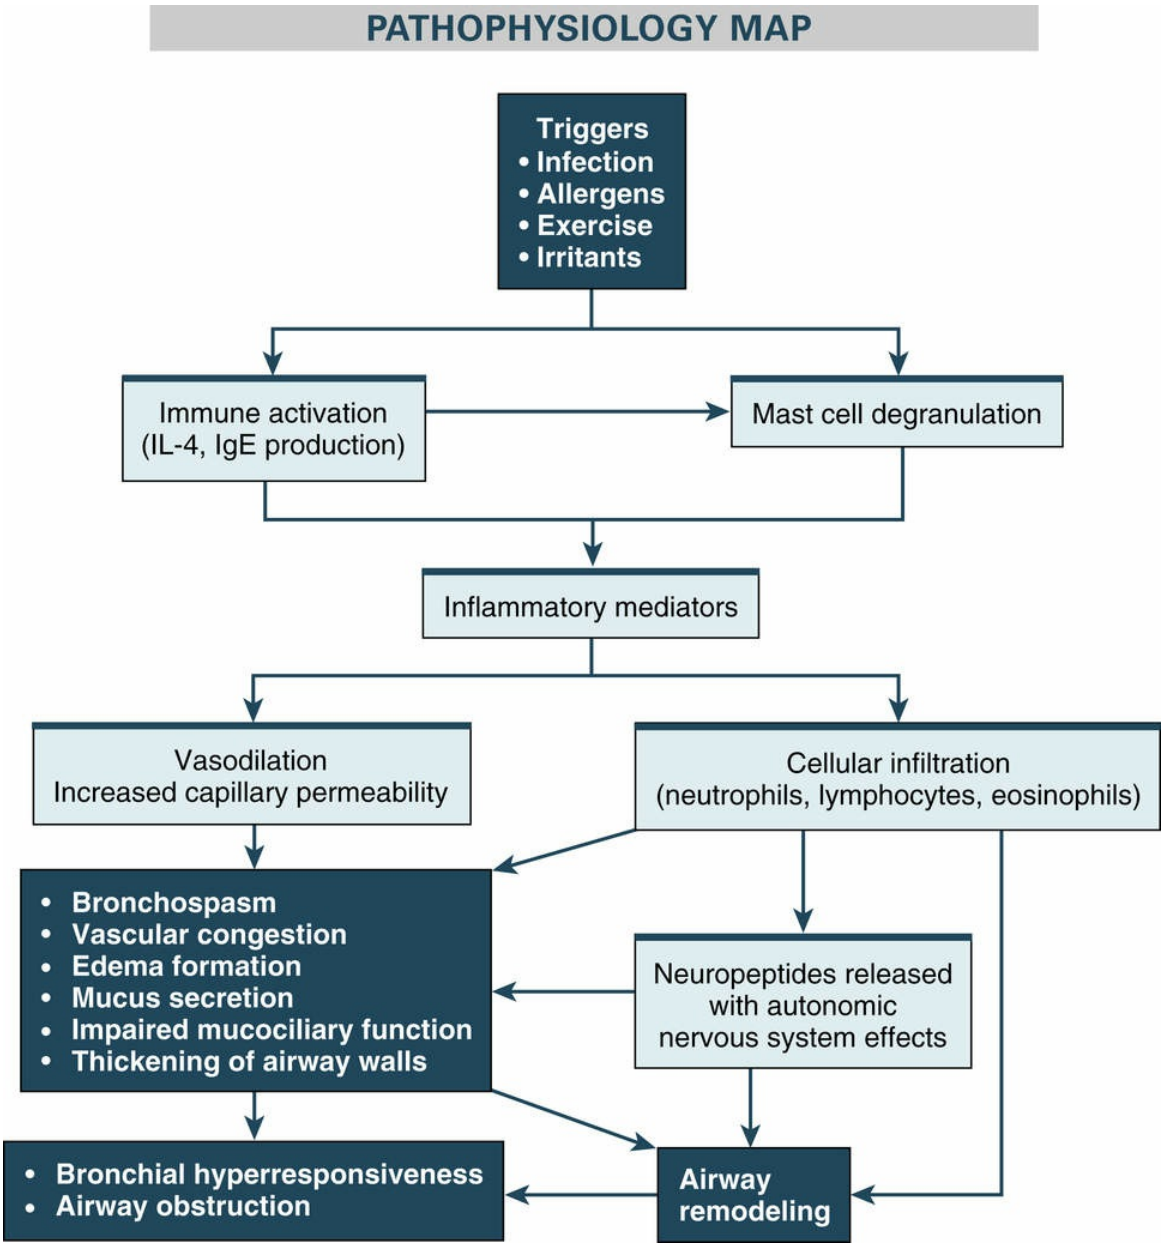

FIG. 28.1 Pathophysiology of asthma.
Adapted from McCance KL, Huether SE, Brashers, VL, Rote, NS, editors: *Pathophysiology: The biologic basis for disease in adults and children,* ed 7, St Louis, 2015, Elsevier.

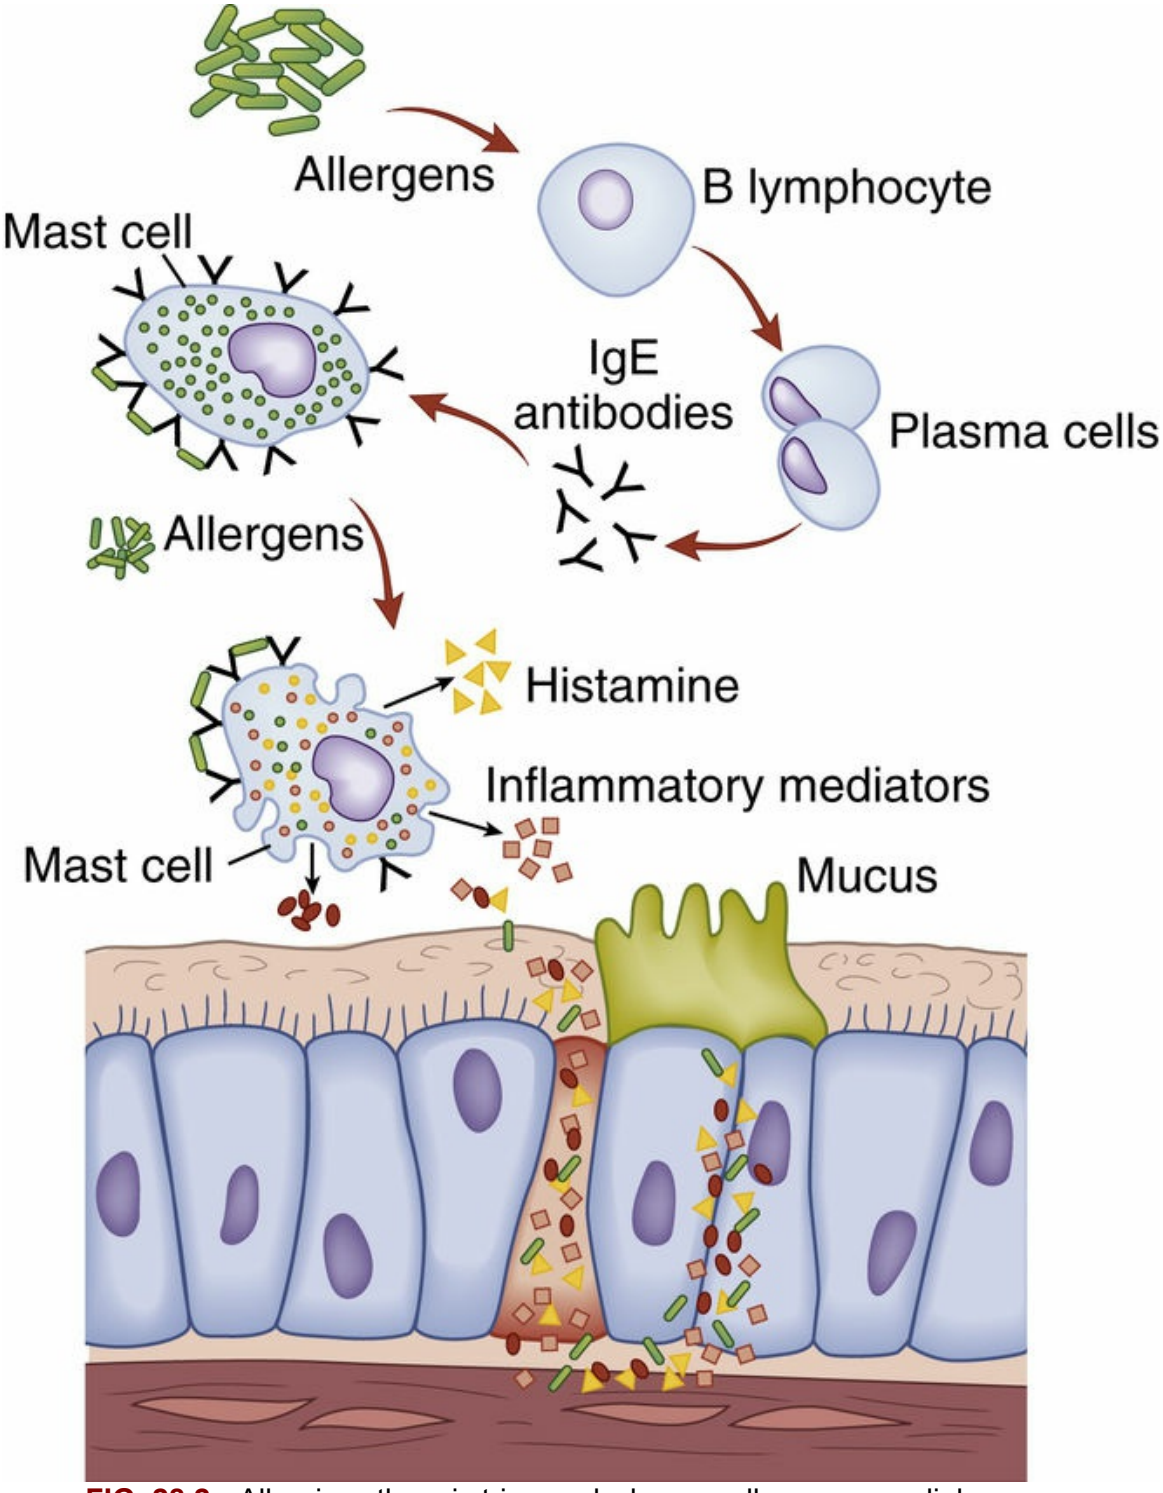

FIG. 28.2 Allergic asthma is triggered when an allergen cross-links *IgE* receptors on mast cells, which are then activated to release histamine and other inflammatory mediators (early-phase response). A late-phase response may occur due to further inflammation.

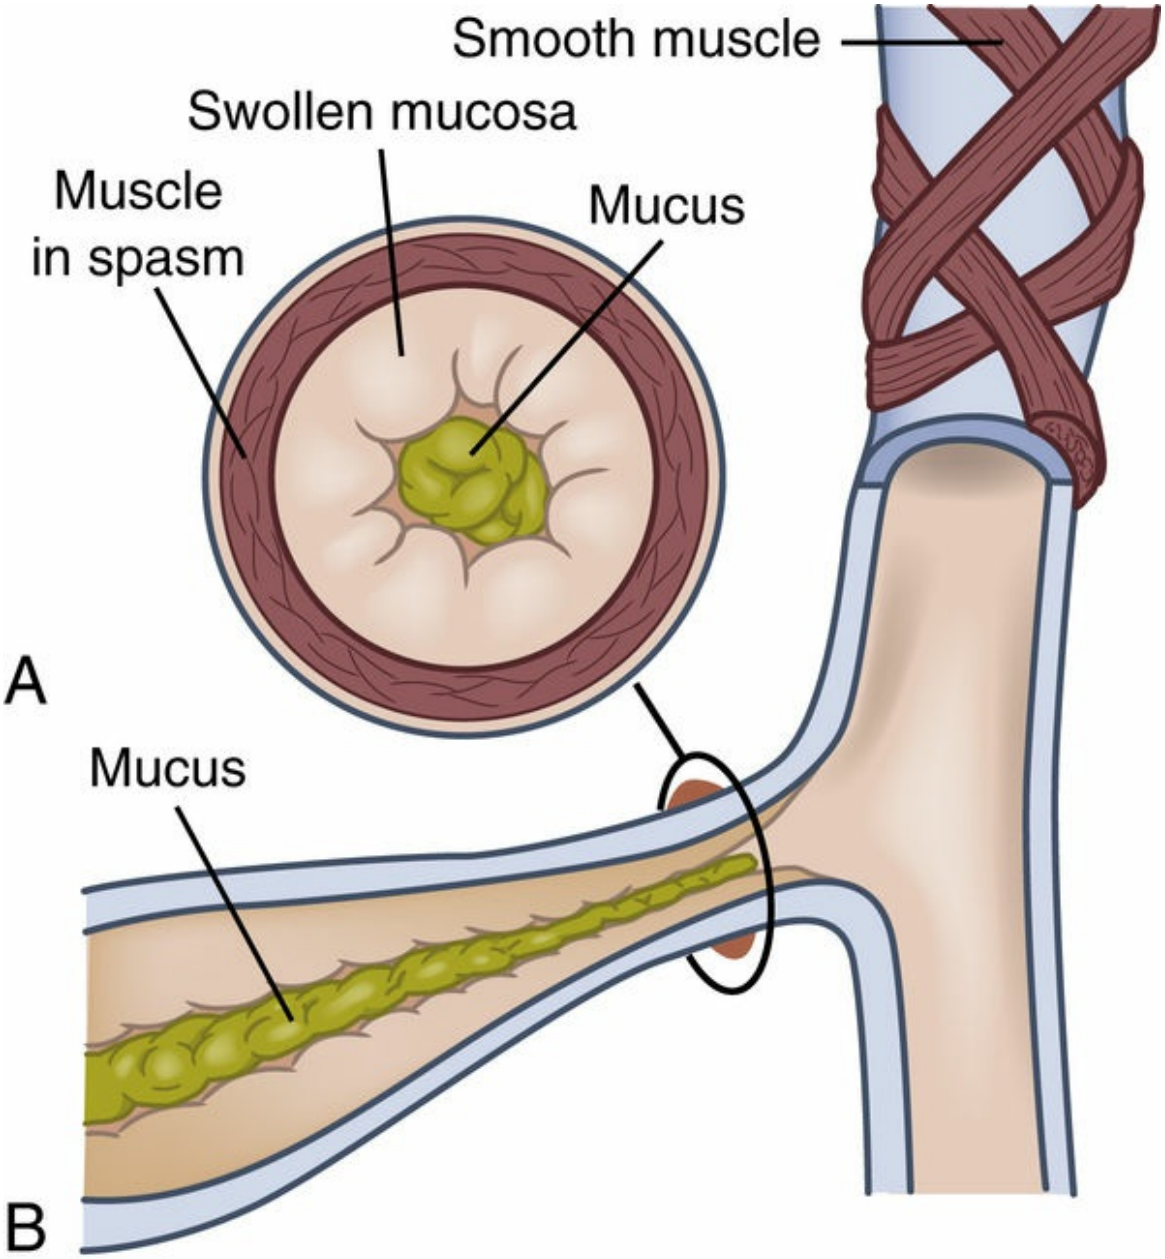

FIG. 28.3 Factors causing expiratory obstruction in asthma. **A,** Cross section of a bronchiole occluded by muscle spasm, swollen mucosa, and mucus in the lumen. **B,** Longitudinal section of a bronchiole. Redrawn from Price SA, Wilson LM: *Pathophysiology: Clinical concepts of disease processes,* ed 6, St Louis, 2003, Mosby.

Clinical Manifestations

The characteristic manifestations are wheezing, cough, dyspnea, and chest tightness after exposure to a risk factor or trigger. Normally the

bronchioles constrict during expiration. However, in asthma, the airways become narrower than usual because of bronchospasm, edema, and mucus. As a result, it takes longer for the air to move out of the bronchioles (airflow obstruction). This causes the characteristic wheezing, air trapping, and hyperinflation of the lungs. As a result, expiration may be prolonged.

The most common finding during an acute asthmatic event is wheezing on auscultation. For wheezing to occur, the patient must be able to move enough air to make the sound. Wheezing usually occurs first on exhalation. As asthma progresses, the patient may wheeze during inspiration and expiration.

However, wheezing is an unreliable sign to gauge the severity of an attack. Many patients with minor attacks wheeze loudly. Others with severe attacks do not wheeze. The patient with a severe asthma attack may wheeze only during forced expiration or have no audible wheezing because of the marked reduction in airflow.

Decreased or absent breath sounds may signal a significant decrease in air movement resulting from exhaustion and an inability to generate enough muscle force to breathe. Severely decreased breath sounds, often referred to as the "silent chest," are an ominous sign. It means severe airway obstruction and impending respiratory failure.

Safety Alert

Silent Chest

- If the patient has been wheezing, then there is an absence of a wheeze (e.g., silent chest) and the patient is obviously struggling, this is a life-threatening situation. The patient may need mechanical ventilation.

Hyperventilation occurs during an asthma attack as lung receptors respond to increased lung volume from trapped air and airflow

limitation. Decreased perfusion and ventilation of the alveoli and increased alveolar gas pressure lead to ventilation-perfusion abnormalities in the lungs. The patient is hypoxemic early on with decreased $PaCO_2$ and increased pH (respiratory alkalosis) because they are is hyperventilating. As the airflow limitation worsens with air trapping, the patient works much harder to breathe. The $PaCO_2$ normalizes as the patient tires, and then it increases to produce respiratory acidosis. This is an ominous sign of respiratory failure.

In some patients with asthma, cough is the only symptom. This is termed *cough variant asthma.* Bronchospasm is not present or may not be severe enough to cause airflow obstruction or wheezing, but it can increase bronchial tone and cause irritation with stimulation of the cough receptors. The cough may be nonproductive or with secretions. Sputum may be thick, tenacious, and gelatinous, which makes removal difficult.

The examination of the patient with asthma may be normal, especially between attacks. A runny nose, swollen nasal passages, and nasal polyps may be seen. The patient may have eczema and hives, which have been linked to asthma.

Check Your Practice

Your patient with a history of asthma was admitted to the ED in acute respiratory distress. He has been receiving therapy and seems to be responding. You notice he is no longer wheezing.

- Should you consider this finding a sign that he is doing better?

Asthma Classifications

There are several sets of guidelines for classifying asthma. Each set of guidelines has a slightly different perspective about asthma and how to classify the severity when attacks occur. Asthma severity is used to guide treatment decisions. Current guidelines focus on (1) assessing

the severity of the disease at diagnosis and initial treatment and then (2) monitoring periodically to control the disease. All groups endorse the use of short-acting bronchodilators for an acute asthma attack and the importance of an "asthma action plan" to help prevent future attacks from occurring. They promote patient education and adherence to prescribed therapy. Many HCPs use the 2007 the National Heart, Lung, and Blood Institute classification of asthma severity (Table 28.2). It describes asthma as intermittent, mild persistent, moderate persistent, or severe persistent.

Complications

Asthma is characterized by an unpredictable and variable course. Asthma attacks range from minor interferences in breathing to life-threatening episodes. Depending on a person's response, asthma can rapidly progress from normal breathing to an acute, severe attack or a life-threatening medical emergency within a few minutes.

While asthma attacks may have an abrupt onset, most of the time, symptoms occur more gradually. Attacks may last for a few minutes to several hours. Between attacks, the patient may be asymptomatic with normal or near-normal spirometry, depending on the severity of disease. In some people, compromised pulmonary function (indicated by abnormal spirometry results) may lead to a state of continuous symptoms and chronic debilitation. Pneumonia, tension pneumothorax, status asthmaticus, and acute respiratory failure can occur.

Status Asthmaticus

A life-threatening medical emergency, **status asthmaticus** is the most extreme form of an acute asthma attack. It is characterized by hypoxia, hypercapnia, and acute respiratory failure.[9] The patient is unresponsive to treatment with bronchodilators and corticosteroids. The patient may have chest tightness, a severely marked increase in shortness of breath, or suddenly be unable to speak. Hypotension, bradycardia, and respiratory and/or cardiac arrest may occur if we do

not recognize that the patient's condition is getting worse.

The patient must be immediately intubated, and mechanical ventilation started. Hemodynamic monitoring of the patient is critical. Analgesia and sedation are essential. Continuous analgesic infusions (e.g., ketamine, morphine) and sedation with drugs such as propofol (Diprivan) help decrease work of breathing (WOB) and facilitate patient synchrony with the ventilator. In some circumstances, neuromuscular blocking agents may be used. Inhaled anesthetics, such as isoflurane or halothane, are an option for those not responding to conventional treatment. IV magnesium sulfate, which has a bronchodilator effect, may be given to patients with a very low FEV_1 (forced expiratory volume in 1 second) or peak flow (less than 40% of predicted or personal best) or those who do not respond to initial treatment.

Diagnostic Studies

The tests we use to diagnose asthma are shown in Table 28.3. In general, the HCP should consider a diagnosis of asthma if various indicators (e.g., manifestations, health history, peak flow variability, spirometry) are positive.

Underdiagnosis of asthma is common. A detailed history is important to determine if a person has had similar attacks, which are often precipitated by a known trigger. Because wheezing and cough occur with a variety of disorders (e.g., COPD, GERD, vocal cord problems, heart failure), it is important to determine if asthma or some other disease process is the cause of these problems. A comparison of asthma and COPD is shown in Table 28.4.

TABLE 28.2 Classification of Asthma Severity

Asthma Severity				
	Persistent			
Components of Severity	**Intermittent**	**Mild**	**Moderate**	**Severe**
Impairment				
Symptoms	≤2 days/wk	>2 days/wk, not daily	Daily	Continuous
Nighttime awakenings	≤2/mos	3–4/mos	>1/wk, not nightly	Often 7/wk
SABA use for symptoms	≤2 days/wk	>2 days/wk, not daily	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function*	Normal FEV_1 between attacks FEV_1 >80% FEV_1/FVC normal	FEV_1 >80% predicted FEV_1/FVC normal	FEV_1 60%–80% predicted FEV_1/FVC reduced by 5%	FEV_1 <60% predicted FEV_1/FVC reduced by 5%
Risk				
Attacks requiring oral corticosteroids	0–1/yr	≥2/yrs even in the absence of impairment		
	Consider severity and interval since last attack.			
	Frequency and severity may fluctuate over time.			
	Relative annual risk for exacerbation may be related to FEV_1.			
Recommended Step for Initiating Treatment	Step 1	Step 2	Step 3†	Step 4 or 5†
	Reevaluate asthma control in 2–6 wk and adjust therapy as needed			

ercent predicted values for FEV_1 or ratio of FEV_1/FVC. Normal FEV_1/FVC: 8–19 yr, 85%; 20–39 yr, 80%; 40–59 yr, 75%; 60–80 yr, 70%.

† Consider short-term corticosteroid therapy.

Guidelines for Using Table

- Assign patients to the most severe step in which any feature occurs. Clinical features may overlap across steps. Determine level of severity by assessment of both impairment and risk. Assess impairment by patient's recall of previous 2–4 wk spirometry results.
- A person's classification should change over time with treatment. After treatment, the focus switches to the level of control, not the classification of severity.
- Patients at any level of severity of chronic asthma can have mild, moderate, or severe asthma attacks. Some patients with intermittent asthma have severe and life-threatening attacks separated by long periods of normal lung function and no symptoms.

no 08-4051, Bethesda, MD, 2007, National Institutes of Health.

Table 28.3 Interprofessional CareAsthma

Diagnostic Assessment

- History and physical examination
- Spirometry, including response to bronchodilator therapy
- Peak expiratory flow rate (PEFR)
- Chest x-ray
- Measurement of oximetry
- Allergy skin testing (if indicated)
- Blood level of eosinophils and IgE (if indicated)

Management

- Identify and avoid or eliminate triggers
- Patient and caregiver teaching
- Drug therapy (Tables 28.6 and 28.7 and Figs. 28.4 and 28.5)
- Asthma action plan (Fig. 28.9)
- Desensitization (immunotherapy) if indicated
- Assess for control (e.g., Asthma Control Test [ACT])*

Acute Attacks

- SaO_2 monitoring
- ABGs
- Inhaled β_2-adrenergic agonists
- Inhaled anticholinergics

- O_2 by nasal cannula or mask
- IV or oral corticosteroids
- IV fluids
- IV magnesium
- Intubation and assisted ventilation

* See *www.asthmacontroltest.com*.

The peak expiratory flow rate (PEFR) measured by the peak flow meter (at home or in a health care setting) is a test of lung function (see Table 25.17). PEFR measurements can help predict an asthma attack or monitor the severity of disease. Test results depend on the patient's age, gender, and height. Since types of peak flow meters vary, PEFR should be compared with the patient's own previous best measurements using their own meter.

Spirometry is usually normal between asthma attacks if the patient has no other underlying pulmonary disease. However, the patient with asthma may show an obstructive pattern including a decrease in forced vital capacity (FVC), FEV_1, PEFR, and FEV_1 to FVC ratio (FEV_1/FVC) (see Table 25.16).

When spirometry is scheduled, the patient must stop taking any bronchodilator drugs for 6 to 12 hours before the test. Spirometry can be done before and after the administration of a bronchodilator to determine the degree of the response. This helps determine reversibility of airway obstruction, which is critical information for diagnosing asthma. A positive (favorable) response to the bronchodilator is an increase of more than 200 mL and an increase of more than 12% between preadministration and postadministration values.[10]

We can use a hand-held, point-of-care device to measure fractional exhaled nitric oxide (FENO). FENO levels are increased in people with asthma associated with eosinophilic-induced airway inflammation. FENO may be used to gauge loss of asthma control and

attacks, assess a patient's adherence to therapy, or determine if more inhaled or oral antiinflammatory medication is needed.[11]

TABLE 28.4 Comparison of Asthma and COPD*

	Asthma	COPD
Clinical Features		
Age	Usually <40 yr (onset)	Usually 40–50 yr (onset)
Smoking history	Not causal	Often long history (>10–20 pack-years)
Health and family history	Presence of allergy, rhinitis, eczema. Family history of asthma	Infrequent allergies. May have exposure to environmental pollutants. With α_1-antitrypsin deficiency, family history of lung or liver disease without smoking history
Clinical symptoms	Intermittent, vary day to day, worse at night or early morning	Slowly progressive and persistent
Dyspnea	Absent except in attacks or poor control	Dyspnea during exercise
Sputum	Infrequent	Often
Disease course	Stable (with attacks)	Progressive worsening (with exacerbations)
Diagnostic Study Results		
ABGs	Normal between or during attacks	Between exacerbations in advanced COPD • Often low-normal pH and PaO_2 • High-normal $PaCO_2$ with normal to high HCO_3^- (compensated respiratory acidosis)
pH	↑ Early in attack, then ↓ if prolonged or severe attack	N→↓
PaO_2	↓	N→↓
$PaCO_2$	↓ Early in attack, then ↑ if prolonged or severe attack	N→↑
Chest x-ray	May show hyperinflation	Hyperinflation. May have cardiac enlargement, flattened diaphragm
Lung volumes	Often normalizes	Never normalizes
• **Total lung capacity**	Increased	Increased
• **Residual volume**	Increased	Increased
• **FEV_1**	Decreased or normal	Decreased
• **FEV_1/FVC**	Normal to decreased	Decreased (<70%)

* Patients may have features of both asthma and COPD.

Increased serum eosinophil counts and IgE levels are highly suggestive of atopy. Allergy skin testing may be used to determine sensitivity to specific allergens. However, a positive skin test does not necessarily mean that the allergen is causing the asthma attack. On the

other hand, a negative allergy test does not mean that the asthma event is not allergy related. (Allergy testing is discussed in Chapter 13.)

A chest x-ray in an asymptomatic patient with asthma is usually normal. A routine chest x-ray is usually not done unless other manifestations, such as fever, chills, or upper airway stridor, are present. It can show if something else is causing symptoms similar to those of asthma (e.g., pneumonia, foreign body in the airway.)

A sputum specimen for culture and sensitivity may be done to rule out bacterial infection, especially if the patient has purulent sputum, a history of upper respiratory tract infection (URI), a fever, or an increased white blood cell (WBC) count. However, most asthma attacks are viral, and sputum cultures are rarely done on an outpatient basis.

Interprofessional Care

The goal of care is to achieve and maintain control of the disease. Once the patient is diagnosed, guidelines provide direction about medications (based on steps) the patient needs (Fig. 28.4). The HCP will step up the medication therapy as asthma symptoms worsen and step down the medication as the patient achieves control (Table 28.5). The level of control is determined by the patient's medication use, symptoms, and PEFR or FEV_1.

During an acute attack, signs and symptoms, medication use, and PEFR or FEV_1 measurements can be used to help identify the severity of an asthma attack and guide us in providing the most appropriate treatment. The goal is to achieve rapid control of the symptoms and return the patient to their daily functioning at the best possible level. Management of acute asthma attacks is shown in Fig. 28.5.

Patients with mild or moderate asthma attacks are often seen in the community at an outpatient clinic. These attacks occur no more than twice per week, with minimal interference in day-to-day activity. The patient is alert, oriented, and speaks in sentences. The patient may describe chest tightness, varying degrees of difficulty breathing, and a

slight increase in the use of asthma drugs. O_2 saturation is usually greater than 90% on room air and PEFR greater than 50% of predicted or personal best.

Inhaled bronchodilators and oral corticosteroids are the mainstays of treatment for mild to moderate asthma attacks. Monitor the patient's vital signs. Most improve within 60 minutes of starting therapy. Teach the patient the importance of a follow-up appointment with the HCP. Oral corticosteroids will be part of the discharge plan for a moderate attack and, based on the patient's history and HCP preference, sometimes for a mild attack. If the patient's condition is slow to respond, does not respond, or the HCP suspects that some other condition may be occurring or contributing to the acute attack, the patient should be transferred to an acute care facility.

In a severe attack the patient is still alert and oriented, but may be tachycardic, tachypneic, and focused on breathing. Respiratory rates greater than 30 breaths/min may be present. Accessory muscle use may be seen. The patient may be agitated from hypoxemia. If not immediately audible, auscultation of the lungs may reveal inspiratory or expiratory wheezing. The patient often sits forward to maximize diaphragmatic movement. Time permitting, percussion of the lungs indicates hyperresonance. PEFR is 50% or less of predicted or of personal best. Symptoms may re-occur, sometimes daily, and there is interference with activities of daily living (ADLs).

A severe acute attack is usually frightening enough for patients to go to the ED. In many cases, a severe attack will warrant hospital admission. Management of the patient with a severe attack focuses on correcting hypoxemia and continually observing and/or improving ventilation. Supplemental O_2 is given by nasal cannula or mask to achieve a PaO_2 of at least 60 mm Hg or O_2 saturation greater than 93%. O_2 monitoring should be continuous with pulse oximetry.

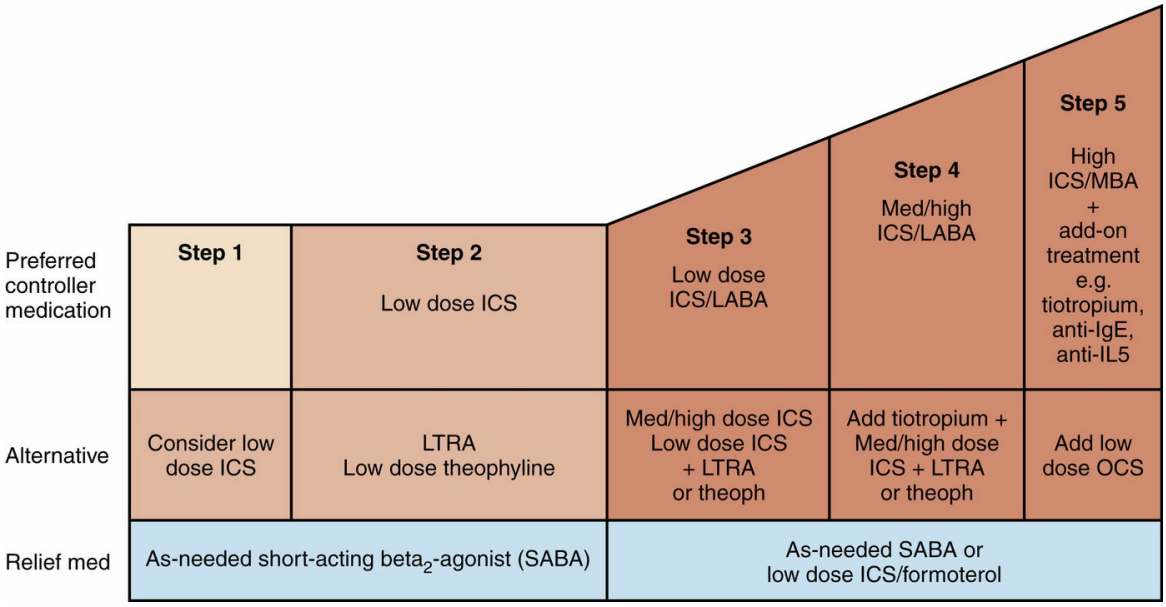

FIG. 28.4 Stepwise approach to asthma treatment.
Modified from GINA evidence-based strategy document, 2018.

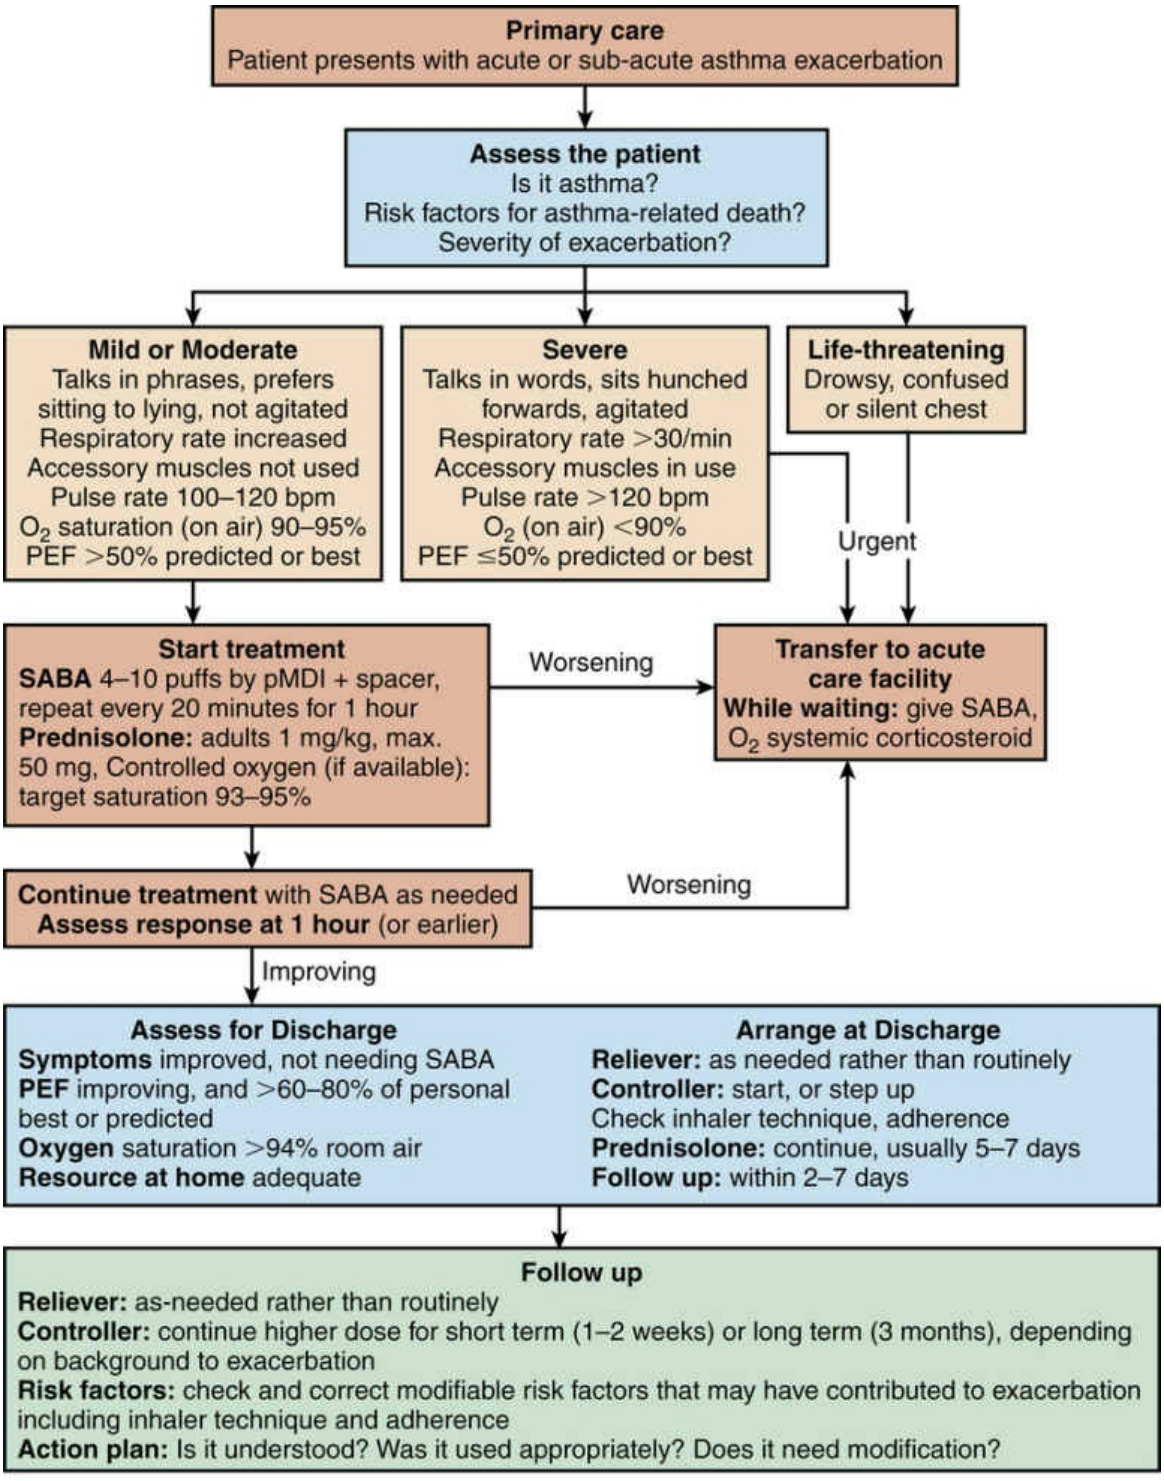
TABLE 28.5 Components of Asthma Control

Classification of Asthma Control			
Components of Control	Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment			
Symptoms	≤2 days/wk	>2 days/wk	Throughout the day
Nighttime Awakenings	≤2/mo	1–3/wks	≥4/wks
Interference with normal activity	None	Some limitation	Extremely limited
SABA use	≤2 days/wk	>2 days/wk	Several times/day
FEV_1 or PEFR	>80% predicted/personal best	60%–80% predicted/personal best	<60% predicted/personal best
Risk			
Attacks requiring oral corticosteroids	0–1/yr	≥2/yr	≥2/yr
Progressive loss of lung function	Consider severity and interval since last attack.		
Treatment-related adverse effects	Evaluation requires long-term follow-up. Can vary in intensity from none to very troublesome and worrisome. Level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended Action for Treatment (based on assessment of control)	• Maintain current step. • Regular follow-up every 1–6 mos to maintain control. • Consider step down if well controlled for at least 3 mo.	• Step up one step. • Reevaluate in 2–6 wk. • For side effects, consider alternative treatment options.	• Consider oral corticosteroids. • Step up 1 or 2 steps and reevaluate in 2 wk. • For side effects, consider alternative treatment options.

Source: Adapted from National Asthma Education and Prevention



Program, National Heart, Lung, and Blood Institute: *Expert Panel Report 3: Guidelines for the diagnosis and management of asthma,* NIH pub no 08-4051, Bethesda, MD, 2007, National Institutes of Health.

Bedside PEFR may be used to monitor airflow obstruction. Serial PEFR results, oximetry, and measurement of arterial blood gases (ABGs) give information about the severity of the attack and the response to therapy. Obtaining a PEFR during a severe asthma attack is usually not possible. However, if it can be obtained and is less than 200 L/min, it indicates severe obstruction in all but very small adults.

Careful monitoring of the patient's heart rate, respiratory rate and rhythm, and BP are essential. Bronchodilators and oral corticosteroids will be part of the treatment plan. The "silent chest" is an ominous clinical finding. It often signals impending respiratory failure. Immediate notification of the HCP is required.

Drug Therapy

Drug therapy for asthma can be complex and overwhelming for many practitioners, including you. It is important to understand the intended purpose, desired effect, side effects, and when to use different drugs. Asthma drugs are divided into 2 general types: (1) *quick relief,* or *rescue medications,* to treat attacks, and (2) long-term control medications (Table 28.6).

O_2: oxygen; PEF: peak expiratory flow; SABA: short-acting $beta_2$-agonist (doses are for salbutamol)

FIG. 28.5 Management of patient with acute asthma attack.
Modified from GINA evidence-based strategy document, 2018.
Retrieved from *https://ginasthma.org*.

The patient's medical history, medication plan, and severity of

attack helps the HCP determine which types of drugs are best suited to control asthma symptoms. Current guidelines all suggest a stepwise approach to drug therapy. Common drugs used in asthma therapy are discussed in Table 28.7.

The mainstay of asthma treatment is inhalation of short-acting β_2-adrenergic agonist (SABA) bronchodilators. All patients need a quick-relief or "rescue" medication. Short-acting SABAs, such as albuterol (ProAir HFA, Proventil HFA, Ventolin HFA), are the most effective rescue drugs for asthma.

In patients with a moderate to severe attack, inhaled ipratropium (Atrovent) is used in conjunction with a SABA. Combivent is a combination of both ipratropium and albuterol. Oral and, in some situations, IV corticosteroids may be given to patients who do not initially respond to SABA alone.

Patients with asthma who have frequent attacks also must be on a long-term ("controller") medication. Inhaled corticosteroids (ICSs) (e.g., fluticasone [Flovent Diskus or HFA]) are the most effective long-term controllers to treat inflammation. Some ICSs are used in combination with long-acting bronchodilators (LABAs) to gain better asthma control.

Bronchodilators

The 3 classes of bronchodilator drugs used in asthma therapy are β_2-adrenergic agonists (also referred to as β_2-agonists), methylxanthines and derivatives, and anticholinergics.

β_2-Adrenergic Agonist Drugs

These drugs may be SABAs or LABAs. Because inhaled SABAs are the most effective drugs for relieving acute bronchospasm (as seen in an acute attack), they are known as *rescue medications.* These drugs have an onset of action within minutes and are effective for 4 to 8 hours. They act by stimulating β-adrenergic receptors in the bronchioles, thus producing bronchodilation. They also increase mucociliary clearance.

TABLE 28.6 Drug TherapyQuick Relief vs. Long-Term Control of Asthma

Quick-Relief ("Rescue") Medications

Bronchodilators

Short-acting inhaled β_2-adrenergic agonists (e.g., albuterol [Proventil HFA])
Anticholinergics (inhaled) (e.g., ipratropium [Atrovent HFA])*

Antiinflammatory Drugs

Corticosteroids (systemic) (e.g., prednisone)†

Long-Term ("Controller") Medications

Antiinflammatory Drugs

Corticosteroids
- Inhaled (e.g., fluticasone [Flovent Diskus or HFA])
- Oral (e.g., prednisone)

LTMAs (e.g., montelukast [Singulair])
Anti–IgE (omalizumab [Xolair])

Bronchodilators

Long-acting inhaled β_2-adrenergic agonists (e.g., salmeterol [Serevent])
Long-acting oral β_2-adrenergic agonists (e.g., albuterol [VoSpire ER])
Methylxanthines (e.g., theophylline [Theo-24])

* Used as alternative if patient has intolerable side effects to albuterol or in ED for severe attacks.
† Considered quick-relief drugs when used in a short burst (3–10 days) at the start of therapy or during a period of gradual deterioration. Corticosteroids are not used for immediate relief of an ongoing attack.

β_2-Adrenergic agonists are useful in preventing bronchospasm triggered by exercise and other stimuli because they prevent the release of inflammatory mediators from mast cells. They do not inhibit the late-phase response of asthma or have antiinflammatory effects. If used often, inhaled β_2-adrenergic agonists may cause tremors, anxiety, tachycardia, palpitations, and nausea.

Too frequent use of β_2-adrenergic agonists indicates poor asthma control, may mask asthma severity, and may lead to reduced drug effectiveness. The use of SABAs should be limited to less than 2 times weekly. SABA inhalers should last for months. SABAs are not to be used for long-term control. They should not be used alone for recurrent, repeated asthma attacks. Use of long-term bronchodilators with inhaled corticosteroids or other drugs can achieve this goal better if prescribed and used properly.

LABAs, including salmeterol (Serevent Diskus) and formoterol (Foradil), are effective for 12 hours. LABAs are added to a daily dose of ICSs for long-term control of moderate to severe persistent asthma and prevention of symptoms, particularly at night. When LABAs are added to a patient's daily regimen of corticosteroids, they decrease the need for SABAs and allow patients to achieve better asthma control with a lower dosage of ICSs.

LABAs should never be used alone as asthma therapy. They should only be used if the patient is on an ICS. Tell patients that these drugs should not be used to treat acute symptoms or to obtain quick relief from bronchospasm. Teach the patient that these drugs are used only once every 12 hours.

Combination therapy using an ICS and a LABA is available in

several inhalers (e.g., fluticasone/salmeterol [Advair] and budesonide/formoterol [Symbicort]). The combinations are more convenient, improve adherence, and ensure that patients receive the LABA together with an ICS.

Drug Alert

β_2-Adrenergic Agonists

- Use with caution in patients with cardiac disorders.
- Both SABAs and LABAs may cause increased BP and heart rate, central nervous system stimulation, and dysrhythmias.

Drug Alert

Long-Acting β_2-Adrenergic Agonists (LABAs)

- Should not be the first or only drug used to treat asthma.
- Should be added to the treatment plan only if other controller medicines do not control asthma.
- Do not use to treat wheezing that is getting worse.
- Always use a SABA to treat sudden wheezing.

Methylxanthines

Sustained-release methylxanthine (theophylline) preparations are not a first-line controller medication. They are used only as an alternative therapy. Methylxanthine is a bronchodilator with mild antiinflammatory effects. The exact mechanism of action is unknown.

The main problems with theophylline are the high incidence of interaction with other drugs and the side effects. These include

nausea, headache, insomnia, gastrointestinal (GI) distress, tachycardia, dysrhythmias, and seizures. Because theophylline has a narrow margin of safety, monitor serum blood levels regularly to determine if drug levels are within therapeutic range.

Drug Alert

Theophylline

- Teach patient to report signs of toxicity: nausea, vomiting, seizures, insomnia.
- Avoid caffeine to prevent intensifying adverse effects.

Anticholinergic Drugs

Anticholinergic drugs affect the muscles around the bronchi (large airways). When the lungs are irritated, these bands of muscle can tighten, causing bronchoconstriction via the parasympathetic nervous system. Anticholinergics work by preventing these muscles from tightening. Consequently, these drugs promote bronchodilation.

Anticholinergic drugs are less effective than equivalent doses of SABAs in asthma. However, they are more effective in COPD patients. Therefore short-acting anticholinergic drugs are not used in the routine management of asthma, except for in severe acute asthma attacks.

Antiinflammatory Drugs

Corticosteroids

Chronic inflammation is a key component of asthma. Corticosteroids are antiinflammatory drugs that reduce bronchial hyperresponsiveness, block the late-phase response, and inhibit migration of inflammatory cells. Corticosteroids are more effective in improving asthma control than any other long-term drug.

To gain prompt control in acute attacks, oral corticosteroids are used. ICSs must be used for 1 to 2 weeks before maximum therapeutic effects can be seen. Some ICSs (e.g., fluticasone, budesonide [Pulmicort Flexhaler]) begin to have a therapeutic effect in 24 hours. Long-term, maintenance doses of oral corticosteroids may be needed to control asthma in patients with severe chronic asthma. ICSs must be used on a fixed schedule.

TABLE 28.7 Drug TherapyAsthma and Chronic Obstructive Pulmonary Disease (COPD)

Drug	Route of Administration	Comments
Anticholinergics		
Short Acting (SAMA)		
ipratropium (Atrovent HFA)	Nebulizer, MDI	Approved for COPD. May provide additive benefit to SABA in moderate to severe asthma attacks (used in ED with no benefit beyond that). Use in asthma as alternative for patients with intolerable side effects with SABA. Temporary blurred vision with eye contact. Use cautiously in patients with narrow-angle glaucoma or prostatic enlargement
Long Acting (LAMA)		
aclidinium bromide (Tudorza, Pressair)	DPI	Approved only for COPD. Do not give with other anticholinergics. Not for acute relief of bronchospasm. Dosed twice daily
revefenacin (Yupelri)	Nebulizer	Approved only for COPD. Dosed once daily as maintenance treatment. Do not give with other anticholinergics. Use cautiously in patients with narrow-angle glaucoma
tiotropium (Spiriva HandiHaler)	DPI	Approved only for COPD. Blurred vision if powder comes in contact with eyes. Must not use ipratropium while on tiotropium. Patients with COPD must use SABA or short-acting anticholinergics for quick-relief medication. Maximum effect 1 wk after starting drug. Dosed once daily
umeclidinium (Incruse Ellipta)	DPI	Approved only for COPD. Dosed once daily as maintenance treatment of airflow obstruction
β_2-Adrenergic Agonists		
Inhaled: Short Acting (SABA)		
albuterol (Proventil HFA, Ventolin HFA, Proair HFA, AccuNeb, VoSpire ER [oral only])	Nebulizer, MDI, oral tablets, including extended release NOTE: Oral tablets not for acute use, only long acting	Use with caution in patients with cardiac disorders because β-agonists may cause ↑ BP and heart rate, CNS stimulation/excitation, and ↑ risk for dysrhythmias. Has rapid onset of action (1–3 min). Duration of action is 4–8 hr. Ventolin HFA is the only albuterol MDI with a counter
levalbuterol (Xopenex, Xopenex HFA)	Nebulizer, MDI	Too frequent use can result in loss of effectiveness. Efficacy no better than other SABAs
Inhaled: Long Acting (LABA)	*In asthma:* Never use as monotherapy. Use in combination with ICSs. *In COPD:* Can be used as monotherapy. Not used for rapid relief of dyspnea	
arformoterol (Brovana)	Nebulizer	See formoterol. For chronic COPD use
formoterol (Foradil Aerolizer, Perforomist)	DPI, nebulizer (Perforomist)	Can affect blood glucose levels. Use with caution in patients with diabetes
indacaterol (Arcapta Neohaler)	DPI	Only once-daily LABA. For chronic COPD use. Not intended to treat asthma
olodaterol (Striverdi Respimat)	MDI	2 puffs daily. Less expensive than other LABAs
salmeterol (Serevent Diskus)	DPI	Not to exceed 2 puffs q12hr. Not used for acute attacks. Has a counter
Corticosteroids		
hydrocortisone (Solu-Cortef)	IV	Alternate-day therapy minimizes side effects. Oral dose should be taken in morning with food or milk. When given in high dosages, observe for GI distress. Long-term therapy requires vitamin D and calcium supplements to prevent osteoporosis. Discontinue gradually to prevent adrenal insufficiency. If symptoms recur during tapering, notify HCP
methylprednisolone (Medrol, Solu-Medrol)	Oral, IV	
prednisone	Oral	
Inhaled		
beclomethasone (Qvar)	MDI	Not recommended for acute asthma attack. May not see effects until after at least 2 weeks of regular treatment
budesonide (Pulmicort Flexhaler)	DPI	Same as above
ciclesonide (Alvesco)	MDI	Oral candidiasis and other localized oropharyngeal effects (e.g., hoarseness). Fewer side effects than other ICSs because of small particle size with minimal activation in oropharynx
fluticasone (Flovent HFA, Flovent Diskus, Arnuity Ellipta)	MDI, DPI	Not recommended for acute asthma attack. Rinse mouth with water or mouthwash after use to prevent oral fungal infections. Use of spacer device with MDI may decrease incidence of oral candidiasis. May not see effects until after at least 2 wks of regular treatment
mometasone (Asmanex Twisthaler)	DPI	Not recommended for acute asthma attack. May not see effects until after at least 2 wks of regular treatment
Leukotriene Modifiers		
Leukotriene Receptor Blocker		

Drug	Route of Administration	Comments
montelukast (Singulair)	Oral tablets, chewable tablets, oral granules	Not used to treat acute asthma episodes
zafirlukast (Accolate)	Oral tablets	Take at least 1 hr before or 2 hrs after meals. Affects metabolism of erythromycin and theophylline. Not used to treat acute asthma episodes

Table Continued

Drug	Route of Administration	Comments
Leukotriene Inhibitor		
zileuton (Zyflo, Zyflo CR)	Oral tablets	Monitor liver enzymes. May interfere with metabolism of warfarin and theophylline. Not used to treat acute asthma episodes
Methylxanthines		
***IV agent:* aminophylline (second-line therapy)** ***Oral:* theophylline**	Oral tablets, IV, elixir, sustained-release tablets	Wide variety of response to drug metabolism exists. Half-life is ↓ by smoking and ↑ by heart failure and liver disease. Cimetidine, ciprofloxacin, erythromycin, and other drugs may rapidly ↑ theophylline levels. Taking drug with food or antacids may help GI effects. Use limited to situations in which other long-term bronchodilators not available or not affordable
Monoclonal Antibodies		
Anti-IgE		
omalizumab (Xolair)	Subcutaneous	Only for moderate to severe, persistent, allergic asthma with symptoms not adequately controlled by ICSs. Not for acute bronchospasm. Give only under direct medical supervision biweekly or monthly, depending on IgE levels and weight. Observe patient for a minimum of 2 hrs after giving because anaphylaxis can occur
Anti-Interleukin 5		
mepolizumab (Nucala)	Subcutaneous	Only used for maintenance in patients with severe asthma attacks despite receiving current asthma medications. Given once every 4 wks by health care professional
reslizumab (Cinqair)	IV only	
Phosphodiesterase Inhibitor Type 4 (PDE-4)		
roflumilast (Daliresp)	Oral	Only used in severe COPD to reduce exacerbation frequency. Not to be used for acute bronchospasm. GI symptoms occur within 6 mos of starting therapy. Teach patients to report any psychiatric symptoms (e.g., anxiety, depression, suicidal thoughts). Do not use with theophylline
Combination Agents		
SAMA/SABA		
ipratropium/albuterol (Combivent Respimat, DuoNeb)	Nebulizer (DuoNeb), inhalation spray (Combivent Respimat)	Patients must be careful not to overuse. Respimat is an inhaler, but propellant free, unlike an MDI. Respimat is independent of inspiratory flow. Has dose indicator
ICS/LABA		
budesonide/formoterol (Symbicort)	MDI	Has a counter
fluticasone/salmeterol (Advair Diskus or HFA)	DPI, MDI	Has a counter. Comes in 3 strengths
fluticasone/vilanterol (Breo Ellipta)	DPI	Dose once daily
mometasone furoate/formoterol fumarate (Dulera)	MDI	Not for relief of acute bronchospasm
LAMA/LABA		
umeclidinium/vilanterol (Anoro Ellipta)	DPI	Anticholinergic/LABA for COPD. Not for relief of acute bronchospasm

When ICSs are used, asthma can usually be controlled without significant systemic side effects since little systemic drug absorption

occurs from these drugs. However, ICSs at the highest dosage levels have been associated with side effects (e.g., easy bruising, decreased bone mineral density). Oropharyngeal candidiasis, hoarseness, and dry cough are local side effects caused by inhalation of corticosteroids. These problems can be reduced or prevented by using a spacer with the metered-dose inhaler (MDI) and by gargling with water or mouthwash after each use. Using a spacer or holding device can help get more medication into the lungs.

Women, especially postmenopausal women, who have asthma and use corticosteroids should take adequate amounts of calcium and vitamin D and take part in regular weight-bearing exercise. (Osteoporosis is discussed in Chapter 63.)

Leukotriene Modifiers

Leukotrienes are inflammatory mediators produced from arachidonic acid metabolism. They are potent bronchoconstrictors. Some leukotrienes cause airway edema and inflammation, contributing to the symptoms of asthma. Leukotriene modifying agents (LTMAs) block the release of some substances from mast cells and eosinophils, thereby producing both bronchodilator and antiinflammatory effects. LTMAs include leukotriene receptor blockers (zafirlukast [Accolate], montelukast [Singulair]) and leukotriene synthesis inhibitors (zileuton [Zyflo CR]). These drugs interfere with the synthesis or block the action of leukotrienes.

LTMAs do not reverse bronchospasm in acute asthma attacks. They are used only for prophylactic and maintenance therapy. One advantage of these drugs is that they are taken orally.

Anti-IgE

Omalizumab (Xolair) is a monoclonal antibody to IgE that decreases circulating free IgE levels. Omalizumab prevents IgE from attaching to mast cells, thus preventing the release of chemical mediators. This drug is indicated for patients with moderate to severe asthma, or those not controlled with ICSs alone. Omalizumab is given subcutaneously every 2 to 4 weeks. The drug has a risk for

anaphylaxis, so patients must receive the medication in an HCP's office where this potential emergency can be treated.

Anti-Interleukin 5

Mepolizumab (Nucala) and reslizumab (Cinqair) are monoclonal antibodies to interleukin-5 (IL-5). IL-5 is a major cytokine involved in the inflammatory response in asthma by promoting eosinophil activity. By inhibiting IL-5, these drugs inhibit the production and survival of eosinophils. They are used for patients who have a history of severe asthma attacks despite using current asthma medication.

Nonprescription Combination Drugs

Several nonprescription combination drugs are available OTC. They are usually combinations of a bronchodilator (ephedrine) and an expectorant (guaifenesin). Often patients seek OTC drugs because they are less expensive than prescription medication. Many people consider these drugs safe because they can be obtained without a prescription. In general, they should be avoided due to their potential side effects.

Inhalers containing epinephrine may be available. These agents are advertised as drugs to relieve bronchospasm. Those containing ephedrine and epinephrine are potentially dangerous because they stimulate the central nervous and cardiovascular systems, causing nervousness, heart palpitations and dysrhythmias, tremors, insomnia, and increased BP. Many respiratory products containing ephedrine are behind the counter at pharmacies or need a prescription. This limited access is to prevent the diversion of ephedrine to the production of methamphetamine. Many OTC products have been reformulated with phenylephrine, instead of ephedrine, which works well topically but has modest effects in the oral form.

It is important to teach patients about the dangers associated with nonprescription combination drugs. These drugs are high risk and possibly unsafe to a patient with underlying heart problems because tachycardia and hypertension often occur. For the patient who insists on taking these drugs, caution them to read and follow the directions

on the label.

Inhalation Devices for Drug Delivery

Many asthma drugs are given by inhalation because the onset of action is faster and systemic side effects are reduced. Inhalation devices include MDIs, dry powder inhalers (DPIs), and nebulizers.

Inhalers

MDIs are small, hand-held, pressurized devices that deliver a measured dose of drug with each activation. The dosing is usually 1 or 2 puffs. Depending on the specific MDI, a spacer or holding chamber (e.g., AeroChamber, InspirEase [Fig. 28.6]) is used to reduce the amount of drug delivered to the oropharynx and improve the amount of drug delivered to the lungs. Spacers also help people who have hand-breath coordination problems.

FIG. 28.6 Example of an AeroChamber spacer used with a metered-dose inhaler.
From Potter PA, Perry AG, Stockert P, et al: *Fundamentals of nursing,* ed 9, St Louis, 2017, Mosby.

TABLE 28.8 Problems Using a Metered-Dose Inhaler (MDI)

- Not coordinating activation with inspiration
- Activating MDI in the mouth while breathing through nose
- Inspiring too rapidly
- Not holding the breath for 10 sec (or as close to 10 sec as possible)

- Holding MDI upside down or sideways
- Inhaling more than 1 puff with each inspiration
- Not shaking MDI before use (if indicated)
- Not waiting enough time between each puff
- Not opening mouth wide enough (if using open mouth technique), causing medication to bounce off teeth, tongue, or palate
- Not having adequate strength to activate MDI
- Not being able to understand and follow directions

International law mandates all MDIs have an ozone-friendly propellant that is a hydrofluoroalkane (HFA). This propellant is nontoxic, evaporates almost instantly once it forces medicine out of the MDI canister, and is not harmful to the patient. The number of times an MDI must be primed and the frequency of priming vary widely, so read the package insert with the patient.

The patient who needs to use several MDIs is often unclear about the order in which to take the medications. Historically it was recommended that SABAs be used first to open the airway and improve the delivery of subsequent medication. However, this recommendation is not evidence based. It is also a potential source of confusion to patients because SABAs are usually used on an as-needed basis.

One of the major problems with metered-dose drugs is the potential for overuse (more than 2 canisters per month) rather than seeking needed medical care (Table 28.8). As the patient has more asthmatic symptoms, they may use the β_2-adrenergic agonist MDI much more often. β_2-Adrenergic agonists help by relieving bronchospasm. They do not treat the inflammatory response. Therefore teach the patient the correct therapeutic use of these drugs.

Another problem is technique. Any MDI is effective only if taken properly. Review MDI technique during each visit as a standard part of care. The patient needs to know the correct way to determine whether the MDI is empty and how to effectively clean and care for

the device (Fig. 28.7).

Using an inhaler seems simple, but most patients do not use it the right way. When you use your inhaler the wrong way, less medicine gets to your lungs. (Your physician may give you other types of inhalers.)

For the next 2 weeks, read these steps aloud as you do them or ask someone to read them to you. Ask your physician or nurse to check how well you are using your inhaler.

Use your inhaler in one of the three ways pictured below (**A** or **B** is best, but **C** can be used if you have trouble with **A** or **B**).

Steps for Using Your Inhaler

Getting ready	1. Take off the cap and shake the inhaler. 2. Breathe out all the way. 3. Hold your inhaler the way your doctor said (**A, B,** or **C** below).
Breathe in slowly	4. As you start breathing in **slowly** through your mouth, press down on the inhaler **one** time. (If you use a holding chamber, first press down on the inhaler. Within 5 seconds, begin to breathe in slowly.) 5. Keep breathing in **slowly,** as deeply as you can.
Hold your breath	6. Hold your breath as you count to 10 slowly, if you can. 7. For inhaled quick-relief medicine (β_2-agonists), wait about 1 minute between puffs. There is no need to wait between puffs for other medicines.

A. Hold inhaler 1 to 2 inches in front of your mouth (about the width of two fingers).

B. Use a spacer/holding chamber. These come in many shapes and can be useful to any patient.

C. Put the inhaler in your mouth.

Clean Your Inhaler as Needed

Look at the hole where the medicine sprays out from your inhaler. If you see "powder" in or around the hole, clean the inhaler. Remove the metal canister from the L-shaped plastic mouthpiece. Rinse only the mouthpiece and cap in warm water. Let them dry overnight. In the morning, put the canister back inside. Put the cap on.

Know When to Replace Your Inhaler

For medicines you take each day (an example): Say your new canister has 200 puffs (number of puffs is listed on canister) and you are told to take 8 puffs per day.

$$8 \text{ puffs per day} \overline{)\ 200 \text{ puffs in canister}} \quad 25 \text{ days}$$

So this canister will last 25 days. If you started using this inhaler on May 1, replace it on or before May 25. You can write the date on your canister.

For **quick-relief medicine take as needed** and count each puff.

Do not put your canister in water to see if it is empty as water may enter MDI and impair inhaler.

FIG. 28.7 How to use your metered-dose inhaler correctly.

DPIs are simpler to use than MDIs. The DPI contains dry, powdered

medication and is breath activated (Fig. 28.8). No propellant is used. Instead, an aerosol is created when the patient inhales through a reservoir containing a dose of powder.

DPIs have several advantages over MDIs: (1) less manual dexterity is needed, (2) there is no need to coordinate device puffs with inhalation, and (3) no spacer is needed. Disadvantages are that some common drugs are not yet available in DPIs, and the medication may clump if exposed to humidity. Since the medicine is delivered only by the patient's inspiratory effort, patients with a low FEV_1 (less than 1 L) may not be able to inspire the medication. Table 28.9 describes how to effectively use a DPI.

Differences between MDIs and DPIs are described in Table 28.10. Aerosolized medication delivery systems, when used with comparable drug doses, provide equivalent efficacy. Therefore patients should use the device best suited to their needs.

Nebulizers

Nebulizers are small machines used to convert drug solutions into mists. The mist can be inhaled through a face mask or mouthpiece held between the teeth. Nebulizers are usually used for those who have severe asthma or difficulty with the MDI inhalation. They do not provide better delivery of medication than a spacer with an inhaler.

Nebulizers are usually powered by a compressed air or O_2 generator. At home, the patient may have an air-powered compressor. In the hospital, wall O_2 or compressed air powers the nebulizer.

Aerosolized medication orders must include the medication, dose, diluent, and whether it is to be nebulized with O_2 or compressed air. The advantage of nebulization therapy is that it is easy to use. Medications that are routinely nebulized include albuterol and ipratropium.

FIG. 28.8 Example of a dry powder inhaler (DPI).
From Potter PA, Perry AG, Stockert P, et al: *Fundamentals of nursing,* ed 9, St Louis, 2017, Mosby.

TABLE 28.9 Patient TeachingHow to Use a Dry Powder Inhaler (DPI)

Include the following instructions when teaching a patient to use a DPI:

1. Remove mouthpiece cap or open the device according to manufacturer's instructions. Check for dust or dirt. If there is an external counter, note the number of doses left.
2. Load the medicine into the inhaler or engage the lever to allow the medicine to become available. Some DPIs re held upright while loading. Others are held sideways or in a horizontal

position.
3. Do not shake your medicine.
4. Tilt your head back slightly and breathe out, getting as much air out of your lungs as you can. Do not breathe into your inhaler because this could affect the dose.
5. Close your lips tightly around the mouthpiece of the inhaler.
6. Breathe in deeply and quickly. This will ensure that the medicine moves down deeply into your lungs. You may not taste or sense the medicine going into your lungs.
7. Hold your breath for 10 seconds or as long as you can to disperse the medicine into your lungs.
8. If there is an external counter, note the number of doses left. It should be 1 less than the number in step 1 above.
9. Do not keep your DPI in a humid place, such as a shower room, because the medicine may clump.

The patient is placed in an upright position that allows for most efficient breathing to ensure adequate penetration and deposition of the aerosolized medication. The patient must breathe slowly and deeply through the mouth and hold each inspiration for 2 to 3 seconds. Deep diaphragmatic breathing helps ensure delivery of the medication. Tell the patient to breathe normally in between large, inhaled breaths. After treatment, have the patient cough effectively.

To reduce the potential for bacterial growth, review cleaning procedures for home respiratory equipment with the patient. An effective home-cleaning method is to wash the nebulizer daily in soap and water, rinse it with water, and soak it for 20 to 30 minutes in a 1:1 white vinegar–water solution, followed by a water rinse and air drying.

Patient Teaching Related to Drug Therapy

One of the major factors determining success in asthma management is the correct administration of drugs. The drug regimen can be confusing and complex. When teaching patients about their medications, include the name, purpose, dosage, method of

administration, and when to use. It is essential that the patient understand the difference between rescue and controller medications, the importance of monitoring their response to therapy, and, most importantly, when to recognize that symptoms are not improving and help is required. Review side effects, appropriate action if side effects occur, and how to properly prime, use, and clean devices. Some patients may benefit from keeping a diary to record medication use, wheezing, or coughing, PEFR, side effects of drugs, and activity level. This information will help the HCP adjust the medication if needed.

TABLE 28.10 Comparison of Metered-Dose and Dry Powder Inhalers

	Metered-Dose Inhaler (MDI)	Dry Powder Inhaler (DPI)
Shake before use	May be needed for some (e.g., albuterol), but not for others (Read package insert)	No
Inspiration	Slow	Rapid
Spacer	May be used with inhaled corticosteroids or for more effective delivery (Read package insert)	Not used
Counting device	Many have an external device, but some do not	Most preloaded forms include counter
Inhalations/dose	Often 2/dose	Often 1/dose
Cleaning	Use water for plastic case	Avoid moisture

Several factors can affect the correct use of inhalation devices. These include advanced age, changes in physical dexterity (e.g., arthritis in hands, coordination), psychologic state (e.g., cognition), affordability, convenience, and administration time and preference.

Poor adherence with medication therapy is a major challenge in the long-term management of chronic asthma. Lack of adherence often occurs when the patient is symptom free and does not use the long-term therapy (e.g., ICS) regularly because no immediate benefit is felt.

The patient does not realize that ICSs are needed to treat the ongoing inflammatory process.

Explain the importance and purpose of taking the long-term therapy regularly, emphasizing that maximum improvement may take 1 week or longer. Tell the patient that without regular use, swelling in the airways may progress and asthma will likely worsen over time. Collaborate with social services to help lower income patients obtain medications.

Make sure that patients understand exactly how to use their inhaler device (Fig. 28.7). Give them printed instructions. At every clinic visit or hospitalization, reassess the patient's inhaler technique. If package inserts are available, you can review them before teaching the patient.

Nursing Management: Asthma

Nursing Assessment

If a patient is not in acute distress, obtain a detailed health history, including information about triggers and what has helped alleviate asthma attacks in the past. Subjective and objective data that should be obtained from a patient with asthma are outlined in Table 28.11.

TABLE 28.11 Nursing AssessmentAsthma

Subjective Data
Important Health Information

Past health history: Allergic rhinitis, sinusitis, or skin allergies. Previous asthma attack and hospitalization or intubation. Symptoms worsened by triggers in the environment. GERD. Occupational exposure to chemical irritants (e.g., paints, dust)

Medications: Adherence to medication, inhaler technique. Use of antibiotics. Pattern and amount of short-acting β_2-adrenergic agonist used per week. Medications that may trigger an attack in susceptible persons, such as aspirin, NSAIDs, β-adrenergic blockers

Functional Health Patterns

Health perception–health management: Family history of allergies or asthma. Recent URI or sinus infection

Activity-exercise: Fatigue, decreased or absent exercise tolerance. Dyspnea, cough (especially at night), productive cough with yellow or green sputum or sticky sputum. Chest tightness, feelings of suffocation, air hunger, talking in short sentences or

words or phrases, sitting upright to breathe

Sleep-rest: Awakened from sleep because of cough or breathing difficulties, insomnia

Coping–stress tolerance: Emotional distress, stress in work environment or home

Objective Data

General

Restlessness or exhaustion, confusion, upright or forward-leaning body position

Integumentary

Diaphoresis, cyanosis (circumoral, nail bed), eczema

Respiratory

Nasal discharge, nasal polyps, mucosal swelling. Crackles, decreased or absent breath sounds, and wheezes (inspiratory, expiratory, or both) on auscultation. Hyperresonance on percussion. Sputum (thick, white, tenacious), ↑ work of breathing with use of accessory muscles. Intercostal and supraclavicular retractions. Tachypnea with hyperventilation. Prolonged expiration

Cardiovascular

Tachycardia, pulsus paradoxus, jugular venous distention, hypertension or hypotension, premature ventricular contractions

Possible Diagnostic Findings

Abnormal ABGs during attacks, ↓ O_2 saturation, serum and sputum eosinophilia, ↑ serum IgE, positive skin tests for allergens, chest x-ray showing hyperinflation with attacks, abnormal pulmonary function tests showing ↓ flow rates; FVC, FEV_1, PEFR, and FEV_1/FVC ratio that improve between attacks and with bronchodilators

Nursing Diagnoses

Nursing diagnoses for the patient with asthma may include:

- Impaired breathing
- Activity intolerance
- Anxiety
- Lack of knowledge

Additional information on nursing diagnoses and interventions is presented in eNursing Care Plan 28.1 on the website for this chapter.

Planning

The overall goals are that the patient with asthma will achieve asthma control, as evidenced by (1) minimal symptoms during the day and night, (2) acceptable activity levels (including exercise), (3) maintaining greater than 80% of personal best PEFR, (4) few or no adverse effects of therapy, (5) no acute attacks of asthma, and (6) adequate knowledge to carry out the plan of care.

Nursing Implementation

Health Promotion

Your role in preventing asthma attacks or decreasing their severity

focuses primarily on teaching both the patient and caregiver. Teach the patient to identify and avoid known personal triggers for asthma (e.g., cigarette smoke, pet dander) and irritants (e.g., cold air, aspirin, foods, cats, indoor air pollution) (Table 28.1). Washing bedclothes in hot water or cooler water with detergent and bleach has some effect on allergen levels. Avoiding furred animals is suggested, but pet allergens are impossible to avoid. Pet allergens can be found in many public areas for months even after removal of the animal. Many people are allergic to cockroach remains and the dried droppings, so measures to avoid or control cockroaches are partly effective in removing allergens.

When cold air cannot be avoided, dressing properly with scarves or using a mask helps reduce the risk for an asthma attack. Aspirin and NSAIDs should be avoided if they are known to trigger an attack. Many OTC drugs contain aspirin. Teach the patient to read the labels carefully. Nonselective β-blockers (e.g., propranolol [Inderal]) are contraindicated because they inhibit bronchodilation. Selective β-blockers (e.g., atenolol [Tenormin]) should be used with caution. Desensitization (immunotherapy) may be partially effective in decreasing the patient's sensitivity to known allergens (see Chapter 13).

Prompt diagnosis and treatment of URIs and sinusitis may prevent an asthma attack. If occupational irritants are involved, the patient may need to consider changing jobs. Those who are obese often find that weight loss improves asthma control. Encourage the patient to maintain a fluid intake of 2 to 3 L/day, adequate nutrition, and plenty of rest. If exercise is planned or if the patient has asthma only with exercise, the HCP can suggest a medication regimen for pretreatment or long-term control of symptoms to prevent bronchospasm.

Acute Care

A major goal in asthma care is to maximize the patient's ability to safely manage acute asthma using an asthma action plan developed in conjunction with the HCP (Fig. 28.9). Action plans are important for all people with asthma, especially those who have frequent, acute

attacks. They are based on the patient's asthma symptoms and PEFR. The action plan dictates what symptoms or PEFR necessitates a change in asthma management to gain control.

The patient can take 2 to 4 puffs of a SABA every 20 minutes, up to 3 times, as a rescue plan. Depending on the response (e.g., alleviation of symptoms, improved PEFR), continued SABA use and/or oral corticosteroids may be a part of the home management plan. If symptoms persist or if the patient's PEFR is less than 50% of the personal best, the HCP or emergency medical services must be contacted at once.

When the patient is in the health care agency with an acute attack, it is important to monitor the patient's respiratory and cardiovascular systems. This includes (1) monitoring heart rate and rhythm, respiratory rate and WOB, and BP; (2) monitoring pulse oximetry, PEFR, and ABGs; and (3) auscultating lung sounds.

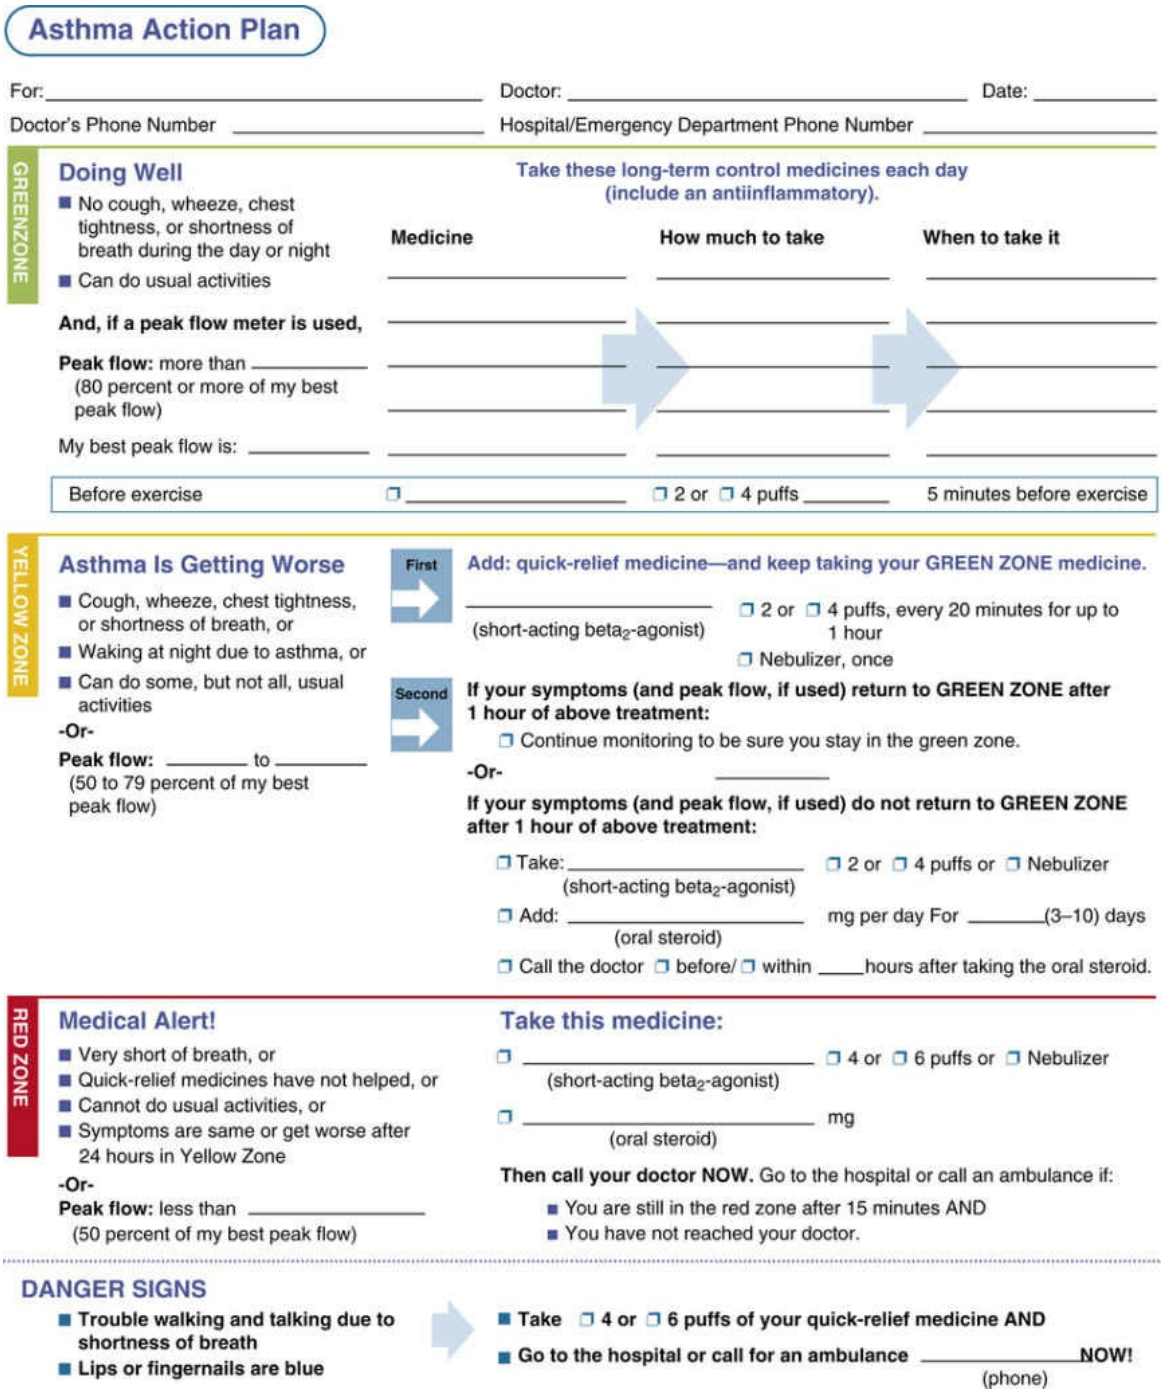


FIG. 28.9 Asthma action plan.
Source: National Heart, Lung, and Blood Institute, Bethesda, MD.

Give drugs as ordered. Louder wheezing may actually occur in airways that are responding to therapy as airflow increases. As improvement continues and airflow increases, breath sounds increase and wheezing decreases. The disappearance of most bronchospasm,

resolution of edema and cellular infiltration of airway mucosa, and the elimination of viscous mucous plugs may take several days to improve. As a result, therapy must be continued even after clinical improvement. Always evaluate the patient's response to therapy.

An important nursing goal during an acute attack is to decrease the patient's anxiety and sense of panic. Position the patient comfortably (usually sitting, in semi- to high-Fowler's position) to maximize chest expansion. A calm, quiet, reassuring attitude may help the patient relax. A technique called "talking down" can help the patient remain calm. In talking down, you gain eye contact with the patient. In a firm, calm voice, coach the patient to use pursed-lip breathing. Pursed-lip breathing keeps the airways open by maintaining positive pressure (Table 28.12). Stay with the patient until the respiratory rate has slowed.

TABLE 28.12 Patient TeachingPursed-Lip Breathing (PLB)

Teach the patient how to do PLB using the following guidelines:

1. Use PLB before, during, and after any activity causing you to be short of breath.
2. Inhale slowly and deeply through the nose.
3. Exhale slowly through pursed lips, as if whistling.
4. Relax your facial muscles without puffing your cheeks—like whistling—while you are exhaling.
5. Make breathing out (exhalation) 3 times as long as breathing in (inhalation).
6. The following activities can help you get the "feel" of PLB:
    - Blow through a straw in a glass of water with the intent of forming small bubbles.
    - Blow a lit candle enough to bend the flame without blowing it out.
    - Steadily blow a table-tennis ball across a table.

- Blow a tissue held in the hand until it gently flaps.

7. Practice 8-10 repetitions of PLB 3 or 4 times a day.

When the acute attack subsides, provide rest and a quiet, calm environment. When the patient is less exhausted, can breathe easier, and beginning to recover, try to obtain a health history and do a physical assessment. If caregivers are present, they may be able to provide information about the patient's health history. This information is important in planning and implementing an individualized nursing care plan.

Ambulatory Care

Control of symptoms can be achieved by teaching the patient about drug therapy and monitoring. Review the written asthma action plan. As part of the plan, the patient must measure PEFR at least daily. PEFR monitoring, when done correctly, is a reliable, objective measurement of asthma control (Table 28.13). Some patients may not perceive changes in their breathing and may have a significant decrease in lung function without any symptoms other than a change in PEFR.

TABLE 28.13 Patient TeachingHow to Use Your Peak Flow Meter

Include the following instructions when teaching the patient to use a peak flow meter:

Why Use a Peak Flow Meter?

- Peak flow meters are used to check your asthma the way that BP cuffs are used to check BP. A peak flow meter is a device that measures how well air moves out of your lungs.
- During an asthma episode, the airways of the lungs usually begin to narrow slowly. The peak flow meter may tell you if there is

narrowing in the airways hours, sometimes even days, before you have any asthma symptoms.

- By taking your medicines early (before symptoms), you may be able to stop the episode quickly and avoid a severe asthma episode.
- The peak flow meter is used to help you and your HCP:
- Learn what makes your asthma worse.
- Decide if your treatment plan is working well.
- Decide when to add or stop medicine.
- Decide when to seek emergency care.

How to Use Your Peak Flow Meter

Complete the following 5 steps with your peak flow meter:

1. Move the indicator to the bottom of the numbered scale.
2. Stand up.
3. Take a deep breath, filling your lungs completely.
4. Place the mouthpiece in your mouth and close your lips around it. Do not put your tongue inside the hole.
5. Blow out as hard and fast as you can in a single blow.
    - Write down the number you get. But if you cough or make a mistake, do not write down the number. Perform the action again.
    - Repeat steps 1 through 5 two more times. Write down the best of the 3 blows in your asthma diary.

Find Your Personal Best Peak Flow Number

- Your personal best peak flow number is the highest peak flow number you can achieve over a 2-week period when your asthma is under good control. Good control is when you feel good and do not have any asthma symptoms.
- Each patient's asthma is different. Your best peak expiratory flow

rate (PEFR) may be higher or lower than the peak flow of someone of your height, weight, and gender. This means that it is important for you to find your own personal best peak flow number, which is the basis for your treatment plan.

- To find your personal best peak flow number, take peak flow readings:
    - At least twice a day for 2-3 weeks, between 12 noon and 2 PM when your peak flow is the highest
    - 15 to 20 minutes after taking inhaled short-acting β_2-agonist (SABA) for quick relief
    - As instructed by your HCP

The Peak Flow Zone System

Once you know your personal best peak flow number, your HCP will put the peak flow numbers into zones that are set up like a traffic light. This will help you know what to do when your peak flow number changes. For example:

- *Green Zone* (more than __L/min [80% of your personal best number]) signals good control. No asthma symptoms are present. Take your medicines as usual.
- *Yellow Zone* (between __ and __L/min [50% to <80% of your personal best number]) signals caution. If you stay in the yellow zone after several measures of peak flow, take an inhaled SABA. If you continue to register peak flow readings in the yellow zone, your asthma may not be under good control. Ask your HCP if you need to change or increase your daily medicines.
- *Red Zone* (<__L/min [<50% of your personal best number]) signals a medical alert. Take an inhaled SABA (quick-relief medicine) right away. Call your HCP and ask what to do or go directly to the ED.

Use the Diary to Keep Track of Your Peak Flow

- Record your personal best peak flow number and peak flow zones in your asthma diary.
- Measure your peak flow when you wake up, *before* taking medicine. Write down your peak flow number in the diary every day, or as instructed by your HCP.

Actions to Take When Peak Flow Numbers Change

- PEFR goes between __ and __L/min (50% to <80% of personal best, yellow zone).

ACTION: Take an inhaled SABA (quick-relief medicine) as prescribed by your HCP.

- PEFR increases ≥20% when measured before and after taking an inhaled SABA (quick-relief medicine).

ACTION: Talk to your HCP about adding more medicine to control your asthma better (e.g., an antiinflammatory medication).

Source: Adapted from National Asthma Education and Prevention Program, National Heart, Lung, and Blood Institute: *Expert Panel Report 3: guidelines for the diagnosis and management of asthma,* NIH pub no 08-4051, Bethesda, Md, 2007, National Institutes of Health.

If a patient's PEFR is within the green zone (usually 80% to 100% of the patient's personal best), the patient should remain on their usual medications. A PEFR within the yellow zone (usually 50% to 80% of personal best) indicates caution. A PEFR in the red zone (50% or less of personal best) indicates a serious problem. In other words, something is triggering the patient's asthma (e.g., viral infection).

Consequently, the written asthma action plan needs to clearly identify the step-up increase in medications during the acute phase of an infection. For example, the patient can use different strategies, such as using the SABA more often. Although it may happen, it is unusual for a patient's PEFR to drop from the green zone to the red zone quickly. Usually the patient has time to make changes in medications, avoid triggers, and notify the HCP. The dose is stepped down once the symptoms subside.

Check Your Practice

A 32-yr-old man is admitted to the ED for an acute attack of asthma. It is his third admission in the past 2 months. He had been watching his 6-yr-old son play soccer when his attack started. He says to you, "I am just not a good father. My son is going to think I am just a 'sicky.' I can't play sports . . . can't . . . even . . . watch him . . . without something happening."

- How would you respond to this man?

It is important to involve the patient's caregivers. They should know where to find the patient's medications. Teach them how to decrease the patient's anxiety if an asthma attack occurs. When the patient is stabilized or controlled, the caregiver can gently remind the patient about monitoring daily PEFR by asking questions, such as "What zone are you in?" or "How's your peak flow today?" A patient and caregiver teaching guide for the patient with asthma is shown in Table 28.14.

Good nutrition is important. Physical exercise (e.g., swimming, walking, stationary cycling) within the patient's limit of tolerance is beneficial. It may require pretreatment with a SABA. Uninterrupted sleep is an important goal. If patients with asthma report lack of sleep because of asthma symptoms, their asthma is not under good control and their plan should be reevaluated.

Informatics in Practice

Home Monitoring of Asthma

- To reduce the rate of hospital readmissions, the patient with asthma may be discharged with a home monitoring system. These systems provide an easy and inexpensive approach to remotely monitoring lung function.
- Asthma home monitoring usually consists of PEFR, pulse oximetry, vital signs, and lung sounds. This information is sent to the HCP so that problems are quickly detected.
- As part of your discharge planning, help the patient obtain a system and review its use.

Validated questionnaires (e.g., Asthma Control Test [ACT] available at *www.asthmacontroltest.com*) can be used to assess quality-of-life in asthma patients. Patients with asthma may have frequent absences from school or work and psychological issues, such as stress, anxiety, despair, and depression.

TABLE 28.14 Patient & Caregiver TeachingAsthma

Include the following information in a teaching plan for the patient with asthma and the caregiver. It will help to improve the patient's quality of life and promote lifestyle changes that support successful living with asthma.

What Is Asthma?

- Basic anatomy and physiology of lung
- Pathophysiology of asthma
- Relationship of pathophysiology to signs and symptoms
- Measurement and correlation of spirometry and peak expiratory

flow rate

What Is Good Asthma Control?

- Personal ideas of good control
- Use Asthma Control Test available at www.asthmacontroltest.com

Obstacles to Asthma Treatment and Control

- Discuss with patient and caregiver about possible obstacles (e.g., denial, poor perception of asthma severity by patient)

Environmental and Trigger Control

- Identify triggers and preventive measures (use trigger diary)
- Avoiding allergens and other triggers
- Need to maintain good hydration

Medications

- Types (include mechanism of action)
- Use of preventive and maintenance (e.g., antiinflammatory) agents
- Write out medication list and schedule
- Asthma Action Plan (Fig. 28.9)
- Correct use of inhalers, spacer, and nebulizer

Pursed-Lip Breathing (Table 28.12)

Correct Use of Peak Flow Meter (Table 28.13)

Asthma Action Plan (Fig. 28.9)

- Peak flow zones
- Individualize asthma action plan with HCP and patient
- Early recognition of infection
- Building a partnership with your HCP
- Questions patients may have about asthma, but patient cannot reach the HCP

For more information, visit the American Lung Association website at *www.lung.org/lung-disease/asthma*.

An increased number of older adults have asthma. This is a special concern because they have more complicated health issues than younger patients with asthma. Issues that face older adults are hypertension, heart disease, costly medications, and difficulty accessing the health care system. Keep these factors in mind when implementing a management plan for older adults.

Disparities in socioeconomic status and access to proper health care, as well as cultural beliefs about asthma may be part of the reason blacks and Hispanics have higher rates of poorly controlled asthma. Seek to explore and eliminate any potential barriers to health care. Use culturally appropriate resources and educational material in languages other than English to help improve knowledge about asthma and asthma control for these persons.

Relaxation therapies (e.g., yoga, meditation, relaxation techniques, breathing techniques) may help a patient relax respiratory muscles and decrease the respiratory rate. (Chapter 6 discusses relaxation breathing and other relaxation strategies.) A healthy emotional outlook is also important in preventing asthma attacks. Asthma support groups are available online and around the country.

Evaluation

The expected outcomes are that the patient with asthma will

- Maintain patent airway with removal of excessive secretions
- Have normal (for the patient) breath sounds and respiratory rate
- Report decreased anxiety with increased control of breathing
- Correctly use medications
- Express confidence in ability to manage asthma

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a preventable, treatable, but often progressive disease characterized by persistent airflow limitation. COPD is associated with an enhanced chronic inflammatory response in the airways and lungs, primarily caused by cigarette smoking and other noxious particles and gases. COPD exacerbations and other coexisting illnesses or co-morbidities may contribute to the overall severity of the disease.

Previous definitions of COPD have included such terms as *chronic bronchitis* and *emphysema.* Neither term is part of the current definition of COPD. **Chronic bronchitis** is the presence of cough and sputum production for at least 3 months in each of 2 consecutive years. It is an independent disease that may precede or follow the development of airflow limitation. **Emphysema**, the destruction of alveoli without fibrosis, describes one of several structural abnormalities in COPD patients.

An estimated 16 million adults in the United States have COPD.[12] The number of people with COPD is greatly underestimated because the disease is usually not diagnosed until it is moderately advanced. COPD is the third leading cause of death in the United States, causing more than 120,000 deaths each year.[12]

Gender Differences

COPD

Men

- COPD is more common in men.
- The number of men with COPD is not increasing.

- Have a poorer response to O_2 therapy compared with women.

Women

- The number of women with COPD is increasing.
- The increase is likely due to more women smoking and increased susceptibility (e.g., smaller lungs and airways).
- More women die from COPD than men.
- Women with COPD have a lower quality of life, more exacerbations, and increased dyspnea, compared with men.

Risk Factors for COPD

Many factors affect the development and progression of COPD. The following discussion addresses the most common risk factors.

Cigarette Smoking

The major risk factor for developing COPD is cigarette smoking. COPD affects about 20% of smokers.[13] COPD should be considered in any person who is over the age of 40 with a smoking history of 10 or more pack-years.

TABLE 28.15 Effects of Tobacco Smoke on Respiratory System

Area of Defect	Acute Effects	Long-Term Effects
Respiratory mucosa		
• **Nasopharyngeal**	↓ Sense of smell	Cancer
• **Tongue**	↓ Sense of taste	Cancer
• **Vocal cords**	Hoarseness	Chronic cough, cancer
• **Bronchus and bronchioles**	Bronchospasm, cough	Chronic bronchitis, asthma, cancer
Cilia	Paralysis, sputum accumulation, cough	Chronic bronchitis, cancer
Mucous glands	↑ Secretions, ↑ cough	Hyperplasia and hypertrophy of glands, chronic bronchitis
Alveolar macrophages	↓ Function	↑ Incidence of infection
Elastin and collagen fibers	↑ Destruction by proteases ↓ Function of antiproteases (α_1-antitrypsin) ↓ Synthesis and repair of elastin	Emphysema

Cigarette smoke has several direct effects on the respiratory tract (Table 28.15). The irritating effect of smoke causes hyperplasia of cells, including goblet cells, thereby increasing mucus production. Hyperplasia reduces airway diameter and makes it harder to clear secretions. Smoking reduces the ciliary activity and may cause actual loss of cilia. Smoking causes abnormal dilation of the distal air space with destruction of alveolar walls. Many cells develop large, atypical nuclei, which are considered a precancerous condition. Smoking causes chronic, enhanced inflammation of various parts of the lung with structural changes and repair (called *remodeling*). The reasons for the inflammatory response are not clearly understood. Genetics may be involved since patients who have never smoked can develop COPD.

Cigarette smoking causes oxidative stress and an imbalance between proteases that break down connective tissue in the lung and antiproteases that protect the lungs. These changes increase with more severe disease and persist even after the patient has stopped smoking. (See Chapter 10 for more details about cigarette smoking.)

Passive smoking is the exposure of nonsmokers to cigarette smoke, also known as *environmental tobacco smoke* (ETS) or secondhand smoke. In adults, ETS is associated with decreased pulmonary function, increased respiratory symptoms, and severe lower respiratory tract infections (e.g., pneumonia). ETS is associated with increased risk for nasal sinus cancer and lung cancer.

Infection

Infections are a risk factor for developing COPD. Severe recurring respiratory tract infections in childhood have been associated with reduced lung function and increased respiratory symptoms in adulthood. It is unclear whether the development of COPD is related to recurrent infections in adults. People who smoke and have human immunodeficiency virus (HIV) infection have an accelerated development of COPD.[14] Tuberculosis is also a risk factor for COPD development.[15]

Asthma

Patients with COPD may have asthma. Asthma may be a risk factor for the development of COPD. There is a considerable pathologic and functional overlap between these disorders (Table 28.4), particularly among older adults, who may have components of both diseases. We call this *asthma-COPD overlap syndrome*.[3]

Air Pollution

High levels of urban air pollution are harmful to people with existing lung disease. However, the effect of outdoor air pollution as a risk factor for the development of COPD is unclear. Another risk factor is exposure to coal and other biomass fuels that are used for indoor heating and cooking. Many people who have never smoked have significant risk because of cooking with these fuels in poorly ventilated areas.

Occupational Chemicals and Dusts

If a person has intense or prolonged exposure to various dusts, vapors, irritants, or fumes in the workplace, symptoms of lung impairment consistent with COPD can develop. If a person has occupational exposure and smokes, the risk for COPD increases.

Aging

Although aging is often considered a risk factor for COPD, the evidence is unclear. Does the aging process lead to COPD, or is COPD

a result of the cumulative exposures that occur over a lifetime? Normal aging results in loss of elastic recoil, stiffening of the chest wall, and decrease in exercise tolerance. The lungs gradually lose their elastic recoil. The thoracic cage becomes stiff and rigid, and the ribs are less mobile. The shape of the rib cage gradually changes because of the increased residual volume (RV), causing it to enlarge and become more rounded. Decreased chest compliance and elastic recoil of the lungs caused by aging affect the mechanical aspects of ventilation and increase the WOB. The number of functional alveoli decrease as peripheral airways lose supporting tissues. Over time, the surface area for gas exchange decreases, and the PaO_2 decreases. Changes in the elasticity of the lungs reduce the ventilatory reserve. These changes are similar to those seen in the patient with COPD.

Genetics

An intriguing question is why some smokers develop COPD and others do not. The fact that a small number of smokers get COPD strongly suggests genetic factors play a major role in who develops COPD. Because of the genetic-environmental interaction, 2 people may have the same smoking history, but only 1 develops COPD. To date, only 1 genetic factor has been clearly identified.

Alpha-1 Antitrypsin Deficiency (AATD)

Alpha-1(α1) antitrypsin deficiency (AATD) is an autosomal recessive disorder that may affect the lungs or liver. AATD is a genetic risk factor for COPD.[16] α1-Antitrypsin (AAT) is a serum protein made by the liver and normally found in the lungs. The main function of AAT, an α_1-protease inhibitor, is to protect normal lung tissue from attack by proteases during inflammation related to smoking and infections. Severe AATD leads to premature bullous emphysema in the lungs. About 3% of all people diagnosed with COPD may have undetected AAT deficiency. Smoking hastens the disease process in these patients.

Pathophysiology

COPD is characterized by chronic inflammation of the airways, lung parenchyma (respiratory bronchioles and alveoli), and pulmonary blood vessels (Fig. 28.10). The pathogenesis of COPD is complex and involves many mechanisms. The defining feature of COPD is airflow limitation not fully reversible during forced exhalation. This is caused primarily by loss of elastic recoil and airflow obstruction, attributable to mucus hypersecretion, mucosal edema, and bronchospasm.

Genetics in Clinical Practice

α_1-Antitrypsin Deficiency (AATD)

Genetic Basis

- Autosomal recessive disorder.
- Mutations in *SERPINA1* gene (found on chromosome 14) cause AAT deficiency.
- Gene provides instructions for the liver to make the protein AAT, which protects the lungs and liver from powerful proteolytic enzymes.
- Without enough functional AAT, proteolytic enzymes destroy alveoli and cause lung disease.

Incidence

- Occurs in 1 in 1700 to 3500 live births in the United States
- People of northern European descent most affected

Genetic Testing

- DNA testing is available.
- Screening of siblings is useful
- Serum assay is available to measure the amount of AAT

Clinical Implications

- AAT deficiency can cause lung and liver disease.
- Onset of disease is between ages 20 and 40 yrs.
- Treatment includes AAT replacement therapy.
- Disease predisposes to early-onset emphysema.

As the disease progresses, abnormalities in airflow limitation, air trapping, and gas exchange worsen. In severe COPD, pulmonary hypertension and systemic manifestations occur. COPD has an uneven distribution of pathologic changes. Severely impaired and/or destroyed areas of lung tissue exist alongside areas of relatively normal lung.

The inflammatory process most often starts with inhalation of noxious particles and gases (e.g., cigarette smoke). The abnormal inflammatory process causes tissue destruction and disrupts the normal defense mechanisms and repair process of the lung. We do not clearly understand the mechanisms for the enhanced inflammatory response. It may be genetically determined.

The predominant inflammatory cells in COPD are neutrophils, macrophages, and lymphocytes. This pattern of inflammatory cells is different from that in asthma, in which eosinophils, mast cells, neutrophils, lymphocytes, and macrophages are the main culprits. Inflammatory cells attract other inflammatory mediators (e.g., leukotrienes) and proinflammatory cytokines (e.g., tumor necrosis factor).

The inflammatory process may be magnified by oxidants, which are made by cigarette smoke and other inhaled particles and released from the inflammatory cells. Oxidants adversely affect the lungs as they inactivate antiproteases (which prevent the natural destruction of

the lungs), stimulate mucus secretion, and increase fluid in the lungs. The result of the inflammatory process is structural changes in the lungs.

After the inhalation of oxidants in tobacco or air pollution, the activity of proteases (which break down the connective tissue of the lungs) increases and the antiproteases (which protect against the breakdown) are inhibited. Therefore the natural balance of protease/antiprotease is tipped in favor of destruction of the alveoli and loss of the lungs' elastic recoil.

Inability to expire air is a main characteristic of COPD. The main site of the airflow limitation is in the smaller airways. As the peripheral airways become obstructed, air is progressively trapped during expiration. The volume of residual air becomes greatly increased in severe COPD as alveolar attachments (similar to rubber bands) to small airways are destroyed. As air is trapped in the lungs, the chest hyperexpands and becomes barrel shaped, because the respiratory muscles are not able to function effectively. Functional residual capacity (FRC) is increased. The residual air, combined with the loss of elastic recoil, makes passive expiration of air difficult. The patient is now trying to breathe in when the lungs are in an "overinflated" state. Thus, the patient becomes dyspneic with limited exercise capacity.

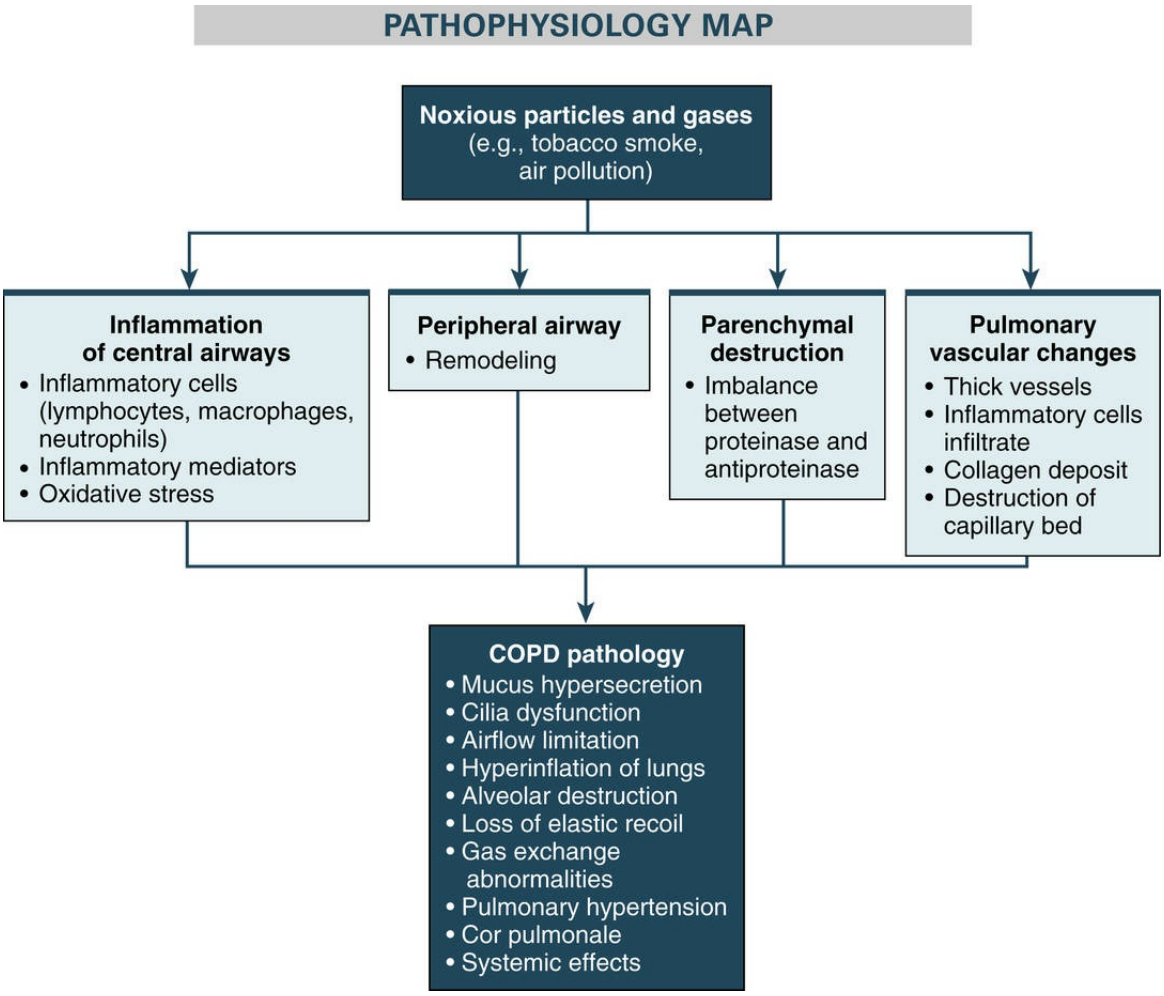

FIG. 28.10 Pathophysiology of chronic obstructive pulmonary disease *(COPD)*.

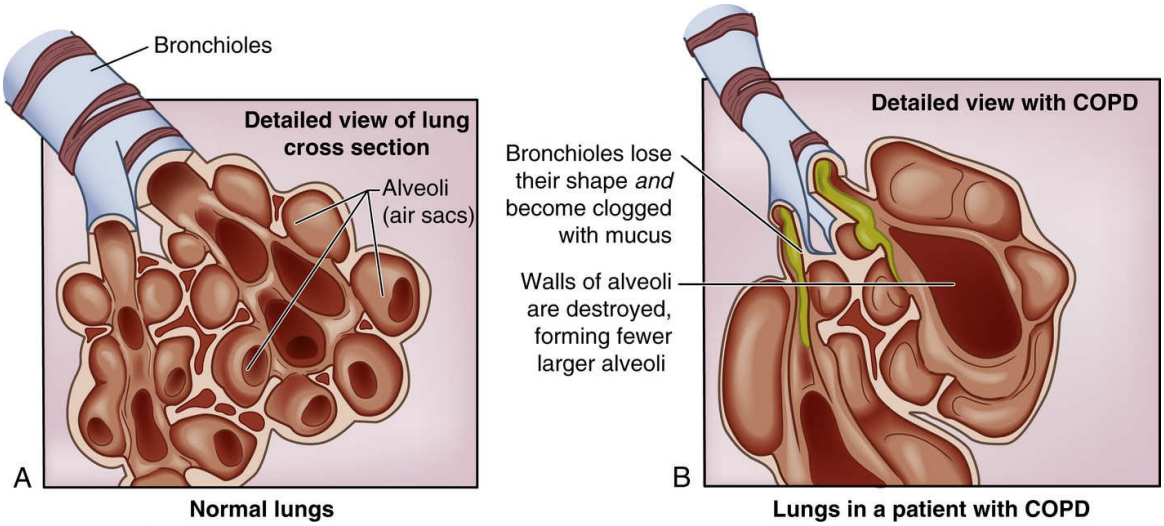

FIG. 28.11 **A,** Normal lungs showing bronchioles and alveoli. **B,** Changes in the bronchioles and alveoli in the lungs of a patient with chronic obstructive pulmonary disease *(COPD)*.

Typically, the patient does not have problems with hypoxemia at rest until late in the disease. Initially, hypoxemia may develop during exercise and the patient may benefit from supplemental O_2. Gas exchange abnormalities result in hypoxemia and hypercapnia (increased CO_2) as the disease worsens. As the air trapping increases, walls of alveoli are destroyed (Fig. 28.11). Bullae (large air spaces in the parenchyma) and blebs (air spaces next to pleurae) can form.

Bullae and blebs are not effective in gas exchange because they do not contain the capillary bed that normally surrounds each alveolus. Therefore a significant ventilation-perfusion (V/Q) mismatch and hypoxemia result. Peripheral airway obstruction also results in V/Q imbalance and, combined with respiratory muscle impairment, leads to CO_2 retention, particularly in severe forms of the disease.

Excess mucus production, resulting in a chronic productive cough, is a feature of persons with predominant chronic bronchitis. However, not all COPD patients have sputum production. When present, excess mucus production is multifactorial, including (1) an increased number of mucus-secreting goblet cells, (2) enlarged submucosal glands, (3) dysfunction of cilia, and (4) stimulation from inflammatory mediators.

In addition to lung disease, COPD is a systemic disease. Chronic inflammation is an underlying problem for many patients. Common

systemic diseases, including osteoporosis, diabetes, and metabolic syndrome, have been seen with COPD. Cardiovascular diseases are common.

Pulmonary vascular changes resulting in mild to moderate pulmonary hypertension may occur late in the course of COPD. The small pulmonary arteries vasoconstrict due to hypoxia. As the disease advances, the structure of the pulmonary arteries changes, resulting in thickening of the vascular smooth muscle. Because of the loss of alveolar walls and the capillaries surrounding them, pressure in the pulmonary circulation increases. Pulmonary hypertension may progress and lead to hypertrophy of the right ventricle of the heart. The right ventricle dilates and may eventually lead to right-sided heart failure.

Classification of COPD

COPD can be classified as mild, moderate, severe, and very severe (Table 28.16). An FEV_1/FVC ratio of less than 70% establishes the diagnosis of COPD. The severity of obstruction (as shown by FEV_1) determines the stage of COPD. The management of COPD is based on the patient's symptoms, classification, and exacerbation history.

Clinical Manifestations

The manifestations of COPD typically develop slowly. A clinical diagnosis of COPD should be considered in any patient who has chronic cough or sputum production, dyspnea, and a history of exposure to risk factors for the disease (e.g., tobacco smoke, occupational dusts). It is sometimes hard to distinguish COPD from asthma, especially if the person has a history of cigarette smoking. However, some clinical features are different (Table 28.4).

A chronic intermittent cough, which is often the first symptom to develop, may be present as the disease becomes apparent to the patient. Patients often dismiss the cough as they associate it with smoking or environmental exposures. The cough may be productive.

Significant airflow limitation may exist without cough or sputum. Typically, dyspnea is progressive, usually occurs with exertion, and is present every day.

Patients may report chest heaviness, not being able to take a deep breath, gasping, increased effort to breathe, and air hunger. Patients tend to ignore symptoms and rationalize that "I'm getting older" or "I'm out of shape." They change behaviors to avoid dyspnea, such as taking the elevator instead of the stairs. Patients will seek out medical care only when dyspnea is severe or when shortness of breath significantly impairs their ability to complete ADLs.

In late stages of COPD, dyspnea may be present at rest. As more alveoli become overdistended, increasing amounts of air are trapped. This causes the diaphragm to flatten, and the patient must work harder to breathe. Effective abdominal breathing is decreased because of the flattened diaphragm from overinflated lungs. The patient becomes more of a chest breather, relying on the intercostal and accessory muscles. However, chest breathing is not particularly efficient, especially over long periods.

TABLE 28.16 Classification of COPD Severity*

Classification is based on postbronchodilator FEV_1

Classification	Level of Severity	FEV_1 Results
GOLD 1	Mild	FEV_1 ≥80% predicted
GOLD 2	Moderate	FEV_1 50%–80% predicted
GOLD 3	Severe	FEV_1 30%–50% predicted
GOLD 4	Very severe	FEV_1 <30% predicted

* A diagnosis of COPD is made when a patient has a FEV_1/FVC <70%.

prevention, diagnosis, and management of COPD. Retrieved from *www.goldcopd.org*.

Wheezing and chest tightness may be present but may vary by time of the day or from day to day, especially in patients with more severe disease. Chest tightness, which often follows activity, may feel similar to muscle contractions.

The person with advanced COPD often has fatigue, weight loss, and anorexia. Even with adequate caloric intake, the patient may still lose weight. Fatigue is a highly prevalent symptom that affects the patient's ADLs. During physical examination, a prolonged expiratory phase is observed. Decreased breath sounds and/or wheezes are auscultated in all lung fields. Because the anteroposterior diameter of the chest is increased ("barrel chest") from the chronic air trapping, the patient may need to breathe louder than normal for breath sounds to be heard with a stethoscope. The patient may sit upright with arms supported on a fixed surface, such as an overbed table *(tripod position).* The patient may naturally purse lips on expiration (pursed-lip breathing) and use accessory muscles, such as those in the neck, to aid with inspiration. Edema in the ankles may be the only clue to right-sided heart involvement (cor pulmonale).

Over time, hypoxemia (PaO_2 less than 60 mm Hg or O_2 saturation less than 88% on room air) may develop with hypercapnia ($PaCO_2$ over 45 mm Hg). The bluish-red color of the skin results from polycythemia and cyanosis. Polycythemia develops from increased production of red blood cells as the body tries to compensate for chronic hypoxemia. Hemoglobin concentrations may reach 20 g/dL (200 g/L) or more. However, the person may have lowered hemoglobin and hematocrit because of chronic anemia.

Complications

Primary complications that can occur in patients with COPD include pulmonary hypertension, cor pulmonale, acute exacerbations, and acute respiratory failure.

Pulmonary Hypertension and Cor Pulmonale

Cor pulmonale results from pulmonary hypertension, which is caused by diseases affecting the lungs or pulmonary blood vessels (Fig. 28.12). It is a late manifestation of COPD. Once the patient develops cor pulmonale, the prognosis worsens. Not all patients with COPD develop cor pulmonale.

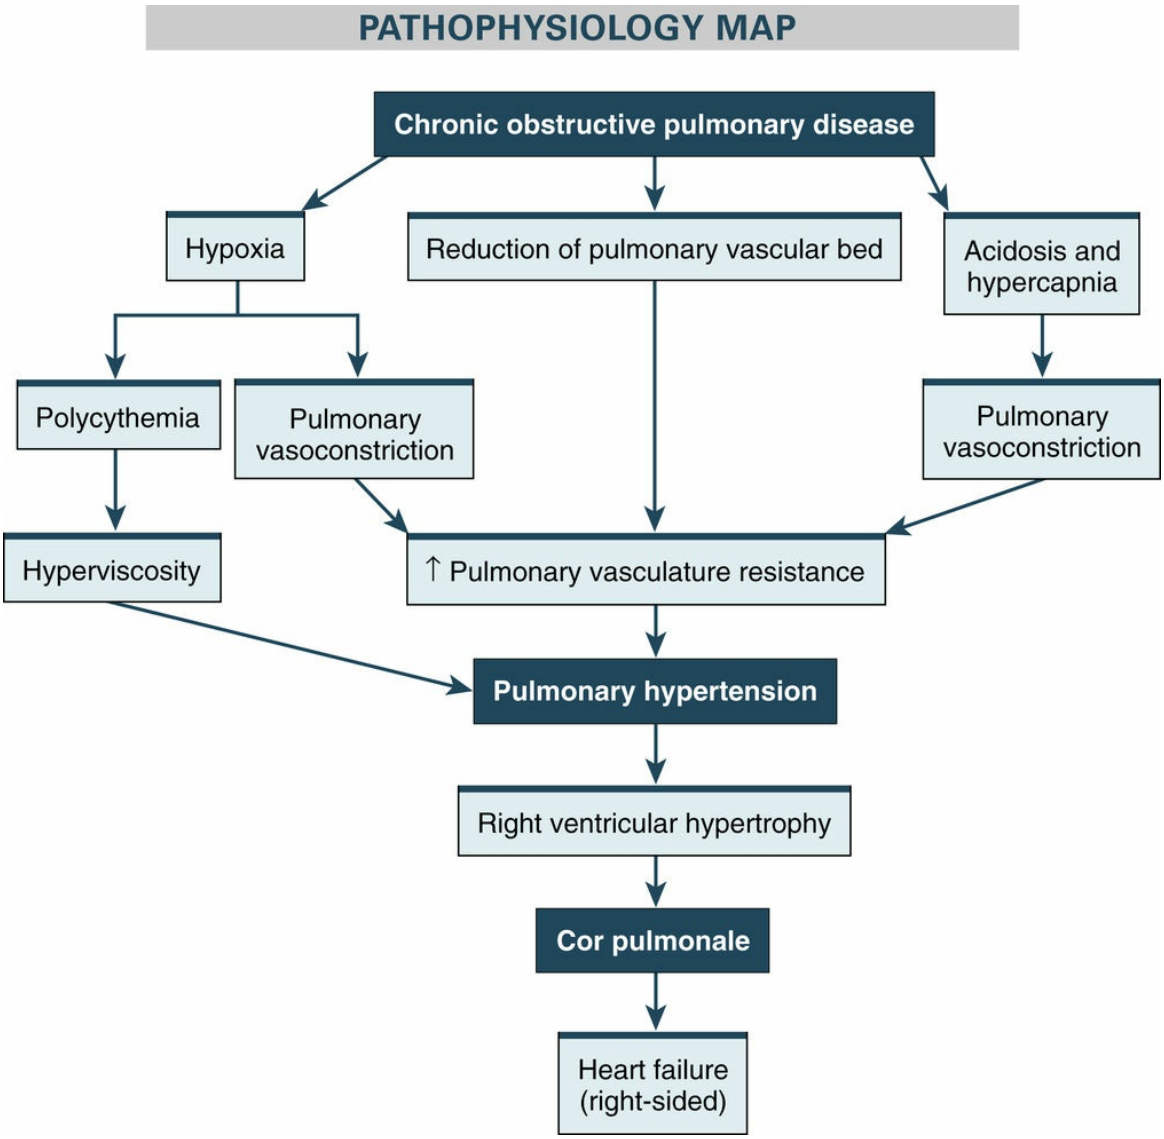

FIG. 28.12 Mechanisms involved in the pathophysiology of pulmonary hypertension and cor pulmonale from COPD.

In COPD, pulmonary hypertension is caused primarily by constriction of the pulmonary vessels in response to alveolar hypoxia. Chronic hypoxia stimulates erythropoiesis, which causes polycythemia. This results in increased viscosity of the blood. These patients have increased pulmonary vascular resistance, and, as a result, develop pulmonary hypertension.

Normally the right ventricle and pulmonary circulatory system are low-pressure systems compared with the left ventricle and systemic circulation. When pulmonary hypertension (pressure within the lungs

increases), the pressures on the right side of the heart must increase to push blood into the lungs. Eventually, because the pressure in the lungs is so high, right-sided heart failure develops.

Dyspnea is the most common symptom of chronic cor pulmonale. Lung sounds are normal, or crackles may be heard in the bases of the lungs bilaterally. Heart sound changes may include the presence of S_3 and S_4 and systolic murmurs.[17] Other manifestations of right-sided heart failure may develop. These include distended neck veins, hepatomegaly with right upper quadrant tenderness, peripheral edema, and weight gain.

Typically, the patient has large pulmonary vessels on chest x-ray and increased pressure on right-sided heart catheterization. Echocardiogram may show right-sided heart enlargement. b-Type natriuretic peptide (BNP) levels, which are used to diagnose heart failure, may be high. Normally BNP levels are used to distinguish cardiac from respiratory causes of dyspnea, but in cor pulmonale the cause of the heart failure is the lung disease.

Treatment of cor pulmonale is initially targeted at managing the underlying cause, including COPD. Continuous low-flow, long-term O_2 therapy is often part of care. Diuretics may be given if left heart failure or pulmonary edema are present but must be used with caution.[18] In some cases, decreases in fluid volume from diuresis can worsen heart function. Long-term anticoagulation therapy is started to help decrease the risk for venous thromboembolism (VTE). (Cor pulmonale is discussed in Chapter 27.)

Acute Exacerbations

An exacerbation of COPD is an acute event characterized by a worsening of the patient's respiratory symptoms. Exacerbations are signaled by an acute change in the patient's usual dyspnea, cough, and/or sputum (e.g., something different from the usual daily patterns). The main causes of exacerbations are bacterial or viral infections.[19] Exacerbations are common and increase in frequency (on average 1 or 2 per year) as the disease progresses. As the severity of

COPD increases, COPD exacerbations are associated with poorer outcomes.

Assess patients for the classic manifestations of exacerbation, including increased dyspnea, increased sputum volume, or increased sputum purulence. They may have malaise, insomnia, fatigue, depression, confusion, decreased exercise tolerance, increased wheezing, or fever.

Exacerbations may be treated at home or in the hospital, depending on severity. The severity is determined by the patient's medical history leading up to the exacerbation, current symptoms, hemodynamic stability, O_2 requirements, WOB, ABGs, and the presence of coexisting diseases.

Your observations will help determine the severity of the exacerbation and whether the patient is treated as an inpatient or outpatient. Assess for new symptoms or worsening of usual symptoms. Be alert for signs of severity, such as use of accessory muscles, central cyanosis, edema in the lower extremities, unstable BP, right-sided heart failure, and altered alertness. Assess the patient's ABGs for respiratory acidosis and worsening hypoxemia, indicating an "acute-on-chronic" respiratory failure. Determine the number of exacerbations per year and if treatment occurred in the home or hospital. The presence of other co-morbid conditions often complicates exacerbations.

SABAs and oral systemic corticosteroids are the typical therapies for exacerbations. SABAs with short-acting anticholinergics are an option. Drug administration by MDI or nebulizer works equally well, although sicker patients often prefer the nebulizer. Antibiotics are given if the exacerbation was caused by a bacterial infection (e.g., pneumonia).

Therapies in the hospital are similar to home management, except supplemental O_2 therapy titrated by ABG measurement may be used. Attempts are made to use noninvasive mechanical methods (e.g., continuous positive airway pressure [CPAP] or bi-level positive airway pressure [Bi-PAP] to support ventilation rather than invasive ventilatory support [e.g., intubation and mechanical ventilation]).

Small doses of diuretics maybe used for those with heart failure.

Teach the patient and caregiver early recognition of the 3 primary manifestations of exacerbations (increased dyspnea, increased sputum volume, or increased sputum purulence) to promote early treatment. This may prevent hospitalization and possible acute respiratory failure.

Acute Respiratory Failure

Patients with severe COPD who have severe exacerbations are at risk for acute respiratory failure. All too often, COPD patients wait too long to contact their HCP when they first develop symptoms suggestive of an exacerbation. Similarly, suddenly stopping a bronchodilator or corticosteroid medication may cause respiratory failure. (Respiratory failure is discussed in Chapter 67.)

Diagnostic Studies

A history and physical examination are extremely important in a diagnostic workup. Spirometry confirms the diagnosis in those suspected of having COPD. Spirometry confirms the presence of airflow obstruction and determines the severity of COPD.

In spirometry, the patient receives a SABA. Post-bronchodilator values are compared with a normal reference value. A diagnosis of COPD is made when the FEV_1/FVC ratio is less than 70%.[20] The value of FEV_1 provides a guideline for the degree of severity of COPD. The lower the FEV_1, the more obstructed are the airways.

Other diagnostic studies that may be done are outlined in Table 28.17. Chest x-rays are not diagnostic but often show a flat diaphragm because of hyperinflated lungs. Patients often have exercise-induced hypoxemia. A physical or respiratory therapist may do a 6-minute walk test. Pulse oximetry readings are taken when the patient is walking and at rest. If values of O_2 saturation are 88% or lower when at rest and the patient is breathing room air, they qualify for supplemental O_2.

Validated questionnaires such as the COPD Assessment Test (CAT) (*www.catestonline.org*) and Clinical COPD Questionnaire (CCQ) (*www.ccq.nl*) are recommended for a comprehensive assessment of symptoms.

ABGs are usually monitored in patients hospitalized with acute COPD exacerbations. ABGs alone are not diagnostic of COPD but help identify the severity of the exacerbation by assessing abnormalities in oxygenation and ventilation. In early stages, there may be a normal or only slightly decreased PaO_2 and a normal $PaCO_2$. In the later stages of COPD, typical findings are a low-normal pH, high-normal or above-normal $PaCO_2$, and high-normal bicarbonate (HCO_3^-). This may indicate either partially or fully compensated respiratory acidosis. The patient has chronically retained CO_2 and the kidneys have conserved HCO_3^- to increase the pH to within the normal range.

Table 28.17 Interprofessional CareChronic Obstructive Pulmonary Disease (COPD)

Diagnostic Assessment

- History and physical examination
- Spirometry
- Chest x-ray
- Serum α_1-antitrypsin levels
- ABGs
- 6-Minute walk test
- COPD Assessment Test (CAT)* or Clinical COPD Questionnaire (CCQ)†

Management

- Cessation of cigarette smoking
- Drug therapies (Tables 28.7 and 28.18)
- Airway clearance techniques
- Breathing exercises and retraining

- Hydration of 2 to 3 L/day (if not contraindicated)
- Immunizations:
    - Influenza yearly
    - Pneumococcal vaccine
- Long-term O_2 (if indicated)
- Progressive plan of exercise, especially walking and upper body strengthening
- Pulmonary rehabilitation program
- Nutritional supplementation
- Treatment of complications
    - Cor pulmonale
    - Acute exacerbations
    - Acute respiratory failure
- Surgical therapy
    - Lung volume reduction
    - Bullectomy
    - Lung transplantation

---

* See *www.catestonline.org*.
† See *www.ccq.nl*.

An ECG may be normal or show signs of right heart failure. An echocardiogram or (MUGA) (cardiac blood pool) scan (see Table 31.7) can be used to evaluate heart function. Sputum for culture and sensitivity may be done if an infection, such as pneumonia, is suspected.

Interprofessional Care

Most patients with COPD are treated as outpatients. They are hospitalized for an acute exacerbation of COPD or complications, such as pneumonia, heart failure, or acute respiratory failure.

Evaluate the patient's exposure to environmental or occupational irritants and determine ways to control or avoid them. For example, teach the patient to avoid, if possible, smoke-filled rooms and air pollutants. The patient with COPD is extremely susceptible to lung infections. The patient with COPD should receive influenza immunization yearly. The pneumococcal vaccine is recommended for all smokers ages 19 or older and all patients with COPD. Guidelines for pneumococcal vaccine are outlined in Table 27.5.

Smoking Cessation

Stopping cigarette smoking in any person with COPD at any level of severity is the most important intervention that can affect the natural progression of COPD. After a person stops smoking, the accelerated decline in pulmonary function found with smoking slows to almost nonsmoking levels. The sooner the smoker stops, the less pulmonary function is lost and the sooner the symptoms decrease, especially cough and sputum production. Smoking cessation is discussed in Chapter 10 and in Tables 10.4 to 10.6.

Drug Therapy

Drugs for COPD can reduce symptoms, increase exercise capacity, improve overall health, and reduce the number and severity of exacerbations. Like asthma, they are given in a stepwise fashion according to the level of airflow obstruction determined from spirometry (FEV_1) and symptoms. Medications are stepped up but usually not stepped down, as in asthma, because in COPD continual symptoms are present (Table 28.18). The inhaled route of medication is preferred and used on a regular or as-needed basis.

Bronchodilator drug therapy relaxes smooth muscles in the airway and improves the ventilation of the lungs, thus reducing the degree of

breathlessness. Patients with COPD do not respond as dramatically to bronchodilator therapy as those with asthma. However, bronchodilator therapy reduces dyspnea and increases FEV_1.

Bronchodilator drugs commonly used are β_2-adrenergic agonists, anticholinergic agents, and, to a much lesser extent, methylxanthines (Table 28.7). The choice of bronchodilator depends on the patient's response. They are given on a scheduled or as-needed basis. When the patient has mild COPD or fewer symptoms, a SABA is used. Albuterol or ipratropium may be used alone, but combining bronchodilators improves their effect and decreases the risk for adverse effects. Albuterol and ipratropium can be nebulized together (DuoNeb) or delivered by inhalation spray (Combivent Respimat).

In the moderate stage of COPD (FEV_1 less than 60%), a LABA is often part of the medication treatment plan. Unlike asthma, they can be used in COPD as monotherapy. Salmeterol and formoterol are widely used LABAs. A SABA may still be used as a "rescue" for dyspnea.

In COPD patients with FEV_1 of less than 60%, regular treatment with ICS is often prescribed with a LABA. Examples of combinations of ICSs with LABAs are fluticasone/salmeterol (Advair) and budesonide/formoterol (Symbicort).

TABLE 28.18 Drug TherapyMedication Guidelines

The treatment guidelines are based on the FEV_1 results.

FEV_1 Results	Treatment Guidelines
FEV_1 60%–80% predicted (with respiratory symptoms)	Treatment with inhaled bronchodilators may be used
FEV_1 <60% predicted (with respiratory symptoms)	Treat with inhaled bronchodilators: anticholinergics or long-acting β_2-agonist
	OR
	Monotherapy with long-acting inhaled anticholinergics or long-acting β_2-agonist
	OR
	Combination therapy with long-acting inhaled anticholinergics, long-acting β_2-agonist, or inhaled corticosteroids

Inhaled long-acting anticholinergics, LABAs, and ICSs all reduce COPD exacerbations. However, in COPD, unlike asthma, ICSs are not used as monotherapy because of the concerns about side effects. Some patients with COPD are on triple therapy with Advair and tiotropium. Oral corticosteroids should not be used for long-term therapy in COPD but are effective for short-term use to treat acute exacerbations.

The use of long-acting theophylline in the treatment of COPD is controversial because it interacts with many drugs. A low dose of theophylline with an ICS may help a few patients with COPD who do not respond to other inhaled medications.

Roflumilast (Daliresp) is an oral medication used to decrease the frequency of exacerbations in patients with severe COPD and chronic bronchitis. This drug is a phosphodiesterase inhibitor. It is an antiinflammatory drug that suppresses the release of cytokines and other inflammatory mediators and inhibits the production of reactive O_2 radicals.

New drug delivery devices are becoming available at a rapid pace. One example is Respimat. It is an easy-to-use, hand-held device that provides a high deposition of drug to the lungs and low mouth and throat deposition. Respimat simplifies coordination between activation of the medication and inhalation without propellant. It is independent of inspiratory flow. Combivent and Spiriva Respimats are examples.

Surgical Therapy

Various surgical procedures are used to help manage severe COPD. However, it is important to remember that not all patients with severe COPD are candidates for surgery.

One type of surgery is *lung volume reduction surgery* (LVRS). The goal of LVRS is to reduce the size of the lungs by removing some of the diseased lung tissue, so that the remaining healthy lung tissue can perform better. Reducing the diseased lung tissue by about 30% results in decreased airway obstruction and increased room for the remaining normal alveoli (small air sacs at the end of each bronchiole) to expand and function.[21] Besides improving lung and chest wall

mechanics, LVRS can allow the diaphragm to return to its normal shape. This allows the patient to breathe more efficiently.

Another type of surgical procedure is *bronchoscopic lung volume reduction surgery*. It involves placing 1-way valves, by bronchoscopy, in the airways leading to the diseased parts of the lung. By completely occluding a specific lobe of the lung, this collapses a certain segment of the lung and produces a result similar to LVRS.[22] Pneumothorax is a common complication. An a *bullectomy*, 1 or more very large bullae are removed. Removal of bullae help decrease WOB.

A lung transplant benefits certain patients with advanced COPD. Although single-lung transplant is the most commonly used technique because of a shortage of donors, bilateral transplantation can be done. (Lung transplantation is discussed in Chapter 27.)

Interprofessional Care: Respiratory Care

Oxygen Therapy

O_2 therapy is often used in the treatment of COPD and other problems associated with hypoxemia. O_2 is a colorless, odorless, tasteless gas that constitutes 21% of the atmosphere. Giving supplemental O_2 increases the partial pressure of O_2 (PO_2) in inspired air. Used clinically, it is considered a prescribed medication. It is the only one that has been linked to improved survival of COPD patients.

O_2 is usually given to treat hypoxemia caused by many other problems, such as shock, pneumonia, and pulmonary emboli. O_2 therapy must be tailored to meet each patient's unique circumstances and physiologic needs. For most patients, the goal of O_2 therapy is to keep the SaO_2 greater than 90% during rest, sleep, and exertion or the PaO_2 greater than 60 mm Hg. These goals may be modified for the patient with moderate to severe COPD. For example, based upon the patient's condition, the HCP may accept an SaO_2 an PaO_2 greater than 88%.

Methods of Administration

There are various methods of administering O_2 (Table 28.19). The device used depends on the patient's underlying condition, fraction of inspired O_2 (FIO_2) needed by the patient and delivered by the device, humidification requirements, patient cooperation, comfort, cost, and financial resources.

O_2 delivery systems are classified as low- or high-flow systems. Most methods of O_2 delivery are low-flow devices that provide O_2 in concentrations that vary with the person's respiratory pattern. Low-flow devices pull in a proportion of room air. This makes the range of FIO_2 known, but the exact FIO_2 hard to determine. Nasal prongs and non-rebreather masks are examples of low-flow O_2 systems. High-flow O_2 delivery devices deliver fixed concentrations of O_2 (e.g., 28%, 35%) independent of the patient's respiratory pattern. The Venturi mask and mechanical ventilators are examples of a high-flow O_2 delivery systems.

Humidification and Nebulization

O_2 obtained from O_2 cylinders or wall systems is dry. Dry O_2 has an irritating effect on mucous membranes and dries secretions. Therefore it is important that O_2 be humidified. Humidification involves the addition of sterile distilled water, attached to the O_2 delivery device, to prevent breathing dry air. For example, a common device used for humidification when the patient has a cannula or a mask is a small plastic jar filled with distilled water called a *bubble-through humidifier*. It is attached to the O_2 source by a flowmeter.

Complications of Oxygen Therapy

Combustion

O_2 supports combustion and increases the rate of burning, so it is important to prohibit smoking or have open flames in the area in which O_2 is being used. A "No Smoking" sign should be prominently displayed on the patient's door. Caution the patient against smoking

cigarettes with an O_2 cannula in place as it can easily ignite and cause significant burns and life-threatening airway issues.

CO_2 narcosis

Chemoreceptors in the respiratory center that control the drive to breathe respond to CO_2 and O_2. Normally, an increase in CO_2 in the blood is a major stimulant of the respiratory center. Over time, some COPD patients with hypercapnia develop a tolerance for high CO_2 levels (the respiratory center loses its sensitivity to high CO_2 levels). For these people, a major "drive" to breathe is hypoxemia. As a result, there is concern about the dangers of giving O_2 to COPD patients and reducing their drive to breathe.

However, the "hypoxic drive" is complex and involves other factors, including ventilation and perfusion. Plus, not all patients with COPD retain CO_2. So, the thought is that it is better to give O_2 to a patient who needs it because the danger of not giving O_2 to a patient far outweighs the risk.

Pulse oximetry and/or ABGs are used as a guide to determine the FIO_2 needed by each patient. Safe administration of O_2 can be achieved by gradually increasing the concentration of O_2 with close monitoring of both PaO_2 and $PaCO_2$. High-flow O_2 devices may be used to have tighter regulation of the FIO_2. Once again, the goal is a pulse O_2 saturation (SpO_2) of at least 90% or a PaO_2 of at least 60 mm Hg. Always remember to assess the patient's mental status and vital signs before starting O_2 therapy and frequently thereafter.

O_2 toxicity

Pulmonary **O_2 toxicity** may result from prolonged exposure to a high level of O_2 (PaO_2). High concentrations of O_2 can result in a severe inflammatory response because of O_2 free radical damage to alveolar-capillary membranes. This causes severe pulmonary edema, shunting of blood, and hypoxemia. Although it is rare, patients can develop acute respiratory distress syndrome (ARDS) (see Chapter 67).

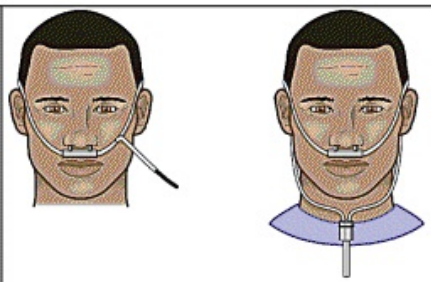
Preventing O_2 toxicity is important. The amount of O_2 applied should be enough to maintain the PaO_2 within a normal or acceptable range for that patient. Monitor ABGs often to evaluate the effectiveness of therapy and guide the tapering of supplemental O_2. The most important rule you can follow is to provide FIO_2 at the lowest possible level, while still maintaining acceptable SaO_2 and PaO_2 values for every patient.

Nursing Management

Oxygen Administration

- Assess need for adjustments in O_2 flow rate.
- Evaluate response to O_2 therapy.
- Monitor patient for signs of adverse effects of O_2 therapy.
- Teach patient and caregivers about home O_2 use.
- Oversee UAP:
    - Use pulse oximetry to measure O_2 saturation and report level to RN.
    - Assist patient with adjustment of O_2 delivery devices (e.g., nasal cannula, face mask).
    - Report to RN any change in patient condition.
- Collaborate with respiratory therapist:
    - Assist RN with choosing optimal O_2 delivery device (e.g., nasal cannula or simple face mask).
    - Make sure equipment is clean and replaced as needed.
    - Check accuracy of O_2 delivery and assess need for adjustments in O_2 flow rate.
    - Evaluate patient response to O_2 therapy.

Infection



Infection can be a complication of O_2 administration. Heated nebulizers present the highest risk. The constant use of humidity supports bacterial growth. The most common organism is *Pseudomonas aeruginosa.* Disposable equipment that operates as a closed system, such as the Ballard closed suctioning system, should be used. Each agency has a policy on the frequency of equipment changes based on the type of O_2 equipment used.

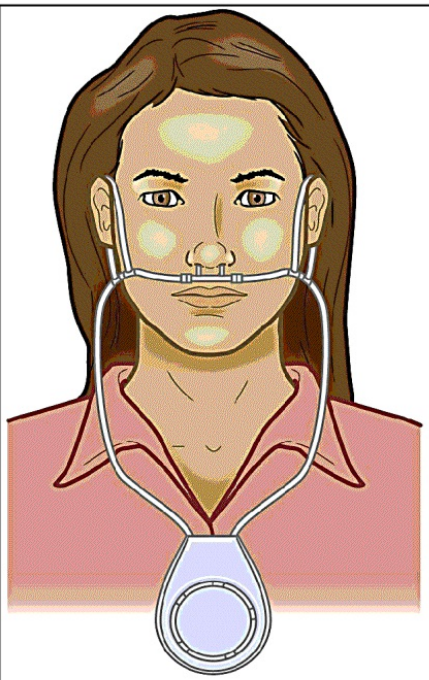
Oxygen Therapy at Home

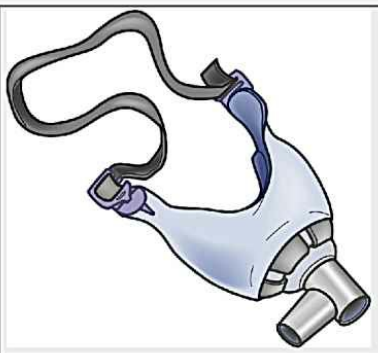
Short-term home O_2 therapy (up to 30 days) may be needed for the patient in whom hypoxemia persists after discharge from the hospital. For example, a patient with underlying COPD who develops a serious respiratory tract infection may need continued O_2 therapy to treat hypoxemia for several weeks after discharge from the hospital. Home health care personnel can measure the patient's oxygenation status after an acute episode to determine if the O_2 is still needed.

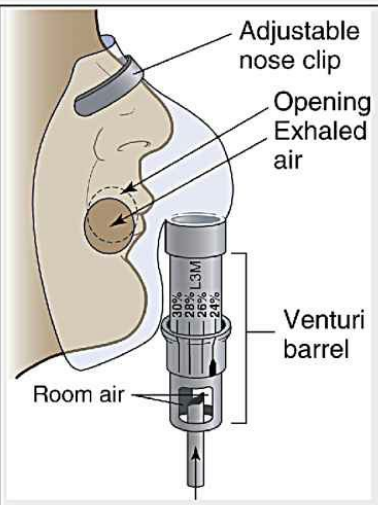
Patients may receive O_2 only during exercise and/or sleep. Evaluate the need for O_2 during these periods with a 6-minute walk test or overnight oximetry. Improved survival occurs in patients with COPD who receive long-term O_2 therapy (LTOT) (more than 15 hr/day) to treat hypoxemia. Periodic reevaluations for the patient who is using LTOT is needed. The patient is reevaluated every 30 to 90 days during the first year of therapy and annually after that if the patient stays stable.

TABLE 28.19 Methods of Oxygen Administration

Description	Nursing Interventions	
Low-Flow Delivery Devices		
Nasal Cannula		
• **Most commonly used device.** • **O_2 delivered via plastic nasal prongs.** • **Safe and simple method** • **Allows some freedom of movement. Patient can eat, talk, or cough while wearing device.** • **Used for a patient requiring low O_2 concentrations.** • **Obtains O_2 concentrations of 24% (at 1 L/min) to 44% (at 6 L/min).**	• Stabilize nasal cannula when caring for a restless patient. • Amount of O_2 inhaled depends on room air and patient's breathing pattern. • Most patients with COPD can tolerate 2 L/min via cannula. • Assess patient's nares and ears for skin breakdown. May need to pad cannula where it sits on ears. • If flow rates are >5 L/min, nasal membranes may dry and place patient at risk for nose bleeding.	
Simple Face Mask		
• **Covers patient's nose and mouth.** • **Used only for short periods, especially when transporting patients.** • **Longer use is typically not tolerated because of tight seal and heat generated around nose and mouth from mask.** • **Achieves O_2 concentrations of 35%–50% with flow rates of 6–12 L/min.** • **Mask provides adequate humidification of inspired air.**	• Wash and dry under mask q4h and PRN. • Mask must fit snugly. • Nasal cannula may be used while patient is eating. • Watch for pressure necrosis at top of ears from elastic straps if patient wears for a longer time. Gauze or other padding may alleviate this problem.	
Partial and Non-Rebreather Masks		
• **Used for short-term (24 hr) therapy for patients needing higher O_2 concentrations (60%–90% at 10–15 L/min).** • **O_2 flows into reservoir bag and mask during inhalation.** • **Bag allows patient to rebreathe about first third of exhaled air (rich in O_2) in conjunction with flowing O_2.** • **Vents stay open on partial mask only. Some agencies prefer this over non-rebreather as a safety issue.**	• O_2 flow rate must be sufficient to keep bag from deflating during inspiration to avoid CO_2 buildup and rebreathing of CO_2. • If deflation occurs, increase flowrate on flowmeter on wall to keep bag inflated. • Mask should fit snugly. • With non-rebreather masks, make sure valves are open during expiration and closed during inhalation to prevent decrease in FIO_2 or build-up in CO_2. • Monitor patient closely, since more advanced interventions may be needed such as CPAP, BiPAP, or intubation with mechanical ventilation.	
Oxygen-Conserving Cannula		







Description	Nursing Interventions	
• **Generally indicated for long-term O_2 therapy at home (e.g., pulmonary fibrosis, pulmonary hypertension).** • **Looks like a "moustache" (Oxymizer) or "pendant" type.** • **Cannula has a built-in reservoir that ↑ O_2 concentration and allows patient to use lower flow, usually 30%–50%, which increases comfort, lowers cost, and can be increased with activities.** • **Can deliver O_2 up to 8 L/min.**	• May cause necrosis over tops of ears. Tubing can be padded. • Cannula cannot be cleaned. Manufacturer recommends changing cannula every week. • More expensive than standard cannulas and may need evaluation with ABGs and oximetry to determine correct flow for patient. • Cannula is highly visible.	 Pendant-type O_2-conserving cannula.

Table Continued

Description	Nursing Interventions	
High-Flow Delivery Devices		
Tracheostomy Collar		
• **Collar attaches to neck with elastic strap and can deliver humidity and O_2 via tracheostomy.** • **Some O_2 concentration is lost into atmosphere because collar does not fit tightly.** • **Venturi device can be attached to flowmeter and thus can deliver exact amounts of O_2 via collar.**	• Secretions collect inside collar and around tracheostomy. Remove collar and clean at least q4hr and PRN to prevent aspiration of fluid and infection. • Because condensation occurs in tubing, periodically drain tubing distal to tracheostomy.	
Tracheostomy T-Piece		
• **Almost identical to tracheostomy collar, but it has a T-connector attached to an O_2 blender.** • **T-piece allows an inline catheter (e.g., Ballard catheter) to be connected for suctioning.** • **Tight fit allows better O_2 and humidity delivery than tracheostomy collar.**	• Because T-piece connectors can disconnect easily, monitor closely. • T-piece connector may pull on a patient's tracheostomy tube, causing irritation and potential tissue damage. Monitor this closely.	
Venturi Mask		
• **Mask can deliver precise, high-flow rates of O_2.** • **Lightweight plastic, cone-shaped mask Masks are available for delivery of 24%, 28%, 31%, 35%, 40%, and 50% O_2.** • **Method is especially helpful for giving low, constant O_2 concentrations to patients with COPD.** • **Adaptors can increase humidification.**	• Entrainment device on mask must be changed to deliver higher concentrations of O_2. • Air entrainment ports must not be occluded. • Uncomfortable. • Must be removed when patient eats. • Patient can talk but voice may be muffled.	
High-Flow Nasal Cannula		

Description	Nursing Interventions	
• **Blends O_2 with compressed air to generate FIO_2 up to 1.0 at flow rate of up to 60 L/min.** • **Active heated humidifier capable of providing 100% body humidity.** • **Soft and flexible nasal prongs.** • **More comfortable than mask.**	• Nasal cannula must be smaller than 50% of nares to allow flow during exhalation and flush out end-expiratory CO_2. • Patients can eat and drink with device in place. • Well tolerated. • Patient may describe feeling of always having to blow nose ("rainout") due to humidification. 	

BiPAP, Biphasic positive airway pressure; *CPAP,* continuous positive airway pressure; *FIO_2,* Fraction of inspired O_2.

FIG. 28.13 A portable liquid O_2 unit can be refilled from a liquid O_2 reservoir unit.
Courtesy Nellcor Puritan Bennett, Pleasanton, CA.

Nasal cannulas, including O_2 conservation systems, deliver O_2 from a central source in the home. The source may be a liquid O_2 storage system, compressed O_2 in tanks or cylinders, or an O_2 concentrator or extractor, depending on the patient's activity level, environment, insurance coverage, and proximity to an O_2 supply company. To increase mobility in the home, the patient can use extension tubing (up to 50 ft) with some devices without adversely affecting the O_2 flow delivery. Small, portable systems, such as liquid O_2, may be used with the patient who is active outside the home.

Home O_2 systems are usually rented from a company that sends a respiratory therapist to the patient's home (Fig. 28.13). The therapist teaches the patient and caregiver how to use the O_2 system, how to care for it, and how to recognize when the supply is running low and must be reordered. A patient and caregiver teaching guide for the use of O_2 at home is shown in Table 28.20.

Encourage the patient who uses home O_2 to remain active and travel normally. If travel is by car, arrangements can be made for O_2 to be available at the destination point. O_2 supply companies can often help with these arrangements. If a patient wishes to travel by bus, train, or airplane, the patient should inform the appropriate people when reservations are made that O_2 will be needed for travel. If there is a potential for the patient to become hypoxic, O_2 needs for flying can be determined by a pulmonary function test, a 6-minute walk test, hypoxic challenge test, or predictive formula.[23] Portable O_2 concentrators are a ready source of renewable O_2 and can be available by recharging at home or with a direct current (DC) (e.g., auto) power supply. Several are approved by airlines for in-flight use. The patient should contact the airline to determine accommodations and policies for in-flight O_2.

Breathing Retraining

The patient with COPD often has dyspnea with an increased respiratory rate. The accessory muscles of breathing in the neck and

upper part of the chest are used excessively to promote chest wall movement. These muscles are not designed for long-term use and as a result the patient has increased fatigue.

TABLE 28.20 Patient & Caregiver TeachingHome Oxygen Use

The company that provides the prescribed O_2 therapy equipment will teach the patient about equipment care. The following are some general instructions that you may include when teaching the patient and caregiver about the use of home O_2:

Decreasing Risk for Infection

- Brush teeth or use mouthwash several times a day.
- Wash nasal cannula (prongs) with a liquid soap and thoroughly rinse once or twice a week.
- Replace cannula every 2 to 4 weeks.
- If you have a cold, replace the cannula after your symptoms pass.
- Always remove secretions that are coughed out.
- If you use an O_2 concentrator, daily unplug the unit and wipe down the cabinet with a damp cloth and dry it.
- Ask the company providing the equipment how often to change the filter.

Safety Issues

- Post "No Smoking" warning signs outside the home.
- O_2 will not "blow up," but it will increase the rate of burning, since it is combustible.
- Do not allow smoking in the home, and do not smoke yourself

while wearing O_2. Nasal cannulas and masks can catch fire and cause serious burns to face and airways.

- Do not use flammable liquids such as paint thinners, cleaning fluids, gasoline, kerosene, oil-based paints, or aerosol sprays while using O_2.
- Do not use blankets or fabrics that carry a static charge, such as wool or synthetics.
- Inform the staff at your electric company if you are using a concentrator. In case of a power failure, they will know the medical urgency of restoring your power.

Adapted from *www.YourLungHealth.org*.

Two main types of breathing retraining exercises are (1) pursed-lip breathing and (2) diaphragmatic breathing. The purpose of **pursed-lip breathing (PLB)** is to prolong exhalation, which prevents bronchiolar collapse and air trapping. PLB is simple, easy to teach and learn, and it gives the patient more control over breathing, especially during exercise and periods of dyspnea (Table 28.12). Patients should be taught to use "just enough" positive pressure with pursed lips because excessive resistance may increase the WOB.

Diaphragmatic (abdominal) breathing focuses on using the diaphragm instead of the accessory muscles of the chest to (1) achieve maximum inhalation and (2) slow the respiratory rate. However, the use of diaphragmatic breathing in patients with COPD may increase the WOB and dyspnea. Patients with moderate to severe COPD with marked hyperinflation may be poor candidates for diaphragmatic breathing.

PLB slows the respiratory rate and is easier to learn than diaphragmatic breathing. In the setting of extreme acute dyspnea, it is most important to focus on helping the patient slow the respiratory rate by using the principles of PLB. Other techniques, such as a calm demeanor, positive encouragement, and guided imagery, may be used to reduce dyspnea.

Airway Clearance Techniques

Many patients with COPD or other conditions who retain secretions (e.g., CF, bronchiectasis) need help to adequately clear their airways. Airway clearance techniques (ACTs) loosen mucus and secretions so they can be cleared by coughing. There are a variety of techniques. These include effective coughing, chest physiotherapy, airway clearance devices, and high-frequency chest ventilation. Respiratory therapists, physical therapists, and nurses can perform these techniques.

ACTs are especially beneficial in patients who have a COPD exacerbation. They are often used in conjunction with other treatments. Typically, the patient receives bronchodilator therapy through an inhaled device (e.g., nebulization) before ACT. Then the ACT is used, followed by effective coughing (e.g., huff coughing).

Effective Coughing

Many patients with COPD have developed ineffective coughing patterns that do not adequately clear the airways of sputum. They fear developing bronchospasm, or spastic coughing, resulting in increased dyspnea. Although other techniques (e.g., chest physiotherapy) are used to loosen secretions and mucus, the patient must cough effectively to bring the secretions to the central airways to expectorate them.

Huff coughing is an effective forced expiratory technique that you can easily teach the patient. Before starting, ensure that the patient is breathing deeply from the diaphragm. Place the patient's hands on the lower lateral chest wall and then ask the patient to breathe deeply through the nose. You should feel the patient's hands move outward, which represents a breath from the diaphragm. Guidelines for effective huff coughing are shown in Table 28.21.

Chest Physiotherapy

Chest physiotherapy (CPT) is mainly used for patients with excessive bronchial secretions who have difficulty clearing them (e.g., CF, bronchiectasis). CPT consists of postural drainage, percussion, and

vibration. CPT should be done by a properly trained person. Complications associated with improperly performed CPT include fractured ribs, bruising, hypoxemia, and discomfort. CPT may be stressful for some patients. Some may develop hypoxemia and bronchospasms.

Postural drainage

Postural drainage is the use of positioning techniques that drain secretions from specific segments of the lungs and bronchi into the trachea. The postural drainage positions used depend on the areas of lung that are involved. This is determined by patient assessment, chest x-rays, chest auscultation, and, when possible, patient preference. For example, some patients with left lower lobe involvement need postural drainage of only the affected region. A person with CF may need postural drainage of all segments.

The purpose of various positions in postural drainage is to drain each segment toward the larger airways. The patient who cannot tolerate a head-down position may use a side-lying position. Aerosolized bronchodilators and hydration therapy are usually given before postural drainage. The chosen postural drainage position is maintained for about 5 minutes during percussion and vibration. A common order is 2 to 4 times a day. In acute situations, postural drainage may be done as often as every 4 hours. Schedule the procedure at least 1 hour before meals or 3 hours after meals.

Beds are available that can rotate and percuss in various postural drainage positions. These are quite effective. Some positions for postural drainage (e.g., Trendelenburg) should not be used on the patient with traumatic brain injury, chest trauma, hemoptysis, heart disease, pulmonary embolus, or any other situation in which the patient's condition is not stable.

Percussion

Percussion is performed in the appropriate postural drainage position with the hands in a cuplike position, with the fingers and thumbs closed (Fig. 28.14). The cupped hand should create an air pocket

between the patient's chest and the hand. Both hands are cupped and used in an alternating rhythmic fashion. If it is done correctly, a hollow sound should be heard. The air-cushion impact facilitates the movement of thick mucus. For patient comfort, place a thin towel over the area to be percussed. The patient may choose to wear a T-shirt or hospital gown.

TABLE 28.21 Patient & Caregiver TeachingEffective Huff Coughing

When teaching effective huff coughing:

1. Help the patient assume a sitting position with head slightly flexed, shoulders relaxed, knees flexed, forearms supported by pillow, and, if possible, feet on the floor.

Then teach the patient to:

2. Inhale slowly through the mouth while breathing deeply from the diaphragm.
3. Hold the breath for 2 to 3 seconds.
4. Forcefully exhale quickly as if one is fogging up a mirror with one's breath (thus creating a "huff"). This moves the secretions to larger airways.
5. Repeat the "huff" 1 or 2 more times while refraining from a "regular" cough.
6. Cough when mucus is felt in the breathing tubes.
7. Rest for 5 to 10 regular breaths.
8. Repeat the huffs (3 to 5 cycles) until you feel you have cleared mucus or you become tired.

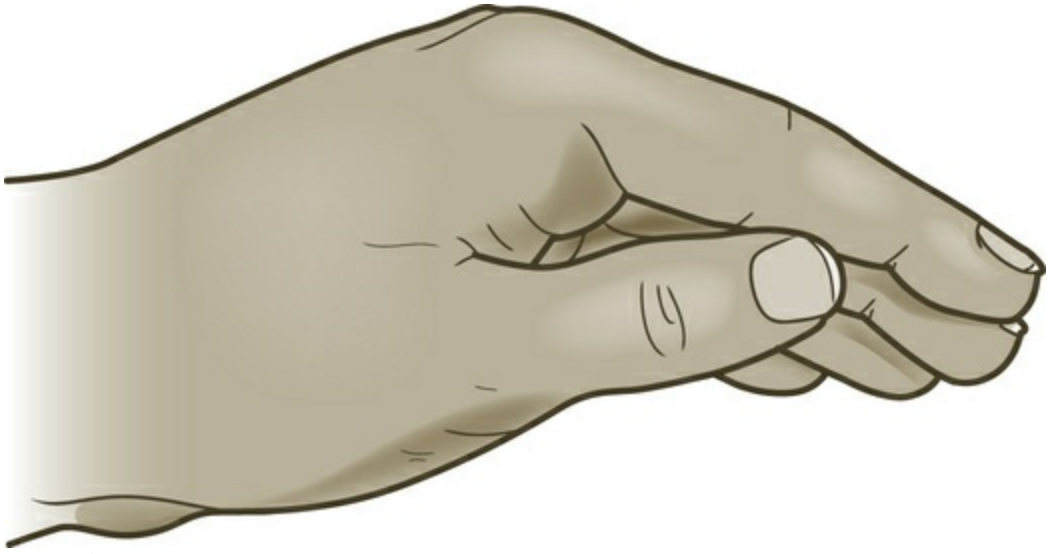


FIG. 28.14 Cupped-hand position for percussion. The hand should be cupped as though scooping up water.

Vibration

Vibration is accomplished by tensing the hand and arm muscles repeatedly and pressing mildly with the flat of the hand on the affected area while the patient slowly exhales a deep breath. Vibrations promote movement of secretions to larger airways. Commercially available mechanical chest vibrators are available for hospital and home use.

Airway Clearance Devices

Various *airway clearance devices* are available to help mobilize secretions. They are easier to tolerate than CPT and take less time than CPT sessions. These devices include the Flutter, Acapella, and TheraPEP Therapy System. These devices use positive expiratory pressure (PEP). They may provide greater benefit to patients with COPD than other ACTs.

The Flutter mucus clearance device is a hand-held device. It is shaped like a small, fat pipe. It provides PEP treatment for patients with mucus-producing conditions. The Flutter has a mouthpiece, a high-density stainless-steel ball, and a cone that holds the ball. When the patient exhales through the Flutter, the steel ball moves, which

causes oscillations (vibrations) in the airways and loosens mucus to allow improved expectoration. The patient must be upright as the angle at which the Flutter is held is critical.

The Acapella is another small hand-held device that combines the benefits of both PEP and airway vibrations to mobilize secretions (Fig. 28.15). It can be used in any setting, since patients are free to sit, stand, or recline.

FIG. 28.15 Acapella airway clearance device. Courtesy Smiths Medical North America.

TheraPEP Therapy System can provide sustained PEP and while delivering aerosols so that the patient can inhale and exhale through it. TheraPEP has a mouthpiece attached to tubing connected to a small cylindric resistor and a pressure indicator. The pressure indicator gives visual feedback about the pressure that the patient needs to hold in an exhalation to receive the PEP.

High-Frequency Chest Wall Oscillation

High-frequency chest wall oscillation uses an inflatable vest (e.g., the Vest Airway system or the SmartVest) with hoses connected to a high-frequency pulse generator. The pulse generator delivers air to the vest, which vibrates the chest. The high-frequency airwaves dislodge mucus from the airways, mobilize the mucus, and move it toward larger airways. The vest can be used without the aid of another person. The unit weighs 23 to 30 lb, is quiet, comes in a suitcase, and is

portable.

Nutritional Therapy

Many COPD patients in the advanced stages are underweight with loss of muscle mass and cachexia. Weight loss is a predictor of a poor prognosis and increased frequency of COPD exacerbations.[23] Malnutrition is multifactorial, including increased inflammatory mediators, increased metabolic rate due to the ventilatory effort, and lack of appetite. Other factors that contribute to malnutrition include taste changes caused by chronic mouth breathing, excessive sputum, fatigue, anxiety, depression, increased energy needs, numerous infections, and side effects of multiple medications.

To decrease dyspnea and conserve energy, the patient should rest for at least 30 minutes before eating and use a bronchodilator before meals. Teach the patient to avoid exercise and treatments for at least 1 hour before and after eating. If a patient desaturates while eating, supplemental O_2 by nasal cannula may be helpful. Encourage activity, such as walking or getting out of bed during the day, to stimulate appetite. Sensations of bloating and feeling full after consuming small amounts can be attributed to swallowing air while eating, side effects of medication (especially corticosteroids and theophylline), and the abnormal position of the diaphragm relative to the stomach in association with hyperinflation of the lungs.

Getting the patient to eat adequate amounts of nutritionally sound foods may be difficult even though well-balanced meals are available. Give the patient or those responsible for meal preparation printed information that can make mealtime easier and more nutritious (Table 28.22).

Underweight patients with COPD need extra protein and calories. They may need 25 to 45 kcal/kg body weight and more than 1.5 g of protein/kg body weight to maintain their weight. The patient with malnutrition may need up to 2.5 g of protein/kg of body weight to begin restoring muscle mass.

TABLE 28.22 Nutritional TherapyMaximizing Food Intake in COPD

Sometimes it is hard for patients with COPD to consume adequate amounts of nutrients. Teach the patients to make mealtimes easier and more nutritious by increasing calories and protein without increasing the amount of food eaten.

- Eat high-calorie foods first.
- Limit liquids at mealtimes.
- Rest before meals.
- Try more frequent meals and snacks.
- Increase calories by adding margarine, butter, mayonnaise, sauces, gravies, and peanut butter to foods.
- Keep favorite foods and snacks on hand.
- Try cold foods, which can make you feel less full than hot foods.
- Keep ready-prepared meals available for times when you have increased shortness of breath.
- Eat larger meals when you are not as tired.
- Avoid foods that you know cause gas (e.g., cabbage, beans, cauliflower).

- Add skim milk powder (2 Tbsp) to regular milk (8 oz) to add protein and calories.
- Use milk or half-and-half instead of water when making soups, cereals, instant puddings, cocoa, or canned soups.
- Add grated cheese to sauces, vegetables, soups, and casseroles.
- Choose dessert recipes that contain egg (e.g., sponge cake, angel food cake, egg custard, bread pudding, rice pudding).

Source: Grodner M, Escott-Stump S, Dorner S: *Nutritional foundations and clinical applications: A nursing approach,* ed 6, St Louis, 2016, Mosby.

A diet high in calories and protein, moderate in carbohydrate, and moderate to high in fat is recommended. It can be divided into 5 or 6 small meals a day.[24] Offer high-protein, high-calorie nutritional supplements between meals. The dietitian is an excellent resource to determine what combination of nutrients and what supplements are best for the patient. (Nutritional supplements are discussed in Chapter 39.)

Gerontologic Considerations: COPD

Older adults have physiologic changes, including reduced lean body mass, decreased respiratory muscle strength, increased dyspnea, and lower exercise tolerance that may increase the burden of disease from COPD. This may lead to a higher incidence of acute exacerbations, which require hospitalization. Smoking cessation is a key intervention but can be hard to achieve.

COPD is often complicated by the presence of co-morbidities, such as heart disease, serious infections, osteoporosis, psychological problems (depression, anxiety), impaired cognition, and lung cancer. The presence of co-morbidities can make it harder for patients to cope with the stress of an exacerbation. Assessment of co-morbidities can aid in ensuring comprehensive and safe management, especially during an exacerbation.

Older adults may have difficulty handling the increased secretions during an acute COPD exacerbation. Drugs used to manage the acute exacerbation can complicate disease management and increase the chance of adverse events. Assess for potential drug-drug interactions, especially in patients being treated for coexisting co-morbidities.

Some drugs used to treat common disorders, such as hypertension, can worsen COPD symptoms. If possible, nonspecific β-blockers should be avoided since they can block the β_2 receptors in the airway and cause bronchoconstriction. Similarly, ACE inhibitors may cause a dry cough or worsen a present cough. In some circumstances, it may not always be possible to eliminate these drugs.

Older adults may not be adherent to drug therapies due to cognitive

impairment and complexity of the multiple medications at different times of the day. An attempt to simplify the medication regimen with written large-font action plans can be an important intervention in patients with poor memory and vision impairment. Arthritis in the hands can hinder the person from using proper technique for MDIs. Review MDI technique during clinic visits and have DPI or spacers prescribed (if possible) because they are easier to use. Long-term use of ICSs has the potential of causing local and systemic side effects, including cataracts, glaucoma, and osteoporosis. Monitoring of ocular pressures, bone densitometry, and using the lowest possible ICS dose is recommended.

Older patients with COPD generally have impaired quality of life. An important role for us is to focus on ways to improve quality of life. Psychologic and emotional support becomes imperative to help patients achieve successful outcomes. In the later stages of COPD, palliative and hospice care can help manage symptoms and improve the quality of the rest of their lives, which is important.

Nursing Management: COPD

Nursing Assessment

Subjective and objective data that should be obtained from a person with COPD are outlined in Table 28.23.

Nursing Diagnoses

The nursing diagnoses for the patient with COPD may include:

- Impaired breathing
- Activity intolerance
- Impaired nutritional status
- Difficulty coping

Additional information on nursing diagnoses and interventions is presented in eNursing Care Plan 28.2 available on the website for this chapter.

Planning

The overall goals are that the patient with COPD will have (1) relief from symptoms, (2) ability to perform ADLs and improved exercise tolerance, (3) no complications related to COPD, (4) knowledge and ability to implement a long-term treatment plan, (5) prevention of disease progression, and (6) overall improved quality of life.

Nursing Implementation

Health Promotion

The incidence of COPD would decrease dramatically if people would not begin smoking or would stop smoking. Counseling the patient in smoking cessation is vital. It is the only way to slow the progression of

COPD. As health care professionals, nurses who smoke should reevaluate their own smoking behavior and its relationship to their health. Nurses and other HCPs who smoke should be aware that the odor of smoke is obvious on their clothes and hair. It can be offensive or tempting to patients.

Early diagnosis and treatment of respiratory tract infections and exacerbations of COPD help prevent progression of the disease. People with COPD should avoid others who are sick, practice good hand-washing techniques, take drugs as prescribed, exercise regularly, and maintain a healthy weight. Avoiding or controlling exposure to occupational and environmental pollutants and irritants is another preventive measure to maintain healthy lungs. Patients with COPD should have influenza and pneumococcal pneumonia vaccines.

TABLE 28.23 Nursing AssessmentChronic Obstructive Pulmonary Disease

Subjective Data

Important Health Information

Past health history: Long-term exposure to chemical pollutants, respiratory irritants, occupational fumes, dust; recurrent respiratory tract infections; previous hospitalizations

Medications: Use of O_2 and duration of O_2 use, bronchodilators, corticosteroids, antibiotics, anticholinergics, OTC drugs, illicit substances

Functional Health Patterns

Health perception–health management: Smoking (pack-years, including passive smoking, willingness to stop smoking, and previous attempts); what was smoked (e.g., cigarettes, pipes,

cigars, e-cigarettes, hookahs, etc.); family history of respiratory disease (especially α_1-antitrypsin deficiency)

Nutritional-metabolic: Anorexia, weight loss or gain

Activity-exercise: Increasing dyspnea and/or increase in sputum volume or purulence; fatigue, ability to perform ADLs; swelling of feet; progressive dyspnea, especially on exertion; ability to walk up 1 flight of stairs without stopping; wheezing; recurrent cough; sputum production (especially in the morning); orthopnea

Elimination: Constipation, gas, bloating

Sleep-rest: Insomnia; sitting up position for sleeping, paroxysmal nocturnal dyspnea

Cognitive-perceptual: Headache, chest or abdominal soreness

Coping–stress tolerance: Anxiety, depression

Objective Data

General

Debilitation, restlessness, assumption of upright position

Integumentary

Cyanosis (bronchitis), pallor or ruddy color, poor skin turgor, thin skin, digital clubbing, easy bruising; peripheral edema (cor pulmonale)

Respiratory

Rapid, shallow breathing; inability to speak; prolonged expiratory phase; pursed-lip breathing; wheezing; crackles, decreased or bronchial breath sounds; ↓ chest excursion and diaphragm movement; use of accessory muscles; hyperresonant or dull chest sounds on percussion

Cardiovascular

Tachycardia, dysrhythmias, jugular venous distention, distant heart tones, right-sided S_3 (cor pulmonale), edema (especially in feet)

Gastrointestinal

Ascites, hepatomegaly (cor pulmonale)

Musculoskeletal

Muscle atrophy, ↑ anteroposterior diameter (barrel chest)

Possible Diagnostic Findings

Abnormal ABGs (compensated respiratory acidosis, ↓ PaO_2 or SaO_2, ↑ $PaCO_2$), polycythemia, pulmonary function tests showing expiratory airflow obstruction (e.g., low FEV_1, low FEV_1/FVC, large RV), chest x-ray showing flattened diaphragm and hyperinflation or infiltrates

Families with a history of COPD, as well as AATD, should be aware of the genetic nature of the disease. They may want to consider consulting a pulmonologist about regular spirometry screening, even if they do not have symptoms. Genetic counseling may be appropriate for the patient with AATD deficiency who is planning to have children.

Acute Care

The patient with COPD needs hospitalization for acute exacerbations of COPD, brought on by pneumonia or heart failure and associated

complications, such as cor pulmonale and respiratory failure. Once the crisis has been resolved, reassessment of the degree and severity of any underlying problems is needed. The information obtained will help in planning care going forward and may assist with changes in the treatment plan that will be needed after discharge.

Ambulatory Care

The interprofessional team works together to individualize the treatment plan for COPD patients. By far the most important aspect in the long-term care of the patient with COPD is teaching. A large part of your role is to teach patients self-management of their disease. A patient and caregiver teaching guide is shown in Table 28.24.

Pulmonary Rehabilitation

Pulmonary rehabilitation can be done in an inpatient or outpatient setting or in the home. Components of pulmonary rehabilitation vary, but usually include exercise training, smoking cessation, nutrition counseling, and education. Physical therapists or nurses who have experience in respiratory care are often responsible for managing pulmonary rehabilitation centers. Pulmonary rehabilitation indicated for any degree of airway obstruction or GOLD classification. It works best if the patient starts when COPD is in a moderate stage, but even patients who have advanced COPD can benefit. Pulmonary rehabilitation relieves dyspnea and fatigue, improves emotional function, and enhances the sense of control that people have over their COPD.

Pulmonary rehabilitation may be inaccessible to some because of disability, transportation, geographic location, or cost. One alternative program to in-person pulmonary rehabilitation uses the Internet or gaming technology. However, the HCP must approve these types of programs to ensure safety.

Informatics in Practice

E-Mail and Texting for COPD Patients

- Sometimes patients with COPD or those who use O_2 therapy have difficulty speaking because of shortness of breath.
- Encourage your patient to use typed messages, such as e-mail, to communicate.
- Texting and instant messaging family and friends are good alternatives to having phone conversations.

Activity Considerations

The patient with severe COPD typically uses upper thoracic and neck muscles to breathe rather than the diaphragm. Thus the patient has difficulty performing upper extremity activities, particularly those that require raising the arm above the head. Exercise training leads to energy conservation, which is an important part in COPD rehabilitation. Exercise training of the upper extremities may improve muscle function and help to reduce dyspnea.

Often the patient is already using some alternative energy-saving practices for ADLs. Explore alternative methods of hair care, shaving, showering, and reaching.

An occupational therapist may help with ideas in these areas. Assuming a tripod posture (elbows supported on a table, chest in fixed position) and placing a mirror on the table while using an electric razor or hair dryer conserves much more energy than when the patient stands in front of a mirror to shave or blow-dry hair.

TABLE 28.24 Patient & Caregiver TeachingChronic Obstructive Pulmonary Disease

Include the following information in the teaching plan to assist the patient with COPD and the caregiver to improve quality of life through promoting lifestyle practices that support successful living with COPD:

What Is COPD?

- Basic anatomy and physiology of lung
- Basic pathophysiology of COPD
- Signs and symptoms of COPD, exacerbation
- How to tell COPD from the common cold, flu, pneumonia
- Tests to assess breathing

Breathing and Airway Clearance Exercises

- Pursed-lip breathing (Table 28.12)
- Airway clearance technique: huff cough (Table 28.21)

Energy Conservation Techniques

- Daily activities (e.g., waking up, bathing, grooming, shopping, traveling)
- Consult with physical therapist and occupational therapist

Medications

Types (include mechanism of action and types of devices)

- Establishing medication schedule
- Correct use of inhalers, spacer, and nebulizer
- Reason for use of O_2 equipment
- Guide for home O_2 use and equipment

Psychosocial/Emotional Issues

Open discussion (sharing with patient and/or caregiver)

- Concerns about interpersonal relationships (e.g., intimacy)
- Problems with emotions (e.g., depression, anxiety, panic)

- Dependency

  Treatment decisions and end-of-life issues

- Support and rehabilitation groups

COPD Management Plan

Nurse and patient develop and write up COPD management plan that meets individual needs.

- Focus on self-management
- Need to report changes
- Cause of acute exacerbations
- Recognition of signs and symptoms of respiratory infection, heart failure
- Reduce risk factors, especially smoking cessation
- Exercise program of walking and arm strengthening
- Yearly follow-up

Healthy Nutrition (Table 28.22)

- Ways to lose weight (if overweight)
- Ways to gain weight (if underweight)
- Consultation with dietitian

For more information, see American Lung Association at www.lung.org/lung-disease/copd.

If the patient uses home O_2 therapy, O_2 should be used during hygiene because these tasks are energy consuming. Encourage the patient to make a schedule and plan daily and weekly activities,

leaving plenty of time for rest periods. In severe COPD, the patient should try to sit as much as possible when performing activities. Another energy-saving tip is to exhale when pushing, pulling, or exerting effort during an activity and inhale during rest.

Regular physical exercise is important for patients with COPD. To ensure long-term adherence, the exercise plan must be individualized and easy to perform. Walking or other endurance exercises (e.g., cycling) combined with strength training are the best interventions to strengthen muscles and improve the patient's endurance. Teach the patient coordinated walking with slow, pursed-lip breathing. Many patients with moderate or severe COPD are anxious and fearful of walking or performing exercise. Both patients and their caregivers need support while they build the confidence they need to walk, perform daily exercises, or help with these activities.

Developing exercise endurance is very important. If it takes longer than 5 minutes to return to baseline, the patient has most likely "overdone it" and should proceed at a slower pace during the next exercise period. Keeping a diary or log of the exercise program may help. Stationary cycling can be used either alone or with walking. Cycles and treadmills are particularly good when weather prevents walking outside.

Fatigue, sleep problems, and dyspnea are common problems. Of these symptoms, dyspnea seems to be the one that most affects the patient's ability to carry out daily activities. Therefore focus your interventions on improving dyspnea, which should then improve the patient's overall functional performance.

Patients often ask whether moving to a warmer or drier climate will help. In general, such moves are generally not beneficial. Discourage moves to places with an elevation of 4000 ft or more because of the lower partial pressure of O_2 found in the air at higher elevations. A disadvantage of moving may be that a person leaves a job, friends, and familiar environment, which could be psychologically stressful. This may outweigh any advantage gained from being in a different climate.

Evidence-Based Practice

Physical Activity and COPD

You are working as a nurse in a pulmonary clinic with R.P., a 71-yr-old man who was recently discharged from the hospital with a new diagnosis of COPD. He tells you he has been inactive for most of the past 8 months because his breathing seems to worsen with any type of physical activity.

Making Clinical Decisions

Best Available Evidence. Patients with COPD who take part in regular moderate physical activity (e.g., brisk walking) have fewer severe flare-ups and are less likely to be readmitted to the hospital. Physical activity improves lung function and lessens depressive symptoms. The season of the year and temperature can be barriers to outdoor exercise.

Clinician Expertise. Physical inactivity is common in patients with COPD. You are aware that inactivity may place R.P. at a greater risk for functional decline and readmission.

Patient Preference and Values. R.P. tells you that he misses taking walks every day with his wife and dog. He is wondering if he would be able to resume this activity at a slower pace.

Implications for Practice

1. What important factors will you discuss with R.P. about physical activity and COPD?
2. How would you assess R.P.'s willingness and motivation to engage in physical activity?
3. How would you involve the interprofessional team members to assist R.P. in regular physical activity?

Reference for Evidence

Kantorowski A, Wan E.S, Homsy D, et al. Determinants and outcomes of change in physical activity in COPD. *ERJ Open Res*. 2018;4:1.

Psychosocial Considerations

Coping is a challenge for the COPD patient and family. As the disease progresses, patients with COPD are often confronted with many lifestyle changes that may involve decreased ability to care for themselves, decreased energy for social activities, and loss or change in a job.

When a patient with COPD is first diagnosed or has complications that require hospitalization, expect a variety of emotional responses. Emotions often expressed include denial, anger, frustration from increased dependence, and loneliness from social isolation. Guilt may result if the disease was caused primarily by cigarette smoking.

Patients experience many losses as the disease progresses. Because many patients have depression and anxiety, assess for both. Ask patients if they "feel down or blue" most of the time. Do they appear anxious about being able to control their breathlessness or know what to do if they have an exacerbation? Are they showing concern over more difficulty in self-care activities, such as bathing? How is the family coping with the patient's disease? The patient with COPD may benefit from stress management techniques (e.g., massage, muscle relaxation).

It is important to convey a sense of understanding and caring to the patient. Teach patients about COPD and their treatment, which can provide a sense of control. It is important to include caregivers in the teaching so they can help the patient cope physically and emotionally. Support groups at local American Lung Association chapters (e.g., the Better Breathers Club), hospitals, and clinics can be helpful.

Consultation with a mental health therapist may be needed for proper screening and diagnosis of depression or other mental health problems. Cognitive and behavioral therapy along with COPD teaching may improve the quality of life. Drugs may be used to treat

both depression and anxiety. Buspirone (BuSpar), used to treat anxiety, has few respiratory effects. Benzodiazepines should be avoided because they may depress the respiratory drive and may be habit forming. When the patient becomes anxious because of dyspnea, the use of pursed-lip breathing and SABAs may be appropriate.

Sexuality and Sexual Activity

Modifying sexual activity can contribute to healthy psychologic well-being. First, assess the patient's concerns related to sexuality and functioning. Ask open-ended questions to determine if the patient wants or is willing to discuss concerns. You could ask, "How has your breathing problem affected how you see yourself as a person?" Another question could be, "How does your shortness of breath affect your desire for intimacy with your partner?" These types of questions give the patient an opening to discuss concerns.

Dyspnea, the predominant symptom in COPD, should not be a major problem with success in sexual functioning, except for patients in severe late stages. If the patient can walk up 2 flights of stairs or walk briskly, they likely have enough energy for sexual activity. Using an inhaled bronchodilator before sexual activity can help ventilation. The patient may find these suggestions helpful: (1) plan sexual activity during the part of the day when breathing is best, which is usually late morning or early afternoon (plus older men often achieve an erection more easily in the morning); (2) use slow pursed-lip breathing; (3) refrain from sexual activity after eating or drinking alcohol; (4) choose less stressful positions during intercourse (missionary position for men is the worst); and (5) use O_2 if prescribed.

Most patients with COPD are older. Many of the sexual performance issues experienced by the patient with COPD are changes related to aging. You can teach the patient the "normalcy" of the changes. The patient with coexisting heart disease should obtain advice from an HCP related to appropriate levels of activity. Open communication between partners about their needs and expectations and any changes that may be needed is important.

Sleep

Adequate sleep is extremely important to maintain quality of life and productivity. Most patients with COPD have sleep problems. Hyperinflation of the lungs and reduction in ventilation can result in severe drops in O_2 saturation (down to 60% or less) during sleep. This leads to an increased workload on the heart. Hypercapnia may contribute to more frequent awakening. The net result is sleeping poorly and waking up unrefreshed and fatigued.

Current tobacco use, depression, and anxiety are all common in COPD and lead to more trouble sleeping. β_2-Agonists may cause restlessness and insomnia. Postnasal drip or nasal congestion may cause coughing and wheezing at night. Nasal saline sprays or rinses before sleep and in the morning may help. If the patient is prescribed O_2 therapy, using it at night may decrease insomnia. If the patient is a restless sleeper, snores, stops breathing while asleep, and tends to fall asleep during the day, the patient may need testing for sleep apnea (see Chapter 7).

End-of-Life Considerations

The trajectory of COPD is a gradual decline in health characterized by increasing exacerbations that are associated with an increased risk for death. In the later, severe stages of this disease, palliative, end-of-life, and hospice care are important components of care for the patient with advanced COPD.

Patients need to know that symptoms can be managed, but COPD cannot be cured. End-of-life issues and advance directives are important topics for discussion in the latter stages of COPD. This may be hard for the patient and family to consider because of the uncertainty of the disease.

Evaluation

The expected outcomes are that the patient with COPD will

- Maintain a patent airway by effectively coughing
- Have an effective rate, rhythm, and depth of respirations
- Have clear breath sounds
- Return to pre-exacerbation baseline respiratory function
- Have $PaCO_2$ and PaO_2 values that return to normal for the patient

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive, multisystem disease characterized by altered transport of sodium and chloride ions in and out of epithelial cells. This defect primarily affects the lungs, GI tract (pancreas and biliary tract), and reproductive tract.

The first signs and symptoms typically occur in childhood, but some patients are not diagnosed until they are adults. The severity and progression of the disease vary. With early diagnosis and improvements in therapy, the prognosis of patients with CF has significantly improved. The median predicted survival in 1970 was 16 years of age. Today it has increased to more than 37.5 years.[25]

Ethical/Legal Dilemmas

Advance Directives

Situation

L.H., an 84-yr-old man with end-stage COPD, is admitted to the hospital in respiratory failure. He is intubated in the ED and placed on a ventilator. L.H. sometimes responds by opening his eyes. His advanced personal directive (AD) was drawn up 5 years ago, and copies were given to his wife and HCP at that time. His wife brings the documents to the critical care unit and tells you that the hospital must stop treating her husband, and as per his request, allow him to die. However, the patient's oldest son is threatening the hospital with a lawsuit if the staff does not provide full care to his father.

Ethical/Legal Points for Consideration

- A Living Will, one form of AD, permits persons to state their own preferences and refusals should the person become terminally ill or be in a situation in which there is no hope of recovery and the

person is not able to speak for themselves.

- The Durable Power of Attorney for Health Care, another form of AD, permits persons to identify a proxy to make health care decisions in the event the person is incapacitated.
- The National POLST Paradigm is an approach to end-of-life planning that emphasizes documenting patients' wishes about the care they receive.[1]
- AD laws vary from state to state concerning the need for witnesses and designating the proxy.
- Some families are deeply divided about decisions for their loved ones, and conflicts often arise when feelings of remorse or guilt and money and/or property are involved. This situation requires you to notify the HCP, engage social work and spiritual care, and ask for a family conference. In some circumstances, a consult from the ethics committee may be needed.
- HCPs are obligated to follow the patient's ADs when a patient is no longer able to speak for himself or herself.
- In your scope of nursing practice, you need to (1) be informed about the decision-making laws and regulations in your state, (2) make AD documents available to patients, (3) teach patients and families about ADs, (4) determine if all involved HCPs are aware of the ADs, (5) assist the patient and family in communicating with the HCP when a "no code" or "DNR" (do not resuscitate) order is requested, and (6) assist the conflicted family in obtaining appropriate counseling when needed.

Discussion Questions

1. What should you do next with the information provided by L.H.'s wife?
2. The HCP has asked that you organize a family conference. How should you address the needs of each member of this family in L.H.'s plan of care?
3. What resources can you use to facilitate decision making in this

situation?

4. What would be your approach to L.H.'s plan of care?

Etiology and Pathophysiology

Genetic Link

CF is an autosomal recessive disorder. The CF gene is found on chromosome 7, which makes a protein called *CF transmembrane conductance regulator (CFTR).* The CFTR protein localizes to the epithelial surface of the airways, GI tract, and ducts of the liver, pancreas, and sweat glands. Under normal conditions, CFTR regulates sodium and chloride movement in and out of epithelial cells. However, mutations in the *CFTR* gene change this protein in such a way that the channels are blocked. As a result, cells that line the passageways of the lungs, pancreas, intestines, and other organs make secretions that are low in sodium chloride content (thus low in water content), making mucus abnormally thick and sticky (Fig. 28.16). This mucus plugs up the ducts in these organs, causing scarring in the organs and resulting in organ failure. The high concentrations of sodium and chloride in the sweat of the patient with CF result from decreased chloride reabsorption in the sweat duct.

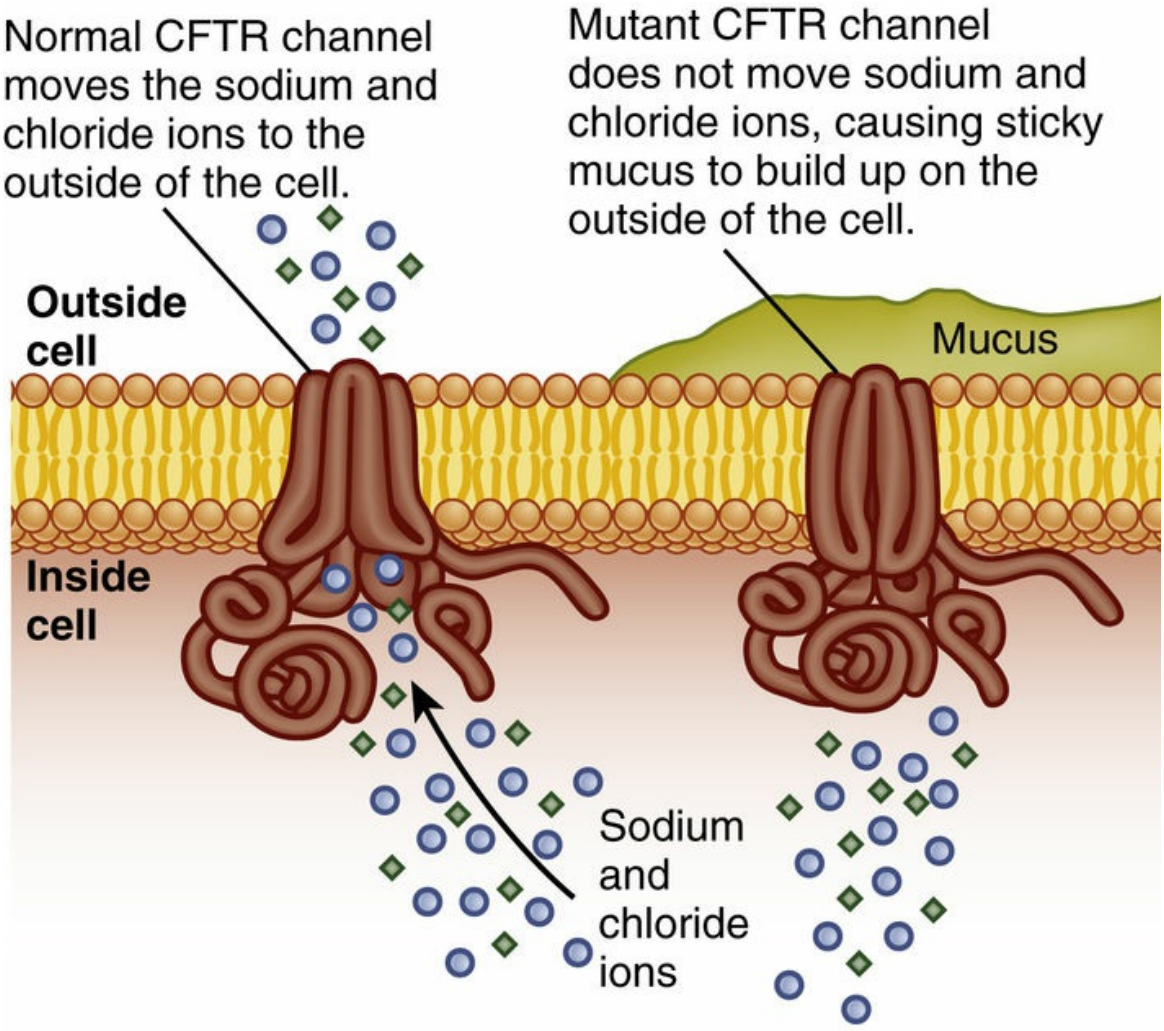

FIG. 28.16 People with cystic fibrosis inherit a defective gene on chromosome 7 called *cystic fibrosis transmembrane conductance regulator (CFTR).* The protein made by this gene normally helps sodium and chloride move in and out of cells. If the protein does not work correctly, the movement of sodium and chloride is blocked, and an abnormally thick sticky mucus is produced on the outside of the cell.

Genetics in Clinical Practice

Cystic Fibrosis (CF)

Genetic Basis

- Autosomal recessive disorder
- Caused by mutations in CF transmembrane regulator *(CFTR)* gene on chromosome 7
- *CFTR* gene provides the instructions for making the protein that controls the channel that transports sodium and chloride
- There are more than 17,000 different mutations of the *CFTR* gene
- Mutations in the *CFTR* gene disrupt the function of the channels, preventing them from regulating the flow of sodium, chloride, and water across cell membranes

Incidence

- In the United States, 1 in 3000 white births
- Less common in other ethnic populations (1 in 15,000 blacks, 1 in 9200 Hispanics, 1 in 30,000 Asian Americans)
- One in 20 to 25 whites are carriers of the gene

Genetic Testing

- Blood-based DNA testing is available for disease and carrier states.
- All 50 states require CF screening for all newborns.
- Testing is usually done in children if CF is suspected or if parents are possible carriers.
- In parents who are known carriers, amniocentesis or chorionic villus sampling in pregnant women may be useful for prenatal testing.

Clinical Implications

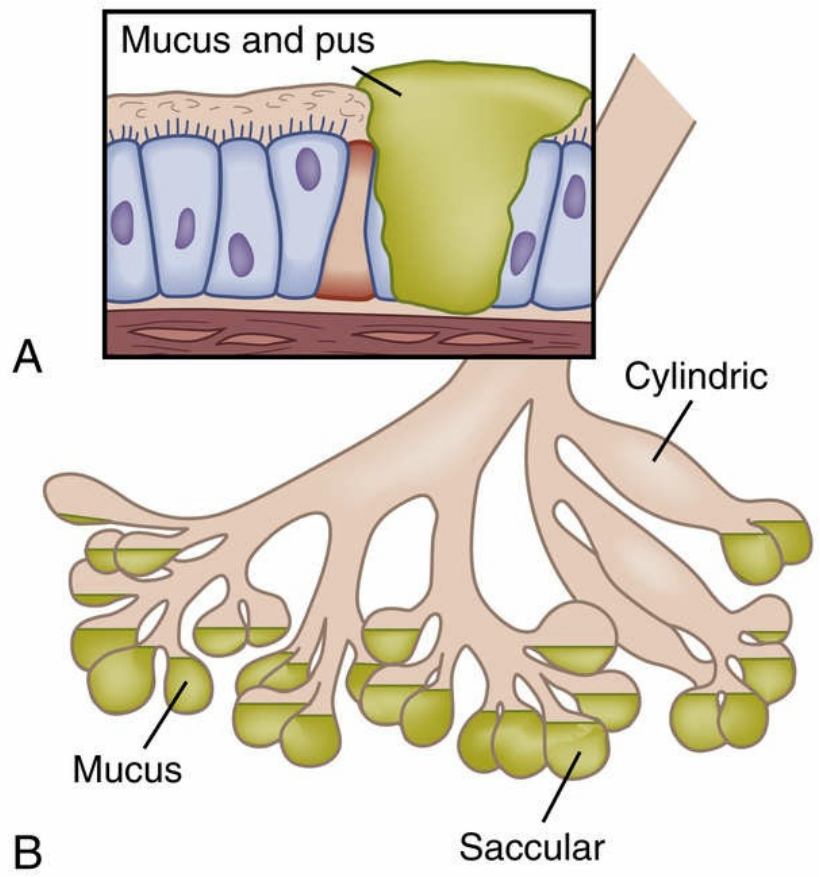
- CF has a wide range of clinical expression of disease.
- Most people who have a child with CF are not aware of a family

history of disease.

- CF screening should be offered to all people of reproductive age regardless of family history.

The hallmark of CF is its effect on the airways. CF can affect both upper and lower respiratory tracts. URI manifestations may include chronic sinusitis and nasal polyposis. CF progresses from being a disease of the small airways *(chronic bronchiolitis)* to involvement of the larger airways that causes destruction of lung tissue. The mucus lining the airways becomes dehydrated and tenacious due to defects in chloride secretion and sodium absorption. Cilia motility is decreased, allowing mucus to adhere to the airways. The bronchioles become obstructed with thick secretions, leading to scarring of the airways (bronchiectasis), air trapping, and hyperinflation of the lungs.

CF is characterized by a persistent, chronic airway infection that cannot be cured. *P. aeruginosa* is by far the most common organism in adults. Other organisms include *Staphylococcus aureus, H. influenzae,* and less often, but more seriously, *Burkholderia cepacia.* Antibiotic resistance develops after multiple exposure to antibiotics. Pulmonary inflammation is associated with the chronic infection and can cause a decrease in respiratory function, further narrowing the lumen of the airways. Inflammatory mediators (e.g., interleukins, oxidants, proteases released by neutrophils) are increased and contribute to disease progression.



Lung disorders that initially occur are chronic bronchiolitis and bronchiectasis (Fig. 28.17). Over a long period, pulmonary vascular remodeling occurs because of local hypoxia and arteriolar vasoconstriction. Pulmonary hypertension, enlarged pulmonary arteries, and cor pulmonale occur in the later phases of the disease. Blebs and large cysts in the lung are severe manifestations of lung destruction. Pneumothorax may occur. Hemoptysis is caused by proliferation of capillaries in response to chronic infection. During exacerbations, erosion of these capillaries occurs. Hemoptysis may range from scant streaking to major bleeding, which can be fatal.

Pancreatic insufficiency is caused by mucous plugging of the

pancreatic exocrine ducts. This results in atrophy of the gland and progressive fibrotic cyst formation. The pancreas's exocrine function may be completely lost. Because of this dysfunction, pancreatic enzymes, such as lipase, amylase, and proteases (trypsin, chemotrypsin), are not made in sufficient amounts to allow for absorption of nutrients. Malabsorption of fat, protein, and fat-soluble vitamins (A, D, E, and K) occurs. Fat malabsorption results in steatorrhea. Protein malabsorption results in failure to grow and gain weight. Osteopenia and osteoporosis are common. They are related to malnutrition, malabsorption of vitamin D, insufficient testosterone levels, and chronically elevated inflammatory cytokines.[26]

We believe CF-related diabetes mellitus (CFRD) is caused by underdevelopment of pancreatic islet cells (in utero) and destruction of islet cells over the person's lifetime. CFRD is unique because it has characteristics of both type 1 and type 2 diabetes. The pancreas in people with CF makes insulin, but they make it too late to fully respond to carbohydrate intake.

Persons with CF often have other GI problems, including GERD, gallstones, and pancreatitis. The liver and gallbladder can be damaged by mucus deposits in the ducts. Liver enzymes may become chronically elevated, with cirrhosis developing over time. Portal hypertension can occur. Distal intestinal obstruction syndrome (DIOS) results from an intermittent obstruction, often in the terminal ileum at the point of the ileocecal junction. It is caused by thickened, dehydrated stool and mucus. The patient may appear to have a small bowel obstruction. DIOS develops because of chronic malabsorption related to exocrine dysfunction, under- or over-dosing of pancreatic replacement enzyme supplementation, dehydration, and swallowing of mucus.

Cut surfaces of lung show markedly distended peripheral bronchi filled with mucopurulent secretions.
C, From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

Clinical Manifestations

The manifestations vary depending on the severity of the disease. The disease severity may vary greatly, both within families and among different families. Mutations do not affect carriers.

The median age at diagnosis of CF is 6 to 8 months of age. Two thirds are diagnosed in the first year of life.[27] Currently every state has mandatory newborn screening for CF, which has allowed for early intervention. An initial finding of meconium ileus in the newborn infant prompts the diagnosis in 20% of people with CF. Other signs that suggest a CF diagnosis in childhood are acute or persistent respiratory symptoms (wheezing, coughing, frequent pneumonia), failure to thrive or malnutrition, steatorrhea (large, oily, frequent bowel movements), bronchiectasis, and family history. Without treatment, a large, protuberant abdomen may develop with an emaciated appearance of the extremities. Both males and females have delayed puberty.

In adults, patients often present with atypical symptoms, such as new-onset diabetes or infertility problems. One of the most common symptoms of CF in the adult is frequent cough. With time, the cough becomes persistent and produces viscous, purulent, often yellow or greenish sputum. The most common bacteria in the airways of adults is *Pseudomonas*. Other respiratory problems include recurring lung infections, such as bronchiolitis, bronchitis, and pneumonia. As the disease progresses, periods of clinical stability are interrupted by exacerbations characterized by increased cough, weight loss, increased sputum, and decreased pulmonary function. Over time, the

exacerbations become more frequent, bronchiectasis worsens, and the recovery of lost lung function is less complete, which may ultimately lead to respiratory failure.

Patients who develop DIOS may have right lower quadrant pain (the area of the ileocecal valve), loss of appetite, nausea, emesis, and a palpable mass. Insufficient pancreatic enzyme release causes the typical pattern of protein and fat malabsorption with a person being thin with a low body mass index (BMI) and frequent bulky, foul-smelling stools.

Both males and females have delayed puberty. Some women with CF have difficulty conceiving. The cervical mucus may be thickened. During exacerbations, menstrual irregularities and secondary amenorrhea are common. Most women with CF can become pregnant. Most pregnancies result in viable infants.

Nearly all men with CF have reproductive issues because their vas deferens fails to develop in utero, so there is no transport of sperm from storage in the testes to the penile urethra. However, they make sperm normally, and with assisted reproductive technology, can father a child.

Complications

Complications in CF include CFRD and bone, sinus, and liver disease. With advanced lung disease, digital clubbing occurs. Respiratory failure and cor pulmonale caused by pulmonary hypertension are late complications of CF. Pneumothorax, a rare but serious complication, is caused by the formation of bullae and blebs. A small amount of blood in sputum is common in the CF patient because of chronic lung infection. Massive hemoptysis, though, is also rare but can be life-threatening.

Diagnostic Studies

The diagnostic criteria for CF include a combination of clinical presentation, family history, laboratory, and genetic testing. The sweat glands of CF patients secrete normal volumes of sweat, but sodium

chloride cannot be absorbed from sweat as it moves through the sweat duct. As a result, 4 times the normal amount of sodium and chloride is excreted in sweat. This abnormality usually does not directly affect the person's general health, but helps confirm a diagnosis of CF.

The sweat chloride test is the gold standard for diagnosis of CF. It is done with the pilocarpine iontophoresis method.[28] Pilocarpine is placed on the skin and carried by a small electric current to stimulate sweat production. This part of the process takes about 5 minutes. The patient will feel a slight tingling or warmth. Next, the area (usually an arm) is wrapped in plastic to help facilitate sweating. The sweat is collected on filter paper or gauze and then analyzed for sweat chloride concentrations. The test takes about 1 hour. Sweat chloride values above 60 mmol/L are considered positive for the diagnosis of CF. A second sweat chloride test is done at the same time (1 test in each arm) to confirm the diagnosis.

Genetic testing is often used if the results from a sweat chloride test are uncertain. A blood sample or cells taken inside the cheek (buccal smear) are sent to a laboratory that specializes in genetic testing. Most laboratories test for only the most common mutations of the CF gene. Because more than 1700 mutations cause CF, screening for all mutations is hard and done only at a specialty laboratory.

Interprofessional Care

An interprofessional team should be involved in the care of a patient with CF. The Cystic Fibrosis Foundation provides funding for and accredits more than 120 CF care centers nationwide. The high quality of specialized care available throughout the care center network has led to the improved length and quality of life for people with CF. These care centers offer the best care, treatments, and support for those with CF. The teams at these care centers include a nurse, physician, respiratory therapist, physical therapist, dietitian, social worker, and often a nurse practitioner.

Management of pulmonary problems in CF aims at relieving airway obstruction and controlling infection. Drainage of thick bronchial

mucus is assisted by aerosol and nebulization treatments of drugs used to dilate the airways, liquefy mucus, and promote clearance.

The abnormal viscosity of CF secretions is increased by concentrated deoxyribonucleic acid (DNA) from neutrophils involved in chronic infection. Agents that degrade the DNA in CF sputum (e.g., inhaled dornase alfa [Pulmozyme]) increase airflow and reduce the number of acute exacerbations. Inhaled hypertonic saline (7%) increases osmolality, allowing water to collect on airway surfaces. It is effective in clearing mucus and decreases the frequency of exacerbations. Some patients also need bronchodilators (e.g., β_2-adrenergic agonists) to control bronchospasm, but the long-term benefit is not known.

ACTs are critical since the normal ciliary motion in CF airways is impaired. CPT (including postural drainage with percussion and vibration) and high-frequency chest wall oscillation loosen mucus. Clearance is achieved by specialized expiratory techniques aimed at using airflow to remove the loosened secretions. Examples include PEP devices (Fig. 28.15), breathing exercises, pursed-lip breathing (Table 28.12), and huff coughing (Table 28.21). Persons with CF may prefer a certain technique or device that works well for them in a daily routine. No clear evidence exists that any ACT is better than the others.

Most patients with CF die of complications from lung infection. Standard treatment of infections includes antibiotics for exacerbations in conjunction with airway clearance. Early intervention with antibiotics is useful. Antibiotic choice should be based on sputum culture results. They may be given for 10 days to 3 weeks or longer. Some need chronic suppressive therapy. Prolonged high-dose therapy (larger doses, more frequent dosing) may be needed because many drugs are abnormally metabolized and rapidly excreted in the patient with CF.

If home support and resources are adequate, the CF patient and caregiver may be able to administer IV antibiotic therapy at home independently. The usual treatment is 2 antibiotics with different mechanisms of action (e.g., cephalosporin and an aminoglycoside).

The patient with cor pulmonale or hypoxemia may need home O_2 therapy.

Oral agents used for mild exacerbations (e.g., increased cough and sputum) include a semisynthetic penicillin, trimethoprim/sulfamethoxazole (to treat *S. aureus*) or oral quinolones, especially ciprofloxacin (to treat *P. aeruginosa*). The quinolones are used with caution because of the rapid development of resistant strains.

Most patients have *Pseudomonas* infection, which can be hard to treat over time because the organism develops resistance to antibiotics. *Pseudomonas* can form a biofilm that protects the organism from antibiotics. One commonly used antibiotic to treat patients with chronic *Pseudomonas* infection is aerosolized tobramycin (TOBI). It is given twice a day, every day, every other month. Azithromycin used longer than 6 months decreases the frequency of pulmonary exacerbations, especially in those infected with *Pseudomonas.* It is also thought to act as an antiinflammatory.

Patients with a large pneumothorax need chest tube drainage, perhaps repeatedly. Sclerosing of the pleural space or partial pleural stripping and pleural abrasion may be done for recurrent episodes of pneumothorax. With massive hemoptysis, bronchial artery embolization is done. CF has become a leading reason for lung transplantation.

The management of pancreatic insufficiency includes pancreatic enzyme replacement of lipase, protease, and amylase (e.g., pancrelipase [Pancreaze, Creon, Zenpep]) taken before each meal and snack. Adequate intake of fat, calories, protein, and vitamins is important. Fat-soluble vitamins (A, D, E, and K) must be supplemented, since they are malabsorbed. Use of caloric supplements improves nutritional status. Dietary salt is indicated whenever sweating is excessive, such as during hot weather, when fever is present, or from intense physical activity. Hyperglycemia may need insulin treatment.

If the patient develops DIOS with partial or complete bowel obstruction, every attempt is made to manage the condition medically.

Options include prokinetic agents (e.g., macrolide antibiotics, metoclopramide), mucolytics (oral N-acetylcysteine), stimulant laxatives, lactulose, and polyethylene glycol (PEG) electrolyte solution (MiraLAX, GoLYTELY).[29] Careful monitoring of bowel habits and patterns is essential for CF patients. If DIOS does not resolve with medical treatment, surgery may be done to prevent the development of ischemic bowel.

Ivacaftor (Kalydeco), a CFTR modulator, is used to treat patients who have mutations in a specific *CFTR* gene. It is not effective in patients with CF who have 2 copies (homozygous) of the *F508* mutation in the *CFTR* gene (the most common mutation that results in CF). If a patient's genotype is unknown, a CF mutation test should be done to detect the presence of a CFTR mutation. Combinations drugs, such as ivacaftor/lumacaftor (Orkambi), are used to treat CF patients with specific gene mutations. All patients diagnosed with CF should have CFTR genotyping. This will help determine if they carry a mutation that would be appropriate for CFTR modulator therapy.

Nursing Management: Cystic Fibrosis

Nursing Assessment

Subjective and objective data that should be obtained from the patient with CF are presented in Table 28.25.

Nursing Diagnoses

Nursing diagnoses for the patient with CF may include:

- Impaired airway clearance
- Impaired respiratory system function
- Impaired nutritional status
- Difficulty coping

TABLE 28.25 Nursing AssessmentCystic Fibrosis

Subjective Data
Important Health Information

Past health history: Recurrent respiratory and sinus infections, persistent cough with excessive sputum production
Medications: Use of and compliance with bronchodilators, antibiotics

Functional Health Patterns

Health perception–health maintenance: Family history of cystic fibrosis, diagnosis of cystic fibrosis in childhood, genetic testing in offspring
Nutritional-metabolic: Dietary intolerances, voracious appetite,

weight loss, heartburn

Elimination: Intestinal gas. Large, frequent bowel movements, constipation

Activity-exercise: Fatigue, ↓ exercise tolerance, amount and type of exercise. Dyspnea, cough, excessive mucus or sputum production, coughing up blood, airway clearance techniques

Cognitive-perceptual: Abdominal pain

Sexuality-reproductive: Delayed menarche, menstrual irregularities, problems conceiving or fathering a child

Coping–stress tolerance: Anxiety, depression, problems adapting to diagnosis

Objective Data

General

Restlessness; failure to thrive

Integumentary

Cyanosis (circumoral, nail bed), digital clubbing; salty skin

Eyes

Scleral icterus

Respiratory

Sinus congestion, postnasal drip, persistent runny nose. Decreased breath sounds, adventitious breath sounds (crackles, wheezes). Sputum (thick, light or dark, tenacious), ↑ WOB, use of accessory muscles of respiration, barrel chest, hemoptysis (rare)

Cardiovascular

Tachycardia

Gastrointestinal

Protuberant abdomen; abdominal distention; foul, fatty stools

Possible Diagnostic Findings

Abnormal ABGs and pulmonary function tests; abnormal sweat chloride test, chest x-ray, fecal fat analysis

Planning

The overall goals are that the patient with CF will have (1) adequate airway clearance, (2) absence of respiratory infection, (3) adequate nutritional support to maintain appropriate BMI, (4) ability to perform ADLs, (5) recognition and treatment of complications related to CF, and (6) active participation in planning and implementing an achievable treatment plan.

Nursing Implementation

Acute care for the patient with CF includes relief of bronchoconstriction, airway obstruction, and airflow limitation. Interventions include aggressive CPT, antibiotics, and O_2 therapy in severe disease. Good nutrition is important.

Aerobic exercise is effective in clearing the airways. Important needs to consider when planning an aerobic exercise program for the patient with CF are (1) meeting increased nutritional demands of exercise, (2) observing for dehydration, and (3) drinking large amounts of fluid and replacing salt losses.

As these persons continue into adulthood, you can help them in

gaining independence by helping them assume responsibility for their care and life goals. An important issue to discuss is sexuality. Delayed development of secondary sex characteristics and irregular menses are common. The issue of marrying and having children is difficult. Genetic counseling is an appropriate suggestion for the couple considering having children. Another concern is the uncertainty surrounding the shortened life span of the parent with CF.

Other crises and life transitions that must be dealt with in the young adult include persisting with employment goals, developing motivation to achieve, learning to cope with the treatment program, and adjusting to the need for dependence if health fails. Disclosing the CF diagnosis to friends, potential spouses, or employers may pose significant emotional, social, psychological, and financial challenges.

CF imposes a significant emotional and financial burden on the patient and family. In many situations, the cost of drugs, special equipment, and health care poses considerable financial hardship. The burden of living with a chronic disease at a young age can be emotionally overwhelming. There is a higher incidence of depression among persons with CF than their unaffected peers. Issues related to costs of health care, burden of self-care, career choices, fertility, and decreased life expectancy, may lead to depression. Community resources are available to help patients and caregivers. The Cystic Fibrosis Foundation can be a source of information and support.

Bronchiectasis

Etiology and Pathophysiology

Bronchiectasis is characterized by permanent, abnormal dilation of medium-sized bronchi. It is the result of inflammatory changes that destroy elastic and muscular structures supporting the bronchial wall. There is a continuing cycle of inflammation, airway damage, and remodeling, enhanced by the accumulation of neutrophils in the airways. Airways can become colonized with microorganisms (e.g., *Pseudomonas*), which causes the bronchial walls to weaken and pockets of infection to form (Fig. 28.17).

When the walls of the bronchial system are injured, the mucociliary mechanism is damaged, allowing bacteria and mucus to accumulate within the pockets. Bacteria attract neutrophils, which enhances inflammation and causes edema. Stasis of thickened mucus occurs due to impaired clearance of mucus by the cilia. This results in a reduced ability to clear mucus from the lungs and decreased expiratory airflow.

A variety of problems can result in bronchiectasis. CF is the main cause of bronchiectasis in children. In adults, the main cause is bacterial infections of the lungs. A wide variety of infectious agents initiate bronchiectasis. It can follow a single episode of severe pneumonia or infection that was either not treated or received delayed treatment. Other causes are obstruction of an airway with mucus plugs or generalized impairment of pulmonary defenses. Several systemic diseases, such as inflammatory bowel disease, rheumatoid arthritis, or immune disorders (e.g., acquired immunodeficiency syndrome [AIDS]) are associated with bronchiectasis.

Clinical Manifestations

The hallmark is persistent cough with consistent production of thick, tenacious, purulent sputum. In rare situations, some patients with severe disease and upper lobe involvement may have no sputum

production and little cough. Recurrent infections injure blood vessels. Large connections (anastomoses) may develop between blood vessels in the lungs, and hemoptysis may occur. In severe cases the bleed can be life-threatening. Other manifestations are pleuritic chest pain, dyspnea, wheezing, clubbing of digits, weight loss, and anemia. On auscultation, adventitious sounds can be heard (e.g., crackles, wheezes).

Diagnostic Studies

A person who presents with a chronic productive cough with copious purulent sputum (which may be blood streaked) should be suspected of having bronchiectasis. A CT scan is the gold standard for diagnosing bronchiectasis.[30]

Chest x-rays may show nonspecific abnormalities. Spirometry usually shows an obstructive pattern, including a decrease in FEV_1 and FEV_1/FVC. Sputum may give information about the presence of active infection and the severity of impairment. Patients often have *H. influenzae, S. aureus,* or *P. aeruginosa,* with the latter leading to more frequent exacerbations and rapid decline in lung function. A complete blood cell count and AAT level may be done.

Interprofessional and Nursing Management: Bronchiectasis

Bronchiectasis is hard to treat. Therapy is aimed at treating acute flare-ups and preventing a decline in lung function. Antibiotics are the mainstay of treatment. They are often given for a minimum of 14 days. Antibiotics may be given orally, IV, or inhaled (nebulizer). Choice of antibiotic primarily depends on culture results or most likely organism. The patient needs to understand the importance of taking prescribed drugs to obtain maximum effectiveness. Long-term antibiotic therapy is given to patients who have symptoms that recur a few days after stopping antibiotics. Concurrent bronchodilator therapy with SABAs, LABAs, or anticholinergics can prevent bronchospasm and stimulate mucus clearance. Some patients receive oral and inhaled corticosteroids.

One important goal is to promote drainage and removal of mucus. Various ACTs can be used to facilitate secretion removal. CPT with postural drainage is widely used. Direct hydration of the respiratory system may help with the expectoration of secretions. Hyperosmolar agents (e.g., hypertonic saline) given by nebulizer can liquefy secretions. At home, a steamy shower can be effective.

Teach the patient and caregiver manifestations to report to the HCP. These include increased sputum production, increasing dyspnea, fever, chills, and chest pain. Teach patients when to contact the HCP if hemoptysis occurs. Some patients may periodically expectorate a "spot" of blood that is usual for them and do not require urgent attention. However, if the patient expectorates a moderate to large amount of blood, they should contact the HCP at once. In the acute care setting, elevate the head of the bed, and place the patient in a side-lying position with the suspected bleeding side down. Closely monitor vital signs and respiratory status.

Maintaining hydration is important to liquefy secretions. Unless contraindicated, teach the patient to drink at least 2 to 3 L of fluid

daily. To achieve this, tell the patient to increase intake by 1 glass per day until they reach that goal. Have the patient use low-sodium fluids, thereby avoiding systemic fluid retention. Rest is important to prevent overexertion.

Good nutrition is important but may be difficult to maintain because the patient is often anorexic. Oral hygiene to cleanse the mouth and remove dried sputum crusts may improve the patient's appetite. Offer foods that are appealing, in smaller quantities and more often since they may increase the patient's desire to eat.

Surgical resection of parts of the lungs, which was common in the past, has largely been replaced by more effective supportive and antibiotic therapy. For select patients who are disabled in spite of maximal therapy, lung transplantation may be an option. Massive hemoptysis may require surgical resection.

Case Study

Chronic Obstructive Pulmonary Disease

© iStockphoto/Thinkstock.

Patient Profile

H.M. is a 68-yr-old white, married, retired female police officer. She has been in the hospital for 6 days with an acute COPD exacerbation and will be discharged tomorrow.

Subjective Data

- Before admission, had 4 days of exceptional shortness of breath

and increased volume of sputum, which turned greenish
- Increased Ventolin HFA use (at home) to 5 or 6 times a day for dyspnea
- Described having "jitters" and "racing heart"
- Had 3 or 4 COPD exacerbation in the past year that were managed at home
- 30 pack-year history of smoking; smokes half a pack per day now to "clear out lungs" in the morning
- Eats a regular diet but "gets full fast"
- Cannot climb 1 flight of stairs without stopping; walks down the flat driveway 10 yards without difficulty
- Awakens 2-3 times per night coughing and short of breath

Objective Data
Physical Examination

- Weight 129 lb, height 5 ft 8 in, BMI 20 kg/m^2
- Temperature 37.8° C (100° F), pulse 86 (regular), respiratory rate 28 (shallow, slightly labored), BP 136/76 mm Hg
- Increased anteroposterior diameter of chest (barrel shaped)
- Slight use of accessory (neck) muscles with breathing
- Distant breath sounds with occasional expiratory wheezes
- 1+ non-pitting edema (ankles and feet bilaterally)

Diagnostic Studies

- Last spirometry: decreased FEV_1 (48%) and FEV_1/FVC (62%)
- ABG on admission: pH 7.34, $PaCO_2$ 59 mm Hg, HCO_3^- 27 mEq/L, PaO_2 68 mm Hg
- ABG (24 hours after admission): pH 7.30, $PaCO_2$ 63 mm Hg,

HCO_3^- 29 mEq/L, PaO_2 64 mm Hg

- WBC: 14,000/μL on admission
- Chest x-ray: hyperinflation, flat diaphragm, no sign of pneumonia
- Sputum: negative (no organisms present)

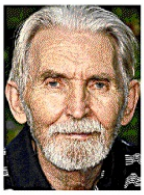
Interprofessional Care

- GOLD 3 (severe) COPD with acute exacerbation
- O_2 2 L via nasal catheter while in hospital
- Prednisone 40 mg/day PO for 5 days
- Levofloxacin 750 mg/day PO for 10 days
- Ipratropium HFA MDI 2 puffs 4 times a day
- At discharge: Advair Diskus 250/50 one inhalation q12hr

Discussion Questions

1. What classic manifestations indicate the patient had a COPD exacerbation?
2. What are some likely causes of her COPD?
3. What symptoms in H.M. indicate the overuse of inhalers? Which drug would cause the symptoms described?
4. ***Patient-Centered Care:*** What is one suggestion you could make to H.M. that could halt the progression of her lung disease?
5. Why would H.M. "feel full fast" when eating? What could you do to minimize this issue?
6. Interpret the ABGs. What is your impression of each ABG? In comparing both ABGs, do you see a pattern?
7. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
8. ***Evidence-Based Practice:*** H.M.'s son has been trying to convince his mother to quit smoking for many years without success. He

asks you to tell his mother the results of her spirometry to convince her it is time to quit. Will this approach work?



9. ***Priority Decision:*** What are nursing priorities for discharge planning and teaching?
10. Develop a conceptual care map for H.M.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Case Study

Managing Care of Multiple Patients

You are assigned to care for the following 4 patients on a medical-surgical unit. You are sharing 1 UAP with another RN.

Patients	
 © Fuse/Thinkstock.	F.T. is a 70-yr-old man with a history of COPD who was admitted yesterday with bilateral lower lobe pneumonia. He is receiving O_2 at 2 L/min via nasal cannula and IV antibiotics. His last pulse oximetry reading was 92%.
 © iStockphoto/Thinkstock.	M.R. is a 69-yr-old man who is 3 days postoperative following a total laryngectomy with tracheostomy for treatment of laryngeal cancer. He is receiving intermittent feeding via a percutaneous endoscopic gastrostomy (PEG) tube and last received pain medication 4 hours ago.
 © iStockphoto/Thinkstock.	J.H. is a 52-yr-old man admitted with right lower lobe pneumonia. A bronchoscopy with biopsy showed small cell lung cancer. He is intermittently confused and anxious with rapid, shallow respirations. He and his family are currently considering his treatment options.
 © iStockphoto/Thinkstock.	H.M. is a 68-yr-old woman admitted 6 days ago with a COPD exacerbation. She has not been able to ambulate much because of her shortness of breath. She is on oral prednisone and ipratropium. She is being discharged later today. She is to start Advair Diskus and chronic O_2 therapy at home after discharge.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide a rationale for your decision.
2. ***Collaboration:*** Which morning tasks can you delegate to the UAP *(select all that apply)*?
    a. Take vital signs and a pulse oximetry reading on F.T.
    b. Assess M.R.'s pain level and show him how to administer his feeding.

c. Assist H.M. with AM care and gather belongings in anticipation of discharge.
d. Provide coffee for J.H.'s family as they await a family meeting with the HCP.
e. Teach F.T. how to do pursed-lip breathing and titrate O_2 to obtain pulse oximetry >95%.

3. ***Priority Decision and Collaboration:*** While you are assessing J.H., the UAP tells you that H.M. is reporting chest pain and worsening shortness of breath. M.R. is requesting pain medication. What should you do *first*?
    a. Ask the UAP to get H.M.'s vital signs while you give M.R. pain medication.
    b. Ask the UAP to increase H.M.'s O_2 to 4 L/min while you assess M.R.'s pain.
    c. Ask the UAP to obtain a stat 12-lead ECG on H.M. while you perform a focused assessment.
    d. Ask the UAP to have another RN give M.R. his pain medication while you go directly to H.M.'s room.

Case Study Progression

After assessing H.M., you notify her HCP. A stat 12-lead ECG is done, and a blood sample is drawn to check cardiac enzymes. H.M.'s chest pain is not relieved by sublingual nitroglycerin. You then give 4 mg IV morphine. H.M. states that her pain is "a little better" but continues to report dyspnea. The 12-lead ECG and cardiac enzyme results are all within normal limits.

4. Because of H.M.'s reduced mobility, you recognize that she is at risk for developing _____ and anticipate the HCP will order which tests to determine the cause of her current symptoms?
    a. BNP and echocardiogram
    b. D-dimer and spiral CT scan
    c. CBC and abdominal flat-plate x-ray

d. Serum electrolytes and renal ultrasound

5. While the charge nurse goes with H.M. to the radiology department, you turn your attention back to your remaining 3 patients. Before giving M.R.'s 8 AM enteral feeding, you find his PEG tube clogged. Which action should you take *next*?
    a. Flush the tube with warm water, using a back-and-forth motion.
    b. Obtain an x-ray to confirm the tube is still placed in the stomach.
    c. Notify the HCP so that surgery to insert new tube can be scheduled.
    d. Instill 30 mL of cranberry juice into the tube and recheck in 1 hour.
6. When preparing F.T.'s AM medications, you note that he is scheduled to receive the following antibiotics at 8 AM: levofloxacin 750 mg in 150 mL normal saline over 90 minutes (once daily) and cefazolin 1 gram in 100 mL normal saline over 30 minutes (every 8 hrs). He has only one IV site. Which action is *most* appropriate?
    a. Obtain a second peripheral IV site.
    b. Call the HCP to change the administration times.
    c. Check with pharmacy to see if they can be mixed together in the same IV bag.
    d. Administer the cefazolin first because it takes the least amount of time to infuse.
7. ***Management Decision:*** J.H.'s son calls you on the telephone to ask about his father's current condition and long-term prognosis. Which initial response would be *most* appropriate?
    a. Ask the person calling what the code word is to identify himself or herself as family.
    b. Tell the caller that you are not allowed to discuss any information over the telephone.
    c. Empathize with the son's need to know his father's long-term prognosis.
    d. Ask J.H.'s son what the HCP has told him to clarify

his understanding of the situation.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient is concerned that he may have asthma. Of the symptoms that he describes to the nurse, which ones suggest asthma or risk factors for asthma? *(select all that apply)*
   a. Allergic rhinitis
   b. Prolonged inhalation
   c. Cough, especially at night
   d. Gastric reflux or heartburn
   e. History of chronic sinusitis
2. Which findings indicate that a patient is developing status asthmaticus? *(select all that apply)*
   a. PEFR <300 L/min
   b. Positive sputum culture
   c. Unable to speak in complete sentences
   d. Lack of response to conventional treatment
   e. Chest x-ray shows hyperinflated lungs and a flattened diaphragm
3. Which statement indicates the patient with asthma requires further teaching about self-care?
   a. "I use my corticosteroid inhaler when I feel short of breath."
   b. "I get a flu shot every year and see my HCP if I have an upper respiratory tract infection."

c. “I use my inhaler before I visit my aunt who has a cat, but I only visit for a few minutes because of my allergies.”

d. “I walk 30 minutes every day but sometimes I have to use my bronchodilator inhaler before walking to prevent me from getting short of breath.”

4. Which medications would be *most* appropriate to administer to a patient experiencing an acute asthma attack? *(select all that apply)*

a. montelukast (Singulair)

b. inhaled hypertonic saline

c. albuterol (Proventil HFA)

d. ipratropium (Atrovent HFA)

e. salmeterol (Serevent Diskus)

5. The plan of care for the patient with chronic obstructive pulmonary disease (COPD) should include *(select all that apply)*

a. exercise such as walking.

b. high flow rate of O_2 administration.

c. low-dose chronic oral corticosteroid therapy.

d. use of peak flow meter to monitor the progression of COPD.

e. breathing exercises, such as pursed-lip breathing that focus on exhalation.

6. The major advantage of a Venturi mask is that it can

a. deliver up to 80% O_2.

b. provide continuous 100% humidity.

c. deliver a precise concentration of O_2.

d. be used while a patient eats and sleeps.

7. Which guideline should the nurse include when teaching a patient how to use a metered-dose inhaler (MDI)?

a. After activating the MDI, breathe in as quickly as you can.

b. Estimate the amount of remaining medicine in the MDI by floating the canister in water.

c. Disassemble the plastic canister from the inhaler and rinse both pieces under running water every week.

d. To determine how long the canister will last, divide the total number of puffs in the canister by the puffs needed per day.

8. Which treatments would the nurse expect to implement in the management plan of a patient with cystic fibrosis? *(select all that apply)*

a. Sperm banking

b. IV corticosteroids on a chronic basis

c. Airway clearance techniques (e.g., Acapella)

d. GoLYTELY given as needed for severe constipation

e. Inhaled tobramycin to combat *Pseudomonas* infection

9. A patient who has bronchiectasis asks the nurse, "What conditions would warrant a call to the clinic?"

a. Blood clots in the sputum

b. Sticky sputum on a hot day

c. Increased shortness of breath after eating a large meal

d. Production of large amounts of sputum on a daily basis

1. a, c, d, e, 2. a, c, d, 3. a, 4. c, d, 5. a, e, 6. c, 7. d, 8. a, c, d, e, 9. a

Problems of Oxygenation: Transport

OUTLINE

29. Assessment: Hematologic System

30. Hematologic Problems

29

Assessment

Hematologic System

Sandra Irene Rome

LEARNING OUTCOMES

1. Describe the structures and functions of the hematologic system.
2. Distinguish among the different types of blood cells and their functions.
3. Explain the process of hemostasis.
4. Link the age-related changes in the hematologic system to differences in findings of hematologic studies.
5. Obtain significant subjective and objective assessment data related to the hematologic system from a patient.
6. Perform a physical assessment of the hematologic system using the appropriate techniques.
7. Distinguish normal from common abnormal findings of a physical assessment of the hematologic system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the hematologic system.

Conceptual Focus

Clotting
Functional Ability
Gas Exchange
Infection
Pain
Perfusion

Hematology is the study of blood and blood-forming tissues. This

includes the bone marrow, blood, spleen, and lymph system. You need a basic knowledge of hematology to be able to evaluate several important concepts in the clinical setting. A functioning hematologic system is needed to support the patient's ability to transport oxygen (O_2) and carbon dioxide (CO_2), maintain intravascular volume, coagulate blood, and combat infections.

Structures and Functions of Hematologic System

Bone Marrow

Blood cell production (**hematopoiesis**) occurs within the bone marrow. *Bone marrow* is the soft material that fills the central core of bones. There are 2 types of bone marrow, yellow (adipose) and red (hematopoietic). Red marrow actively makes blood cells. In adults, red marrow is found primarily in the flat and irregular bones, such as the ends of long bones, pelvic bones, vertebrae, sacrum, sternum, ribs, flat cranial bones, and scapulae.

All 3 types of blood cells (red blood cells [RBCs], white blood cells [WBCs], and platelets) develop from a common hematopoietic stem cell in the bone marrow. The hematopoietic *stem cell* is best described as an immature blood cell that can self-renew and differentiate into hematopoietic precursor cells. Several types of blood cells form as the cells mature and differentiate (Fig. 29.1).

The bone marrow responds by a negative feedback system to the need for specific blood cells by increasing that cell's production. Various factors or cytokines (e.g., erythropoietin, granulocyte colony-stimulating factor [G-CSF], stem cell factor, thrombopoietin) stimulate the bone marrow. This results in differentiation of the stem cells into one of the committed hematopoietic cells (e.g., RBC). For example, when tissue hypoxia occurs, the kidney secretes erythropoietin. It circulates to the bone marrow and causes proerythroblasts to differentiate in the bone marrow.[1]

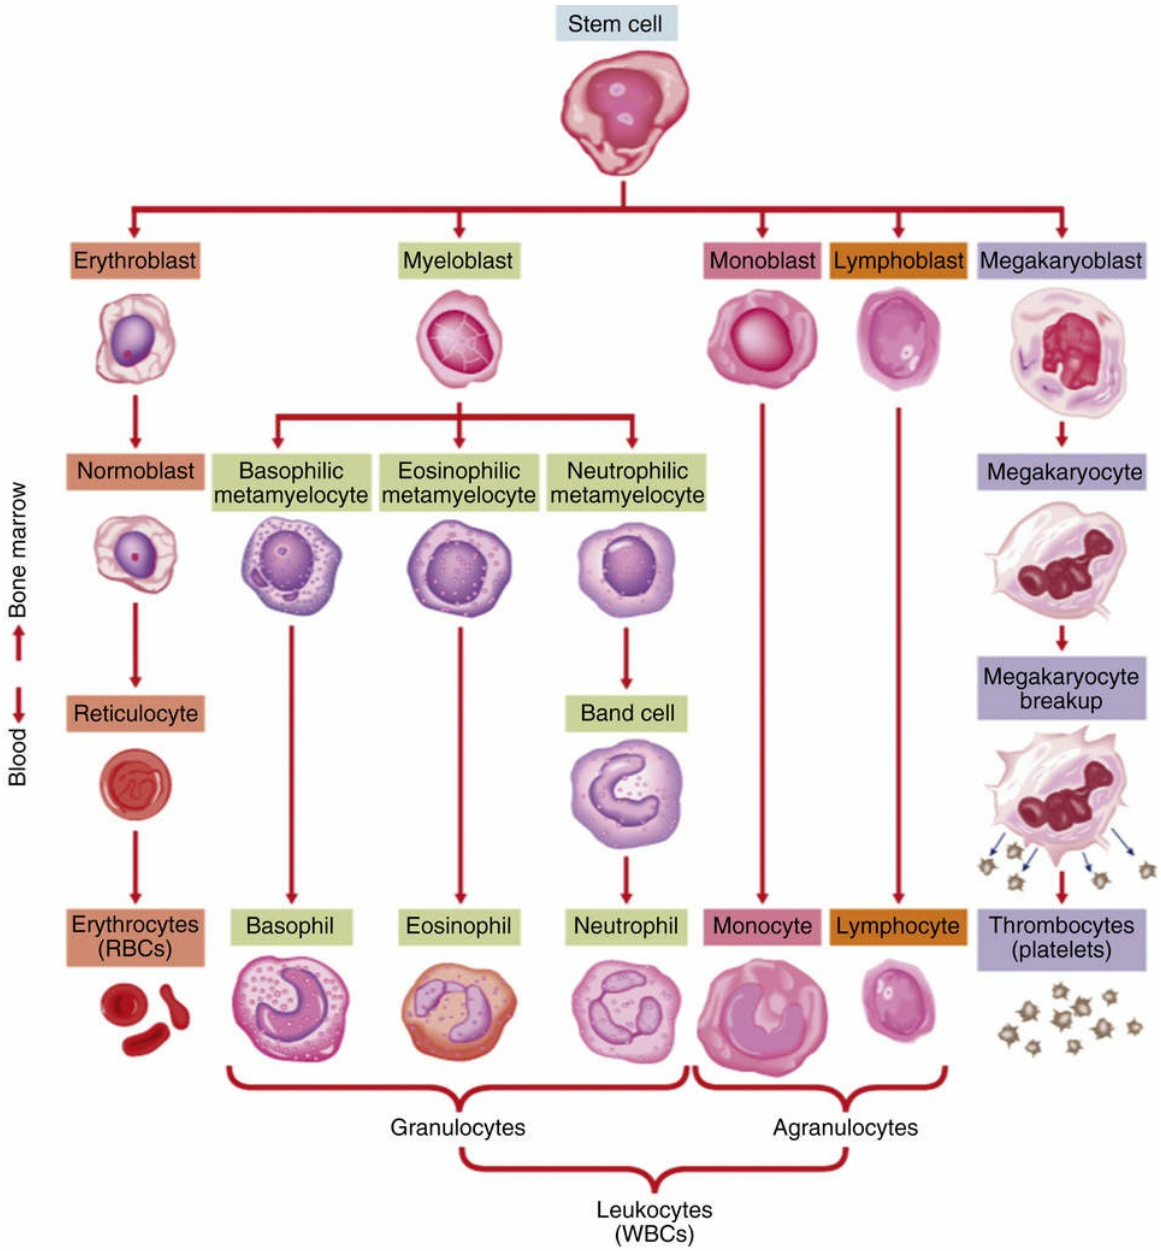

FIG. 29.1 Development of blood cells.

Blood

Blood is a type of connective tissue that has 3 major functions: transportation, regulation, and protection (Table 29.1). Blood has 2 major components: plasma and blood cells. In an adult weighing between 150 and 180 lb, the volume of blood is usually between 4.7 and 5.5 L (5 to 6 quarts).

Plasma

About 55% of blood is plasma[1] (Fig. 29.2). Plasma is composed mainly of water. It also contains proteins, electrolytes, gases, nutrients (e.g., glucose, amino acids, lipids), and waste. The term *serum* refers to plasma minus its clotting factors. Plasma proteins include albumin, globulin, and clotting factors (mostly fibrinogen). Albumin is a protein that helps maintain oncotic pressure in the blood.[1] The liver makes most plasma proteins. The exception is antibodies (immunoglobulins). They are made by plasma cells.

Blood Cells

About 45% of the blood (Fig. 29.2) is composed of formed elements, or blood cells. The 3 types of blood cells are *erythrocytes* (RBCs), *leukocytes* (WBCs), and *thrombocytes* (platelets). The primary function of RBCs is O_2 transportation. WBCs help protect the body from infection. Platelets promote blood coagulation.

TABLE 29.1 Functions of Blood

Function	Examples
Protection	• Maintaining homeostasis of blood coagulation • Combating invasion of pathogens and other foreign substances
Regulation	• Fluid and electrolyte balance • Acid-base balance • Body temperature • Maintaining intravascular oncotic pressure
Transportation	• O_2 from lungs to cells • Nutrients from GI tract to cells • Hormones from endocrine glands to tissues and cells • Metabolic waste products (e.g., CO_2, NH_3, urea) from cells to lungs, liver, and kidneys

Erythrocytes

The primary functions of RBCs include transport of gases (both O_2 and CO_2) and assistance in maintaining acid-base balance. RBCs are flexible cells with a unique biconcave shape. This flexibility allows the

cell to change its shape so that it can easily pass through tiny capillaries. The cell membrane is thin to facilitate diffusion of gases.

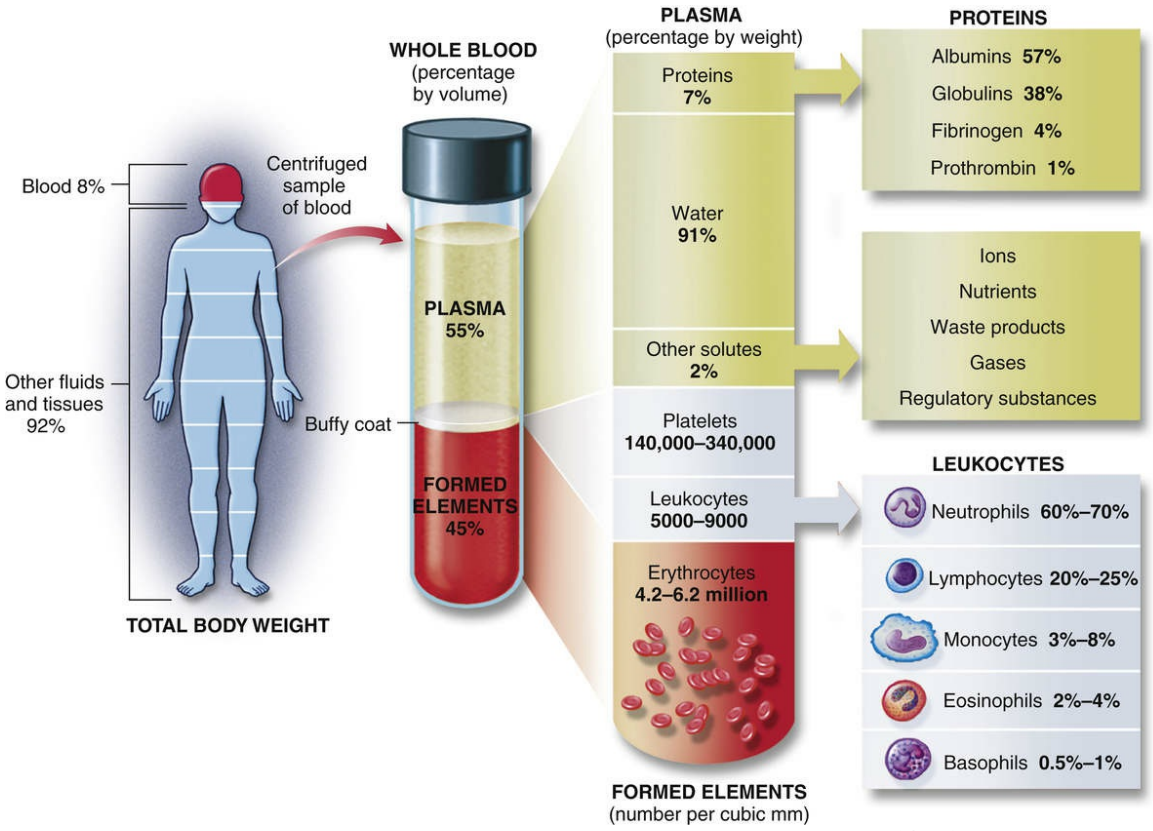

FIG. 29.2 Blood components in a healthy adult. Normally, 45% of the blood is composed of blood cells and 55% is composed of plasma. From Patton KT, Thibodeau GA: *Structure & function of the body,* ed 15, St Louis, 2016, Mosby.

RBCs are primarily composed of a large molecule called *hemoglobin*. Hemoglobin is a complex protein-iron compound composed of heme (an iron compound) and globin (a simple protein). It binds with O_2 and CO_2. As RBCs circulate through the capillaries surrounding alveoli within the lung, O_2 attaches to iron on the hemoglobin. We refer to this O_2-bound hemoglobin as *oxyhemoglobin.* It gives arterial blood its bright red appearance. As RBCs flow to body tissues, O_2 detaches from the hemoglobin and diffuses from the capillary into tissue cells. CO_2 diffuses from tissue cells into the capillary, attaches to

the globin part of hemoglobin, and is transported to the lungs for removal. Hemoglobin also acts as a buffer and plays a role in maintaining acid-base balance. This buffering function is described in Chapter 16.

Erythropoiesis (the process of RBC production) is regulated by cellular O_2 requirements and general metabolic activity. Erythropoiesis is stimulated by hypoxia and controlled by *erythropoietin,* a glycoprotein growth factor made and released primarily by the kidney. Erythropoietin stimulates the bone marrow to increase RBC production. We make about 2.5 million RBCs per second. The normal life span of RBCs is about 120 days. The availability of nutrients influences erythropoiesis. Many essential nutrients are needed for erythropoiesis. These include protein, iron, folate (folic acid), cobalamin (vitamin B_{12}), riboflavin (vitamin B_2), pyridoxine (vitamin B_6), pantothenic acid, niacin, ascorbic acid (vitamin C), copper, and vitamin E. Endocrine hormones, such as thyroxine, corticosteroids, and testosterone, also affect RBC production. For example, hypothyroidism is often associated with anemia.[1]

Several distinct cell types evolve during RBC maturation (Fig. 29.1). The **reticulocyte** is an immature RBC. Reticulocytes can develop into mature RBCs within 48 hours of release into the circulation. A mature RBC lacks a nucleus and cannot undergo mitotic division. Assessing the number of reticulocytes is a useful way to evaluate the rate and adequacy of RBC production.[1]

Hemolysis (destruction of RBCs) by monocytes and macrophages removes abnormal, defective, damaged, and old RBCs from circulation. Hemolysis normally occurs in the bone marrow, liver, and spleen. Because one of the components of RBCs is bilirubin, hemolysis of these cells results in increased bilirubin the body must process. When hemolysis occurs by normal mechanisms, the liver conjugates and excretes all the bilirubin in bile.

Leukocytes

Leukocytes (WBCs) appear white when separated from blood. Like the RBCs, WBCs originate from stem cells within the bone marrow (Fig. 29.1). They may eventually reside in the thymus or secondary lymphoid tissues, such as the spleen, lymph nodes, and Peyer patches. There are several types of WBCs. Each has a different function. WBCs that have granules in the cytoplasm are *granulocytes* (also known as *polymorphonuclear leukocytes*). Granulocytes include neutrophils, basophils, and eosinophils.

WBCs that do not have granules in the cytoplasm are *agranulocytes.* They include lymphocytes, monocytes, and natural killer cells. Lymphocytes and monocytes are *mononuclear cells* because they have only one discrete nucleus. WBCs have a widely variable life span. Granulocytes may live for only hours. Some T lymphocytes may live for years.

Granulocytes

The primary function of the granulocytes is *phagocytosis,* a process by which WBCs engulf any unwanted organism and then digest and kill it. They can migrate through vessel walls and to the sites where they are needed. The *neutrophil* is the most common type of granulocyte, making up 60% to 70% of all WBCs. Neutrophils are the primary phagocytic cells involved in acute inflammatory responses. Once they engulf the pathogen, they die in 1 to 2 days.[1] Hematopoietic growth factors (e.g., G-CSF, granulocyte-macrophage colony-stimulating factor [GM-CSF]) stimulate neutrophil production and maturation (see Table 13.3).

We call a mature neutrophil a *segmented neutrophil,* or "seg" or "polysegmented neutrophil," because the nucleus is segmented into 2 to 5 lobes connected by strands. An immature neutrophil is a *band* (for the band appearance of the nucleus). Although band cells are sometimes found in the peripheral circulation of normal people and are capable of phagocytosis, the mature neutrophil is much more effective. An increase in neutrophils in the blood is a common indicator of infection and tissue injury.

Eosinophils make up only 2% to 4% of all WBCs. They have a similar

but reduced ability for phagocytosis. One of their primary functions is to engulf antigen-antibody complexes formed during an allergic response. High eosinophil levels occur with some cancers, such as Hodgkin's lymphoma, in parasitic infections, and in various skin diseases and connective tissue disorders.[1]

Basophils make up less than 2% of all WBCs. They have cytoplasmic granules that contain chemical mediators, such as heparin and histamine. A basophil responds to stimulation by an antigen or by tissue injury by releasing substances from the granules. This is part of the response seen in allergic and inflammatory reactions. *Mast cells* are like basophils, but they reside in connective tissues. They play a key role in inflammation, permeability of blood vessels, and smooth muscle contraction.

Lymphocytes

Lymphocytes make up 20% to 25% of the WBCs in the blood.[1] They form the basis of the cellular and humoral immune responses. Two lymphocyte subtypes are B cells and T cells. T-cell precursors originate in the bone marrow. They migrate to the thymus gland for further differentiation into T cells. *Natural killer (NK) cells* are lymphocytes that kill virus-infected cells and activate T cells and phagocytes. They do not need prior exposure to antigens. Dendritic cells are the primary phagocytic cells in the peripheral organs and skin. Most lymphocytes briefly circulate in the blood and reside in lymphoid and other tissues. Details of lymphocyte function are discussed in Chapter 13.

Monocytes

Monocytes, the other type of agranular WBC, make up about 3% to 8% of the total WBCs.[1] Monocytes are potent phagocytic cells that ingest small or large masses of matter, such as bacteria, dead cells, tissue debris, and old or defective RBCs. These cells are present in the blood for only a brief time before they migrate into the tissues and become macrophages. In addition to macrophages that have

differentiated from monocytes, tissues also have resident macrophages. These resident macrophages have special names (e.g., Kupffer cells in the liver, osteoclasts in the bone, alveolar macrophages in the lung). They protect the body from pathogens at these entry points and are more phagocytic than monocytes. Macrophages interact with lymphocytes to facilitate humoral and cellular immune responses.

Thrombocytes

The primary function of thrombocytes, or *platelets,* is to start the clotting process by producing an initial platelet plug at a site of injury. Platelets circulate suspended in plasma in an unactivated state. They must be available in enough numbers and be structurally and metabolically sound for blood clotting to occur. Platelet activation starts at the site of any capillary damage. Increasing numbers of platelets accumulate to form an initial platelet plug that is stabilized with clotting factors. About one third of the platelets in the body are stored in the spleen.

Platelets originate from stem cells within the bone marrow (Fig. 29.1). The stem cell undergoes differentiation by transforming into a *megakaryocyte,* which fragments into platelets. Platelet production is partly regulated by *thrombopoietin* (TPO), a growth factor that acts on bone marrow to stimulate platelet production. TPO is primarily made in the liver. During inflammation, interleukin 6 (IL-6) causes us to make more TPO, which increases production of platelets and potential thrombosis. Typically, platelets have a life span of only 8 to 11 days.

Normal Iron Metabolism

Our iron requirement is 25 mg daily. We get iron from food and dietary supplements. Our body absorbs only 1 mg of every 10 to 20 mg of iron we eat. The rest comes from the continued recycling of iron from RBCs.[1] As part of normal iron metabolism, iron is recycled after macrophages in the liver and spleen phagocytize, or ingest and destroy, old and damaged RBCs.

After dietary iron is absorbed in the duodenum and proximal jejunum, it is transported through the plasma by transferrin (Fig. 29.3). Transferrin is made in the liver. How much iron is bound to transferrin is a reliable indicator of the iron supply for developing RBCs.

About two thirds of total body iron is bound to heme in RBCs (hemoglobin) and muscle cells (myoglobin). The other one third of iron is stored as ferritin and hemosiderin (degraded form of ferritin) in the bone marrow, spleen, liver, and macrophages (Fig. 29.3). When we do not replace stored iron, hemoglobin production is reduced. Normally there is very little iron loss except from blood loss. We lose about 3% daily in urine, sweat, bile, and epithelial cells in the gastrointestinal (GI) tract.

Normal Clotting Mechanisms

Hemostasis describes the arrest of bleeding. This process is important in minimizing blood loss when various body structures are injured. The sequence of events includes (1) vascular injury and subendothelial exposure, (2) adhesion, (3) activation, (4) aggregation, (5) platelet plug formation, and (6) clot retraction and dissolution.

Vascular Injury and Subendothelial Exposure

When a blood vessel is injured, an immediate local vasoconstrictive response occurs. Vasoconstriction reduces the leakage of blood from the vessel by restricting the vessel size and pressing the endothelial surfaces together. The latter reaction enhances vessel wall stickiness and keeps the vessel closed after vasoconstriction subsides. Vascular spasm may last for 20 to 30 minutes. This allows time for the body to activate the platelet response and plasma clotting factors. The platelet response and plasma clotting factors are triggered by endothelial injury and the release of substances such as thromboxane A_2 (TXA_2). Platelets begin to fill endothelial gaps.[1]

Adhesion

The loss of endothelial cells exposes adhesive glycoproteins, such as collagen and von Willebrand factor (vWF), to which more platelets adhere. The stickiness is termed *adhesiveness.* The formation of clumps is termed *aggregation* or *agglutination.*

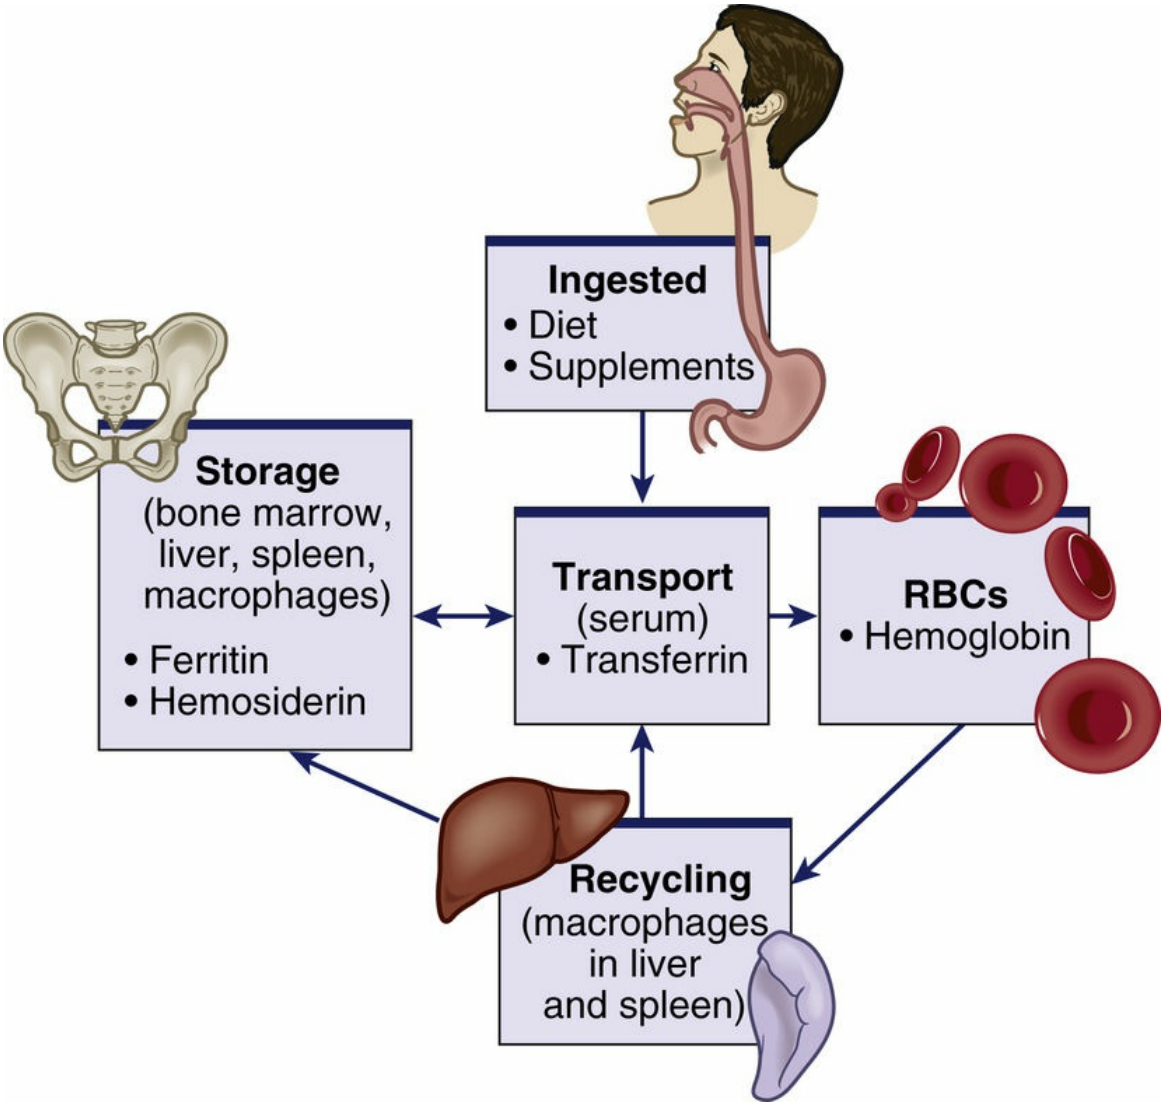

FIG. 29.3 Normal iron metabolism. Iron is ingested in the diet or from supplements. Macrophages break down ingested RBCs. Iron is returned to blood bound to transferrin or stored as ferritin or hemosiderin.

Activation

The interaction described previously causes the platelets to undergo an activation process. This leads to changes in platelet shape. The platelets then can bind adhesive proteins, including fibrinogen and vWF. Release of various platelet granules (including adenosine phosphate [ADP]) recruits and activates other platelets, clotting factors, and growth factors. As Fig. 29.4 shows, platelet lipoproteins stimulate necessary conversions in the clotting process.

Aggregation

Platelet aggregation is stimulated by TXA_2 and ADP, which induce fibrinogen receptors on the platelet. The formation of a visible fibrin clot on the platelet plug is the conclusion of a complex series of reactions involving different clotting (coagulation) factors. We label plasma clotting factors with both names and Roman numerals (Table 29.2).

Plasma proteins circulate in inactive forms until stimulated to start clotting through 1 of 2 pathways, intrinsic or extrinsic (Fig. 29.4). The *intrinsic pathway* is activated by collagen exposure from endothelial injury when the blood vessel is damaged. The *extrinsic pathway* is activated when tissue factor or tissue thromboplastin is released extravascularly from injured tissues.

Regardless of how we begin to clot, coagulation ultimately follows the same final common pathway of the clotting cascade. Thrombin, in the common pathway, is the most powerful enzyme in the coagulation process (Fig. 29.4). It converts fibrinogen to fibrin, which is an essential part of a blood clot.

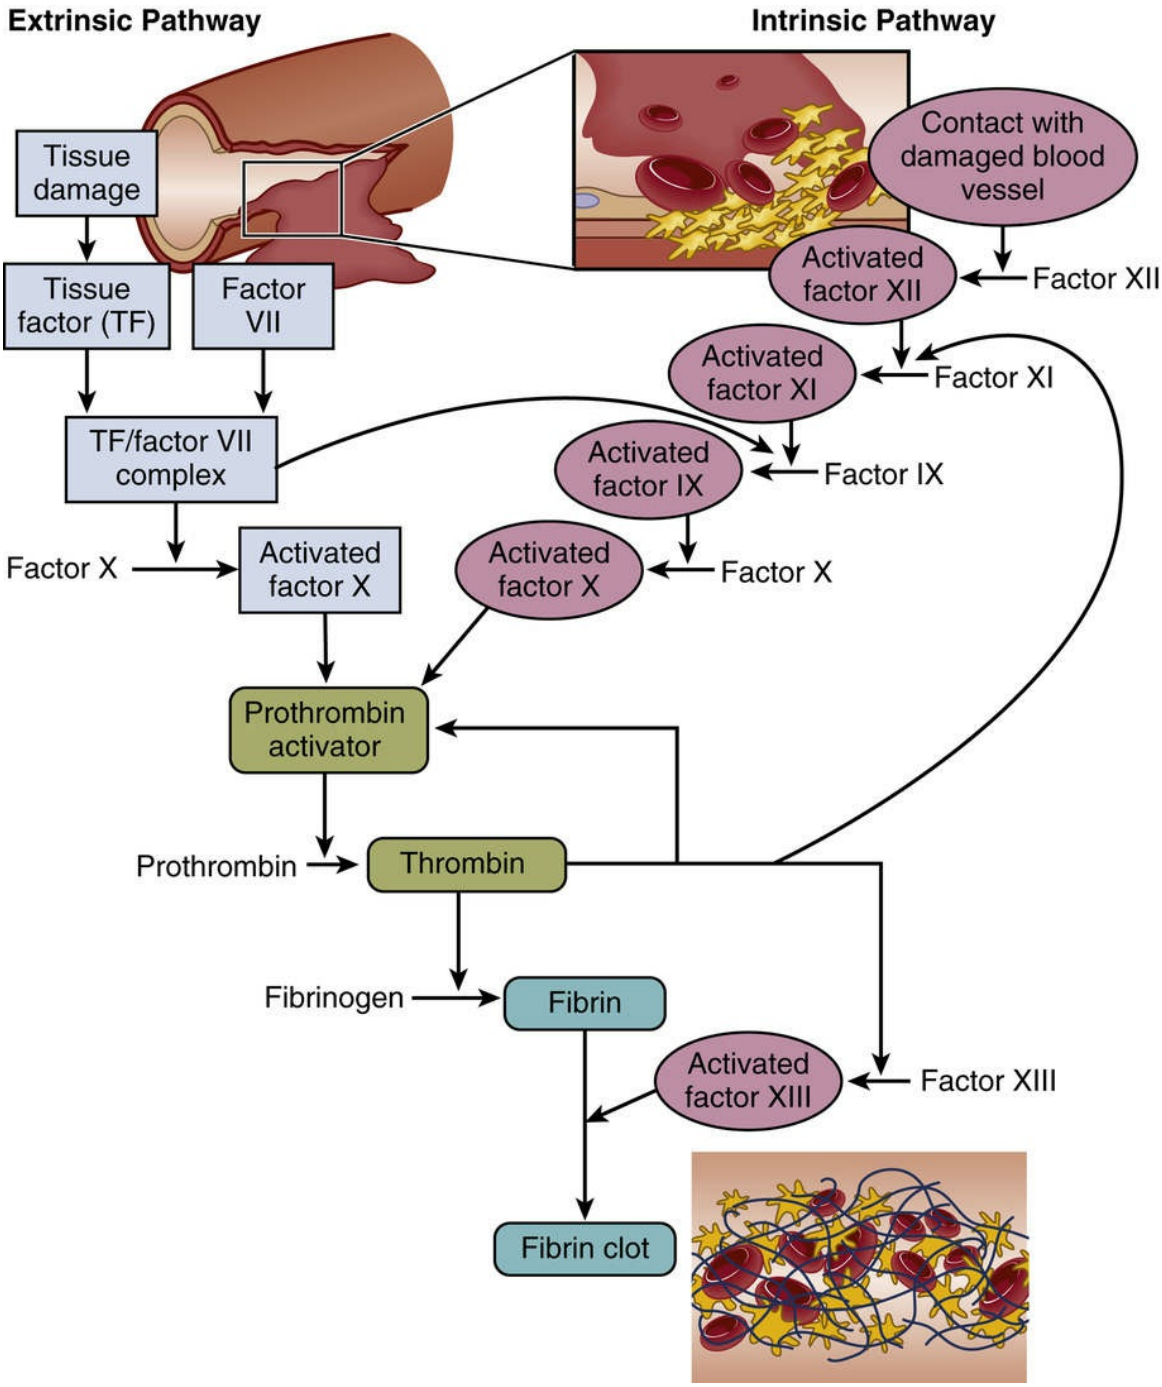

FIG. 29.4 Coagulation mechanism showing steps in the intrinsic pathway and extrinsic pathway as they would occur in the test tube.

TABLE 29.2 Coagulation Factors

Coagulation Factor	Action
I Fibrinogen	Source of fibrin to form a clot. Made in liver
II Prothrombin	Converted to thrombin, which then activates fibrinogen into fibrin as well as factors V, VII, VIII, XI, XIII, protein C, platelets
III Tissue factor, tissue thromboplastin	Released from damaged endothelial cells and activates the extrinsic pathway by reacting with factor VII
IV Calcium	Required cofactor at several points in the coagulation cascade
V Proaccelerin (labile) factor	Binds with factor X to activate prothrombin
VI	Not in use (obsolete)
VII Stable factor, proconvertin	Forms a complex with factor III and activates factors IX and X
VIII Antihemophilic factor	Works with factor IX and calcium to activate factor X
IX Christmas factor	Together with factor VIII, activates factor X
X Stuart factor	Activates conversion of factor II (prothrombin) to thrombin
XI Plasma thromboplastin antecedent	Activates factor IX when calcium is present
XII Hageman factor	Activates factor XI, which starts the intrinsic pathway
XIII Fibrin-stabilizing factor	Cross-links fibrin strands and stabilizes fibrin clot

Platelet Plug Formation

The final blood clot is a meshwork of protein strands that stabilizes the platelet plug and traps other cells, such as RBCs, phagocytes, and microorganisms.

Clot Retraction and Dissolution

Just as some blood elements foster coagulation *(procoagulants),* others interfere with clotting *(anticoagulants).* This counter mechanism to blood clotting keeps blood in its fluid state.

Antithrombin activity, vessel and platelet activity, and fibrinolysis contribute to anticoagulation. As the name implies, antithrombins keep blood in a fluid state by antagonizing thrombin, a powerful coagulant. Endogenous heparin, antithrombin III, protein C, and

protein S are examples of anticoagulants.

The second means of keeping blood in its fluid form is **fibrinolysis**, a process resulting in the dissolution of the fibrin clot. The fibrinolytic system starts when plasminogen is activated by substances such as tissue plasminogen activator (t-PA) and urokinase-like plasminogen activator (u-PA) to plasmin (Fig. 29.5). Thrombin is 1 of the substances that can activate the conversion of plasminogen to plasmin, thereby promoting fibrinolysis. The plasmin attacks either fibrin or fibrinogen by splitting the molecules into smaller elements known as *fibrin split products* (FSPs) or *fibrin degradation products* (FDPs). You can find more about FSPs in Table 29.8 and in the discussion of disseminated intravascular coagulation (DIC) in Chapter 30.

Excessive fibrinolysis predisposes the patient to bleeding. In this situation, bleeding results from the destruction of fibrin in platelet plugs or from the anticoagulation effects of increased FSPs. Increased FSPs lead to impaired platelet aggregation, reduced prothrombin, and an inability to stabilize fibrin.

Spleen

The spleen is the largest lymphoid organ. It is found in the upper left quadrant of the abdomen. The spleen has 4 major functions: hematopoietic, filtration, immunologic, and storage. The *hematopoietic function* is shown by the spleen's ability to make RBCs during fetal development. The *filtration function* is shown by the spleen's ability to remove old and defective RBCs from the circulation by the mononuclear phagocyte system. Filtration also involves the reuse of iron. The spleen can catabolize hemoglobin released by hemolysis and return the iron part of the hemoglobin to the bone marrow for reuse. The spleen plays a vital role in filtering circulating bacteria, especially encapsulated organisms such as gram-positive cocci. The spleen's rich supply of lymphocytes, monocytes, and stored immunoglobulins plays a role in *immunologic function*. The *storage function* is reflected in its role as a storage site for RBCs and platelets. The spleen can store more than 300 mL of blood. We store about one third of platelets in the spleen.

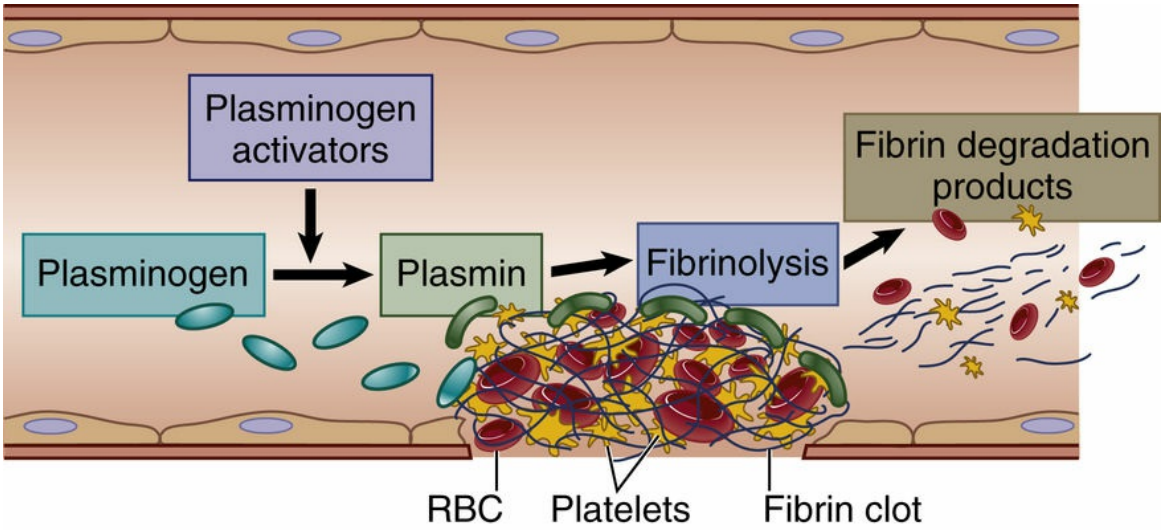

FIG. 29.5 Fibrinolytic system.

Lymph System

The lymph system, consisting of lymph fluid, lymphatic capillaries, ducts, and lymph nodes, carries fluid from the interstitial spaces to the blood. It is through the lymph that proteins and fat from the GI tract and certain hormones can return to the circulatory system. The lymph system also returns excess interstitial fluid to the blood.

Lymph fluid is pale yellow interstitial fluid that has diffused through lymphatic capillary walls. The lymphatic vessels collect interstitial fluid from the tissues and transport it as lymph through vessels and eventually to the thoracic duct, which drains into the superior vena cava. The formation of lymph fluid increases when interstitial fluid increases, thereby forcing more fluid into the lymph system. When too much interstitial fluid develops or when something interferes with the reabsorption of lymph, *lymphedema* develops. Lymphedema may occur as a complication of mastectomy or lumpectomy with dissection of axillary nodes. In this situation, lymphedema is caused by the obstruction of lymph flow from the removal of lymph nodes.

The lymphatic capillaries are thin-walled vessels that have an irregular diameter. They are larger than blood capillaries and do not have valves.

The *lymph nodes* are also part of the lymphatic system. They are round, oval, or bean shaped. Structurally, the nodes are small clumps of lymphatic tissue. They are found in groups along lymph vessels at various sites. There are more than 200 lymph nodes throughout the body, with the greatest number being in the abdomen surrounding the GI tract. They vary in size according to their location. Lymph nodes are situated both superficially and deep. We can palpate superficial nodes. Evaluating deep nodes requires radiologic examination.[2] A primary function of lymph nodes is filtration of pathogens and foreign particles that are carried by lymph to the nodes.

Liver

The liver has metabolic, secretory, vascular, and storage functions. It makes all the procoagulants that are essential to hemostasis and blood coagulation and secretes bilirubin and bile. It stores iron that exceeds tissue needs, which can occur with frequent blood transfusions or diseases that cause iron overload. *Hepcidin,* made by the liver, is a key regulator of iron balance. Iron overload or inflammation stimulates hepcidin synthesis. Hepcidin inhibits the release of stored iron from enterocytes (in the intestines) and macrophages. So, when iron is deficient, hepatocytes make less hepcidin. This results in the release of stored iron and an increase in dietary absorption. Other functions of the liver are described in Chapters 38 and 43.

Gerontologic Considerations: Effects of Aging on Hematologic System

Aging leads to a decrease in bone marrow mass and cellularity and an increase in bone marrow fat.[3] 90% of the marrow space is occupied by hematopoietic tissue at birth. This is reduced to 50% at age 30 and 30% at age 70.[4] Although the older adult can still maintain adequate blood cell levels, the reduced reserve capacity leaves the older adult more vulnerable to possible problems with clotting, transporting O_2, and

fighting infection, especially during periods of increased demand. This contributes to an older adult having a decreased ability to compensate for an acute or chronic illness.

Hemoglobin levels may begin to decrease in both men and women after middle age, with low-normal levels seen in most older people. Total serum iron, total iron-binding capacity, and intestinal iron absorption are all decreased in older adults. The RBC plasma membranes are more fragile. This may account for a slight increase in mean corpuscular volume (MCV) and a slight decrease in mean corpuscular hemoglobin concentration (MCHC) of RBCs in some older adults. While iron deficiency may cause low hemoglobin levels, other factors, such as GI bleeding, renal disease, testosterone deficiency, or bone marrow dysfunction, should be ruled out.[5] In 30% to 40% of cases, there is no specific cause of anemia. This is called "unexplained anemia in the elderly."[6] Cytokine levels may be high, but the amount of inflammation is not enough to increase hepcidin levels.[4] Healthy older patients are not able to make reticulocytes in response to hemorrhage or hypoxemia as well as younger adults. This is likely due to a blunted response to erythropoietin.[4]

Aging generally does not affect the total WBC count and differential. There may be a slight increase in neutrophils and a decrease in lymphocytes. However, the function of lymphocytes decreases, blunting the response to infection.[1] During an infection, the older adult may have only a minimal elevation in the total WBC count. This suggests decreased bone marrow reserve of granulocytes in older adults and reflects the possible impaired stimulation of hematopoiesis. Older adults are at higher risk for developing neutropenia from treatments.[6]

The number of platelets is unaffected by the aging process, but functionally they may have increased adhesiveness. Clotting factors increase with age. Thus aging is associated with an increased chance of clotting problems, such as venous thromboembolism.[3] Changes in vascular integrity related to aging can manifest as easy bruising.

Table 29.3 outlines the effects of aging on hematologic studies. Immune changes related to aging are detailed in Chapter 13.

TABLE 29.3 Gerontologic Assessment DifferencesEffects of Aging on Hematologic Studies

Study	Changes
CBC Studies	
Hemoglobin (Hgb)	Usually normal in women; possibly slight ↓ in men
Mean corpuscular hemoglobin concentration (MCHC)	May be slightly ↓
Mean corpuscular volume (MCV)	May be slightly ↑
Platelets	Unchanged; possible ↑ in adhesiveness
White blood cell (WBC) count	Decreased response to infection
Clotting Studies	
D-dimers	↑
Erythrocyte sedimentation rate (ESR)	↑ Significantly
Factors V, VII, IX	May be ↑
Fibrinogen	May be ↑
Partial thromboplastin time	May be ↓
Iron Studies	
Erythropoietin	May be ↑
Ferritin	↑
Serum iron	↓
Total iron-binding capacity	↓

Assessment of Hematologic System

Much of the evaluation of the hematologic system is based on a thorough health history and presenting signs and symptoms.

Subjective Data

Important Health Information

Past Health History

Determine if the patient has had prior hematologic problems. Ask about problems with anemia, bleeding problems, and blood disorders. Ask about related medical conditions, such as malabsorption or liver (e.g., hepatitis, cirrhosis), kidney, or spleen problems. Patients may

have received a solid organ transplant, may have lost a spleen to traumatic injury, or may have a history of IV drug or alcohol use that affects their risk for hematologic problems. A history of recent or recurrent infections or problems with blood clotting is important to note.

Medications

A complete medication history is an important part of a hematologic assessment. Ask about the use of vitamins, herbal products, or dietary supplements. Many medications may interfere with normal hematologic function.[3] Those on long-term anticoagulant therapy, such as warfarin, are at risk for bleeding problems. Chemotherapy drugs used to treat cancer (see Chapter 15) and antiretroviral agents used to treat human immunodeficiency virus (HIV) infection (see Chapter 14) may cause bone marrow depression. A patient previously treated with chemotherapy agents, particularly alkylating agents, has a higher risk for developing a secondary cancer of leukemia or lymphoma.

Surgery or Other Treatments

Ask the patient about specific surgical procedures. This includes splenectomy, tumor removal, prosthetic heart valve placement, surgical excision of the duodenum (where iron absorption occurs), partial or total gastrectomy (which removes parietal cells, thus reducing intrinsic factor needed for the absorption of cobalamin [vitamin B_{12}]), gastric bypass (the duodenum may be bypassed and parietal cell surface area decreased), and ileal resection (where cobalamin absorption takes place). Assess how wound healing progressed postoperatively and if and when any bleeding problems occurred in relation to the surgery. Discuss wound healing and bleeding as responses to injuries (including minor trauma) and dental extractions. Determine the number of previous blood transfusions and any complications with administration. The risk for transfusion reactions and iron overload increases with the number of blood transfusions.

Case Study

Patient Introduction

© Lisa F. Young/iStock.

A.J. is a 63-yr-old white woman who is brought to the emergency department by her husband. He came home from work and found his wife at home, weak and lying in bed after she returned from work.

She says she has been slowly getting more and more "cold and tired," but "that is what happens when you continue to work at this age." Her husband states that she has become more tired over the last couple of weeks and "her skin looks whiter." She has been having trouble working all day and even gets short of breath when doing simple errands. She also recently had a "bad cold and sinus infection" that only improved after 2 courses of antibiotics. A.J. says, "I've noticed I've had a lot of bruising lately."

Discussion Questions

1. What are the possible causes of A.J.'s weakness, pallor, and shortness of breath?
2. Is her condition stable or an emergency?
3. What type of assessment is most appropriate for A.J.: comprehensive, focused, or emergency? On what basis did you make that decision? What would be your priority?
4. What assessment questions would you ask A.J.?

You will learn more about A.J. and her condition as you read through this assessment chapter.(See p. 594 for more information on A.J.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Functional Health Patterns

Key questions to ask a patient with a hematologic problem are outlined in Table 29.4.

Health Perception–Health Management Pattern

Ask the patient to describe the usual and present state of health. Gather complete demographic data, including age, gender, race, and ethnic background. Ask if there is any family history of hematologic problems.

Genetic Risk Alert

- Hematologic problems with a strong genetic link include sickle cell anemia, hemophilia, thalassemia, and hemochromatosis.
- People with a family history of these problems have a much greater risk for developing them.
- Leukemia, pernicious anemia, and clotting disorders may have a genetic predisposition.

When taking a family health history, ask about jaundice, anemia, cancer, RBC disorders, such as sickle cell disease, and bleeding disorders, such as hemophilia and clotting disorders.

Assess risk factors, such as alcohol and cigarette use, that may disrupt the hematologic system. Alcohol is caustic to the GI mucosa and can cause damage that results in GI bleeding, esophageal varices, and decreased absorption of cobalamin and other nutrients.

Chronic alcohol users often have vitamin deficiencies. Alcohol exerts a damaging effect on platelet function and the liver, where we make clotting factors. Consequently, bleeding problems can develop and should be expected in cases of known chronic alcohol use. Illicit drug use is important to determine, since many of these drugs may affect hematopoiesis.

Cigarette smoking increases low-density lipoprotein (LDL) cholesterol and levels of CO_2, leading to hypoxia and changing the anticoagulant properties of the endothelium. Smoking increases platelet reactivity, plasma fibrinogen, hematocrit, and blood viscosity.

Nutritional-Metabolic Pattern

Obtain the patient's weight. Determine if the patient has had anorexia, nausea, vomiting, or oral discomfort. A dietary history may give clues about the cause of anemia. Iron, cobalamin, and folic acid are needed for the development of RBCs. Iron and folic acid deficiencies are

associated with inadequate intake of foods such as meat, fish, eggs, leafy green vegetables, legumes, citrus fruits, and whole-grain and enriched breads, cereals, and rice. A diet with foods high in iron may offset folic acid deficiencies.[7]

Hematemesis (bright red, brown, or black vomitus) is a manifestation of an underlying problem and always needs investigating. Peptic ulcer disease is a common cause of hematemesis.

Explore any changes in the skin's texture, color, or temperature. Ask about bleeding gum tissue or bleeding from anywhere on the body. Ask about any lumps or swelling in the neck, armpits, or groin. Specifically, ask what the lumps feel like (i.e., hard or soft, tender or nontender) and if they are mobile or fixed. Primary lymph tumors are usually not painful. A nontender, consistently swollen lymph node may be a sign of a cancer, such as Hodgkin's or non-Hodgkin's lymphoma. Enlarged, tender lymph nodes are usually associated with an acute infection.[8] Explore any reports of fever. Determine if the patient currently has a fever, recurring fevers, chills, or night sweats.

Ask patients if they have a history of heart or lung diseases. Cardiovascular problems, such as valvular disease or hypertension, may predispose patients to hemolysis. Many medications used to treat cardiovascular disease can cause problems with hematopoietic cell production or coagulation. Lung problems that lead to hypoxemia may cause chronic stimulation of erythropoietin and result in *polycythemia* (excess RBCs).

Elimination Pattern

Ask if there has been blood in the urine or stool or if black, tarry stools have occurred. Ask the patient if they have had a recent stool tested for occult blood or colonoscopy.

Activity-Exercise Pattern

Because fatigue is a prominent symptom in many hematologic problems, ask about feelings of tiredness. Determine any weakness or feelings of heavy extremities. Assess for apathy, malaise, dyspnea, or palpitations. Note any change in the patient's ability to perform

regular exercise and/or activities of daily living (ADLs), especially as they relate to a history of falling.

Sleep-Rest Pattern

Determine whether the patient feels rested after a night's sleep. Fatigue secondary to a hematologic problem often does not resolve after sleep.

Cognitive-Perceptual Pattern

Assess for any *arthralgia* (joint pain) that may be caused by a hematologic problem. Pain in the joint may occur with an autoimmune disorder, such as rheumatoid arthritis. It may occur with gout from increased uric acid production due to hematologic cancer or hemolytic anemia. Aching bones may result from pressure of expanding bone marrow with diseases such as leukemia. *Hemarthrosis* (blood in a joint) occurs in the patient with bleeding disorders and can be painful.

TABLE 29.4 Health HistoryHematologic System

Health Perception–Health Management

- Do you have any problem performing daily activities because of a lack of energy?*
- Do you smoke cigarettes or drink alcohol?*
- Do you take any prescribed or over-the-counter medications?*
- Are you taking any herbs?* Home remedies?*
- Have you in the past or are you currently consuming illegal drugs? What agents? What route? How often? When did you last use?
- Have you ever received a blood transfusion?*
- Is there any family history of anemia, cancer, bleeding, or clotting

problems?*

- Have you had any surgeries?*

Nutritional-Metabolic

- Do you have any problems with eating, chewing, or swallowing?*
- Have you had any mouth sores, sore tongue, swollen or sore gums, oral bleeding?*
- What kind of diet do you follow? If a vegetarian, do you eat eggs, milk products, fish?
- How has your appetite been?
- Have you had any changes in your weight in the past year?*
- Do you take any vitamins, nutritional supplements, or iron?*
- Is nausea and vomiting a problem for you?*
- Have you ever had any unusual bleeding or bruising?*
- Have there been recent changes in the condition or color of your skin?*
- Have you had night sweats or cold intolerance?*
- Have you noticed any swelling in your armpits, neck, or groin?*

Elimination

- Have you had black or tarry stools?* Have you had light, clay-colored stools?*
- Have you noticed any blood or dark “tea color” in your urine?*
- Has your urine had a foul odor or cloudiness?
- Have you had any decrease in urine output?*
- Do you ever have diarrhea or change in bowel patterns?*

Activity-Exercise

- Do you have any shortness of breath at rest? With activity?*
- Do you have any limitations in joint motion?* Have any of your joints been swollen?*
- Do you have a problem with unsteady gait? Have you fallen recently?*
- Do you exercise regularly? What type and how often?*
- After activity, do you ever notice bleeding or bruising?*

Sleep-Rest

- Have you had excessive fatigue recently?*
- Are you more tired than usual?*
- Do you feel rested on awakening? If no, explain.

Cognitive-Perceptual

- Have you had any numbness or tingling?*
- Have you had any problems with your vision, hearing, or taste?*
- Have you noticed any changes in your mental function?*
- Do you have any pain, such as bone, joint, or abdominal pain, or abdominal fullness?*
- Do you have pain when moving your joints?*
- Have your muscles been sore or achy recently?*

Self-Perception–Self-Concept

- Does your health problem make you feel differently about

yourself?*

- Do you have any physical changes that cause you distress?*

Role-Relationship

- Does your occupation bring you into contact with hazardous substances?*
- Has your present illness caused a change in your roles and relationships?*

Sexuality-Reproductive

- Has your hematologic problem caused any sexual or intimacy problems that concern you?*
- *Women:* When was your last menses? Do you consider your cycle normal? How long does your bleeding usually last? Have you had any increase in cramping or clotting?* Have there been any changes in the amount of flow?*
- *Men:* Do you ever have impotence?*
- Have you had unprotected sex in the past 6 months?* Was your partner someone new or a person with whom you have had a long-term sexual relationship?

Coping–Stress Tolerance

- Do you have a support system to help you when needed?
- What coping strategies do you use when your symptoms are worse?
- Do you have any specific symptoms when you feel stressed?*

Value-Belief

- Do you have any personal or religious objection to receiving blood or blood products?*
- Do you have any conflicts between your planned therapy and your value-belief system?*

---

* If yes, describe.

Note any paresthesias, numbness, and tingling as they may be related to a hematologic disorder. Assess for any changes in vision, hearing, taste, or mental status.

Self-Perception–Self-Concept Pattern

Determine the effect of the health problem on the patient's perception of self and personal abilities. Assess the effect of certain problems, such as bruising, petechiae, and lymph node swelling, on the patient's personal appearance.

Role-Relationship Pattern

Ask the patient about any past or present occupational or household exposures to radiation or chemicals. If such exposure has occurred, determine the type, amount, and duration of the exposure.

A person who has been exposed to radiation, as a treatment modality or by accident, has a higher incidence of certain hematologic problems. The same is true of a person who has been exposed to certain chemicals (e.g., benzene, lead, naphthalene, phenylbutazone). These chemicals are often used by potters, dry cleaners, and people in occupations that use adhesives. Ask the patient about a history in the military. Many Vietnam War veterans were exposed to a dioxin-containing defoliant (Agent Orange), which is linked with leukemia and lymphoma. Assess the effect of the present illness on the patient's

usual roles and responsibilities.

Sexuality-Reproductive Pattern

Take a careful menstrual history from women, including the age at which menarche and menopause began, duration and amount of bleeding, incidence of clotting and cramping, and any associated problems. Ask men if they have any problems related to impotence or prolonged erections. Ask the patient about sexual behavior that may increase the risk for HIV infection.

Coping–Stress Tolerance Pattern

The patient with a hematologic problem often needs help with ADLs. Ask the patient if adequate support is available to meet daily needs. Determine the patient's usual methods of handling stress. In the patient with platelet disorders or hemophilia, the potential for hemorrhage can be so frightening that usual life patterns may be drastically curtailed, affecting the person's quality of life.

Value-Belief Pattern

Treatment for some hematologic problems involves blood transfusions or a bone marrow transplant. Determine if these treatments conflict with the patient's value-belief system, including the patient's cultural and religious beliefs related to blood and blood transfusions. Notify the HCP if you identify any conflicts.

Case Study

Subjective Data

© Lisa F. Young/iStock.

A focused subjective assessment of A.J. revealed the following information:

Past Medical History: History of mild osteoarthritis. No surgical history. Prefers to take care of self with "natural therapy" and has not seen an HCP for 5 years, except for the recent sinus infection.

Medications: Metamucil 1 Tbsp/day PO; vitamins C, E, and D with calcium.

Health Perception–Health Management: A.J. denies family or

personal history of anemia, cancer, or bleeding disorders. She believes she comes from a family with great genes for longevity because they "eat organic foods." She admits to drinking 1 glass of red wine with her evening meal "because it's good for your heart." She is a nonsmoker and cannot understand her gradual increase in shortness of breath with exertion. She says she really can't do anything anymore without having to stop and catch her breath. She says, "It's tough getting old."

Nutritional-Metabolic: A.J. and her husband eat a lot of pasta "because it is cheap." She uses a lot of garlic for flavoring and the "health benefit of it." Although not a vegetarian, she eats little meat.

Elimination: Denies black or tarry stool. Occasional constipation. No problems with urination. Urine without odor.

Activity-Exercise: A.J. is having a hard time performing ADLs without having to stop and catch her breath. Denies dyspnea at rest. States joints are stiff on arising in morning and after sitting but able to get around OK and work at her secretarial job. States her walking is steady but weak. No history of falling.

Sleep-Rest: Typically sleeps 8 to 9 hr/night with no trouble falling asleep. She still feels tired and needs to nap during her lunch break and during her days off.

Cognitive-Perceptual: Denies any numbness or tingling. Admits to being a little hard-of-hearing but can still see "pretty good."

Value-Belief: Prefers natural therapies over traditional medication.

Discussion Questions

1. What subjective assessment findings are of most concern to you?
2. Based on these subjective assessment findings, what type of physical assessment should you perform?
3. What should you include in the physical assessment? For what would you be looking?
4. How will you individualize the physical assessment based on

the information from A.J. and her husband?

You will learn more about the physical examination of the hematologic system in the next section.(See p. 598 for more information on A.J.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Objective Data

Physical Examination

A complete physical examination is needed to accurately examine all systems that affect or are affected by the hematologic system. A patient's presenting symptoms may not immediately point to a hematologic problem (Tables 29.5). For example, paresthesias of the lower extremities may not appear to be a hematologic problem, but when combined with other findings and risk factors, may indicate cobalamin deficiency and resulting pernicious anemia. Although you should perform a full physical examination on patients suspected of a hematologic disorder, certain aspects of that examination are specifically relevant. These include skin, lymph nodes, spleen, and liver.

Lymph Node Assessment

Assess lymph nodes symmetrically and take note of location, size (in centimeters), degree of fixation (e.g., movable, fixed), tenderness, and texture. Examine superficial lymph nodes with light palpation (Fig. 29.6). To assess superficial lymph nodes, lightly palpate the nodes using the pads of the fingers. Then gently roll the skin over the area and concentrate on feeling for lymph node enlargement. We cannot palpate deep lymph nodes. They are evaluated by radiologic examination.

Ordinarily, lymph nodes are not palpable in adults. If a node is palpable, it should be small (0.5 to 1 cm), mobile, firm, and nontender to be considered a normal finding. A node that is tender, hard, fixed, or enlarged (regardless if it is tender or not) is an abnormal finding

and needs further investigation. Tender nodes are usually a result of inflammation. Hard or fixed nodes suggest cancer.[8]

Develop a sequence when examining the lymph nodes. A convenient sequence is to start at the head and neck. First, palpate the preauricular, posterior auricular, occipital, tonsillar, submandibular, submental, superficial cervical, posterior cervical chain, deep cervical chain, and supraclavicular nodes. Next, palpate the axillary lymph nodes and pectoral, subscapular, and lateral groups of nodes. Then examine the epitrochlear nodes, found in the antecubital fossa between the biceps and triceps muscles. Last, palpate the inguinal lymph nodes, found in the groin.

Palpation of Liver or Spleen

The liver and spleen are normally not detectable by palpating the abdomen. An enlarged liver or spleen may be detectable by percussion or palpation. Measure the degree of liver enlargement by the number of fingerbreadths it extends below the rib border. The spleen may be harder to detect because of its deep location in the left abdomen. Specific techniques for palpating the liver and spleen are described in Chapter 38.

Skin Assessment

Skin assessment may be a valuable source of information about the hematologic system. Examine the skin over the entire body in a systematic manner (e.g., starting with the face and oral cavity and moving downward over the body). In patients with RBC disorders, the skin may be pale or pasty or it may have a cyanotic tinge in severe anemia. Erythrocytosis often causes small vessel occlusions causing a purple, mottled appearance of the face, nose, fingers, or toes. Color changes in dark-skinned persons are best assessed in the sclera, conjunctiva, buccal mucosa, tongue, lips, nail beds, and palms.[8] *Clubbing of the fingers* (discussed in Chapter 25) can be seen with chronic anemia. Skin examination is discussed in Chapter 22.

TABLE 29.5 Assessment AbnormalitiesHematologic System

Finding	Description	Possible Etiology and Significance
Abdomen		
Distended abdomen	A larger than normal abdominal profile. May be soft or firm, tender or nontender, and accompanied by other symptoms, such as nausea, vomiting, or rebound tenderness	Lymphoma may manifest as abdominal adenopathy, mass(es), or bowel obstruction
Hepatomegaly	Palpable liver	Leukemia, cirrhosis, or fibrosis secondary to iron overload from sickle cell disease or thalassemia
Splenomegaly	Palpable spleen	Anemia, thrombocytopenia, leukemia, lymphomas, leukopenia, mononucleosis, malaria, cirrhosis, trauma, portal hypertension
Eyes		
Blurred vision, diplopia, visual field cuts	Decreased visual acuity or areas of blindness (field cuts)	Anemia, extreme leukocytosis, polycythemia, hyperviscosity may cause visual abnormalities. Thrombocytopenia may cause intraocular hemorrhage with visual abnormalities. Excessive clotting may cause thromboses in circulation to the brain that cause visual field cuts
Conjunctival pallor	Paleness. Decreased or absence of coloration in the conjunctiva	Low Hgb level (anemia)
Jaundiced sclera	Yellow appearance of sclera	Accumulation of bile pigment resulting from rapid or excessive hemolysis or liver disease or infiltration
Heart and Chest		
Altered blood pressure	*Hypertension:* >140/90 mm Hg	May occur initially as a compensatory mechanism for anemia
	Hypotension: <90 mm Hg systolic or >40 mm Hg drop from baseline	Infectious process, blood loss, compromised cardiovascular compensatory mechanisms
	Orthostasis: heart rate >20 beats/min increase or blood pressure >20 mm Hg decrease from baseline when moving from a lying position to either sitting or standing	Common with anemia, especially if also accompanied by low blood volume
Low O_2 saturation	O_2-carrying capacity as reflected by O_2 saturation by pulse oximetry	O_2 saturation may be decreased in cases of severe anemia
Palpitations	Feeling the heartbeat, flutter, or pound in chest	Anemia, fluid volume overload, hypotension with impending syncope, hypertension, dysrhythmias
Sternal tenderness	Abnormal sensitivity to touch or pressure on sternum	Leukemia resulting from increased bone marrow cellularity, causing increase in pressure and bone erosion. Multiple myeloma because of stretching of periosteum
Tachycardia	Heart rate >100 beats/min	Compensatory mechanism in anemia to increase cardiac output
Lymph Nodes		
Lymphadenopathy	Lymph nodes enlarged (>1 cm). May be tender to touch	Infection, foreign infiltrations, systemic disease such as leukemia, lymphoma, Hodgkin's lymphoma, metastatic cancer
Mouth		
Gingival and mucous membrane changes	Pallor, gingival and mucosal ulceration, swelling, or bleeding	Low Hgb level (anemia), neutropenia thrombocytopenia. Inability of impaired leukocytes to combat oral infections. Gingival hyperplasia may be present with some types of leukemia
Smooth tongue	Tongue surface smooth and shiny. Mucosa thin and red from decreased papillae	Pernicious anemia, iron-deficiency anemia
Musculoskeletal System		
Arthralgia	Joint pain	Sickle cell disease from hemarthrosis (bleeding into joints)
Bone pain	Pain in pelvis, ribs, spine, sternum	Multiple myeloma related to enlarged tumors that stretch periosteum. Bone invasion by leukemia cells, bone demineralization resulting from various cancers, sickle cell disease
Joint swelling	Fluid-filled spaces surrounding joints	Occurs with hemophilia and sickle cell anemia as hemarthrosis causes inflammation
Nervous System		
Headache, nuchal rigidity	Pain in the cranium, potentially involving one area or extending from frontal area to back of neck	Generalized headache is a common manifestation of mild to moderate anemia. Severe headache with or without visual changes may signal intracranial hemorrhage due to thrombocytopenia

Table Continued

Paresthesias of feet and hands, ataxia	Numbness sensation and extreme sensitivity in central and peripheral nerves. Impaired muscle movement	Cobalamin (vitamin B_{12}) deficiency or folate deficiency
Weakness	Lacking physical strength or energy	Low Hgb level (anemia)
Nose		
Epistaxis	Spontaneous bleeding from nares	May occur with low platelet counts, especially if patient bends down for a long time, tries to lift a heavy item, or performs an intense Valsalva maneuver
Skin		
Chloroma	A tumor arising from myeloid tissue and containing a pale green pigment	Acute myelogenous leukemia that has infiltrated the skin
Cyanosis	Bluish discoloration of skin and mucous membranes	Anemia, excess concentration of deoxyhemoglobin in blood
Excoriation	Scratch or abrasion of skin	Scratching from intense pruritus
Flushing	Transient, episodic redness of skin (usually around face and neck)	Increase in Hgb (polycythemia), congestion of capillaries. Flushing of palms of hands or soles of feet sign of anemia
Jaundice	Yellow appearance of skin and mucous membranes	Accumulation of bile pigment caused by rapid or excessive hemolysis or liver damage
Leg ulcers	Prominent on the malleoli on the ankles	Sickle cell disease
Pallor of skin or nail beds	Paleness. Decreased or absence of skin coloration	Low Hgb level (anemia)
Plasmacytoma	Tumor arising from abnormal plasma cells	Multiple myeloma that has infiltrated tissue
Pruritus	Unpleasant cutaneous sensation that provokes the desire to rub or scratch skin	Hodgkin's lymphoma, cutaneous lymphomas, infiltrative leukemias, increased bilirubin

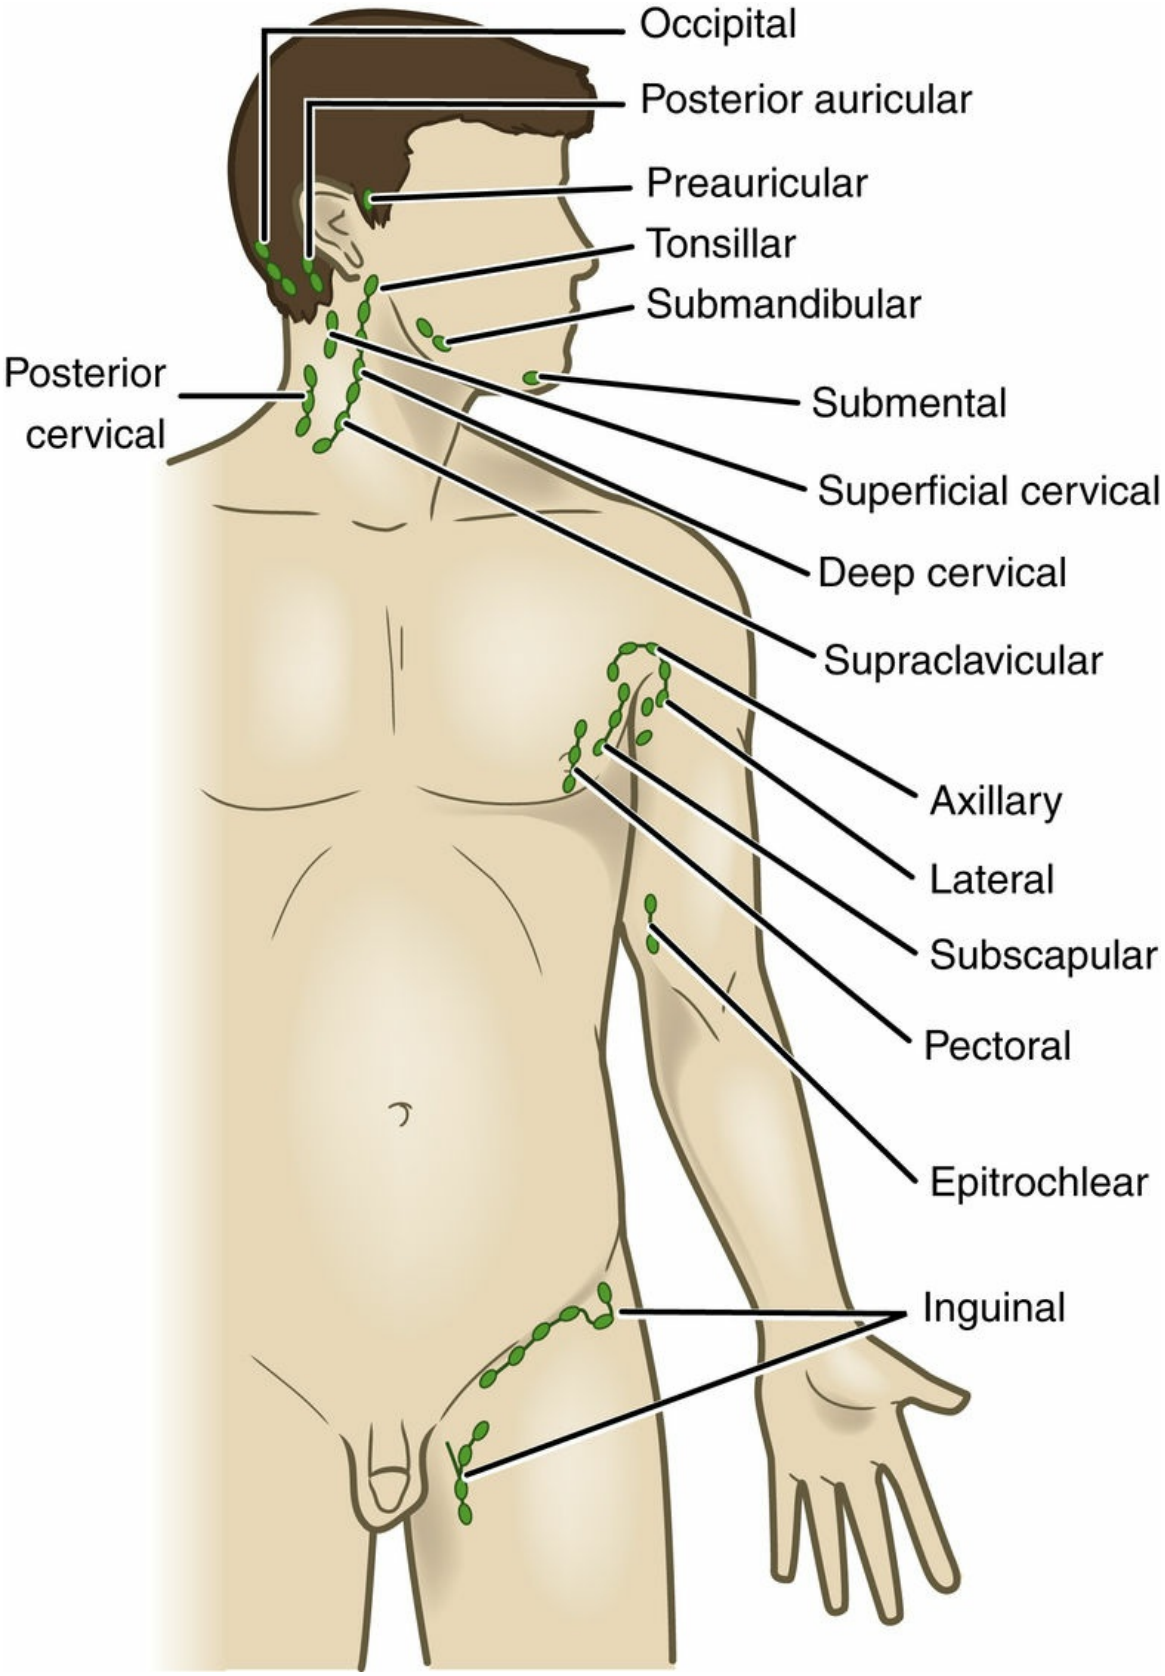

FIG. 29.6 Palpable superficial lymph nodes.

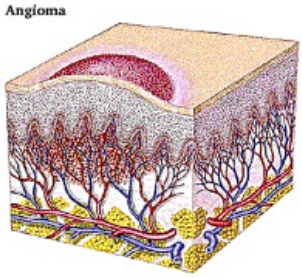
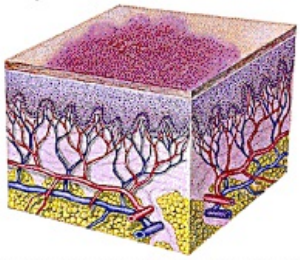
WBC disorders may cause infectious or cancerous skin lesions. These may occur anywhere and have a variable distribution pattern.

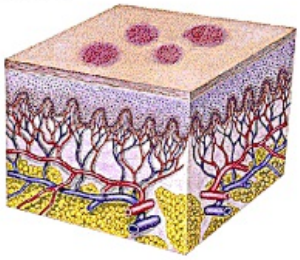
Look for findings that can indicate bleeding disorders. Assess for **petechiae** (small purplish red pinpoint lesions), **ecchymoses** (bruising), and *spider nevus* (a form of *telangiectasia*) (Table 29.6). The location of petechiae can indicate an accumulation of blood in the skin or mucous membranes. Small vessels leak under pressure, and the platelet numbers are not enough to stop the bleeding. Petechiae are more likely to occur where clothing constricts the circulation. In general, skin and mucosal bleeding means a platelet disorder, while spontaneous bleeding into joints or muscles means a coagulation factor problem.

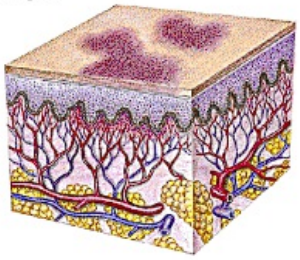
A *focused assessment* is used to assess the status of previously identified hematologic problems and to monitor for signs of new problems. A focused assessment of the hematologic system is shown in the box on p. 598.

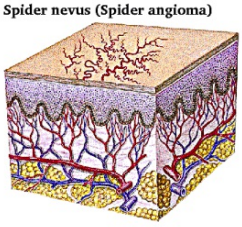
TABLE 29.6 Assessment AbnormalitiesVascular Skin Lesions

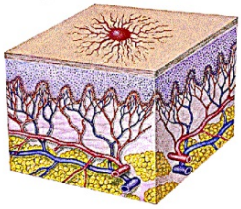












Finding	Description	Possible Etiology and Significance
Angioma 	Benign tumor. Consists consisting of blood or lymph vessels	Most are congenital. May disappear spontaneously
Ecchymosis (bruise) 	Hemorrhagic spots of varied size, Flat. Round or irregular	Decreased platelets or clotting factors resulting in hemorrhage into skin. Vascular abnormalities. Break in blood vessel walls from trauma
Petechiae 	Pinpoint, flat, round area >2 mm. Purple, dark red, or brown	Same as above
Purpura 	Flat purple or reddish discoloration. <5 mm. Do not blanche.	Same as above

Table Continued

Spider nevus (Spider angioma) 	Has a round, red, central part and branching radiations resembling a spider's web. Usually found on face, neck, or chest	High estrogen levels as in pregnancy or liver disease
Telangiectasia 	Fine, irregular red lines	Permanently dilated small blood vessels. Usually caused by sun damage or aging. May be seen with varicose veins, scleroderma, rosacea.

Figures from Ball JW, et al: *Seidel's guide to physical examination,* ed 9, St Louis, 2019, Mosby.

Case Study

Objective Data: Physical Examination

© Lisa F. Young/iStock.

Physical examination findings of A.J. are as follows:

BP 100/70 (lying), 88/60 (standing); apical pulse 110 (lying), 124 (standing), but regular in rhythm. Respiratory rate 26, temperature 96.8°F (36°C), O_2 saturation 90% on room air. No jugular venous distention. Weight 106 lb (48 kg). Height 5 ft 1 in. Skin pale and 2 ecchymoses on her arms and 1 on her left lower leg. A few scattered petechiae on both ankles. No jaundice noted. Conjunctivae pale. Tongue smooth and shiny. Lungs clear but diminished breath sounds in the bases bilaterally. No visible bleeding. No enlarged lymph nodes, spleen, or liver noted. General weakness with dyspnea on

exertion. No numbness or tingling or peripheral edema.

Discussion Questions

1. Which physical assessment findings are of most concern to you?
2. Based on the results of the subjective and physical assessment findings, what diagnostic studies do you think may be ordered for A.J.?

You will learn more about diagnostic studies in relation to the hematologic system in the next section.(See p. 604 for more information on A.J.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Diagnostic Studies of Hematologic System

The most direct means of evaluating the hematologic system is through laboratory analysis (Tables 29.7, 29.8, 29.9, and 29.10) and other diagnostic studies (Table 29.11).[9]

Laboratory Studies

Complete Blood Count

The complete blood count (CBC) involves several laboratory tests (Table 29.7). In addition to the CBC, a *peripheral smear* may be done. The smear is used to look at the *morphology* (shape and appearance) of the blood cells and may help with the diagnosis. For example, many immature *blast* WBCs may indicate acute leukemia.

Focused Assessment

Hematologic System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Unusual bleeding or bruising	Y	N
Black, tarry stool	Y	N
Blood in vomitus	Y	N
Swelling in neck, armpits, or groin	Y	N
Dark-colored urine	Y	N
Fatigue	Y	N
Heart palpitations	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values.

CBC	✓
WBC count with differential	✓
Clotting: PT, INR, aPTT, platelets	✓
Hgb, Hct	✓

Objective: Physical Examination

Inspect

Skin for lesions or color changes	✓

Auscultate

BP for change or orthostasis	✓

Palpate

Pulse for tachycardia	✓
Liver and spleen for enlargement	✓
Lymph nodes for lymphadenopathy	✓

aPTT, Activated partial thromboplastin time; *INR*, international normalized ratio; *PT*, prothrombin time.

TABLE 29.7 Diagnostic StudiesComplete Blood Count Studies

Study	Description and Purpose	Reference Intervals
Hemoglobin (Hgb)	Measures gas-carrying capacity of RBC	*Female:* 12–16 g/dL (120–160 g/L) *Male:* 14–18 g/dL (140–180 g/L)
Hematocrit (Hct)	Measure of packed cell volume of RBCs expressed as a percentage of the total blood volume	*Female:* 37%–47% (0.37–0.47) *Male:* 42%–52% (0.42–0.52)
Total RBC count (erythrocyte count)	Number of circulating RBCs per volume of blood	*Female:* 4.2–5.4 × 10^6/μL (4.2-5.4 × 10^{12}/L) *Male:* 4.7–6.1 × 10^6/μL (4.7–6.1 × 10^{12}/L)
Red cell indices		
Mean corpuscular volume (MCV)	Determination of relative size of RBCs. Low MCV reflection of microcytosis. High MCV reflection of macrocytosis	80–95 fL
Mean corpuscular hemoglobin (MCH)	Measurement of average weight of Hgb/RBCs. Low MCH indicates microcytosis or hypochromia. High MCH indicates macrocytosis	27–31 pg
Mean corpuscular hemoglobin concentration (MCHC)	Evaluates RBC saturation with Hgb. Low MCHC indicates hypochromia. High MCHC occurs with spherocytosis	32%–36% (0.32–0.36)
RBC morphology	Examination of shape and size of RBCs	No variation in RBC morphology
Reticulocyte count	Number of immature red blood cells released from the bone marrow into the blood	0.5%–2.0% of RBC
WBC count	Total number of WBCs	5000–10,000/μL (5–10 × 10^9/L)
WBC differential	Determines whether each kind of WBC is present in proper proportion. Determine absolute value of each type of WBC by multiplying the percentage of cell type by total WBC count and dividing by 10	*Segmented neutrophils:* 55%–70% (0.55–0.70) *Banded neutrophils:* 0–8% (0–0.08) *Eosinophils:* 1%–4% (0.01–0.04) *Basophils:* 0.5%–1% (0.005–0.01) *Lymphocytes:* 20%–40% (0.20–0.40) *Monocytes:* 2%–8% (0.02–0.08)
Platelet count	Number of circulating platelets	150,000–400,000 × 10^3/L (150–400 × 10^9/L)

TABLE 29. 8 Diagnostic StudiesClotting Studies

Study	Description and Purpose	Reference Intervals
Activated clotting time (ACT)	Evaluates intrinsic coagulation status. More accurate than aPTT. Used during dialysis, coronary artery bypass procedure, arteriograms	70–120 sec
Activated partial thromboplastin time (aPTT)	Assesses intrinsic coagulation by measuring factors I, II, V, VIII, IX, X, XI, XII. Higher in patients receiving heparin	30–40 sec
Antithrombin (antithrombin III)	Naturally occurring protein made by liver that inhibits coagulation by inactivating thrombin and other factors. Lower in DIC and hypercoagulable disorders	17–30 mg/dL (170–300 mg/L) or 80%–120% of standard
Bleeding time	Duration of bleeding after a standardized superficial puncture wound of the skin measuring the integrity of the platelet plug	1–9 min
Capillary fragility test (tourniquet test, Rumpel-Leede test)	Reflects capillary integrity when pressure is applied to various areas of the body. Positive test indicates thrombocytopenia, toxic vascular reactions	<2 petechiae or negative
D-dimer	Assay to measure a fragment of fibrin that forms because of fibrin degradation and clot lysis. Used as an adjunctive measure in diagnosis of hypercoagulable conditions (e.g., DIC, pulmonary embolism)	<250 ng/mL (<250 mcg/L)
Fibrin split products (FSPs) or fibrin degradation products (FDPs)	Reflects degree of fibrinolysis and predisposition to bleed (if present). Screening test for DIC. High levels associated with DIC, advanced cancer, severe inflammation	<10 mcg/mL (<10 mg/L)
Fibrinogen (factor I)	Reflects level of fibrinogen. Increase is a possible sign of enhancement of fibrin formation, making patient hypercoagulable. Decrease means the patient may be predisposed to bleeding.	200–400 mg/dL (2–4 g/L)
International normalized ratio (INR)	Standardized system of reporting prothrombin time (PT) based on a reference calibration model. Calculated by comparing patient's PT with a control value	0.8–1.1
Plasminogen	Assesses for deficiency of plasminogen in patients who have multiple thromboembolic episodes	2.4–4.4 units/mL
Platelet count	Number of circulating platelets	150,000–400,000 × 10^3/L (150–400 × 10^9/L)
Prothrombin time (PT)	Assesses extrinsic coagulation by measuring factors I, II, V, VII, X	11–12.5 sec
Thrombin time	Reflects adequacy of thrombin and time to clot. Prolonged thrombin time means that coagulation is inadequate secondary to decreased thrombin activity	10–15 sec

DIC, Disseminated intravascular coagulation.

TABLE 29.9 ABO and Rh Blood Groups

Blood Type	Antigens Present on Rbc		Antibodies Possibly Present in Plasma		Percent of General Population
	A or B	Rh (D)	A or B	Rh (D)	
O	—	—	A, B	Rh	35
O+	—	Rh	A, B	—	7
A	A	—	B	Rh	35
A+	A	Rh	B	—	7
B	B	—	A	Rh	8
B+	B	Rh	A	—	2
AB	A, B	—	—	Rh	4
AB+	A, B	Rh	—	—	2

TABLE 29.10 Diagnostic StudiesMiscellaneous Blood Studies

Study	Description and Purpose	Normal Values
Bilirubin	Measures degree of RBC hemolysis or liver's inability to excrete normal quantities of bilirubin. Increase in indirect bilirubin with hemolysis. Increase in direct bilirubin with obstructive problems (e.g., gallstones, liver tumor)	*Total:* 0.3–1.0 mg/dL (5.1–17.0 µmol/L) *Direct:* 0.1–0.3 mg/dL (1.7–5.1 µmol/L) *Indirect:* 0.2–0.8 mg/dL (3.4–12.0 µmol/L)
Blood smear (peripheral blood smear)	Reviews color, size, shape, quantity of cells in peripheral blood. Provides significant amount of information about problems affecting RBCs, WBCs, or platelets	Normal quantity of each cell type, normal size, shape and color of RBCs, normal WBC differential count and platelets
Coombs test	Differentiation among types of hemolytic anemias. Detection of immune antibodies and Rh factor	Negative
• **Direct**	Detects antibodies that are attached to RBCs	Negative
• **Indirect**	Detects circulating antibodies against red cells in serum	Negative
Cobalamin (vitamin B_{12})	Level of cobalamin available for production of new RBCs	160–950 pg/mL (118–701 pmol/L)
Erythrocyte sedimentation rate (ESR)	Measures sedimentation or settling of RBCs in 1 hr. Inflammatory process cause a change in plasma proteins, resulting in aggregation of RBCs and making them heavier. The faster the sedimentation rate, the higher the ESR	< 20 mm/hr (some gender variation)
Erythropoietin	Measures degree of hormonal stimulation to bone marrow to stimulate the release of RBCs	5–25 mU/mL (5–30 U/L)
Ferritin	Major iron storage protein. Is normally present in blood in concentrations directly related to iron storage	10–300 ng/mL (10–300 mcg/L)
Folic acid (folate)	Amount of folic acid (folate) available for RBC production	5–25 ng/mL (11–57 nmol/L)
Haptoglobin	A serum glycoprotein that binds to Hgb released into the bloodstream by hemolysis. Decreased with red cell hemolysis. Increased with infection, inflammation, cancer	50–220 mg/dL
Hemoglobin (Hgb) electrophoresis	Proteins involved in development of Hgb molecule have a definitive pattern of separation on electrophoresis. This pattern is changed with abnormal Hgb synthesis (e.g., thalassemia) or sickle cell anemia (where Hgb S is increased)	Normal Hb A1: > 95% Hb A2: 2%–3% Hb F: 0.8%–2% Hb S: 0 Hb C: 0
Homocysteine	An intermediate amino acid formed during the metabolism of the essential amino acid methionine. Rapidly metabolized through pathways that require cobalamin (vitamin B_{12}) and folic acid. Increased in cobalamin and folic acid deficiency	*Normal:* 4–14 µmol/L
Iron		
• **Iron total**	Reflects amount of iron combined with proteins in serum. Accurate indicator of status of iron storage and use	*Male:* 80–180 mcg/dL (14–32 µmol/L) *Female:* 60–160 mcg/dL (11–29 µmol/L)
• **(Total) iron-binding capacity (TIBC)**	Measures all proteins available for binding iron. Transferrin represents the largest quantity of iron-binding proteins. Therefore TIBC is an indirect measure of transferrin, an evaluation of the amount of extra iron that can be carried	250–460 mcg/dL (45–82 µmol/L)
Lactic dehydrogenase (LDH)	Intracellular enzyme present in almost all body tissues. Levels rise in response to cell damage. Increased levels confirm diagnosis of injury or disease. Used as a nonspecific marker of hematologic cancer growth and response to treatment	100–190 U/L
Methylmalonic acid (MMA)	Indirect test for cobalamin (vitamin B_{12}). MMA metabolism requires cobalamin. Decreased levels with cobalamin deficiency. Helps distinguish cobalamin deficiency from folic acid deficiency	< 3.6 µmol/mmol creatinine
Microglobulin (beta$_2$ microglobulin)	Protein found on the surface of all cells. Increased in cancers such as lymphoma, leukemia, or multiple myeloma. May be used as a tumor marker	*Blood:* 0.7–1.8 mcg/mL *Urine:* ≤ 300 mcg/L *Spinal fluid:* ≤ 2.4 mg/L
Serum protein electrophoresis (SPEP)	Separates proteins in blood on basis of electric charge. Helps detect hyperglobulinemic states, such as in multiple myeloma or some lymphomas	Normal banding pattern of albumin and globulins. Increase in any protein *(protein spike)* is abnormal
Transferrin	Largest of proteins that bind to iron. Increased in most people with iron-deficiency anemia	*Male:* 215–365 mg/dL (2.15–3.65 g/L) *Female:* 250–380 mg/dL (2.5–3.8 g/L)
Transferrin saturation (%)	Decreased in iron-deficiency anemia. Increased in hemolytic and megaloblastic anemia	*Male:* 20%–50% *Female:* 15%–50%

TABLE 29.11 Diagnostic StudiesHematologic System

Study	Description and Purpose	Nursing Responsibility
Molecular, Cytogenetic, and Gene Analysis Studies		
Cancer genomics (genotyping) **Cell surface immunophenotyping (flow cytometry)** **Chromosomal karyotyping** **Fluorescence in situ hybridization (FISH)**	Assesses for genetic or chromosomal abnormalities of cancer cells. Uses peripheral blood (e.g., leukemia), biopsy specimen (bone marrow, lymph node, tissue), or CSF. Used to confirm diagnosis and determine treatment modalities and prognosis	*Before:* Explain purpose of testing to patient. HCP will provide specific significance.
Procedures		
Bone marrow biopsy (Fig. 29.7)	Technique involves removal of bone marrow through a locally anesthetized site to evaluate status of blood-forming tissue. Used to diagnose and monitor aplastic anemia, multiple myeloma, myelodysplastic syndromes, leukemia, and some lymphomas	*Before:* Explain procedure to patient. Obtain signed consent form. Perform a surgical time-out before procedure. Analgesics may be given to enhance patient comfort and cooperation. *After:* Apply pressure dressing. Assess biopsy site for bleeding and apply pressure as needed. Tenderness at the puncture site for a few days may be normal. Assess for infection.
Lumbar puncture (LP)	Done to obtain CSF for testing for cancer, infection, and degenerative brain diseases. May be used to give chemotherapy to the central nervous system	*During:* Help position patient and provide support. *After:* Watch site for bleeding and signs of infection. Spinal headaches may occur. Follow postprocedure orders for how long the patient should lie flat. Encourage the patient to drink fluids.
Lymph node biopsy	Used to obtain lymph tissue for histologic examination to determine diagnosis and therapy	*Before:* Explain procedure to patient. Obtain signed consent form.
• **Closed (needle) or fine needle**	Done at the bedside or in an outpatient area. An extremely small needle is used to reduce risk for tracking cancer cells through normal subcutaneous tissue	*After:* Watch site for bleeding and monitor vital signs, especially if platelet count is low. Change sterile dressing as ordered. Inspect wound for healing and infection.
• **Open**	Done in operating room or procedure area using either local or general anesthesia. After making an incision, the lymph node and surrounding tissue are excised whenever possible	
Radioisotope Studies		
Bone scan	Radioactive isotope is injected IV and taken up by the bones. Uniform uptake is normal. Increased uptake seen in osteomyelitis, certain fractures, and bone cancer	*Before:* Patient may be asked to drink 4–6 glasses of water and then void before imaging (to see pelvic bones). Obtain IV access for injection of isotope.
SPECT scan (single-photon emission computed tomography)	Radioactive isotope is injected IV. Images from radioactive emissions used to evaluate the structures, such as spleen, liver, bone, and possible tumors. Patient is not a source of radioactivity	*Before:* Obtain IV access for injection of isotope. *After:* Have the patient drink fluids to aid in the excretion of the isotope.
Radiologic Studies		
Computed tomography (CT) scan	Noninvasive radiologic examination using computer-assisted x-ray evaluates the lymph nodes. Contrast medium used in abdominal studies of liver or spleen. Spiral (helical) CT scans used to evaluate lymph nodes	*Before:* Assess for iodine sensitivity if contrast medium used. IV and/or oral contrast may be given prior to procedure, depending on the area being studied. Patient may need to be NPO for 4 hr. *After:* Have patient drink fluids to avoid renal problems with any contrast.
Liver, spleen, or abdominal ultrasound	Noninvasive probe is lubricated and slid across the abdomen to detect density and borders of the abdominal organs. Can detect irregular borders, masses, vascular structure, fluid collections, and biliary tree	*During:* Patients must be comfortable lying flat and having probe compress abdomen.
Magnetic resonance imaging (MRI)	Noninvasive procedure produces sensitive images of soft tissue (central nervous system, neck and back, bones and joints, heart, breasts). An IV contrast agent (gadolinium) may be given. Provides a better contrast between normal tissue and pathologic tissue than CT	*Before:* Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function before test. Have patient remove all metal objects. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During:* Patient must lie completely still during scan.

Table Continued

Study	Description and Purpose	Nursing Responsibility
Positron emission tomography (PET)	Glucose-containing nuclear tracer substance is injected and taken up by metabolically active cells. Follow-up scan shows different-colored tissues based on metabolic rate. Because cancer cells have an increased uptake of glucose, "hot spots" reflecting increased glucose consumption indicate the presence of active cancer. CT scanning may be done in conjunction or images fused.	*Before:* Obtain IV access to inject the tracer substance. Patients should be NPO, except for water and medications, for at least 4 hr prior. Hold glucose-containing IV solutions and change to normal saline. Check the blood glucose levels as high levels may interfere with test. May need bowel preparation depending on area being studied. *After:* Encourage fluids to excrete radioactive substance.
Skeletal x-ray	X-rays done as a bone survey to detect lytic lesions associated with multiple myeloma. Bone scans do not identify lesions in this condition because there is no uptake of radioactive isotopes due to lack of blood supply.	No specific nursing responsibilities.
Urine Studies		
Bence Jones protein (free kappa and lambda light chains)	An electrophoretic measurement used to detect Bence Jones protein, which is found in most cases of multiple myeloma. May be present in some other hematologic disorders and metastatic cancers. Negative finding is normal.	*During:* Obtain random urine specimen early in the morning. If a 24-hr urine collection is done, discard first specimen, and collect all urine voided during the 24 hr, keeping on ice or refrigerated. Remind patient not to put toilet paper in urine collection container.

Although the status of each cell type is important, diseases or treatment of diseases can disrupt the entire system. When the entire CBC is suppressed, a condition termed **pancytopenia** (marked decrease in the number of RBCs, WBCs, and platelets) exists.

Red Blood Cells

The total RBC count is reported as RBC × 10^6/μL. However, the total RBC count is not fully reliable in determining the adequacy of RBC function. We must evaluate other data, such as hemoglobin, hematocrit, and RBC indices. Normal values of some RBC tests are different for men and women because normal values are based on body mass. Men usually have a larger body mass than women.

The *hemoglobin (Hgb) value* is reduced in cases of anemia, hemorrhage, and hemodilution, such as that occurring with excess fluid volume. Increased hemoglobin is found in polycythemia or in states of hemoconcentration, which can develop from volume depletion (dehydration). Reductions and elevations of the hematocrit value and RBC count occur with the same conditions that raise and lower the hemoglobin value.

The *hematocrit (Hct) value* is determined by spinning blood in a centrifuge. This causes RBCs and plasma to separate. The RBCs, being the heavier elements, settle to the bottom (Fig. 29.2). The hematocrit value is the percent of RBCs compared with the total blood volume. The hematocrit value generally is 3 times the hemoglobin value.

RBC indices are special indicators that reflect RBC volume, color, and hemoglobin saturation (Table 29.7).[9] These parameters give insight into the cause of anemia. The significance of these parameters is discussed more in Chapter 30.

White Blood Cells

The WBC count gives two different sets of information. The first is a total count of WBCs in 1 μL of peripheral blood. A WBC count over 10,000/μL is associated with infection, inflammation, tissue injury or death, and cancer (e.g., leukemia, lymphoma). Although the degree of WBC elevation does not necessarily predict the severity of illness, it can give clues to the cause. Extremely high WBC counts (e.g., greater than 25,000/μL) occur with certain types of leukemia. A WBC count less than 5000/μL (**leukopenia**) is associated with bone marrow depression, severe or chronic illness, and other types of leukemia.

The second aspect of the WBC count, the *differential count,* measures the percent of each type of WBC. The WBC differential gives valuable clues in determining the cause of illness. When infections are severe, we release more granulocytes from the bone marrow as a compensatory mechanism. To meet the increased demand, many young, immature polymorphonuclear neutrophils *(bands)* are released into circulation. More mature neutrophils are called *polymorphonuclear segmented neutrophils (segs)*. Together, bands and segs make up the *absolute neutrophil count* (ANC). The usual laboratory procedure is to report the WBCs in order of maturity, with the less mature forms on the left side of the written report. That is why we call the presence of many immature cells a *"shift to the left."*

The WBC differential is very important because it is possible for the total WBC count to be essentially normal despite a marked change in 1 type of WBC. For example, a patient may have a normal WBC count of 8800/μL, but the differential count may show that the proportion of lymphocytes is only 10%. This is an abnormal finding that needs further investigation.

When the bone marrow does not make enough neutrophils, neutropenia occurs. **Neutropenia** is a condition in which the ANC is

less than 1000 cells/μL. Severe neutropenia is associated with an ANC of less than 500 cells/μL. You calculate the ANC by multiplying the total WBC count by the percentage of neutrophils. Neutropenia results from many disease processes, such as leukemia, or from bone marrow depression (see Chapter 30). It is associated with a high risk for infection and death from sepsis.

Platelet Count

The platelet count is the number of platelets per microliter of blood. Normal platelet counts are between 150,000 and 400,000/μL. Counts below 100,000/μL signify a condition termed **thrombocytopenia**. Bleeding may occur with thrombocytopenia. Spontaneous hemorrhage is possible once platelet counts fall below 10,000/μL, depending on the clinical situation.[6] A more extensive description of clotting studies is given in Table 29.8.

Thrombocytosis is defined as too many platelets. It occurs with inflammation and some cancers (see Chapter 30). The most likely complication of thrombocytosis is excessive clotting.

Blood Typing and Rh Factor

Blood group antigens (A and B) are found only on RBC membranes. They form the basis for the ABO blood typing system. The presence or absence of 1 or both of the 2 inherited antigens is the basis for the 4 blood groups: A, B, AB, and O. Blood group A has A antigens, group B has B antigens, group AB has both antigens, and group O has neither A nor B antigens. Each person has antibodies in the serum termed *anti-A* and *anti-B* that react with A or B antigens. These antibodies are found when the corresponding antigen is absent from the RBC surface. For example, B antibodies are found in the serum of people with blood group A (Table 29.9).

Blood reactions based on ABO incompatibilities result from intravascular hemolysis of the RBCs. RBCs *agglutinate* (or clump) when a serum antibody is present to react with the antigens on the RBC membrane. For example, agglutination would occur in the blood of a person with type A blood if he or she receives blood transfused

from a person with B antigens (i.e., type B or AB). The anti-B antibodies in the type A blood would react with the B antigens, starting the process that results in RBC hemolysis. Blood component compatibilities for transfusions are outlined in Table 30.32.

The *Rh system* is based on a third antigen, D, which is also on the RBC membrane. Rh-positive people have the D antigen, while Rh-negative people do not. Rh-positive blood is indicated with a "+" after the ABO group (e.g., AB+). Rh status is determined by a Coombs test (Table 29.10).

Because of transfusion therapy or during childbirth, a Rh-negative person may be exposed to Rh-positive blood. After exposure during childbirth, a Rh-negative mother forms an antibody, anti-D, which acts against Rh antigens (Rh-positive people normally have no anti-D). In future pregnancies the mother's anti-D antibodies can cross the placenta and attack the RBCs of a Rh-positive fetus, causing hemolysis of the RBCs. A pregnant Rh-negative woman should receive Rho(D) immune globulin (RhoGAM) injections to prevent anti-D antibodies from forming.

Iron Metabolism

The laboratory tests used to evaluate iron metabolism include serum iron, total iron-binding capacity (TIBC), serum ferritin, and transferrin saturation. Tests for nutritional deficiencies leading to defective RBC production may be done (Table 29.10).[9]

Serum iron is a measurement of the amount of protein-bound iron circulating in the serum. TIBC gives a measurement of all proteins that act to bind or transport iron between the tissues and bone marrow. Although this indirect measurement is a general reflection of the amount of transferrin present in the circulation, it overestimates transferrin levels by 16% to 20% because it measures other proteins that can bind iron. These alternative proteins bind iron only when transferrin is more than half saturated. TIBC varies inversely with tissue iron stores. It is higher when iron stores are low and lower when iron stores are high.

Transferrin saturation is a better indicator of the availability of iron

for erythropoiesis than serum iron. Unlike serum iron, the iron bound to transferrin is readily available for the body to use. You calculate transferrin saturation by dividing serum iron by TIBC and multiplying by 100. For example, a patient with a serum iron level of 100 mcg/dL and a TIBC of 300 mcg/dL would have a transferrin saturation of about 33%.

Under normal conditions, the serum ferritin concentration correlates closely with body iron stores. In normal patients, 1 ng/mL of ferritin corresponds to 8 to 10 mg of stored iron.

Biopsies

Biopsy procedures specific to hematologic assessment are bone marrow examination and lymph node biopsy. In general, these procedures are done when a peripheral blood smear is nonspecific. Furthermore, a biopsy provides information that is needed for diagnosis and treatment planning.

Bone Marrow Examination

Bone marrow examination is important in evaluating many hematologic problems. It may involve aspiration only or aspiration with biopsy (Table 29.11). The benefits gained from bone marrow examination are (1) a full evaluation of hematopoiesis and (2) the ability to get specimens for cytopathologic and chromosomal analysis. The preferred site for both aspiration and biopsy of bone marrow is the posterior iliac crest. A physician, nurse practitioner, or physician's assistant can perform a bone marrow aspiration and biopsy. The patient may receive local anesthesia and sedation to minimize anxiety and pain.

For bone marrow aspiration, the skin over the puncture site is cleansed with a bactericidal agent. The skin, subcutaneous tissue, and periosteum are injected with a local anesthetic agent. Once the area is anesthetized, a bone marrow needle is inserted through the cortex of the bone. The stylet of the needle is then removed, the hub is attached to a 10-mL syringe, and 0.2 to 0.5 mL of the fluid marrow is aspirated

(Fig. 29.7). The patient will have pain when the periosteum is penetrated and with aspiration. Although the pain will last only a few seconds, it can be quite uncomfortable. After the marrow aspiration, the needle is removed. Pressure is applied over the aspiration site to ensure hemostasis, then the site is covered with a sterile pressure dressing.

Although complications of bone marrow aspiration are minimal, there is a chance of damaging underlying structures. Other complications include hemorrhage (if the patient is thrombocytopenic) and infection (if the patient is leukopenic).

Monitor the patient's vital signs until stable and assess the site for excess drainage or bleeding. If bleeding is present, have the patient lie on that side for 30 to 60 minutes to keep pressure on the site. If the bed is too soft, have the patient lie on a rolled towel to provide more pressure. You may give analgesics for postprocedure pain. Soreness over the puncture site for 3 to 4 days after the procedure is normal.

Lymph Node Biopsy

Lymph node biopsy involves obtaining lymph tissue for histologic examination to determine the diagnosis and help plan therapy. This may be done by either an open biopsy or a closed (needle) biopsy.

If the results from a needle biopsy are negative, it may only mean that the cancer cells were not part of the tissue in the biopsy specimen. However, a positive finding may be enough evidence for confirming a diagnosis. This technique is rarely used to confirm an initial diagnosis because larger specimens, such as excisional biopsies are usually needed to perform cytopathologic tests.

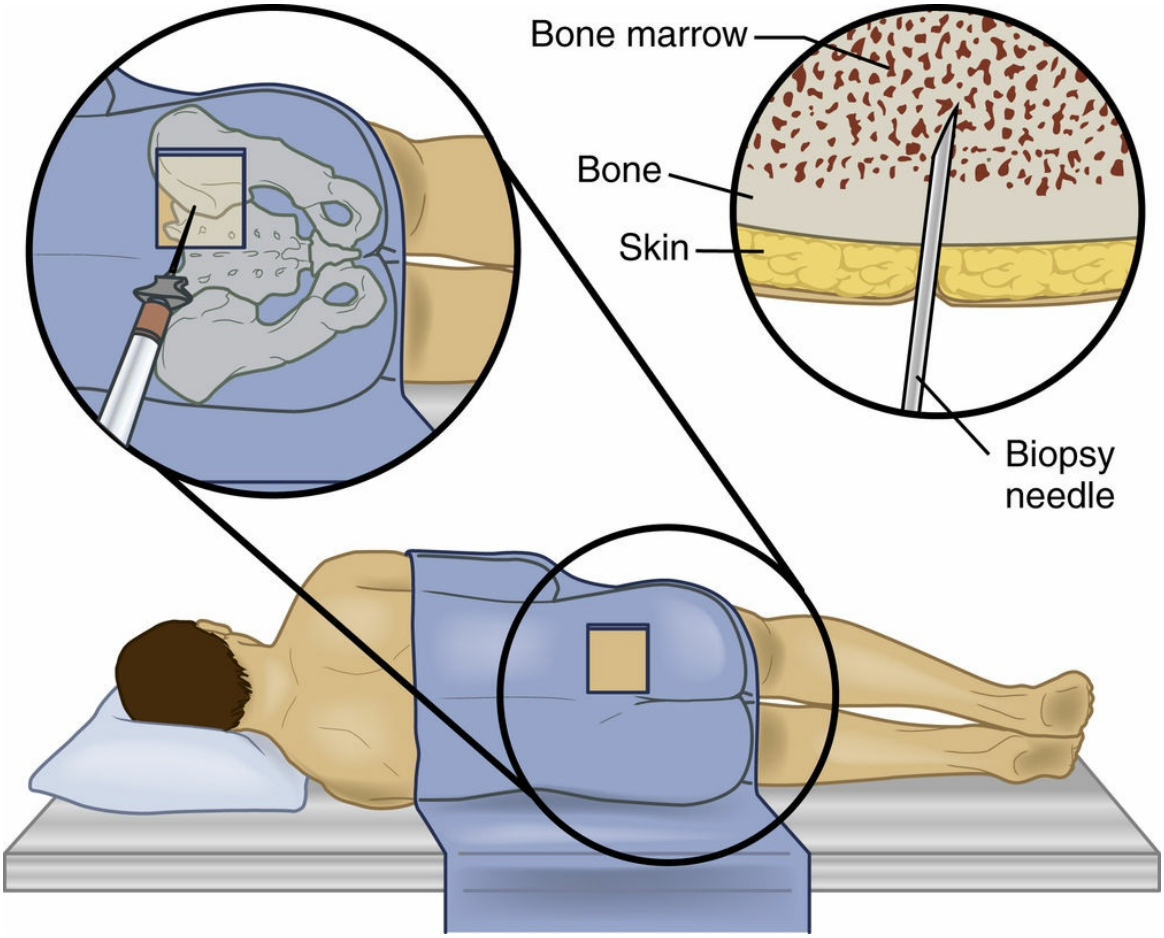


FIG. 29.7 Bone marrow aspiration from the posterior iliac crest.

Molecular Cytogenetics and Gene Analysis

Testing for specific genetic or chromosomal variations in hematologic conditions is often helpful in diagnosis and staging (Table 29.11). These results help determine treatment options and prognosis. If a large number of abnormal cells are circulating in the blood, such as in acute leukemia, these tests may be done on peripheral blood. However, testing is usually done on samples from bone marrow, lymph node biopsies, and sometimes cerebrospinal fluid (CSF).[9] For example, fluorescence in situ hybridization (FISH) identifies genetic defects using nucleic probes that are complementary to a targeted region of deoxyribonucleic acid (DNA). It can identify an abnormal extra chromosome 8, which is common in certain leukemias.

Chromosomal karyotyping allows each set of chromosomes to be painted different colors. This helps identify normal from abnormal banding patterns.[9] It can be used to identify the translocation of chromosome 22 to 9 in the Philadelphia chromosome of chronic myelogenous leukemia. More information on genetics is available in Chapter 12.

Case Study

Objective Data: Diagnostic Studies

© Lisa F. Young/iStock.

The HCP orders the following diagnostic studies for A.J.:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine), PT/PTT
- Arterial blood gases
- Chest x-ray

A.J.'s CBC reveals an Hgb of 5.9 g/dL, Hct of 18.2%, WBC of 2600/μL (2.6×10^9/L), platelet count of 72,000/μL, PT = 18 sec, aPTT = 37.

The arterial blood gases and chest x-ray are normal. The HCP orders more blood work, including a WBC differential and RBC indices and admits her to the hospital for further evaluation.

Discussion Questions

1. Are these the diagnostic studies that you expected to be ordered?
2. Which diagnostic study results are abnormal?
3. Which diagnostic study results are of most concern to you? What other studies may be ordered on admission?

This case study is continued in Chapter 30 on p. 652.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A person who lives at a high altitude may normally have an increased Hgb and RBC count because
   a. high altitudes cause vascular fluid loss, leading to hemoconcentration.
   b. hypoxia caused by decreased atmospheric O_2 stimulates erythropoiesis.
   c. the function of the spleen in removing old RBCs is impaired at high altitudes.
   d. impaired production of platelets leads to proportionally higher red cell counts.
2. Cancer arising from granulocytic cells in the bone marrow will have the primary effect of causing

a. risk for hemorrhage.

b. altered oxygenation.

c. decreased production of antibodies.

d. decreased phagocytosis of bacteria.

3. An anticoagulant such as warfarin that interferes with prothrombin production will alter the clotting mechanism during

a. platelet aggregation.

b. activation of thrombin.

c. the release of tissue thromboplastin.

d. stimulation of factor activation complex.

4. When reviewing laboratory results of an older patient with an infection, the nurse would expect to find

a. mild leukocytosis.

b. decreased platelet count.

c. increased hemoglobin and hematocrit levels.

d. decreased erythrocyte sedimentation rate (ESR).

5. Significant information from the patient's health history that relates to the hematologic system includes

a. jaundice.

b. bladder surgery.

c. early menopause.

d. multiple pregnancies.

6. While assessing the lymph nodes, the nurse should

a. apply gentle, firm pressure to deep lymph nodes.

b. palpate the deep cervical and supraclavicular nodes last.

c. lightly palpate superficial lymph nodes with the pads of the fingers.

d. use the tips of the second, third, and fourth fingers to apply deep palpation.

7. If a lymph node is palpated, what is a normal finding?

a. Hard, fixed nodes

b. Firm, mobile nodes

c. Enlarged, tender nodes

d. Hard, nontender nodes

8. Nursing care for a patient immediately after a bone marrow biopsy and aspiration includes *(select all that apply)*

a. giving analgesics as needed.

b. preparing to start a blood transfusion.

c. giving preprocedure and postprocedure antibiotic medications.

d. having the patient lie still to keep the sterile pressure dressing intact.

e. monitoring vital signs and assessing the site for excess drainage or bleeding.

9. You are taking care of a male patient who has the following laboratory values from his CBC: WBC 6.5 × 10^3/μL, Hgb 13.4 g/dL, Hct 40%, platelets 50 × 10^3/μL. What are you *most* concerned about?

a. The patient is neutropenic.

b. The patient has an infection.

c. There is an increased risk for bleeding.

d. Fall risk precautions are needed due to anemia.

1. b, 2. d, 3. b, 4. a, 5. a, 6. c, 7. b, 8. a, d, e, 9. c

Hematologic Problems

Sandra Irene Rome

LEARNING OUTCOMES

1. Describe the general clinical manifestations and complications of anemia.
2. Distinguish the etiologies, clinical manifestations, diagnostic findings, and interprofessional and nursing management of iron-deficiency, megaloblastic, and aplastic anemias.
3. Explain the nursing management of anemia from blood loss.
4. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of anemia caused by increased erythrocyte destruction.
5. Describe the pathophysiology and nursing and interprofessional management of polycythemia.
6. Explain the pathophysiology, clinical manifestations, and interprofessional and nursing management of various types of thrombocytopenia.
7. Describe the types, clinical manifestations, diagnostic findings, and interprofessional and nursing management of hemophilia and von Willebrand disease.
8. Explain the pathophysiology, diagnostic findings, and interprofessional and nursing management of disseminated intravascular coagulation.
9. Describe the etiology, clinical manifestations, and

interprofessional and nursing management of neutropenia.

10. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of myelodysplastic syndrome.
11. Compare and contrast the distinguishing clinical and laboratory findings of the major types of leukemia.
12. Explain the nursing and interprofessional management of acute and chronic leukemias.
13. Compare Hodgkin's lymphoma and non-Hodgkin's lymphomas in terms of clinical manifestations, staging, and interprofessional and nursing management.
14. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of multiple myeloma.
15. Describe the spleen disorders and related interprofessional care.
16. Describe the nursing management of the patient receiving transfusions of blood and blood components.

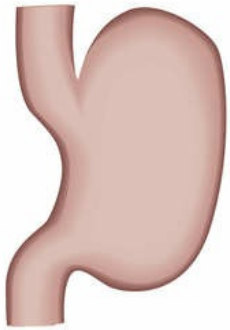
Conceptual Focus

Cellular Regulation
Clotting
Fatigue
Functional Ability
Gas Exchange
Immunity
Infection
Pain
Perfusion

There are a wide range of blood conditions and cancers. Because blood has so many essential functions, when hematologic problems

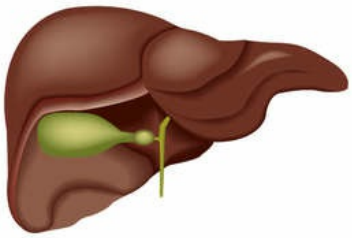


occur the patient is affected in multiple ways. Patients with anemia and hematologic cancer may have to cope with fatigue. Compromised immunity and the risk for infection is a concern among patients with hematologic cancer and a common side effect of therapy. Pain is a common symptom associated with cancer and sickle cell disease. Clotting is an important protective mechanism that allows us to maintain homeostasis when injury occurs. Excessive clotting can impair perfusion, while inadequate clotting can lead to blood loss and fluid volume deficits. This chapter will discuss the interprofessional and nursing care of common hematologic problems and their associated concepts.

Anemia

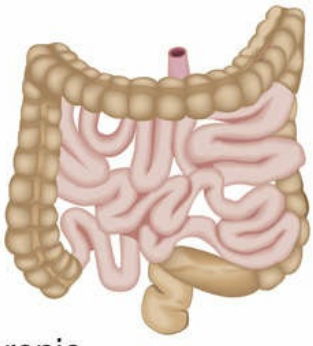
Definition and Classification

Anemia is a deficiency in the number of erythrocytes (red blood cells [RBCs]), the quantity or quality of hemoglobin, and/or volume of packed RBCs (hematocrit). It is a common condition with many diverse causes, such as blood loss, impaired production of RBCs, or increased destruction of RBCs (Fig. 30.1). Because RBCs transport O_2, RBC disorders can lead to tissue hypoxia. This hypoxia accounts for many of the signs and symptoms of anemia. Anemia is not a specific disease. It is a manifestation of a pathologic process.



Decreased RBC Production

Deficient nutrients
- Iron
- Cobalamin
- Folic acid



Decreased erythropoietin

Decreased iron availability

Blood Loss

Chronic
- Bleeding duodenal ulcer
- Colorectal cancer
- Liver disease

Acute
- Acute trauma
- Ruptured aortic aneurysm
- GI bleeding

Increased RBC Destruction

Hemolysis
- Sickle cell disease
- Medication (e.g., methyldopa [Aldomet])
- Incompatible blood
- Trauma (e.g., cardiopulmonary bypass)

FIG. 30.1 Causes of anemia.

TABLE 30.1 Morphologic Classification of Anemia

Morphology	Etiology
Normocytic, normochromic (normal size and color) MCV 80–95 fL, MCH 27–31 pg	Acute blood loss, hemolysis, chronic kidney disease, chronic disease, cancers, endocrine disorders, starvation, aplastic anemia, sickle cell anemia, pregnancy
Microcytic, hypochromic (small size, pale color) MCV <80 fL, MCH <27 pg	Iron-deficiency anemia, vitamin B_6 deficiency, copper deficiency, thalassemia, lead poisoning
Macrocytic (megaloblastic), normochromic (large size, normal color) MCV >95 fL, MCH >31 pg	Cobalamin (vitamin B_{12}) deficiency, folic acid deficiency, liver disease (including effects of alcohol use)

MCH, Mean corpuscular hemoglobin; *MCV*, mean corpuscular volume.

TABLE 30.2 Etiologic Classification of Anemia

Decreased RBC Production

Decreased Hemoglobin Synthesis

- Iron deficiency
- Sideroblastic anemia (decreased porphyrin)
- Thalassemia (decreased globin synthesis)

Decreased Number of RBC Precursors

- Aplastic anemia and inherited disorders (e.g., Fanconi syndrome)
- Anemia of myeloproliferative diseases (e.g., leukemia) and myelodysplasia
- Chronic diseases or disorders
- Medications and chemicals (e.g., chemotherapy, lead)
- Radiation

Defective DNA Synthesis

- Cobalamin (vitamin B_{12}) deficiency
- Folic acid deficiency

Blood Loss
Acute

- Blood vessel rupture
- Splenic sequestration crisis
- Trauma

Chronic

- Gastritis
- Menstrual flow
- Hemorrhoids

Increased RBC Destruction (Hemolytic Anemias)
Acquired (Extrinsic)

- Antibodies against RBCs
- Infectious agents (e.g., malaria) and toxins

- Physical destruction
- Extracorporeal circulation
- Disseminated intravascular coagulopathy (DIC)
- HELLP syndrome (hemolysis, high liver enzymes, low platelets associated with pregnancy)
- Prosthetic heart valves
- Thrombotic thrombocytopenic purpura (TTP)
- Widespread cancer

Hereditary (Intrinsic)

- Abnormal hemoglobin (sickle cell disease)
- Enzyme deficiency (glucose-6-phosphate dehydrogenase [G6PD])
- Membrane abnormalities (paroxysmal nocturnal hemoglobinuria, hereditary spherocytosis)

We diagnose anemia based on a complete blood count (CBC), reticulocyte count, and peripheral blood smear. Once we identify anemia, further investigation is done to determine its specific cause.[1]

Anemia can result from primary hematologic problems or develop as a secondary consequence of diseases or disorders of other body systems. We classify the types of anemia according to either *morphology* (cellular characteristic) or *etiology* (cause). Morphologic classification is based on RBC size and color (Table 30.1). Etiologic classification is related to the clinical conditions causing the anemia (Table 30.2).[2] Although the morphologic system is the most accurate means of classifying anemias, it is easier to discuss patient care by focusing on the cause of the anemia.

Promoting Health Equity

Hematologic Problems

- Sickle cell disease has a high incidence among African Americans.
- Thalassemia has a high incidence among blacks and people of Mediterranean origin.
- Tay-Sachs disease has the highest incidence in families of Eastern European Jewish origin, especially the Ashkenazi Jews.
- Pernicious anemia has a high incidence among Scandinavians and blacks.

TABLE 30.3 Manifestations of Anemia

Body System	Severity of Anemi		
	Mild (Hgb 10–12 g/dL [100–120 g/L])	Moderate (Hgb 6–10 g/dL [60–100 g/L])	Severe (Hgb <6 g/dL [<60 g/L])
Cardiovascular	Palpitations	Increased palpitations, "bounding pulse"	Tachycardia, increased pulse pressure, systolic murmurs, intermittent claudication, angina, HF, myocardial infarction
Eyes	None	None	Icteric conjunctiva and sclera, retinal hemorrhage, blurred vision
Gastrointestinal	None	None	Anorexia, hepatomegaly, splenomegaly, difficulty swallowing, sore mouth
General	None or mild fatigue	Fatigue	Sensitivity to cold, weight loss, lethargy
Integument	None	None	Pallor, jaundice, pruritus
Mouth	None	None	Glossitis, smooth tongue
Musculoskeletal	None	None	Bone pain
Pulmonary	Exertional dyspnea	Dyspnea	Tachypnea, orthopnea, dyspnea at rest
Neurologic	None	"Roaring in the ears"	Headache, vertigo, irritability, depression, impaired thought processes

Clinical Manifestations

The manifestations of anemia are caused by the body's response to tissue hypoxia. Specific manifestations vary depending on how fast the anemia has evolved, its severity, and any coexisting disease. We often use hemoglobin (Hgb) levels to determine the severity of anemia.

Mild anemia (Hgb 10 to 12 g/dL [100 to 120 g/L]) may exist without causing symptoms. If symptoms develop, it is because the patient has

an underlying disease or has a compensatory response to heavy exercise. Symptoms include palpitations, dyspnea, and mild fatigue.

In moderate anemia (Hgb 6 to 10 g/dL [60 to 100 g/L]), there is an increase in cardiopulmonary symptoms. The patient may have them while resting, as well as with activity.

In severe anemia (Hgb less than 6 g/dL [60 g/L]), the patient has many manifestations involving multiple body systems (Table 30.3).

Integumentary Manifestations

Skin manifestations include pallor, jaundice, and pruritus. Pallor results from reduced amounts of hemoglobin and reduced blood flow to the skin. Jaundice occurs when hemolysis of RBCs causes increased concentration of serum bilirubin. Hemolysis also causes pruritus because of increased serum and skin bile salt concentrations. Check the sclera of the eyes and mucous membranes for jaundice because they reflect skin changes more accurately, especially in a dark-skinned person.

Cardiopulmonary Manifestations

Cardiopulmonary manifestations of severe anemia result from the heart and lungs trying to provide adequate amounts of oxygen (O_2) to the tissues. Cardiac output is maintained by increasing the heart rate and stroke volume. The low viscosity of the blood contributes to the development of systolic murmurs and bruits. In extreme cases or when concomitant heart disease is present, angina pectoris and myocardial infarction (MI) may occur if myocardial O_2 needs cannot be met. Heart failure (HF), cardiomegaly, pulmonary and systemic congestion, ascites, and peripheral edema may develop if the heart is overworked for an extended period.

Nursing and Interprofessional Management: Anemia

This section discusses general management of anemia. Specific care related to various types of anemia is discussed later in this chapter. More information on the nursing care of the patient with anemia is presented in eNursing Care Plan 30.1.

Nursing Assessment

Subjective and objective data you should obtain from a patient with anemia are outlined in Table 30.4. Assess the patient's knowledge about adequate nutritional intake and adherence to safety precautions to prevent cardiopulmonary stress, falls, and injury.

Nursing Diagnoses

Nursing diagnoses for the patient with anemia include:

- Fatigue
- Impaired nutritional intake
- Ineffective tissue perfusion

Planning

The overall goals are that the patient with anemia will (1) assume normal activities of daily living, (2) maintain adequate nutrition, and (3) develop no complications related to anemia.

Nursing Implementation

Correcting the cause of the anemia is the goal of therapy. The many causes of anemia necessitate different nursing interventions specific to the patient's needs. Acute interventions may include blood

transfusions, drug therapy (e.g., erythropoietin, vitamin supplements), and O_2 therapy to stabilize the patient. Dietary and lifestyle changes (described in sections on specific types of anemia) can reverse some anemias.

For the patient with fatigue, encourage alternate rest and activity periods. Help the patient prioritize activities to accommodate energy levels. Arrange physical activities (e.g., avoid activity right after meals) to reduce competition for O_2 supply to vital functions. Aid with regular physical activities (e.g., ambulation, transfers, personal care) to minimize fatigue and risk for injury from falls. Monitor the patient's cardiorespiratory response to activity (e.g., tachycardia, dysrhythmias, dyspnea, diaphoresis, pallor, respiratory rate).

TABLE 30.4 Nursing AssessmentAnemia

Subjective Data
Important Health Information

Past health history: Recent blood loss or trauma; chronic liver, endocrine, or renal disease (including dialysis); GI disease (malabsorption syndrome, ulcers, gastritis, or hemorrhoids); inflammatory disorders (especially Crohn's disease); smoking, exposure to radiation or chemical toxins (arsenic, lead, benzenes, copper); infectious diseases (HIV) or recent travel with possible exposure to infection; angina, myocardial infarction; history of falling

Medications: Use of vitamin and iron supplements; aspirin, anticoagulants, oral contraceptives, phenobarbital, penicillins, nonsteroidal antiinflammatory drugs, omeprazole, phenacetin, phenytoin, sulfonamides, herbal products

Surgery or other treatments: Recent surgery, small bowel resection, gastrectomy, prosthetic heart valves, chemotherapy, radiation therapy

Dietary history: General dietary patterns, alcohol consumption

Functional Health Patterns

Health perception–health management: Family history of anemia; malaise
Nutritional-metabolic: Nausea, vomiting, anorexia, weight loss; dysphagia, dyspepsia, heartburn; night sweats, cold intolerance
Elimination: Hematuria, decreased urine output; diarrhea, constipation, flatulence, tarry stools, bloody stools
Activity-exercise: Fatigue, muscle weakness and decreased strength; dyspnea, orthopnea, cough, hemoptysis; palpitations; shortness of breath with activity
Cognitive-perceptual: Headache; abdominal, chest, and bone pain; painful tongue; paresthesias of feet and hands; pruritus; changes in vision, taste, or hearing; vertigo; hypersensitivity to cold; dizziness
Sexuality-reproductive: Menorrhagia, metrorrhagia; recent or current pregnancy; male impotence

Objective Data
General

Lethargy, apathy, general lymphadenopathy, fever

Integumentary

Pale skin and mucous membranes; blue, pale white, or icteric sclera; cheilitis (inflammation of the lips); poor skin turgor; brittle, spoon-shaped fingernails; jaundice; petechiae; ecchymoses; nose or gingival bleeding; poor healing; dry, brittle, thinning hair

Respiratory

Tachypnea

Cardiovascular

Tachycardia, systolic murmur, dysrhythmias; postural hypotension, widened pulse pressure, bruits (especially carotid); intermittent claudication, ankle edema

Gastrointestinal

Hepatosplenomegaly; glossitis; beefy, red tongue; stomatitis; abdominal distention; anorexia

Neurologic

Headache, roaring in the ears, confusion, impaired judgment, irritability, ataxia, unsteady gait, paralysis, loss of vibration sense

Possible Diagnostic Findings

↓ RBCs, ↓ Hgb; ↓ Hct; ↑ or ↓ reticulocytes, ↑ or ↓ MCV; possible ↓ serum iron, ferritin, folate, or cobalamin (vitamin B_{12}); heme-positive stools; ↓ serum erythropoietin level; ↑ or ↓ LDH, bilirubin, transferrin (Table 30.6)

Determine, in collaboration with the dietitian, the number of calories and type of nutrients needed to meet nutritional requirements. Provide information about nutritional needs and how to meet them to increase the patient's intake of essential nutrients.

Encourage increased intake of foods listed in Table 30.5 that are high in the nutrients needed for erythropoiesis.[2,3]

Gerontologic Considerations: Anemia

Modest changes in RBC mass occur in older adults. Healthy older men have a modest decline in Hgb of about 1 g/dL after age 70, in part because of the decreased production of testosterone. Only a minimal decrease in Hgb (about 0.2 g/dL) occurs in healthy women older than age 70.[1]

Anemia is not a normal finding in older adults. However, the prevalence increases starting from the seventh decade of life. For many, anemia is related to an underlying cause, such as iron deficiency, bleeding, chronic disease/inflammation, renal insufficiency, or a hematologic problem. For those with no identifiable cause, it may be due to cytokine dysregulation with aging.[3]

Manifestations of anemia in older adults may include pallor, confusion, ataxia, fatigue, and worsening cardiovascular and respiratory problems. Unfortunately, anemia may go unrecognized in older adults because we mistake these manifestations for normal aging changes or overlook them because of another health problem. By recognizing signs of anemia, you can play a key role in the care of older adults with anemia.

Anemia Caused by Decreased Erythrocyte Production

Normally RBC production (termed *erythropoiesis*) is in equilibrium with RBC destruction and loss. This balance ensures that an adequate number of RBCs is always available. The normal life span of an RBC is 120 days. There are 3 problems that lead to decreased RBC production: (1) decreased hemoglobin synthesis from iron-deficiency anemia, thalassemia, and sideroblastic anemia; (2) defective deoxyribonucleic acid (DNA) synthesis in RBCs (e.g., cobalamin deficiency, folic acid deficiency) may lead to megaloblastic anemias; and (3) diminished availability of erythrocyte precursors may result in aplastic anemia and anemia of chronic disease (Table 30.2).

Iron-Deficiency Anemia

Iron-deficiency anemia is the most common nutritional disorder in the world. Those most susceptible to iron-deficiency anemia are the very young, those on poor diets, and women in their reproductive years.[4] Normally, we lose 1 mg of iron daily in urine, bile, sweat, sloughing of epithelial cells from the skin and intestinal mucosa, and minor bleeding.[2]

Etiology

Iron-deficiency anemia may develop because of inadequate dietary intake, malabsorption, blood loss, or hemolysis. Normal dietary iron intake is usually enough to meet the needs of men and older women. It may be inadequate for people with higher iron needs (e.g., menstruating or pregnant women).

TABLE 30.5 Nutritional TherapyNutrients for Erythropoiesis

Role in Erythropoiesis	Food Sources
Amino Acids (Protein)	
Heme and plasma membrane synthesis and structure	Eggs, meat, milk and milk products (cheese, ice cream), poultry, fish, legumes, nuts, soy
Cobalamin (Vitamin B_{12})	
Synthesis of DNA, RBC maturation, facilitates folate metabolism	Meat, eggs, enriched grain products, milk and dairy foods, fish (especially salmon)
Copper	
Mobilizes iron from tissues to plasma	Shellfish, whole grains, beans, nuts, potatoes, organ meats, dark leafy greens, dried fruits
Folic Acid	
Synthesis of DNA and RNA, RBC maturation	Green leafy vegetables, enriched grain products and breakfast cereals, orange juice, peanuts, avocado
Iron	
Hemoglobin synthesis	Lean beef, turkey, pork and chicken, fish, legumes, dark green leafy vegetables, whole-grain and enriched bread and cereals, beans
Niacin	
RBC maturation	Peanut butter, beef, poultry, fish, avocado; enriched and fortified grains
Pantothenic Acid (Vitamin B_5)	
Heme synthesis	Meats, vegetables, cereal grains, legumes, eggs, milk
Pyridoxine (Vitamin B_6)	
Heme synthesis	Beef, pork, chicken, fish, fortified cereals, potatoes, bananas, nuts, beans
Riboflavin (Vitamin B_2)	
Oxidative reactions	Milk and dairy foods, enriched bread and other grain products, lean meats, eggs, green leafy vegetables
Vitamin C (Ascorbic Acid)	
Maintains iron in its ferrous form, aids in iron absorption	Citrus fruits, green leafy vegetables, strawberries, potatoes, kiwi fruit, tomatoes, green and red bell peppers
Vitamin E	
Heme synthesis. Protection against oxidative damage to RBCs	Vegetable oils, salad dressings, margarine, wheat germ, whole-grain products, seeds, nuts, peanut butter

Iron malabsorption may occur after certain types of gastrointestinal (GI) surgery and in malabsorption syndromes. Iron absorption occurs in the duodenum. So, malabsorption may occur after a surgical procedure that involves removal or bypass of the duodenum. Or, it may occur if disease of the duodenum alters or destroys the absorption surface.

Blood loss is a major cause of iron deficiency in adults. The major sources of chronic blood loss are from the GI and genitourinary (GU) systems. GI bleeding is often not obvious. It may exist for a considerable time before the problem is identified. Loss of 50 to 75 mL of blood from the upper GI tract is enough for stools to appear black *(melena).* The black color results from the iron in the RBCs.

Common causes of GI blood loss are peptic ulcer, gastritis, esophagitis, diverticula, hemorrhoids, and cancer. GU blood loss occurs primarily from menstrual bleeding. The average monthly menstrual blood loss is about 45 mL and causes the loss of about 22

mg of iron. Postmenopausal bleeding can contribute to anemia in susceptible older women. In addition to anemia of chronic kidney disease, dialysis treatment may cause iron-deficiency anemia because of the blood lost in the dialysis equipment and frequent blood sampling.

Clinical Manifestations

In the early course of iron-deficiency anemia, the patient may not have any symptoms. As the disease becomes chronic, any of the general manifestations of anemia may develop (Table 30.3). In addition, specific manifestations may occur related to iron-deficiency anemia. Pallor is the most common finding. *Glossitis* (inflammation of the tongue) is the second most common. Another finding is *cheilitis* (inflammation of the lips). The patient may report headache, paresthesias, and a burning sensation of the tongue, all of which are caused by lack of iron in the tissues.

Diagnostic Studies

Laboratory abnormalities characteristic of iron-deficiency anemia are shown in Table 30.6. Other diagnostic studies (e.g., stool occult blood test) are done to determine the cause of the iron deficiency. Endoscopy and colonoscopy may detect GI bleeding. A bone marrow biopsy may be done if other tests are inconclusive.

Interprofessional and Nursing Management

The main goal is to treat the underlying problem that is causing iron loss or reduced intake (e.g., malnutrition, alcoholism) or poor absorption of iron. We also direct efforts toward replacing iron (Table 30.7). Teach the patient which foods are good sources of iron (Table 30.5). If nutrition is already adequate, increasing iron intake by dietary means may not be enough. The patient may need oral, or occasionally, parenteral iron supplements. If the iron deficiency is from acute blood loss, the patient may need a transfusion of packed RBCs.

Drug Therapy

Oral iron is a good option because it is inexpensive and convenient. Many iron preparations are available. When giving iron, consider the following factors:

1. Iron is absorbed best from the duodenum and proximal jejunum. So, enteric-coated or sustained-release capsules, which release iron farther down in the GI tract, are counterproductive and expensive.
2. The daily dose should provide 150 to 200 mg of elemental iron. This can be taken in 3 or 4 daily doses, with each tablet or capsule of the iron preparation containing between 50 and 100 mg of iron (e.g., a 325-mg tablet of ferrous sulfate contains 65 mg of elemental iron).[3]
3. Iron is best absorbed in an acidic environment. For this reason and to avoid binding the iron with food, iron should be taken about an hour before meals, when the duodenal mucosa is most acidic. Taking iron with vitamin C (ascorbic acid) or orange juice, which contains ascorbic acid, enhances iron absorption. Gastric side effects, however, may necessitate taking iron with meals.

TABLE 30.6 Laboratory Results in Anemia

Etiology of Anemia	Hgb/Hct	MCV	Reticulocytes	Serum Iron	TIBC	Transferrin	Ferritin	Bilirubin	Serum B_{12}	Folate

MCV, Mean corpuscular volume; *N,* normal; *TIBC,* total iron-binding capacity.

TABLE 30.7 Interprofessional CareIron-Deficiency Anemia

Diagnostic Assessment

- History and physical examination
- Hgb and Hct (hematocrit) levels
- RBC count, including morphology
- Reticulocyte count
- Serum iron
- Serum ferritin
- Serum transferrin
- Total iron-binding capacity (TIBC)
- Stool examination for occult blood

Management

- Identification and treatment of underlying cause
- Drug therapy
- Oral: ferrous sulfate or ferrous gluconate
- IM or IV: iron dextran, sodium ferrous gluconate, iron sucrose
- Nutritional therapy (Table 30.5)
- Transfusion of packed RBCs

4. Undiluted liquid iron may stain the patient's teeth. Therefore it should be diluted and ingested through a straw.
5. GI side effects may occur, including heartburn, constipation,

and diarrhea. Have the patient stay upright for 30 minutes after taking oral forms. If side effects develop, the dose and type of supplement may be adjusted. For example, many people who need supplemental iron cannot tolerate ferrous sulfate because of the effects of the sulfate base. However, ferrous gluconate may be a better substitute. Tell patients that iron preparations will cause their stools to become black because the GI tract excretes excess iron. Constipation is common. The patient should start on stool softeners and laxatives, if needed, when started on iron.

Drug Alert

Iron

- Some IV iron preparations have a risk for an allergic reaction, so monitor the patient accordingly.
- Oral iron should be taken about 1 hr before meals.
- Vitamin C (ascorbic acid) enhances iron absorption.

In some situations, it may be necessary to give iron parenterally. Parenteral use of iron is indicated for malabsorption, intolerance of oral iron, a need for iron beyond oral limits, or poor patient adherence in taking the oral preparations of iron. Parenteral iron can be given IM or IV. Sodium ferrous gluconate and iron sucrose are alternatives and may carry less risk for life-threatening anaphylaxis.[3]

Because IM iron solutions may stain the skin, use separate needles for withdrawing the solution and injecting the medication. Use a Z-track injection technique.

Reassess the Hgb and RBC count to evaluate the response to therapy. Stress adherence with dietary and drug therapy. To replenish the body's iron stores, the patient needs to take iron therapy for 2 to 3 months after the Hgb level returns to normal. Monitor patients who

need lifelong iron supplementation for potential liver problems related to the iron storage.

Thalassemia

Etiology

Thalassemia is a group of diseases involving inadequate production of normal hemoglobin, which decreases RBC production. Thalassemia is due to an absent or reduced globulin protein. α-Globin chains are absent or reduced in α-thalassemia, and β-globin chains are absent or reduced in β-thalassemia. Hemolysis also occurs as most erythroblasts are destroyed by mononuclear phagocytes in the marrow.[2] Thalassemia is commonly found in members of ethnic groups whose origins are near the Mediterranean Sea and equatorial or near-equatorial regions of Southeastern Asia, the Middle East, India, Pakistan, China, Southern Russia, and Africa.[3]

Genetic Link

Thalassemia has an autosomal recessive genetic basis (see Fig. 12.4 and Table 12.2). A person with thalassemia may have a heterozygous or homozygous form of the disease. A person who is heterozygous has 1 thalassemic gene and 1 normal gene and has *thalassemia minor* (or thalassemic trait), which is a mild form of the disease. A homozygous person has 2 thalassemic genes, causing a severe condition known as *thalassemia major*.[3]

Clinical Manifestations

The patient with thalassemia minor is often asymptomatic. The patient has mild to moderate anemia with *microcytosis* (small cells) and *hypochromia* (pale cells), mild splenomegaly, bronzed color of the skin, and bone marrow hyperplasia.[2]

Thalassemia major is a life-threatening disease in which growth, both physical and mental, is often slowed. The person with thalassemia major is pale and displays other general symptoms of anemia (Table 30.3). The symptoms develop in childhood by 2 years of

age and can cause growth and developmental deficits. Jaundice from the hemolysis of RBCs is prominent. There is pronounced splenomegaly, since the spleen continuously tries to remove the damaged red cells. Hepatomegaly and cardiomyopathy may occur from iron deposition.

Informatics in Practice

Using the Internet to Access Information on Unfamiliar Diseases

- If you are assigned to take care of a patient with a disease or disorder that you are not familiar with, such as thalassemia, access a reputable source on the Internet, such as the National Institutes of Health, and do a quick search.
- Within minutes, you can learn the pathophysiology of thalassemia or other disease, treatment options, complications that you will need to monitor, and recommended medical and nursing interventions.
- Using this readily available information will help you deliver high-quality, evidence-based care.

As the bone marrow responds to the reduced O_2-carrying capacity of the blood, RBC production is stimulated. The marrow becomes packed with immature erythroid precursors that die. This stimulates further erythropoiesis, leading to chronic bone marrow hyperplasia and expansion of the marrow space. This may cause thickening of the cranium and maxillary cavity. Thrombocytosis after spleen dysfunction and/or removal may occur.

Cardiac complications from iron overload, lung disease, and hypertension also contribute to early death. Endocrine problems (diabetes, growth retardation, hypogonadism), osteoporosis, pulmonary hypertension, and thrombosis may be present.[1]

Interprofessional Care

The laboratory abnormalities of thalassemia major are outlined in Table 30.6. No specific drug or diet therapies are effective in treating thalassemia. Thalassemia minor does not need treatment because the body adapts to the reduction of normal hemoglobin.

Thalassemia major is managed with blood transfusions or exchange transfusions in conjunction with chelating agents that bind to iron. Transfusions are given to keep the Hgb level around 10 g/dL (100 g/L), depending on the manifestations.[1] Chelating agents reduce the iron overloading that occurs with chronic transfusion therapy. Drugs used include oral deferasirox (Exjade, JadeNu) or deferiprone (Ferriprox), or IV or subcutaneous deferoxamine (Desferal).[1] Ascorbic acid supplements may be needed during chelation therapy, since they increase urine excretion of iron. Ascorbic acid should only be taken with chelation therapy because it increases the absorption of dietary iron. It is given, along with folic acid, if there is evidence of hemolysis. Zinc supplements may be needed since zinc is reduced with chelation therapy. Iron supplements should not be given.

Because RBCs are sequestered in the enlarged spleen, the patient may need a splenectomy. Hepatic, heart, and lung function are monitored and treated as needed.

Although hematopoietic stem cell transplantation (HSCT) is the only cure for patients with thalassemia, the risk of this procedure may outweigh its benefits. With proper iron chelation therapy, patients are living longer.

TABLE 30.8 Causes of Megaloblastic Anemia

Cobalamin (Vitamin B_{12}) Deficiency

- Chronic alcoholism
- Dietary deficiency

- Deficiency of gastric intrinsic factor
    - Celiac disease
    - Gastrectomy
    - Gastric bypass
    - *Helicobacter pylori*
    - Pernicious anemia
- Increased requirement (pregnancy)
- Intestinal malabsorption

Folic Acid Deficiency

- Chronic alcoholism
- Chronic hemodialysis (folic acid lost during dialysis)
- Dietary deficiency (e.g., leafy green vegetables, citrus fruits)
- Drugs interfering with absorption or use of folic acid
    - Methotrexate
    - Antiseizure drugs (e.g., phenobarbital, phenytoin)
- Increased requirement (pregnancy)
- Malabsorption syndromes
    - Celiac disease
    - Crohn's disease
    - Small bowel resection

Drug-Induced Suppression of DNA Synthesis

- Alkylating agents
- Folate antagonists
- Metabolic inhibitors

Inborn Errors

- Defective folate metabolism
- Defective transport of cobalamin

Erythroleukemia

Megaloblastic Anemias

Megaloblastic anemias are a group of disorders caused by impaired DNA synthesis and characterized by the presence of large RBCs. When DNA synthesis is impaired, defective RBC maturation results. The RBCs are large *(macrocytic)* and abnormal. We call them *megaloblasts.* Macrocytic RBCs are easily destroyed because they have fragile cell membranes. Most megaloblastic anemias result from cobalamin (vitamin B_{12}) and folic acid deficiencies. They can also occur from congenital disorders, suppression of DNA synthesis by drugs, inborn errors of cobalamin and folic acid metabolism, and *erythroleukemia* (malignant blood disorder characterized by a proliferation of erythropoietic cells in bone marrow) (Table 30.8).[5]

Cobalamin Deficiency

The most common cause of cobalamin deficiency is **pernicious anemia**. It is caused by an absence of *intrinsic factor* (IF). Pernicious anemia is a disease of insidious onset. It begins in middle age or later (usually after age 40), with 60 years being the most common age at diagnosis. Pernicious anemia occurs most often in persons of Northern European ancestry (particularly Scandinavians) and blacks.[1]

Etiology

Normally, the parietal cells of the gastric mucosa secrete a protein termed *IF.* IF is required for cobalamin (extrinsic factor) absorption. Cobalamin is normally absorbed in the distal ileum. Without IF, cobalamin will not be absorbed. In pernicious anemia, the gastric mucosa is not secreting IF because of either gastric mucosal atrophy or autoimmune destruction of parietal cells. In the autoimmune process, antibodies are directed against the gastric parietal cells and/or IF itself. Because parietal cells also secrete hydrochloric acid (HCl), in pernicious anemia there is a decrease in HCl in the stomach. An acid

environment in the stomach is required for the secretion of IF.

Cobalamin deficiency can occur in patients who have had GI surgery (e.g., gastrectomy, gastric bypass); patients who have had a small bowel resection involving the ileum; and patients with Crohn's disease, ileitis, celiac disease, diverticula of the small intestine, or chronic atrophic gastritis (Table 30.8). In these cases, cobalamin deficiency results from the loss of IF-secreting gastric mucosal cells or impaired absorption of cobalamin in the distal ileum. Cobalamin deficiency also occurs with excess alcohol or hot tea ingestion, smoking, long-term users of H_2-histamine receptor blockers and proton pump inhibitors, and those who are strict vegetarians.[2]

There is a familial predisposition for pernicious anemia, so evaluate patients who have a positive family history of pernicious anemia for symptoms. Although the disease cannot be prevented, early detection and treatment can lead to reversal of symptoms.

Clinical Manifestations

General manifestations of anemia related to cobalamin deficiency develop because of tissue hypoxia (Table 30.3). GI manifestations include a sore, red, beefy, and shiny tongue; anorexia, nausea, and vomiting; and abdominal pain. Typical neuromuscular manifestations include weakness, paresthesias of the feet and hands, reduced vibratory and position senses, ataxia, muscle weakness, and impaired thought processes ranging from confusion to dementia. Because cobalamin deficiency–related anemia has an insidious onset, it may take several months for manifestations to develop.

Diagnostic Studies

Laboratory data reflective of cobalamin-deficiency anemia are outlined in Table 30.6. The RBCs appear large (macrocytic) and have abnormal shapes. This structure contributes to RBC destruction because the cell membrane is fragile. Serum cobalamin levels are low.

Serum folate levels are reviewed. If they are normal and cobalamin

levels are low, it suggests that megaloblastic anemia is due to a cobalamin deficiency. A serum test for anti-IF antibodies may be done that is specific for pernicious anemia. Patients with pernicious anemia have an increased risk for gastric cancer. They may undergo an upper GI endoscopy and biopsy of the gastric mucosa at the time of diagnosis and at appropriate intervals afterward.

Testing of serum methylmalonic acid (MMA) (high in cobalamin deficiency) and serum homocysteine (high in both cobalamin and folic acid deficiencies) helps determine the cause of this type of anemia.

Interprofessional and Nursing Management

If IF is lacking or if absorption in the ileum is impaired, the patient will not be able to absorb cobalamin regardless of how much they ingest. For this reason, increasing dietary cobalamin does not correct this anemia. Parenteral vitamin B_{12} (cyanocobalamin, hydroxocobalamin) or intranasal cyanocobalamin (Nascobal) is needed. Without cobalamin administration, the patient will die in 1 to 3 years. A typical treatment schedule consists of 1000 mcg/day of cobalamin IM for 2 weeks and then weekly until the hemoglobin is normal and then monthly for life.

High-dose oral cobalamin and sublingual cobalamin are options for those in whom GI absorption is intact.

The nursing measures discussed in eNursing Care Plan 30.1 for the patient with anemia are appropriate for the patient with cobalamin-deficiency anemia. In addition to these measures, assess for neurologic difficulties that are not fully corrected by replacement therapy. Implement measures to reduce the risk for injury from the decreased sensitivity to heat and pain related to neurologic impairment. Protect the patient from falling, burns, and trauma. In some people, the neuromuscular complications may not be reversible and physical therapy may be needed.

Folic Acid Deficiency

Folic acid (folate) deficiency also causes megaloblastic anemia. Folic acid

is needed for DNA synthesis leading to RBC formation and maturation. Common causes of folic acid deficiency are listed in Table 30.8.

The manifestations of folic acid deficiency are similar to those of cobalamin deficiency. The disease develops insidiously. The patient's symptoms may be attributed to other coexisting problems (e.g., cirrhosis, esophageal varices). GI problems may include stomatitis, cheilosis, dysphagia, flatulence, and diarrhea. Thiamine deficiency, which is often present with folate deficiency, can cause neurologic symptoms.[2]

The diagnostic findings for folic acid deficiency are shown in Table 30.6. The serum folate level is low (normal is 5 to 25 ng/mL [11 to 57 nmol/L]), with a normal serum cobalamin level.

We treat folic acid deficiency with replacement therapy. The usual dosage is 1 mg/day by mouth. The patient with malabsorption or chronic alcoholism may need up to 5 mg/day. The duration of treatment depends on the reason for the deficiency. Teach the patient to eat foods high in folic acid (Table 30.5). The nursing measures discussed in eNursing Care Plan 30.1 for the patient with anemia are appropriate for the patient with folic acid deficiency anemia.

Anemia of Chronic Disease

Anemia of chronic disease (also called *anemia of inflammation*) can be caused by cancer, autoimmune and infectious disorders (human immunodeficiency virus [HIV], hepatitis, malaria), HF, or chronic inflammation. Bleeding episodes can contribute to anemia of chronic disease.

Anemia of chronic disease is associated with an underproduction of RBCs and mild shortening of RBC survival. The RBCs are usually normocytic, normochromic, and hypoproliferative. The anemia is usually mild. It can become more severe if the underlying disorder is not treated.

This type of anemia, which usually develops after 1 to 2 months of disease activity, has an immune basis. The cytokines released in these conditions, particularly interleukin-6 (IL-6), cause an increased uptake and retention of iron within macrophages (see Fig. 29.3). This leads to a diversion of iron from circulation into storage sites with subsequent limited iron available for erythropoiesis. There is reduced RBC life span, suppressed production of erythropoietin, and an ineffective bone marrow response to erythropoietin. We think cytokine dysregulation may be the cause of this type of anemia in elderly and obese patients when no other cause can be found.[6]

For any chronic disease, other factors may contribute to the anemia. For example, with renal disease, the primary factor causing anemia is decreased erythropoietin, a hormone made in the kidneys that stimulates erythropoiesis. With impaired renal function, erythropoietin production is decreased (see Chapter 46).

Anemia of chronic disease must first be recognized and distinguished from anemia of other causes. High serum ferritin and increased iron stores distinguish it from iron-deficiency anemia. Normal folate and cobalamin blood levels distinguish it from megaloblastic anemias from folate and cobalamin deficiencies.

The best treatment of anemia of chronic disease is to correct the underlying disorder. If the anemia is severe, blood transfusions may

be needed, but they are not recommended for long-term treatment. Erythropoietin therapy is used for anemia related to renal disease (see Chapter 46) and cancer and its therapies (see Chapter 15). Its use is limited, though, because of the increased risk for thromboembolism and death in some patients.

Aplastic Anemia

Aplastic anemia is a disease in which the patient has peripheral blood *pancytopenia* (decrease of all blood cell types—RBCs, white blood cells [WBCs], and platelets) and hypocellular bone marrow. The spectrum can range from a moderate condition managed with erythropoietin or blood transfusions to very severe with potentially fatal hemorrhage and sepsis. The incidence of aplastic anemia is rare, with an annual rate of 2 to 5 new cases per million per year.[3]

Etiology

About 70% of aplastic anemias are due to autoimmune activity by autoreactive T lymphocytes. [3] The cytotoxic T cells target and destroy the patient's own hematopoietic stem cells. Other anemias may be acquired from toxic injury to bone marrow stem cells or result from an inherited stem cell defect (Table 30.9).

Clinical Manifestations

Aplastic anemia can manifest abruptly (over days) or insidiously over weeks to months. It can vary from mild to very severe. The patient may have symptoms caused by suppression of any or all bone marrow elements. General manifestations of anemia, such as fatigue and dyspnea, as well as cardiovascular and cerebral responses, may be seen (Table 30.3). The patient with neutropenia (low neutrophil count) is susceptible to infection and is at risk for septic shock and death. Thrombocytopenia is manifested by a predisposition to bleeding (e.g., petechiae, bruising, nosebleeds).

TABLE 30.9 Causes of Aplastic Anemia

- Chemical agents and toxins (e.g., benzene, insecticides, arsenic, alcohol)
- Drugs (e.g., alkylating agents, antiseizure drugs, antimetabolites, antimicrobials, gold, nonsteroidal antiinflammatory drugs, antithyroid medications, allopurinol)
- Immune suppression of stem cells by autoreactive T-lymphocytes
- Inherited stem cell defect (e.g., Fanconi anemia)
- Radiation
- Toxic injury to bone marrow stem cells
- Viral and bacterial infections

Diagnostic Studies

Laboratory studies confirm the diagnosis. Because aplastic anemia affects all marrow elements, hemoglobin, WBC, and platelet values are decreased. Other RBC indices are generally normal (Table 30.6). The condition is therefore classified as a normocytic, normochromic anemia. The reticulocyte count is low.

We can further evaluate aplastic anemia by assessing various iron studies. The serum iron and total iron-binding capacity (TIBC) may be high as initial signs of erythropoiesis suppression. Bone marrow biopsy, aspiration, and pathologic examination may be done. The marrow in aplastic anemia is hypocellular with increased yellow marrow (fat content).

Interprofessional and Nursing Management

Management of aplastic anemia is based on identifying and removing the causative agent (when possible) and providing supportive care until the pancytopenia reverses. Nursing interventions appropriate for the patient with pancytopenia from aplastic anemia are discussed in eNursing Care Plan 30.1 for anemia, eNursing Care Plan 30.2 for thrombocytopenia, and eNursing Care Plan 30.3 for neutropenia (available on the website for this chapter). Nursing actions are directed at preventing complications from infection and hemorrhage.

The prognosis of severe untreated aplastic anemia is poor. However, advances in medical management, including HSCT and immunosuppressive therapy with antithymocyte globulin (ATG), steroids, and cyclosporine or cyclophosphamide, have improved outcomes significantly.[7] ATG is a horse serum that contains polyclonal antibodies against human T cells. ATG and cyclosporine are discussed in Chapter 13. Eltrombopag (Promacta), an oral thrombopoietin receptor agonist, can increase platelet counts. High-dose cyclophosphamide, alemtuzumab, or androgens may be helpful in select patients who do not respond to other therapies.[1]

The treatment of choice for adults younger than 55 years of age who do not respond to the immunosuppressive therapy and who have a human leukocyte antigen (HLA)–matched, half-matched, or unrelated donor, is an HSCT.[7] The best results occur in younger patients who have not had previous blood transfusions. Prior transfusions increase the risk for graft rejection. HSCT is discussed in Chapter 15.

For older adults without a donor, the treatment of choice is immunosuppression with ATG and cyclosporine, steroids, and eltrombopag.[3] Patients who need ongoing supportive blood transfusion should be on an iron-binding agent to prevent iron overload.

Anemia Caused by Blood Loss

An acute or chronic problem can cause anemia from blood loss.

Acute Blood Loss

Acute blood loss occurs because of sudden hemorrhage. Causes of acute blood loss include trauma, complications of surgery, and conditions or diseases that disrupt vascular integrity. There are 2 clinical concerns in such situations. First, a sudden reduction in the total blood volume can lead to hypovolemic shock. Second, if the acute loss is more gradual, the body maintains its blood volume by slowly increasing the plasma volume. Although this preserves circulating fluid volume, the number of RBCs available to carry O_2 is significantly decreased.

TABLE 30.10 Manifestations of Acute Blood Loss

Volume Lost*		
%	mL	Manifestations
10	500	None or rare vasovagal syncope
20	1000	No detectable signs or symptoms at rest. Tachycardia with exercise and slight postural hypotension
30	1500	Normal supine blood pressure and pulse at rest. Postural hypotension and tachycardia with exercise
40	2000	BP, central venous pressure, and cardiac output below normal at rest; air hunger; rapid, thready pulse and cold, clammy skin
50	2500	Shock, lactic acidosis, and potential death

* Based on an adult with a total blood volume of 5 L.

Clinical Manifestations

The manifestations of anemia from acute blood loss are caused by the body's attempts to maintain an adequate blood volume and meet O_2 requirements. Table 30.10 outlines the manifestations of patients with varying degrees of blood volume loss. It is essential to understand that the signs and symptoms the patient has are more important than the laboratory values. For example, an adult with a bleeding peptic ulcer who had a 750-mL hematemesis (15% of a normal total blood volume) within the past 30 minutes may have postural hypotension

but have normal values for hemoglobin and hematocrit. Over the next 36 to 48 hours, most of the blood volume deficit will be replaced by the movement of fluid from the extravascular into the intravascular space. Only then will the hemoglobin and hematocrit reflect the blood loss.

Assess the patient's expression of pain. Internal hemorrhage may cause pain because of tissue distention, organ displacement, and nerve compression. Pain may be localized or referred. In the case of retroperitoneal bleeding, the patient may not have abdominal pain. Instead the patient may have numbness and pain in a lower extremity from compression of the lateral cutaneous nerve, which is in the region of the first to third lumbar vertebrae. The major complication of acute blood loss is shock (see Chapter 66).

Diagnostic Studies

When blood volume loss is sudden, plasma volume has not yet had a chance to increase. The loss of RBCs is not reflected in laboratory data, and values may seem normal or high for 2 to 3 days. However, once the plasma volume is replaced, the RBC mass is less concentrated. Then, RBC, hemoglobin, and hematocrit levels are low and reflect the actual blood loss.

Interprofessional and Nursing Management

Interprofessional care is initially concerned with (1) replacing blood volume to prevent shock and (2) finding the source of the hemorrhage and stopping the blood loss. IV fluids used in emergencies include dextran, hetastarch, albumin, and crystalloid electrolyte solutions, such as lactated Ringer's solution. The amount of infusion varies with the solution used. Blood transfusions (packed RBCs) can be used depending on the volume lost. If a large volume of blood is lost, platelets, plasma, and cryoprecipitate may be needed because large volumes of RBCs dilutes the patient's own coagulation system. (See more on managing shock in Chapter 66.)

The body needs 2 to 5 days to make more RBCs in response to

increased erythropoietin. The patient may need supplemental iron because the availability of iron affects the marrow production of RBCs. When anemia exists after acute blood loss, dietary sources of iron will probably not be enough to maintain iron stores. Therefore oral or parenteral iron preparations are given.

In the case of trauma, it may be impossible to prevent blood loss. For the postoperative patient, carefully monitor the blood loss from various drainage tubes and dressings and implement appropriate actions. The nursing care for the patient with anemia resulting from acute blood loss will likely include giving blood products (described at the end of this chapter on pp. 647–651).

The anemia should begin to correct itself once the source of hemorrhage is found, blood loss is controlled, and fluid and blood volumes are replaced. There should be no need for long-term treatment of this type of anemia.

Chronic Blood Loss

The sources of chronic blood loss are similar to those of iron-deficiency anemia (e.g., bleeding ulcer, hemorrhoids, menstrual and postmenopausal blood loss). The effects of chronic blood loss are usually related to the depletion of iron stores and considered an iron-deficiency anemia. Management of chronic blood loss anemia involves identifying the source and stopping the bleeding. Supplemental iron may be needed.

Anemia Caused by Increased Erythrocyte Destruction

The third major cause of anemia is **hemolytic anemia**, a condition caused by the destruction or hemolysis of RBCs at a rate that exceeds production. Hemolysis can occur because of problems intrinsic or extrinsic to the RBCs. *Intrinsic hemolytic anemias,* which are usually hereditary, result from defects in the RBCs themselves (Table 30.2).

More common are the *acquired hemolytic anemias*. In this type of anemia, the RBCs are normal, but external factors are causing damage (Table 30.2). Macrophages, particularly those in the spleen, liver, and bone marrow, destroy RBCs that are old, defective, or moderately damaged. Fig. 30.2 shows the sequence of events involved in extravascular hemolysis.

The patient with hemolytic anemia has the general manifestations of anemia and specific manifestations related to this type of anemia (Table 30.3). Jaundice is likely because the increased destruction of RBCs causes an elevation in bilirubin levels. The spleen and liver may enlarge because of their hyperactivity, which is related to macrophage phagocytosis of the defective RBCs.

In all causes of hemolysis, a major focus of treatment is to maintain renal function. When RBCs are hemolyzed, the hemoglobin molecule is released and filtered by the kidneys. The accumulation of hemoglobin molecules can obstruct the renal tubules and lead to acute tubular necrosis (see Chapter 46).

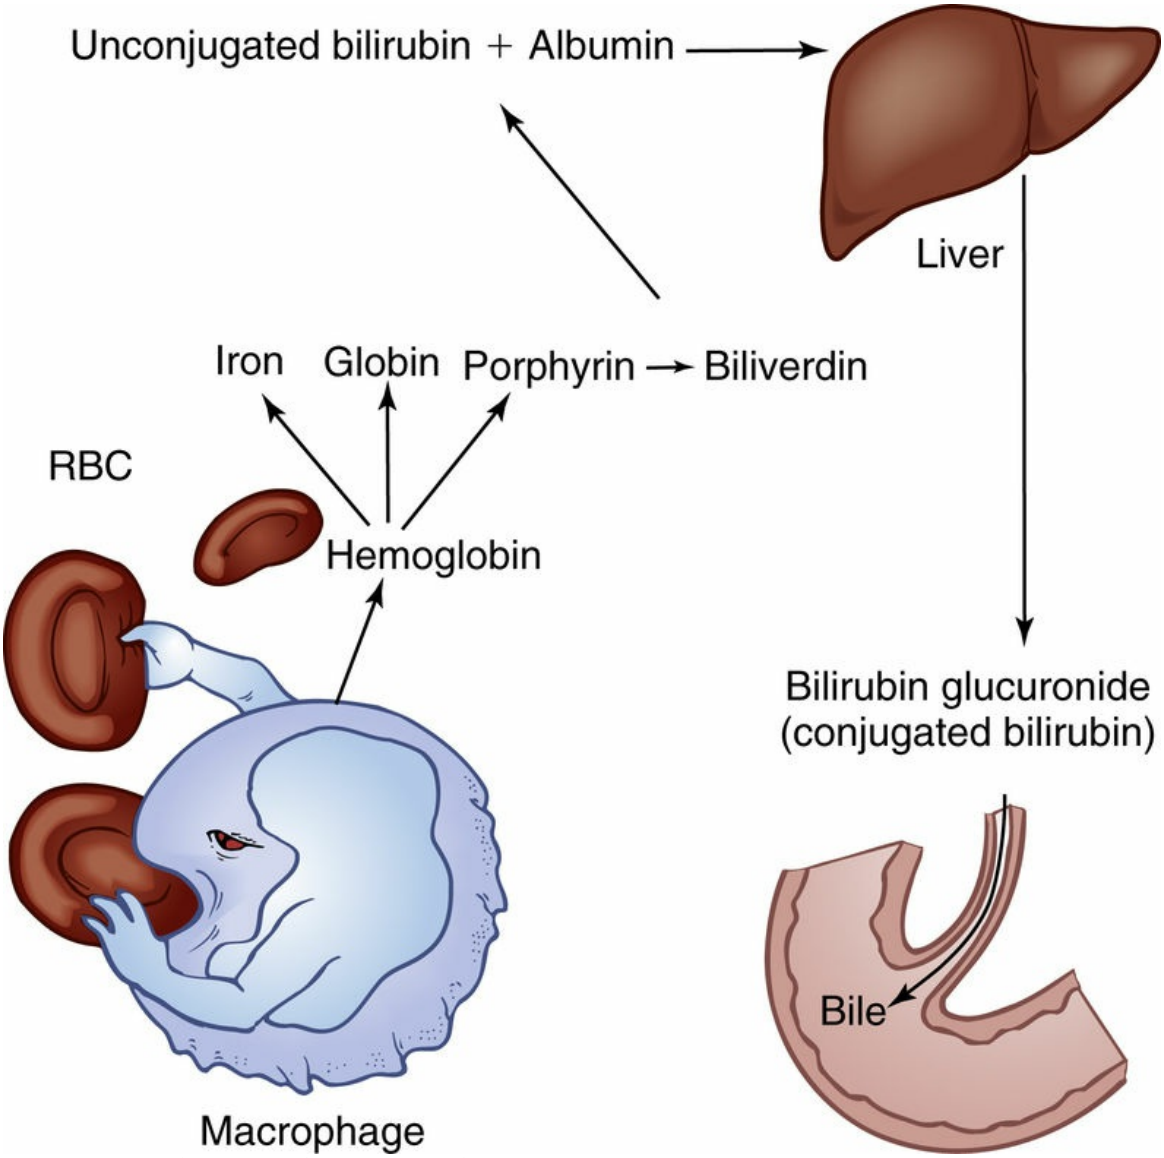

FIG. 30.2 Sequence of events in extravascular hemolysis.

Sickle Cell Disease

Sickle cell disease (SCD) is a group of inherited, autosomal recessive disorders characterized by an abnormal form of hemoglobin in the RBC. Because this is a genetic disorder, SCD is usually found during routine neonatal screening. Although median survival can now exceed 45 years old, the disease often results in irreversible damage of the lungs, kidneys, brain, retina, or bones that significantly affects patients' quality of life.[8]

Etiology and Pathophysiology

Genetic Link

In SCD, the abnormal hemoglobin, *hemoglobin S* (Hgb S), results from the substitution of valine for glutamic acid on the β-globin chain of hemoglobin (see Fig. 12.3). Hgb S causes the RBC to stiffen and elongate, taking on a sickle shape in response to low O_2 levels (Fig. 30.3).

Types of SCD disorders include sickle cell anemia, sickle cell–thalassemia, sickle cell Hgb C disease, and sickle cell trait. *Sickle cell anemia* is the most severe of the SCD syndromes. It occurs when a person is homozygous for hemoglobin S (Hgb SS), meaning the person has inherited Hgb S from both parents. *Sickle cell–thalassemia* and *sickle cell Hgb C* occur when a person inherits Hgb S from one parent and another type of abnormal hemoglobin (such as thalassemia or Hgb C) from the other parent. Both these forms of SCD are less common and less severe than sickle cell anemia. *Sickle cell trait* occurs when a person is heterozygous for hemoglobin S (Hgb AS). This means the person has inherited hemoglobin S from one parent and normal hemoglobin (Hgb A) from the other parent. Sickle cell trait is typically a mild to asymptomatic condition.

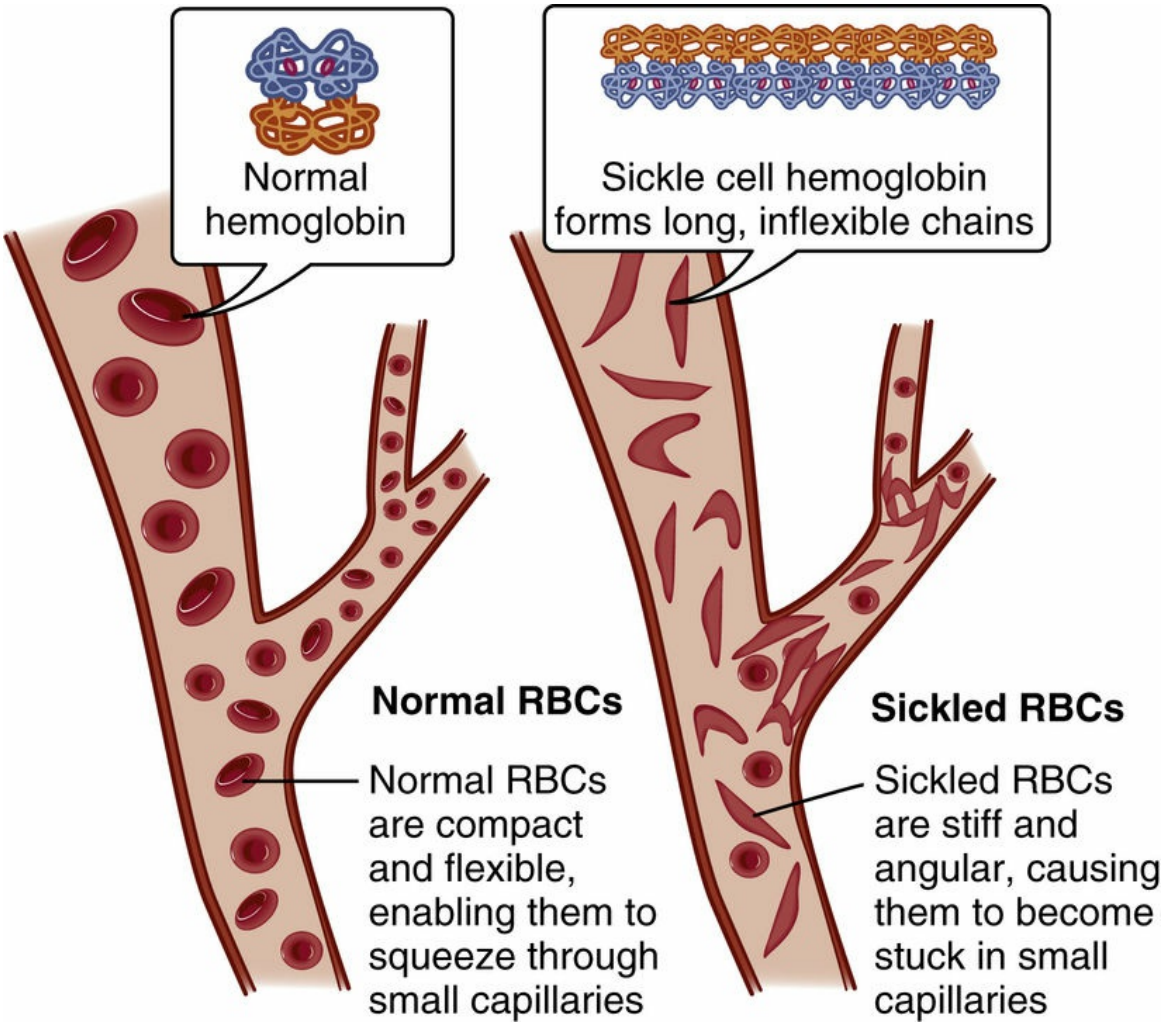

FIG. 30.3 In sickle cell, the hemoglobin forms long inflexible chains and alters the shape of the red blood cells (RBCs). The sickled RBCs can become stuck in the capillaries and occlude the blood flow.

Genetics in Clinical Practice

Sickle Cell Disease[9]

Genetic Basis

- Autosomal recessive disorder
- Mutation in β-globin *(HBB)* gene found on chromosome 11

- Various versions of β-globin result from different mutations in the *HBB* gene
- Hgb S variant involves substitution of valine for glutamic acid in the β-globin gene

Incidence

- Most common inherited blood disorder in the United States
- Affects about 100,000 Americans
- Occurs in about 1 of every 365 African American births
- Occurs in about 1 of every 16,300 Hispanic American births
- Affects people of Mediterranean, Caribbean, Arabian, and East Indian descent
- 1 in 13 African American babies is born with sickle cell trait

Genetic Testing

- DNA testing is available
- Electrophoresis of hemoglobin and sickling screening test are most often used

Clinical Implications

- Sickle cell trait is the carrier state for SCD and is a mild type of SCD
- If both parents have the trait, there is a 1 in 4 chance that their baby will have SCD
- Genetic counseling is recommended for people with a family history of SCD so they can understand the risks for transmitting the genetic mutation

Sickling Episodes

The major pathophysiologic event of SCD is the sickling of RBCs (Fig. 30.3). Sickling episodes are most often triggered by low O_2 tension in the blood. Hypoxia or deoxygenation of the RBCs can be caused by viral or bacterial infection, high altitude, emotional or physical stress, surgery, and blood loss. Infection is the most common precipitating factor. Other events that can trigger or sustain a sickling episode include dehydration, increased hydrogen ion concentration (acidosis), increased plasma osmolality, decreased plasma volume, and low body temperature. A sickling episode can also occur without an obvious cause.

Sickled RBCs become rigid and take on an elongated, crescent shape (Fig. 30.3). Sickled cells cannot easily pass through capillaries or other small vessels and can cause vascular occlusion, leading to acute or chronic tissue injury. The resulting hemostasis promotes a self-perpetuating cycle of local hypoxia, deoxygenation of more RBCs, and more sickling. Circulating sickled cells are hemolyzed by the spleen, leading to anemia. At first, sickling is reversible with reoxygenation. It eventually becomes irreversible because of cell membrane damage from recurrent sickling. Vaso-occlusive phenomena and hemolysis are the clinical hallmarks of SCD.

Sickle cell crisis is a severe, painful, acute exacerbation of RBC sickling, causing a vaso-occlusive crisis. As sickled cells impair blood flow, vasospasm occurs, further restricting blood flow. Severe capillary hypoxia causes changes in membrane permeability, leading to plasma loss, hemoconcentration, thrombi, and further circulatory stagnation. Tissue ischemia, infarction, and necrosis eventually occur from lack of O_2. Shock is a possible life-threatening consequence of sickle cell crisis because of severe O_2 depletion of the tissues and a reduction of the circulating fluid volume. Sickle cell crisis can begin suddenly and persist for days to weeks.

The frequency, extent, and severity of sickling episodes are highly variable and unpredictable. They depend on the percent of Hgb S present. People with sickle cell anemia have the most severe form because the RBCs have a high percent of Hgb S.

Clinical Manifestations

The effects of SCD vary from person to person, the severity of which may be due to genetic variants. Many people with sickle cell anemia are in reasonably good health most of the time. However, they may have chronic health problems and pain because of organ tissue hypoxia and damage (e.g., involving the kidneys or liver).

The typical patient is anemic but asymptomatic except during sickling episodes. Because most people with sickle cell anemia have dark skin, pallor is easier to detect by examining the mucous membranes. The skin may have a grayish cast. Because of the hemolysis, jaundice is common, and patients are prone to gallstones (cholelithiasis).

The main symptom associated with sickling is pain. The pain severity can range from trivial to excruciating. During sickle cell crisis, the pain is severe because of ischemia of tissue. The episodes can affect any area of the body or several sites simultaneously. The back, chest, extremities, and abdomen are affected most often. Pain episodes are often accompanied by other manifestations, such as fever, swelling, tenderness, tachypnea, hypertension, nausea, and vomiting.

Complications

With repeated episodes of sickling, there is gradual involvement of all body systems, especially the spleen, lungs, kidneys, and brain. Organs that need large amounts of O_2 are most often affected and form the basis for many of the complications of SCD (Fig. 30.4). Infection is a major cause of morbidity and mortality in patients with SCD. One reason for this is the failure of the spleen to phagocytize foreign substances as it becomes infarcted and dysfunctional (usually by 2 to 4 years of age) from the sickled RBCs. The spleen becomes small because of repeated scarring, a phenomenon termed *autosplenectomy*.

Pneumonia is the most common infection and often is of pneumococcal origin. Infections can be so severe that they cause an aplastic and hemolytic crisis and gallstones. *Aplastic crisis* can be so severe that it causes a temporary shutdown of RBC production in the

bone marrow.

Acute chest syndrome is a term used to describe acute pulmonary complications that include pneumonia, tissue infarction, and fat embolism. It is characterized by fever, chest pain, cough, lung infiltrates, and dyspnea. Pulmonary infarctions may cause pulmonary hypertension, MI, and cor pulmonale. The heart may become ischemic and enlarged, leading to HF. Retinal vessel obstruction may result in hemorrhage, scarring, retinal detachment, and blindness. The increased blood viscosity and the lack of O_2 can injure the kidneys. Renal failure may occur. Pulmonary embolism or stroke can result from thrombosis and infarction of cerebral blood vessels. Bone changes may include osteoporosis and osteosclerosis after infarction. Chronic leg ulcers can result from the hypoxia and are especially prevalent around the ankles. *Priapism* (persistent penile erection) may occur if penile veins become occluded.

Diagnostic Studies

A peripheral blood smear may reveal sickled cells and increased, abnormal reticulocytes. Hemoglobin electrophoresis may be done to determine the amount of hemoglobin S and SCD from other variants.

Because of the accelerated RBC breakdown, the patient has characteristic findings of hemolysis (jaundice, high serum bilirubin levels) and abnormal laboratory test results (Table 30.6). Skeletal x-rays show bone and joint deformities and flattening. MRI can diagnose a stroke caused by blocked cerebral vessels from sickled cells. Doppler studies can assess for deep vein thromboses (DVT). A chest x-ray can diagnose infection or organ malfunction.

Interprofessional and Nursing Management

Interprofessional care for a patient with SCD is directed toward (1) preventing sequelae from the disease; (2) alleviating the manifestations from the complications of the disease; (3) minimizing end-organ damage; and (4) continuously assessing for and promptly treating serious sequelae, such as acute chest syndrome, that can lead

to immediate death.[8]

A patient in sickle cell crisis may need hospitalization. O_2 therapy treats hypoxia and controls sickling. Assess for any changes in respiratory status and encourage incentive spirometry. Rest can reduce metabolic requirements. DVT prophylaxis (using anticoagulants) should be prescribed. Fluids are given to reduce blood viscosity and maintain renal function. Priapism is managed with pain medication, fluids, and nifedipine (Procardia). If it does not resolve within a few hours, a urologist may be called.[10]

Transfusion therapy is indicated when an aplastic crisis occurs. Aggressive RBC exchange transfusion programs may be implemented for patients who have frequent crises or serious complications, such as acute chest syndrome. These patients, like those with thalassemia major, may need iron chelation therapy to reduce transfusion-produced iron overload.

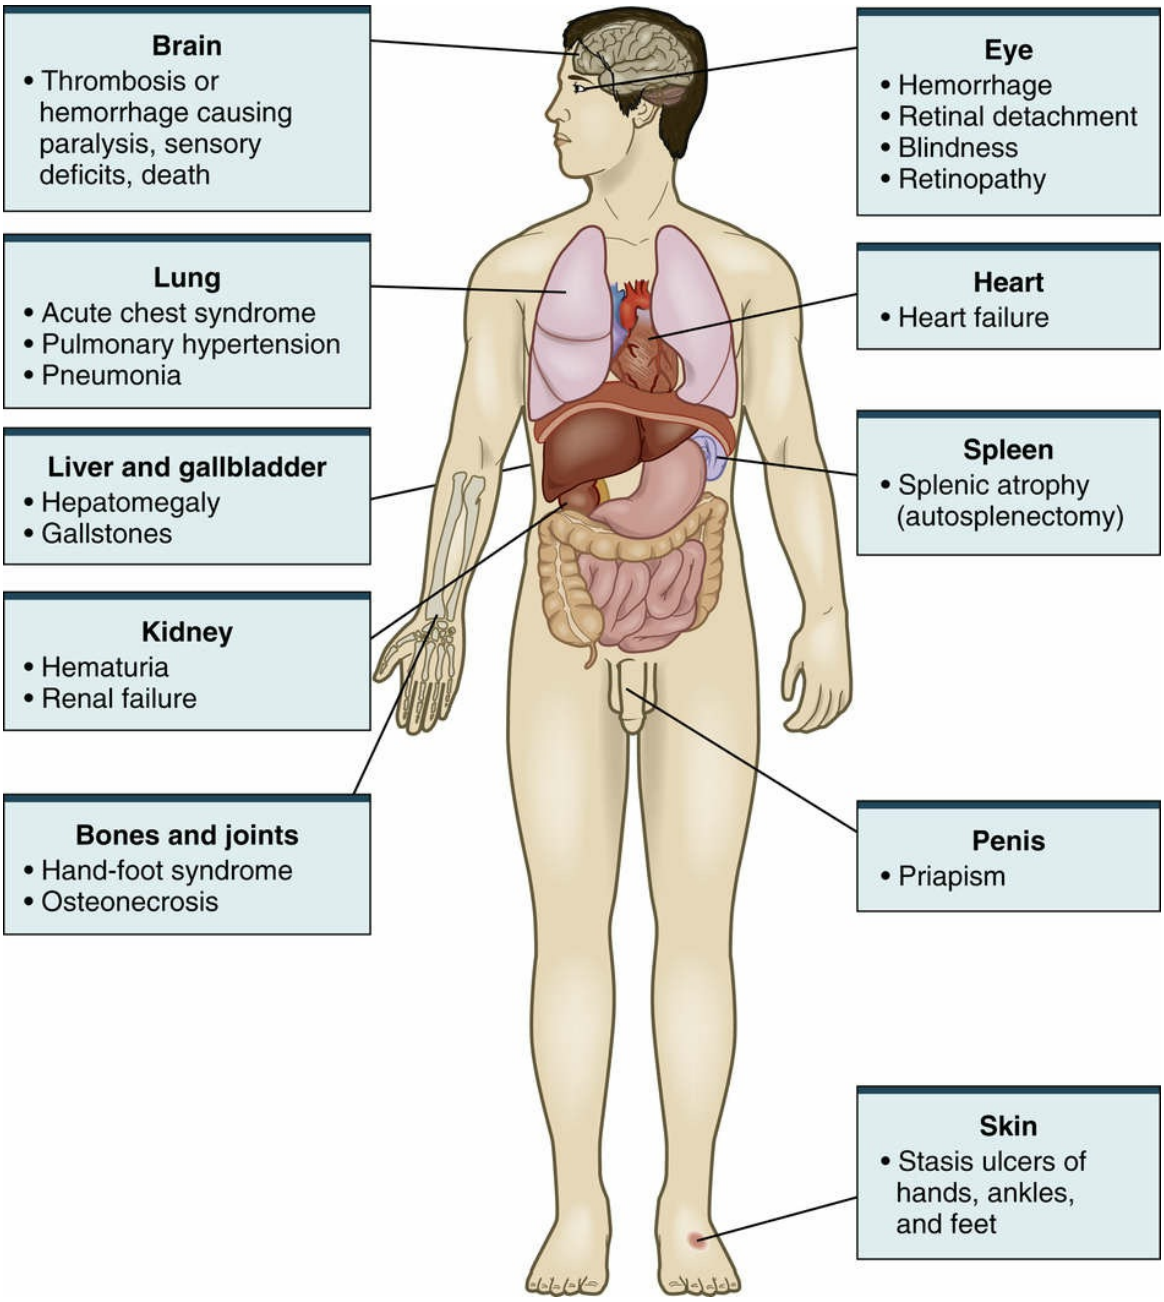

FIG. 30.4 Clinical manifestations and complications of sickle cell disease.
Modified from McCance KL, Huether SE: *Pathophysiology: The biologic basis for disease in adults and children*, ed 7, St Louis, 2014, Mosby.

Check Your Practice

A 21-year-old African American woman was just admitted to the

emergency department (ED) after a ski trip to Colorado. She is in excruciating pain in her chest and abdomen. She is short of breath and her O_2 saturation is 86%. Your examination reveals that her heart rate is 110 bpm and respiratory rate 28/minute. She has crackles in the lungs. She has had 6 previous ED admissions for sickle cell crises.

- What are your priorities for her nursing care?

Undertreatment of sickle cell pain is a major problem. Lack of understanding can lead HCPs to underestimate the severity of acute and chronic pain. SCD patients may develop tolerance, and larger doses of pain medication may be needed to reduce pain to a tolerable level. During an acute crisis, optimal pain control usually includes large doses of continuous (rather than as-needed) opioid analgesics, along with breakthrough analgesia, often in the form of patient-controlled analgesia (PCA). Morphine and hydromorphone are the drugs of choice.

Because patients may be having different types and sites of pain, as well as acute and chronic pain, a holistic approach should be used that addresses the pain and its impact on the patient's quality of life (see Chapter 8).[8] In addition to opioids, adjunctive measures, such as nonsteroidal antiinflammatory agents, antineuropathic pain drugs (e.g., antidepressants, antiseizure drugs), local anesthetics, or nerve blocks may be used. Occupational and physical therapy can optimize functioning. Referral to social and chaplain services can help address social, emotional, and spiritual needs.

Infection is a frequent complication. Any febrile illness in a patient with SCD is an emergency. Infections, such as chronic leg ulcers, may be treated with rest, antibiotics, warm saline soaks, mechanical or enzyme debridement, and grafting, if needed. Patients with acute chest syndrome are treated with broad-spectrum antibiotics, O_2 therapy, fluid therapy, and possibly exchange transfusion. Blood transfusions are done sparingly between crises since patients develop antibodies to RBCs and iron overload. Because chronic hemolysis results in increased use of folic acid stores, the patient should take an

oral folic acid supplement.

Hydroxyurea (Hydrea) is the only medication that is clinically beneficial. This drug increases the production of hemoglobin F (fetal hemoglobin) and alters the adhesion of sickled RBCs to the endothelium. The increase in Hgb F is accompanied by a reduction in hemolysis, an increase in hemoglobin concentration, and a decrease in sickled cells and painful crises.[10] Dietary supplementation with oral glutamine, an amino acid, can reduce the number and frequency of pain crises and hospitalizations.[11]

HSCT is the only available treatment that can cure some patients with SCD but is not widely available. The selection of appropriate recipients, scarcity of appropriate donors, risk, and cost-effectiveness limit its use. (HSCT is discussed in Chapter 15.) Gene therapy approaches are under investigation.[8]

Ethical/Legal Dilemmas

Pain Management

Situation

N.C., a 21-yr-old African American man, presents to the ED in sickle cell crisis reporting excruciating pain. He is known to several of the nurses and HCPs in the ED. A nurse remarks to you that it must be time for his "fix" of pain drugs.

Ethical/Legal Points for Consideration

- The standard of care for pain management requires that (1) a pain assessment is done based on the patient's self-report, (2) the best possible relief of pain is provided under the circumstances, and (3) competent and compassionate care is provided to all patients.
- The pain assessment also includes reviewing the patient's medical record to determine if there are health care issues or conditions (e.g., frequent ED visits to request pain medication)

that may affect the patient's response to pain and pain management.

- You have a duty to notify the HCP of those issues or conditions. Document patient behaviors related to pain management. Be objective (factual observations) rather than subjective, such as labeling ("the patient is in withdrawal").
- When pain relief is inadequate, you must notify the HCP. Make sure the HCP has assessed the patient and based the plan of care on that assessment.
- Somnolence assessment is essential as part of your pain reassessment.

Discussion Questions

1. How can you teach your peers about pain assessment and management?
2. What factors do you need to include in your assessment and management of N.C.?

Patient teaching and support are important in the long-term care of the patient with SCD. The patient and caregiver must understand the basis of the disease and the reasons for supportive care and ongoing pertinent screening tailored to SCD manifestations. Teach the patient ways to avoid crises. Review steps to avoid dehydration and hypoxia, such as avoiding high altitudes and seeking medical attention quickly to counteract problems, such as upper respiratory tract infections. Teach patients to maintain adequate fluid intake. Immunizations, such as pneumococcal, *H. influenzae,* influenza, and hepatitis, should be given. Screening for retinopathy should begin at age 10. Each person with SCD should have a reproductive life plan.[10] Teaching about pain control is needed because the pain during a crisis may be severe and often requires considerable analgesia. Minor pain episodes that are not associated with infection or other symptoms that need medical attention can sometimes be managed at home.

Acquired Hemolytic Anemia

Acquired hemolytic anemia results from hemolysis of RBCs from extrinsic factors. These factors include (1) physical destruction, (2) antibody reactions, and (3) infectious agents and toxins (Table 30.2).[3]

Physical destruction of RBCs results from the exertion of extreme force on the cells. Traumatic events causing disruption of the RBC membrane include hemodialysis, extracorporeal circulation used in cardiopulmonary bypass, and prosthetic heart valves. In addition, the force needed to push blood through abnormal vessels, such as those that have been burned, irradiated, or affected by vascular disease (e.g., diabetes), may physically damage RBCs.

RBCs can be fragmented and destroyed as they try to pass through abnormal arterial or venous microcirculation. The RBCs are sheared as they try to pass by excess platelet aggregation and/or fibrin polymer formation, such as is seen in thrombotic thrombocytopenic purpura (TTP) and disseminated intravascular coagulation (DIC) (discussed later in this chapter).

Antibodies may destroy RBCs by the mechanisms involved in antigen-antibody reactions. In blood transfusion reactions, the recipient's antibodies attack and hemolyze donor cells. Autoimmune antibody reactions occur when people develop antibodies against their own RBCs. This can be an idiopathic (no prior hemolytic history) or from other autoimmune diseases (e.g., systemic lupus erythematosus [SLE]), leukemia, lymphoma, or medications (penicillin, ibuprofen, metformin, chlorpromazine, procainamide).

Infectious agents cause hemolysis in 3 ways: (1) by invading the RBC and destroying its contents (e.g., parasites, such as in malaria), (2) by releasing hemolytic substances (e.g., *Clostridium perfringens*), and (3) by generating an antigen-antibody reaction (e.g., *Mycoplasma pneumoniae*). Various agents may be toxic to RBCs and cause hemolysis. These hemolytic toxins involve chemicals, such as oxidative drugs, arsenic, lead, copper, and bee stings or spider bites.

Laboratory findings in hemolytic anemia are shown in Table 30.6.

Treatment and management of acquired hemolytic anemias involve general supportive care until the causative agent can be eliminated or at least made less injurious to the RBCs. Because a hemolytic crisis is a potential consequence, be ready to institute appropriate emergency therapy. This includes aggressive hydration and electrolyte replacement to reduce the risk for kidney injury caused by hemoglobin (from RBC lysis) clogging the kidney tubules and subsequent shock. Supportive care may include giving corticosteroids and blood products or removing the spleen.

The patient with chronic hemolytic anemia may need folate replacement. To suppress the RBC destruction, immunosuppressive agents may be used, such as glucocorticoids or rituximab (Rituxan), which is a monoclonal antibody to B-cell CD20. For severe cases associated with hemolysis, thrombocytopenia, and acute kidney injury, plasma exchange and eculizumab (Soliris), a monoclonal antibody to complement protein C5, are options.[12]

Other Red Blood Cell Disorders

Hemochromatosis

Hemochromatosis is an iron overload disorder. Although a genetic defect is the most common cause, it may occur with diseases such as sideroblastic anemia. It also may be caused by liver disease and the chronic blood transfusions used to treat thalassemia and SCD.

Genetic Link

The genetic disorder *(hereditary hemochromatosis)* is an autosomal recessive disorder characterized by increased intestinal iron absorption and, as a result, increased tissue iron deposition.

Genetics in Clinical Practice[13]

Hemochromatosis

Genetic Basis

- Autosomal recessive disorder
- Caused by mutations in the *HAMP*, *HFE*, *HFE2*, *SLC40A1*, and *TFR2* genes
- These genes play a key role in regulating the absorption, transport, and storage of iron
- Mutations in these genes impair the control of iron absorption during digestion and change the distribution of iron to other parts of the body, resulting in iron accumulation in tissues and organs

Incidence

- Most common genetic disease in people of European ancestry
- The C282Y mutation of the *HFE* gene is the most common
- About 4 to 5 of every 1000 whites carry 2 copies of the *HFE* gene; 1 of every 10 carries one copy
- Affects 1 in 200 to 500 in the United States
- Very low prevalence in other ethnic populations

Genetic Testing

- DNA testing is available and recommended for all first-degree relatives of people with the disease
- American Hemochromatosis Society recommends genetic testing regardless of family history

Clinical Implications

- Most Americans who have the gene mutation do not know it until diseases becomes apparent
- Clinical expression is variable and depends on dietary iron, blood loss, and other modifying factors
- Early treatment can prevent serious complications
- If untreated, progressive iron deposits can lead to multiple organ failure

The normal range for total body iron is 40 mg/kg in women and 50 mg/kg in men. People with hemochromatosis accumulate iron at an increased rate and may exceed total iron concentrations of 50 g.[1]

Symptoms usually do not develop until after age 40 years in men and after 50 years in women.[13] Early symptoms are nonspecific and include fatigue, arthralgia, impotence, abdominal pain, and weight loss. Later, the excess iron accumulates in the liver and causes liver enlargement and eventually cirrhosis. Excess iron is deposited in the

liver, pancreas, heart, joints, and endocrine glands, resulting in diabetes, skin pigment changes (bronzing), heart problems (e.g., cardiomyopathy), arthritis, and testicular atrophy. Physical examination reveals an enlarged liver and spleen and pigmentation changes in the skin.

Laboratory values show a high serum iron, TIBC, and serum ferritin. Testing for known genetic mutations confirms the diagnosis. Liver biopsy can quantify the amount of iron and establish the degree of organ damage.

The goal of treatment is to remove excess iron from the body and minimize any symptoms the patient may have. Iron removal is achieved by removing 500 mL of blood each week for 2 to 3 years until the iron stores in the body are depleted. Then blood is removed less often to maintain iron levels within normal limits.

Iron chelating agents may be used. Deferoxamine, which chelates and removes accumulated iron via the kidneys, can be given IV or subcutaneously. Deferasirox and deferiprone are oral agents that chelate iron. Chelating agents form a complex with iron and promote its excretion from the body.[1] Iron accumulation can be reduced by dietary changes, such as avoiding vitamin C and iron supplements, uncooked seafood, and iron-rich foods.

Management of organ involvement (e.g., diabetes, HF) is the same as conventional treatment for these problems. The most common causes of death are cirrhosis, liver failure, liver cancer, and HF. With early diagnosis and treatment, life expectancy is normal. However, many cases go undetected and untreated.

Polycythemia

Polycythemia is the production and presence of increased numbers of RBCs. The increase in RBCs can be so great that blood circulation is impaired because of the increased blood viscosity *(hyperviscosity)* and volume *(hypervolemia).*

Etiology and Pathophysiology

The 2 types of polycythemia are primary polycythemia, or polycythemia vera, and secondary polycythemia (Fig. 30.5). Their causes and pathogenesis differ, although their complications and manifestations are similar.

Primary Polycythemia

Polycythemia vera is a chronic myeloproliferative disorder. It involves not only RBCs, but also WBCs and platelets, with an increased production of all these blood cells. This leads to enhanced blood viscosity and blood volume and congestion of organs and tissues with blood. Splenomegaly and hepatomegaly are common. Patients have hypercoagulopathies that predispose them to clotting. The disease develops insidiously and follows a chronic, vacillating course. The median age at diagnosis is 60 years old, with a slight male predominance.

Genetic Link

Polycythemia vera is associated with mutations in the Janus kinase-2 *(JAK2)* gene. The *JAK2* gene provides instructions for making a protein that promotes proliferation of cells, especially blood cells from hematopoietic stem cells. Polycythemia vera begins with 1 or more DNA mutations of a single hematopoietic stem cell. Most cases of polycythemia vera are not inherited. They are associated with genetic changes that are somatic, which means they are acquired during a person's lifetime and are present only in certain cells.

Secondary Polycythemia

Secondary polycythemia can be either hypoxia driven or hypoxia independent. In hypoxia-driven secondary polycythemia, hypoxia stimulates erythropoietin (EPO) production in the kidneys, which in turn stimulates RBC production. The need for O_2 may result from high altitude, lung disease, cardiovascular disease, alveolar hypoventilation, defective O_2 transport, or tissue hypoxia.

EPO levels may return to normal once the hemoglobin stabilizes at a higher level. In this situation, secondary polycythemia is a physiologic response in which the body tries to compensate for a problem, rather than a pathologic response. Hypoxia-driven secondary polycythemia is discussed in Chapter 28.

In hypoxia-independent secondary polycythemia, cancer or benign tumor tissue makes EPO. Serum EPO levels often stay increased in these situations. Splenomegaly does not occur with secondary polycythemia.

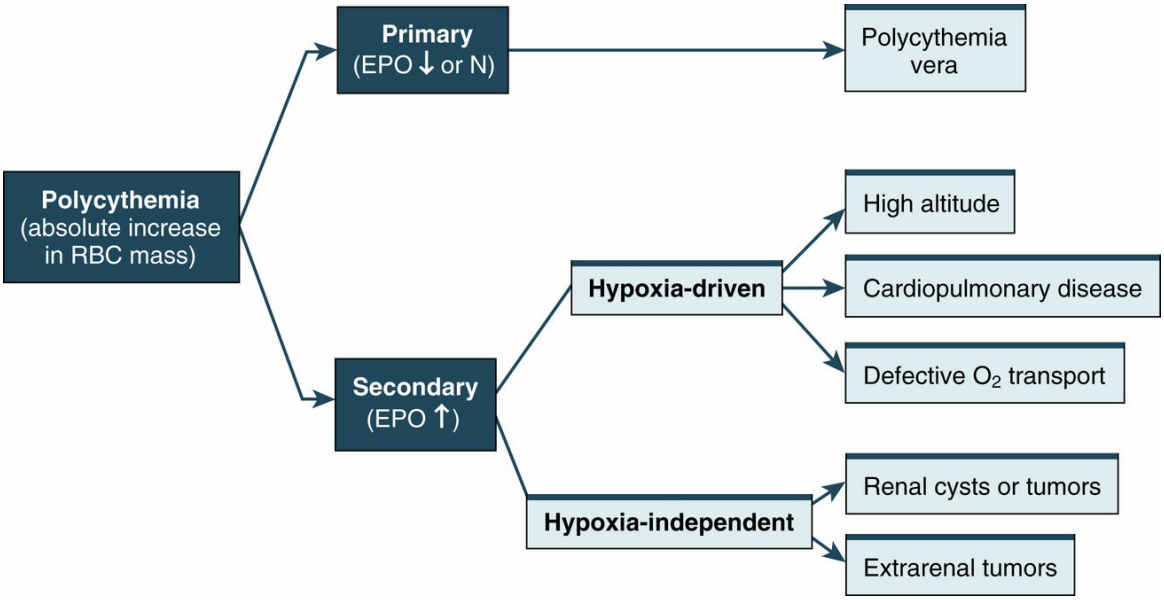

FIG. 30.5 Differentiating between primary and secondary polycythemia. *EPO,* Erythropoietin; *N,* normal.

Clinical Manifestations and Complications

Circulatory manifestations of polycythemia vera occur because of the hypertension caused by hypervolemia and hyperviscosity. They are often the first manifestations and include headache, vertigo, dizziness, tinnitus, and visual changes. Generalized pruritus (often exacerbated by a hot bath) may be a striking symptom and is related to histamine release from an increased number of basophils. Paresthesias and *erythromelalgia* (painful burning and redness of the hands and feet) may be present. The patient may have angina, HF, intermittent claudication, and thrombophlebitis, which may be complicated by embolization. These manifestations are caused by blood vessel distention, impaired blood flow, circulatory stasis, thrombosis, and tissue hypoxia from the hypervolemia and hyperviscosity. The most common serious acute complication is stroke from a thrombosis.

Hemorrhagic phenomena caused by either vessel rupture from overdistention or inadequate platelet function may result in petechiae, bruising, nosebleeds, or GI bleeding. Hemorrhage can be acute and catastrophic. Hepatomegaly and splenomegaly from organ engorgement may contribute to satiety and fullness. The patient may have pain from peptic ulcer caused either by increased gastric secretions or liver and spleen engorgement. *Plethora* (ruddy complexion) may be present. Uric acid is one of the products of RBC destruction. As RBC destruction increases, uric acid production increases, leading to hyperuricemia and gout.

Although the incidence is low, myelofibrosis and leukemia develop in some patients with polycythemia vera. These disorders may be caused by the chemotherapeutic drugs used to treat the disease, or they may be caused by a disorder in the stem cells that progresses to erythroleukemia. The major cause of morbidity and mortality from polycythemia vera is related to thrombosis (e.g., stroke).

Diagnostic Studies

The laboratory manifestations seen in a patient with polycythemia vera include (1) high hemoglobin and RBC count with microcytosis;

(2) low to normal EPO level (secondary polycythemia has a high level); (3) high WBC count with basophilia and neutrophilia; (4) high platelet count (thrombocytosis) and platelet dysfunction; (5) high leukocyte alkaline phosphatase, uric acid, and cobalamin levels; and (6) high histamine levels.[3] Bone marrow examination in polycythemia vera shows hypercellularity of RBCs, WBCs, and platelets.

Interprofessional and Nursing Management

Treatment is directed toward reducing blood volume and viscosity and bone marrow activity. Phlebotomy is the mainstay of treatment. The aim of phlebotomy is to reduce the hematocrit and keep it less than 45%.[14] Generally, at the time of diagnosis 300 to 500 mL of blood may be removed every few days until the hematocrit is reduced to acceptable levels.[14] Phlebotomy then may be needed every 2 to 3 months, reducing the blood volume by about 500 mL each time. A person managed with repeated phlebotomies eventually becomes deficient in iron, although this effect is rarely symptomatic. Avoid iron supplementation. Hydration therapy can reduce the blood's viscosity.

Myelosuppressive agents, such as hydroxyurea, busulfan (Myleran), and chlorambucil (Leukeran), may be given.[3] Ruxolitinib (Jakafi), which inhibits the expression of the *JAK2* mutation, is given to patients who have not responded to hydroxyurea.[14] Other therapies include anagrelide (Agrylin), which can reduce the platelet count and inhibit platelet aggregation. Low-dose aspirin is used to prevent clotting. α-Interferon (α-IFN) and pegylated interferon are given to women of childbearing age or those with intractable pruritus. Allopurinol (Zyloprim) may reduce the number of acute gouty attacks.[3]

When acute exacerbations of polycythemia vera develop, you have several nursing responsibilities. Depending on the agency's policies, you may either assist with or perform the phlebotomy. Assess fluid intake and output during hydration therapy to avoid fluid overload (which worsens circulatory congestion) or fluid deficit (which makes

the blood even more viscous). If myelosuppressive agents are used, give the drugs as ordered, observe the patient, and teach the patient about the side effects of the drugs.

Assess the patient's nutritional status, since inadequate food intake can result from GI symptoms of fullness, pain, and dyspepsia. Begin activities and/or medications to decrease thrombus formation. Start active or passive leg exercises and ambulation when possible.

Because of its chronic nature, polycythemia vera requires ongoing evaluation. Assess the patient for complications.

Problems Of Hemostasis

Hemostasis involves the vascular endothelium, platelets, and coagulation factors, which normally function together to stop hemorrhage and repair vascular injury. These mechanisms are described in Chapter 29. Disruption in any of these components may result in bleeding or thrombotic disorders.

Three major disorders of hemostasis discussed in this section are (1) thrombocytopenia (low platelet count), (2) hemophilia and von Willebrand disease (inherited disorders of specific clotting factors), and (3) DIC.

Thrombocytopenia

Etiology and Pathophysiology

Thrombocytopenia is a reduction of platelets below 150,000/μL (150 × 10^9/L). Acute, severe, or prolonged decreases from this normal range can result in abnormal hemostasis that presents as prolonged bleeding from minor trauma or spontaneous bleeding without injury.

Platelet disorders occur because of impaired production, increased destruction, or abnormal distribution (Table 30.11).[15] While they can be inherited (e.g., Wiskott-Aldrich syndrome), most are acquired. A common cause of acquired disorders is the ingestion of certain drugs.[1] Although some drugs are directly myelosuppressive (e.g., chemotherapy, ganciclovir), the usual mechanism of drug-related thrombocytopenia is accelerated platelet destruction caused by antibodies. Antibodies attack the platelets when the drug binds to the platelet surface.

Some drugs can affect platelet aggregation. Aspirin doses as low as 81 mg can alter platelet aggregation. Normal function is restored when new platelets are made.

Immune Thrombocytopenia

The most common acquired thrombocytopenia is a syndrome of abnormal destruction of circulating platelets termed *immune thrombocytopenia* (ITP). ITP is an acquired immune disorder in which the thrombocytopenia results from antiplatelet antibodies, impaired platelet production, and T-cell–mediated destruction of platelets.[16] In ITP, platelets are coated with antibodies. These platelets function normally; however, when they reach the spleen, these antibody-coated platelets are mistaken as foreign and destroyed by macrophages. Decreased platelet production contributes to ITP. Sometimes autoimmune disease (such as SLE) or infection, such as *Helicobacter pylori* or viral infection (HIV), contributes to this disorder.[16]

Platelets normally survive 8 to 10 days. However, in ITP, platelet survival is shortened. Generally, the syndrome presents as an acute condition in children and a chronic condition in adults.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is an uncommon syndrome characterized by hemolytic anemia, thrombocytopenia, neurologic abnormalities, fever (in the absence of infection), and renal abnormalities. Not all features are present in all patients. Because it is almost always associated with hemolytic-uremic syndrome (HUS), TTP is often referred to as *TTP-HUS*. The disease is associated with enhanced aggregation of platelets, which form microthrombi that deposit in arterioles and capillaries.

TABLE 30.11 Causes of Acquired Thrombocytopenia

Impaired Platelet Production

- Cancers and other disorders
    - Aplastic anemia
    - Leukemia, lymphoma, myeloma, myelodysplastic disorders
    - Marrow metastases by solid tumors
- Drugs (chemotherapy, others)
- Immune thrombocytopenia (ITP)
- Infections, bacterial, fungal, or viral (hepatitis C virus, HIV, cytomegalovirus)
- Nutritional deficiencies, alcoholism
- Radiation

Increased Platelet Destruction

- Artificial surfaces (e.g., cardiopulmonary bypass, hemodialysis)
- Disseminated intravascular coagulation (DIC)
- Heparin-induced thrombocytopenia (HIT)
- Pregnancy-related
- Thrombotic microangiopathy
    - Thrombotic thrombocytopenic purpura (TTP)
    - Atypical Hemolytic Uremic Syndromes (aHUS)

Abnormal Platelet Distribution

- Dilution (massive blood transfusion, fluids)
- Splenic sequestration

In most cases, TTP is caused by the deficiency of a plasma enzyme (ADAMTS13) that breaks down the von Willebrand clotting factor (vWF) into normal size. vWF is the most important protein-mediating platelet adhesion to damaged endothelial cells. Without the enzyme, unusually large amounts of vWF attach to activated platelets, promoting platelet aggregation.

TTP occurs primarily in previously healthy adults, with a slight female predominance. The syndrome may be idiopathic (thought to be due to an autoimmune disorder against ADAMTS13) or due to certain drug toxicities (e.g., chemotherapy, cyclosporine, quinine, oral contraceptives, valacyclovir, clopidogrel [Plavix]), pregnancy or preeclampsia, infection, or a known autoimmune disorder, such as SLE or scleroderma.[3] TTP is a medical emergency because bleeding and clotting occur at the same time.

Heparin-Induced Thrombocytopenia

One of the risks associated with the use of heparin is the development of the life-threatening condition called *heparin-induced thrombocytopenia* (HIT), also called *heparin-induced thrombocytopenia and thrombosis syndrome* (HITTS). Typically, patients develop thrombocytopenia 5 to

10 days after the onset of heparin therapy. HIT should be suspected if the platelet count falls by more than 50% or falls to below 150,000/μL. As many as 5% of patients on heparin therapy develop HIT.[3,17]

Although the major problem of HIT is venous thrombosis, arterial thrombosis can occur. DVT and pulmonary emboli most often result as a complication of the thromboses. Other complications include arterial vascular infarcts, resulting in skin necrosis, stroke, and end-organ damage (e.g., kidneys). Symptoms of bleeding are unusual because the platelet count rarely drops below 20,000/μL.

FIG. 30.6 Acute immune thrombocytopenic purpura often presents with purpuric lesions.
From Forbes CD, Jackson WF: *Colour atlas and text of clinical medicine,* ed 3, London, 2003, Mosby.

In HIT, platelet destruction and vascular endothelial injury are the 2 major responses to an immune-mediated response to heparin. Platelet factor 4 (PF4) (protein made and released by platelets) binds to heparin. This PF4-heparin complex then binds to the platelet surface, leading to further platelet activation and release of more PF4, thus creating a positive feedback loop. Antibodies are created against the PF4-heparin-platelet complex. They are removed prematurely from circulation, leading to thrombocytopenia and platelet-fibrin thrombi.

Clinical Manifestations

Many patients with thrombocytopenia are asymptomatic. The most common symptom is bleeding, usually mucosal or cutaneous. Mucosal bleeding may manifest as nosebleeds and gingival bleeding. Large bullous hemorrhages may appear on the buccal mucosa because of the lack of vessel protection by the submucosal tissue.

Bleeding into the skin is seen as petechiae, purpura, or superficial ecchymoses. *Petechiae* are small, flat, red or reddish brown microhemorrhages (see Table 29.6). When the platelet count is low, RBCs may leak out of the blood vessels and into the skin to cause petechiae. When there are many petechiae, we call the resulting reddish skin *purpura* (Fig. 30.6). Purplish lesions caused by hemorrhage are termed *ecchymoses.* Pain and tenderness are sometimes present.

The major complication of thrombocytopenia is hemorrhage. The hemorrhage may be insidious or acute and internal or external. It may occur in any area of the body, including the joints, retina, and brain. Cerebral hemorrhage may be fatal. Insidious hemorrhage may be first detected by discovering the anemia that accompanies blood loss. Be aware of manifestations that reflect internal blood loss, including weakness, fainting, dizziness, tachycardia, abdominal pain, and hypotension. Prolonged bleeding after routine procedures, such as venipuncture or IM injection, may indicate thrombocytopenia.

Because thrombocytopenia can be accompanied by vascular thromboses, signs and symptoms of vascular ischemic problems may occur (see Chapter 37). For example, subtle confusion, headache, or even serious manifestations, such as seizures and coma due to TTP-related thrombosis, may occur. Because signs and symptoms may be subtle, astute and thorough assessment of the patient is essential.

TABLE 30.12 Laboratory Results in Thrombocytopenia and DIC

Laboratory Test	ITP	TTP	HIT	DIC
Platelets	↓↓↓↓	↓↓↓	↓↓	↓↓↓
Hemolysis				
Haptoglobin	N	↓	N	↓
Hgb	N	↓↓	N	N or ↓
Indirect bilirubin	N	↑	N	N or ↑
LDH	N	↑↑↑	N	↑

Other tests	ITP IgG assay, platelet activation/function assay, *Helicobacter pylori*, hepatitis C, HIV, bone marrow biopsy	ADAMTS13 Urinalysis (for proteinuria, hematuria), Creatinine	Platelet activation/function assay, PF4-heparin complex (antigen assay)	

Diagnostic Studies

The platelet count is decreased in thrombocytopenia. Any reduction below 150,000/μL (150 × 10^9/L) may be termed *thrombocytopenia.* However, prolonged bleeding from trauma or injury does not usually occur until platelet counts are less than 50,000/μL (50 × 10^9/L).[1] When the count drops below 20,000/μL (20 × 10^9/L), spontaneous, life-threatening hemorrhages (e.g., intracranial bleeding) can occur. Platelet transfusions are generally not recommended until the count is below 10,000/μL (10 × 10^9/L) unless the patient is actively bleeding.[3]

The patient's history and clinical examination, along with comparisons of laboratory parameters, help to determine the cause of the thrombocytopenia. Table 30.12 compares the types of thrombocytopenia.

Laboratory tests that assess secondary hemostasis or coagulation, such as the prothrombin time (PT) and aPTT, can be normal even in severe thrombocytopenia. If they are increased, this may point toward DIC.

Specific assays, such as ITP antigen-specific assay, platelet activation/function assay, or PF4-heparin complex for HIT, can be

done to assist with the diagnosis. In TTP, testing for deficiency of ADAMTS13 is not always diagnostic, so an increase of lactate dehydrogenase (LDH) may help establish the diagnosis. When thrombocytopenia occurs with anemia characterized by altered RBC morphology, including *spherocytes* (small, globular, completely hemoglobinated RBCs), fragmented cells (schistocytes), and pronounced reticulocytosis, a diagnosis of TTP should be suspected. These findings are partially a result of intravascular fibrin deposition causing a "slicing" of RBCs. In TTP, thrombocytopenia may be severe, but coagulation studies are normal.

TABLE 30.13 Interprofessional CareThrombocytopenia

Diagnostic Assessment

- History and physical examination
- Bone marrow aspiration and biopsy
- CBC, including platelet count
- Specific laboratory studies (Table 30.12)

Management
Immune Thrombocytopenic Purpura

- Corticosteroids
- IV immunoglobulin (IVIG)
- Anti-Rh_o(D)
- Rituximab (Rituxan)
- Romiplostim (Nplate)
- Eltrombopag (Promacta)
- Splenectomy

- Immunosuppressives (e.g., cyclosporine)
- Platelet transfusions
- Epsilon-aminocaproic acid (Amicar)

Thrombotic Thrombocytopenic Purpura

- Identification and treatment of cause
- Plasmapheresis (plasma exchange)
- Corticosteroids
- Rituximab (Rituxan)
- Immunosuppressives (e.g., cyclophosphamide)
- Splenectomy

Heparin-Induced Thrombocytopenia

- Direct thrombin inhibitor (argatroban [Acova])
- Indirect thrombin inhibitor (fondaparinux [Arixtra])
- Synthetic thrombin inhibitor (bivalirudin)
- Plasmapheresis (plasma exchange)
- Warfarin (Coumadin)
- Thrombolytic agents

Decreased Platelet Production

- Identification and treatment or removal of cause
- Corticosteroids
- Platelet transfusions

Bone marrow examination may be done to rule out production problems as the cause of thrombocytopenia (e.g., leukemia, aplastic anemia, other myeloproliferative disorders) or when other tests are

inconclusive. When destruction of circulating platelets is the cause, bone marrow analysis shows *megakaryocytes* (precursors of platelets) to be normal or increased, even though circulating platelets are reduced. The absence or decreased number of megakaryocytes on bone marrow biopsy is consistent with thrombocytopenia caused by decreased bone marrow production (e.g., aplastic anemia).

Interprofessional Care

Interprofessional care of thrombocytopenia differs based on the cause. Removal or treatment of the underlying cause or disorder is sometimes sufficient. The patient with thrombocytopenia should avoid aspirin and other drugs that affect platelet function or production. The following sections discuss management strategies for the different causes of thrombocytopenia (Table 30.13).

Immune Thrombocytopenic Purpura

Multiple therapies are used to manage the patient with ITP. If the patient is asymptomatic, therapy may not be used unless the patient's platelet count is below 30,000/μL.[1] Corticosteroids (e.g., prednisone, methylprednisolone) are used initially to treat ITP because of their ability to suppress the phagocytic response of splenic macrophages. This alters the spleen's recognition of platelets and increases the life span of the platelets. Corticosteroids depress antibody formation and reduce capillary leakage.

High doses of IV immunoglobulin (IVIG) and a component of IVIG, anti-Rh_o(D) (anti-D, WinRho), may be used in the patient who is unresponsive to corticosteroids or splenectomy or for whom splenectomy is not an option. We think that one way these agents work is by competing with the antiplatelet antibodies for macrophage receptors in the spleen. Rituximab (Rituxan) may be used for its ability to lyse activated B cells, thus reducing the immune recognition of platelets. Romiplostim (Nplate) and eltrombopag (Promacta) are used for patients with chronic ITP who had an insufficient response to the other treatments. These drugs are thrombopoietin receptor agonists,

thus increasing platelet production.[1]

Splenectomy may be needed if the patient does not respond to treatment. Two thirds of patients benefit from splenectomy, resulting in a sustained remission.[3] The effectiveness of splenectomy is based on 4 factors. First, the spleen has an abundance of the macrophages that sequester and destroy platelets. Second, structural features of the spleen enhance the interaction between antibody-coated platelets and macrophages. Third, some antibody synthesis occurs in the spleen, so antiplatelet antibodies decrease after splenectomy. Fourth, the spleen normally sequesters around one third of the platelets, so its removal increases the number of platelets in circulation.

Immunosuppressive therapy (e.g., cyclosporine) may be used in refractory cases (Table 30.13).[1] Platelet transfusions may increase platelet counts in cases of life-threatening hemorrhage. Platelets should not be given prophylactically because of the risk for antibody formation. The usual indication for giving platelets is for a platelet count less than 10,000/μL or if there is expected bleeding before a procedure. Epsilon-aminocaproic acid (EACA, Amicar), an antifibrinolytic agent, may treat severe bleeding.[3]

Thrombotic Thrombocytopenic Purpura

TTP may be treated in a variety of ways. The first step is to treat the underlying disorder (e.g., infection) or remove the causative agent, if known. If untreated, TTP usually results in irreversible renal failure and death. Plasma exchange (plasmapheresis) (see Chapter 13) can aggressively reverse platelet consumption by supplying the appropriate vWF and enzyme (ADAMTS13) and removing the large vWF molecules that bind with platelets. Treatment should be continued daily until the patient's platelet counts normalize and hemolysis has ceased. Corticosteroids may be given with this treatment.[3]

Rituximab is used for patients who are refractory to plasma exchange. It decreases the level of inhibitory ADAMTS13 IgG antibodies. Other immunosuppressants, such as cyclosporine or

cyclophosphamide, are options. Splenectomy may be considered in patients who are refractory to plasma exchange or immunosuppression. Platelet administration is generally contraindicated because this may lead to new vWF-platelet complexes and increased clotting.[3]

Heparin-Induced Thrombocytopenia

All forms of heparin must be stopped when HIT is first recognized. This includes heparin flushes for vascular catheters.

To maintain anticoagulation, the patient should be started on a direct thrombin inhibitor, such as argatroban. Fondaparinux (Arixtra), a factor Xa inhibitor (indirect thrombin inhibitor), or bivalirudin (a synthetic thrombin inhibitor) may be used.[17] Warfarin should be started only when the platelet count has reached 150,000/μL. If the clotting is severe, the most commonly used treatment modalities are plasmapheresis to clear the platelet-aggregating IgG from the blood, protamine sulfate to interrupt the circulating heparin, thrombolytic agents to treat the thromboembolic events, and surgery to remove clots. Platelet transfusions are not effective because they may enhance thromboembolic events.[3]

Patients who have had HIT should never receive heparin or low-molecular-weight heparin (LMWH) again. This should be clearly marked in the patient's medical record.

Thrombocytopenia From Decreased Platelet Production

The management of acquired thrombocytopenia is based on finding the cause and treating the disease or removing the causative agent. If the precipitating factor is unknown, the patient may receive corticosteroids. Platelet transfusions are given if life-threatening hemorrhage develops.

Often acquired thrombocytopenia is caused by another underlying condition (e.g., aplastic anemia, leukemia) or therapy used to treat another problem. For example, in acute leukemia all blood cell types may be depressed. Plus, the patient may receive chemotherapeutic

drugs that cause bone marrow suppression. If the patient can be supported throughout the course of chemotherapy-induced thrombocytopenia, the thrombocytopenia will also resolve.

Nursing Management: Thrombocytopenia

Nursing Assessment

Subjective and objective data that should be obtained from a patient with thrombocytopenia are outlined in Table 30.14.

Nursing Diagnoses

The main nursing diagnosis for the patient with thrombocytopenia is risk for bleeding.

Planning

The overall goals are that the patient with thrombocytopenia will (1) have no bleeding, (2) maintain vascular integrity, and (3) manage home care to prevent any complications related to an increased risk for bleeding.

Nursing Implementation

Health Promotion

Discourage the use of over-the-counter (OTC) medications known to be causes of acquired thrombocytopenia and reduced platelet function. Some have aspirin as an ingredient. Aspirin reduces platelet adhesiveness, thus contributing to bleeding.

Encourage persons to have a complete medical evaluation if manifestations of bleeding tendencies (e.g., prolonged nosebleeds, petechiae) develop. Observe for early signs of thrombocytopenia in the patient receiving cancer chemotherapy drugs.

Acute Care

The goal during acute episodes of thrombocytopenia is to prevent or

control hemorrhage (see eNursing Care Plan 30.2 on the website for this chapter). In the patient with thrombocytopenia, bleeding is usually from superficial sites. Deep bleeding (into muscles, joints, and abdomen) usually occurs only when clotting factors are decreased. Stress that a minor nosebleed or new petechiae may indicate potential hemorrhage and to notify the HCP.

TABLE 30.14 Nursing AssessmentThrombocytopenia

Subjective Data

Important Health Information

Past health history: Recent hemorrhage, excessive bleeding, or viral illness; HIV infection; cancer (especially leukemia or lymphoma); aplastic anemia; SLE; cirrhosis; exposure to radiation or toxic chemicals; DIC

Medications: Many medications, including chemotherapy agents, valproic acid (Depakote), furosemide (Lasix), gold, nonsteroidal antiinflammatory drugs, penicillin

Functional Health Patterns

Health perception–health management: Family history of bleeding problems; malaise

Nutritional-metabolic: Bleeding gingiva; coffee-ground or bloody vomitus; easy bruising

Elimination: Hematuria, dark or bloody stools

Activity-exercise: Fatigue, weakness, fainting; nosebleeds, hemoptysis; dyspnea

Cognitive-perceptual: Pain and tenderness in bleeding areas (e.g., abdomen, head, extremities); headache

Sexuality-reproductive: Menorrhagia, metrorrhagia

Objective Data

General

Fever, lethargy

Integumentary

Petechiae, bruising, purpura

Gastrointestinal

Splenomegaly, abdominal distention; heme-positive stools

Possible Diagnostic Findings

Platelet count <150,000/μL (150 × 10^9/L), prolonged bleeding time, ↓ hemoglobin and hematocrit; normal or ↑ megakaryocytes in bone marrow examination

Bleeding from the posterior nasopharynx may be hard to detect because the blood may be swallowed. If you cannot avoid a subcutaneous injection, use a small-gauge needle and apply direct pressure for at least 5 to 10 minutes after the injection. An ice pack may be helpful. Avoid IM injections. Help the patient understand the importance of adhering to self-care measures that reduce the risk for bleeding (Table 30.15).

Note that many of these disorders may be accompanied by vascular clotting, and appropriate assessment and management should be taken (see Chapter 37). As bleeding occurs, RBCs and coagulation factors are consumed along with platelets. It is important to monitor all blood cell and coagulation studies.

In a woman with thrombocytopenia, menstrual blood loss may

exceed the usual amount and duration. Counting sanitary napkins used during menses is another important intervention to detect excess blood loss. Blood loss of 50 mL will completely soak a sanitary napkin. Suppression of menses with hormonal agents may be needed during predictable periods of thrombocytopenia (e.g., during chemotherapy and HSCT) to reduce blood loss from menses.

Closely monitor the platelet count, coagulation studies, hemoglobin, and hematocrit. Together these give vital information about potential or actual bleeding.

TABLE 30.15 Patient & Caregiver TeachingThrombocytopenia

Include the following instructions when teaching a patient or caregiver the precautions to take when the platelet count is low.

1. Notify your HCP of any symptoms of bleeding. These include:
    - Black, tarry, or bloody bowel movements
    - Black or bloody vomit, sputum, or urine
    - Bleeding from the mouth or anywhere in the body
    - Bruising or small red or purple spots on the skin
    - Difficulty talking, sudden weakness of an arm or leg, confusion
    - Headache or changes in how well you can see
2. Ask your HCP about restrictions in your normal activities, such as vigorous exercise or lifting weights. Generally, walking is safe. Wear sturdy shoes or slippers. If you are weak and at risk for falling, get help or supervision when getting out of bed or chair.
3. Do not blow your nose forcefully; gently pat it with a tissue if needed. For a nosebleed, keep your head up and apply firm pressure to the nostrils and bridge of your nose. If bleeding continues, place an ice bag over the bridge of your nose and the nape of your neck. If you are unable to stop a nosebleed after 10

minutes, call your HCP.
4. Do not bend down with your head lower than your waist.
5. Prevent constipation by drinking plenty of fluids. Do not strain when having a bowel movement. Your HCP may prescribe a stool softener. Do not use a suppository, an enema, or a rectal thermometer without the permission of your HCP.
6. Shave only with an electric razor. Do not use blades.
7. Do not tweeze your eyebrows or other body hair.
8. Do not puncture your skin, such as getting tattoos or body piercing.
9. Do not use any medication that can prolong bleeding, such as aspirin. Other medications and herbs can have similar effects. If you are unsure about any medication, ask your HCP or pharmacist about it in relation to your thrombocytopenia.
10. Use a soft-bristle toothbrush to prevent injuring the gums. Flossing is usually safe if done gently using the thin tape floss. Do not use alcohol-based mouthwashes since they can dry your gums and increase bleeding.
11. Women who are menstruating should keep track of the number of pads that are used per day. When you start using more pads per day than usual or bleed more days, notify your HCP. Do not use tampons; only use sanitary pads.
12. Ask your HCP before you have any invasive procedures done, such as a dental cleaning, manicure, or pedicure.

The proper administration of platelet transfusions is an important nursing responsibility. This is discussed under Blood Component Therapy later in this chapter.

Ambulatory Care

Monitor the patient with ITP who is receiving treatment for the response to therapy. Teach the person with acquired thrombocytopenia to avoid causative agents when possible (Table 30.11). If the patient cannot avoid causative agents (e.g., chemotherapy), teach them to avoid injury or trauma during these

periods and to be aware of the signs and symptoms of bleeding caused by thrombocytopenia (Table 30.15).

Patients with either ITP or acquired thrombocytopenia should have planned periodic medical evaluations to assess and treat situations in which exacerbations and bleeding are likely to occur. Address the impact of either an acute or a chronic condition on the patient's quality of life.

Evaluation

The expected outcomes are that the patient with thrombocytopenia will

- Have no evidence of bleeding or bruising
- State needed knowledge and skills to manage disease process

TABLE 30.16 Types of Hemophilia

Type	Inheritance Pattern
Hemophilia A	
Factor VIII	Recessive sex-linked (transmitted by female carriers, displayed almost exclusively in men)
Hemophilia B	
Factor IX	Recessive sex-linked (transmitted by female carriers, displayed almost exclusively in men)
von Willebrand Disease	
vWF, variable factor VIII deficiencies and platelet dysfunction	Autosomal dominant, seen in both genders Recessive (in severe forms of the disease)

vWF, von Willebrand factor.

Hemophilia and Von Willebrand Disease

Hemophilia is an X-linked recessive genetic disorder caused by a defective or deficient coagulation factor. The 2 major types of hemophilia, which can occur in mild to severe forms, are *hemophilia A* (classic hemophilia, factor VIII deficiency) and *hemophilia B* (Christmas disease, factor IX deficiency). *von Willebrand disease* is a related disorder involving a deficiency of the von Willebrand coagulation protein. Factor VIII is made in the liver and circulates as a complex with vWF.

Hemophilia A is 4 times as common as hemophilia B.[18] Although rare, there are cases of *acquired hemophilia A*, which is due to the development of antibodies against the body's own factor VIII. von Willebrand disease is the most common congenital bleeding disorder.[19]

Genetic Link

The inheritance patterns of hemophilia and von Willebrand disease are compared in Table 30.16. (X-linked genetic disorders are discussed in Chapter 12 and Table 12.2.)

Genetics in Clinical Practice[1,3]

Hemophilia A and B

Genetic Basis

- X-linked recessive disorder
- *Hemophilia A:* Caused by mutations in the *F8* gene that provides instructions for making coagulation factor VIII

- *Hemophilia B:* Caused by mutations in the *F9* gene that provides instructions for making coagulation factor IX
- Mutations in the *F8* or *F9* gene lead to the production of an abnormal version or reduced amounts of coagulation factors

Incidence

- *Hemophilia A:* 1 in 5000 to 10,000 male births
- *Hemophilia B:* 1 in 25,000 to 30,000 male births

Genetic Testing

- DNA testing is available

Clinical Implications

- Female carriers transmit the genetic defect to 50% of their sons, 50% of their daughters are carriers
- Males with hemophilia do not transmit the genetic defect to their sons, but all their daughters are carriers
- Though rare, female hemophilia can occur if a male with hemophilia mates with a female carrier
- Replacement therapy is available for factors VIII and IX

Clinical Manifestations and Complications

The manifestations of hemophilia A and B are similar. All manifestations relate to bleeding, and any bleeding episode in persons with hemophilia may lead to a life-threatening hemorrhage. Manifestations and complications related to hemophilia include (1) slow, persistent, prolonged bleeding from minor trauma and small cuts; (2) delayed bleeding after minor injuries (the delay may be

several hours or days); (3) uncontrollable hemorrhage after dental extractions or irritation of the gingiva with a hard-bristle toothbrush; (4) nosebleeds, especially after a blow to the face; (5) GI bleeding from ulcers and gastritis; (6) hematuria and potential renal failure from GU trauma and splenic rupture resulting from falls or abdominal trauma; (7) bruising and subcutaneous hematomas (Fig. 30.7) and possible compartment syndrome; (8) neurologic signs, such as pain, anesthesia, and paralysis, which may develop from nerve compression caused by hematoma formation; and (9) hemarthrosis (bleeding into the joints) (Fig. 30.8), which may lead to joint injury and deformity severe enough to cause crippling (most often in knees, elbows, and ankles).[1]

In children, these manifestations may lead to the diagnosis. In adults, these may be the first sign of a newly diagnosed mild form of the disease that escaped detection through a childhood free of major injuries, dental procedures, or surgeries.

FIG. 30.7 Severe ecchymoses in a person with hemophilia after a fall.

FIG. 30.8 Acute hemarthrosis of the knee is a common complication of hemophilia.
From Forbes CD, Jackson WF: *Colour atlas and text of clinical medicine,* ed 3, London, 2003, Mosby.

Diagnostic Studies

Laboratory studies are done to determine the type of hemophilia present. Any factor deficiency within the intrinsic system (factor VIII, IX, XI, or XII or vWF) will yield the laboratory results outlined in Table 30.17.

Interprofessional Care

The goals of interprofessional care are to prevent and treat bleeding. Care for persons with hemophilia or von Willebrand disease requires (1) preventive care, (2) the use of replacement therapy during acute bleeding episodes and as prophylaxis, and (3) the treatment of the complications of the disease and its therapy. Today, most patients can expect almost normal life spans free of bloodborne illnesses because of improved preparation of replacement products, improved screening of blood donor populations, and use of recombinant replacement factors.[1,3]

Replacement of deficient clotting factors is the primary means of supporting a patient with hemophilia. Replacement therapy may be

given before surgery and dental care as a prophylactic measure. Table 30.18 lists examples of replacement therapy. Fresh frozen plasma, once commonly used for replacement therapy, is rarely used today.

For mild hemophilia A and certain subtypes of von Willebrand disease, desmopressin acetate (DDAVP), a synthetic analog of vasopressin, may be used to stimulate an increase in factor VIII and vWF. This drug acts on platelets and endothelial cells to cause the release of vWF, which then binds with factor VIII, thus increasing its concentration. It can be given IV, subcutaneously, or by intranasal spray. Beneficial effects (e.g., decreased bleeding time) of DDAVP when given IV are seen within 30 minutes and can last for more than 12 hours. Because the effect of DDAVP is short lived, the patient must be closely monitored and repeated doses may be needed. It is an appropriate therapy for minor bleeding episodes and dental procedures. The intranasal form may be used as home therapy for some patients with mild to moderate forms of the disease.

TABLE 30.17 Laboratory Results in Hemophilia

Test	Results
Bleeding time	Prolonged in von Willebrand disease because of structurally defective platelets. Normal in hemophilia A and B because platelets not affected
Factor assays	Reductions of factor VIII in hemophilia A, factor IX in hemophilia B, vWF in von Willebrand disease
Partial thromboplastin time	Prolonged because of deficiency in intrinsic clotting system factor
Platelet count	Normal. Adequate platelet production
Prothrombin time	Normal. No involvement of extrinsic system
Thrombin time	Normal. No impairment of thrombin-fibrinogen reaction

vWF, von Willebrand factor.

TABLE 30.18 Drug TherapyReplacement Factors for Hemophilia

Factor VIII	Factor IX	Von Willebrand	For Patients Who Have Inhibitors

* For acquired hemophilia A.

Antifibrinolytic therapy (tranexamic acid [Cyklokapron] and EACA) inhibits fibrinolysis by inhibiting plasminogen activation in the fibrin clot, thus enhancing clot stability. These agents stabilize clots in areas of increased fibrinolysis, such as the oral cavity, and in patients with difficult episodes of nosebleeds and menorrhagia. Topical thrombin and fibrin sealants may be used for mucosal bleeding.

Complications of the treatment of hemophilia include development of inhibitors to factors VIII or IX, transfusion-transmitted infectious disorders (hepatitis, HIV), allergic reactions, and thrombotic complications with the use of factor IX because it contains activated coagulation factors. Patients with vWF may develop antibodies against vWF concentrates, the infusion of which could cause life-threatening anaphylaxis. Thus replacement factors for these patients should not contain vWF.

The most common problems with acute management are starting factor replacement therapy too late and stopping it too soon. Minor bleeding episodes should be treated for at least 72 hours. Surgery and traumatic injuries may need longer therapy. Chronically, development of inhibitors to the factor products has occurred and needs individualized expert patient management. Designated treatment centers in the United States and many other countries

provide interprofessional care of hemophilia and related disorders. Gene transfer therapy has been used on an experimental basis to treat hemophilia.[1]

Nursing Management: Hemophilia

Nursing Implementation

Health Promotion

Because of the hereditary nature of hemophilia, referral of affected persons for genetic counseling before reproduction is an important measure. This is especially important because many persons with hemophilia live into adulthood. Reproductive concerns and long-term effects are issues that you should include in the patient's care plan.

Acute Care

Interventions are related primarily to controlling bleeding and include the following:

1. Stop the topical bleeding as quickly as possible. Apply direct pressure or ice, pack the area with Gelfoam or fibrin foam, and apply topical hemostatic agents, such as thrombin.
2. Give the specific coagulation factor to raise the patient's level of the deficient coagulation factor. Monitor the patient for signs and symptoms, such as hypersensitivity.
3. When joint bleeding occurs, in addition to giving replacement factors, it is important to use the "RICE" protocol. Rest the involved joint to prevent crippling deformities from hemarthrosis, ice the joint for 20 minutes every 3 to 4 hours, compress/wrap the joint, and elevate.[1] Give analgesics to reduce severe pain. Do not use aspirin and aspirin-containing compounds. As soon as bleeding ceases, encourage mobilization of the affected area through range-of-motion exercises and physical therapy. Avoid weight bearing until all swelling has resolved and muscle strength has returned. Orthotics may be prescribed.
4. Manage any life-threatening complications that may develop

because of hemorrhage or side effects from coagulation factors. Examples include nursing interventions to prevent or treat airway obstruction from hemorrhage into the neck and pharynx, recognition of compartment syndrome in an extremity, and early assessment and treatment of intracranial bleeding.

Ambulatory Care

Home management is a primary consideration for the patient with hemophilia because the disease follows a progressive, chronic course. The quality and length of life may be significantly affected by the patient's knowledge of the illness and how to live with it. Refer the patient and caregiver to a local chapter of the National Hemophilia Foundation to encourage associations with others who are dealing with the problems of hemophilia.[18] Provide ongoing assessment of the patient's adaptation to the illness. Psychosocial support and assistance should be readily available as needed.

Most of the long-term care measures are related to patient teaching. Teach the patient to recognize disease-related problems and to learn which problems can be resolved at home and which require hospitalization. Immediate medical attention is needed for severe pain or swelling of a muscle or joint that restricts movement or inhibits sleep and for a head injury, swelling in the neck or mouth, abdominal pain, hematuria, melena, and skin wounds in need of suturing.

Teach the patient to perform daily oral hygiene without causing trauma. Understanding how to prevent injuries is another consideration. Teach the patient to take part only in noncontact sports (e.g., golf) and to wear gloves when doing household chores to prevent cuts or abrasions from knives, hammers, and other tools. The patient should wear a Medic Alert tag to ensure that HCPs know about the hemophilia in case of an accident. Many patients or their caregivers can be taught to self-administer the factor replacement therapies at home.

Evaluation

The overall expected outcomes are similar to those for the patient with thrombocytopenia (see p. 626).

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a serious bleeding and thrombotic disorder that results from abnormally initiated and accelerated clotting. Subsequent decreases in clotting factors and platelets ensue, which may lead to uncontrollable hemorrhage. The term DIC can be misleading because it suggests that blood is only clotting. However, there is profuse bleeding that results from the aggregation of platelets and clotting factors. DIC is always caused by an underlying disease or condition. That underlying problem must be treated for the DIC to resolve.

Etiology and Pathophysiology

DIC is not a disease. It is an abnormal response of the normal clotting cascade stimulated by a disease process or disorder.[2,3] The diseases and disorders known to predispose a patient to DIC are listed in Table 30.19. DIC can occur as an acute, catastrophic condition, or it may exist at a subacute or chronic level. Each condition may have 1 or multiple triggering mechanisms to start the clotting cascade. For example, tumors and traumatized or necrotic tissue release tissue factors into circulation. Endotoxin from gram-negative bacteria activates several steps in the coagulation cascade.

Tissue factor is released at the site of tissue injury and by some cancers, such as leukemia, and enhances normal coagulation mechanisms. Abundant intravascular thrombin, the most powerful coagulant, is made (Fig. 30.9). It catalyzes the conversion of fibrinogen to fibrin and enhances platelet aggregation. There is widespread fibrin and platelet deposition in capillaries and arterioles, resulting in thrombosis. This process can lead to multiorgan failure.

TABLE 30.19 Risk Factors for DIC

Acute DIC

Cancers
- Acute leukemia
- Metastatic solid tumors

Hemolytic processes
- Acute hemolysis from infection or immunologic disorders
- Transfusion of mismatched blood

Obstetric conditions
- Abruptio placentae
- Amniotic fluid embolism
- HELLP syndrome
- Septic abortion or pregnancy

Septicemia (bacterial, viral, fungal, parasitic)

Shock
- Anaphylactic
- Cardiogenic
- Hemorrhagic

Tissue damage
- Acute anoxia (e.g., after cardiac arrest)
- Extensive burns and trauma
- Fulminant hepatitis
- Heatstroke
- Postoperative damage, especially after extracorporeal membrane oxygenation
- Prosthetic devices
- Severe head injury
- Snakebites
- Transplant rejections
- Vascular disorders (e.g., aortic aneurism)

Subacute DIC

Cancer
- Metastatic cancer
- Myeloproliferative/lymphoproliferative cancers

Obstetric
- Retained dead fetus

Chronic DIC

- Cancer
- Liver disease
- SLE

In addition, clotting inhibitory mechanisms, such as antithrombin III (AT III) and protein C, are depressed. Excess clotting activates the fibrinolytic system, which in turn breaks down the newly formed clot, creating fibrin split products (FSPs). These products have anticoagulant properties and inhibit normal blood clotting. As FSPs accumulate and clotting factors are depleted, the blood loses its ability to clot. A stable clot cannot be formed at injury sites, which predisposes the patient to hemorrhage.

Chronic and subacute DIC is most often seen in patients with long-standing illnesses, such as cancer or autoimmune disease. Occasionally these patients have subclinical disease manifested only by laboratory abnormalities. However, the clinical spectrum ranges from easy bruising to hemorrhage, and from hypercoagulability to thrombosis.

Clinical Manifestations

DIC has both bleeding and thrombotic manifestations. Multiple factors cause bleeding manifestations of DIC (Fig. 30.9). They result

from consumption and depletion of platelets and coagulation factors, as well as clot lysis and formation of FSPs that have anticoagulant properties. Bleeding in a person with no history or obvious cause should be questioned because it may be one of the first manifestations of acute DIC.

Bleeding manifestations include manifestations in the (1) skin, such as pallor, petechiae, purpura, oozing blood, venipuncture site bleeding, hematomas, and occult hemorrhage; (2) respiratory system (e.g., tachypnea, hemoptysis, and orthopnea); (3) cardiovascular system, such as tachycardia and hypotension; (4) GI tract, such as upper and lower GI bleeding, abdominal distention, and bloody stools; (5) urinary tract (e.g., hematuria); (6) neurologic system, such as vision changes, dizziness, headache, mental status changes, and irritability; and (7) musculoskeletal system (e.g., bone and joint pain).

Thrombotic manifestations are a result of fibrin or platelet deposition in the microvasculature (Fig. 30.9). These manifestations affect the (1) skin (e.g., cyanosis, ischemic tissue necrosis, hemorrhagic necrosis) (Fig. 30.10); (2) respiratory system (e.g., tachypnea, dyspnea, pulmonary emboli, and acute respiratory distress syndrome [ARDS]); (3) cardiovascular system (e.g., ECG changes, venous distention); (4) GI tract (e.g., abdominal pain, paralytic ileus); and (5) kidney damage and oliguria, leading to failure.

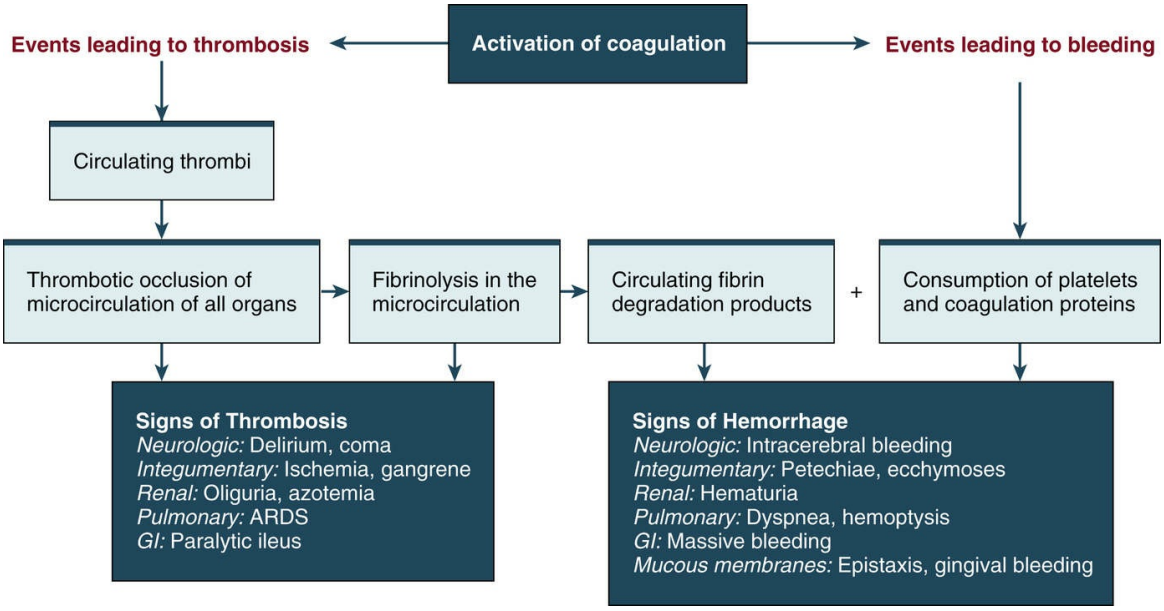

FIG. 30.9 Sequence of events that occur during DIC.

FIG. 30.10 Gangrene resulting from severe DIC.

Diagnostic Studies

Tests to diagnose acute DIC are listed in Table 30.20. As more clots are made in the body, more breakdown products from fibrinogen and fibrin are formed. These are termed *fibrin split products* (FSPs), and they interfere with blood coagulation by (1) coating the platelets and interfering with platelet function; (2) interfering with thrombin and thus disrupting coagulation; and (3) attaching to fibrinogen, which interferes with the polymerization process necessary to form a stable clot. D-dimer, a polymer resulting from the breakdown of fibrin (and not fibrinogen), is a specific marker for the degree of fibrinolysis. In

general, tests that measure raw materials needed for coagulation (e.g., platelets, fibrinogen) are reduced and values that measure clotting times are prolonged. Fragmented RBCs (schistocytes), indicative of partial occlusion of small vessels by fibrin thrombi, may be found on blood smears.

Interprofessional Care

It is important to diagnose DIC quickly, stabilize the patient (e.g., oxygenation, volume replacement), treat the underlying causative disease or problem, and control the ongoing thrombosis and bleeding. Depending on its severity, a variety of methods are used to manage DIC (Fig. 30.11). First, if chronic DIC is diagnosed in a patient who is not bleeding, no therapy for DIC is needed. Treatment of the underlying disease may be enough to reverse the DIC (e.g., chemotherapy when DIC is caused by cancer). Second, when the patient with DIC is bleeding, therapy is directed toward providing support with needed blood products while treating the primary disorder.

Blood products are given cautiously based on specific component deficiencies to patients who have serious bleeding, are at high risk for bleeding (e.g., surgery), or require invasive procedures. Blood product support with platelets, cryoprecipitate, and fresh frozen plasma (FFP) is usually reserved for a patient with life-threatening hemorrhage.[20] Therapy stabilizes a patient, prevents exsanguination or massive thrombosis, and permits institution of definitive therapy to treat the underlying cause. Cryoprecipitate replaces factor VIII and fibrinogen and is given if the fibrinogen level is below 100 mg/dL (1 g/L).[1] FFP is given only to patients with significant bleeding and a prolonged PT and aPTT. It replaces all clotting factors except platelets and is a source of antithrombin.

TABLE 30.20 Laboratory Results in Acute DIC

Test	Finding in Acute DIC
Screening Tests	
Prothrombin time (PT)	Prolonged
Partial thromboplastin time (PTT)	Prolonged
Activated partial thromboplastin time (aPTT)	Prolonged
Fibrinogen	Reduced
Platelets	Reduced
Thrombin time	Prolonged
Special Tests	
Antithrombin III (AT III)	Reduced
D-dimers (cross-linked fibrin fragments)	Increased
Factor assays (prothrombin and factors V, VIII, X, XIII)	Reduced but may give misleading results, since V and VIII rise with inflammation
Fibrin split products (FSPs)	Increased
Peripheral blood smear	Schistocytes present
Plasminogen, tissue plasminogen activator	Reduced
Proteins C and S	Reduced

A patient with thrombosis is often treated by anticoagulation with heparin or LMSH. Heparin is used in the treatment of DIC only when the benefit (reduce clotting) outweighs the risk (further bleeding). Antithrombin III (ATnativ) may be useful in fulminant DIC, although it increases the risk for bleeding. Chronic DIC does not respond to oral anticoagulants. It is controlled with long-term use of heparin.

Nursing Management: Disseminated Intravascular Coagulation

Nursing Diagnoses

Nursing diagnoses for the patient with DIC may include the following:

- Risk for bleeding
- Ineffective tissue perfusion
- Acute pain
- Impaired cardiac output

Nursing Implementation

Be alert to the development of DIC, especially with the precipitating factors listed in Table 30.19. Remember that because DIC is caused by an underlying disease, that problem must be managed while providing supportive care for the manifestations of DIC.

Appropriate nursing interventions are essential to the survival of a patient with acute DIC. Astute ongoing assessment, active attention to manifestations of DIC, and prompt administration of prescribed therapies are crucial. Table 30.14 and eNursing Care Plan 30.2 (available on the website for this chapter) provide assessments and interventions appropriate for the patient with DIC.

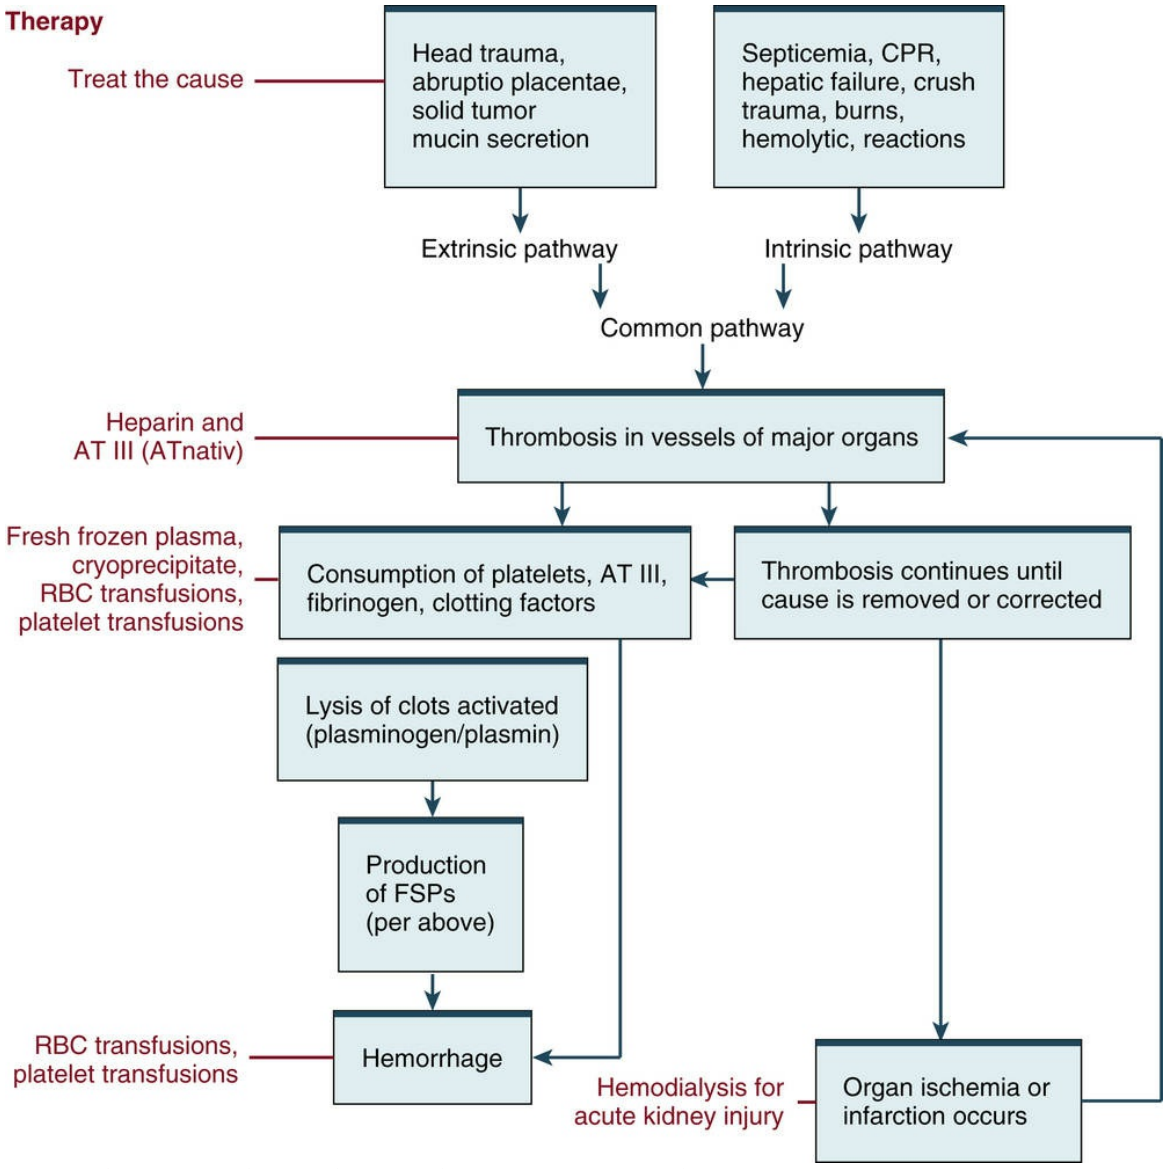

FIG. 30.11 Sites of action for therapies in DIC. *AT III,* Antithrombin III; *FSPs,* fibrin split products.

Early detection of bleeding and clotting, both occult and overt, must be a primary goal. Assess for signs of external bleeding (e.g., petechiae, oozing at IV or injection sites), signs of internal bleeding (e.g., increased heart rate, changes in mental status, increasing abdominal girth, pain), and any signs that microthrombi may be causing clinically significant organ damage (e.g., decreased renal output). Minimize tissue damage and protect the patient from sources of bleeding. Give blood products and medications correctly. Blood product transfusion is discussed later in this chapter on pp. 647–651.

Neutropenia

Leukopenia refers to a decrease in the total WBC count (granulocytes, monocytes, and lymphocytes). *Granulocytopenia* is a deficiency of granulocytes, which include neutrophils, eosinophils, and basophils. The neutrophilic granulocytes (neutrophils), which play a key role in phagocytizing pathogenic microbes, are closely monitored in clinical practice as an indicator of a patient's risk for infection. A reduction in neutrophils is termed **neutropenia**. Some clinicians use the terms granulocytopenia and neutropenia interchangeably because the largest constituency of granulocytes is the neutrophils.

The *absolute neutrophil count* (ANC) is determined by multiplying the total WBC count by the percent of neutrophils. *Neutropenia* is defined as ANC less than 1000 cells/μL (1×10^9/L). Normally, neutrophils range from 2200 to 7700 cells/μL. *Severe neutropenia* is defined as an ANC less than 500 cells/μL.[21]

In considering the clinical significance of neutropenia, it is important to know whether the decrease in the neutrophil count was gradual or rapid, the degree of neutropenia, and the duration. The faster the drop and the longer the duration, the greater the chance of life-threatening infection, sepsis, and death. Other factors and co-morbid conditions, such as immune disorders (e.g., HIV), being older than 60, having an existing infection, being in the hospital, and having chronic obstructive pulmonary disease, can increase the risk for a serious infection.[22]

Neutropenia is a clinical consequence that occurs with a variety of conditions or diseases (Table 30.21). It can be an expected effect, a side effect, or an unintentional effect of certain drugs. The most common cause of neutropenia is the use of chemotherapy and immunosuppressive therapy in the treatment of cancer and autoimmune disease. A term we use to describe the lowest point of neutropenia (and other blood cells) in a patient treated with chemotherapy is *nadir*.

Clinical Manifestations

The patient with neutropenia is predisposed to infection with opportunistic pathogens and nonpathogenic organisms from the normal body flora. When the WBC count is low or immature WBCs are present, normal phagocytic mechanisms are impaired. The classic manifestations of inflammation—redness, heat, and swelling—may not occur. WBCs are the major component of pus. Therefore, in the patient with neutropenia, pus formation (e.g., as a visible skin lesion or as lung infiltrates on a chest x-ray) is absent.

TABLE 30.21 Common Causes of Neutropenia

Autoimmune Disorders

- Felty syndrome
- Systemic lupus erythematosus

Drugs

- Alkylating agents (busulfan)
- Antiinflammatory drugs (indomethacin)
- Antimetabolites (methotrexate, mercaptopurine, cytarabine)
- Antimicrobial agents (ganciclovir, penicillin G, trimethoprim/sulfamethoxazole)
- Antitumor antibiotics (daunorubicin, doxorubicin)
- Cardiovascular drugs (captopril, procainamide)
- Diuretics (hydrochlorothiazide)
- Miscellaneous (ticlopidine, penicillamine)

Hematologic Disorders

- Aplastic anemia
- Congenital (cyclic neutropenia)
- Fanconi syndrome
- Idiopathic neutropenia
- Leukemia
- Myelodysplastic syndrome

Infections

- Fulminant bacterial infection (e.g., typhoid fever, miliary tuberculosis)
- Parasitic
- Rickettsial
- Viral (e.g., hepatitis, influenza, HIV, measles)

Others

- Bone marrow infiltration (e.g., carcinoma, tuberculosis, lymphoma)
- Hemodialysis
- Hypersplenism (e.g., portal hypertension, storage diseases [e.g., Gaucher disease])
- Nutritional deficiencies (cobalamin, folic acid)
- Severe sepsis

Safety Alert

Neutropenia

- A low-grade fever in neutropenic patients is of great significance

because it may indicate infection and lead to septic shock and death unless treated promptly.

- Neutropenic fever (≥100.4°F [38°C] and/or new signs or symptoms suggesting infection and a neutrophil count <500/μL) is a medical emergency.[22]
- Blood cultures should be drawn STAT and antibiotics started within 1 hr.

When fever occurs in a neutropenic patient, it is assumed to be caused by infection and requires immediate attention. The immunocompromised, neutropenic patient has little or no ability to fight infection. So, minor infections can lead rapidly to sepsis and death. The mucous membranes of the throat and mouth, skin, perineal area, and pulmonary system are common entry points for pathogenic organisms in susceptible hosts.

Manifestations related to infection at these sites include sore throat and dysphagia, ulcerative lesions of the pharyngeal and buccal mucosa, diarrhea, rectal tenderness, vaginal itching or discharge, shortness of breath, and nonproductive cough. Any report of minor pain or any other symptom by the patient may be significant and should be reported to the HCP at once. These seemingly minor problems can progress to fever, chills, sepsis, septic shock, and death if not recognized and treated early.

TABLE 30.22 Interprofessional CareNeutropenia

Diagnostic Assessment

- History and physical examination
- Risk assessment for severity and duration of neutropenia
- WBC count with differential count
- WBC morphology
- Hgb and Hct

- Reticulocyte and platelet count
- Bone marrow aspiration or biopsy
- Cultures of nose, throat, sputum, urine, stool, obvious lesions, blood (as indicated)
- Chest x-ray or other diagnostic tests

Management

- Identification and removal of cause of neutropenia (if possible)
- Identification of site of infection (if present) and causative organism
- Antimicrobial therapy (prophylactically or empiric)
- Blood cultures drawn STAT, before antibiotics
- Prophylactic hematopoietic myeloid growth factors after myelosuppressive chemotherapy
- Strict hand hygiene
- Patient hygiene (daily skin and frequent oral care; chlorhexidine bathing should be done in the inpatient setting if the patient has a central venous catheter)
- Single-patient room, positive-pressure or high-efficiency particulate air (HEPA) filtration, depending on risk
- Community isolation and home precautions (if outpatient)
- Nutritional therapy (dietary instruction) on foods to avoid and safe food handling
- Safe activity and ambulation to maintain physical and pulmonary function

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor.

Systemic infections caused by bacterial, fungal, and viral organisms are common in patients with neutropenia. The patient's own flora

(normally nonpathogenic) contributes significantly to life-threatening infections. Organisms known to be common sources of infection include gram-positive coagulase-negative *Staphylococcus* and *Staphylococcus aureus* and gram-negative *E. coli, Klebsiella, Enterobacter,* and *Pseudomonas aeruginosa*.[22] Fungi involved include *Candida* (usually *C. albicans*) and *Aspergillus* organisms. Viral infections caused by reactivation of herpes simplex and zoster are common after prolonged periods of neutropenia, such as in HSCT patients.[23]

Diagnostic Studies

The primary diagnostic tests for assessing neutropenia are the peripheral WBC count and bone marrow aspiration and biopsy (Table 30.22). A total WBC count of less than 4000/μL (4×10^9/L) reflects leukopenia. However, only a differential count can confirm the presence of neutropenia (neutrophil count less than 1000/μL [1×10^9/L]). If the differential WBC count reflects an absolute neutropenia of 500 to 1000/μL (0.5 to 1.0×10^9/L), the patient is at moderate risk for a bacterial infection. An absolute neutropenia of less than 500/μL (0.5×10^9/L) places the patient at severe risk. Patients with acute leukemia who present with a high WBC may in fact have neutropenia, because most of the WBCs are ineffective leukemia blasts cells.

A peripheral blood smear assesses for immature forms of WBCs (e.g., bands). The hematocrit level, reticulocyte count, and platelet count are done to evaluate bone marrow function. Review the patient's recent past and current drug history. If the cause of neutropenia is unknown, a bone marrow aspiration and biopsy is done to examine cellularity and cell morphology. Other studies may be done to assess spleen and liver function.

Interprofessional and Nursing Management

The nursing and interprofessional care of neutropenia includes (1) determining the cause of the neutropenia, (2) instituting antibiotic therapy promptly, (3) identifying the offending organisms if an

infection has developed, (4) giving hematopoietic growth factors prophylactically after chemotherapy, and (5) implementing protective practices (e.g., strict hand washing, skin and oral hygiene) (Table 30.22).[24]

Sometimes, the cause of the neutropenia can be easily treated (e.g., nutritional deficiencies). However, neutropenia can be a side effect that must be tolerated as a necessary step in therapy (e.g., chemotherapy, radiation therapy). In some situations, the neutropenia resolves when the primary disease or disorder is treated.

Nursing Management

Caring for the Patient With Neutropenia

All members of the health care team have important roles in preventing infection in the patient with neutropenia. Careful hand washing is an important preventive measure. It should be done before, during, and after patient care by everyone caring for the patient.

- Determine the type of isolation precautions that need to be started, if any.
- Assess patient for signs and symptoms of infection.
- Screen visitors for infectious diseases.
- Place the patient on a neutropenic diet to protect them from bacteria found in some foods.
- Obtain cultures of sputum, throat, lesions, wounds, urine, and feces.
- Give antibiotics and hematopoietic growth factors.
- Teach patient and visitors about hand washing.
- Provide teaching about how to avoid infection, including the need for skin care and oral hygiene.
- Teach the patient and caregivers about signs and symptoms of

infection and what to do if they occur.

Monitor the neutropenic patient for signs and symptoms of infection (e.g., any fever 100.4°F [38°C] or greater) and early septic shock. Early identification of a potentially infective organism depends on obtaining cultures from various sites. Serial blood cultures (at least 2) or 1 from a peripheral site and 1 from a venous access device should be done promptly and antibiotics started within 1 hour.

Giving broad-spectrum antibiotics is usually by the IV route because of the rapidly lethal effects of infection. However, some oral antibiotics are highly effective and routinely used for prophylaxis against infection in some neutropenic patients. The use of a third- or fourth-generation cephalosporin with broad microorganism coverage (e.g., cefepime, ceftazidime) or a carbapenem (e.g., imipenem/cilastatin [Primaxin]) will be started and augmented depending on the patient's response and/or results of the diagnostic tests.

Begin therapy promptly and observe the patient for side effects of antimicrobial agents. Ongoing febrile episodes or a change in the patient's assessment requires a call to the HCP for assessment, or more cultures, diagnostic tests, or antimicrobial therapies. The longer the neutropenia, the greater the risk is for a fungal infection. Antifungal therapy is started whenever a culture is positive, or in patients who do not become afebrile with broad-spectrum antibiotic coverage.

Cultures of sputum, throat, lesions, wounds, urine, and feces may part of patient surveillance. Depending on the clinical situation, it may be necessary to do CT scans, bronchoscopy with bronchial brushings, or lung biopsy to diagnose the cause of pneumonic infiltrates. Invasive diagnostic studies are often contraindicated because of the concern of introducing infection and the fact that these patients are also often thrombocytopenic. Despite these many tests, the causative organism is found in only 20% to 30% of neutropenic patients. Thus the priority is to obtain the blood cultures and begin the antibiotic at once. Ongoing monitoring is essential as early identification and

appropriate management can prevent death from sepsis.[25]

Myeloid growth factors (see Table 15.15) can be used to prevent neutropenia or to reduce its severity and duration.[24] Once neutropenia has occurred, these agents are generally not as effective.

Keep the following care principles in mind: (1) the patient's normal flora is the most common source of microbial colonization and infection; (2) transmission of organisms from humans most often occurs by direct contact with the hands; (3) air, food, water, and equipment provide opportunities for infection transmission; and (4) HCPs, visitors, and other patients with infections also can be sources of infection transmission under certain conditions.

Hand washing is the single most important preventive measure to minimize the risk for infection in the neutropenic patient. Strict hand washing by staff and visitors using an antiseptic hand wash before and after contact is the major method to prevent transmission of harmful pathogens.

Separate immunocompromised patients from those who are infected or have conditions that increase the probability of transmitting infections (e.g., poor hygiene caused by lack of understanding or cognitive dysfunction). Often patients can be managed on an outpatient basis if the patient and caregiver can monitor for fever and other signs of infection and then report promptly to a nearby health care facility (Table 30.23).[1,21] If the patient is hospitalized, a private room should be used. High-efficiency particulate air (HEPA) filtration is an air-handling method with a high-flow filtering system that can reduce or eliminate the number of aerosolized pathogens in the environment used for hematopoietic stem cell transplant patients. Care routines in a HEPA environment are the same as care in any other private room. Neutropenic precaution guidelines may be used, such as prophylactic antibiotics and antifungals. Teach the patient and caregiver to avoid potentially hazardous foods, such as raw and undercooked meats and eggs and soft cheeses with molds.[1] The nursing measures discussed in eNursing Care Plan 30.3 (available on the website for this chapter) are important in the treatment of the patient with neutropenia.

Do not overlook quality-of-life issues for the patient with neutropenia. Fatigue, malaise, a decrease in functioning, and social isolation require coaching on safe activity.

TABLE 30.23 Patient & Caregiver TeachingNeutropenia

Include the following instructions when teaching a patient or caregiver the precautions to take when the neutrophil count is low:

1. WASH YOUR HANDS frequently and make sure those around you wash their hands frequently, especially if they help with your care. You may also use an antibacterial hand gel.
2. Notify your nurse or HCP if you have any of the following:
   - Fever ≥100.4°F (38°C)*
   - Chills or feeling hot
   - Redness, swelling, discharge, or new pain on or in your body
   - Changes in urination or bowel movements
   - Cough, sore throat, mouth sores, or blisters
3. If you are at home, take your temperature as directed and follow instructions on what to do if you have a fever.
4. Avoid crowds and people with colds, flu, or infections. If you are in a public area, wear a mask and use hand sanitizing gel frequently.
5. Avoid uncooked meats, seafood, or eggs and unwashed fruits and vegetables. Ask your HCP about specific dietary guidelines for you.
6. Bathe or shower daily. Use a moisturizer to prevent skin from drying and cracking.
7. Maintain some daily activity as instructed by your health care team. This may include walking and moderate exercise while avoiding crowds.
8. Brush your teeth with a soft toothbrush 4 times daily. You may

floss once daily if it does not cause excessive pain or bleeding. Avoid alcohol-based mouthwashes.

9. Do not garden or clean up after pets. You may feed and pet your dog or cat if you wash your hands well after handling.

---

* Need to verify cut-off temperature with HCP.

Myelodysplastic Syndrome

Myelodysplastic syndrome (MDS) is a group of related hematologic disorders characterized by peripheral blood cytopenias (from ineffective blood cell production) and changes in the cellularity of the bone marrow with dysplastic changes. In MDS, *hematopoiesis* is disorderly and ineffective. The estimated incidence is 4.9 per 100,000 people per year in the United States. Although it can occur in all age-groups, the highest prevalence is in people over 80 years of age, at which point the rate increases to 59.8 per 100,000.[26]

Etiology and Pathophysiology

The etiology of MDS is unknown. People who have received radiation therapy, had chemotherapy with alkylating agents (e.g., chlorambucil, cyclophosphamide, melphalan), or were exposed to industrial solvents (e.g., benzene) have a higher risk for developing MDS than people who have not had these exposures. About 50% of MDS patients have an overt chromosome abndormality.[1,3] Rarely, genetic disorders are responsible for the disease.

We refer to MDS as a *clonal disorder because* some bone marrow stem cells continue to function normally, while others do not. The abnormal clone of the stem cells is usually found in the bone marrow. Eventually, it may be found in the circulation.

Sometimes, one type of MDS transforms into another. Depending on the subtype, MDS may progress to acute myelogenous leukemia (AML).[26] In contrast to AML, in which the leukemic cells show little normal maturation, the clonal cells in MDS always display some degree of maturity. Disease progression is slower than in AML, and sometimes treatment is not needed.

Clinical Manifestations

Manifestations result from neoplastic transformation of the immature

hematopoietic stem cells in the bone marrow. MDS often presents as infection and bleeding caused by inadequate numbers of ineffectively functioning circulating granulocytes or platelets. It may be found in the older adult during testing for the symptoms of anemia, thrombocytopenia, or neutropenia. It may be diagnosed incidentally from a routine CBC. During the advanced stage of MDS, life-threatening anemia, thrombocytopenia, and neutropenia occur.

Diagnostic Studies

Bone marrow biopsy with aspirate analysis is essential for both the diagnosis and classification of the specific type of MDS. The patient with MDS has peripheral cytopenia and changes in the bone marrow (hypocellular or hypercellular). Laboratory data and bone marrow studies help rule out other causes of the dysplasia, such as nonmalignant disorders, cobalamin and folate deficiencies, and infections.

Interprofessional and Nursing Management

Treatment of MDS is based on the premise that the aggressiveness of treatment should match the aggressiveness of the disease. This is based on the amount and type of dysplasia in the bone marrow, specific genetic mutations, anticipated patient tolerance, and patient preference.[26] Supportive treatment consists of hematologic monitoring (serial bone marrow and peripheral blood examinations), antibiotic therapy, or transfusions with blood products along with iron chelators to prevent iron overload.

Low-risk patients often can be treated with EPO, myeloid growth factors, and thrombopoietin.[26] Some patients are treated with intensive chemotherapy and/or HSCT. Azacitidine (Vidaza) and decitabine (Dacogen) are drugs that help restore normal growth control and differentiation of hematopoietic cells and reduce the frequency of transformation of MDS to acute leukemia. Side effects include myelosuppression, nausea, vomiting, constipation or diarrhea,

renal dysfunction, and injection site redness.

Other treatments for MDS include lenalidomide (Revlimid), cytarabine with or without antitumor antibiotics (anthracyclines), antithymocyte globulin, and cyclosporine.[25,26] Chemotherapy and allogeneic HSCT are used in appropriate patients with high-risk features to treat bone marrow dysfunction of MDS and restore it with normal hematopoiesis.

Nursing care of a patient with MDS is like that of a patient with manifestations of anemia, thrombocytopenia, and neutropenia. (See eNursing Care Plan 30.1 for the patient with anemia, eNursing Care Plan 30.2 for the patient with thrombocytopenia, and eNursing Care Plan 30.3 for the patient with neutropenia. The eNursing Care Plans are available on the website for this chapter.)

Leukemia

Leukemia is the general term used to describe a group of cancers affecting the blood and blood-forming tissues of the bone marrow, lymph system, and spleen. Leukemia occurs in all age-groups. It results in an accumulation of dysfunctional cells because of a loss of regulation in cell division. An estimated 62,130 new cases are diagnosed each year. Leukemias account for 29% of all childhood cancers. Of those, 76% are lymphoid leukemias.[27] Leukemia follows a progressive course that is eventually fatal if untreated. However, progress in successful cancer treatments has been most rapid for hematopoietic and lymphoid cancers in the past 3 decades.[27]

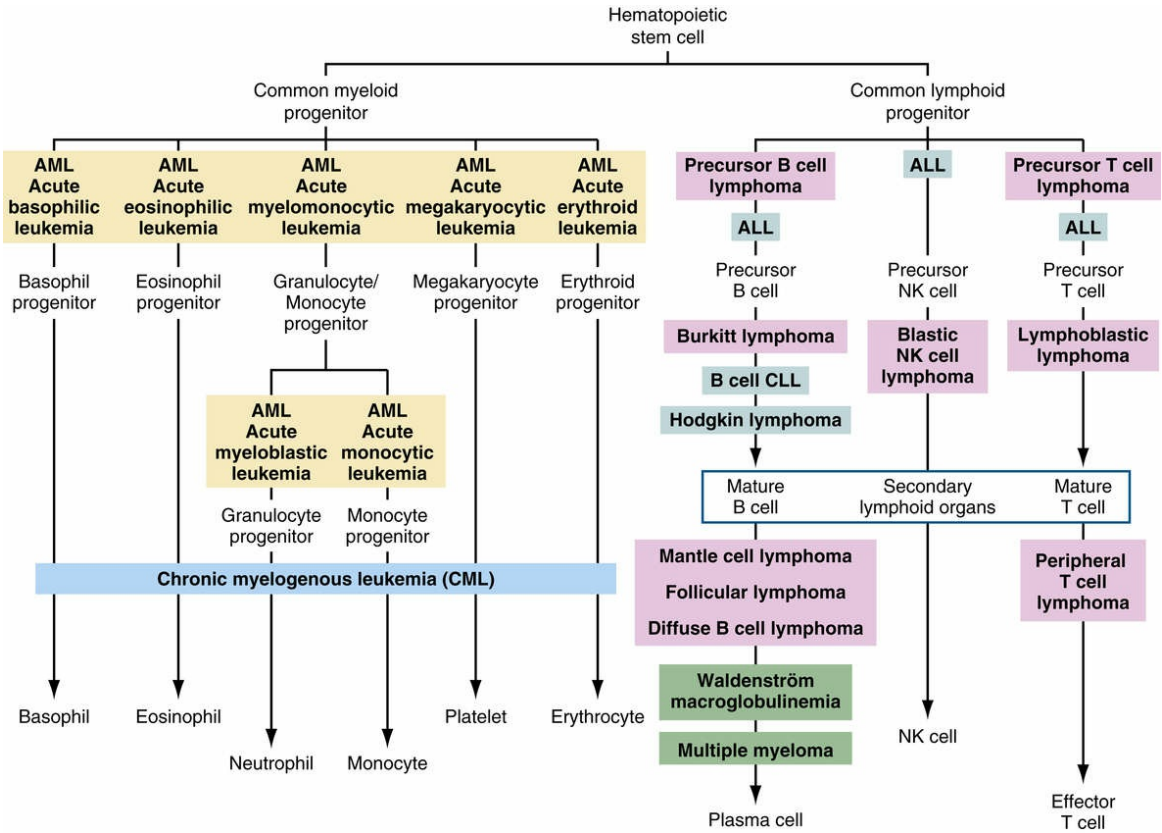

FIG. 30.12 Origins of leukemias, lymphomas, and myeloma. Differentiation pathways of blood-forming cells and the point at which the malignant clone originates.

Modified from Huether SE, McCance KL, editors: *Understanding pathophysiology,* ed 7, St Louis, 2017, Elsevier.

Etiology and Pathophysiology

Leukemia has no single cause. It is now known that all cancers, including leukemia, begin as a mutation in the DNA of certain cells. Most leukemias result from a combination of factors, including genetic and environmental influences. Abnormal genes *(oncogenes)* can cause many types of cancers, including leukemias (see Chapter 15). Chemical agents (e.g., benzene), chemotherapeutic agents (e.g., alkylating agents, topoisomerase II inhibitors), viruses, radiation, and immunologic deficiencies have all been associated with the development of leukemia. Depending on the type of leukemia, other potential causes are exposure to pesticides (farmworkers), smoking, and obesity.[3]

Although ribonucleic acid (RNA) retroviruses cause several leukemias in animals, a viral cause for a human leukemia has been established for only some patients with adult T-cell leukemia/lymphoma. This form of leukemia is endemic in southwestern Japan and parts of the Caribbean and is caused by the human T-cell leukemia virus, type 1 (HTLV-1).[28] Leukemia occurs more often in those with certain congenital or inherited abnormalities (e.g., Down syndrome). Chronic lymphocytic leukemia has a familial trend.[3]

Classification

Leukemia is classified based on acute versus chronic disease and on the type of WBC involved. The terms *acute* and *chronic* refer to cell maturity and nature of disease onset. Acute leukemia is characterized by the clonal proliferation of immature hematopoietic cells. The leukemia develops after malignant transformation of a single type of immature hematopoietic cell, followed by cellular replication and expansion of that malignant clone (Fig. 30.12). Chronic leukemias

involve more mature forms of the WBC. The disease onset is more gradual.

Leukemia classified by the type of leukocyte involved is described as myelogenous or lymphocytic origin. By combining the acute and chronic categories with the cell type involved, one can identify 4 major types of leukemia: acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic myelogenous (granulocytic) leukemia (CML), and chronic lymphocytic leukemia (CLL). Other defining features of these leukemic subtypes are shown in Table 30.24.

Acute Myelogenous Leukemia

AML represents about one third of all leukemias, and it makes up about 80% of the acute leukemias in adults.[3,29] Its onset is often abrupt and dramatic. A patient may have serious infections and abnormal bleeding from the onset of the disease.

TABLE 30.24 Types of Leukemia

Age of Onset	Clinical Manifestations	Diagnostic Findings
Acute Myelogenous Leukemia (AML)		
Accounts for 15%–20% of acute leukemia in children and 80% in adults. Increase in incidence with advancing age after 60 yr.	Fatigue and weakness, headache, mouth sores, anemia, bleeding, fever, infection, sternal tenderness, gingival hyperplasia, mild hepatosplenomegaly (one third of patients)	Low RBC count, Hgb, Hct, platelet count. Low to high WBC count with myeloblasts. High LDH. Hypercellular bone marrow with myeloblasts.
Acute Lymphocytic Leukemia (ALL)		
Median diagnosis is 15 yr with 57.2% diagnosed at younger than 20 yr. About 27% of cases are diagnosed at age 4 or older and only 11% at age 65 or older.	Fever, pallor, bleeding, anorexia, fatigue, and weakness. Bone, joint, and abdominal pain. Generalized lymphadenopathy, infections, weight loss, hepatosplenomegaly, headache, mouth sores, neurologic manifestations: CNS involvement, increased intracranial pressure (nausea, vomiting, lethargy, cranial nerve dysfunction) from meningeal infiltration. Men may have painless enlargement of the scrotum.	Low RBC, Hgb, Hct, platelet count. Low, normal, or high WBC count. High LDH. Hypercellular bone marrow with lymphoblasts. Lymphoblasts may be in cerebrospinal fluid. Presence of Philadelphia chromosome (up to 30% of patients). Up to 15% may have a mediastinal mass.
Chronic Myelogenous Leukemia (CML)		
Increase in incidence with advancing age, with median age at diagnosis of 67. Rare in children.	No symptoms early in disease. Fatigue and weakness, fever, sternal tenderness, weight loss, joint pain, bone pain, massive splenomegaly, increase in sweating.	Low RBC count, Hgb, Hct. High platelet count early, lower count later. ↑ Banded neutrophils and myeloblasts and often basophils, normal number of lymphocytes, and normal or low number of monocytes. Nucleated red cells are common. Low leukocyte alkaline phosphatase. Presence of Philadelphia chromosome in ≥90% of patients.
Chronic Lymphocytic Leukemia (CLL)		
Increase in incidence with advancing age after 65 yr, with predominance in men.	Frequently no symptoms. Detection of disease often during examination for unrelated condition, chronic fatigue, anorexia, splenomegaly and lymphadenopathy, hepatomegaly. May progress to fever, night sweats, weight loss, fatigue, and frequent infections.	Mild anemia and thrombocytopenia with disease progression. Total WBC count >100,000/μL. Increase in peripheral lymphocytes and lymphocytes in bone marrow. May have autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, and hypogammaglobulinemia.

AML is characterized by uncontrolled proliferation of myeloblasts, the precursors of granulocytes. There is hyperplasia of the bone marrow. The manifestations are usually related to replacement of normal hematopoietic cells in the marrow by leukemic myeloblasts and, to a lesser extent, to infiltration of other organs and tissue (Table 30.24).

Acute Lymphocytic Leukemia

ALL is the most common type of leukemia in children and accounts for about 20% of acute leukemia cases in adults.[3,30] In ALL, immature small lymphocytes proliferate in the bone marrow. Most are of B-cell origin. Most patients have fever at the time of diagnosis. Signs and symptoms may appear abruptly with bleeding or fever, or they may be insidious with progressive weakness, fatigue, bone and/or joint pain, and bleeding tendencies.

Central nervous system (CNS) manifestations are especially common in ALL and are a serious problem. Infiltration into other

tissues and lymph nodes can occur.[3]

Chronic Myelogenous Leukemia

CML is caused by excessive development of neoplastic granulocytes in the bone marrow. These granulocytes are in all stages of development. They move into the peripheral blood in massive numbers and infiltrate the liver and spleen.[31]

The natural history of CML is a chronic stable phase followed by the development of a more acute, aggressive phase referred to as the *blastic phase.* The chronic phase of CML can last for several years. It usually can be well controlled with treatment. Even with treatment, the chronic phase of the disease eventually progresses to the accelerated phase, ending in a blastic phase. Once CML transforms to an acute or blastic phase, it must be treated more aggressively, similar to an acute leukemia.

Genetic Link

The *Philadelphia chromosome* originates from the translocation between the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. The protein that is encoded by the newly created *BCR-ABL* gene on the Philadelphia chromosome interferes with normal cell cycle events, such as the regulation of cell proliferation.

The Philadelphia chromosome, which is present in about 90% or more of patients with CML, is a diagnostic hallmark of CML.[31] In addition, its presence is an important indicator of residual disease or relapse after treatment. However, the presence of the Philadelphia chromosome is not specific to diagnose CML. It is also found in ALL and occasionally in AML.

Chronic Lymphocytic Leukemia

CLL is the most common leukemia in adults in Western countries.[32] CLL is characterized by the production and accumulation of functionally inactive but long-lived, small, mature-appearing lymphocytes. B cells are usually involved. The lymphocytes infiltrate

the bone marrow, spleen, and liver. Lymph node enlargement (lymphadenopathy) is present throughout the body.

Complications are rare in early-stage CLL but may develop as the disease advances. Pressure on nerves from enlarged lymph nodes causes pain and even paralysis. Mediastinal node enlargement leads to pulmonary symptoms. Because CLL is usually a disease of older adults, treatment decisions must be made by considering the progression of the disease and the side effects of treatment. Many patients in the early stages of CLL do not need treatment. Others are followed closely and receive treatment only when the disease progresses. About one-third need immediate treatment at the time of diagnosis.

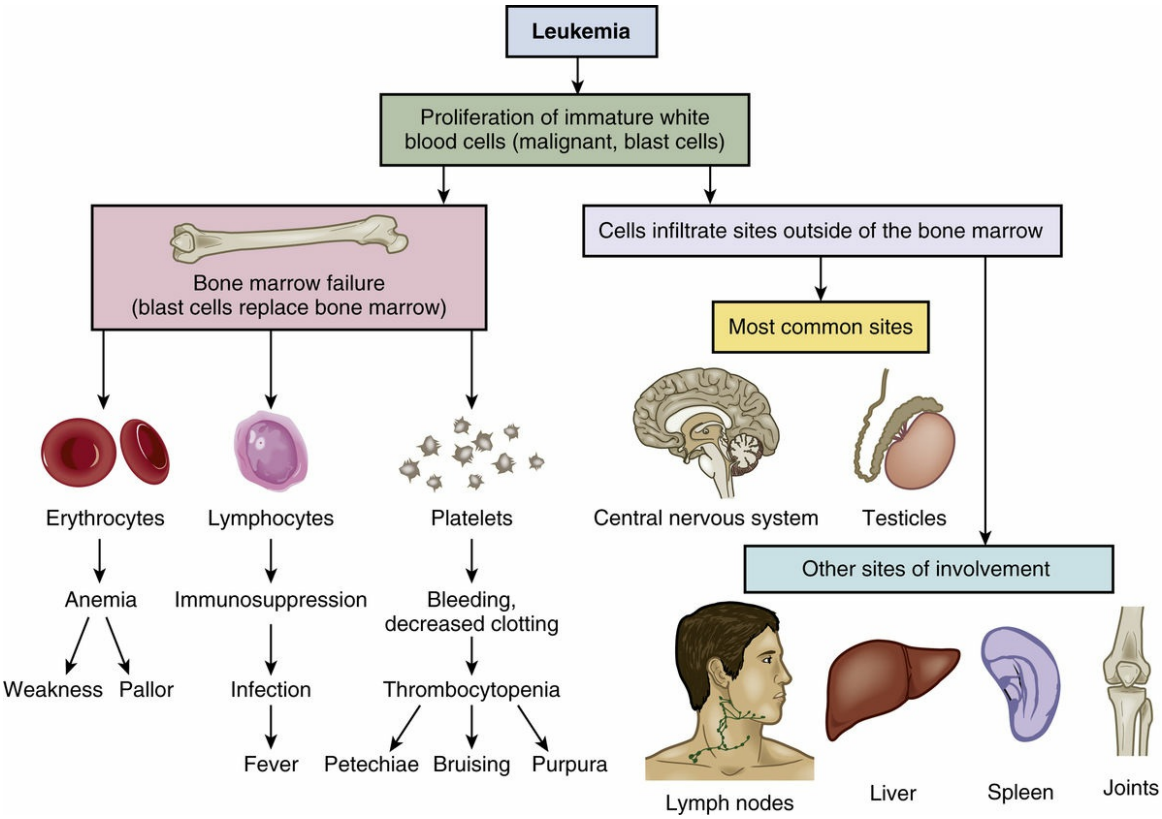

FIG. 30.13 Pathophysiology of leukemia.
Modified from McKinney ES, James SR, Murray SS, et al: *Maternal-child nursing,* Philadelphia, 2000, Saunders.

Other Leukemias

Occasionally the subtype of leukemia cannot be identified. The cancerous leukemic cells may have lymphoid, myeloid, or mixed characteristics. Often these patients do not respond to treatment and have a poor prognosis. Other rare types include hairy cell and biphenotypic (both abnormal myeloid and lymphoid clones) leukemias.

Overlap Between Leukemia and Lymphoma

Overlap exists between leukemia and non-Hodgkin's lymphoma (NHL) because both involve proliferation of lymphocytes or their precursors (Fig. 30.12). A leukemia-like picture with peripheral lymphocytosis and bone marrow involvement may be present in about 15% of adults with some types of NHL.[3] Patients with more extensive nodal involvement (especially mediastinal), fewer circulating abnormal cells, and fewer blast forms in the marrow are considered to have lymphoma. A prominent leukemic phase is less common in aggressive lymphomas, except Burkitt's, lymphoblastic lymphomas, and those classified as "double hit," meaning they have a double oncogene mutation.[3,33]

Clinical Manifestations

The manifestations of leukemia are varied (Table 30.24). They relate to problems caused by bone marrow failure and the formation of leukemic infiltrates (Fig. 30.13). Bone marrow failure results from (1) bone marrow overcrowding by abnormal cells and (2) inadequate production of normal marrow elements. The patient is predisposed to anemia, thrombocytopenia, and decreased number and function of WBCs.

As leukemia progresses, fewer normal blood cells are made. The abnormal WBCs continue to accumulate because they do not go through the normal cell life cycle to death *(apoptosis).* The leukemic cells may infiltrate the patient's organs, leading to problems such as splenomegaly, hepatomegaly, lymphadenopathy, bone pain,

meningeal irritation, and oral lesions. Solid masses resulting from collections of leukemic cells, called *chloromas,* can occur. A high leukemic white count in the peripheral blood (more than 100,000 cells/μL) can cause the blood to thicken and potentially block circulatory pathways. This is called *leukostasis.* It can be life threatening.

Diagnostic Studies

Peripheral blood evaluation and bone marrow examination are the primary methods of diagnosing and classifying the types of leukemia. Morphologic, histochemical, immunologic, and cytogenetic methods are used to identify leukemic cell types, stage of development, and significant genetic mutations. Knowing the type of leukemia is important because each type has a different prognosis and treatment options. For example, in CML, the finding of the Philadelphia chromosome is an important diagnostic indicator. It is also sometimes present in ALL and affects the treatment as well.[30,31] Other studies, such as lumbar puncture and PET/CT scans, can detect leukemic cells outside of the blood and bone marrow.

Interprofessional Care

Once a diagnosis of leukemia has been made, care focuses on the initial goal of attaining remission. Age and cytogenetic analysis often help form the basis of important treatment decisions. Because chemotherapy is the mainstay of the treatment, you need to understand the principles of cancer chemotherapy. Radiation and biologic therapies also may be used. (See the section on chemotherapy in Chapter 15.)

In some cases, such as nonsymptomatic patients with CLL, watchful waiting with active supportive care may be appropriate. Although a patient may not be cured, attaining remission or disease control is a realistic option for many patients. In some cases, cure is a realistic goal. In *complete remission,* there is no evidence of overt disease on physical examination, and the bone marrow and peripheral blood appear normal. *Minimal residual disease* is defined as tumor cells that

cannot be detected by morphologic examination but can be identified by molecular testing. *Partial remission* is characterized by a lack of symptoms and a normal peripheral blood smear, but there is still evidence of disease in the bone marrow. *Molecular remission* means that all molecular studies are negative for residual leukemia. The patient's prognosis is directly related to the ability to maintain a remission. The patient's prognosis becomes more unfavorable with each relapse. After each relapse, the succeeding remission may be harder to achieve and shorter in duration.

Sometimes patients have such a high WBC count (e.g., 100,000 cells/μL or more) that initial emergent treatment may include leukapheresis and hydroxyurea. The purpose of these treatments is to reduce the WBC count and risk for leukemia cell–induced thrombosis.

Stages of Chemotherapy

Chemotherapy is often divided into 3 stages: induction, postinduction or postremission (consolidation), and maintenance.

Induction Therapy

The first stage, *induction therapy*, is the attempt to bring about a remission. Induction is aggressive treatment that seeks to destroy leukemic cells in the tissues, peripheral blood, and bone marrow to eventually restore normal hematopoiesis on bone marrow recovery. During induction therapy, a patient may become critically ill because the bone marrow is severely depressed by the chemotherapeutic agents. Nursing interventions focus on neutropenia, thrombocytopenia, and anemia. Common chemotherapy agents for induction of AML include cytarabine and an antitumor antibiotic (anthracycline), such as daunorubicin, idarubicin, or mitoxantrone.[29] After 1 course of induction therapy, around 70% of newly diagnosed patients younger than 60 achieve complete remission. It is assumed that leukemic cells persist undetected after induction therapy. This could lead to relapse within a few months without further therapy.[29]

Postinduction or Postremission Therapy

Terms used to describe postinduction or postremission chemotherapy include *intensification* and *consolidation*. *Intensification therapy,* or high-dose therapy, may be given immediately after induction therapy for several months. Other drugs that target the cell in a different way than those given during induction may be added.

Consolidation therapy is started after a remission is achieved. It may consist of 1 or 2 more courses of the same drugs given during induction or involve high-dose therapy (intensive consolidation). The purpose of consolidation therapy is to eliminate remaining leukemic cells that may not be clinically or pathologically evident.

Maintenance Therapy

Maintenance therapy may be used and involves treatment with lower doses of the same drugs used in induction or other drugs given every few weeks for a prolonged period. Like consolidation or intensification, the goal is to keep the body free of leukemic cells. This is often used with ALL and extends for several years.[30]

TABLE 30.25 Drug TherapyLeukemia

Drug Therapy	Other Therapy
Acute Myelogenous Leukemia	
arsenic trioxide, azacitidine, cladribine, clofarabine, cytarabine, daunorubicin, decitabine, enasidenib, etoposide, fludarabine, gemtuzumab ozogamicin, idarubicin, midostaurin, mitoxantrone, thioguanine, tretinoin, venetoclax **Combination chemotherapy of cytarabine and antitumor antibiotic (most common)**	Allogeneic hematopoietic stem cell transplant (HSCT) (see Chapter 15)
Acute Lymphocytic Leukemia	
blinatumomab, clofarabine, cyclophosphamide, cytarabine, dasatinib, daunorubicin, dexamethasone, doxorubicin, etoposide, imatinib, inotuzumab ozogamicin, L-asparaginase, 6-mercaptopurine, methotrexate, nelarabine, pegaspargase, ponatinib, prednisone, rituximab, vincristine **Combination chemotherapy of several agents is common over a prolonged time**	Cranial radiation therapy, intrathecal methotrexate or cytarabine, allogeneic HSCT, CAR-T cell therapy (see Chapter 15)
Chronic Myelogenous Leukemia	
bosutinib, dasatinib, hydroxyurea, imatinib, nilotinib, omacetaxine, ponatinib **Combination chemotherapy with any of the following: busulfan, cytarabine, daunorubicin, etoposide, L-asparaginase, 6-mercaptopurine, methotrexate, mitoxantrone, prednisone, vincristine**	Radiation, HSCT, α-interferon, leukapheresis
Chronic Lymphocytic Leukemia	
Alemtuzumab, chlorambucil, bendamustine, cyclophosphamide, fludarabine, ibrutinib, idelalisib, lenalidomide, obinutuzumab, ofatumumab, pentostatin, prednisone, rituximab, venetoclax, vincristine	Radiation, splenectomy, colony-stimulating factors, allogeneic HSCT

Drug Therapy Regimens

The therapeutic agents used to treat leukemia vary. Table 30.25 gives examples of treatment regimens used in various types of leukemia.

Combination therapy is the mainstay of treatment for leukemia. The 3 purposes for using multiple drugs are to (1) decrease drug resistance, (2) minimize the drug toxicity by using multiple drugs with varying toxicities, and (3) interrupt cell growth at multiple points in the cell cycle.

Some therapeutic drugs are aimed at small molecules that promote the growth and differentiation of leukemic cells. For example, all-*trans* retinoic acid, which treats acute promyelocytic leukemia (a type of AML), causes normal differentiation of the promyelocytes which has arrested in this type of leukemia by the translocation of the *PML* gene on chromosome 15 to the *RARA* gene on chromosome 17 (t15;17).[29] Midostaurin is a multikinase inhibitor that inhibits this growth pathway in AML patients with the *FLT3* mutation. [29] Imatinib (Gleevec) and other tyrosine-kinase inhibitors target the BCR-ABL protein that is present in nearly all patients with CML and some patients with ALL.[30,31] This drug kills only cancer cells, leaving healthy cells alone.

The use of specific targeted therapy in the form of monoclonal antibodies is an important treatment modality in hematopoietic cancers, but cures with these therapies alone are rare (see Table 15.13 and Fig. 15.16). Rituximab binds to the B-cell antigen (CD20) and is a treatment for CLL.[32] Alemtuzumab (Campath), a treatment for CLL, binds to CD52, a panlymphocyte antigen present on both T and B cells.[32]

Other Treatments

In addition to chemotherapy, corticosteroids and radiation therapy have a role in the treatment of the patient with leukemia. Total body radiation may be used to prepare a patient for bone marrow transplantation. Radiation may be restricted to certain areas (fields,) such as the liver and spleen, or other organs affected by infiltrates. In

ALL, prophylactic intrathecal methotrexate or cytarabine is given to decrease the chance of CNS involvement, which is common in this type of leukemia. When CNS leukemia does occur, cranial radiation is an option. Immunotherapy and targeted therapy, such as monoclonal antibodies and chimeric antigen receptor (CAR) T cells, may be indicated for specific leukemias. (Immunotherapy and targeted therapy are discussed in Chapter 15.)

Hematopoietic Stem Cell Transplantation

HSCT is another type of therapy used for patients with different forms of leukemia. The goal of HSCT is to eliminate all leukemic cells from the body using combinations of chemotherapy with or without total body irradiation. This treatment eradicates the patient's hematopoietic stem cells, which are then replaced with those of an HLA-matched sibling, HLA-half-matched relative, volunteer donor *(allogeneic)*, or identical twin *(syngeneic)*. (HSCT is discussed in Chapter 15.)

The primary complications for patients with allogeneic HSCT are graft-versus-host disease (GVHD), relapse of leukemia, and infection and sepsis. Because HSCT has serious associated risks, the patient must weigh the significant risks for treatment-related death or treatment failure (relapse) with the hope of cure.

Nursing Management: Leukemia

Nursing Assessment

Subjective and objective data that should be obtained from a patient with leukemia are outlined in Table 30.26.

Nursing Diagnoses

Nursing diagnoses for the patient with leukemia include those for anemia (see p. 608), thrombocytopenia (see p. 625), and neutropenia (see eNursing Care Plan 30.3, available on the website).

Planning

The overall goals are that the patient with leukemia will (1) understand and adhere to the treatment plan; (2) have minimal side effects and complications associated with both the disease and its treatment; and (3) establish realistic hope and goals, feeling supported during periods of treatment, relapse, or remission.

Nursing Implementation

Acute Care

The nursing role during acute phases of leukemia is extremely challenging because the patient has many physical and psychosocial needs. As with other forms of cancer, the diagnosis of leukemia can evoke great fear and be equated with death. It may be viewed as a hopeless, horrible disease with many painful and undesirable consequences. The treatment and prognosis of each patient with leukemia are driven by many factors, such as age and type of leukemia. Therefore you must understand the patient's type of leukemia, prognosis, treatment plan, and goals. By doing this, you can help the patient realize that, although the future may be uncertain, one can have a meaningful quality of life while in remission or with

disease control and that, in some cases, there is reasonable hope for cure.

TABLE 30.26 Nursing AssessmentLeukemia

Subjective Data
Important Health Information

Past health history: Exposure to chemical toxins (e.g., benzene, arsenic), radiation, or viruses (HTLV-1); chromosome abnormalities (Down syndrome, Klinefelter syndrome, Fanconi syndrome), immunologic deficiencies; organ transplantation; frequent infections; bleeding tendencies
Medications: Chemotherapy
Surgery or other treatments: Radiation exposure; prior radiation and chemotherapy for cancer

Functional Health Patterns

Health perception–health management: Family history of leukemia; malaise
Nutritional-metabolic: Mouth sores, weight loss; chills, night sweats; nausea, vomiting, anorexia, dysphagia, early satiety; easy bruising
Elimination: Hematuria, decreased urine output; diarrhea, dark or bloody stools
Activity-exercise: Fatigue with progressive weakness; dyspnea, nosebleeds, cough
Cognitive-perceptual: Headache; muscle cramps; sore throat; generalized sternal tenderness, bone, joint, abdominal pain; paresthesias, numbness, tingling, visual changes
Sexuality-reproductive: Prolonged menses, menorrhagia, metrorrhagia, impotence

Objective Data

General

Fever, generalized lymphadenopathy, lethargy

Integumentary

Pallor or jaundice; petechiae, ecchymoses, purpura, reddish brown to purple cutaneous infiltrates, macules, and papules

Cardiovascular

Tachycardia, systolic murmurs

Gastrointestinal

Gingival bleeding and hyperplasia; oral ulcerations, herpes and *Candida* infections; perirectal irritation and infection; hepatomegaly, splenomegaly

Neurologic

Seizures, disorientation, confusion, decreased coordination, cranial nerve palsies, papilledema

Musculoskeletal

Muscle wasting, bone pain, joint pain

Possible Diagnostic Findings

Low, normal, or high WBC count with shift to the left (↑ blast cells) and neutropenia; anemia, ↓ hematocrit and hemoglobin, thrombocytopenia, specific chromosome abnormalities; hypercellular bone marrow aspirate or biopsy with myeloblasts, lymphoblasts, and markedly ↓ normal cells

HTLV-1, Human T-cell leukemia virus, type 1.

The family needs help adjusting to the stress of this abrupt onset of serious illness and the losses imposed by the sick role (e.g., dependence, withdrawal, changes in role responsibilities, changes in body image). The diagnosis of leukemia often brings with it the need to make difficult decisions at a time of profound stress for the patient and family.

Patients may have co-morbid conditions that affect treatment decisions. Important nursing interventions include (1) maximizing the patient's physical functioning, (2) teaching patients that acute side effects of treatment are usually temporary, and (3) encouraging patients to discuss their quality-of-life issues.

You are an important advocate in helping the patient and family understand the complexities of treatment decisions and manage the side effects and toxicities. This may include making sure the HCP addresses fertility concerns. A patient may need a long hospitalization or may need to temporarily relocate to an appropriate treatment center. This situation can lead a patient to feel deserted and isolated at a time when support is most needed. You have contact with a patient many hours a day and can help reverse feelings of abandonment and loneliness by balancing the demanding technical needs with a humanistic, caring approach. The needs of the patient with leukemia are best met by an interprofessional team (e.g., psychiatric and oncology clinical nurse specialists, case managers, dietitians, chaplains, and social workers).

From a physical care perspective, you are challenged to make astute assessments and plan care to help the patient manage the severe side effects of chemotherapy. The life-threatening results of bone marrow

suppression (neutropenia, thrombocytopenia, and anemia) require aggressive nursing interventions. Other critical aspects of care include anticipating, monitoring for, and helping to treat emergencies, such as DIC, tumor lysis syndrome, leukostasis, and cytokine release syndrome. Complications of chemotherapy may affect the patient's GI tract, nutritional status, skin and mucosa, cardiopulmonary status, liver, kidneys, and neurologic system. (Nursing interventions related to chemotherapy are discussed in Chapter 15.)

Review all drugs being given, including the mechanism of action, purpose, routes of administration, doses, potential side effects, safe handling considerations, and toxic effects. Assess laboratory data reflecting the effects of the drugs and sequelae of the disease. Unlike treatments for solid tumors, chemotherapy is given to patients with leukemia even if they have severe myelosuppression, since the underlying disorder is causing the problem and will not resolve unless treated. Quality nursing care significantly affects patient survival and comfort during aggressive chemotherapy.

Ambulatory Care

Ongoing care for the patient with leukemia is necessary to monitor for signs and symptoms of disease control or relapse. For a patient receiving long-term or maintenance chemotherapy, the fatigue of long-term chronic disease management can become discouraging. Teach the patient and caregiver the importance of continued diligence in disease management and the need for follow-up care. Review the drugs, self-care measures, and when to seek medical attention.

The goals of rehabilitation for long-term survivors of leukemia are to manage the physical, psychologic, social, and spiritual consequences and delayed effects from the disease and its treatment. Assistance may be needed to reestablish the various relationships that are a part of the patient's life. Involving the patient in survivor networks and support groups or services may help the patient adapt to living after a life-threatening illness. Exploring national and community resources (e.g., American Cancer Society, Leukemia & Lymphoma Society) may reduce the financial burden and the feelings

of dependence. Provide resources for spiritual support.

TABLE 30.27 Comparison of Hodgkin's and Non-Hodgkin's Lymphoma

	Hodgkin's Lymphoma	Non-Hodgkin's Lymphoma
Cellular origin	B lymphocytes	B lymphocytes (88%) T or natural killer lymphocytes (12%)
Extent of disease	Localized to regional but may be more widespread. Spreads to adjacent tissues	Disseminated, can spread to other areas of the body
B symptoms (fever, drenching night sweats, weight loss)	Common	Uncommon
Extranodal involvement	Rare	Common

Vigilant follow-up care helps to ensure that we recognize and treat the cancer survivor's unique needs. Often these needs may need a referral or consultation. For example, physical therapy personnel may develop an exercise program to prevent posttreatment deficits caused by drug-induced peripheral neuropathy. Most patients should receive a pneumococcal vaccine and an annual influenza vaccine.

Evaluation

The expected outcomes are that the patient with leukemia will

- Cope effectively with the diagnosis, treatment regimen, and prognosis
- Have no complications related to the disease or its treatment
- Feel supported throughout treatment

Lymphomas

Lymphomas are cancers originating in the bone marrow and lymphatic structures resulting in the proliferation of lymphocytes. Lymphomas make up 4% to 5% of all cancers in the United States.[27] Two major types of lymphoma are Hodgkin's lymphoma and non-Hodgkin's lymphoma (NHL). A comparison of these 2 types of lymphoma is shown in Table 30.27.

Hodgkin's Lymphoma

Hodgkin's lymphoma, also called *Hodgkin's disease,* makes up about 10% of all lymphomas. It is characterized by proliferation of abnormal giant, multinucleated cells, called *Reed-Sternberg cells,* or it's variant, *Hodgkin cells* (mononucleated), which proliferate in the lymph nodes.[3] The disease has a bimodal age-specific incidence, occurring most frequently in persons from 15 to 30 years of age and above 55 years of age.[34] Each year, about 8260 new cases of Hodgkin's lymphoma are diagnosed, with around 1070 deaths.[27] Long-term survival exceeds 80% for all stages.[34]

Etiology and Pathophysiology

Although the cause of Hodgkin's lymphoma is unknown, we think several key factors play a role in its development. The main interacting factors include infection with Epstein-Barr virus (EBV), genetic predisposition, and exposure to occupational toxins. The incidence of Hodgkin's lymphoma is increased in those with HIV infection.[1]

FIG. 30.14 Enlarged cervical lymph node in the neck of a man with Hodgkin lymphoma.
From Howard MR, Hamilton PJ: *Haematology: An illustrated colour atlas,* ed 4, London, 2013, Churchill Livingston.

The disease likely starts in a single location (it starts in cervical lymph nodes in 60% to 70% of patients) and then spreads along adjacent lymphatics.[3] However, in recurrent disease, it may spread more diffuse. It eventually infiltrates other organs, especially lungs, spleen, and liver. When the disease begins above the diaphragm, it stays confined to lymph nodes for a variable time. Disease originating below the diaphragm often spreads to extralymphoid sites, such as the liver. There are 5 histologic subtypes. Nodular sclerosis is the most common.[1]

Clinical Manifestations

The onset of symptoms in Hodgkin's lymphoma is usually gradual. The initial development is most often enlargement of cervical, axillary, or inguinal lymph nodes (Fig. 30.14). A mediastinal node mass is the second most common location. The nodes are movable and nontender. Enlarged nodes are not painful unless they exert pressure on adjacent nerves.

The patient may notice weight loss, fatigue, weakness, fever, chills, tachycardia, or night sweats. A group of initial findings, including fever (over 100.4°F [38°C]), drenching night sweats, and weight loss (exceeding 10% in 6 months), are termed *B symptoms*. They correlate with a worse prognosis. After having even small amounts of alcohol, patients with Hodgkin's lymphoma may have a rapid onset of pain at the site of disease. The cause for the alcohol-induced pain is unknown. Generalized pruritus without skin lesions may develop. Cough, dyspnea, stridor, and dysphagia may all reflect mediastinal node involvement.

In more advanced disease, there may be hepatomegaly and splenomegaly. Anemia results from increased destruction and decreased production of RBCs. Other physical signs vary depending on where the disease is located. For example, intrathoracic involvement may lead to superior vena cava syndrome. Enlarged retroperitoneal nodes may cause palpable abdominal masses or interfere with renal function. Jaundice may occur from liver involvement. Spinal cord compression leading to paraplegia may occur with extradural involvement. Bone pain occurs from bone involvement.

Diagnostic and Staging Studies

Peripheral blood analysis, excisional lymph node biopsy, bone marrow examination, and radiologic studies are important means of evaluating Hodgkin's lymphoma. Abnormalities in the CBC, such as a microcytic hypochromic anemia, are variable and not diagnostic. Leukopenia and thrombocytopenia may develop, but they are usually a consequence of treatment, advanced disease, or superimposed hypersplenism. Other blood studies may show increased erythrocyte sedimentation rate, high leukocyte alkaline phosphatase from liver and bone involvement, hypercalcemia from bone involvement, and hypoalbuminemia from liver involvement.

Radiologic evaluation can help define all sites and determine the clinical stage of the disease. PET and CT scans are used to stage and then assess the response to therapy and to distinguish residual tumor

from fibrotic masses after treatment. These scans may show increased uptake (by PET) and masses, such as renal displacement caused by retroperitoneal node enlargement, abdominal or mediastinal lymph node enlargement, and liver, spleen, bone, and brain infiltration.

Interprofessional and Nursing Management

Using all the information from the various diagnostic studies, HCPs determine a clinical stage of disease (Fig. 30.15).[34] The final staging is based on the clinical stage (extent of the disease), presence of B symptoms, and other unfavorable prognostic features. Treatment depends on the nature and extent of the disease. The terms used in staging involve an A or B classification, depending on whether systemic symptoms are present at diagnosis, and a Roman numeral (I to IV) that reflects the location and extent of the disease.[34]

Once the stage of Hodgkin's lymphoma is determined, management focuses on selecting a treatment plan. The standard for chemotherapy is the ABVD regimen: doxorubicin (**A**driamycin), **b**leomycin, **v**inblastine, and **d**acarbazine. Patients with favorable early-stage disease receive 2 to 4 cycles of chemotherapy.[3] Patients with early-stage disease but unfavorable prognostic features (e.g., B symptoms) or intermediate-stage disease receive 4 to 6 cycles of chemotherapy. Advanced-stage Hodgkin's lymphoma is treated more aggressively using 6 to 8 cycles of chemotherapy. A common regimen is BEACOPP (**b**leomycin, **e**toposide, doxorubicin [**A**driamycin], **c**yclophosphamide, vincristine [**O**ncovin], **p**rocarbazine, and **p**rednisone).[3,34] The role of involved-site radiation as a supplement to chemotherapy varies depending on the extent of disease and the presence of resistant disease after chemotherapy.[34] Response to therapy is determined by PET and CT scans and other diagnostic tests (e.g., bone marrow biopsy).

A variety of chemotherapy regimens and newer agents, such as brentuximab vedotin, nivolumab, bendamustine, and pembrolizumab are used to treat patients who have relapsed or refractory disease.[34] Ideally, once remission is obtained, a curative option may be intensive

chemotherapy with the use of autologous or allogeneic HSCT.[34] HSCT has allowed patients to receive higher, potentially curative doses of chemotherapy while reducing life-threatening leukopenia (see Chapter 15). Combination chemotherapy works well because, as in leukemia, the drugs used have an additive antitumor effect without increasing side effects. As with leukemia, therapy must be aggressive. Potentially life-threatening problems are an issue in the attempt to achieve a remission.

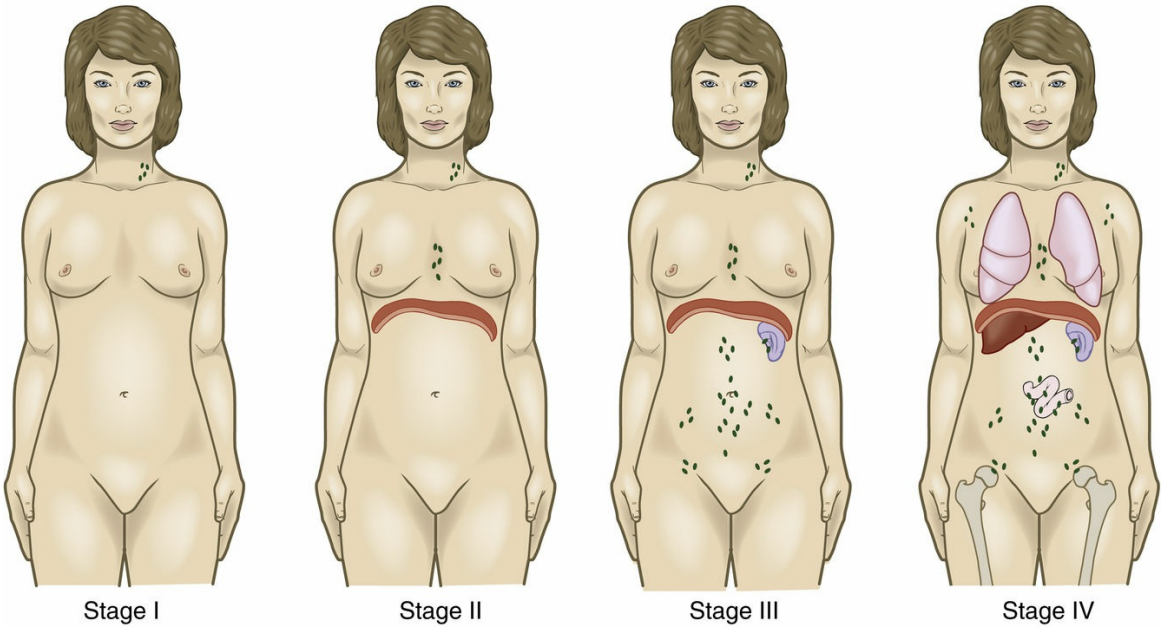

FIG. 30.15 Staging system for Hodgkin's lymphoma and non-Hodgkin's lymphoma. *Stage I,* Involvement of single lymph node (e.g., cervical node). *Stage II,* Involvement of 2 or more lymph nodes on one side of diaphragm. *Stage III,* Lymph node involvement above and below the diaphragm. *Stage IV,* Involvement outside of diaphragm (e.g., liver, bone marrow). The stage is followed by the letter *A* (absence) or *B* (presence) to indicate significant systemic symptoms (e.g., fever, night sweats, weight loss).

Maintenance chemotherapy does not contribute to increased survival after achieving complete remission. Occasionally, single drugs may be given palliatively to those who cannot tolerate intensive combination therapy. A serious consequence of the treatment for Hodgkin's lymphoma is the later development of secondary cancers

and potential long-term toxicities from the treatment, such as endocrine (hypothyroidism), heart, and lung dysfunction. Secondary solid tumor cancers may occur 10 years after treatment for Hodgkin's lymphoma.[34] The most common secondary cancers are lung and breast cancer, especially with radiation therapy. Patients should have close follow-up and screening for early detection of these problems.

The nursing care for Hodgkin's lymphoma is based on managing problems related to the disease (e.g., pain caused by a tumor, superior vena cava syndrome), pancytopenia, and other side effects of therapy. Because the survival of patients with Hodgkin's lymphoma depends on their response to treatment, supporting the patient through the consequences of treatment is extremely important.

Psychosocial considerations are as important as they are with leukemia. However, the prognosis for Hodgkin's lymphoma is better than that for many forms of cancer. Address the physical and spiritual consequences of the patient's disease. Fertility issues may be of concern because this disease is often seen in adolescents and young adults. Help to ensure that these issues are addressed soon after diagnosis. Evaluating patients for long-term effects of therapy is important because delayed consequences of disease and treatment may not be apparent for many years. Secondary cancers and delayed effects are discussed in Chapter 15.

Evidence-Based Practice

Exercise and Hematologic Cancer

You are a nurse caring for G.R., a 59-yr-old male patient with non-Hodgkin's lymphoma who is receiving chemotherapy. Due to a decrease in red blood cells and platelets, he was told to rest and avoid the high level of physical exercise he once enjoyed. He misses his active lifestyle and now admits to you that he is "somewhat depressed."

Making Clinical Decisions

Best Available Evidence. Aerobic exercise, especially walking and stretching, to maintain mobility may improve physical functioning, fatigue, and depression in patients with hematologic cancers.

Clinician Expertise. You know recommendations to decrease intensive physical exercise may diminish quality of life for many patients, especially for people who are used to being physically active.

Patient Preferences and Values. G.R. is considering joining a neighborhood bicycling club so that he can "feel better."

Implications for Nursing Practice

1. Why is intensive exercise contraindicated in someone who is getting chemotherapy or acutely ill?
2. What precautions would you discuss with G.R. before he increases his exercise level?
3. How would you involve G.R. in monitoring his fatigue?
4. As G.R. seeks ways to improve his quality of life, how would you support him?

Multiple Myeloma

Multiple myeloma, or *plasma cell myeloma,* is a condition in which cancerous plasma cells proliferate in the bone marrow and destroy bone. Multiple myeloma accounts for about 1.8% of all cancers and for about 17% of all hematologic cancers.[27] The disease is more common in men than women and more common in blacks than whites.[3] It generally occurs between the ages of 65 and 74 years old, with an average onset age of 69 years.[36] Because of the variety of treatments that can be provided throughout the course of the disease, over 40% of patients have more than a 10-year survival rate.[1]

Etiology and Pathophysiology

The cause of multiple myeloma is unknown. It is possible that exposure to organic chemicals (such as benzene), herbicides, and insecticides may play a role. Viral infections, such as HIV, may influence the risk for developing multiple myeloma.[37]

The disease process involves excess production of plasma cells. Normal plasma cells are activated B cells, which make immunoglobulins (antibodies) that normally protect the body. In multiple myeloma, instead of a variety of plasma cells making antibodies to fight different infections, myeloma tumors make monoclonal antibodies. *Monoclonal* means they are all of one kind, making them ineffective and even harmful. Not only do they not fight infections, but they infiltrate the bone marrow. These monoclonal proteins (called *M proteins*) are made up of 2 light chains and 2 heavy chains. *Bence Jones proteins* are the light chain part of these monoclonal antibodies. They may show up in the urine in many patients with multiple myeloma.[1]

Furthermore, plasma cell production of excess, abnormal amounts of cytokines (interleukins [ILs]; IL-4, IL-5, and IL-6) plays a key role in the pathologic process of bone destruction. As myeloma protein

increases, normal plasma cells are reduced. This further compromises the body's normal immune response. Proliferation of cancerous plasma cells and the overproduction of immunoglobulin and proteins may result in the end-organ effects of myeloma on the bone marrow, bone, and kidneys and possibly the spleen, lymph nodes, liver, and even heart muscle.

Clinical Manifestations

Multiple myeloma develops slowly and insidiously. The patient often does not have symptoms until the disease is advanced. Skeletal pain is the major manifestation. Pain in the pelvis, spine, and ribs is particularly common and triggered by movement. Diffuse osteoporosis develops as the myeloma protein destroys bone. Osteolytic lesions are seen in the skull, vertebrae, long bones, and ribs. Vertebral destruction can lead to collapse of vertebrae with ensuing compression of the spinal cord. Loss of bone integrity can lead to the development of pathologic fractures.

Bony degeneration causes calcium loss from bones, eventually causing hypercalcemia. Hypercalcemia may cause renal, GI, or neurologic problems, such as polyuria, anorexia, confusion, and heart problems. A serum *hyperviscosity syndrome* leading to cerebral, lung, renal, and other organ dysfunction can occur in some patients. Even without hyperviscosity, high protein levels caused by the myeloma protein can result in renal tubular obstruction, interstitial nephritis, and renal failure. The patient may have anemia, thrombocytopenia, neutropenia, and immune dysfunction from the replacement of normal bone marrow with plasma cells. Neurologic problems may be caused by regional myeloma cell growth compressing the spinal cord or cranial nerves, or by perineuronal or perivascular deposition of the abnormal protein.[1,38]

Diagnostic Studies

Evaluating multiple myeloma involves laboratory, radiologic, and bone marrow examination. M protein is often found in the blood and

urine. Possible findings include pancytopenia, hypercalcemia, Bence Jones protein in the urine, and a high serum creatinine.

Skeletal bone surveys, MRI, and/or PET and CT scans show distinct areas of destroyed bone; generalized thinning of the bones; or fractures, especially in the vertebrae, ribs, pelvis, and bones of the thigh and upper arms. Bone marrow analysis shows significantly increased numbers of plasma cells in the bone marrow. The simplest measure of staging and prognosis in multiple myeloma is based on blood levels of 2 markers: β_2-microglobulin and albumin. In general, higher levels of β_2-microglobulin and lower levels of albumin are associated with a poorer prognosis. Cytogenetic studies of the bone marrow plays a role in prognostic stratification. For example, deletion of chromosome 17p13 is considered a high risk (poor prognostic) feature.[36]

Interprofessional and Nursing Management

Interprofessional care involves managing both the disease and its symptoms. The current treatment options include corticosteroids, chemotherapy, immunotherapy, targeted therapy, and HSCT.[36] Multiple myeloma is seldom cured. Treatment can relieve symptoms, produce remission, and prolong life. Control of pain and prevention of pathologic fractures are goals of management.

Bisphosphonates, such as pamidronate and zoledronic acid, inhibit bone breakdown and are used to treat skeletal pain and hypercalcemia. They inhibit bone resorption without inhibiting bone formation and mineralization. They are given monthly by IV infusion. A major focus of nursing care relates to patient safety due to the bone involvement and sequelae from bone breakdown. Because of the potential for pathologic fractures, use caution when moving and ambulating the patient. A slight twist or strain in the wrong area (e.g., a weak area in the patient's bones) may cause a fracture.

Drug Alert

Zoledronic Acid (Zometa)

- Make sure the patient is adequately hydrated before giving drug.
- Renal toxicity may occur if IV infusion of drug is given in less than 15 min.
- Patients should have a dental exam prior to first dose and ongoing monitoring for osteonecrosis of the jaw.[36]

Kyphoplasty is sometimes used to control spine vertebral disease. *Kyphoplasty* is a minimally invasive procedure (usually done in an interventional radiology area) that injects cement to stabilize the vertebral compression.

Chemotherapy includes a corticosteroid (dexamethasone or prednisone) plus 2 chemotherapy agents, such as bortezomib and lenalidomide or bortezomib and cyclophosphamide. The goal is to reduce the number of plasma cells. Initial treatment depends on whether the patient is a future bone marrow transplant candidate and predicted tolerance of therapy. High-dose chemotherapy followed by HSCT has evolved as the standard of care in eligible patients.[36]

Immunotherapy and targeted therapy are options. Immunomodulator drugs (described in Chapter 15) include thalidomide, lenalidomide, and pomalidomide. Proteosome inhibitors include bortezomib, carfilzomib, and ixazomib. Panobinostat is a drug that affects enzymes that promote cancer cell growth. Daratumumab is a monoclonal antibody against CD38, a protein which is found on the surface of myeloma cells.

Other drugs can treat some complications of multiple myeloma. For example, IV furosemide promotes renal excretion of calcium. Although tumor lysis is rare, once chemotherapy is started, allopurinol may be given to prevent any renal damage from uric acid accumulation (from cell breakdown). Because of the myeloma proteins, the patient is at risk for renal dysfunction and electrolyte and

fluid imbalances.

Ambulation and adequate hydration are used to treat hypercalcemia, dehydration, and potential renal damage. Weight bearing helps the bones resorb some calcium. Maintaining adequate hydration helps minimize problems from hypercalcemia and prevent protein precipitates from causing renal tubular obstruction. IV fluids may be given to maintain a urine output of 1.5 to 2 L/day if the patient does not already have renal compromise.

In some patients, the levels of plasma proteins are so high that it causes a hyperviscosity of the blood leading to neurologic changes, renal insufficiency, and other problems related to lack of blood flow. In this instance plasmapheresis is used.

Pain management requires innovative and knowledgeable nursing interventions. Analgesics, such as nonsteroidal antiinflammatory drugs, acetaminophen, or an acetaminophen/opioid combination, may be more effective than opioids alone in diminishing bone pain. Braces, especially for the spine, may help control pain. As in any pain management situation, assess the patient and implement measures to control pain (see Chapter 8). Peripheral neuropathy is common with several therapies for multiple myeloma and can contribute to discomfort, the inability to do basic activities of daily living, and the risk for injury from falling.

Patients are at risk for DVT related to chemotherapy and immobility and should have preventive measures employed.[36]

Assessment and prompt treatment of infection are important in the care of patients with multiple myeloma. Recurrent infections may be due to a decrease in the production of normal immunoglobulins, the ineffectiveness of the overproduced and abnormal immunoglobulins, corticosteroids, and/or neutropenia because of the bone marrow infiltration or side effects of treatment.

The patient's psychosocial needs require sensitive, skilled management. Help the patient and significant others adapt to changes fostered by chronic illness and adjust to the losses related to the disease process, while helping to maximize functioning and quality of life. The patient with multiple myeloma may have remissions and

exacerbations. Patients may be on dialysis because of myeloma-induced renal failure. Acute care is needed at various times during the illness.

The final, acute phase is unresponsive to treatment and usually short in duration. Help the patient and family navigate needed resources, such as palliative or hospice care, social services, and spiritual care, as appropriate.

Disorders of the Spleen

Many illnesses can affect the spleen. Most can cause some degree of *splenomegaly* (enlarged spleen) (Table 30.30).[2] However, an enlarged spleen may be present in some people without any evidence of disease. The term *hypersplenism* refers to the occurrence of splenomegaly and peripheral cytopenias (anemia, leukopenia, and thrombocytopenia).[2] The degree of splenic enlargement varies with the disease. For example, massive splenic enlargement may occur with infectious mononucleosis, chronic myelogenous leukemia, and thalassemia major. Mild splenic enlargement occurs with HF and SLE. The normal spleen holds 350 mL of blood. About one third of the platelet mass is stored in the spleen.

TABLE 30.30 Common Causes of Splenomegaly

Congestion

- Acquired hemolytic anemia
- Cirrhosis of the liver
- HF (portal hypertension)
- Portal or splenic vein thrombosis
- Sickle cell disease
- Thalassemia

Infections and Inflammations

- Autoimmune diseases: systemic lupus erythematosus, rheumatoid arthritis
- Bacterial infections: endocarditis, splenic abscess, syphilis, tuberculosis, Rocky Mountain spotted fever, typhoid fever

- Fungal infections: histoplasmosis, systemic candidiasis
- Parasitic infections: malaria, trypanosomiasis, schistosomiasis, leishmaniasis
- Viral infections: human immunodeficiency virus, cytomegalovirus, mononucleosis

Infiltrative Diseases and Tumors or Cysts

- Acute and chronic leukemia
- Amyloidosis
- Gaucher disease
- Lymphomas
- Polycythemia vera
- Other primary or secondary tumors and cysts
- Sarcoidosis

When the spleen enlarges, its normal filtering and storage capacity increases. Consequently, there is often a reduction in the number of circulating blood cells as they engorge the spleen. In addition, there are unusual findings in the peripheral smear, such as pitted or pocked RBCs or Howell-Jolly bodies. These findings aid in diagnosing a malfunctioning spleen. A slight to moderate enlargement of the spleen is usually asymptomatic and found during routine examination of the abdomen. While massive splenomegaly can be well tolerated, the patient may have abdominal discomfort and early satiety. Other techniques to assess the size of the spleen include radionuclide colloid liver-spleen scan, CT or PET scan, MRI, and ultrasound scan.[3]

Occasionally a splenectomy is done as part of the evaluation or treatment of splenomegaly. Another major reason for splenectomy is splenic rupture. The spleen may rupture from trauma; inadvertent tearing during other surgical procedures; and diseases, such as mononucleosis, malaria, and lymphoid tumors. After a splenectomy, there can be a dramatic increase in peripheral RBC, WBC, and platelet

counts.

Nursing responsibilities for patients with spleen disorders vary depending on the problem. Splenomegaly may be painful. The patient may need analgesics; care in moving, turning, and positioning; and evaluation of lung expansion because spleen enlargement may impair diaphragmatic excursion. If anemia, thrombocytopenia, or leukopenia develops from splenic enlargement, institute nursing measures to support the patient and prevent life-threatening complications. After a splenectomy, observe the patient for hemorrhage and shock.

After splenectomy, immunologic deficiencies may develop, such as low IgG levels. Patients have a lifelong risk for infection, especially from encapsulated organisms, such as *Pneumococcus* species. This risk is reduced by immunization with pneumococcal vaccine.[3]

Blood Component Therapy

Blood component therapy is often used to manage hematologic diseases. Many therapeutic and surgical procedures depend on blood product support. However, blood component therapy only temporarily supports the patient until the underlying problem is resolved. Because transfusions are not free from hazards, they should be used only if needed.

Avoid developing a complacent attitude about this common but potentially dangerous therapy. Make sure that the HCP has discussed the risks, benefits, and alternatives with the patient and that this is recorded in the medical record.

Traditionally, the term *blood transfusion* meant the administration of whole blood. Blood transfusion now has a broader meaning because of the ability to give specific components of blood, such as platelets, packed RBCs, or plasma. Usually, a specific component is ordered. Whole blood is rarely used except in cases of massive hemorrhage, severe coagulopathy, shock, or in military settings (Table 30.31). [1]

Administration Procedure

Blood components may be given through a 22-gauge IV needle, cannula, or catheter. Smaller gauges, such as 25-gauge, may be used in neonates.[39] Larger sizes (e.g., 18- or 16-gauge) in adults may be preferred if rapid transfusions are given or if the infusion is sluggish. Smaller needles can be used for platelets, albumin, and clotting factor replacement. Verify the patency of the venous access before requesting the blood component from the blood bank. Most blood product administration tubing is of a "Y type" with a macroaggregate filter (170 to 260 microns; filters out particulate). One arm of the Y is for the isotonic saline solution and the other arm of the Y for the blood product. You may use infusion pumps or syringes approved for blood administration according to agency policy.[39]

Ethical/Legal Dilemmas

Religious Beliefs

Situation

W.D., an 81-yr-old woman with dementia, is transferred from a nursing home to a hospital because of GI bleeding from an unknown cause. Some of her family members tell you that she is a Jehovah's Witness and must not receive blood products. If she does not have exploratory surgery and transfusions, the surgeon believes that she will die.

Ethical/Legal Points for Consideration

- Competent adults have the right to make health care decisions, including the right to refuse treatment, based on their religious beliefs.
- If the patient is determined to be incompetent and a guardian has been appointed, the guardian has the legal right to make the consent or refusal.
- If the HCP believes that the treatment is essential to preserve life and health and there is no legal decision maker, a request is made for a legal determination of whether the patient is incapable of consent or refusal. If the judge agrees, the patient is made a ward of the court for this issue. Usually the HCP is directed to make a decision based on the patient's best interests.

Discussion Questions

1. What resources do you have available to consult about religious practices?
2. How could you determine if the family were acting in W.D.'s best interest or their own?
3. What nonblood alternatives are available for Jehovah's

Witnesses?

Safety Alert

Blood Transfusions

- Do not use dextrose solutions, lactated Ringer's solution, or any other solution other than 0.9% sodium chloride for giving blood because they will cause RBC hemolysis.
- Exceptions to the above restrictions may be appropriate, such as in trauma situations. These solutions, approved by the FDA, include ABO-compatible plasma and 5% albumin. Follow agency policy.[39]
- Do not give any additives, including medications, in the same tubing as the blood unless you first clear the tubing with saline solution.

After obtaining the blood or blood components from the blood bank, make a positive identification of the blood product and recipient. Improper product-to-patient identification is the most common cause of hemolytic transfusion reactions, thus placing a great responsibility on nurses to carry out the identification procedure appropriately. Follow the policy and procedures at your agency. Most have a dual-checking system with 2 licensed persons checking the patient identification with the labeled blood component. The blood bank is responsible for typing and crossmatching the donor's blood with the recipient's blood. The result of any needed compatibility testing should be on the product bag or tag.

Table 30.32 outlines blood component compatibilities for transfusions.[37,39] ABO compatibility is not a prerequisite for platelet transfusions. However, after multiple platelet transfusions, a patient may develop anti-HLA antibodies to the transfused platelets. With the use of lymphocyte typing to match HLA types of the donor and

recipient, multiple platelet transfusions can be given with fewer complications to those who develop antibodies to platelets. The patient may be premedicated with an antihistamine (e.g., diphenhydramine) and hydrocortisone to decrease the chance of reacting to platelet transfusions if there is a history of reactions.[39]

TABLE 30.31 Common Blood Products

Description	Special Considerations	Indications for Use
Albumin		
Prepared from plasma. **Can be stored for 5 yr.** **Available in 5% or 25% solution.** **Heat treated and does not transmit viruses.**	Albumin 25% expands the blood volume by about 3.5 times, Hyperosmolar solution acts by moving water from extravascular to intravascular space.	Hypovolemic shock, hypoalbuminemia, after large-volume paracentesis, replacement in plasmapheresis.
Cryoprecipitates and Commercial Concentrates		
Prepared from fresh frozen plasma. **10–15 mL/bag.** **Can be stored for 1 yr. Once thawed, must be used within 5 days.**	See also Table 30.18.	Replacement for fibrinogen deficiency, usually due to DIC, severe liver disease, or massive transfusion. Has other clotting factors, especially factor VIII, factor XIII, and von Willebrand factor.
Fresh Frozen Plasma		
Liquid portion of whole blood is separated from cells and frozen. **1 unit contains about 250 mL.** **Rich in clotting factors but contains no platelets.** **Can be stored for up to 1 yr, depending on storage.** **Must be used within 24 hr after thawing.**	Use in treating hemorrhagic shock is being replaced by pure preparations, such as albumin and plasma expanders.	Bleeding caused by deficiency in clotting factors (e.g., DIC, hemorrhage, massive transfusion, liver disease, vitamin K deficiency, excess warfarin).
Frozen RBCs		
Prepared from RBCs using glycerol for protection and frozen. **Can be stored for 10 yr.**	Must be used within 24 hr of thawing. Successive washings with saline solution remove most WBCs and plasma proteins.	Autotransfusion. Stockpiling or rare donors for patients with alloantibodies.
Packed RBCs		
Prepared from whole blood by sedimentation or centrifugation. **1 unit contains 250–350 mL.** **Can be stored up to 42 days depending on processing (anticoagulants and preservatives).**	Use of RBCs for treatment allows remaining components of blood (e.g., platelets, albumin, plasma) to be used for other purposes. Less danger of fluid overload. Preferred RBC source because they are more component specific. Leukocyte depletion (leukoreduction) by filtration, washing, or freezing is frequently used, Decreases non-hemolytic febrile or mild allergic reactions in patients who receive frequent transfusions. Reduces transmission of cytomegalovirus.	Severe or symptomatic anemia, acute blood loss. 1 unit of RBCs can be expected to increase Hgb by 1 g/dL or Hct by 3% in a typical adult. 1 unit can replace a blood loss of 500 mL.
Platelets		
Prepared from fresh whole blood. **An apheresed single donation is usually 200–400 mL in volume.** **May be pooled from multiple donors.**	Can obtain multiple units from 1 donor by plateletpheresis. Can be kept at room temperature in the blood bank under gentle agitation for 1–5 days depending on type of collection and storage bag used. For patients who receive frequent transfusions and become refractory, may give leukocyte reduced, HLA, or type specific to prevent alloimmunization to HLA antigens.	Bleeding caused by thrombocytopenia. May be contraindicated in thrombotic thrombocytopenic purpura and HITT except in life-threatening hemorrhage. Average corrected count increment is 10×10^9/L. Failure to have an increase may be due to fever, sepsis, splenomegaly, or DIC or development of antibodies *(refractory)*.

DIC, Disseminated intravascular coagulation; *HITT,* heparin-induced thrombocytopenia and thrombosis; *HLA,* human leukocyte antigen.

TABLE 30.32 Blood Component Compatibilities for Transfusions

	Donor Product			
Recipient's Type	**Packed Red Blood Cells**	**Plasma**	**Platelets**	**Cryoprecipitate**

AB−	AB−, B−, A−, O−			

Nursing Management

Blood Transfusions

Role of Nursing Personnel
Registered Nurse (RN)

- Complete a baseline physical assessment of the patient as a basis to assess changes during and after the transfusion.
- Ensure that the IV line has an appropriate needle, catheter, or cannula, and that it is patent.
- Double-check patient identification and blood product identification data with another licensed nurse (consider state nurse practice act and agency policy).
- Adjust infusion rate of transfusion according to patient needs, provider's order, and agency policy.
- Assess patient for signs of transfusion reactions.
- Delegate UAP to take vital signs as directed.
- Evaluate for therapeutic effect of blood product (improvement in CBC, increased blood pressure, decreased bleeding).
- Monitor for signs of circulatory overload (e.g., shortness of breath) if the transfusion is given rapidly.

Role of Other Team Members
Blood Bank Personnel

- Responsible for typing and crossmatching the donor's blood with the recipient's blood.
- Note the result of the compatibility testing on the product bag or tag.
- When handing off the blood or blood component to nursing personnel, ensure that a positive identification is made with product and patient's information.

Take the patient's vital signs before beginning the transfusion so that you have a baseline measure. If the patient has abnormal vital signs (e.g., high fever), call the HCP to clarify if you should give the blood component. Start the blood as soon as it is brought to the patient. Do not refrigerate it on the nursing unit. If the blood is not started within 30 minutes, return it to the blood bank for storage. During the first 15 minutes or 50 mL of blood infusion, stay with the patient. If there are any untoward reactions, they are most likely to occur during this time. The rate of infusion during this period should be no more than 2 mL/min. Do not infuse packed RBCs quickly except in an emergency. Rapid infusion of cold blood may cause the patient to become chilled. If rapid replacement of large amounts of blood is needed, a blood-warming device may be used. Other blood components, such as fresh frozen plasma and platelets, may be given over 15 to 30 minutes. Refer to your agency's policy and procedure.

After the first 15 minutes, vital signs are usually retaken. The rate of infusion is determined by the prescriber's orders, the patient's clinical condition, and the product being infused. Observe the patient periodically throughout the transfusion (e.g., every 30 minutes) and up to 1 hour after the transfusion. Most patients not in danger of fluid overload can tolerate the infusion of 1 unit of packed RBCs over 2 hours. The transfusion should not take more than 4 hours to give because of the increased risk for bacterial growth in the product once

it is out of refrigeration.

Blood Transfusion Reactions

A *blood transfusion reaction* is an adverse reaction to blood transfusion therapy. It can range in severity from mild symptoms to a life-threatening condition. Because complications of transfusion therapy may be significant, careful evaluation of the patient is needed. Common signs and symptoms are associated with more than 1 type of adverse reaction. Blood transfusion reactions can be classified as acute or delayed[1,39] (Tables 30.33 and 30.34).

Check Your Practice

Your 82-yr-old male patient with severe iron-deficiency anemia is receiving his second unit of packed RBCs. He received his first transfusions without any problems. He is now reporting chills and feels like his heart is racing.

- What should you do?

If a transfusion reaction occurs, take the following steps: (1) stop the transfusion; (2) maintain a patent IV line with saline solution; (3) notify the blood bank and the HCP immediately; (4) recheck identifying tags and numbers; (5) monitor vital signs and urine output; (6) treat symptoms per HCP order; (7) save the blood bag and tubing and send them to the blood bank for examination; (8) collect required blood and urine specimens at intervals based on the hospital policy to evaluate for hemolysis; and (9) document on transfusion reaction form and patient chart. The blood bank and laboratory are responsible for identifying the type of reaction.

A transfusion reaction is a *serious reportable event* (SRE) and a *sentinel event*. These events are discussed in Chapter 1.

Acute Transfusion Reactions

The most common cause of hemolytic reactions is transfusion of ABO-incompatible blood (Table 30.33). This is an example of a type II cytotoxic hypersensitivity reaction (see Chapter 13). Severe hemolytic reactions are rare. Mislabeling specimens and giving blood to the wrong person cause most acute hemolytic reactions. This again points to the importance of using proper patient identifiers when drawing blood samples and when giving medications and blood products.

Delayed Transfusion Reactions

Delayed transfusion reactions include delayed hemolytic reactions (discussed previously), infections, and iron overload (Table 30.34).

Autotransfusion

Autotransfusion, or autologous transfusion, involves removing whole blood from a person and transfusing that blood back into the same person. This avoids problems of incompatibility, allergic reactions, and disease transmission. Methods of autotransfusion include:

- *Autologous donation* or *elective phlebotomy* (predeposit transfusion). A person donates blood before a planned surgical procedure. The blood can be frozen and stored for up to 10 years. Usually the blood is stored without being frozen and given to the person within a few weeks of donation. This technique is especially beneficial to the patient with a rare blood type or for any patient who may be expected to need limited blood product support during a major surgical procedure (e.g., elective orthopedic surgery).

TABLE 30.33 Acute Transfusion Reactions

Cause	Manifestations	Management	Prevention
Acute Hemolytic Reaction			
Infusion of ABO-incompatible whole blood, RBCs, or components containing as little as 10 mL of RBCs. **Antibodies in the recipient's plasma attach to antigens on transfused RBCs, causing RBC destruction.**	Reactions usually develop in first 15 min. Fever with or without chills; back, abdominal, chest or flank pain; infusion site pain, tachycardia, dyspnea, tachypnea, hypotension, hemoglobinuria, acute jaundice, dark urine, bleeding, acute kidney injury, shock, cardiac arrest, DIC, death.	• Treat shock and DIC if present. • Draw blood samples for serologic testing slowly to avoid hemolysis from the procedure. Send urine specimen to the laboratory. • Maintain BP with IV colloid solutions. Give diuretics as prescribed to maintain urine flow. • Insert indwelling urinary catheter or measure voided amounts to monitor hourly urine output. Dialysis may be needed if renal failure occurs. • Do not transfuse more RBC-containing components until blood bank has provided newly crossmatched units.	Verify and document patient identification from sample collection to component infusion (e.g., visually compare label on sample collection and blood component with patient identification).
Febrile, Nonhemolytic Reaction			
Sensitization to donor WBCs (most common), platelets, or plasma proteins.	Sudden chills, rigors, and fever (rise in temperature of >1°C), headache, vomiting.	Give antipyretics as prescribed (acetaminophen). Do not restart transfusion unless HCP orders.	Consider leukocyte-reduced blood products (filtered, washed, or frozen) for patients with a history of 2 or more such reactions. Give acetaminophen or diphenhydramine 30 min before transfusion.
Mild Allergic Reaction			
Sensitivity to foreign plasma proteins. **More common in people with history of allergies.**	Flushing, itching, pruritus, urticaria (hives).	• Give antihistamine, corticosteroid, epinephrine, as ordered. • If symptoms are mild and transient, transfusion may be restarted slowly with HCP's order. • Do not restart transfusion if fever or pulmonary symptoms develop.	Treat prophylactically with antihistamines or steroids. Consider washed RBCs and platelets.
Anaphylactic and Severe Allergic Reaction			
Sensitivity to donor plasma proteins. **Infusion of IgA proteins to IgA-deficient recipient who has developed IgA antibody.**	Anxiety, abdominal pain, urticaria, dyspnea, wheezing, progressing to cyanosis, bronchospasm, hypotension, shock, and possible cardiac arrest.	• Start CPR, if indicated. Administer O_2. • Have epinephrine ready for injection. • Antihistamines, corticosteroids, β_2-agonists may be given. Do not restart transfusion.	Transfuse extensively washed RBC products from which all plasma has been removed. Use blood from IgA-deficient donor. Use autologous components.
Circulatory Overload Reaction			
Fluid given faster than the circulation can accommodate. **People with cardiac or renal disease at risk.**	Cough, dyspnea, pulmonary congestion, adventitious breath sounds, headache, hypertension, tachycardia, distended neck veins.	• Place patient upright with feet in dependent position. • Obtain chest x-ray STAT if ordered. • Administer prescribed diuretics, O_2, morphine.	Adjust transfusion volume and flow rate based on patient size and clinical status. Have blood bank divide future units into smaller aliquots for better spacing of fluid infused.
Sepsis			

Cause	Manifestations	Management	Prevention
Transfusion of bacterially infected blood components.	Rapid onset of chills, rigors, high fever, vomiting, diarrhea, marked hypotension, or shock.	• Obtain culture of patient's blood. • Treat septicemia as directed—antibiotics, IV fluids, vasopressors,	Collect, process, store, and transfuse blood products according to blood banking standards and complete the transfusion within 4 hr of starting time.
Transfusion-Related Acute Lung Injury (TRALI) Reaction			
Reaction between transfused antileukocyte antibodies and recipient's leukocytes, causing pulmonary inflammation and capillary leak.	Fever, chills, hypotension, tachypnea, frothy sputum, dyspnea, hypoxemia, respiratory failure. Noncardiogenic pulmonary edema. Leading cause of transfusion-related deaths. Arises within 1–6 hr of transfusion.	• Draw blood for arterial blood gases and HLA or antileukocyte antibodies. Obtain chest x-ray STAT. • Provide O_2 and administer corticosteroids (diuretics of no value) as ordered. • Start CPR if needed and provide ventilatory and BP support if needed.	Provide leukocyte-reduced products. Identify donors who are implicated in TRALI reactions and do not allow them to donate.

Table Continued

Cause	Manifestations	Management	Prevention
Massive Blood Transfusion Reaction			
Can occur with replacement of 10 or more RBC units within 24 hr. **RBC transfusions do not contain clotting factors, albumin, and platelets.**	Hypothermia and cardiac dysrhythmias (from rapid infusion of large quantities of cold blood). Citrate toxicity and hypocalcemia (from the use of citrate as a storage solution). Hypocalcemia (citrate binds calcium). Hyperkalemia or hypokalemia.	• When patients receive massive transfusions of blood products, monitor clotting status and electrolyte levels.	Use blood-warming equipment. Infuse 10% calcium gluconate with citrated blood products. Because of dilution effect on coagulation due to massive RBC transfusion, platelets and plasma will also be given.

DIC, disseminated intravascular coagulation; *HLA,* human leukocyte antigen; *IgA,* immunoglobulin A.

TABLE 30.34 Delayed Transfusion Reactions

Manifestations	Prevention and Management
Delayed Hemolytic	
Fever, mild jaundice, decreased hemoglobin. Occurs as early as 3 days or as late as several months posttransfusion as the result of destruction of transfused RBCs by alloantibodies not detected during crossmatch.	Generally, no acute treatment is needed. Hemolysis may be severe enough to warrant further transfusions.
Hepatitis B*	
Increased liver enzymes (AST and ALT), anorexia, malaise, nausea and vomiting, fever, dark urine, jaundice. Usually resolves spontaneously within 4–6 wk. Chronic carrier state can develop and result in permanent damage to the liver.	Hepatitis B virus can be detected in donated blood by the presence of hepatitis B surface antigen (HBsAg). Treat symptomatically.
Hepatitis C*	
Similar to hepatitis B, but symptoms are usually less severe. Chronic liver disease and cirrhosis may develop.	Before testing of anti-HCV in donated blood, accounted for 90%–95% of all posttransfusion hepatitis. Treat with direct-acting antivirals and symptomatically.
Iron Overload	
Excess iron is deposited in heart, liver, pancreas, and joints, causing dysfunction. HF, dysrhythmias, impaired thyroid and gonadal function, diabetes, arthritis, cirrhosis. Occurs in patients receiving >20 units for chronic anemia (e.g., sickle cell anemia, β-thalassemia) over time.	May be prevented by deferoxamine, which chelates and removes accumulated iron via the kidneys, given IV or subcutaneously. Deferasirox and deferiprone, oral agents that chelate iron, may be used. Phlebotomy may be used.
Other	
Cytomegalovirus (CMV), HIV, human herpesvirus type 6 (HSV-6), Epstein-Barr virus (EBV), human T cell leukemia virus, HTLV-1, and malaria. Most recent threats have been agents that primarily affect animals but have been transmitted to the blood supply through the food supply, or vectors, such as mosquitoes or ticks. These include *Plasmodium* species (malaria), dengue fever virus, West Nile virus, *Trypanosoma cruzi* (Chagas' disease), *Babesia* species (babesiosis), human herpesvirus 8 (KS virus), and variant Creutzfeldt-Jakob disease ("mad cow disease").	Treatment based on the cause. Ways of detecting some agents are now used, such as the nucleic acid test for West Nile virus, Zika virus, HIV, and *T. cruzi*. Donor screening has been the only available method to reduce the risk for donor-contaminated blood for others. Leukocyte-reduced components may reduce virus transmission. Patients may be monitored serologically (e.g., CMV titers are followed for allogeneic stem cell transplant patients).

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *HCV,* hepatitis C virus; *CMV,* cytomegalovirus; *HTLV-1,* human T-cell leukemia virus, type 1; *KS,* Kaposi sarcoma.

* New cases of transfusion-related hepatitis B and C are not common.

- *Autotransfusion.* A method for replacing blood volume that involves safely and aseptically collecting, filtering, and returning the patient's own blood lost during a major surgical procedure or from a traumatic injury. It is an important way to safely replace volume and stabilize bleeding patients.

Autotransfusion collection devices are most often used with surgery. Some allow blood to be automatically and continuously reinfused. Others require collecting the blood for a time (usually no longer than 4 hours) and then reinfusing it. Drainage after the first 24 hours or drainage that is suspected to contain pathogens is generally not reinfused. Anticoagulants may be added before reinfusion. Clots

that develop after blood is filtered through the collection system can sometimes prevent reinfusion of the blood. Sometimes the collected blood is depleted of its normal coagulation factors. So, monitoring coagulation studies in the patient receiving an autotransfusion is important.[1]

Case Study

Leukemia

© Lisa F. Young/iStock.

Patient Profile

A.J. is a 63-yr-old white woman who is brought to the ED by her husband (see the Chapter 29 case study). She has become progressively weaker and was admitted for further evaluation.

Subjective Data

- Progressive weakness over the last couple of weeks
- Has had a recent sinus infection that resolved after 2 courses of antibiotics

- Reports periodic shortness of breath
- Has noticed a lot of bruising lately

Objective Data
Physical Examination

- Has scattered petechiae on both ankles and 2 ecchymoses on her arms and 3 on her left lower leg
- Her skin is very pale
- BP 100/70 (lying), 88/60 (standing), temperature 96.8°F (36°C), respiratory rate 26/min, apical pulse 110/min (lying), 124/min (standing), O_2 saturation 90% on room air

Laboratory Results

- Hct 18.2%
- Hgb 5.9 g/dL, WBC count 2600/μL (2.6×10^9/L)
- Platelet count 72,000/μL (72×10^9/L)
- Peripheral blood smear shows that 80% of the WBCs are blasts
- PT 18 sec, aPTT 37 sec
- LDH 560 units/L

Bone Marrow Biopsy

- Multiple myeloblasts (>50%)

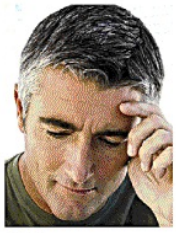
Interprofessional Care

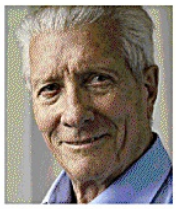
- Consultation with a hematologist-oncologist
- 2 units of packed red blood cells

- *Diagnosis:* acute myelogenous leukemia

Discussion Questions

1. What components of the laboratory test results and bone marrow biopsy suggest acute leukemia?
2. How is acute myelogenous leukemia treated?
3. What is A.J.'s prognosis?
4. What are the life-threatening problems that can occur because of this disease and treatment? How can you anticipate and assess for these problems?
5. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
6. ***Priority Decision:*** What are the priority nursing interventions for A.J.?
7. ***Patient-Centered Care:*** What are the priorities for patient teaching with a newly diagnosed adult with leukemia?
8. Collaboration: What members of the interprofessional team are likely to be involved in A.J.'s care?
9. ***Evidence-Based Practice:*** A.J. becomes fatigued after starting chemotherapy. She wants to know if she can still work and do household chores even if she is so fatigued. What is your best advice for her?
10. Develop a conceptual care map for A.J.





Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Case Study

Managing Care of Multiple Patients

You are working on the oncology unit and have been assigned to care for the following 4 patients. You have 1 UAP who is assigned to help

you, and there are 2 other RNs on your clinical unit.

Patients	
 (© Lisa F. Young/iStock.)	A.J. is a 63-yr-old white woman admitted with severe anemia (Hgb 5.9 g/dL and Hct 18.2%). Her WBC count is 2600/μL and platelet count is 72,000/μL. She prefers to take care of herself with "natural therapy" and has not seen an HCP for 5 years. A.J. is having difficulty performing ADLs without having to stop and catch her breath. She received 2 units of RBCs. After a further workup, she is diagnosed with acute myelocytic leukemia (AML). She starts chemotherapy tomorrow.
 (© g-stockstudio/iStock/Thinkstock.)	J.J. is a 52-yr-old white man newly diagnosed with acute lymphocytic leukemia (ALL). His most recent vital signs are BP 100/70, temperature 102.2°F (39°C), respiratory rate 26/min, pulse 110. Laboratory results reveal Hgb 6.9 g/dL, Hct 20%, WBC count 120,000/μL (120×10^9/L), and platelet count 25,000/μL (25×10^9/L). He is admitted for blood transfusions and induction therapy.
 (© Studio Grand Ouest/iStock/Thinkstock.)	P.H. is a 45-yr-old woman who is currently receiving chemotherapy for treatment of ovarian cancer. She is admitted with fever and chills. Her WBC count is 2200/μL (2.2×10^9/L), with an absolute neutrophil count (ANC) of 400/μL (0.4×10^9/L). She will begin IV antibiotic therapy. Her most recent vital signs are BP 118/60, temperature 99.2°F (37.3°C), respiratory rate 20/min, pulse 98.
 (© Ridofranz/iStock.)	G.L. is a 67-yr-old man who came to the ED yesterday evening with abdominal pain. A CT scan of the abdomen revealed several masses in his lymphatic system. The HCP suspects non-Hodgkin's lymphoma and admits him for a diagnostic workup. He currently rates his pain as a 3 on a scale of 0 to 10.

Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide a rationale for your decision.
2. ***Collaboration:*** Which tasks could you delegate to the UAP *(select all that apply)*?

a. Assist A.J. to a chair after completing her AM care.
b. Obtain the first unit of blood for J.J. from the blood bank.
c. Explain the importance of isolation to P.H. and her family.
d. Ask A.J. why she has not received regular medical care for 5 years.
e. Assess G.L. for other clinical manifestations of non-Hodgkin's lymphoma.

3. ***Priority and Delegation Decision:*** When you enter J.J.'s room, you find him somewhat confused and lethargic. His family states he had just had a severe coughing episode. What initial action would be the *most* appropriate?
    a. Perform a focused neurologic examination.
    b. Call respiratory therapy to give him a breathing treatment.
    c. Have the UAP stay with J.J. while you page the HCP STAT.
    d. Ask his family members if they have a copy of his living will.

Case Study Progression

J.J.'s HCP orders a repeat CBC and an emergency CT scan of the head. Your supervisor makes arrangements for another RN to accompany J.J. to the CT scan while you prepare to administer the first unit of RBCs.

4. The HCP orders ferrous sulfate 325 mg TID for A.J. You teach A.J. to take her iron *(select all that apply)*
    a. at breakfast time in the morning.
    b. with orange juice to increase absorption.
    c. 1 hour before meals to facilitate absorption.
    d. 2 hours after eating to minimize side effects.
    e. whenever she feels tired or is short of breath with activity.

5. When teaching P.H.'s family about neutropenic precautions, you stress that the *most* important intervention to prevent infection is
    a. hand hygiene.
    b. wearing a mask.
    c. keeping P.H. in a private room.
    d. limiting the number of visitors in her room.
6. G.L. asks you to explain the diagnostic testing he can expect to undergo related to the suspected lymphoma. Which tests will you explain to him *(select all that apply)*?
    a. PET scan
    b. Bone marrow biopsy
    c. Peripheral blood smear
    d. Excisional lymph node biopsy
    e. Lymphangiography of internal lymph nodes
7. ***Management Decision:*** An RN from the float pool arrives to accompany J.J. to CT scan at the same time the UAP arrives with the first unit of packed RBCs. Which intervention would be *most* appropriate?
    a. Put the unit of RBCs in the refrigerator to start when J.J. returns to the floor.
    b. Ask the RN to verify the correct unit of RBCs with you and start the infusion.
    c. Give the RN an SBAR report and ask her to start the blood on the way to CT scan.
    d. Ask the RN if she would prefer to give the blood or hold it for J.J.'s return to the unit.

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphomas (NHLs) are a broad group of cancers of primarily B, T, natural killer (NK), histiocytic, and dendritic cells.[33] They affect persons of all ages. There are over 75 types. They are categorized by the level of differentiation (maturity), cell of origin, immunophenotype (cell surface markers), and genetic and clinical features.[33,35] The most common subtypes in the United States are diffuse large B-cell lymphoma, follicular lymphoma, marginal zone lymphoma, mantle cell lymphoma, and peripheral T-cell lymphoma not otherwise specificed.[33] A simplified example of the classification system is shown in Table 30.28.[33,35]

A variety of presentations and courses occur, from indolent (slowly developing) to rapidly progressive disease. NHL is the most commonly occurring hematologic cancer. It causes 3% to 4% of cancer-related deaths. Each year about 72,240 new cases of NHL are diagnosed and 20,140 deaths occur.[27]

Etiology and Pathophysiology

As with Hodgkin's lymphoma, the cause of NHL is usually unknown. NHLs may result from chromosomal translocations, infections, environmental factors, and immunodeficiency states. Chromosomal translocations have a key role in the pathogenesis of many NHLs. Viruses and bacteria implicated in the pathogenesis of NHL, include HTLV-1, EBV, human herpesvirus 8, hepatitis B and C, *H. pylori, Chlamydophila psittaci, Campylobacter jejuni,* and *Borrelia burgdorferi*.[3] Environmental factors linked to the development of NHL include chemicals (e.g., pesticides, herbicides, solvents, organic chemicals, wood preservatives). NHL is more common in people who have inherited immunodeficiency syndromes, have used immunosuppressive agents (e.g., to prevent rejection after an organ transplant or to treat autoimmune disorders), or received

chemotherapy or radiation therapy.

NHL does not have a hallmark feature that parallels the Hodgkin or Reed-Sternberg cell of Hodgkin's lymphoma. However, all NHLs involve lymphocytes arrested in various stages of development and may mimic a leukemia. For example, small lymphocytic lymphoma (SLL) and CLL result from malignant proliferation of small B lymphocytes, with most CLL disease within the bone marrow versus the lymph nodes. Some NHLs can begin outside the lymph nodes.

TABLE 30.28 Classification of Non-Hodgkin's Lymphoma*

B-Cell Lymphomas

- Burkitt's lymphoma
- Diffuse large B-cell lymphoma (DLBCL)
- Follicular lymphoma
- Mantle cell lymphoma
- Marginal zone B-cell lymphoma (MALT)
- Plasmablastic lymphoma
- Small lymphocytic lymphoma/chronic lymphocytic leukemia

T-Cell and NK-Cell Lymphomas

- Anaplastic large T-cell lymphoma
- Extranodal NK/T cell lymphoma
- Lymphoblastic lymphoma
- Mycosis fungoides and Sézary syndrome
- Peripheral T-cell lymphoma, not otherwise specified (NOS)

Posttransplant Lymphoproliferative Disorders

(PTLD)

- Infectious mononucleosis-like PTLD

Histocytic and Dendritic Cell Tumors

- Langerhans cell histiocytosis

---

* This is only a partial list.

Diffuse large B-cell lymphoma, the most common aggressive lymphoma, starts in the lymph nodes, usually in the neck or abdomen. Burkitt's lymphoma is the most aggressive disease. We think it begins in B-cell blasts in the lymph nodes.

Clinical Manifestations

The method of spread can be unpredictable. Most patients have widespread disease at the time of diagnosis (Fig. 30.16). The primary manifestation is painless lymph node enlargement. The lymphadenopathy can wax and wane in indolent disease. Because the disease has usually spread, other symptoms are present depending on where the disease is present (e.g., hepatomegaly with liver involvement, neurologic symptoms with CNS disease). NHL can manifest in nonspecific ways, such as an airway obstruction, hyperuricemia and renal failure from tumor lysis syndrome, pericardial tamponade, and GI symptoms. Patients with high-grade lymphomas may have lymphadenopathy and B symptoms, such as fever, night sweats, and weight loss.

Diagnostic and Staging Studies

Diagnostic studies used for NHL resemble those used for Hodgkin's

lymphoma. However, because NHL is more often in extranodal sites, more diagnostic studies may be done. These include an MRI or lumbar puncture to rule out CNS disease, a bone marrow biopsy to determine bone marrow infiltration, or a barium enema or upper endoscopy to look for GI involvement. Clinical staging, as described for Hodgkin's lymphoma, helps guide therapy (Fig. 30.15). Establishing the precise histologic subtype through biopsy is extremely important. NHL is classified based on morphologic, genetic, immunophenotypic (cell surface antigens, CD20, CD52), and clinical features. In early NHL, the CBC may be normal, but some lymphomas manifest in a "leukemic" phase.

Treatment is guided by the cell type, cytogenetic studies, and clinical behavior: *indolent* (low grade), aggressive (high grade), or *highly aggressive* (very high grade). Other factors, known as the International Prognostic Index (IPI), may be considered for each subtype. These include the clinical stage, number of extranodal sites, serum LDH, WBC count, and patient's age and performance status.[33,35] Immunologic, cytogenetic, and molecular studies are used for making therapeutic decisions and assessing prognosis. Other studies might include blood tests for tumor lysis; screening for hepatitis, HIV, and other infections; skin biopsies; bone marrow biopsies; and lumbar punctures. The prognosis for NHL is based on the histopathology.

FIG. 30.16 Non-Hodgkin's lymphoma involving the spleen. The presence of an isolated mass is typical.
From Cotran RS, Kumar V, Abbas AK: *Robbins pathologic basis of disease,* ed 6, Philadelphia, 1999, Saunders.

Interprofessional and Nursing Management

Treatment for NHL involves chemotherapy, biotherapy, radiation, and sometimes phototherapy and topical therapy (Table 30.29).[35] Ironically, more aggressive lymphomas (diffuse large B cell) are generally more responsive to treatment. In contrast, indolent lymphomas (e.g., follicular lymphomas) have a naturally long course but are hard to effectively treat.[33]

Patients with low-grade (indolent) lymphoma may live 10 years or more without treatment. However, some early therapies can be well tolerated and may reduce the time to progression of the disease. Those that have an infectious basis, such as *H. pylori* gastric lymphomas, may be treated with antibiotic or antiviral therapy. HSCT may help in certain subtypes of aggressive or refractory lymphomas. Chimeric antigen receptor (CAR) T-cell immunotherapy may be used.

Rituximab, a monoclonal antibody against the CD20 antigen on the surface of normal and malignant B cells, is used to treat NHL in combination with other agents. Once bound to the cells, rituximab causes lysis and cell death. Numerous chemotherapy combinations

are used to try to overcome the resistant nature of this disease. Targeted therapies are becoming more prevalent (Table 30.29).

Drug Alert

Rituximab (Rituxan)

- Monitor patient for signs of severe hypersensitivity infusion reactions, especially with first infusion.
- Manifestations may include hypotension, bronchospasm, dysrhythmias, angioedema, and cardiogenic shock.
- Screen for history of hepatitis because the drug may reactivate hepatitis.

Another therapy for some types of NHL is the monoclonal antibody ibritumomab tiuxetan (Zevalin). It contains a radioactive particle that can kill cancer cells. The therapy targets the CD20 antigen, which is on the surface of mature B cells and B-cell tumors. Targeting allows for the delivery of the radiation directly to the cancer cells. Side effects include pancytopenia. Use radiation precautions in caring for these patients. Teach patients about safety issues and how to minimize the risk for radiation exposure to staff and others.

In general, T-cell lymphomas are harder to treat. They are often treated aggressively up front, often followed by an HSCT. Cutaneous T-cell lymphomas may be treated with topical corticosteroids or topical chemotherapy for limited-stage disease. For more diffuse disease, treatment may include methotrexate, α-interferon, brentuximab vedotin, or other drugs.[35]

The nursing care for NHL is similar to that for Hodgkin's lymphoma. It is based on managing problems related to the disease (e.g., pain caused by the tumor, spinal cord compression, tumor lysis syndrome), pancytopenia, and other side effects of therapy. However, because NHL can be more extensive and involve specific organs (e.g.,

CNS, spleen, liver, GI tract, bone marrow), it is important to understand the subtype and extent of the disease. For example, a patient with known involvement of the colon may report acute abdominal pain. The patient would likely have abdominal guarding and an enlarged and tympanic abdomen. This could indicate a bowel perforation and be considered a medical emergency. A patient with a Burkitt's NHL beginning chemotherapy would be at high risk for tumor lysis syndrome and would need frequent laboratory studies and monitoring, as well as strict documentation of intake and output. Cancer-related therapies and side effects are discussed in Chapter 15.

TABLE 30.29 Treatment of Non-Hodgkin's Lymphoma *

Recommended Therapies	Common Chemotherapy Combinations
Indolent (Low Grade) Follicular Lymphoma, Marginal Zone B-Cell Lymphoma, Mucosa-Associated Lymphoid Tissue (MALT)	
• **Observation until disease progression for asymptomatic patients with low-volume tumors and normal blood counts** • **External beam irradiation for local, limited disease** • **Single-agent rituximab, obinutuzumab** • **Single-agent chemotherapy (bendamustine, chlorambucil, cyclophosphamide, idelalisib)** • **Rituximab with another agent (bendamustine, fludarabine, lenalidomide)** • **Combination chemotherapy (R-CHOP or other)** • **Radioimmunotherapy** • **Hematopoietic stem cell transplant (HSCT)**	**R-CHOP:** rituximab, cyclophosphamide, doxorubicin hydrochloride, vincristine (Oncovin), prednisone **R-CVP:** rituximab, cyclophosphamide, vincristine, prednisone **RFND:** rituximab, fludarabine, mitoxantrone (Novantrone), dexamethasone ± rituximab
Aggressive (Intermediate or High Grade) Mantle Cell, Diffuse Large B-Cell, T-Cell, Natural Killer Cell Lymphomas	
• **Combination chemotherapy with localized radiation if needed** • **Aggressive combination chemotherapy for 3–8 cycles with rituximab with local radiation if needed** • **Intrathecal chemotherapy if needed** • **Single agent or other combination treatment, depending on subtype and response (e.g., acalabrutinib, alemtuzumab, asparaginase, belinostat, bendamustine, bortezomib, brentuximab vedotin, cladribine, gemcitabine, ibrutinib, lenalidomide, oxaliplatin, romidepsin, venetoclax)** • **HSCT**	**CHOP** ± rituximab (see above) **ICE** (or "RICE" with rituximab): ifosfamide, cyclophosphamide, etoposide **R-EPOCH:** rituximab, etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, doxorubicin hydrochloride **ESHAP ± R:** etoposide, methylprednisolone (Solu-Medrol), high-dose cytarabine (Ara-C), cisplatin (Platinol), with or without rituximab **Hyper-CVAD ± R:** hyperfractionated cyclophosphamide, vincristine, doxorubicin (Adriamycin), dexamethasone alternating with high-dose methotrexate and cytarabine with or without rituximab **DHAP ± R:** dexamethasone, high-dose cytarabine (Ara-C), cisplatin (Platinol), with or without rituximab
Highly Aggressive (e.g., Burkitt's Lymphoma)	
• **Aggressive combination chemotherapy for 3–8 cycles** • **HSCT**	**R-EPOCH:** rituximab, etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, doxorubicin hydrochloride **Hyper-CVAD ± R** (see above) **CODOX-M:** cyclophosphamide, vincristine (Oncovin), doxorubicin, high-dose methotrexate, with or without rituximab (includes intrathecal methotrexate)

* The acronym for some drug regimens use the trade name of chemotherapy agents. In some cases, the trade name drug has been discontinued, and the drug currently used is the generic version.

The patient undergoing external beam radiation therapy has special nursing needs. The skin in the radiation field needs special care. Concepts related to safety issues with radiation therapy are important to include in the plan of care (see Chapter 15).

Psychosocial considerations are important. Help the patient and family understand the disease, treatment, and expected and potential side effects. Some aggressive treatments need close follow-up and even inpatient admission. Fertility issues may be of concern in young patients. As in Hodgkin's lymphoma, evaluation of patients with NHL for long-term effects of therapy is important because the delayed consequences of disease and treatment may not become apparent for many years.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In a severely anemic patient, the nurse would expect to find
   a. cyanosis and cardiomegaly.
   b. pulmonary edema and fibrosis.
   c. dyspnea at rest and tachycardia.
   d. ventricular dysrhythmias and wheezing.
2. When obtaining assessment data from a patient with a microcytic, hypochromic anemia, the nurse would ask the patient about
   a. folic acid intake.
   b. dietary intake of iron.
   c. a history of gastric surgery.
   d. a history of sickle cell anemia.
3. Nursing interventions for a patient with severe anemia related to peptic ulcer disease include *(select all that apply)*
   a. instructions for high-iron diet.
   b. taking vital signs every 8 hours.
   c. monitoring stools for occult blood.
   d. teaching self-injection of erythropoietin.
   e. administration of cobalamin (vitamin B_{12}) injections.
4. The nursing management of a patient in sickle cell crisis includes *(select all that apply)*

a. monitoring CBC.

b. optimal pain management and O_2 therapy.

c. blood transfusions if needed and iron chelation.

d. rest as needed and deep vein thrombosis prophylaxis.

e. administration of IV iron and diet high in iron content.

5. A complication of the hyperviscosity of polycythemia is

a. thrombosis.

b. cardiomyopathy.

c. pulmonary edema.

d. disseminated intravascular coagulation (DIC).

6. When caring for a patient with thrombocytopenia, the nurse instructs the patient to

a. dab his or her nose instead of blowing.

b. be careful when shaving with a safety razor.

c. continue with physical activities to stimulate thrombopoiesis.

d. avoid aspirin because it may mask the fever that occurs with thrombocytopenia.

7. The nurse would expect that a patient with von Willebrand disease undergoing surgery would be treated with administration of vWF and

a. thrombin.

b. factor VI.

c. factor VII.

d. factor VIII.

8. DIC is a disorder in which

a. the coagulation pathway is genetically altered, leading to thrombus formation in all major blood vessels.

b. an underlying disease depletes hemolytic factors in the blood, leading to diffuse thrombotic episodes and infarcts.

c. a disease process stimulates coagulation processes with resultant thrombosis, as well as depletion of clotting factors, leading to diffuse clotting and hemorrhage.

d. an inherited predisposition causes a deficiency of clotting factors that leads to overstimulation of coagulation processes in the vasculature.

9. Priority nursing actions when caring for a hospitalized patient with a new-onset temperature of 102.2°F (39°C) and severe neutropenia include *(select all that apply)*

a. starting the prescribed antibiotic STAT.

b. drawing peripheral and central line blood cultures.

c. ongoing monitoring of the patient's vital signs for septic shock.

d. taking a full set of vital signs and notifying the physician immediately.

e. administering transfusions of WBCs treated to decrease immunogenicity.

10. Because myelodysplastic syndrome arises from the pluripotent hematopoietic stem cell in the bone marrow, laboratory results the nurse would expect to find include a(n)

a. excess of T cells.

b. excess of platelets.

c. deficiency of granulocytes.

d. deficiency of all cellular blood components.

11. The most common type of leukemia in adults in western countries is

a. acute myelocytic leukemia.

b. acute lymphocytic leukemia.

c. chronic myelocytic leukemia.

d. chronic lymphocytic leukemia.

12. Multiple drugs are often used in combinations to treat leukemia and lymphoma because

a. there are fewer toxic and side effects.

b. the chance that one drug will be effective is increased.

c. the drugs are more effective without causing side effects.

d. the drugs work by different mechanisms to maximize killing of cancer cells.

13. The nurse is aware that a major difference between Hodgkin's lymphoma and non-Hodgkin's lymphoma is that

a. Hodgkin's lymphoma occurs only in young adults.

b. Hodgkin's lymphoma is considered potentially curable.

c. non-Hodgkin's lymphoma can manifest in multiple areas.

d. non-Hodgkin's lymphoma is treated only with radiation therapy.

14. A patient with multiple myeloma becomes confused and lethargic. The nurse would expect that these clinical manifestations may be explained by diagnostic results that

indicate

a. hyperkalemia.

b. hyperuricemia.

c. hypercalcemia.

d. CNS myeloma.

15. When reviewing a patient's hematologic laboratory values after a splenectomy, the nurse would expect to find

a. RBC abnormalities.

b. increased WBC count.

c. decreased hemoglobin.

d. decreased platelet count.

16. Complications of transfusions that can be decreased by using leukocyte depletion or reduction of RBC transfusion are

a. chills and hemolysis.

b. leukostasis and neutrophilia.

c. fluid overload and pulmonary edema.

d. transmission of cytomegalovirus and fever.

1. c, 2. b, 3. a, c, 4. a, b, c, d, 5. a, 6. a, 7. d, 8. c, 9. a, b, c, d, 10. d, 11. d, 12. d, 13. c, 14. c, 15. b, 16. d

LEARNING OUTCOMES

1. Discern the anatomic location and function of the pericardial layers, atria, ventricles, and valves.
2. Relate the coronary circulation to the areas of heart muscle supplied by the major coronary arteries.
3. Distinguish the structure and function of arteries, veins, capillaries, and endothelium.
4. Describe the mechanisms involved in the regulation of blood pressure.
5. Relate the various waveforms on a normal electrocardiogram to the associated cardiac events.
6. Obtain significant subjective and objective assessment data related to the cardiovascular system from a patient and/or caregiver.
7. Perform a physical assessment of the cardiovascular system using the appropriate techniques.
8. Distinguish normal from abnormal findings of a physical assessment of the cardiovascular system.

9. Link the age-related changes of the cardiovascular system to the differences in assessment findings.
10. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the cardiovascular system.

Structures and Functions of Cardiovascular System

Heart

Structure

The heart is a 4-chambered hollow muscular organ normally about the size of a fist. It lies within the thorax in the mediastinal space that separates the right and left pleural cavities. The heart is composed of 3 layers: a thin inner lining, the *endocardium;* a layer of muscle, the *myocardium;* and an outer layer, the *epicardium.* The heart is covered by a fibroserous sac called the *pericardium.* This sac consists of 2 layers: the inner *(visceral)* layer of the pericardium (part of the epicardium) and the outer *(parietal)* layer. A small amount of pericardial fluid (around 10 to 15 mL) lubricates the space between the pericardial layers *(pericardial space)* and prevents friction between the surfaces as the heart contracts.

The septum vertically divides the heart. The interatrial septum creates a right and left atrium. The interventricular septum creates a right and left ventricle. The thickness of the wall of each chamber is

different. The atrial myocardium is thinner than that of the ventricles. The left ventricular wall is 2 to 3 times thicker than the right ventricular wall. The thickness of the left ventricle is needed to make the force needed to pump the blood into the systemic circulation.[1]

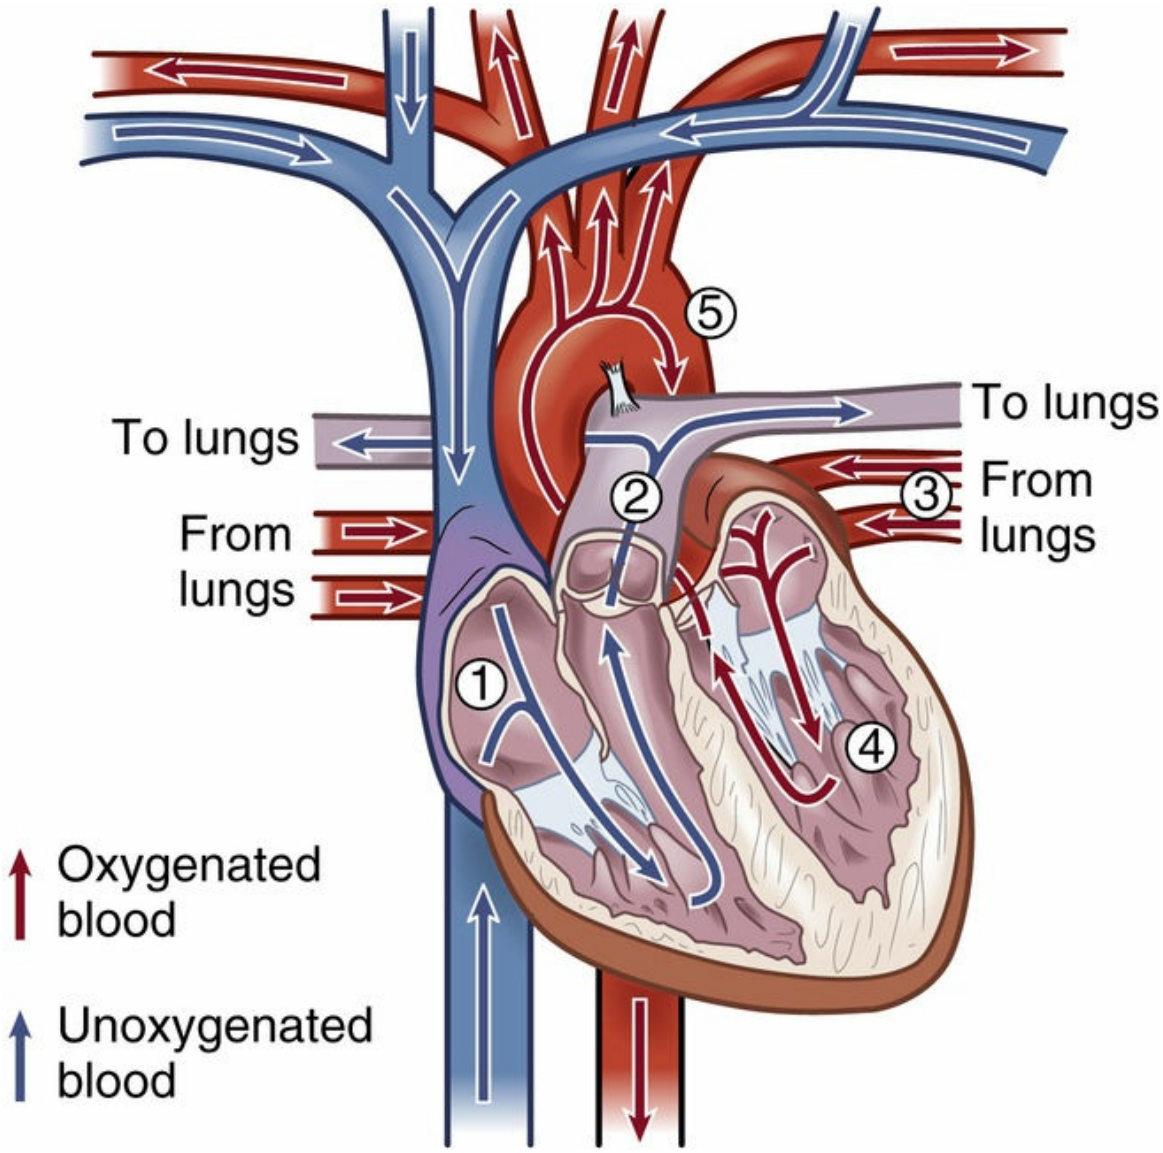

FIG. 31.1 Schematic representation of blood flow through the heart. *Arrows* show direction of flow. *1,* The right atrium receives venous blood from the inferior and superior venae cava and the coronary sinus. The blood then passes through the tricuspid valve into the right ventricle. *2,* With each contraction, the right ventricle pumps blood through the pulmonic valve into the pulmonary artery and to the lungs. *3,* Oxygenated blood flows from the lungs to the left atrium by way of

the pulmonary veins. *4,* It then passes through the mitral valve and into the left ventricle. *5,* As the heart contracts, blood is ejected through the aortic valve into the aorta and thus enters the systemic circulation.

Blood Flow Through Heart

The blood flow through the heart is shown in Fig. 31.1.

Heart Valves

The 4 valves of the heart keep blood flowing in a forward direction. The cusps of the mitral and tricuspid valves are attached to thin strands of fibrous tissue called *chordae tendineae* (Fig. 31.2). Chordae are anchored in the papillary muscles of the ventricles. This support system prevents the eversion of the leaflets into the atria during ventricular contraction. The pulmonic and aortic valves (also known as *semilunar valves*) prevent blood from regurgitating into the ventricles at the end of each ventricular contraction.

Blood Supply to Myocardium

The myocardium has its own blood supply, the *coronary circulation* (Fig. 31.3). Blood flow into the 2 major coronary arteries occurs primarily during **diastole** (relaxation of the myocardium). The left coronary artery arises from the aorta and divides into 2 main branches: the left anterior descending artery and left circumflex artery. These arteries supply the left atrium, left ventricle, interventricular septum, and part of the right ventricle. The right coronary artery also arises from the aorta, and its branches supply the right atrium, right ventricle, and part of the posterior wall of the left ventricle. In 90% of people, the atrioventricular (AV) node and the bundle of His receive blood supply from the right coronary artery. For this reason, blockage of this artery often causes serious defects in cardiac conduction.

The divisions of coronary veins parallel the coronary arteries. Most of the blood from the coronary system drains into the coronary sinus (a large channel), which empties into the right atrium near the entrance of the inferior vena cava.[1]

Conduction System

The conduction system consists of specialized tissue responsible for creating and transporting the electrical impulse, or **action potential**. This impulse starts depolarization of the heart cells and leads to heart muscle contraction (Fig. 31.4, *A*). The electrical impulse normally begins in the sinoatrial (SA) node (pacemaker of the heart). Impulses from the SA node travel through interatrial pathways to depolarize the atria, resulting in a contraction.

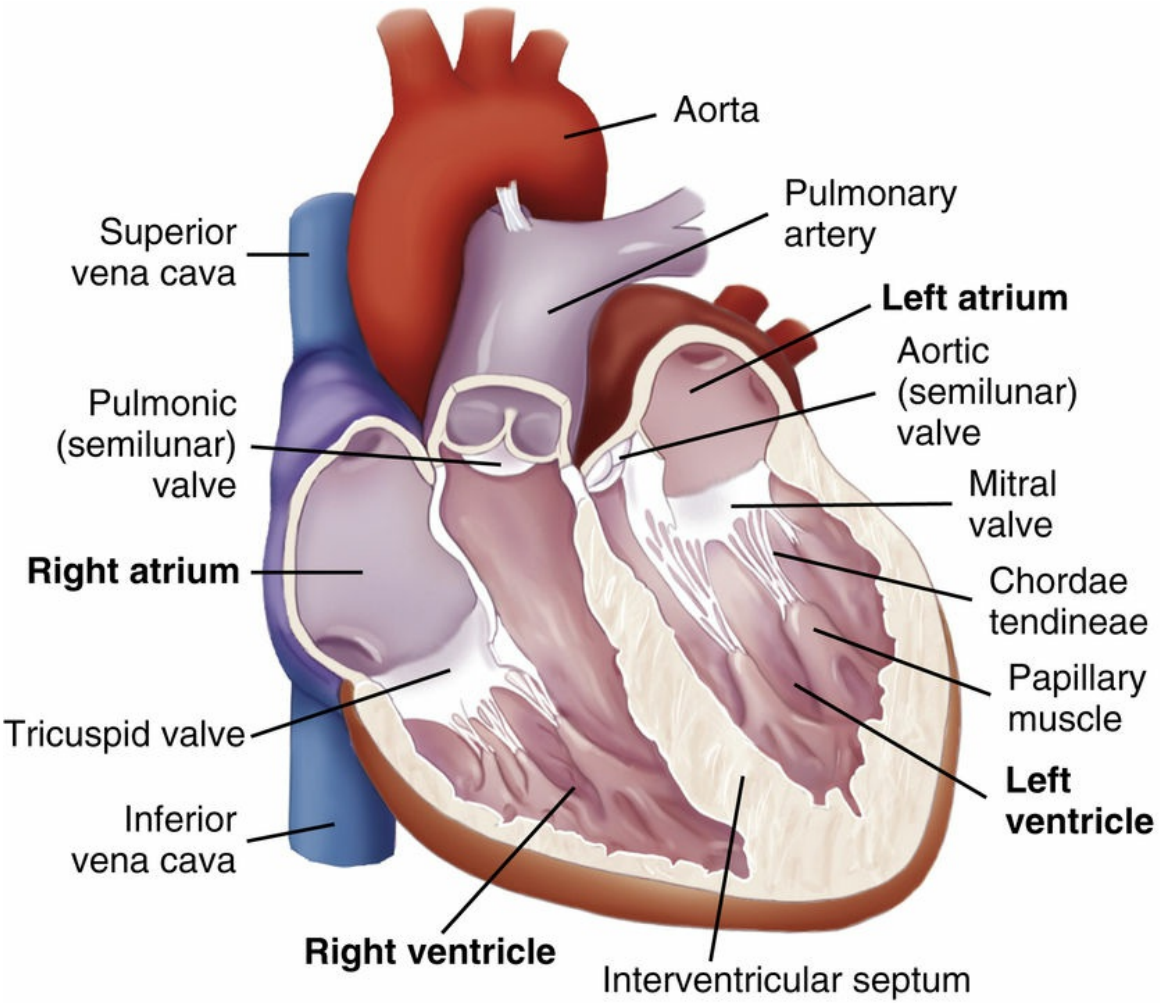

FIG. 31.2 Anatomic structures of the heart and heart valves.

The electrical impulse travels from the atria to the AV node through internodal pathways. The signal then moves through the bundle of

His and the left and right bundle branches. The left bundle branch has 2 divisions: anterior and posterior. The action potential moves through the walls of both ventricles via *Purkinje fibers.* The ventricular conduction system delivers the impulse within 0.12 second. This triggers a synchronized right and left ventricular contraction and ejection of blood into the pulmonary and systemic circulations.

Last, repolarization occurs when the contractile and conduction pathway cells regain their resting polarized condition. Heart muscle cells have a compensatory mechanism that makes them unresponsive or refractory to restimulation during the action potential. During ventricular contraction, there is an *absolute refractory period* during which heart muscle does not respond to any stimuli. After this period, heart muscle gradually recovers its excitability, and a *relative refractory period* occurs by early diastole.

Electrocardiogram

The electrical activity of the heart can be detected on the body surface using electrodes. It is recorded on an electrocardiogram (ECG). We use the letters *P, QRS, T,* and *U* to name the separate waveforms (Fig. 31.4, *B*). The first waveform, the P wave, begins with the firing of the SA node. It represents depolarization of the atria. The QRS complex represents depolarization from the AV node throughout the ventricles. There is a delay of impulse transmission through the AV node that accounts for the time between the beginning of the P wave and the beginning of the QRS wave. The T wave represents repolarization of the ventricles. The U wave, if seen, may represent repolarization of the Purkinje fibers. A large U wave may occur with hypokalemia.[2]

Intervals between these waves (PR, QRS, and QT intervals) reflect the time it takes for the signal to travel from 1 area of the heart to another. We can measure these time intervals. Changes from these time references often indicate pathologic conditions. See Chapter 35 for a complete discussion of ECG monitoring.

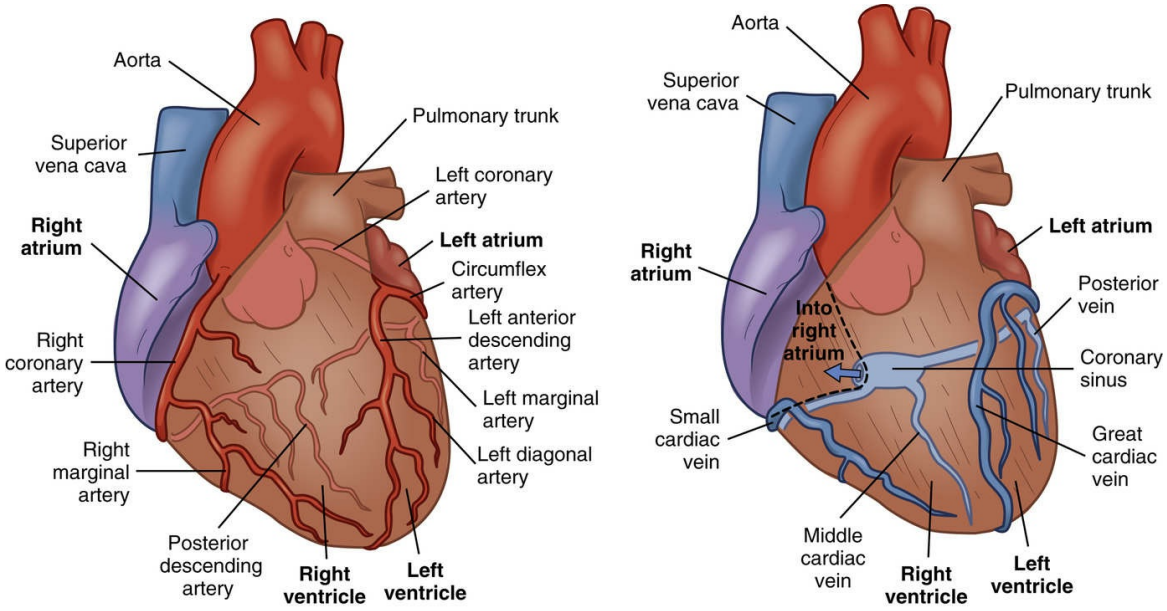

FIG. 31.3 Coronary arteries and veins.

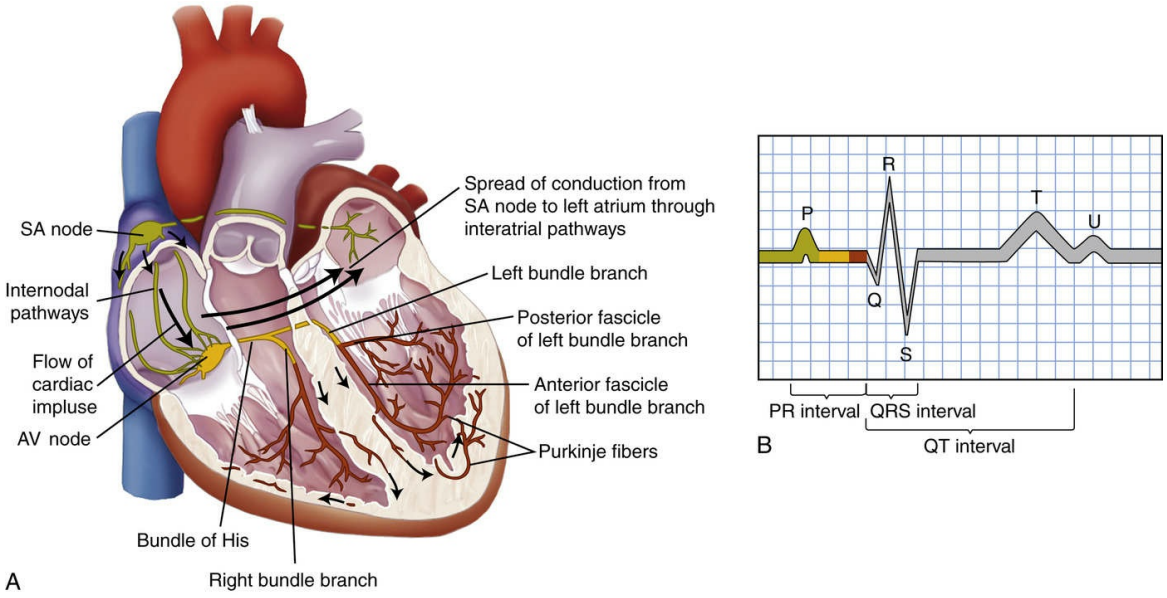

FIG. 31.4 **A,** Conduction system of the heart. *AV,* Atrioventricular; *SA,* sinoatrial. **B,** The normal electrocardiogram (ECG) pattern. The P wave represents depolarization of the atria. The QRS complex indicates depolarization of the ventricles. The T wave represents repolarization of the ventricles. The U wave, if present, may represent repolarization of the Purkinje fibers, or it may be associated with hypokalemia. The PR, QRS, and QT intervals reflect the time it takes for the impulse to travel from one area of the heart to another.

Mechanical System

Depolarization triggers mechanical activity. **Systole**, contraction of the heart muscle, results in ejection of blood from the ventricles. Relaxation of the heart muscle, *diastole,* allows for filling of the ventricles. **Cardiac output (CO)** is the amount of blood pumped by each ventricle in 1 minute. It is calculated by multiplying the amount of blood ejected from the ventricle with each heartbeat: *stroke volume* (SV) times heart rate (HR) per minute:

$$CO = SV \times HR$$

For the normal adult at rest, CO is maintained in the range of 4 to 8 L/min. **Cardiac index (CI)** is the CO divided by the body surface area (BSA). The CI reflects the relative CO for the body size. The normal CI is 2.8 to 4.2 L per minute per meter squared ($L/min/m^2$).[3]

Factors Affecting Cardiac Output

Numerous factors can affect either the HR or SV and thus the CO. The HR, which is controlled primarily by the autonomic nervous system, can reach as high as 180 beats/min for short periods without harmful effects. With rapid HRs, there is less time for diastolic filling and perfusion of the coronary arteries. The factors affecting the SV are preload, contractility, and afterload. Increasing preload, contractility, and afterload increases the workload of the heart muscle, resulting in increased O_2 demand.

The Frank-Starling law states that, to a point, the more the myocardial fibers are stretched, the greater their force of contraction. The volume of blood stretching the ventricles at the end of diastole, before the next contraction, is called **preload**. Preload can be increased by conditions such as hypertension, aortic valve disease, and hypervolemia. Preload is decreased when a rapid HR or hypovolemia

reduces ventricular filling during diastole. Contractility can be increased by epinephrine and norepinephrine released by the sympathetic nervous system. Increasing contractility raises the SV by increasing ventricular emptying. [3]

Afterload is the peripheral resistance against which the left ventricle must pump. Afterload depends on the size of the ventricle, wall tension, and arterial BP. If the arterial BP is elevated, the ventricles meet increased resistance to ejection of blood, increasing the work demand. Eventually this results in *ventricular hypertrophy*, an enlargement of the heart muscle without an increase in CO or the size of chambers. Although we often think of afterload as affecting left heart function, both right and left ventricles work against resistance. The right ventricle pumps against the afterload of pulmonary arterial resistance.

Cardiac Reserve

The cardiovascular system must respond to many situations in health and illness (e.g., exercise, stress, hypovolemia). The ability to respond to these demands by altering CO is termed **cardiac reserve**.

Vascular System

Blood Vessels

The 3 major types of blood vessels are the arteries, veins, and capillaries. Arteries, except for the pulmonary artery, carry oxygenated blood away from the heart. Veins, except for the pulmonary veins, carry deoxygenated blood toward the heart. Small branches of arteries and veins are arterioles and venules, respectively. Blood circulates from the left side of the heart into arteries, arterioles, capillaries, venules, and veins, and then back to the right side of the heart.

Arteries and Arterioles

The arterial system differs from the venous system by the amount and

type of tissue that make up arterial walls (Fig. 31.5). The large arteries have thick walls composed mainly of elastic tissue. This elastic property cushions the impact of the pressure created by ventricular contraction and provides recoil that propels blood forward into the circulation. Large arteries contain some smooth muscle. Examples of large arteries are the aorta and pulmonary artery.

Arterioles have more smooth muscle and little elastic tissue. Arterioles serve as the major control of arterial BP and distribution of blood flow. They respond readily to local conditions such as low oxygen (O_2) and increasing levels of carbon dioxide (CO_2) by dilating or constricting.

The innermost lining of the arteries is the endothelium. The endothelium maintains hemostasis, promotes blood flow, and, under normal conditions, inhibits blood coagulation. When the endothelial surface is disrupted (e.g., rupture of an atherosclerotic plaque), the coagulation cascade is initiated and results in the formation of a fibrin clot.

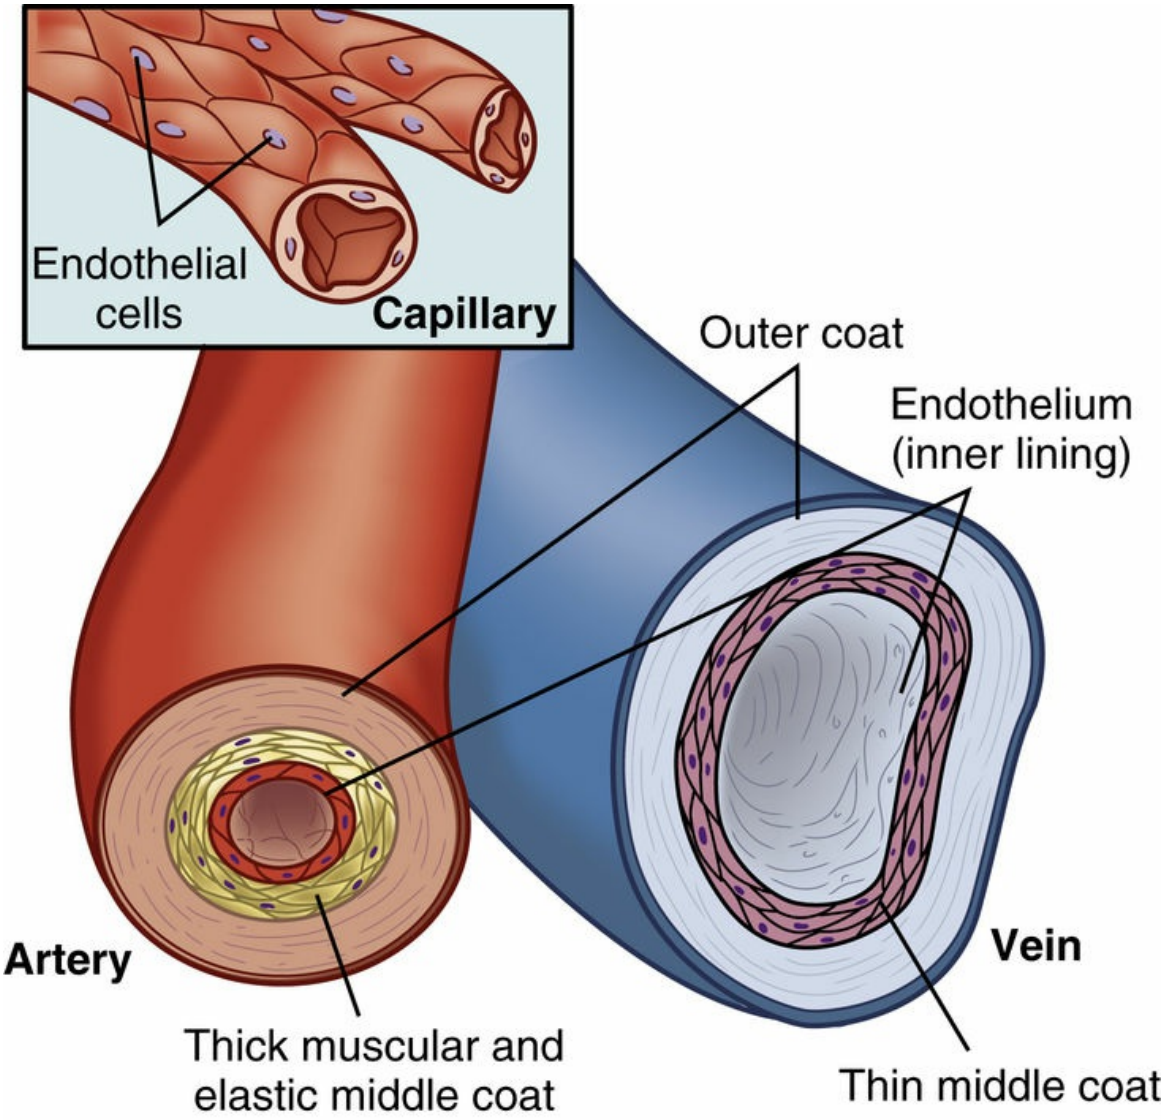

FIG. 31.5 Comparative thickness of layers of the artery, vein, and capillary.

Capillaries

The thin capillary wall, made up of endothelial cells, has no elastic or muscle tissue (Fig. 31.5). The exchange of cellular nutrients and metabolic end products takes place through these thin-walled vessels. Capillaries connect the arterioles and venules.

Veins and Venules

Veins are large-diameter, thin-walled vessels that return blood to the

right atrium (Fig. 31.5). The venous system is a low-pressure, high-volume system. The larger veins have semilunar valves at intervals to maintain the blood flow toward the heart and to prevent backward flow. The amount of blood in the venous system is affected by several factors. These include arterial flow, compression of veins by skeletal muscles, changes in thoracic and abdominal pressures, and right atrial pressure.

The largest veins are the *superior vena cava,* which returns blood to the heart from the head, neck, and arms, and the *inferior vena cava,* which returns blood to the heart from the lower part of the body. Pressure in the right side of the heart affects these large vessels. Elevated right atrial pressure can cause distended neck veins or liver engorgement because of resistance to blood flow.

Venules are smaller vessels made up of a small amount of muscle and connective tissue. Venules collect blood from the capillary beds and channel it to the larger veins.

Regulation of Cardiovascular System

Autonomic Nervous System

The autonomic nervous system consists of the sympathetic nervous system and parasympathetic nervous system (see Chapter 55).

Effect on Heart

Stimulation of the sympathetic nervous system increases the HR, speed of impulse conduction through the AV node, and force of atrial and ventricular contractions. This effect is mediated by specific sites in the heart called *beta (β)-adrenergic receptors,* which are receptors for norepinephrine and epinephrine.

In contrast, stimulation of the parasympathetic system (mediated by the vagus nerve) slows the HR by decreasing the impulses from the SA node and thus conduction through the AV node.

Effect on Blood Vessels

The source of neural control of blood vessels is the sympathetic

nervous system. Alpha$_1$ (α_1)-adrenergic receptors are found in vascular smooth muscles. Stimulation of α_1-adrenergic receptors results in vasoconstriction. Decreased stimulation to α_1-adrenergic receptors causes vasodilation. Sympathetic nervous system receptors that influence BP are described in Table 32.1.

The parasympathetic nerves have selective distribution in the blood vessels. For example, blood vessels in skeletal muscle do not receive parasympathetic input.

Baroreceptors

Baroreceptors in the aortic arch and carotid sinus (at the origin of the internal carotid artery) are sensitive to stretch or pressure within the arterial system. Stimulation of these receptors (e.g., volume overload) sends information to the vasomotor center in the brainstem. This results in temporary inhibition of the sympathetic nervous system and enhancement of the parasympathetic influence, causing a decreased HR and peripheral vasodilation. Decreased arterial pressure causes the opposite effect.

Chemoreceptors

Chemoreceptors are found in the aortic and carotid bodies and the medulla. They can cause changes in respiratory rate and BP in response to increased arterial CO_2 pressure (hypercapnia) and, to a lesser degree, decreased plasma pH (acidosis) and arterial O_2 pressure (hypoxia). Chemoreceptors in the medulla stimulate the vasomotor center to increase BP.[3]

Blood Pressure

The **arterial blood pressure** is a measure of the pressure exerted by blood against the walls of the arterial system. **The systolic blood pressure (SBP)** is the peak pressure exerted against the arteries when the heart contracts. The **diastolic blood pressure (DBP)** is the residual pressure in the arterial system during ventricular relaxation (or

filling).

The main factors influencing BP are CO and *systemic vascular resistance* (SVR):

$$BP = CO \times SVR$$

SVR is the force opposing the movement of blood. This force is created primarily in small arteries and arterioles. Normal BP is SBP <120 mm Hg and DBP <80 mm Hg[4] (see Chapter 32).

Measurement of Arterial Blood Pressure

We can measure BP by using invasive and noninvasive techniques. The invasive technique consists of catheter insertion into an artery. The catheter is attached to a transducer, and the pressure is measured directly (see Chapter 65).

Noninvasive, indirect measurement of BP can be done with a sphygmomanometer and stethoscope. The sphygmomanometer consists of an inflatable cuff and a pressure gauge. The BP is measured by auscultating for sounds of turbulent blood flow through a compressed artery (termed **Korotkoff sounds**). The brachial artery is the recommended site for taking a BP.

After placing the right size cuff on the upper arm, inflate the cuff to a pressure 20 to 30 mm Hg above the SBP. This causes blood flow in the artery to cease. If the SBP is not known, estimate the pressure by palpating the brachial pulse and inflating the cuff until the pulse ceases. The pressure noted at this time is the estimated SBP. Inflate the BP cuff 20 to 30 mm Hg above this number.

As you lower the pressure in the cuff, listen to the artery for Korotkoff sounds. There are 5 phases of Korotkoff sounds. The first phase is a tapping sound caused by the spurt of blood into the constricted artery as the pressure in the cuff is gradually deflated. This sound is the SBP. The fifth phase occurs when the sound disappears,

which is the DBP.[5]

BP is recorded as the ratio of SBP to DBP (e.g., 120/80 mm Hg). Sometimes, an *auscultatory gap* occurs, which is a loss of sound between the SBP and DBP. Proper BP technique (e.g., using the correct cuff size, positioning arm at heart level) is essential for correct readings (see Table 32.12).

Another noninvasive way to measure BP indirectly is an automated device that uses oscillometric measurements to assess BP. Though this method does not involve auscultation, the same attention to proper technique is essential for accuracy.

We can assess SBP and pulse using a Doppler ultrasonic flowmeter. The hand-held transducer is positioned over the artery (identified by audible, pulsatile sounds). The cuff is applied above the artery, inflated until the sounds disappear, and then inflated another 20 to 30 mm Hg beyond that point. The cuff is then slowly deflated. The point where sounds return is the SBP.

Pulse Pressure and Mean Arterial Pressure

Pulse pressure is the difference between the SBP and DBP. It is normally about one third of the SBP. If the BP is 120/80 mm Hg, the pulse pressure is 40 mm Hg. An increased pulse pressure due to an increased SBP may occur during exercise or in people with atherosclerosis of the larger arteries. A decreased pulse pressure may occur with heart failure (HF) or hypovolemia.

Another measurement related to BP is **mean arterial pressure (MAP)**. The MAP refers to the average pressure within the arterial system that is felt by organs in the body. It is not the average of the DBP and SBP, because the length of diastole exceeds that of systole at normal HRs. MAP is calculated as follows:

$$MAP = (SBP + 2\,DBP) \div 3$$

A person with a BP of 120/60 mm Hg has an estimated MAP of 80 mm Hg. A MAP greater than 60 mm Hg is needed to perfuse the vital organs of an average person under most conditions. When the MAP is low for a period of time, vital organs are underperfused and will become ischemic.

Gerontologic Considerations: Effects of Aging on the Cardiovascular System

One of the greatest risk factors for cardiovascular disease (CVD) is age. CVD is the leading cause of death in adults older than age 65. The most common cardiovascular problem is coronary artery disease (CAD) due to atherosclerosis. Many of the physiologic changes in the cardiovascular system of older adults are a result of the combined effects of the aging process, disease, environmental factors, and lifetime health behaviors rather than just age alone.[6]

Age-related changes in the cardiovascular system and differences in assessment findings are found in Table 31.1. With increased age, the amount of collagen in the heart increases and elastin decreases. These changes affect the heart muscle's ability to stretch and contract.[6] One of the major changes in the cardiovascular system is the response to physical or emotional stress. In times of increased stress, CO and SV decrease due to reduced contractility and HR response. Aging does not really affect the resting supine HR. When the patient changes positions (e.g., sits upright), the sympathetic nerve pathway results in a blunted (reduced) HR response.[7]

TABLE 31.1 Gerontologic Assessment DifferencesCardiovascular System

Changes	Differences in Assessment Findings
Chest Wall	
Kyphosis	Altered chest landmarks for palpation, percussion, and auscultation. Distant heart sounds
Heart	
Myocardial hypertrophy, ↑ collagen and scarring, ↓ elastin	↓ Cardiac reserve, HF. S_4 may be present
Downward displacement	Difficulty in isolating apical pulse.
↓ CO, HR, SV in response to exercise or stress	↓ Response to exercise and stress. Slowed recovery from activity
Cellular aging and fibrosis of conduction system	↓ Amplitude of QRS complex and slight lengthening of PR, QRS, and QT intervals. Irregular cardiac rhythms, ↓ maximal HR, ↓ HR variability
Valvular rigidity from calcification, sclerosis, or fibrosis, impeding complete closure of valves	Systolic murmur (aortic or mitral) possible without a sign of cardiovascular disease
Blood Vessels	
Arterial stiffening caused by loss of elastin in arterial walls, thickening of intima of arteries, and progressive fibrosis of media	↑ In SBP and possible ↑ or ↓ in DBP. Possible widened pulse pressure. Pedal pulses diminished. Intermittent claudication
Venous tortuosity increased	Inflamed, painful, or cordlike varicosities. Dependent edema

Heart valves become thicker and stiffer from lipid accumulation, degeneration of collagen, and fibrosis. The aortic and mitral valves are most often affected. These changes result in either regurgitation of blood when the valve should be closed or narrowing of the orifice of the valve *(stenosis)* when the valve should be open. The turbulent blood flow across the affected valve results in a **murmur**.

Numbers of pacemaker cells in the SA node and conduction cells in the internodal tracts, bundle of His, and bundle branches decrease with age. These changes contribute to the development of sinus and atrial dysrhythmias and heart blocks. Many older adults have an abnormal resting ECG that shows increases in the PR, QRS, and/or QT intervals.[7]

The autonomic nervous system control of the cardiovascular system changes with aging. The number and function of β-adrenergic receptors in the heart decrease with age. So, the older adult not only has a decreased response to physical and emotional stress but also is less sensitive to β-adrenergic agonist drugs. Exercise results in a much smaller increase in CO for older adults than for younger adults.[7]

With age, arteries and veins thicken and become less elastic. Arteries increase their sensitivity to vasopressin (antidiuretic hormone). Both changes increase SBP with a decreased or unchanged DBP, increasing the pulse pressure. Valves in the large leg veins do not return the blood to the heart as effectively, often resulting in

dependent edema.[6]

Orthostatic hypotension may be related to drugs and/or decreased baroreceptor function. *Postprandial hypotension* (decrease in BP of at least 20 mm Hg that occurs within 75 minutes after eating) may occur in otherwise healthy older adults. Both orthostatic and postprandial hypotension may be related to falls in older adults. Despite the changes associated with aging, the heart can function adequately under most circumstances.

Patient Introduction

© Jupiterimages/Banana-Stock/Thinkstock.

L.P., a 63-yr-old Asian American man, is brought to the hospital by ambulance at 6 AM after reporting chest tightness, shortness of breath (SOB), and "heart pounding" (palpitations). The paramedics started an IV and O_2 at 2 L/min via nasal cannula. They obtained a 12-lead ECG and gave him 4 chewable baby ASA and a nitroglycerin tablet. L.P. is pain free on arrival to the emergency department, but still has

palpitations.

Discussion Questions

1. Is L.P.'s condition stable or unstable?
2. What are the possible causes of L.P.'s chest tightness, SOB, and palpitations?
3. What type of assessment is most appropriate for L.P.: emergency, focused, or comprehensive? On what basis did you make that decision?
4. What assessment questions will you ask him?

You will learn more about L.P. and his condition as you read through this assessment chapter.

(See p. 664 for more information on L.P.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Assessment of Cardiovascular System

Subjective Data

A careful health history and physical examination will help you distinguish symptoms that reflect a cardiovascular problem from problems of other body systems. Explore and record all cues that alert you to the possibility of underlying CVD.

Important Health Information

History of Present Illness

Ask the patient what problem has brought him or her to seek health care. Fully explore all symptoms the patient reports.

Past Health History

Many illnesses affect the cardiovascular system directly or indirectly. Ask the patient about a history of angina, diabetes, alcohol and

tobacco use, anemia, rheumatic fever, streptococcal throat infections, congenital heart disease, stroke, hypertension, thrombophlebitis, dysrhythmias, and varicosities. Fully explore any symptoms the patient may have. Ask about shortness of breath, fatigue, dizziness with position changes, syncope, edema, intermittent claudication, and palpitations.

Assess for allergies to drugs, food, or the environment. Determine whether the patient has ever had a drug reaction or an allergic or anaphylactic reaction. Ask specifically about any allergic reaction to contrast media.

Medications

Assess the patient's current and past use of medications. Include over-the-counter (OTC) and prescription drugs and herbal supplements. For example, aspirin prolongs the blood clotting time and is in some drugs used to treat cold symptoms. Record the dose and time last taken for each. Assess for noncardiac drugs that can adversely affect the cardiovascular system (Table 31.2).

TABLE 31.2 Potential Cardiovascular Effects of Select Noncardiac Drugs

Drug Classification	Examples	Cardiovascular Effects
Anticancer agents	daunorubicin doxorubicin	Dysrhythmias, cardiomyopathy
Antipsychotics	chlorpromazine haloperidol	Dysrhythmias, orthostatic hypotension
Corticosteroids	cortisone prednisone	Hypotension, edema, potassium depletion
Hormone therapy, oral contraceptives	estrogen + progestin (Prempro)	MI, thromboembolism, stroke, hypertension
Nonsteroidal antiinflammatory drugs (NSAIDs)	celecoxib (Celebrex) diclofenac ibuprofen	MI, stroke, hypertension, HF
Psychostimulants	amphetamines cocaine	Tachycardia, angina, MI, hypertension, dysrhythmias
Tricyclic antidepressants	amitriptyline doxepin (Silenor)	Dysrhythmias, orthostatic hypotension

Surgery or Other Treatments

Ask the patient about specific treatments, past surgeries, or hospital admissions related to cardiovascular problems. Explore any admissions or procedures performed for cardiovascular symptoms. Note whether a baseline ECG or a chest x-ray has been done.

Functional Health Patterns

The strong correlation between lifestyle and cardiovascular health supports the need to review each functional health pattern. Key questions to ask a person with a cardiovascular problem are listed in Table 31.3.

Health Perception–Health Management Pattern

Ask the patient about the presence of major cardiovascular risk factors. These include abnormal serum lipids, hypertension, sedentary lifestyle, diabetes, obesity, and tobacco use. Estimate the number of pack-years of tobacco use (number of packs smoked per day multiplied by the number of years the patient has smoked). Note the patient's attitude about tobacco use and attempts and methods used to stop. Record the type of alcohol used, amount, frequency, and any changes in the reaction to it. Note any use of habit-forming or recreational drugs.

Genetic Risk Alert

Coronary Artery Disease

- Specific genetic links, especially related to lipoprotein genes, have been found for some families with CAD.
- The clustering of CAD in families is strong if there is early age of onset affecting several relatives.

Cardiomyopathy

- Autosomal dominant mutations can cause hypertrophic cardiomyopathy.
- X-linked and autosomal dominant mutations can cause dilated cardiomyopathy.

Hypertension

- Hypertension results from a complex interplay between genetic and environmental factors.
- Lifestyle choices (e.g., smoking, lack of exercise) may trigger genetic tendencies to hypertension.

Genomic studies have found over 60 common genetic variants highly associated with CAD.[8] Confirmed illnesses of blood relatives can highlight any genetic or familial tendencies toward CAD, hypertension, varicosities, bleeding, diabetes, atherosclerosis, and stroke. Note any family members who had heart disease at an early age (<50 years of age for men; <55 years of age for women). Last, assess for family health history of noncardiac problems such as lung, kidney, or liver disease and obesity, because they can affect the cardiovascular system.

Nutritional-Metabolic Pattern

Being underweight or overweight may indicate potential cardiovascular problems. Assess the patient's weight history (e.g., over the past year) in relation to height. Determine the amount of salt and saturated fats in the patient's typical diet. In addition to food habits, which may be influenced by culture, explore the patient's attitudes and plans about diet and weight management.

Elimination Pattern

The patient taking diuretics may report increased voiding and/or nocturia. Ask about any history of incontinence or constipation, including use of drugs (prescribed and OTC) for constipation. Teach patients with heart problems to avoid straining *(Valsalva maneuver)* during a bowel movement. Ask patients if they have swelling of the lower extremities and if it resolves when their feet are elevated.

Activity-Exercise Pattern

The benefit of exercise for cardiovascular health is clear, with aerobic exercise being most beneficial. Record the types, duration, intensity, and frequency of exercise. Ask about symptoms during exercise (e.g., chest pain, shortness of breath, claudication) that may indicate a cardiovascular problem.

Sleep-Rest Pattern

Cardiovascular problems often disrupt sleep. *Paroxysmal nocturnal dyspnea* (attacks of shortness of breath, especially at night that awaken the patient) and *Cheyne-Stokes respiration* (periods of very shallow breaths to alternating periods of apnea and deep, rapid breathing) are associated with HF. Note the number of pillows needed to sleep or the need to sleep upright in a chair *(orthopnea)* and whether this has changed recently.

Sleep apnea is associated with an increased risk for life-threatening dysrhythmias, especially in patients with HF. Nocturia, a common finding with cardiovascular patients, interrupts normal sleep patterns.

Cognitive-Perceptual Pattern

Ask both the patient and caregiver about cognitive-perceptual problems. Cardiovascular problems such as dysrhythmias, hypertension, and stroke may cause difficulties with syncope, language, and memory. Report pain associated with the cardiovascular system (e.g., chest pain, claudication).

Self-Perception–Self-Concept Pattern

Acute cardiovascular events may affect the patient's self-perception. Invasive diagnostic procedures often lead to body image concerns. When CVD is chronic, the patient may describe an inability to "keep up" previous levels of activity, affecting quality of life.

Role-Relationship Pattern

Gender, race, and age are all related to cardiovascular health. The patient's marital status, role in the household, employment status, number of children and their ages, living environment, and caregivers help you to identify strengths and support systems in the patient's life. Assess the patient's satisfaction with life roles, since this may alert you to possible areas of stress or conflict.

TABLE 31.3 Health HistoryCardiovascular System

Health Perception–Health Management

- Do you practice any measures to decrease risk factors for heart disease?*
- Have you noticed an increase in heart symptoms such as chest pain or dyspnea?*
- Does your heart problem cause you to be less able to care for yourself?*
- Do you foresee any potential self-care problems because of your heart problem?*
- Have you ever used tobacco? If yes, in what form, how much, and for how long? Have you tried to quit? If yes, what methods have you tried? Are you interested in more information about quitting?
- How often and how much alcohol do you drink?

Nutritional-Metabolic

- Describe your usual daily diet, including salt, fat, and liquid intake.
- What is your present weight? What was your weight 1 year ago? If different, explain.
- Does eating cause fatigue or shortness of breath?*

Elimination

- Do your feet or ankles ever swell?* If yes, how far up your legs? Does it go away after sleeping all night?
- Have you ever taken drugs to help you get rid of excess fluid or to relieve constipation?*
- Are you having any problems related to urination?*
- Do you ever strain to have a bowel movement?

Activity-Exercise

- Are your daily activities or exercise limited because of your heart problem?*
- When were you last able to comfortably perform your usual activities or exercise?
- Do you have any discomfort or symptoms because of exercise or any activity?*
- Can you comfortably walk and talk at the same time?
- How often do you attend activities outside your home?
- What was your most strenuous activity in the last few weeks compared with 6 months ago?

Sleep-Rest

- How many pillows do you sleep on at night? Has this changed recently?*
- Do you ever wake up suddenly and feel as if you cannot catch your breath?*
- Do you have a history of sleep apnea?*
- Do you ever sleep in a chair at night? Is yes, how often?
- How many times a night do you awaken to urinate?

Cognitive-Perceptual

- Do you ever have dizziness or fainting?*
- Do you ever find it hard to express yourself or to remember things?*
- Do you have any pain (e.g., chest pain, leg pain with activity) because of your heart problem?*

Self-Perception–Self-Concept

- Have your perceptions of yourself changed since you were diagnosed with heart disease?*
- How has your heart disease affected the quality of your life?

Role-Relationship

- Has this illness affected any of the roles that you play in your daily life?*
- How has your heart disease affected your significant others?

Sexuality-Reproductive

- Has your heart disease caused a change in your sexual activity?*
- Do you have any heart-related symptoms during sexual activity?*
- Do any of your drugs affect your ability to take part in sexual activities?*
- *Females:* Are you currently taking oral contraceptives, hormonal therapy, or drug therapy for breast cancer?
- *Males:* Are you taking any drugs to treat erectile dysfunction?

Coping–Stress Tolerance

- Describe your normal coping mechanisms during times of stress or anxiety.
- To whom or where would you turn during a time of stress? Are these people or services helping you now?*
- Do you practice any stress reduction techniques?*
- Do you have a history of depression?*
- Do you feel capable of handling your present health situation?
- Do you have any heart symptoms (e.g., chest pain, palpitations) during times of stress or anger?*

Values-Beliefs

- What influence have your values or beliefs had during your illness?
- Do you feel any conflicts between your values or beliefs and the plan of care?*
- Describe any cultural or religious beliefs that may influence the management of your heart problem.

* If yes, describe.

Sexuality-Reproductive Pattern

Ask the patient about the effect of the cardiovascular problem on sexual activity. Because some patients fear sudden death during sexual intercourse, they may change their sexual behavior. Fatigue, chest pain, or shortness of breath may limit sexual activity. Erectile dysfunction (ED) may be a symptom of peripheral vascular disease and/or a side effect of some drugs used to treat CVD (e.g., β-blockers, diuretics). Ask male patients about the use of drugs for ED (phosphodiesterase inhibitors, e.g., sildenafil [Viagra]). These drugs are contraindicated if the patient is taking a nitrate because the combination can cause significant hypotension.[9]

Ask female patients if they use oral contraceptives, hormone therapy (HT) for symptoms of menopause, or drug therapy for breast cancer. Women who smoke tobacco and use oral contraceptives are at increased risk for blood clots (e.g., venous thromboembolism). Similarly, there is an increased risk for CVD with the use of HT and selective estrogen-receptor modulators (e.g., tamoxifen).[9]

Coping–Stress Tolerance Pattern

Ask the patient to identify sources of stress and the usual methods of coping with stress. Potentially stressful areas include health concerns, marital relationships, family and friends, occupation, and finances.

Work-related stress, depression, and inadequate social support are risk factors for CVD and heart events. Ask the patient about each of these factors. Information about support systems such as family, extended family and friends, counselors, or religious groups can give vital insight when planning care.

Values-Belief Pattern

Individual values and beliefs, which are greatly affected by culture, may play a key role in the real or potential conflict that a patient faces

when dealing with CVD. Some patients may attribute their illness to punishment from God; others may think that a "higher power" can help them. Information about a patient's values and beliefs will help you provide support during periods of crisis.

Case Study

Subjective Data

@ Jupiterimages/Banana-Stock/Thinkstock.

A focused subjective assessment of L.P. revealed the following information:

- ***Past Medical History:*** History of hypertension, mitral valve prolapse with mild regurgitation, HF, and type 2 diabetes.
- ***Oral Medications:*** Lisinopril (Prinivil) 10 mg/day, metoprolol

(Lopressor) 50 mg twice daily, ASA 81 mg/day , furosemide 40 mg/day, and glipizide (Glucotrol) 5 mg/day.

- ***Health Perception–Health Management:*** L.P. denies any history of chest pain or CAD. He reports feeling fine until this morning when he awoke and developed SOB, chest tightness, and palpitations while walking to the bathroom. He thought he was having a heart attack, so his wife called 911. Denies smoking or alcohol intake. SOB and chest tightness are now gone, but he continues to feel palpitations.
- ***Elimination:*** Denies edema or nocturia. States he takes Lasix in the morning and typically "passes urine until lunchtime."

Discussion Questions

1. Which subjective assessment findings are of most concern to you?
2. How will you individualize the assessment based on his age, ethnic/cultural background, and condition?
3. Is this an appropriate time to teach him about the proper use of nitroglycerin tablets? Why or why not?
4. What should you include in your physical assessment?

You will learn more about the physical examination of the cardiovascular system in the next section. (See p. 667 for more information on L.P.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Objective Data

Physical Examination

Vital Signs

Observe the patient's general appearance and obtain vital signs. Measure BP bilaterally. Readings can vary from 5 to 15 mm Hg

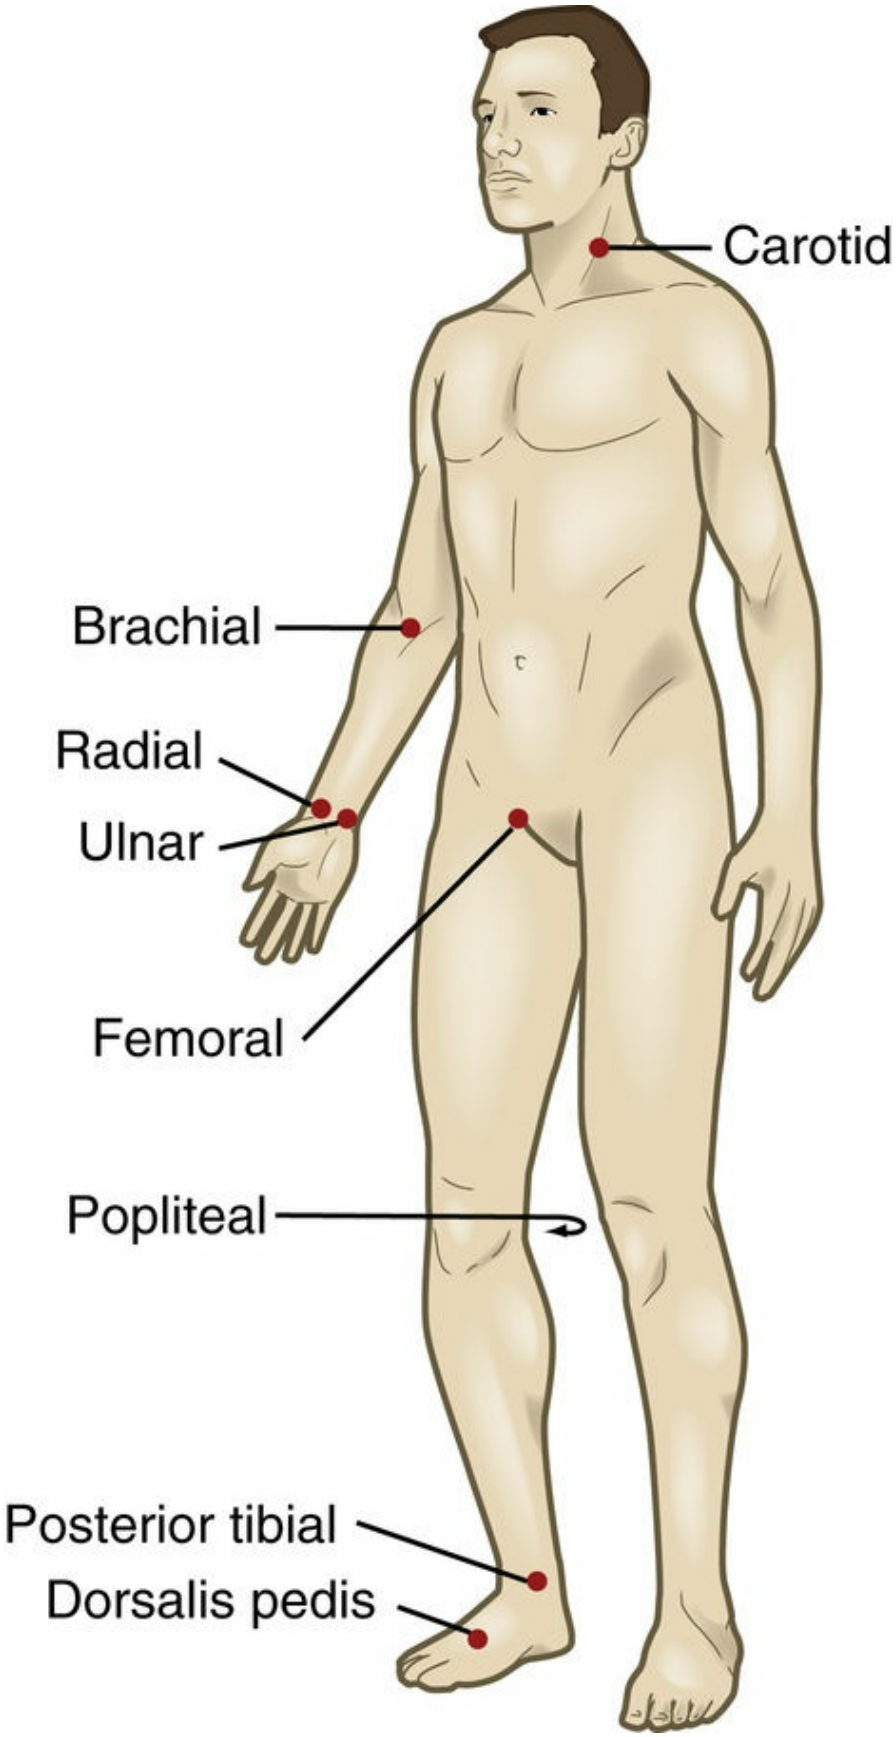
between arms. Use the arm with the highest BP for later measurements. Obtain an orthostatic (postural) BP and HR while the patient is supine, sitting with legs dangling, and standing. SBP should not decrease more than 20 mm Hg from the supine to the standing position. HR should not increase more than 20 beats/min from the supine to the standing position.

Peripheral Vascular System

Inspection

Inspect the skin for color, hair distribution, and venous pattern. Check the extremities for edema, dependent rubor, clubbing of the nail beds, varicosities, and lesions such as stasis ulcers. Edema in the legs can be caused by gravity, varicosities, or right-sided HF.

Inspect the large neck veins (internal and external jugular) while gradually moving the patient from a supine position to an upright (30 to 45 degrees) position. Distention and prominent pulsations of the neck veins, referred to as *jugular venous distention,* can be caused by right-sided HF.



Carotid
Brachial
Radial
Ulnar
Femoral
Popliteal
Posterior tibial
Dorsalis pedis

FIG. 31.6 Common sites for palpating arteries.

Palpation

Palpate the upper and lower extremities for temperature, moisture, pulses, and edema bilaterally to assess for symmetry. Look for edema by depressing the skin over the tibia or medial malleolus for 5 seconds. Normally, there is no depression after you release pressure. If pitting edema is present, grade it from 1+ (mild pitting, slight brief indentation) to 4+ (very deep pitting, indentation that lasts a long time).

Palpate the pulses in the neck and extremities for rhythm and force of arterial blood flow. Palpate each carotid pulse separately to avoid vagal stimulation and dysrhythmias. Compare the characteristics of the arteries in the right and left extremities simultaneously to determine symmetry.

When palpating the arteries identified in Fig. 31.6, rate the force of the pulse using the following scale:

0 = Absent
1+ = Weak
2+ = Normal
3+ = Increased, full, bounding

Note the rigidity (hardness) of the artery. The normal pulse feels like a tap, but a narrowed or bulging vessel wall vibrates. The term for a palpable vibration is *thrill*.

Capillary refill is used to assess arterial flow to the extremities. Position the patient's hands near the level of the heart and squeeze a nail bed briefly to produce blanching. Color should return to the nail bed in less than 2 seconds with normal tissue perfusion and CO.

Auscultation

An artery that is narrowed or has a bulging wall may create turbulent blood flow. This abnormal flow can cause a buzzing or humming

termed a *bruit,* heard with the bell of the stethoscope over the vessel. Auscultate major arteries such as the carotid arteries, abdominal aorta, and femoral arteries as part of the initial cardiovascular assessment. Abnormalities of the peripheral vascular system are described in Table 31.4.

TABLE 31.4 Assessment AbnormalitiesCardiovascular System

Finding*	Description	Possible Etiology* and Significance
Inspection		
Central cyanosis	Bluish or purplish tinge in central areas such as tongue, conjunctivae, inner surface of lips	Inadequate O_2 saturation of arterial blood because of pulmonary or cardiac disorders (e.g., congenital defects)
Clubbing of nail beds	Obliteration of normal angle between base of nail and skin	Endocarditis, congenital defects, prolonged O_2 deficiency
Color changes in extremities with postural change	Pallor, cyanosis, mottling of skin after limb elevation. Dependent rubor (reddish blue discoloration). Glossy skin	Chronic decreased arterial perfusion
Jugular venous distention	Distended neck (jugular) veins with patient sitting at 30- to 45-degree angle	High right atrial pressure, right-sided HF
Peripheral cyanosis	Bluish or purplish tinge in extremities or in nose and ears	Reduced blood flow from HF, vasoconstriction, cold environment
Splinter hemorrhages	Small red to black streaks under fingernails	Infective endocarditis (infection of endocardium, usually in area of cardiac valves)
Ulcers	*Venous:* Necrotic crater-like lesion usually found on lower leg at medial malleolus. Characterized by slow wound healing	Poor venous return, varicose veins, incompetent venous valves
	Arterial: Pale ischemic base, well-defined edges usually found on toes, heels, lateral malleoli	Arteriosclerosis, diabetes
Varicose veins	Visible dilated, discolored, tortuous vessels in lower extremities	Incompetent valves in vein
Palpation		
Pulse		
< 60 beats/min	Bradycardia	Rest or sleeping, SA or AV node damage, athletic conditioning, side effect of drugs (e.g., β-blockers), hypothyroidism
> 100 beats/min	Tachycardia	Exercise, anxiety, shock, need for increased cardiac output, hyperthyroidism
Absent	Lack of pulse	Atherosclerosis, trauma, embolus
Bounding	Sharp, brisk, pounding pulse	Hyperkinetic states (e.g., anxiety, fever), anemia, hyperthyroidism
Displaced point of maximal impulse (apical pulse)	Palpate (or auscultate) the point of maximal impulse below the fifth ICS and to the left of the MCL	Cardiac enlargement because of coronary artery disease, HF, cardiomyopathy
Irregular	Regularly irregular or irregularly irregular. Skipped beats	Dysrhythmias
Pulsus alternans	Regular rhythm, but strength of pulse varies with each beat	HF, cardiac tamponade
Rigidity	Stiffness or inflexibility of vessel wall	Atherosclerosis
Thready	Weak, slowly rising pulse easily obliterated by pressure	Blood loss, decreased cardiac output, aortic valve disease, peripheral arterial disease
Thrill	Vibration of vessel or chest wall	Aneurysm, aortic regurgitation, arteriovenous fistula
Extremities		
Abnormal capillary refill	Blanching of nail bed for ≥ 2 sec after release of pressure	Possible reduced arterial capillary perfusion, anemia
Asymmetry in limb circumference	Measurable swelling of involved limb	Venous thromboembolism, varicose veins, lymphedema
Cold extremities	Hands and/or feet cold to touch. External covering needed for comfort	Intermittent claudication, peripheral arterial disease, low cardiac output, severe anemia
Pitting edema of lower extremities or sacral area	Visible finger indentation after application of firm pressure, weight gain, tightening of clothing (including shoes), marks or indentations from constricting garments	Interruption of venous return to heart, right-sided HF
Unusually warm extremities	Hands and feet warmer than normal	Thyrotoxicosis
Auscultation		
3rd heart sound (S_3)	Extra heart sound, low pitched, heard in early diastole. Similar to sound of a gallop	Left ventricular failure. Volume overload. Mitral, aortic, or tricuspid regurgitation. Hypertension (possible)
4th heart sound (S_4)	Extra heart sound, low pitched, heard in late diastole. Similar to sound of a gallop	Forceful atrial contraction from resistance to ventricular filling (e.g., in left ventricular hypertrophy, aortic stenosis, hypertension, coronary artery disease)
Arterial bruit	Turbulent flow sound in peripheral artery	Arterial obstruction or aneurysm
Heart murmurs	Turbulent sounds occurring between normal heart sounds. Characterized by loudness, pitch, shape, quality, duration, timing	Heart valve disorder, abnormal blood flow patterns
Pericardial friction rub	High-pitched, scratchy sound heard during S_1 and/or S_2 at the apex. Heard best with patient sitting and leaning forward, and while holding breath at the end of expiration	Pericarditis

Finding*	Description	Possible Etiology* and Significance
Pulse deficit	Apical heart rate exceeding peripheral pulse rate	Dysrhythmias, most often atrial fibrillation/flutter or premature ventricular contractions

* Limited to common abnormal assessment findings and etiologic factors. (Further discussion of conditions listed may be found in Chapters 32 to 37, 65, and 66.)

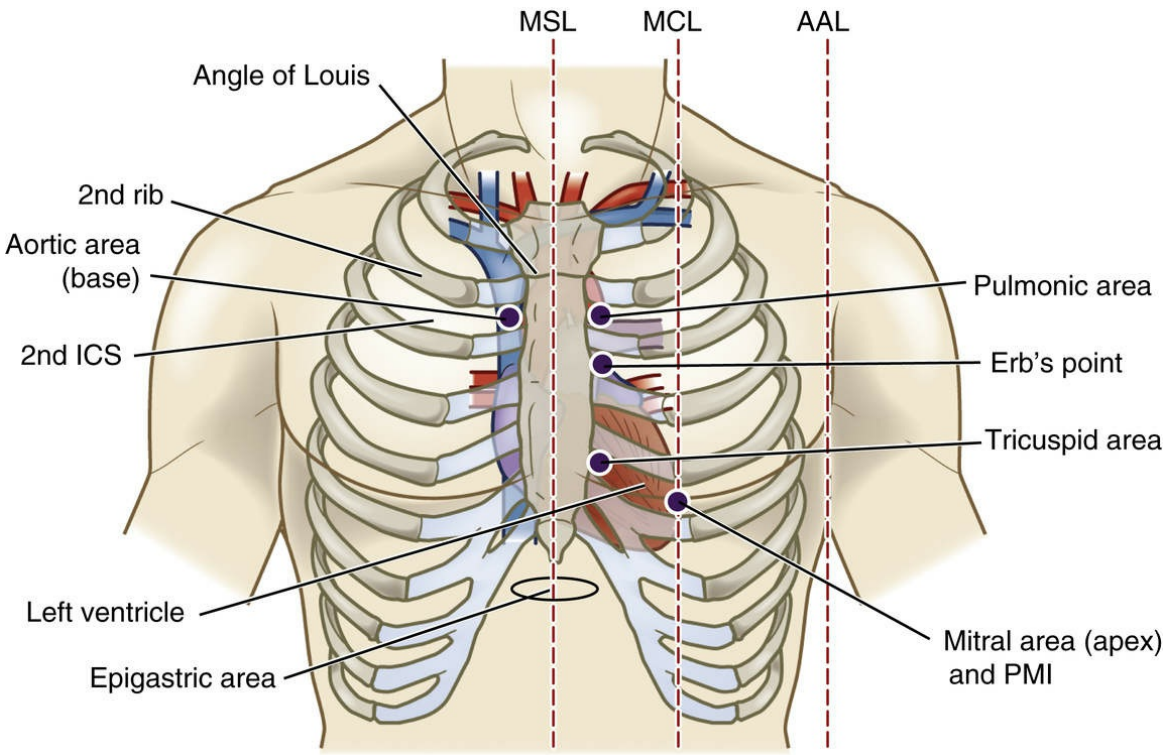


FIG. 31.7 Orientation of the heart within the thorax and cardiac auscultatory areas. *Red lines* indicate the midsternal line *(MSL),* midclavicular line *(MCL),* and anterior axillary line *(AAL). ICS,* Intercostal space; *PMI,* point of maximal impulse.

Thorax

Inspection and palpation

Begin examining the thorax with a general inspection and palpation. Next, inspect and palpate the areas where the heart valves project their sounds by finding the intercostal spaces (ICSs). The raised notch,

the *angle of Louis,* is where the manubrium and body of the sternum join at the level of the second rib. It is palpable in the midline of the sternum. Palpate for the 2nd ICS then count each ICSs to find specific auscultatory areas (Fig. 31.7).

Locate the following auscultatory areas: aortic area in the second ICS to the right of the sternum, pulmonic area in the second ICS to the left of the sternum, tricuspid area in the fifth left ICS close to the sternum, and mitral area in the left midclavicular line at the fifth ICS. A fifth auscultatory area is *Erb's point,* located at the third left ICS near the sternum. Normally, we cannot feel pulsations in these areas unless the patient has a thin chest wall.

A heart valve disorder may be present if you feel abnormal pulsations or thrills. Next, inspect and palpate the epigastric area on either side of the midline just below the xiphoid process. In a thin person, you may see pulsations from the abdominal aorta. Normally, you can palpate it here. Next, inspect the precordium, which is over the heart, for heaves. **Heaves** are sustained lifts of the chest wall in the precordial area that you can see or palpate. They may be caused by left ventricular hypertrophy. Normally no pulsations are seen or felt here.

When the patient is supine, palpate the mitral valve area for the **point of maximal impulse (PMI)** (also called the *apical pulse*). This reflects the pulsation of the apex of the heart. The PMI lies medial to the midclavicular line in the 4th or 5th ICS. If you can palpate the PMI, record its position in relation to the midclavicular line and ICSs. If the PMI is below the fifth ICS and left of the midclavicular line, the heart may be enlarged.

Auscultation

Normal heart sounds are made by the movement of blood through the heart valves. These sounds can be heard through a stethoscope placed on the chest wall. The first heart sound (S_1) is associated with closure of the tricuspid and mitral valves. It has a soft lubb sound. The second heart sound (S_2) is associated with closure of the aortic and pulmonic valves. It has a sharp dupp sound. S_1 signals the beginning of systole.

S_2 signals the beginning of diastole (Fig. 31.8). Listen to the auscultatory areas in sequence (Fig. 31.7).

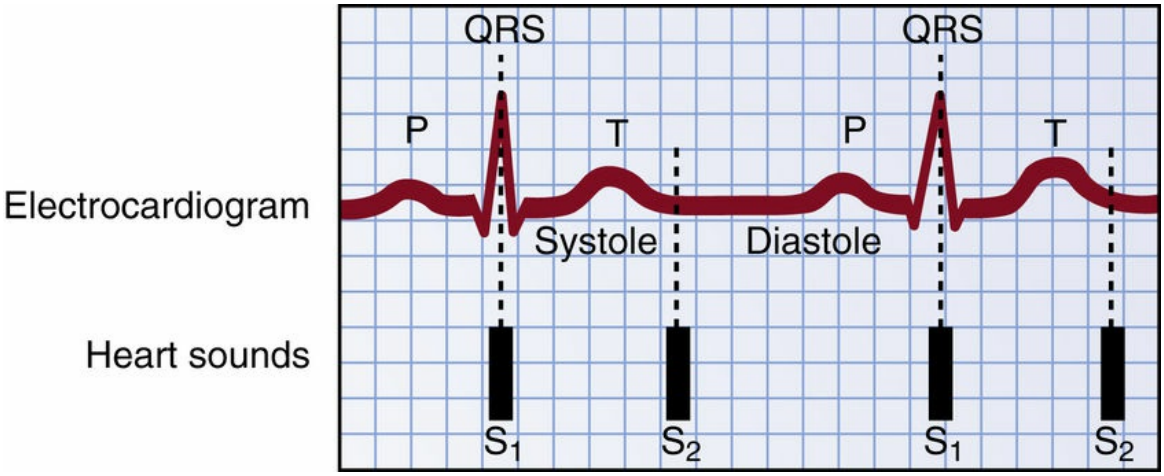

FIG. 31.8 Relationship of electrocardiogram, cardiac cycle, and heart sounds.

S_1 and S_2 are heard best with the diaphragm of the stethoscope because they are high pitched. Extra heart sounds (S_3 or S_4), if present, are heard best with the bell of the stethoscope because they are low pitched. Have the patient lean forward while sitting to enhance the sounds from the second ICSs (aortic and pulmonic areas). Place the patient in a left side-lying position to enhance the sounds at the mitral area.

When auscultating the apical area, simultaneously palpate the radial pulse. Determine whether the rhythm is regular or irregular while listening and feeling. If the apical and radial pulses are not equivalent, count the apical pulse while a second person simultaneously counts the radial pulse for 1 full minute. A difference between the 2 numbers, called a *pulse deficit,* can indicate dysrhythmias.

Normally no sound is heard between S_1 and S_2. An exception to this is a normal splitting of S_2, which is best heard at the pulmonic area during inspiration. Splitting of S_2 can be abnormal if it is heard during expiration or if it is constant (fixed) during the respiratory cycle.

Describe any sounds heard in addition to S_1 and S_2.

The S_3 heart sound is a low-intensity vibration of the ventricular walls usually associated with decreased compliance of the ventricles during filling. An S_3 heart sound may be normal (physiologic) in young adults. It is pathologic in patients with left-sided HF or mitral valve regurgitation. S_3 is heard closely after S_2 and is known as a *ventricular gallop.*

The S_4 heart sound is a low-frequency vibration caused by atrial contraction. It precedes S_1 of the next cycle and is known as an *atrial gallop.* An S_4 heart sound may be normal in older adults with no evidence of heart disease. It is pathologic in patients with CAD, cardiomyopathy, left ventricular hypertrophy, or aortic stenosis.

Murmurs, if heard, are graded on a 6-point Roman numeral scale based on loudness and recorded as a ratio. I/VI means a murmur that is barely audible with the stethoscope, heard only in a quiet room and then not easily. VI/VI means a murmur that we can hear with the stethoscope lifted just off the chest wall.

Pericardial friction rubs are sounds that occur when inflamed surfaces of the pericardium (pericarditis) move against each other. They are high-pitched, scratchy sounds that may be intermittent and may last several hours to days. Friction rubs are heard best at the apex with patients upright, leaning forward, and holding their breath after expiration.[5]

Record the characteristics of any abnormal sounds. This includes the timing (during systole or diastole), location (the anatomic site on the chest where it is heard the loudest), position (heard best when the patient is supine, sitting and leaning forward, or in the left side-lying position), and any other findings (irregular apical pulse or palpable chest wall heaves) associated with the sound.

Abnormal assessment findings are described in Table 31.4.
A method of recording data from the cardiovascular assessment is shown in Table 31.5.

A *focused assessment* is used to evaluate the status of previously identified cardiovascular problems and to monitor for signs of new

problems. A focused assessment of the cardiovascular system is outlined in the box on this page.

Case Study

Objective Data: Physical Examination

© Jupiterimages/Banana-Stock/Thinkstock.

Physical examination findings of L.P. are as follows:

- BP 100/54, apical-radial pulse 154, pulse irregular, respiratory rate 20, temperature 98.2° F (36.8° C), O_2 saturation 94% on room air
- Awake, alert, and oriented ×3
- Lungs clear on auscultation; systolic murmur present

- Heart monitor shows atrial fibrillation with a rapid ventricular response
- +1 pedal pulses bilaterally
- No peripheral edema, jugular venous distention, or heaves noted

Discussion Questions

1. Which physical assessment findings are of most concern to you?
2. Based on the results of the subjective and physical assessment findings, what diagnostic studies do you think will be ordered for L.P.?

You will learn more about diagnostic studies related to the cardiovascular system in the next section.

(See p. 676 for more information on L.P.)

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

TABLE 31.5 Normal Physical Assessment of Cardiovascular System

Inspection	No pallor or cyanosis. PMI not visible. No JVD with patient at 45-degree angle
Palpation	Skin warm. Capillary refill <2 sec. PMI palpable in 4th ICS at left MCL. No thrills or heaves. Slight palpable pulsations of abdominal aorta in epigastric area. Carotid and extremity pulses 2+ and equal bilaterally. No pedal or sacral edema
Auscultation	S_1 and S_2 heard. Apical-radial pulse rate equal, 72, and regular. No murmurs or extra heart sounds

ICS, Intercostal space; *JVD,* jugular venous distention; *MCL,* midclavicular line; *PMI,* point of maximal impulse.

Focused Assessment

Cardiovascular System

Use this checklist to remind you of the key assessment steps.

Subjective

Ask the patient about the following and note responses.

Chest pain, discomfort	Y	N
Palpitations	Y	N
Shortness of breath (especially when lying down or at rest)	Y	N
Edema in legs or any part of body	Y	N
Leg pain during exercise	Y	N
Excess urination at night	Y	N

Objective: Diagnostic

Check the following for critical values or changes.

Cardiac biomarkers	✓
Hematocrit, hemoglobin, platelets	✓
Glucose, electrolytes, BUN, creatinine	✓
Electrocardiogram	✓
Chest x-ray	✓

Objective: Physical Examination

Inspect and Palpate

Anterior chest wall for pulsations and heaves	✓
Pulses for symmetry, quality, and rhythm	✓

Auscultate

Bilateral blood pressures	✓
Heart for rate, rhythm, and sounds	✓

Diagnostic Studies of Cardiovascular System

Numerous diagnostic tests are available to assess the cardiovascular system. Tables 31.6, 31.7, and 31.8 describe common serology studies, diagnostic studies, and interventional study procedures. Select studies are discussed in more detail next.

Blood Studies

Many blood studies provide information about the cardiovascular system. For example, some reflect the O_2-carrying capacity (red blood cell count and hemoglobin) and coagulation properties (clotting times) of the blood. See Chapter 29 and Tables 29.7, 29.8, and 29.10 about hematology studies.

Cardiac Biomarkers

When cells are injured, they release their contents, including enzymes and other proteins, into the circulation. These *biomarkers* are useful in the diagnosis of acute coronary syndrome (ACS) (Table 31.6). Interpreting biomarker level results requires you to consider the time elapsed from the onset of symptoms. Other data (patient symptoms, history, and ECG changes) complete the diagnostic picture for the patient with suspected ACS.

TABLE 31.6 Serology StudiesCardiovascular System

Study	Reference Interval*	Description and Purpose
Biomarkers		
b-Type natriuretic peptide (BNP)	<100 pg/mL (100 pmol/L)	Peptide that causes natriuresis. High in HF. Levels increased after nesiritide (Natrecor) infusion and for 1 month after cardiac surgery.
CK-MB	Concentrations <4%–6% of total creatine kinase (CK)	Tests for myocardial cell injury. High levels highly indicative of MI. Serum levels increase within 3–6 hr after MI, peak after 12–24 hours, normalize within 48 hours. Explain purpose of serial sampling.
Copeptin	<10 pmol/L	Reflects arginine vasopressin (AVP) concentration. High levels highly indicative of MI. Higher in men, after exercise, and with stress. Influenced by fasting and water load.
C-reactive protein (CRP)	High-sensitivity (hs) CRP assay. *Lowest risk:* <1 mg/dL *Moderate risk:* 1–3 mg/dL *High risk:* >3 mg/dL	Marker of inflammation. May help predict risk for cardiac disease and cardiac events such as an acute MI. High in bacterial infections and inflammatory disorders.
Homocysteine	4–14 µmol/L Levels may increase with age	Amino acid made during protein catabolism. Risk factor for cardiovascular disease. Associated with vitamin B_{12} and folate deficiencies.
NT-Pro-BNP	*≤74 yr:* 124 pg/mL *>75 yr:* 449 pg/mL	Helps to assess severity of HF. Levels are higher in women and patients with renal insufficiency.
Troponin (cardiac)	*Troponin T (cTnT)* <0.1 ng/mL (<0.1 mcg/L) *Troponin I (cTnI)* *Negative:* <0.03 ng/mL (<0.03 mcg/L)	Contractile proteins released after an MI. Both troponin T and troponin I test for cardiac injury/ischemia. Serial sampling needed: draw 3 sets of troponins 3–6 hours apart.
Lipids		
Cholesterol	<200 mg/dL (<5.2 mmol/L) (varies with age and gender)	A blood lipid associated with arteriosclerosis. High level is a risk factor for cardiovascular heart disease. Can obtain in a nonfasting or fasting state.
Lipoprotein (a) (Lp[a])	<30 mg/dL (<0.3 g/L)	High levels indicate an increased risk for atherosclerosis, MI, and stroke. Can obtain in a nonfasting or fasting state.
Lipoprotein-associated phospholipase A_2 (Lp-PLA_2)	*Low risk:* ≤151 ng/mL *Moderate risk:* 152–194 ng/mL *High risk:* ≥195 ng/mL	Indicates inflammation and increased risk for CAD. Serum levels are measured by the PLAC test. Can obtain in a nonfasting or fasting state.
Lipoproteins (HDL, LDL)	HDL Recommended *Male:* >45 mg/dL *Female:* >55 mg/dL *Low risk for CAD:* ≥60 mg/dL *High risk for CAD:* <40 mg/dL LDL <130 mg/dL *Moderate risk for CAD:* 130–159 mg/dL *High risk for CAD:* >160 mg/dL	There are marked day-to-day fluctuations, so more than 1 level is needed for accurate diagnosis. Can be obtained in a nonfasting or fasting state. Assess risk for heart disease by dividing the total cholesterol level by the HDL level and obtaining a ratio. *Low risk:* Ratio <3 *Average risk:* Ratio 3–5 *Increased risk:* Ratio >5
Triglycerides	*Male:* 40–160 mg/dL *Female:* 35–135 mg/dL	Mixtures of fatty acids. Elevations are associated with cardiovascular disease and diabetes. Avoid alcohol for 24 hr before testing. Can obtain in a nonfasting or fasting state.

* Reference ranges for the laboratory tests vary by agency because of differences in equipment and reagents used.

Cardiac-specific troponin is a heart muscle protein released into circulation after injury or infarction. Two subtypes, cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI), are specific to

heart muscle. Normally the level in the blood is very low, so a rise in level is diagnostic of myocardial infarction (MI) or injury. cTnT and cTnI are detectable within hours (on average 4 to 6 hours) of MI or injury, peak at 10 to 24 hours, and can be detected for up to 10 to 14 days. Troponin is the biomarker of choice in the diagnosis of ACS. High-sensitivity troponin (hs-cTnT, hs-cTnI) assays may provide even earlier detection of a heart event.[10] Fig. 33.15 shows the changes in cardiac markers related to an MI.

Copeptin, a substitute marker for arginine vasopressin (AVP), can be detected immediately in patients with an acute MI. Considering both troponin and copeptin levels together may provide increased sensitivity for rapidly diagnosing acute MI.[10] High circulating copeptin levels are associated with increased mortality in patients with HF.[11]

Creatine kinase (CK) enzymes are found in a variety of organs and tissues and occur as 3 isoenzymes. These isoenzymes are specific to skeletal muscle (CK-MM), brain and nervous tissue (CK-BB), and the heart (CK-MB). CK-MB rise is specific for MI or injury. Levels begin to increase 3 to 6 hours after symptom onset, peak in 12 to 24 hours, and return to baseline within 12 to 48 hours after MI.[12] In some acute care settings, CK is no longer used for diagnosis of acute MI.[13]

TABLE 31.7 Diagnostic StudiesCardiovascular System

Study	Description and Purpose	Nursing Responsibility
Electrocardiography (ECG)		
12-lead ECG	Electrodes are placed on the chest and extremities, allowing the ECG machine to record cardiac electrical activity from 12 different views. A resting 12-lead ECG can identify conduction problems, dysrhythmias, position of heart, cardiac hypertrophy, pericarditis, myocardial ischemia or infarction, pacemaker activity, and effectiveness of drug therapy at one point in time.	*Before:* Prepare skin and apply electrodes and leads. Place patient supine (or with head of bed elevated, if short of breath). Tell patient that no discomfort is involved and to lie still to decrease motion artifact. *During:* Ensure the patient lies still to decrease motion artifact.
ECG event monitor or loop recorder	Records rhythm changes that are not frequent enough to be recorded in 1 24-hr period. Can aid in diagnosing the cause of chest pain, palpitations, shortness of breath, and syncope. It allows more freedom than a regular Holter monitor. Some units have electrodes that attach to the chest and have a loop of memory that captures the onset and end of an event. Other types are placed directly on patient's wrist, chest, or fingers and have no loop of memory but record the patient's ECG in real time. Recordings may be transmitted over the phone to a receiving unit.	*Before:* Teach how to use equipment for recording and transmitting events. Teach patient about skin preparation for lead placement or steady skin contact to ensure quality tracings. Tell patient to start recording when symptoms begin or as soon after as possible.
ECG Holter monitoring	Recording of ECG rhythm for 24–48 hr to correlate with symptoms and activities recorded in diary. Encourage normal patient activity to simulate conditions that produce symptoms. Electrodes are placed on chest. A recorder stores information until it is recalled, printed, and analyzed for any rhythm changes.	*Before:* Prepare skin and apply electrodes and leads. Explain importance of keeping an accurate diary of activities and symptoms. Tell patient there is no bathing and showering during monitoring. Skin irritation may develop from electrodes. If device has an event marker, teach patient to push that button when experiencing symptoms.
Signal-averaged ECG (SAECG)	A high-resolution ECG that can identify electrical activity called late potentials, indicating a patient is at risk for developing ventricular dysrhythmias (e.g., ventricular tachycardia).	Same as for 12-lead ECG.
Functional		
6-minute walk test	Distance patient can walk on a flat surface in 6 min. Used to measure response to treatments and determine functional capacity for activities of daily living. Can help assess response to therapy for chronic cardiopulmonary conditions. Useful in those who are debilitated or unable to perform treadmill or exercise bike testing. May be a better measure of fitness for older adults than exercise testing.	*Before:* Tell patient to wear comfortable shoes. Inform patient to carry or pull O_2 if used routinely. *During:* Encourage patient to walk as quickly as possible.
Exercise or stress testing	Provides information on cardiac function and exercise tolerance. A common protocol uses 3-min stages at set speeds and elevation of treadmill belt. The patient can exercise to either predicted peak HR (calculated by subtracting the person's age from 220) or peak exercise tolerance, at which time the test is ended. The test is ended for chest discomfort, significant changes in vital signs from baseline, or significant ECG changes (e.g., ischemia, dysrhythmias). Vital signs and ECG are monitored. The ECG is monitored after exercise for ischemia and rhythm changes or, if ECG changes occurred with exercise, for return to baseline. Important in the diagnosis of CAD. An exercise bike may be used if the patient is unable to walk on the treadmill.	*Before:* Tell patient to wear comfortable clothes and shoes that can be worn for walking or running. Tell patient to report any symptoms. β-Blockers may be held 24 hr before the test because they blunt the HR and limit the patient's ability to achieve maximal HR. Caffeine is held for 24 hr. Patients must refrain from smoking and strenuous exercise for 3 hr before test. Obtain baseline vital signs and 12-lead-ECG. *During:* Monitor vital signs and ECG during each stage of exercise and after until all vital signs and ECG changes have returned to normal or baseline. Monitor patient's response throughout procedure for any signs of distress (e.g., angina, shortness of breath).
Noninvasive hemodynamic monitoring	Obtained using a continuous finger cuff or by thoracic bioreactance method. Possible to obtain repeated measurements of stroke volume, cardiac output, and systemic BP.	Minimal to no risk. Patients who need hemodynamic monitoring are likely to be in perioperative settings, critical care units, and emergency departments. See Chapter 65 for complete information on hemodynamic monitoring.
Imaging		
Chest x-ray	Patient is placed in 2 upright positions to examine lung fields and heart size. The 2 common positions are lateral and posteroanterior (PA) (Fig. 31.9). Helps with the diagnosis of HF and pulmonary edema and visualization of heart size and contour.	*Before:* Ask about frequency of recent x-rays and chance of pregnancy. Provide lead shielding to areas not being viewed. Remove jewelry or metal objects that may obstruct the view of heart and lungs.

Table Continued

Study	Description and Purpose	Nursing Responsibility
Cardiac computed tomography (CT); electron beam CT (EBCT)	Cardiac CT is heart-specific imaging technology with or without IV contrast medium used to evaluate heart anatomy, coronary circulation, and blood vessels. EBCT, or ultrafast CT, uses a scanning electron beam to quantify calcification in coronary arteries and heart valves (Fig. 31.11). IV contrast may be used if calcium scoring is below threshold level. Primarily used for risk assessment in asymptomatic patients and to assess for heart disease in patients with atypical symptoms potentially related to cardiac causes.	*Before:* Assess for contrast allergy. Explain that patient may feel a warm sensation, salty taste after IV contrast injection, nausea. *During:* Patient must lie still during test.
Cardiovascular magnetic resonance imaging (CMRI)	Noninvasive imaging technique obtains information about heart tissue, EF, aneurysms, cardiac output, and patency of proximal coronary arteries. Measures regurgitant fraction that may determine valve repair or replacement. It does not involve ionizing radiation and is an extremely safe procedure. Provides images in multiple planes with uniformly good resolution.	*Before:* Check for pregnancy, allergies, and renal function before test. Have patient remove all metal objects. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication Contraindicated for persons with implanted metallic devices or other metal fragments unless noted to be MRI safe. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. *During:* Patient must lie completely still during test.
Coronary CT angiography (CTA)	Use of CT with injected IV contrast medium to obtain images of coronary vessels and diagnose CAD. Used to evaluate chest pain and monitor the progression of coronary vascular disease.	*Before:* Assess for contrast allergy. Obtain IV access. Remove metal objects before test. The patient may need to fast for several hours prior. A β-blocker may be given before the test to control HR. *During:* Patients must have a regular heart rhythm for accurate testing.
Echocardiogram **• Contrast** **• M-mode** **• 2-dimensional** **• Color-flow imaging (duplex)** **• Real-time 3-dimensional** **• Pharmacologic echocardiogram**	Ultrasound transducer is placed in 4 positions on the chest to record sound waves bounced off the heart. Records direction and flow of blood through the heart and transforms it to audio and graphic data. Measures valve abnormalities, congenital heart defects, wall motion, EF, and heart function. IV contrast agent may be used to enhance images (Fig. 31.10). Pharmacologic Echocardiogram is a substitute for the exercise stress test in persons unable to exercise. IV adenosine, dobutamine, or dipyridamole is given over several minutes or regadenoson (Lexiscan) is given as a single bolus over 10 sec while echocardiogram is performed to detect wall motion abnormalities.	*Before:* Place patient in a left side-lying position. Tell patient about procedure and sensations (pressure and mechanical movement from head of transducer). May be difficult to obtain in patients with COPD due to large amount of air between heart and chest cavity. *Pharmacologic echocardiogram:* *Before:* Obtain baseline vital signs and IV access for injection of drugs. *During:* Monitor vital signs until baseline achieved. Monitor patient for signs and symptoms of distress or side effects (e.g., shortness of breath, dizziness, nausea). Aminophylline may be given to prevent or reverse side effects of dipyridamole.
Exercise (stress) nuclear imaging	Purpose of test is to identify cardiac symptoms and rhythm changes and simulate in a safe environment. Nuclear imaging images are taken at rest. Injection is given at maximum HR (usually 85% of age-predicted maximum) on bicycle or treadmill. Patient then continues exercise for 1 min to circulate the radioactive isotope. Scanning is done 15–60 min after exercise. A resting scan is done 60–90 min after initial infusion or 24 hr later.	*Before:* Tell patient to eat only a light meal between scans. Certain drugs may need to be held for 1–2 days before the scan. Patients should not have caffeine 12 hr prior. Obtain IV access. *During:* If targeted maximum HR is not achieved with exercise, test may be changed to pharmacologic imaging.
Magnetic resonance angiography (MRA)	Used for imaging vascular occlusive disease and abdominal aortic aneurysms. Same as MRI but with use of gadolinium as IV contrast medium.	*Before:* Contraindications include allergies to contrast medium and implanted metallic devices or other metal fragments unless noted to be MRA safe. Discuss any implants before scan. Obtain IV access.
Multigated acquisition (MUGA) (cardiac blood pool) scan	Small amount of the patient's blood is removed, mixed with a radioactive isotope (e.g., Technetium-99m (^{99m}Tc sestamibi), and reinjected IV. With the ECG used for timing, images are obtained during the cardiac cycle. Indicated for patients with MI, HF, or valve disease. Can evaluate the effect of various cardiac or cardiotoxic drugs on the heart and the cardiac EF.	*Before:* Explain procedure to patient. Obtain IV access for removal of blood sample and reinjection of isotope. Start ECG monitoring.
Nuclear imaging	Study involves IV injection of radioactive isotopes (^{99m}Tc sestamibi [Cardiolite]). Radioactive uptake is counted over the heart by scintillation camera. It supplies information about heart contractility, myocardial perfusion, and acute injury.	*Before:* Women must remove bras to decrease breast artifact. Obtain IV access for injection of isotopes. Explain that radioactive isotope used is a small, diagnostic amount and will lose most of its radioactivity in a few hours. Tell patient that they will be lying still on back with arms extended overhead for 20 min. *During:* Repeat scans are done within a few minutes to hours after the injection.

Table Continued

Study	Description and Purpose	Nursing Responsibility
Pharmacologic nuclear imaging	Regadenoson, dipyridamole, or adenosine are given to produce vasodilation for patients unable to tolerate exercise. Vasodilation increases blood flow to well-perfused coronary arteries. Scanning procedure is same. Aminophylline may be given to prevent or reverse side effects of dipyridamole (e.g., shortness of breath, dizziness, nausea). Dobutamine is used if vasodilators are contraindicated.	*Before:* Tell patient to avoid caffeine products and theophylline (for regadenoson or dipyridamole testing) for 12 hr before procedure. Hold calcium channel blockers and β-blockers for 24 hr before the test. *During:* Observe patient for any side effects (e.g., shortness of breath, dizziness, nausea).
Positron emission tomography (PET)	Highly sensitive in distinguishing viable and nonviable heart tissue. Uses 2 radionuclides. Nitrogen-13-ammonia is injected IV first and scanned to evaluate myocardial perfusion. A second radioactive isotope, fluoro-18-deoxyglucose, is then injected and scanned to show myocardial metabolic function. In the normal heart, both scans match, but in an ischemic or damaged heart, they differ. The patient may or may not be stressed. A baseline resting scan is usually done for comparison.	*Before:* Obtain IV access to inject the tracer substance. Patients should be NPO, except for water and medications, for at least 4 hr prior. If exercise is part of testing, patient needs to fast and refrain from tobacco and caffeine for 24 hr before test. Hold glucose-containing IV solutions and change to normal saline. Check blood glucose levels. The glucose level must be between 60–140 mg/dL (3.3–7.8 μmol/L) for accurate glucose metabolic activity. *During:* Patient must lie completely still during scan. *After:* Encourage fluids to excrete radioactive substance.
Single-photon emission computed tomography (SPECT)	Used to determine size or risk for infarction and to determine infarction size. Small amounts of a radioactive isotope (e.g., ^{99m}Tc tetrofosmin [Myoview], thallium-201) are injected IV and recordings are made of the radioactivity emitted over a specific area of the body. Circulation of the isotope can detect coronary artery blood flow, intracardiac shunts, motion of ventricles, EF, and size of the heart chambers.	*Before:* Short fasting period may be needed. Obtain IV access for injection of isotope. Remove all jewelry from chest wall. Start ECG monitoring. *During:* Patient must lie completely still during scan. *After:* Encourage fluids to excrete radioactive substance.
Stress echocardiogram	Combination of exercise test and echocardiogram. Differences in left ventricular wall motion and thickening before and after exercise are evaluated with ultrasound. Postexercise images are taken within 1 min of stopping exercise.	*Before:* Prepare patient for treadmill or exercise bicycle. Tell patient of importance of timely return to examination table for imaging after exercise.
Transesophageal echocardiogram (TEE)	A probe with an ultrasound transducer at the tip is swallowed while the HCP controls angle and depth. As it passes down the esophagus, it sends back clear images of heart size, wall motion, valve abnormalities, endocarditis vegetation, and possible source of thrombi without interference from lungs or chest ribs. A contrast medium may be injected IV for evaluating direction of blood flow if an atrial or ventricular septal defect is suspected. Doppler ultrasound and color-flow imaging can be used concurrently.	*Before:* Tell patient to fast for at least 6 hr before test. Remove dentures. *During:* IV sedation is given and throat locally anesthetized. A bite block is placed in the mouth. Monitor vital signs, specifically O_2 saturation and BP. Perform suctioning as needed during procedure. *After:* Patient may not eat or drink until gag reflex returns. Monitor patient until sedation resolves. Sore throat is temporary. A designated driver is needed if test is done in the outpatient department.

C-Reactive Protein

C-reactive protein (CRP) is made by the liver during periods of acute inflammation. An increased level of CRP is linked with the presence of atherosclerosis and the first occurrence of a heart event. The CRP level may predict the risk for future heart events in patients with MI.[14]

Homocysteine

Homocysteine (Hcy) is an amino acid made during protein catabolism. High Hcy levels can be either hereditary or from dietary deficiencies of vitamin B_6, vitamin B_{12}, or folate. They are linked to a higher risk for CVD, peripheral vascular disease, and stroke. Hcy testing is recommended for patients with a familial predisposition for early CVD or a history of CVD in the absence of common risk

factors.[14]

Cardiac Natriuretic Peptide Markers

There are 3 natriuretic peptides: (1) atrial natriuretic peptide (ANP) from the atrium, (2) b-type natriuretic peptide (BNP) from the ventricles, and (3) c-type natriuretic peptide from endothelial and renal epithelial cells. BNP is the marker of choice for distinguishing between a cardiac or respiratory cause of dyspnea. N-terminal pro-brain natriuretic peptide (NT-pro-BNP) is secreted in the ventricles and is more sensitive but less specific than BNP as a diagnostic marker of HF.[12] When DBP increases (e.g., HF), BNP and NT-pro-BNP are released and increase natriuresis (excretion of sodium in the urine). ANP and BNP are also discussed in Chapter 32 on p. 680 and in Chapter 34 on p. 638.

Serum Lipids

Serum lipids consist of triglycerides, cholesterol, and phospholipids (Table 31.6). These *lipoproteins* circulate in the blood bound to protein. A lipid panel usually measures cholesterol, triglyceride, low-density lipoprotein (LDL), and high-density lipoprotein (HDL).

Triglycerides, the main storage form of lipids, make up about 95% of fatty tissue. Cholesterol, a structural part of cell membranes and plasma lipoproteins, is a precursor of corticosteroids, sex hormones, and bile salts. In addition to being absorbed from food in the gastrointestinal tract, cholesterol can be synthesized in the liver. Phospholipids contain glycerol, fatty acids, phosphates, and a nitrogenous compound. Although formed in most cells, phospholipids usually enter the circulation as lipoproteins synthesized by the liver. Apoproteins are water-soluble proteins that combine with most lipids to form lipoproteins.

TABLE 31.8 Interventional and Invasive

StudiesCardiovascular System

Study	Description and Purpose	Nursing Responsibility
Cardiac catheterization; coronary angiography	Involves insertion of catheter into heart via a vein (for right side of heart) and/or an artery (for left side of heart). Procedure is done to evaluate chest pain and obtain information about the aorta, inferior vena cava, pulmonary artery and veins. Measures pressures within the heart chambers. Contrast medium is injected to help see structures and motion of heart. With coronary angiography, contrast medium is injected directly into coronary arteries to evaluate patency and collateral circulation.	See Table 31.9.
Electrophysiology study (EPS)	Invasive study to record intracardiac electrical activity using catheters (with multiple electrodes) inserted via the femoral or jugular veins into right side of heart. Catheter electrodes record the electrical activity in different heart structures. Can induce and stop dysrhythmias. Insertion of a pacemaker or implantable cardioverter defibrillator (ICD) or ablation of a dysrhythmia pathway may be done during or right after the EPS. See Chapter 35 for more details.	*Before:* Antidysrhythmic drugs may be stopped several days before study. Keep patient NPO 6–8 hr before test. Give premedication to promote relaxation if ordered. Obtain IV access. IV sedation often used during procedure. *After:* Assess vital signs often. Monitor ECG continuously per agency protocol. Patient will be on bedrest for 6–8 hr after procedure.
Fractional flow reserve (FFR)	During cardiac catheterization, a specialized wire is inserted into coronary arteries to measure pressure and flow. Information is used to determine need for angioplasty or stenting on nonsignificant blockages.	Same as for cardiac catheterization.
Invasive hemodynamic monitoring	Invasive and minimally invasive bedside hemodynamic monitoring is done using intraarterial, pulmonary artery, and central vein catheters. Monitors arterial BP, stroke volume variation, pulmonary artery pressure, pulmonary artery wedge pressure, cardiac output, and central venous pressure. Used to evaluate cardiovascular status and response to treatment.	Patients who need invasive hemodynamic monitoring are critically ill and are monitored in critical care units. See Chapter 65 for complete information on hemodynamic monitoring.
Intravascular ultrasound (IVUS)	During cardiac catheterization a small ultrasound probe is introduced into coronary arteries. Used to assess blood vessel patency, size and consistency of plaque, arterial walls, and effectiveness of intracoronary artery treatment.	Same as for cardiac catheterization.
Peripheral arteriography and venography	Peripheral vessel blood flow is assessed by injecting contrast media into appropriate arteries or veins (arteriography and venography). Serial x-ray studies done to detect atherosclerotic plaques, occlusion, aneurysms, venous abnormalities, or traumatic injury. See Table 37.9 for more peripheral vascular diagnostic studies.	*Before:* Assess for contrast allergy. Explain that patient may feel a warm sensation, salty taste after contrast injection. Patient may have nausea. Give mild sedative, if ordered. *During:* Observe patient for allergic reaction to contrast media. *After:* Inspect insertion site for bleeding or swelling. Check extremity with puncture site for pulsation, warmth, color, and motion. Encourage fluids to excrete radioactive substance.

Different classes of lipoproteins contain varying amounts of the naturally occurring lipids. These include:

1. *Chylomicrons:* primarily exogenous triglycerides from dietary fat
2. *Low-density lipoproteins (LDLs):* mostly cholesterol with moderate amounts of phospholipids
3. *High-density lipoproteins (HDLs):* about 50% protein and 50% phospholipids and cholesterol

4. *Very-low-density lipoproteins (VLDLs):* primarily endogenous triglycerides with moderate amounts of phospholipids and cholesterol

Elevations in triglycerides and LDL are strongly associated with CAD. An increased HDL level is associated with a decreased risk of CAD. HDLs serve a protective role by mobilizing cholesterol from tissues.

Although a relationship exists between high serum cholesterol levels and CAD, a measure of total cholesterol alone is not enough for an assessment of CAD. A risk assessment is calculated by comparing the total cholesterol to HDL ratio over time. An increase in the ratio means increased risk. This provides more information than either value alone.

Plasma levels of apolipoprotein A-I (apo A-I) (the major HDL protein) and the ratio of apo A-I to apolipoprotein B (apo B) (the major LDL protein) are stronger predictors of CAD than the HDL cholesterol level alone. Measurements of these lipoproteins can be useful in identifying patients at risk for CAD.

Lipoprotein (a), or Lp(a), has been studied for its role as a risk factor for CAD. Increased levels of Lp(a), especially with increased levels of lactate dehydrogenase (LDH), have been linked with the progression of atherosclerosis, especially in women.

Lipoprotein-associated phospholipase A_2 (Lp-PLA_2) is an inflammatory enzyme expressed in atherosclerotic plaques. High levels of Lp-PLA_2 are related to an increased risk for CAD, especially in black women.[14]

TABLE 31.9 Nursing ManagementCare of the Patient Undergoing Cardiac Catheterization

Preprocedure

- Assess for allergies, especially to contrast dye.
- Perform baseline assessment, including vital signs, pulse oximetry, heart and breath sounds, neurovascular assessment of extremities (e.g., distal pulses, skin temperature, skin color, sensation).
- Withhold food and fluids for 6–12 hours before.
- Assess baseline laboratory values (e.g., cardiac biomarkers, creatinine).
- Teach patient and caregiver about procedure and postprocedure care. Explain the use of local anesthesia at insertion site, placement of catheter, flushed feeling when dye is injected, and possible fluttering sensation of heart as catheter is passed.
- Give sedative and other drugs, as ordered.

Postprocedure

- Perform assessment and compare to baseline: vital signs, pulse oximetry, and heart and breath sounds. Note hypotension or hypertension and signs of pulmonary emboli (e.g., respiratory difficulty).
- Assess neurovascular status, including peripheral pulses, color, and sensation, of extremity per agency protocol.
- Place compression device over arterial site to achieve hemostasis, if indicated.
- Observe insertion site for hematoma and bleeding every 15 min for the first hour, then according to agency policy
- Monitor ECG for dysrhythmias or other changes (e.g., ST segment elevation).
- Monitor patient for chest pain and other sources of pain or discomfort.
- Maintain bedrest as ordered after femoral access.
- Maintain IV and/or oral fluid intake and monitor urine output.

- Teach patient and caregiver about discharge care, including signs and symptoms to report to HCP (e.g., site complications, return of chest pain), and any activity restrictions.

Electrocardiography

Electrocardiogram

The basic P, QRS, and T waveforms (Fig. 31.4, *B*) are used to assess heart activity. Deviations from the normal sinus rhythm can indicate problems in heart function. There are many types of ECG monitoring, including a resting 12-lead ECG, ambulatory ECG monitoring, and exercise or stress testing (Table 31.7). Continuous ambulatory ECG (Holter monitoring) provides diagnostic information over a period of time. See Chapter 35 for a complete discussion of ECG monitoring.

Event Monitor or Loop Recorder

An event monitor or loop recorder is used to record less frequent ECG events. An event monitor is a portable unit that uses electrodes to store ECG data. There are 2 types, external and implantable. External loop recorders are worn for a month. They require electrodes continuously placed on the skin. They must be activated by the patient when symptoms occur. A disadvantage of external recorders is that, if symptoms occur for only a brief time, they may be over before the patient puts on the device and triggers it to record. Likewise, if patients are extremely symptomatic (e.g., syncopal), they may not be physically able to trigger the ECG recording. These devices can be perform a routine pacemaker check over the phone.

An implantable loop recorder is used for patients who may have serious yet infrequent dysrhythmias. This small recorder is implanted through a small incision into the chest wall. It continuously monitors heart activity. It keeps recordings if the patient uses a remote device when symptoms occur or automatically if the HR exceeds or goes below a set rate.

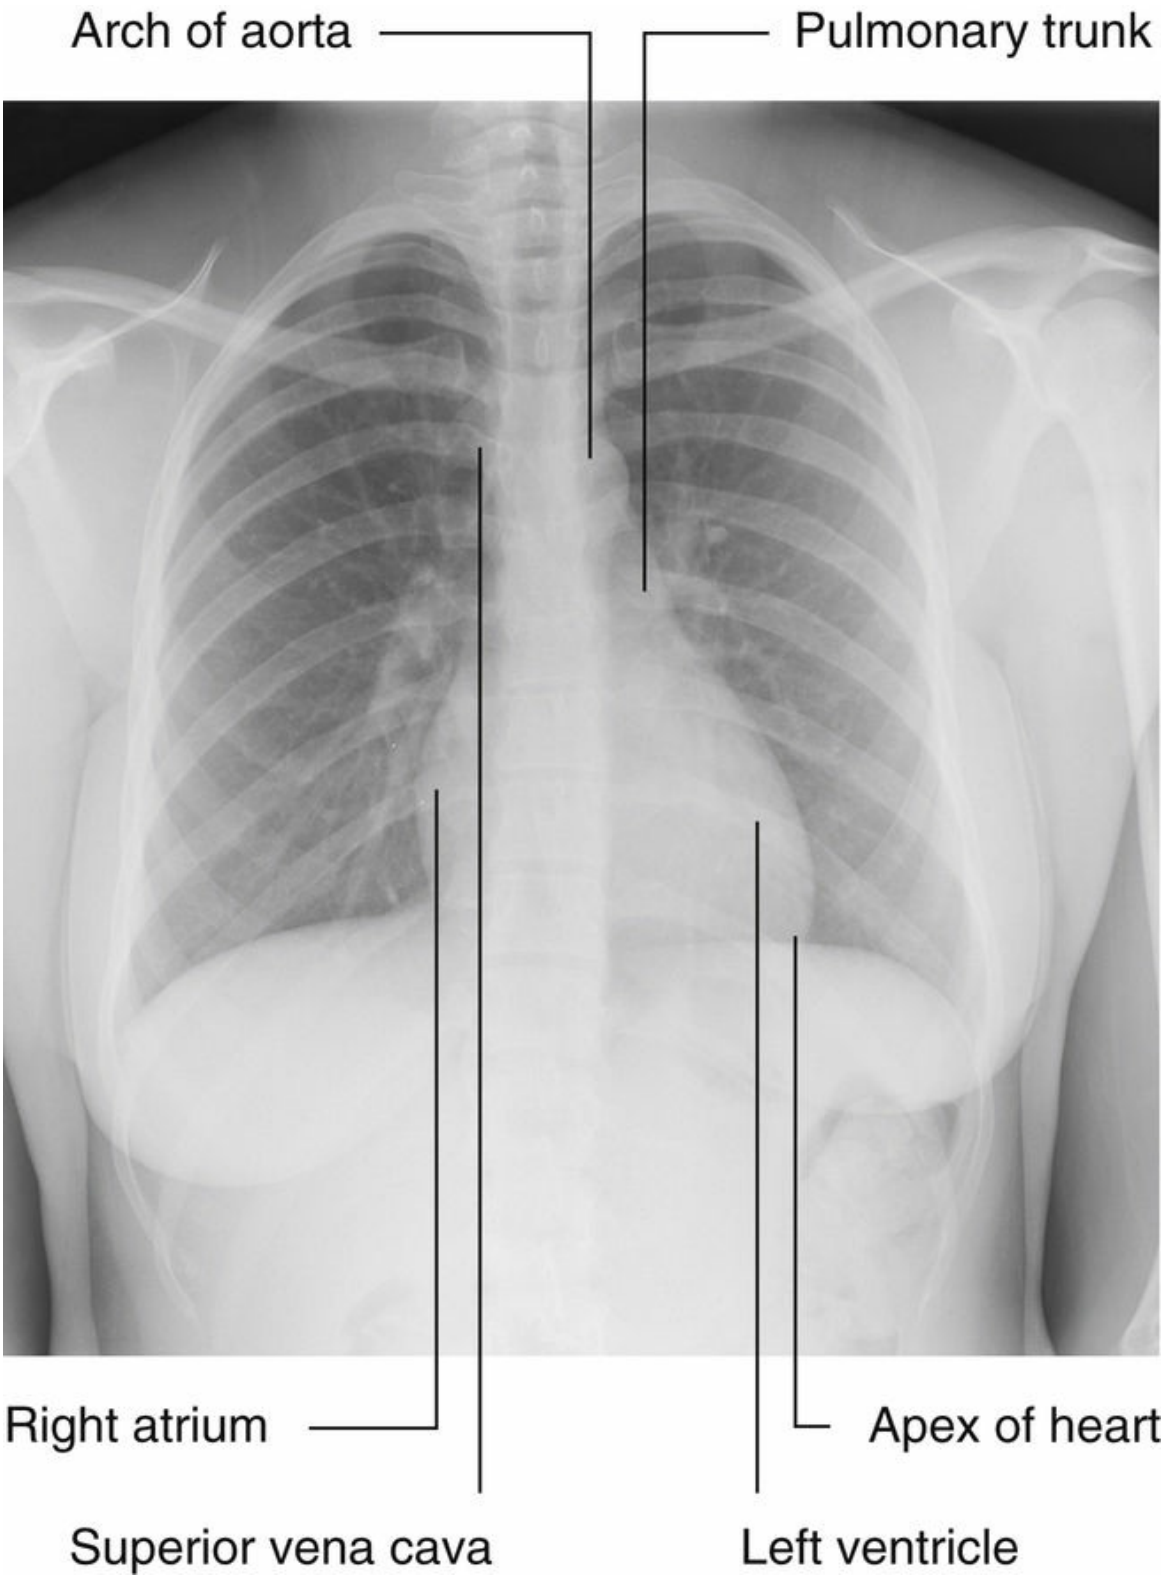

FIG. 31.9 Chest x-ray: standard posterior-anterior view.
From Drake RL, Vogl AW, Mitchell AWM: *Gray's anatomy for students,* ed 2, Philadelphia, 2010, Churchill Livingstone.

Functional Studies

Exercise or Stress Testing

Heart symptoms often occur only with activity because of the demand on the coronary arteries to supply more O_2. Exercise testing can evaluate the heart's response to physical stress. This helps to assess CVD and set limits for exercise programs. Exercise testing is used for persons who can walk unassisted or use a bicycle. It is also helpful for those with normal ECGs that limit diagnostic interpretation (e.g., pacemakers) (Table 31.7). ECG and BP are monitored throughout the exercise period for signs of cardiac stress.

6-Minute Walk Test

A general test of cardiac fitness, often used with older adults, is measuring the distance the patient can walk on a flat surface in 6 minutes. The test can provide a baseline for determining response to treatment and physical therapy.

Noninvasive Hemodynamic Monitoring

Noninvasive hemodynamic monitoring provides information about cardiovascular status changes without the risks of inserting and maintaining invasive devices. SV, CO, and systemic BP are measured using a continuous finger cuff or by thoracic bioreactance.[15] Monitoring stroke volume and CO during complex surgical procedures allows the anesthesia provider to titrate fluids and vasoactive drugs.

Imaging

Chest X-Ray

A radiographic picture of the chest can show heart shape and size and anatomic changes in individual chambers (Fig. 31.9). The chest x-ray records any displacement or enlargement of the heart, extra fluid around the heart (pericardial effusion), and pulmonary congestion

(Table 31.7).

Echocardiography

The echocardiogram uses ultrasound (US) waves to record the movement of the structures of the heart. In the normal heart, US waves directed at the heart are reflected back in typical patterns. *Contrast echocardiography* involves the addition of an IV contrast agent (e.g., agitated saline) to help define the images, especially in technically difficult patients (e.g., obese).

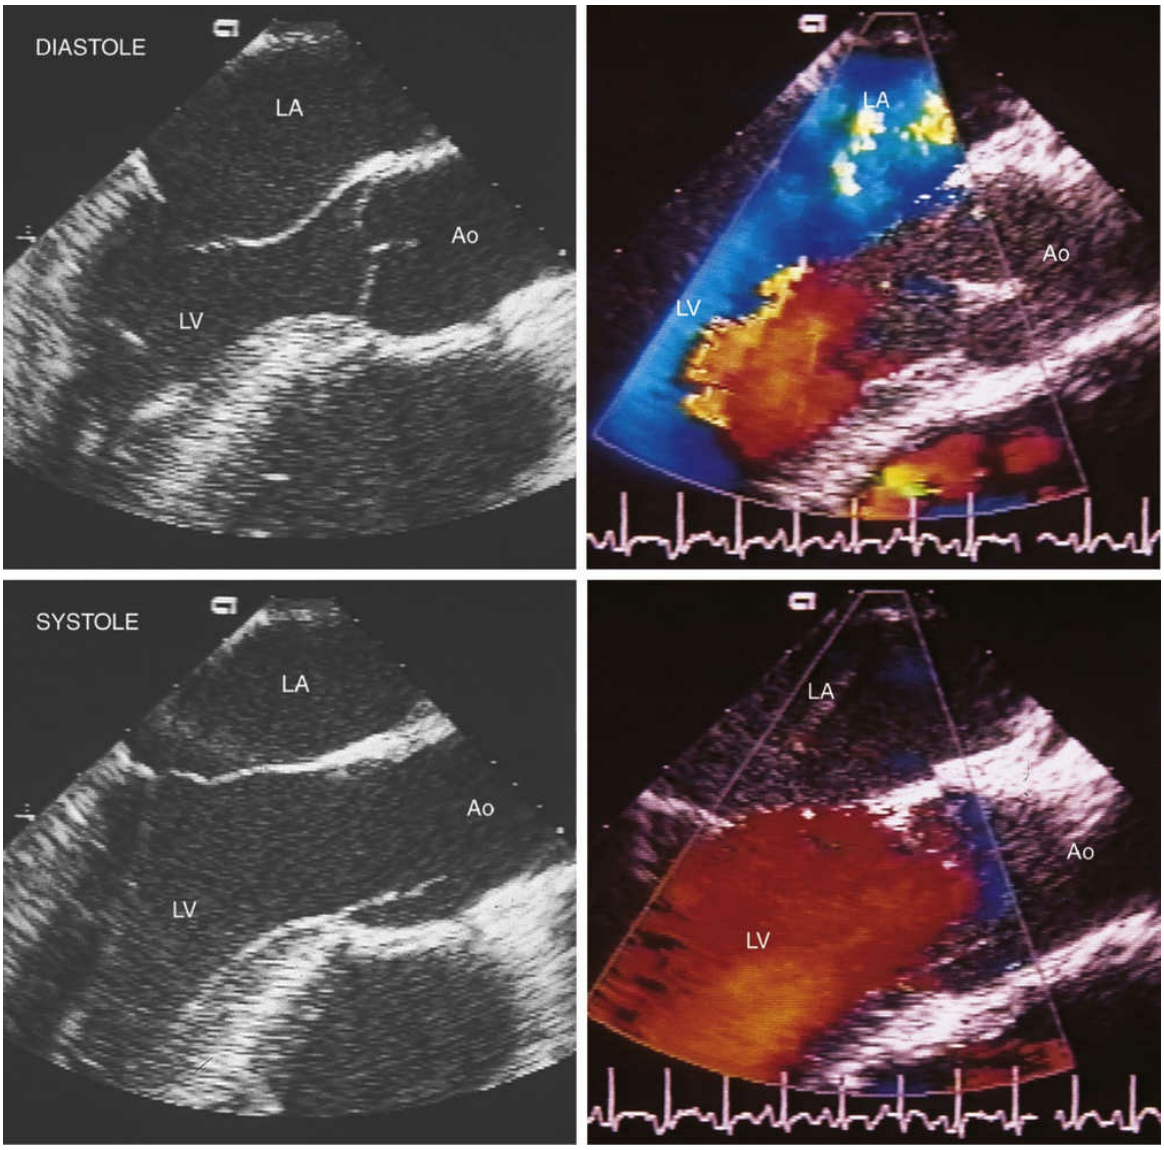

FIG. 31.10 Long-axis images of the aortic and mitral valve with the depth adjusted to optimize evaluation of valve anatomy and motion. The 2-D images *(left)* in diastole *(top)* and systole *(bottom)* show normal aortic and mitral opening and closure. The color flow images *(right)* show normal left ventricular inflow with no aortic regurgitation in diastole *(top)* and normal antegrade flow in the left ventricular outflow tract and no mitral regurgitation in systole *(bottom)*.
From Otto C: *Textbook of clinical echocardiography*, ed 3, St Louis, 2004, Saunders.

The echocardiogram provides information about abnormalities of (1) valvular structures and motion, (2) heart chamber size and contents, (3) ventricular and septal motion and thickness, (4) pericardial sac, and (5) ascending aorta. The **ejection fraction (EF)**, or

the percentage of end-diastolic blood volume that is ejected during systole, can be measured. The EF provides information about the function of the left ventricle during systole.

Two common types of echocardiograms are the *motion-mode (M-mode) echocardiogram* and the *two-dimensional (2-D) echocardiogram.* In the M-mode, a single US beam is directed toward the heart, recording the motion of the intracardiac structures and detecting wall thickness and chamber size. The 2-D echocardiogram sweeps the US beam through an arc, producing a cross-sectional view. This shows correct spatial relationships among the structures.

Doppler technology allows for sound evaluation of the flow or motion of the scanned object (heart valves, ventricular walls, blood flow). *Color-flow imaging (duplex)* is the combination of 2-D echocardiography and Doppler technology (Fig. 31.10). It uses color changes to show the speed and direction of blood flow. Pathologic conditions, such as valvular leaks and congenital defects, can be diagnosed more effectively.

Real-time three-dimensional (3-D) ultrasound is a technology that uses multiple 2-D echo images with computer technology to provide a reconstruction of the heart. This technique gives information about the structures of the heart and how these structures change during the cardiac cycle.

Stress echocardiography combines the information from a stress test with the information from an echocardiogram. A digital computer compares images before and after exercise, revealing wall motion and function. For those persons unable to exercise, IV drugs are used. These include dobutamine, which produces pharmacologic stress on the heart and dipyridamole (Persantine), which vasodilates healthy arteries. Unhealthy arteries do not respond as well, which is seen on the echocardiogram.

Transesophageal echocardiography (TEE) provides more precise echocardiography of the heart than surface 2-D echocardiography by removing interference from the chest wall and lungs (Table 31.7). The TEE uses a flexible endoscope with a US transducer in the tip for imaging of the heart and great vessels. The scope is passed into the

esophagus to the level of the heart. M-mode, 2-D, Doppler, and color-flow imaging can be obtained.

TEE is used often in an outpatient setting for evaluation of mitral valve disease and for identification of endocarditis vegetation, thrombus before cardioversion, or the source of heart emboli. In addition, TEE is used in the operating room to assess intraoperative heart function and in the emergency department to detect suspected aortic dissection.

The risks of TEE are low. However, complications include perforation or tearing of the esophagus, hemorrhage, dysrhythmias, vasovagal reactions, and transient hypoxemia. TEE is contraindicated if the patient has a history of esophageal disorders, dysphagia, or radiation therapy to the chest wall. Patients need sedation during a TEE.

Cardiac Computed Tomography

Cardiac CT is a heart-imaging test that uses CT technology with or without IV contrast (dye) to see the heart anatomy, coronary circulation, and great blood vessels (e.g., aorta, pulmonary veins, artery). This technology is often called *multidetector CT (MDCT) scanning*. Types of CT scans used to diagnose heart disease include coronary CT angiography (CTA) and calcium-scoring CT scan (Table 31.7).

Coronary CTA is a noninvasive test. It can be done faster than a cardiac catheterization with less risk and discomfort to the patient. Patients must have a normal sinus rhythm for this test. Although the use of coronary CTA is increasing, cardiac catheterization is the gold standard to diagnose CAD. Further, when a cardiac catheterization is done, procedures (e.g., angioplasty, stent placement) can be done if coronary blockages are found. Last, the radiation exposure during a cardiac catheterization is less than the exposure during a CTA.

The calcium-scoring CT scan is used to find calcium deposits in plaque in the coronary arteries. The most common method used is the electron beam CT (EBCT) (Fig. 31.11). It can detect early coronary calcification before symptoms develop and confirm CAD in patients

with suspected CAD. The amount of coronary calcium is a predictor of future cardiac events. The calcium score can be used in the risk analysis of patients without known CVD.

Cardiovascular Magnetic Resonance Imaging

Cardiovascular magnetic resonance imaging (CMRI) can detect and find areas of MI in a 3-D view. It is sensitive enough to find even small MIs that are not apparent with single-photon emission computed tomography (SPECT). CMRI aids in the final diagnosis of MI and the assessment of EF. It plays a role in prediction of recovery from MI and in the diagnosis of congenital heart and aortic disorders and CAD. One major advantage of CMRI is that it does not require any radiation to the patient.

Patients with coronary stents can undergo CMRI 6 weeks after stent placement. In patients with older model pacemakers and ICDs, CMRI is discouraged because the magnets can change the function of the devices. However, when there is a strong clinical need and the benefits outweigh the risks, CMRI can be done at centers experienced in this procedure. Many newer models of pacemakers and ICDs are approved for use with MRI.

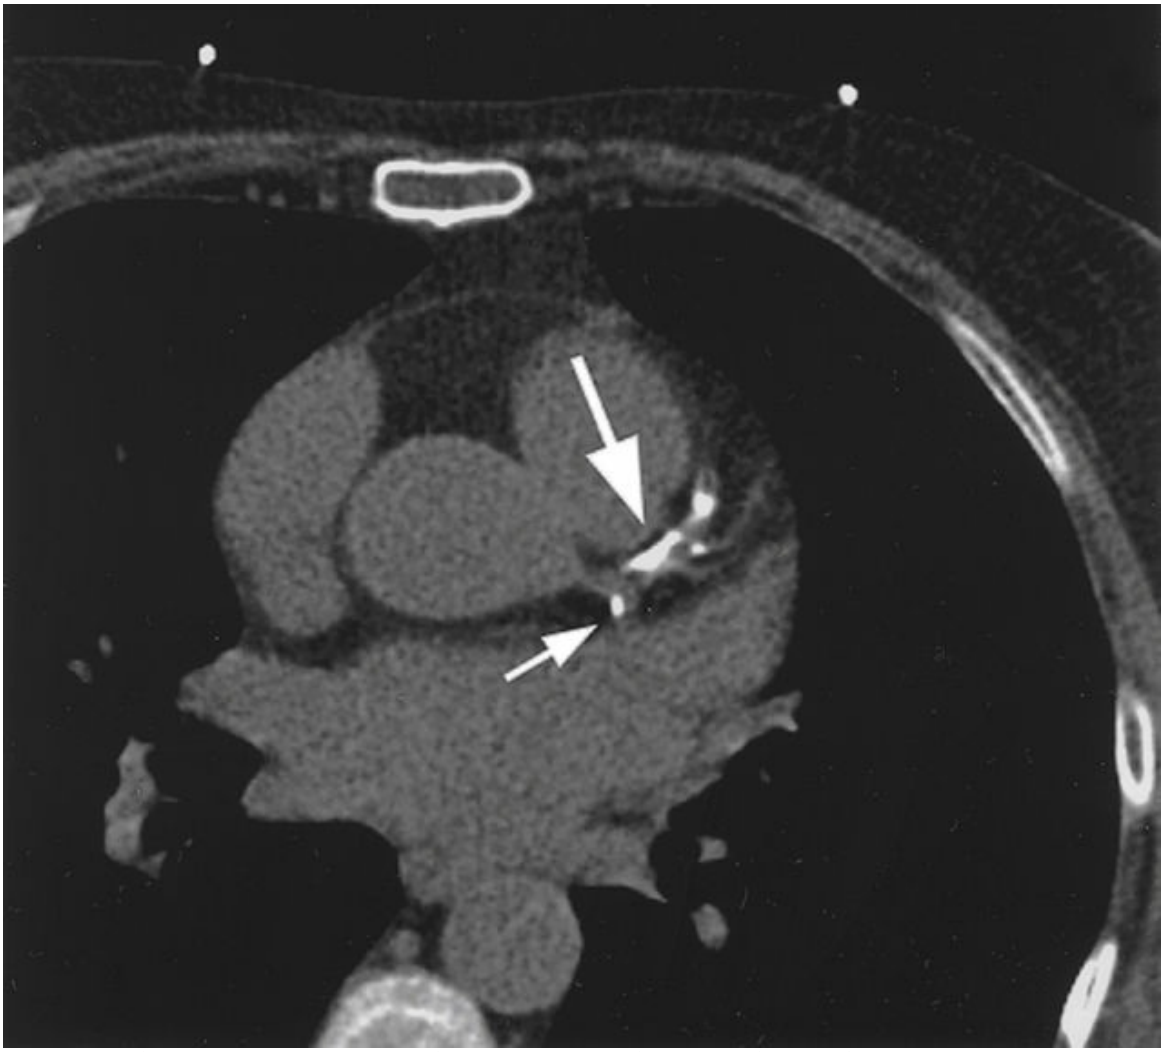

FIG. 31.11 Examples of coronary calcification of the left anterior descending coronary artery *(large arrow)* and left circumflex artery *(small arrow)* as seen on electron beam computed tomography. From Libby P, Bonow R, Zipes D, et al: *Braunwald's heart disease: A textbook of cardiovascular medicine,* ed 8, St Louis, 2008, Saunders.

Nuclear Cardiology

One of the most common nuclear imaging tests is the multigated acquisition (MUGA) or cardiac blood pool scan. This test provides information on wall motion during systole and diastole, heart valves, and EF (Table 31.7).

Perfusion imaging is used with exercise testing to determine whether the coronary blood flow changes with increased activity. Stress perfusion imaging may show an abnormality even when a

resting image is normal. This procedure is used to diagnose CAD, make a prognosis in existing CAD, distinguish viable heart muscle from scar tissue, and determine the potential for success of various interventions (e.g., coronary artery bypass surgery, percutaneous coronary intervention) (see Chapter 33).

Exercise stress perfusion imaging is an option if a patient cannot exercise. IV regadenoson (Lexiscan), dipyridamole, or adenosine (Adenocard) can be given to dilate the coronary arteries and simulate the effect of exercise. After the drug takes effect, the isotope is injected, and the imaging is done.

SPECT uses technetium, thallium, or sestamibi as an imaging agent (isotope). Both obese patients and women with large breasts can have artifact, which can lead to false-positive results. Patients with severe multivessel coronary disease or blockages in their left main coronary artery may have false-negative results.

Positron emission tomography (PET) stress testing is increasingly being used due to its high sensitivity for revealing myocardial ischemia and viability. This type of myocardial perfusion imaging is often performed using rubidium-82. This agent allows for quicker studies with lower radiation exposure and better diagnostic quality.[16]

Interventional and Invasive Studies

Cardiac Catheterization

Cardiac catheterization is a common procedure. It provides information about CAD, coronary spasm, congenital and valvular heart disease, and ventricular function. Cardiac catheterization is also used to measure intracardiac pressures and O_2 levels, as well as CO and EF. With injection of contrast media and fluoroscopy, the coronary arteries can be seen, chambers of the heart can be outlined, and wall motion assessed (Table 31.8).

Cardiac catheterization is done by inserting a radiopaque catheter into the right and/or left side of the heart. For the right side of the heart, the HCP inserts a catheter into the femoral, internal jugular, subclavian, or antecubital vein. Pressures are recorded as the catheter

is moved into the vena cava, right atrium, right ventricle, and pulmonary artery. The catheter is then moved until it is wedged or lodged in position. This blocks the blood flow and pressure from the right side of the heart and looks ahead through the pulmonary capillary bed to the pressure in the left side of the heart *(pulmonary artery wedge pressure).* This pressure assesses the function of the left side of the heart.

Left-sided heart catheterization is done by inserting a catheter into a radial, femoral, or brachial artery. The catheter is passed in a retrograde manner up to the aorta, across the aortic valve, and into the left ventricle.

Coronary angiography is done with a left-sided heart catheterization. The catheter is positioned at the origin of the coronary arteries (Fig. 31.3), and contrast medium is injected into the arteries. Patients often feel a temporary flushed sensation with dye injection. The images show the location and severity of any coronary blockages (see Figs. 31.12 and 33.7).

FIG. 31.12 Angiogram showing a normal left coronary and circumflex artery.
From Drake RL, Vogl AW, Mitchell AWM: *Gray's anatomy for students,* ed 2, Philadelphia, 2010, Churchill Livingstone.

Complications of cardiac catheterization include bleeding or hematoma at the puncture site; allergic reactions to the contrast media; looping or kinking of the catheter; infection; thrombus formation; aortic dissection; dysrhythmias; MI; stroke; and puncture of the ventricles, septum, or lung tissue.

Intravascular Ultrasound

Intravascular ultrasound (IVUS), or intracoronary ultrasound (ICUS), is an invasive procedure done in the catheterization laboratory with coronary angiography. The 2-D or 3-D US images provide a cross-sectional view of the arterial walls of the coronary arteries. In IVUS, a miniature transducer attached to a small catheter is moved to the artery to be studied. Once it is in the artery, US images are obtained. The health of the arterial layers is assessed, including the composition, location, and thickness of any plaque. IVUS can evaluate vessel response to treatments such as stent placement and atherectomy, as well as any complications that may have occurred during the procedure. Patients often have IVUS in addition to angiography or a coronary intervention. Thus nursing care after is similar to that of patient after a cardiac catheterization.

Electrophysiology Study

The electrophysiology study (EPS) records and manipulates the heart's electrical activity using electrodes placed inside the heart chambers. It provides information on SA node, AV node, and ventricular conduction. It is particularly helpful in determining the source and treatment of dysrhythmias. Patients with symptomatic tachydysrhythmias are at risk for sudden cardiac death. Information from an EPS helps to make a correct diagnosis and guides treatment decisions (Table 31.8). In EPS, catheters are inserted like a right-sided heart catheterization. Thus nursing care after EPS is similar to that of a patient after a cardiac catheterization.

Case Study

Objective Data: Diagnostic Studies

© Jupiterimages/Banana-Stock/Thinkstock.

The HCP orders the following initial diagnostic studies for L.P.:

- 12-lead ECG
- CBC, basic metabolic panel (glucose, electrolytes, BUN, creatinine)
- PTT, PT, INR

- Pro-BNP
- Troponin, CK-MB
- TSH, free T_4
- Chest x-ray

The ECG shows atrial fibrillation with a rapid ventricular response. L.P.'s initial troponin and CK-MB levels are within normal limits. Chest x-ray, CBC, and coagulation studies are all within normal limits. The potassium level is 3.1 mEq/L and pro-BNP is high (1204 pg/mL). The HCP orders 250 mL NSS IV bolus; an oral dose of potassium, a loading dose of IV diltiazem followed by a continuous infusion, and weight-based heparin to be started in the emergency department. L.P. will be admitted to the progressive care unit and will have a consult with a cardiologist.

Discussion Questions

1. Are these the diagnostic studies that you expected to be ordered?
2. Which diagnostic study results are abnormal?
3. Which diagnostic study results are of most concern to you?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient with a tricuspid valve disorder has impaired blood flow between the
   a. vena cava and right atrium.
   b. left atrium and left ventricle.

c. right atrium and right ventricle.

d. right ventricle and pulmonary artery.

2. A patient has a severe blockage in his right coronary artery. Which heart structures are *most* likely to be affected by this blockage *(select all that apply)*?

a. AV node

b. Left ventricle

c. Coronary sinus

d. Right ventricle

e. Pulmonic valve

3. The part of the vascular system responsible for hemostasis is the

a. thin capillary vessels.

b. endothelial layer of the arteries.

c. elastic middle layer of the veins.

d. smooth muscle of the arterial wall.

4. When a person's blood pressure rises, the homeostatic mechanism to compensate for an elevation involves stimulation of

a. baroreceptors that inhibit the sympathetic nervous system, causing vasodilation.

b. chemoreceptors that inhibit the sympathetic nervous system, causing vasodilation.

c. baroreceptors that inhibit the parasympathetic nervous system, causing vasodilation.

d. chemoreceptors that stimulate the sympathetic nervous system, causing an increased heart rate.

5. A P wave on an ECG represents an impulse arising at the
   a. SA node and repolarizing the atria.
   b. SA node and depolarizing the atria.
   c. AV node and depolarizing the atria.
   d. AV node and spreading to the bundle of His.
6. Which subjective data related to the cardiovascular system should be obtained from the patient *(select all that apply)*?
   a. Annual income
   b. Smoking history
   c. Religious preference
   d. Number of pillows used to sleep
   e. Blood for basic laboratory studies
7. Which heart valve sound is heard best at the left midclavicular line at the level of the fifth ICS?
   a. Aortic
   b. Mitral
   c. Tricuspid
   d. Pulmonic
8. When assessing a patient, you note a pulse deficit of 23 beats. This finding may be caused by
   a. dysrhythmias.
   b. heart murmurs.
   c. gallop rhythms.
   d. pericardial friction rubs.
9. An expected finding in the assessment of an 81-year-old patient is

a. a narrowed pulse pressure.

b. diminished carotid artery pulses.

c. difficulty isolating the apical pulse.

d. an increased heart rate in response to stress.

10. Which nursing responsibilities are priorities when caring for a patient returning from a cardiac catheterization *(select all that apply)*?

a. Monitoring vital signs and ECG

b. Checking the catheter insertion site and distal pulses

c. Helping the patient to ambulate to the bathroom to void

d. Telling the patient that he will be sleepy from the general anesthesia

e. Teaching the patient about the risks of the radioactive isotope injection

1. c, 2. a, b, d, 3. b, 4. a, 5. b, 6. b, c, d, 7. b, 8. a, 9. c, 10. a, b

Hypertension

Pamela Wilkerson, and Melissa Hutchinson

LEARNING OUTCOMES

1. Relate the pathophysiologic mechanisms associated with primary hypertension to the clinical manifestations and complications.
2. Choose appropriate strategies for the prevention of primary hypertension.
3. Describe the interprofessional care for primary hypertension, including drug therapy and lifestyle modifications.
4. Explain the interprofessional care of the older adult with primary hypertension.
5. Prioritize the nursing management of the patient with primary hypertension.
6. Describe the nursing and interprofessional care of a patient with a hypertensive crisis.

KEY TERMS

blood pressure (BP), p. 678

hypertension, p. 678

hypertensive crisis, p. 695

orthostatic hypotension, p. 692
elevated blood pressure, p. 681
primary hypertension, p. 681

Perfusion
Self-Management

Hypertension, or high blood pressure (BP), is one of the most important modifiable risk factors that can lead to the development of cardiovascular disease (CVD). As BP increases so does the risk for myocardial infarction (MI), heart failure (HF), stroke, and renal disease. Hypertension-induced retinopathy can impair vision. This chapter discusses the nursing and interprofessional care of patients with or at risk for hypertension. Providing comprehensive care will require you to collaborate with many members of the health care team. Patient education is key to hypertension management. Proper nutrition and exercise are important health promotion behaviors.

Current guidelines reveal that around 46% of adults in the United States meet criteria for the general diagnosis of hypertension. Heart disease, often directly related to hypertension, accounts for 23.7% of all deaths each year in the United States.[1,2] The National Health and

Nutrition Examination Survey (NHANES) tracks prevention, treatment, and control of hypertension.[3] Data from NHANES showed that 83% of people 20 years of age and older with hypertension were aware that they had high BP. Of those, 76% were receiving treatment; 48%, though, did not currently have their BP well controlled.[4]

The American College of Cardiology Foundation and the American Heart Association (AHA) provide performance measures for hypertension management that address the treatment and control of BP to target goals. Target goals have been updated with new information from the evidence-based Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults: A Report of the American College of Cardiology/AHA Task Force on Clinical Practice Guidelines and the Systolic Blood Pressure Intervention Trial (SPRINT). Target goals take age and comorbidities into consideration when recommending treatment options.[5]

National guidelines are designed to apply to all racial and ethnic groups. However, specific groups have a higher incidence of risk factors (see boxes on Promoting Health Equity and Gender Differences).[5,6]

Normal Regulation of Blood Pressure

Blood pressure (BP) is the force exerted by the blood against the walls of the blood vessel. It must be adequate to maintain tissue perfusion during activity and rest. Maintaining normal BP and tissue perfusion requires the integration of both systemic factors and local peripheral vascular effects. BP is mainly a function of cardiac output (CO) and systemic vascular resistance (Fig. 32.1).

Promoting Health Equity

Hypertension

All Ethnicities

- There are 3 factors associated with decreased prevalence of hypertension for all ethnicities: People born outside the United States, living in a household that does not speak English in the home, or living in a household with limited time living in the United States

Blacks

- Have the highest prevalence of hypertension in the world
- Are more likely to have resistant hypertension
- Develop hypertension at a younger age than other ethnicities with higher average blood pressure
- Have a higher incidence of hypertension among women than among men
- Have more nocturnal nondipping BP than whites, which is associated with an increase in CVD
- Hypertension is more aggressive and results in more severe end-organ damage
- Have the highest death rate resulting from hypertension
- Make less renin and do not respond well to renin-inhibiting drugs
- Have better BP control with calcium channel blockers and diuretics, especially with monotherapy
- Have a higher risk for angioedema with ACE inhibitors than whites

Hispanics

- Are less likely to receive treatment for hypertension than whites and blacks

- Have lower rates of BP control than whites and blacks
- Have lower levels of awareness of hypertension and its treatment than whites and blacks

Gender Differences

Hypertension

Men

- Before early middle age, hypertension is more common in men.

Women

- Hypertension is 2 to 3 times more common in women who take oral contraceptives than in women who do not.
- A history of preeclampsia may be an early sign of risk for CVD.
- After age 64, hypertension is more common in women. Part of the rise in BP in women is attributed to menopause-related factors, such as estrogen withdrawal, overproduction of pituitary hormones, and weight gain
- It is harder to control hypertension in older women (ages 70 to 79) than in women ages 50 to 69, despite having similar rates of treatment.

CO is the total blood flow through the systemic or pulmonary circulation per minute. It is described as the stroke volume (SV) or the amount of blood pumped out of the left ventricle per beat (about 70 mL) multiplied by the heart rate (HR).

Systemic vascular resistance (SVR) is the force opposing the movement of blood within the blood vessels. The radius of the small arteries and arterioles is the principal factor determining SVR. As

arteries narrow, resistance to blood flow increases. As arteries dilate, resistance to blood flow decreases. A small change in the radius of the arterioles creates a significant change in the SVR. If SVR is increased and CO stays constant or increases, arterial BP will increase.

The mechanisms that regulate BP can affect either CO or SVR or both. Regulation of BP is a complex process involving both short-term (seconds to hours) and long-term (days to weeks) mechanisms. Short-term mechanisms, including the sympathetic nervous system (SNS) and vascular endothelium, are active within a few seconds. Long-term mechanisms include renal and hormonal processes that regulate arteriolar resistance and blood volume. In a healthy person, these regulatory mechanisms work in response to the body's demands.

Sympathetic Nervous System

The nervous system, which reacts within seconds after a drop in BP, increases BP by activating the SNS. Increased SNS activity increases HR, and cardiac contractility produces widespread vasoconstriction in the peripheral arterioles and promotes the release of renin from the kidneys. The net effect of SNS activation is to increase BP by increasing both CO and SVR.

Specialized nerve cells called *baroreceptors* are found in the carotid arteries and arch of the aorta. These cells sense changes in BP and send this information to the vasomotor centers in the brainstem. The brainstem sends this information through complex networks of neurons that excite or inhibit efferent nerves. SNS efferent nerves innervate cardiac and vascular smooth muscle cells. Under normal conditions, a low level of continuous SNS activity maintains vascular tone. BP may be reduced by the withdrawal of SNS activity or by stimulation of the parasympathetic nervous system (PNS). The PNS decreases the HR (via the vagus nerve) and thereby decreases CO.

The neurotransmitter norepinephrine (NE) is released from SNS nerve endings. NE activates receptors in the sinoatrial node, myocardium, and vascular smooth muscle. The response to NE depends on the type of receptors present. SNS receptors are classified

as α_1, α_2, β_1, and β_2 (Table 32.1). The smooth muscle of the blood vessels has α-adrenergic and β_2-adrenergic receptors. α-Adrenergic receptors found in the peripheral vasculature cause vasoconstriction when stimulated by NE. β_1-Adrenergic receptors in the heart respond to NE and epinephrine with increased HR (chronotropic), increased force of contraction (inotropic), and increased speed of conduction (dromotropic). β_2-Adrenergic receptors are activated mainly by epinephrine released from the adrenal medulla and cause vasodilation (Fig. 32.1).

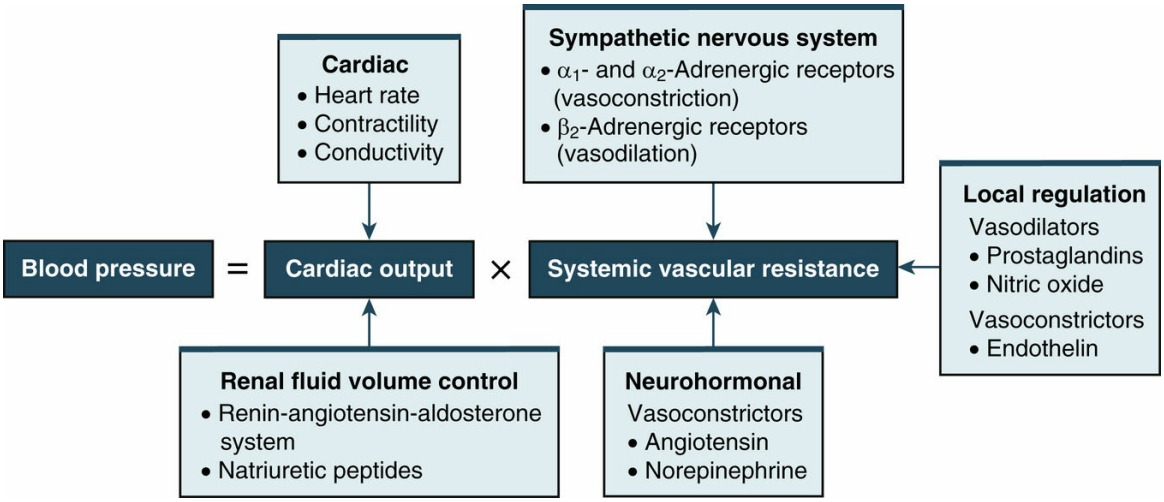

FIG. 32.1 Factors influencing BP. Hypertension develops when one or more of the BP-regulating mechanisms are defective.

TABLE 32.1 Sympathetic Nervous System Receptors Affecting BP

Receptor	Location	Response When Activated
α_1	Vascular smooth muscle	Vasoconstriction
	Heart	Increased contractility (positive inotropic effect)
α_2	Presynaptic nerve terminals	Inhibition of norepinephrine release
	Vascular smooth muscle	Vasoconstriction
β_1	Heart	Increased contractility (positive inotropic effect) Increased heart rate (positive chronotropic effect) Increased conduction (positive dromotropic effect)
	Juxtaglomerular cells of the kidney	Increased renin secretion
β_2	Smooth muscle of blood vessels in heart (e.g., coronary arteries), lungs (e.g., bronchi), and skeletal muscle	Vasodilation
Dopamine receptors	Primarily renal blood vessels	Vasodilation

The sympathetic vasomotor center interacts with many areas of the brain to maintain normal BP under various conditions. It is activated during times of pain, stress, and exercise. The SNS response causes an appropriate increase in CO and BP to adjust to the body's increased O_2 demands. During postural change from lying to standing, there is a transient decrease in BP. The vasomotor center is stimulated, and the SNS response causes peripheral vasoconstriction and increased venous return to the heart. If this reaction did not occur, blood flow to the brain would be inadequate, resulting in dizziness or syncope.

Baroreceptors

Baroreceptors have a vital role in maintaining BP stability during normal activities. They are sensitive to stretching and, when stimulated by an increase in BP, send inhibitory impulses to the sympathetic vasomotor center. SNS inhibition results in decreased HR, decreased force of contraction, and vasodilation in peripheral arterioles.

When baroreceptors sense a fall in BP, the SNS is activated. The result is constriction of the peripheral arterioles, increased HR, and increased contractility of the heart. In long-standing hypertension, the baroreceptors become adjusted to elevated BP levels and recognize this level as their new "normal."

Vascular Endothelium

The vascular endothelium is a single-cell layer that lines the blood vessels. The endothelium is very active and responsible for several critical functions. These include platelet adhesion, coagulation regulation, immune function, and regulating fluid control within the vessel and extravascular space. The endothelium can cause adhesion and aggregation of neutrophils and stimulate smooth muscle growth.

The endothelium is essential to the regulation and maintenance of vasodilating and vasoconstricting substances. Endothelium-derived vasoactive substances include *nitric oxide* (NO) and *prostacyclin*, which are both vasodilators. Another product of the endothelium is *endothelin* (ET), which is a potent vasoconstrictor (Fig. 32.1). Cardiovascular risk factors, such as smoking and diabetes, can reduce functional endothelial cells. This can cause arterial tone changes (through either excessive constriction or dilation), which is an early warning signal of CVD.

Renal System

The kidneys contribute to BP regulation by controlling sodium excretion and extracellular fluid (ECF) volume (see Chapter 44). Sodium retention results in water retention, which causes an increase in ECF volume. This action increases the venous return to the heart and SV. Together these increase CO and BP.

The renin-angiotensin-aldosterone system (RAAS) plays an essential role in BP regulation (Fig. 32.1). The juxtaglomerular apparatus in the kidney secretes renin in response to SNS stimulation, decreased blood flow through the kidneys, or decreased serum sodium concentration. Renin is an enzyme that converts angiotensinogen to angiotensin I. Angiotensin I is then converted to angiotensin II (A-II) by angiotensin-converting enzyme (ACE). A-II increases BP by 2 different mechanisms (see Fig. 44.4). First, A-II is a potent vasoconstrictor and increases SVR. This results in an immediate increase in BP. Second, over a period of hours or days, A-II increases BP indirectly by stimulating the adrenal cortex to secrete

aldosterone.

A-II acts at a local level within the heart and blood vessels. These effects include vasoconstriction and tissue growth that result in remodeling of the vessel walls, which can be due to or caused by endothelial dysfunction. These changes are linked to the development of primary hypertension and the long-term effects of hypertension (e.g., atherosclerosis, renal disease, cardiac hypertrophy).

Prostaglandins (PGE_2 and PGI_2) secreted by the renal medulla have a vasodilator effect on the systemic circulation. This results in decreased SVR and lowering of BP. Heart cells secrete the natriuretic peptides (atrial natriuretic peptide [ANP] and b-type natriuretic peptide [BNP]). They oppose the effects of antidiuretic hormone (ADH) and aldosterone. This results in *natriuresis* (excretion of sodium in urine) and diuresis, resulting in reduced blood volume and BP.

Endocrine System

SNS stimulation results in the release of epinephrine along with a small fraction of NE by the adrenal medulla. Epinephrine increases CO by increasing HR and myocardial contractility. Epinephrine activates β_2-adrenergic receptors in peripheral arterioles of skeletal muscle, causing vasodilation. In peripheral arterioles with only α_1-adrenergic receptors (skin and kidneys), epinephrine causes vasoconstriction.

A-II stimulates the adrenal cortex to release aldosterone. Aldosterone stimulates the kidneys to retain sodium and water, which increases blood volume and CO (see Fig. 44.4).

Increased blood sodium and osmolarity levels stimulates the release of ADH from the posterior pituitary gland. ADH increases the ECF volume by promoting the reabsorption of water in the distal and collecting tubules of the kidneys. The resulting increase in blood volume causes an increase in CO and BP.

Hypertension

Classification of Hypertension

Table 32.2 shows the BP classifications for people 18 years of age and older. Normal blood pressure is defined as a systolic BP (SBP) < 120 mm Hg and a diastolic BP (DBP < 80 mm Hg. **Elevated blood pressure** is defined as an SBP between 120 -129 mm Hg and a DBP < 80 mm Hg. *Hypertension (stage 1)* is defined as an SBP between 130-139 mm Hg and a DBP between 80-89 mm Hg. *Hypertension (stage 2)* is defined as an SBP > 140 mm Hg and a DBP > 90 mm Hg.[5] If either the SBP or DBP is outside of a range, the higher measurement determines the classification. For example, 115/86 would be classified as hypertension stage 1 even though the SBP is within normal limits. SBP increases with age. DBP rises until around 55 years old and then declines. BP classification is based on 2 or more readings, accurately performed on both arms, on 2 separate occasions.

Etiology

Hypertension can result from either primary or secondary causes.

Primary Hypertension

Primary hypertension *(essential* or *idiopathic)* is elevated BP without an identified cause. It accounts for 90% to 95% of all cases of hypertension. Although the exact reason for primary hypertension is unknown, there are multiple contributing factors. These include changes in endothelial function related to either vasoconstricting or vasodilating agents, increased SNS activity, overproduction of sodium-retaining hormones, increased sodium intake, greater than ideal body weight, age, family history, ethnicity, diabetes, tobacco use, and excess alcohol intake.

Secondary Hypertension

Secondary hypertension is elevated BP with a specific cause that often can be identified and corrected (Table 32.3). Secondary hypertension can become resistant, causing cardiovascular

complications if left untreated. This type of hypertension accounts for 5% to 10% of hypertension in adults. Secondary hypertension should be suspected in people who suddenly develop high BP, especially if it is severe. Findings that suggest secondary hypertension relate to the underlying cause. For example, an abdominal bruit heard over the renal arteries may indicate renal disease. It is often present in patients with obstructive sleep apnea. Treatment is aimed at removing or treating the underlying cause. Secondary hypertension is a contributing factor to hypertensive crisis (discussed later in this chapter).

TABLE 32.2 Classification of Hypertension

Category	SBP (mm Hg)		DBP (mm Hg)
Normal	<120	and	<80
Elevated	120–129	and	<80
Hypertension, stage 1	130–139	or	80–89
Hypertension, stage 2	≥140	or	≥90

DBP, Diastolic blood pressure; *SBP*, systolic blood pressure.

Source: Whelton PK, Carey RM, Aronow WS, et al: 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: A report of the American College of Cardiology/AHA Task Force on Clinical Practice Guidelines, *Journal of the American College of Cardiology* 71:e127, 2018.

Pathophysiology of Primary Hypertension

BP rises with any increase in CO or SVR. As hypertension progresses from elevated to stage 1, increases in both blood volume and CO are often present, leading to an increase in SVR. As hypertension progresses, SVR rises, and CO returns to normal. The hemodynamic hallmark of hypertension is a persistently increased SVR. This persistent elevation in SVR may occur in several ways. Table 32.4

shows factors that relate to the development of primary hypertension or contribute to its consequences. Abnormalities of any of the mechanisms involved in maintaining normal BP can result in hypertension (Fig. 32.1).

Genetic Link

Different sets of genes may regulate BP at various times throughout the life span.[2] Genetic variations are associated with the development of hypertension. For example, genetic abnormalities have been associated with a rare form of hypertension characterized by excess levels of potassium. Several genetic variants of substances on the endothelium affect BP and the development of hypertension by influencing the body's sensitivity to salt. When endothelial surface proteins are activated, proinflammatory properties are stimulated, impairing the endothelial cells' ability to activate vasodilatory effects, which leads to hypertension.

Research is currently ongoing to understand the complicated role that endothelial dysfunction and genetics play in the formation and progression of hypertension. We currently recommend screening of children and siblings of persons with hypertension and strongly advising them to adopt healthy lifestyles to minimize their risk for developing hypertension.

Water and Sodium Retention

Excess sodium intake is linked to the development of hypertension. Although most people consume a high-sodium diet, only 1 in 3 will develop hypertension. When sodium is restricted in people with hypertension, their BP usually falls. This suggests that some degree of sodium sensitivity may exist for high sodium intake to trigger the development of hypertension. A high sodium intake may activate a number of systemic mechanisms. Fig. 32.2 shows the relationships among salt intake, BP, and changes in the structure of the heart.

TABLE 32.3 Common Causes of Secondary Hypertension

- Cirrhosis
- Coarctation or congenital narrowing of the aorta
- Drug-related: estrogen replacement therapy, oral contraceptives, corticosteroids, nonsteroidal antiinflammatory drugs (e.g., cyclooxygenase-2 inhibitors), SNS stimulants (e.g., cocaine, monoamine oxidase)
- Endocrine disorders (e.g., pheochromocytoma, Cushing syndrome, thyroid disease)
- Neurologic disorders (e.g., brain tumors, quadriplegia, traumatic brain injury)
- Pregnancy-induced hypertension
- Renal disease (e.g., renal artery stenosis, glomerulonephritis)
- Sleep apnea

In clinical practice, there is not an easy or straightforward test to identify people whose BP will rise with even a small increase in salt intake *(salt sensitive)* versus those who can ingest large amounts of sodium without much change in BP *(salt resistant).* The effect of sodium on BP has a strong genetic component. The effect of sodium is more significant in blacks and middle-aged and older adults. This can increase the potential of renal dysfunction, endothelial dysfunction, and HF in these persons.[7,8]

TABLE 32.4 Risk Factors for Primary Hypertension

Risk Factor	Description
Age	• Systolic BP rises progressively with age. • After age 50, SBP >140 mm Hg is a more important cardiovascular risk factor than diastolic BP
Alcohol	• Excess alcohol intake is strongly associated with hypertension • Moderate intake of alcohol has cardioprotective properties; males should limit their daily intake of alcohol to 2 drinks per day, and 1 drink per day for females
Diabetes	• Hypertension is more common in patients with diabetes • When hypertension and diabetes coexist, complications (e.g., target organ disease) are more severe
Elevated serum lipids	• ↑ Levels of cholesterol and triglycerides are primary risk factors for atherosclerosis • Hyperlipidemia is more common in people with hypertension
Ethnicity	• The incidence of hypertension is 2 times higher in blacks than in whites (See Promoting Health Equity box on p. 679.)
Excess dietary sodium	• High sodium intake can • Contribute to hypertension in salt-sensitive patients • Decrease the effectiveness of certain antihypertensive drugs
Family history	• History of a close blood relative (e.g., parents, sibling) with hypertension is associated with an ↑ risk for developing hypertension
Gender	• Hypertension is more prevalent in men in young adulthood and early middle age • After age 64, hypertension is more prevalent in women (See Gender Differences box on p. 679)
Obesity	• Weight gain is associated with ↑ frequency of hypertension • Risk increases with central abdominal obesity
Sedentary lifestyle	• Regular physical activity can help control weight and reduce cardiovascular risk • Physical activity may ↓ BP
Socioeconomic status	• Hypertension is more prevalent in lower socioeconomic groups and among the less educated
Stress	• People exposed to repeated stress may develop hypertension more often than others • People who develop hypertension may respond differently to stress than those who do not develop hypertension
Tobacco use	• Smoking tobacco greatly ↑ risk for CVD • People with hypertension who smoke tobacco are at even greater risk for CVD

Altered Renin-Angiotensin-Aldosterone Mechanism

High plasma renin activity (PRA) increases the conversion of angiotensinogen to angiotensin I (see Fig. 44.4). This change in the RAAS may contribute to the development of hypertension. Any rise in BP inhibits the release of renin from the renal juxtaglomerular cells. Based on this feedback loop, we would expect low levels of PRA in patients with primary hypertension. However, only about 30% have low PRA, 50% have normal levels, and 20% have high PRA. These normal or high PRA levels may be related to excess renin secretion from ischemic nephrons.

Stress and Increased Sympathetic Nervous System Activity

We have long recognized that factors such as anger, fear, and pain influence BP. Physiologic responses to stress, which are typically protective, may persist to a pathologic degree, resulting in a prolonged increase in SNS activity. Increased SNS stimulation

produces increased vasoconstriction, increased HR, and increased renin release. Increased renin activates the RAAS, leading to elevated BP. People with high levels of repeated psychological stress develop hypertension more than those who have less stress.

Insulin Resistance and Hyperinsulinemia

Defects in glucose, insulin, and lipoprotein metabolism are common in primary hypertension. These defects are not present in secondary hypertension and do not improve when primary hypertension is treated. Insulin resistance is a risk factor in the development of hypertension and CVD. High insulin levels stimulate SNS activity and impair nitrous oxide–mediated vasodilation. Other pressor effects of insulin include vascular hypertrophy and increased renal sodium reabsorption.

Endothelial Dysfunction

Endothelial dysfunction is a marker for CVD, including primary hypertension. Hypertension can manifest as a prolonged vasoconstriction response or as a reduced vasodilator response. High levels of ET may cause prolonged vasoconstriction. Vasodilation effects can be altered by oxygen free radicals, which impair the bioavailability of NO. This leads to cellular dysfunction and an imbalance of the vasodilation and vasoconstriction mechanisms in the endothelium.

Clinical Manifestations

Hypertension is often called the “silent killer” because it is often asymptomatic until it becomes severe and target organ disease occurs. A patient with severe hypertension may have a variety of symptoms secondary to the effects on blood vessels in the various organs and tissues or to the increased workload of the heart. These secondary symptoms include fatigue, dizziness, palpitations, angina, and dyspnea.

In the past, we thought headaches and nosebleeds were symptoms

of hypertension. Unless BP is very high, these symptoms are no more frequent in people with hypertension than in the general population. However, patients with hypertensive crisis (discussed later in the chapter) may have severe headaches, dyspnea, anxiety, and nosebleeds.[9]

Complications

The most common complications of hypertension are *target organ diseases* occurring in the heart (hypertensive heart disease), brain (cerebrovascular disease), peripheral vessels (peripheral vascular disease), kidneys (nephrosclerosis), and eyes (retinal damage) (Fig. 32.3).

Hypertensive Heart Disease

Coronary Artery Disease

Hypertension is a significant risk factor for coronary artery disease (CAD). The mechanisms by which hypertension contributes to the development of atherosclerosis are not fully known. The "response-to-injury" theory of atherogenesis suggests that hypertension disrupts the coronary artery endothelium (see Fig. 33.1). This results in a rigid arterial wall with a narrowed lumen and may account for the high rate of CAD, angina, and MI.

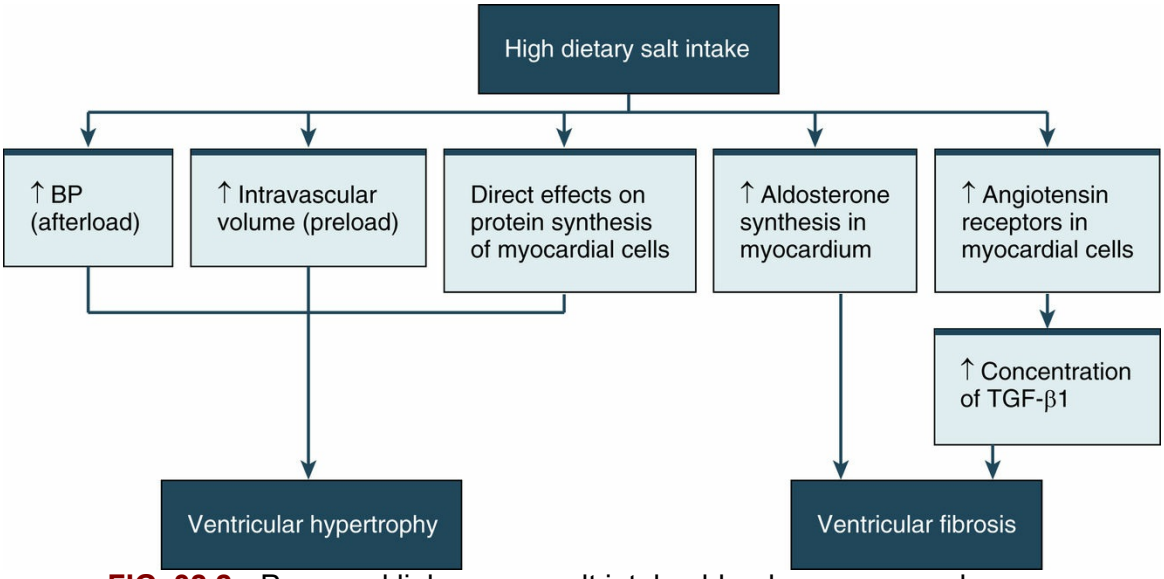

FIG. 32.2 Proposed link among salt intake, blood pressure, and changes in the heart. High dietary salt intake exerts hypertrophic effects on the left (and potentially also on the right) ventricle. Ventricular fibrosis can also result from the high salt intake through mechanisms mediated by the renin-angiotensin-aldosterone system (RAAS). Transforming growth factor-β1 (TGF-β1) is a multifunctional cytokine with fibrogenic properties. Overproduction of TGF-β1 (in part mediated by angiotensin II) results in fibrosis and ventricular dysfunction.

Modified from Frisoli TM, Schmieder RE, Grodzicki T, et al: Salt and hypertension: Is salt dietary reduction worth the effort? *Am J Med* 125:433, 2012.

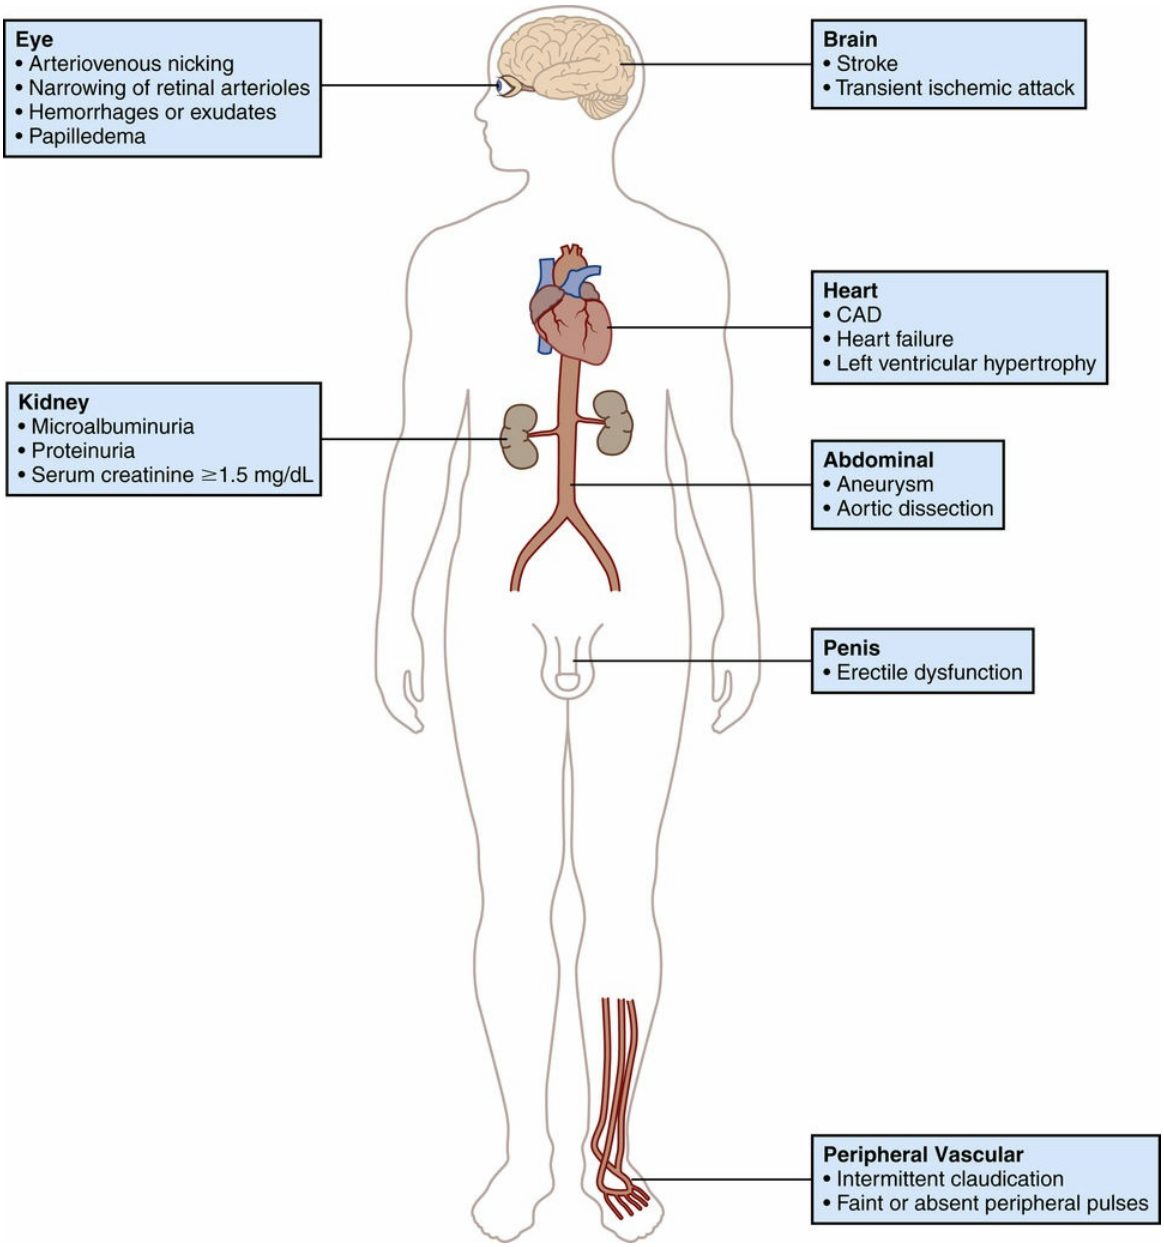

FIG. 32.3 Common complications of hypertension.

Left Ventricular Hypertrophy

Sustained high BP increases the cardiac workload and produces left ventricular hypertrophy (LVH) (Fig. 32.4). Initially, LVH is a compensatory mechanism that strengthens cardiac contraction and increases CO. However, increased contractility increases myocardial work and O_2 demand. Progressive LVH, especially in the presence of CAD, is associated with the development of HF.

Heart Failure

HF occurs when the heart's compensatory mechanisms are overwhelmed and the heart can no longer pump enough blood to meet the body's demands (see Chapter 34). Contractility is depressed, and SV and CO are decreased. The patient may have shortness of breath on exertion, paroxysmal nocturnal dyspnea, and fatigue.

Cerebrovascular Disease

Atherosclerosis is the most common cause of cerebrovascular disease. Hypertension is a significant risk factor for cerebral atherosclerosis and stroke. Even in mildly hypertensive people, the risk for stroke is 4 times higher than in normotensive people. Adequate BP control decreases the risk for stroke.

Atherosclerotic plaques are often found at the bifurcation of the common carotid artery and in the internal and external carotid arteries. Portions of the atherosclerotic plaque or the blood clot that forms with disruption of the plaque may break off and travel to cerebral vessels, producing a thromboembolism. The patient may have transient ischemic attacks or a stroke. These conditions are discussed in Chapter 57.

Hypertensive encephalopathy may occur after a marked rise in BP if autoregulation does not decrease the cerebral blood flow. *Autoregulation* is a physiologic process that keeps cerebral blood flow constant despite fluctuations in BP. Typically, as pressure in the cerebral blood vessels rises, the vessels constrict to maintain constant flow. When BP exceeds the body's ability to autoregulate, the cerebral vessels suddenly dilate, capillary permeability increases, and cerebral edema develops. This produces a rise in intracranial pressure. If left untreated, patients can die quickly from brain damage. Chapter 56 reviews cerebral blood flow and autoregulation.

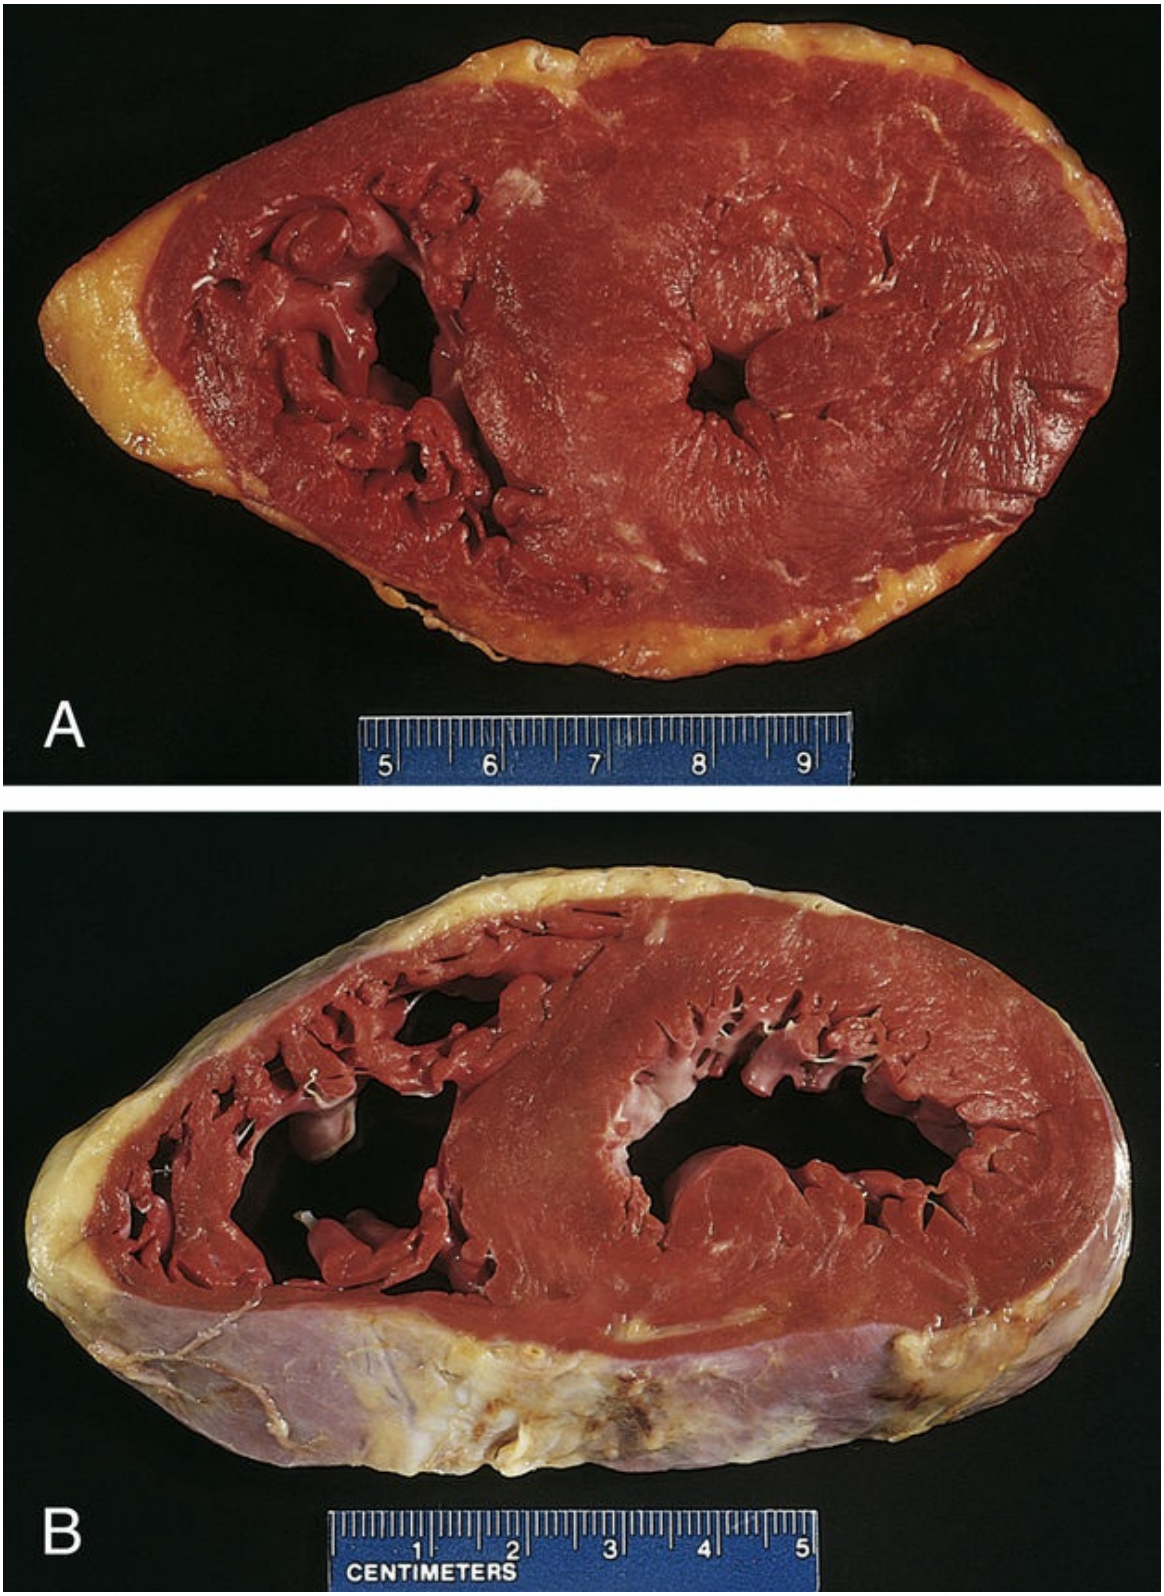

FIG. 32.4 **A,** Massively enlarged heart caused by hypertrophy of the muscle in the left ventricle. **B,** Compare with the thickness of the normal left ventricle. The patient had from severe hypertension.

From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology,* ed 8, Philadelphia, 2007, Saunders.

Peripheral Vascular Disease

Hypertension speeds up the process of atherosclerosis in the peripheral blood vessels. This leads to peripheral vascular disease (PVD), aortic aneurysm, and aortic dissection (see Chapter 37). *Intermittent claudication* (ischemic leg pain precipitated by activity and relieved by rest) is a classic symptom of PVD.

Nephrosclerosis

Hypertension is one of the leading causes of chronic kidney disease (CKD), especially among blacks. Some degree of renal disease is usually present even with mild hypertension. Renal disease results from ischemia caused by the narrowing of the renal blood vessels. This leads to atrophy of the tubules, destruction of the glomeruli, and eventual death of nephrons. Initially intact nephrons can compensate, but these changes may eventually lead to renal failure. Laboratory signs of renal disease are albuminuria, proteinuria, microscopic hematuria, and high serum creatinine and blood urea nitrogen (BUN) levels. Nocturia is an early symptom of renal disease (see Chapter 46).

Retinal Damage

The appearance of the retina gives essential information about the severity and duration of hypertension. We can directly see the blood vessels of the retina with an ophthalmoscope. Damage to the retinal vessels indicates related vessel damage in the heart, brain, and kidneys. Manifestations of severe retinal damage include blurring of vision, retinal hemorrhage, and vision loss.

Diagnostic Studies

Measurement of BP is essential in assessing and monitoring hypertension. Chapter 31 and the Nursing Management section later

in this chapter discuss BP measurement.

Some controversy exists over the diagnostic workup in the initial assessment of a person with hypertension. Most hypertension is classified as primary hypertension. Basic laboratory studies may be done to (1) identify or rule out causes of secondary hypertension, (2) evaluate target organ disease, (3) determine overall cardiovascular risk, or (4) establish baseline levels before starting therapy.

Table 32.5 lists diagnostic studies performed in a person with hypertension. Routine urinalysis, BUN, and serum creatinine levels are used to screen for renal involvement and provide baseline information about kidney function. Creatinine clearance reflects the glomerular filtration rate. Decreases in creatinine clearance indicate renal insufficiency. Chapter 44 discusses serum creatinine and creatinine clearance.

Measurement of serum electrolytes, especially potassium, is essential to detect hyperaldosteronism, a cause of secondary hypertension. Blood glucose levels aid in the diagnosis of diabetes. A lipid profile gives information about risk factors related to atherosclerosis and CVD. Uric acid levels establish a baseline since the levels often rise with diuretic therapy. An electrocardiogram (ECG) gives baseline information about heart status. It can identify the presence of LVH, cardiac ischemia, or previous MI. If LVH is suspected, echocardiography is often done. If the patient's age, history, physical examination, or severity of hypertension points to a secondary cause, further diagnostic testing is needed.

TABLE 32.5 Interprofessional CareHypertension

Diagnostic Assessment

- History and physical examination, including an ophthalmic examination
- Fasting blood glucose

- Routine urinalysis
- Basic metabolic panel with eGFR
- Complete blood count
- Serum lipid profile (total lipids, triglycerides, HDL and LDL cholesterol, total-to-HDL cholesterol ratio)
- Serum uric acid, calcium, and magnesium
- 12-Lead ECG

Optional

- 24-hour urinary creatinine clearance
- Echocardiography
- Liver function studies
- Serum thyroid-stimulating hormone (TSH)

Management

- Periodic BP monitoring
    - Home BP monitoring
    - Ambulatory BP monitoring
    - Every 3 to 6 months by an HCP once goal BP is achieved and stabilized
- Nutritional therapy
    - Restrict salt and sodium
    - Restrict cholesterol and saturated fats
    - Maintain adequate intake of potassium and calcium
    - Weight management
- Regular, moderate physical activity
- Tobacco cessation (see Tables 10.4 through 10.6)
- Moderation of alcohol intake

- Stress management techniques (see Chapter 6)
- Antihypertensive drugs (Tables 32.7, 32.8 and 32.9)
- Patient and caregiver teaching

eGFR, Estimated glomerular filtration rate.

Ambulatory Blood Pressure Monitoring

Some patients have elevated BP readings in a clinical setting and normal readings when BP is measured elsewhere. This phenomenon is referred to as *"white coat"* hypertension. Ambulatory BP monitoring (ABPM) is one method for diagnosing white coat hypertension. It is a noninvasive, fully automated system that measures BP at preset intervals over a 12- to 24-hour period. The equipment is worn continuously for 24 hours, and results are reviewed by the provider. The monitoring equipment includes a BP cuff and a microprocessing unit that fits into a pouch worn on a shoulder strap or belt. Tell patients to hold their arm still by their side when the device is taking a reading. Have them keep a diary of activities that may affect BP. Other potential applications for ABPM include suspected antihypertensive drug resistance, hypotensive symptoms with antihypertensive therapy, episodic hypertension, or SNS dysfunction.

BP has diurnal variability expressed as sleep-wakefulness difference. For day-active people, BP is highest in the early morning, decreases during the day, and is lowest at night. BP at night (during sleep) usually drops by 10% or more from daytime (awake) BP.[5] ABPM verifies the presence of diurnal variability.

Some patients with hypertension do not show a typical nocturnal dip in BP. They are referred to as "nondippers." Patients at highest risk for CVD are "reverse dippers." These patients have an increase in nighttime systolic BP. Current research is focused on using drugs to optimize cardioprotective effects and convert nondippers and reverse dippers to dippers.

Evidence-Based Practice

Lifestyle Changes and Uncontrolled Hypertension

You are caring for F.H., a 43-yr-old black, female patient with a history of poorly controlled hypertension and CKD. She is taking 3 antihypertensive drugs and tells you she no longer can tolerate the side effects (e.g., fatigue, peripheral edema, dry mouth, frequent voiding). She wants to stop taking the drugs and control her hypertension by weight loss, exercise, and reducing her salt intake.

Making Clinical Decisions

Best Available Evidence. Nonpharmacologic interventions to reduce and control BP include weight loss (if appropriate), a DASH diet, and potassium supplementation; regular physical activity; and limiting women to no more than 1 alcohol drink per day. The potential impact of each lifestyle change is a 4-5 mm Hg decrease in SBP and 2-4 mm Hg decrease in DBP. A DASH diet may decrease SBP by about 11 mm Hg. Antihypertensive medications reduce the risk for cerebrovascular events, HF, and overall mortality in patients with concurrent risk for CVD (e.g., diabetes, kidney disease). Most hypertensive patients will need to take 2 or more medications on a long-term basis to achieve their goal BP, in addition to lifestyle changes.

Clinician Expertise. You know lifestyle changes can help reduce and control BP in some patients and should always be encouraged. However, patients with poorly controlled hypertension and target organ disease need medications to control BP and prevent further catastrophic complications (e.g., stroke).

Patient Preferences and Values. F.H. wants to stop her antihypertensive drugs because of unacceptable side effects.

Implications for Nursing Practice

1. What factors would you discuss with F.H. related to hypertension treatment and preventing further target organ disease?
2. Would you support F.H. in her desire to stop taking her prescribed drugs? Why or why not?
3. How can you help F.H. with her intentions to make lifestyle changes?

Interprofessional Care

Table 32.5 summarizes the interprofessional care for a patient with hypertension. Goals include achieving and maintaining goal BP and reducing cardiovascular risk and target organ disease. Lifestyle modifications are a part of therapy for all patients with elevated blood pressure and hypertension.

Lifestyle Modifications

Lifestyle modifications are directed toward reducing the patient's BP and overall cardiovascular risk. The AHA's "Life's Simple 7" steps support ways to modify and improve health. These are (1) manage blood pressure, (2) control cholesterol, (3) reduce blood sugar, (4) get active, (5) eat better, (6) lose weight, and (7) stop smoking. Other modifications by the taskforce on hypertension address sodium restrictions and alcohol intake. Tools used by the AHA are available online at*www.heart.org/HEARTORG/Conditions/My-Life-Check---Lifes-Simple-7_UCM_471453_Article.jsp#.Wm1uaainHIU*.

Weight Reduction

Persons who are overweight have an increased incidence of hypertension and increased risk for CVD. Weight reduction has a significant effect on lowering BP in many people. The effect is seen with even moderate weight loss. A rule of thumb is for every 1 kg of weight lost, BP will decrease by 1 mm Hg. When a person decreases caloric intake, sodium and fat intake are usually also reduced. Although reducing the fat content of the diet has not shown any sustained benefits in BP control, it may slow the progress of atherosclerosis and reduce overall CVD risk (see Chapter 33). Weight reduction through a combination of calorie restriction and moderate physical activity is recommended for overweight patients with hypertension (see Chapter 40).

DASH Eating Plan

The DASH (Dietary Approaches to Stop Hypertension) eating plan stresses fruits, vegetables, fat-free or low-fat milk and milk products, whole grains, fish, poultry, beans, seeds, and nuts. Compared with the typical American diet, the plan has less red meat, salt, sweets, added sugars, and sugar-containing beverages. The DASH eating plan significantly lowers BP and reduces low-density lipoprotein (LDL) cholesterol.[7]

Dietary Sodium Reduction

Healthy adults should restrict sodium intake to 2300 mg/day or less. Blacks, people middle aged and older, and those with hypertension, diabetes, or CKD should restrict sodium to 1500 mg/day or less.[7] This involves avoiding foods known to be high in sodium. The AHA calls 6 food groups that are the highest sodium sources throughout the United States the "Salty Six." They recommend not adding salt and reducing intake of foods in these groups: bread products, lunch meat and cured meats, pizza, soup, sandwiches, and poultry (see Table 34.8).

Most adults exceed the recommended limits for sodium. Average

sodium intake is around 4200 mg/day in men and 3300 mg/day in women.[8] The patient and caregiver, especially the person who prepares the meals, need to learn about low-sodium diets. Teaching should include reading labels of over-the-counter (OTC) drugs, prepared and packaged foods, and health products (e.g., toothpaste containing baking soda) to identify hidden sources of sodium. Review the patient's typical diet to identify foods high in sodium.

Sodium restriction may be enough to control BP in some patients. This may allow for lower drug dosages. Further, moderate sodium restriction lessens the risk for hypokalemia associated with diuretic therapy. However, the response differs between patients who are salt sensitive or salt resistant.

The significance of other dietary elements for the control of hypertension is not certain. Increased levels of dietary potassium and calcium are associated with lower BP in the general population and those with hypertension. People with hypertension should receive adequate intake of these from food sources. Calcium supplements are not recommended to lower BP.

Moderation of Alcohol Intake

Excess alcohol intake is strongly associated with hypertension. Drinking 3 or more alcoholic drinks a day is a risk factor for CVD and stroke. Men should limit their intake of alcohol to no more than 2 drinks per day and women and lighter weight men to no more than 1 drink per day; 1 drink is defined as 12 oz of regular beer, 5 oz of wine (12% alcohol), or 1.5 oz of 80-proof distilled spirits. Excess alcohol intake that results in cirrhosis is a frequent cause of secondary hypertension.

Physical Activity

A physically active lifestyle is essential to promote good health. The AHA and American College of Sports Medicine recommend that adults perform a moderate-intensity aerobic physical activity for at least 30 minutes most days (i.e., more than 5 days per week) with a goal of at least 150 minutes per week. Exercise goals can be achieved

by performing shorter periods of exercise that last at least 10 minutes, several times during a day. Combinations of moderate and vigorous activity are acceptable (e.g., walking briskly for 30 minutes on 2 days of the week and jogging for 20 minutes on 2 other days).[10]

Differences in physical activity guidelines exist for adults age 18 to 65 years, adults over 65 years, and adults age 50 to 64 years with functional limitations. The differences relate to the definition of moderate and vigorous aerobic activity. For adults ages 18 to 65, walking briskly at a pace that noticeably increases the pulse defines moderate-intensity aerobic activity. Jogging at a pace that substantially increases the pulse and causes rapid breathing is an example of vigorous activity for this age group. For all other adults, individual fitness levels guide aerobic intensity.[10]

All adults should perform muscle-strengthening activities using the major muscles of the body at least twice a week. This helps to maintain or increase muscle strength and endurance. Flexibility and balance exercises are recommended at least twice a week for older adults, especially for those at risk for falls.[11] Moderate-intensity activities can lower BP, promote relaxation, and decrease or control body weight. Regular activity of this type can reduce SBP by 4 to 9 mm Hg.[5]

Physical activity is more likely to become a habit if it is safe and enjoyable, fits easily into one's daily schedule, and is inexpensive. Many shopping malls open early in the morning, offering a warm, safe, flat area for walking. Some health clubs offer special "off-peak" rates to encourage physical activity among older adults. Some health insurance carriers offer health club discounts as a benefit to encourage member fitness. Cardiac rehabilitation programs offer supervised exercise and education about cardiovascular risk factor reduction.

Help people with hypertension to increase their physical activity by explaining the need for physical activity, describing the types of physical activities, and aiding in starting an exercise plan. Advise sedentary people to increase activity levels gradually. Those with CVD or other serious health problems need a thorough examination and possibly a stress test before beginning an exercise program.

Avoiding Tobacco Products

Nicotine contained in tobacco causes vasoconstriction and increases BP, especially in people with hypertension. Smoking tobacco is a major risk factor for CVD. The cardiovascular benefits of stopping tobacco use are seen within a year in all age-groups. Strongly encourage everyone, especially patients with hypertension, to avoid tobacco use. Advise those who continue to use tobacco products to monitor their BP during use. Chapter 10 discusses tobacco use and smoking cessation.

Managing Risk Factors

Risk factors can be related to social determinants of health and psychosocial risk factors. These factors can contribute to the risk for developing CVD, and to a poorer prognosis and clinical course in patients with CVD. Social determinants of health are defined by the World Health Organization as "the conditions in which people are born, grow, live, work, and age, and the wider set of forces and systems shaping the conditions of daily life."[12] These factors include socioeconomic status, resources to meet daily needs, emotional and social support systems, stress at work and in family life, educational preparation, access to health care, safe housing, exposure to crime and violence, and negative emotions, such as depression and hostility. Often, these risk factors are clustered. For example, rates of depression tend to be higher in people with job stress or without access to safe housing.

These risk factors have direct effects on the cardiovascular system by activating the SNS and stress hormones. A wide variety of pathophysiologic responses can occur, including hypertension and tachycardia, inflammation, endothelial dysfunction, increased platelet aggregation, insulin resistance, and central obesity.[12]

Social determinants of health and psychosocial risk factors can contribute to CVD indirectly by their impact on lifestyle behaviors and choices. Screening for risk factors is essential so appropriate referrals can be given to help the patient and family. Referrals might include counseling, behavioral interventions, such as community or

religious support systems, social work assistance for finding resources, such as fresh fruits and vegetables, or information on housing assistance. Once basic needs are met, options that can be beneficial might include relaxation training, stress management courses, support groups, and exercise training for people who are not in acute psychologic distress.[13]

Drug Therapy

The following are recommendations for antihypertensive drug therapy from the 2017 High Blood Pressure Clinical Practice Guidelines[5]:

- In patients 65 years or older with an average SBP of more than 130 mm Hg who are ambulatory and living in a community setting, rather than living in a care facility, treatment goals should be to obtain an SBP < 130 mmHg.
- In patients 65 years or older with an average SBP of more than 130 mm Hg who live in a care facility, and/or have multiple comorbidities or limited life expectancy, treatment should be based on patient preference, clinical experiences, and team input.
- In patients over 18 years old with hypertension, known CVD or other risk factors, a BP of 130/80 mm Hg is the goal of treatment.
- In all other patients without CVD or other risk factors, a BP of less than 130/80 mm Hg may be reasonable.

Drugs currently available for treating hypertension have 2 primary actions: (1) decrease the volume of circulating blood and (2) reduce SVR (Tables 32.6, 32.7, and 32.8).[5] Fig. 32.5 shows the various sites and methods of action of antihypertensive agents. Drugs used in the treatment of hypertension include:

TABLE 32.6 Drug TherapyAntihypertensive Agents

Drug	Mechanism of Action	Nursing Considerations
Adrenergic Inhibitors		
Central-Acting α-Adrenergic Agonist		
clonidine (Catapres) **clonidine patch (Catapres-TTS)**	Reduce sympathetic outflow from central nervous system Reduce peripheral sympathetic tone, produces vasodilation, decreases SVR and BP	Sudden discontinuation may cause withdrawal syndrome, including rebound hypertension, tachycardia, headache, tremors, apprehension, sweating Chewing gum or hard candy may relieve dry mouth Alcohol and sedatives increase sedation Transdermal patch may be related to fewer side effects and better adherence
guanabenz **guanfacine (Tenex)**	Same as clonidine	Same as clonidine, but not available in the transdermal formulation
methyldopa	Same as clonidine	Teach patient about daytime sedation and avoiding hazardous activities Taking a single daily dose at bedtime minimizes the sedative effect
α_1-Adrenergic Blockers		
doxazosin (Cardura) **prazosin (Minipress)** **terazosin**	Block α_1-adrenergic effects, producing peripheral vasodilation (decreases SVR and BP) Beneficial effects on lipid profile	Reduced resistance to the outflow of urine in benign prostatic hyperplasia Take at bedtime to reduce risk associated with orthostatic hypotension
phentolamine	Blocks α_1-adrenergic receptors, resulting in peripheral vasodilation (decreases SVR and BP)	Used in the short-term management of pheochromocytoma Used locally to prevent necrosis of skin and subcutaneous tissue after extravasation of adrenergic drug No oral formulation
β-Adrenergic Blockers		
Cardioselective Blockers		
acebutolol (Sectral) **atenolol (Tenormin)** **betaxolol** **bisoprolol** **esmolol (Brevibloc)** **metoprolol (Lopressor)**	Block β_1-adrenergic receptors (Table 32.1) Reduce BP by blocking β-adrenergic effects Decrease CO and reduce sympathetic vasoconstrictor tone Decrease renin secretion by kidneys	Monitor pulse and BP regularly Use with caution in patients with diabetes because may depress the tachycardia associated with hypoglycemia and adversely affect glucose metabolism Drug of choice for patients with a history of an MI or HF Less effective BP reduction in black patients Esmolol is for IV use only Lose cardioselectivity at higher doses
Non-Cardioselective Blockers		
nadolol (Corgard) **pindolol** **propranolol (Inderal)**	Block β_1- and β_2-adrenergic receptors (Table 32.1) Reduce BP by blocking β_1- and β_2-adrenergic effects	Same as cardioselective, except may cause bronchospasm, especially in patients with a history of asthma

Table Continued

Drug	Mechanism of Action	Nursing Considerations
Mixed α- and β-Blockers		
carvedilol (Coreg) **labetalol**	α_1-, β_1-, and β_2-adrenergic blocking properties producing peripheral vasodilation and decreased heart rate (Table 32.1) Reduce CO, SVR, and BP	Same as β-blockers IV form is available for hypertensive crisis in hospitalized patients Keep patient supine during IV administration Assess patient tolerance of upright position (severe orthostatic hypotension) before allowing upright activities (e.g., commode)
Angiotensin Inhibitors		
Angiotensin-Converting Enzyme (ACE) Inhibitors		
benazepril (Lotensin) **captopril** **enalapril (Vasotec)** **fosinopril** **lisinopril (Zestril)** **moexipril** **perindopril** **quinapril (Accupril)** **ramipril (Altace)** **trandolapril (Mavik)**	Inhibit ACE, reduce conversion of angiotensin I to angiotensin II (A-II) Inhibit A-II–mediated vasoconstriction	Aspirin and NSAIDs may reduce effectiveness Adding a diuretic enhances effect, but should not be used with potassium-sparing diuretics Can cause an increase in serum creatinine Inhibit breakdown of bradykinin, which may cause a dry, hacking cough that can occur at any point during treatment, even years later Captopril may be given orally for hypertensive crisis
Angiotensin II Receptor Blockers (ARBs)		
azilsartan (Edarbi) **candesartan (Atacand)** **eprosartan (Teveten)** **irbesartan (Avapro)** **losartan (Cozaar)** **olmesartan (Benicar)** **telmisartan (Micardis)** **valsartan (Diovan)**	Prevent action of A-II and produce vasodilation and increased Na^+ and water excretion	Full effect on BP may not be seen for 3–6 wk Do not affect bradykinin levels, therefore an acceptable alternative to ACE inhibitors in people who develop a dry cough In patients with kidney disease, ACE inhibitors and ARBs should not be used together due to adverse renal effects
Calcium Channel Blockers		
Non-Dihydropyridines		
diltiazem extended release (Cardizem LA) **verapamil intermediate release (Calan)** **verapamil timed-release (Verelan PM)**	Inhibit movement of Ca^{++} across cell membrane, resulting in vasodilation Cardioselective resulting in a decrease in heart rate and slowing of AV conduction	Use with caution in patients with HF Grapefruit juice may increase serum concentrations and toxicity of certain calcium channel blockers; avoid concurrent use Used for supraventricular tachydysrhythmias Avoid in patients with second- or third-degree AV block or left ventricular systolic dysfunction
Dihydropyridines		
amlodipine (Norvasc) **clevidipine (Cleviprex)** **felodipine** **isradipine** **nicardipine sustained release** **nifedipine long acting (Procardia XL)** **nisoldipine (Sular)**	Cause vascular smooth muscle relaxation resulting in decreased SVR and arterial BP	More potent peripheral vasodilators Clevidipine is for IV use only; solution must be changed every 12 hrs Use of sublingual short-acting nifedipine in hypertensive emergencies is unsafe and not effective Serious adverse events (e.g., stroke, acute MI) have occurred IV nicardipine is available for hypertensive crisis in hospitalized patients; change peripheral IV infusion sites every 12 hrs
Direct Vasodilators		
fenoldopam (Corlopam)	Activates dopamine receptors, resulting in systemic and renal vasodilation	IV use only for hypertensive crisis in hospitalized patients Use cautiously in patients with glaucoma Patient should remain flat for 1 hr after administration
hydralazine	Reduces SVR and BP by direct arterial vasodilation	IV use for hypertensive crisis in hospitalized patients Twice-daily oral dosage Not used as monotherapy because of side effects Contraindicated in patients with CAD
minoxidil	Reduces SVR and BP by direct arterial vasodilation	Reserved for treatment of severe hypertension associated with renal failure and resistant to other therapy Once- or twice-daily dosage
nitroglycerin	Relaxes arterial and venous smooth muscle, reducing preload and SVR At a low dose, venous dilation predominates; at a higher dose, arterial dilation is present	IV use for hypertensive crisis in hospitalized patients with myocardial ischemia Given by continuous IV infusion with pump or control device

Drug	Mechanism of Action	Nursing Considerations
sodium nitroprusside	Direct arterial vasodilation reduces SVR and BP	IV use for hypertensive crisis in hospitalized patients Given by continuous IV infusion with pump or control device Arterial BP monitoring BP recommended Wrap IV solutions with an opaque material to protect from light Stable for 24 hrs then metabolized to cyanide, then thiocyanate Monitor thiocyanate levels with prolonged use (>3 days) or doses ≥4 mcg/kg/min

TABLE 32.7 Drug TherapyDiuretic Agents

Drug	Mechanism of Action	Nursing Considerations
Aldosterone Receptor Blockers		
spironolactone (Aldactone) **eplerenone (Inspra)**	Inhibit the Na^+-retaining and K^+-excreting effects of aldosterone in the distal and collecting tubules	Monitor for orthostatic hypotension and hyperkalemia Do not combine with potassium-sparing diuretics or potassium supplements Use with caution in patients on ACE inhibitors or angiotensin II blockers Classified as potassium-sparing diuretics
Loop Diuretics		
bumetanide (Bumex) **furosemide (Lasix)** **torsemide (Demadex)**	Inhibit NaCl reabsorption in the ascending limb of the loop of Henle Increase excretion of Na^+ and Cl^- More potent diuretic effect than thiazides, but shorter duration of action	Monitor for orthostatic hypotension and electrolyte abnormalities Remain effective despite renal insufficiency Diuretic effect increases at higher doses Less effective for hypertension
Thiazide and Related Diuretics		
chlorothiazide **chlorthalidone** **hydrochlorothiazide** **indapamide** **metolazone (Zaroxolyn)**	Inhibit NaCl reabsorption in the distal convoluted tubule Increase excretion of Na^+ and Cl^- Initial decrease in ECF Sustained decrease in SVR Lower BP moderately in 2–4 wk	Monitor for orthostatic hypotension, hypokalemia, and alkalosis May potentiate cardiotoxicity of digoxin by producing hypokalemia Dietary sodium restriction reduces the risk for hypokalemia NSAIDs can decrease diuretic and antihypertensive effect and potentially cause renal impairment Teach patient to supplement with potassium-rich foods
Potassium-Sparing Diuretics		
amiloride (Midamor) **triamterene (Dyrenium)**	Reduce K^+ and Na^+ exchange in the distal and collecting tubules Reduce excretion of K^+, H^+, Ca^{++}, and Mg^{++}	Monitor for orthostatic hypotension and hyperkalemia Contraindicated in patients with renal failure Use with caution in patients on ACE inhibitors or angiotensin II blockers Avoid potassium supplements
Renin Inhibitors		
Aliskiren hemifumarate (Tekturna)	Directly inhibits renin, thus reducing the conversion of angiotensinogen to angiotensin I	May cause angioedema of the face, extremities, lips, tongue, glottis, and/or larynx Not to be used in pregnancy

ECF, extracellular fluid.

- *Adrenergic-inhibiting agents* act by decreasing the SNS effects that increase BP. Adrenergic inhibitors include drugs that work centrally on the vasomotor center and peripherally to inhibit norepinephrine release or to block the adrenergic receptors on blood vessels.

- *Angiotensin-converting enzyme (ACE) inhibitors* prevent the conversion of angiotensin I to angiotensin II and reduce angiotensin II (A-II)–mediated vasoconstriction and sodium and water retention.
- *A-II receptor blockers (ARBs)* prevent angiotensin II from binding to its receptors in the walls of the blood vessels.
- *Calcium channel blockers* (*CCB*) increase sodium excretion and cause arteriolar vasodilation by preventing the movement of extracellular calcium into cells.
- *Direct vasodilators* decrease the BP by relaxing the vascular smooth muscle and reducing SVR.
- *Diuretics* promote sodium and water excretion, reduce plasma volume, and reduce the vascular response to catecholamines.

Drug Alert

Doxazosin (Cardura)

- Use caution when giving the first dose. It is best to give the first dose at bedtime to reduce the first dose BP drop.
- Syncope occasionally occurs 30 to 90 min after the first dose, a too-rapid increase in dose, or addition of another antihypertensive agent to therapy.
- Drug interactions (severe low BP) can occur with patients taking phosphodiesterase inhibitors, such as sildenafil (Viagra) or tadalafil (Cialis).

The preferred first-line therapy for patients with stage 1 hypertension includes nonpharmacologic treatment and 1 first-line pharmacologic drug. The 3 preferred 3 first-line drugs are a thiazide diuretic, a calcium channel blocker, and an ACE inhibitor or ARB. For most patients, a diuretic should be the first drug ordered.[5] Patients with stage 2 hypertension will receive nonpharmacologic treatment

and 2 antihypertensive agents from difference classifications. If a drug is not tolerated or is contraindicated, then a drug from another class is used.

Once antihypertensive therapy is started, patients should return for follow-up and dosage adjustments at monthly intervals until the goal BP is reached. More frequent visits are needed for patients with stage 2 hypertension or with co-morbidities. After BP is at goal and stable, follow-up visits can usually be at 3- to 6-month intervals. Comorbidities (e.g., HF), associated diseases (e.g., diabetes), and the need for ongoing monitoring (e.g., laboratory testing) influence the frequency of visits.

TABLE 32.8 Drug TherapyCombination Therapy for Hypertension

Combinations	Trade Names
Angiotensin-Converting Enzyme Inhibitors and Diuretics	
benazepril/hydrochlorothiazide	Lotensin HCT
enalapril/hydrochlorothiazide	Vaseretic
lisinopril/hydrochlorothiazide	Zestoretic
Angiotensin II Receptor Blockers and Calcium Channel Blockers	
olmesartan/amlodipine	Azor
telmisartan/amlodipine	Twynsta
valsartan/amlodipine	Exforge
Angiotensin II Receptor Blockers and Diuretics	
candesartan/hydrochlorothiazide	Atacand HCT
losartan/hydrochlorothiazide	Hyzaar
olmesartan medoxomil/hydrochlorothiazide	Benicar HCT
valsartan/hydrochlorothiazide	Diovan HCT
Angiotensin II Receptor Blocker, Diuretic, and Calcium Channel Blocker	
amlodipine/hydrochlorothiazide/valsartan	Exforge HCT
β-Blockers and Diuretics	
metoprolol/hydrochlorothiazide	Lopressor HCT
nadolol/bendroflumethiazide	Corzide
olmesartan medoxomil/amlodipine/hydrochlorothiazide	Tribenzor
Calcium Channel Blocker and Angiotensin-Converting Enzyme Inhibitor	
amlodipine/benazepril	Lotrel
Diuretics and Diuretics	
spironolactone/hydrochlorothiazide	Aldactazide
triamterene/hydrochlorothiazide	Dyazide, Maxzide

Patient and Caregiver Teaching Related to Drug Therapy

Side effects of antihypertensive therapy are common and may be so severe or undesirable that the patient does not adhere to the therapy.[5] Telling the patient about side effects that may reduce with time may help the person to continue with therapy. The number or severity of side effects may relate to the dose. It may be necessary to change the drug or decrease the dose. Advise the patient to report all side effects to the HCP.

A common side effect of several of the antihypertensive drugs is orthostatic hypotension. It results from a change in the autonomic nervous system's mechanisms for regulating BP, which are needed for position changes. Consequently, the patient may feel dizzy and faint when assuming an upright position after sitting or lying down. Table 32.12 (later in this chapter) presents specific measures to control or decrease orthostatic hypotension.

Sexual problems may occur with many antihypertensive drugs. This can be a significant reason that patients do not adhere to the treatment plan. Problems can range from reduced libido to erectile dysfunction. Rather than discussing a sexual problem with an HCP, the patient may decide just to stop therapy. Approach the patient on this sensitive subject and encourage discussion of any sexual problems. The sexual problems may be easier for the patient to discuss once you explain that the drug may be the source of the problem.

Changing to another antihypertensive drug can decrease or relieve these side effects. Encourage the patient to discuss sexual issues with the HCP. If the patient is reluctant to do so, offer to alert the HCP to the side effects that the patient has. There are many options for treating hypertension, and a plan that is acceptable to the patient should be the goal.

Some unpleasant side effects result from a drug's therapeutic effect, but these can be decreased. For example, diuretics cause dry mouth and frequent voiding. Sugarless gum or hard candy may help ease the dry mouth. Taking diuretics earlier in the day may limit frequent voiding during the night and preserve sleep.

Resistant Hypertension

Carefully explore all reasons why a patient may not be at goal BP (Table 32.9). *Resistant hypertension* is the failure to reach goal BP in patients who are taking full doses of an appropriate 3-drug therapy regimen that includes a diuretic. Resistant hypertension carries a 2- to 6-fold increase in complications including MI and stroke over other hypertensive patients. Treatments focus on identifying potential factors that could contribute to hypertension, assessing adherence, and evaluating alternative drug combinations. Overactive renal nerves can be a cause of resistant hypertension. Percutaneous catheter-based radiofrequency ablation of the renal nerves (known as *renal denervation*) may help lower BP and SNS activity in patients with resistant hypertension. But, we need more evidence to support this treatment as a standard of care.

Nursing Management: Primary Hypertension

Nursing Assessment

Table 32.10 presents subjective and objective data to obtain from a patient with hypertension.

TABLE 32.9 Causes of Resistant Hypertension

- Causes of pseudoresistant hypertension:
    - Improper BP measurements (i.e., inappropriate BP cuff size)
    - Inadequate drug doses
    - Inappropriate drug therapy
    - Poor adherence to drug regimen (e.g., due to side effects, finances)

- White coat syndrome
- Volume overload
    - Excess salt intake
    - Volume retention from kidney disease
    - Inadequate diuretic therapy
    - Drug-induced
    - Corticosteroids
    - Cyclosporine and tacrolimus (Prograf)
    - Erythropoietin
    - Illegal drugs (e.g., cocaine, amphetamines)
    - Licorice
    - Nonsteroidal antiinflammatory drugs
    - Oral contraceptives
    - OTC dietary or herbal supplements and drugs (e.g., ma huang, bitter orange)
    - Sympathomimetics (e.g., decongestants, diet pills)
- Associated conditions
    - Excess alcohol intake
    - Increasing obesity

Nursing Diagnoses

Nursing diagnoses and collaborative problems for the patient with hypertension include:

- Altered blood pressure
- Ineffective tissue perfusion
- Impaired sexual function
- Potential complication: stroke, MI

Planning

Nursing care focuses on the priority problems of maintaining BP at a level that decreases complications and supporting the patient to manage what may be a complicated drug regimen with many side effects. The overall goals for the patient with hypertension are that the patient will (1) achieve and maintain the goal BP; (2) have minimal side effects of therapy; and (3) manage and cope with this condition.

Nursing Implementation

Health Promotion

Primary prevention of hypertension is a cost-effective approach. Current recommendations for primary prevention include lifestyle modifications that prevent or delay the rise in BP in at-risk people. Following the DASH diet and reducing sodium can lower BP. This diet is recommended for primary prevention in the general population. Dietary changes by the food industry (e.g., reducing the amount of salt in processed foods) may be useful.

The National Heart, Lung, and Blood Institute provides web-based educational materials in several languages for HCPs, patients, and the public to raise awareness about the dangers of high BP. Search available publications at *https://catalog.nhlbi.nih.gov/*.

Individual Patient Evaluation

Hypertension is usually discovered through routine screening for insurance, employment, and military physical examinations. You are in an ideal position to assess for the presence of hypertension, identify the risk factors for hypertension and CAD, and teach patients about these conditions. In addition to BP measurement, a health assessment

should include such factors as age, gender, and race; diet history (including salt and alcohol intake); weight patterns; tobacco use; and family history of CVD, stroke, renal disease, and diabetes. Note all drugs taken, prescribed, OTC, and recreational. Last, ask the patient about a history of high BP and the results of any treatment.

Blood Pressure Measurement

Proper size and correct placement of the BP cuff are critical for accurate measurement (Table 32.11). Place the cuff snugly around the patient's bare upper arm with the midline of the bladder of the cuff (usually marked on the cuff by the manufacturer) placed in line with the brachial artery. Place the patient's arm at the level of the heart during BP measurement. For BP measurements taken in the sitting position, raise and support the arm at the level of the heart. For measurements taken in a supine position, raise and support (e.g., with a small pillow) the arm at heart level. If the arm is resting on the bed, it will be below heart level.

TABLE 32.10 Nursing AssessmentHypertension

Subjective Data
Important Health Information

- *Past health history:* Known duration and past workup of high BP; cardiovascular, cerebrovascular, renal, or thyroid disease; diabetes; pituitary disorders; obesity; dyslipidemia; menopause or hormone replacement status
- *Medications:* Use of any prescription, OTC, recreational, or herbal drugs or products; use of antihypertensive drug therapy

Functional Health Patterns

- *Health perception–health management:* Family history of hypertension or CVD; tobacco use, alcohol use; sedentary lifestyle; health literacy; readiness for change
- *Nutritional-metabolic:* Usual salt and fat intake; weight gain or loss
- *Elimination:* Nocturia
- *Activity-exercise:* Fatigue; dyspnea on exertion, palpitations, exertional chest pain; intermittent claudication, muscle cramps; usual pattern and type of exercise
- *Cognitive-perceptual:* Dizziness; blurred vision; paresthesias
- *Sexual-reproductive:* Erectile dysfunction, decreased libido
- *Coping–stress tolerance:* Stressful life events

Objective Data

Cardiovascular

- SBP consistently >130 mm Hg or DBP >80 mm Hg; orthostatic changes in BP and HR; bilateral BPs significantly different; abnormal heart sounds; laterally displaced apical pulse; decreased or absent peripheral pulses; carotid, renal, or femoral bruits; peripheral edema

Gastrointestinal

- Obesity (BMI ≥30 kg/m^2); abnormal waist-hip ratio

Neurologic

- Mental status changes

Possible Diagnostic Findings

- Abnormal serum electrolytes (especially potassium); ↑ BUN, creatinine, glucose, cholesterol, and triglyceride levels; proteinuria, albuminuria, microscopic hematuria; evidence of ischemic heart disease and left ventricular hypertrophy on ECG; evidence of structural heart disease and left ventricular hypertrophy on echocardiogram; evidence of arteriovenous nicking, retinal hemorrhages, and papilledema on funduscopic examination

BP can be measured using the auscultatory (oscillatory) method.[14] Note any differences in measurements between each arm. Atherosclerosis in the subclavian artery can cause a falsely low reading on the side where the narrowing occurs.

If neither upper arm can be used to measure the BP (e.g., the presence of IV lines, fistula), or if a maximum size BP cuff does not fit the upper arm, use the forearm. In this case, position the proper size cuff midway between the elbow and the wrist. Auscultate Korotkoff sounds over the radial artery or use a Doppler device to note SBP. Use of an oscillometric device on the forearm is acceptable. Forearm and upper arm BPs are not interchangeable.[14]

TABLE 32.11 Blood Pressure Measurement

The patient should not have smoked, exercised, or ingested caffeine within 30 min before measurement.

1. Seat patient with legs uncrossed, feet on the floor, and back supported. Bare patient's arm and support it at heart level.
2. Begin measurement after the patient has rested quietly for

5 min. Ask patient to relax as much as possible and not to talk during the measurement.

3. Use the right cuff size, following instructions for fit and placement according to manufacturer's recommendations.
4. Measure and record BP in both arms initially and note any differences. There are conditions when an extremity should not be used for blood pressures. These exclusions include, but are not limited to, deep venous thrombosis, arteriovenous fistula or graft, peripherally inserted central line (PICC), lymphedema, and limb ischemia. Use the arm with the highest BP and verify the reference point is at the heart.
5. BP should preferably be taken with an oscillometric device, rather than manually. The accuracy of oscillometric devices may be limited if patients are hypertensive, hypotensive, or have heart dysrhythmias (e.g., atrial fibrillation).
6. Patients with atrial fibrillation may HR variations causing variations in BP, so it is recommended to take 3 different measurements over several minutes to confirm the BP.
7. For auscultatory measurement, estimate SBP by palpating the radial pulse and inflating the cuff until the pulse disappears.

   Inflate the cuff 20–30 mm Hg above this level.

8 Deflate the cuff at a rate of 2–3 mm Hg/sec.

9. Record the SBP and DBP. Note the SBP when the first of 2 or more Korotkoff sounds are heard and the DBP when sound disappears.
10. Provide the patient (verbally and in writing) with the BP reading, BP goal, and recommendations for follow-up.
11. Clean BP cuffs between patients according to the agencies policy for reusable medical equipment cleaning.

guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: A report of the American College of Cardiology/AHA Task Force on Clinical Practice Guidelines, *Journal of the American College of Cardiology* 71:e127, 2018.

Safety Alert

Blood Pressure Measurement

- If using the forearm rather than the upper arm for BP measurement, document the site.
- BP cuffs that are too small or too large will result in readings that are falsely high or low, respectively.
- If bilateral BP measurements are not equal, record this finding and use the arm with the highest BP for all future measurements.

Assess for orthostatic (or postural) changes in BP and HR in older adults, people taking antihypertensive drugs, and patients who report symptoms consistent with reduced BP on standing (e.g., light-headedness, dizziness, syncope). Measure serial BP and HR with the patient in the supine, sitting, and standing positions. First, have the patient lie down for 5 minutes then measure BP and HR. Help the patient to a standing position and measure the BP and HR both 1 minute and 3 minutes after standing. Record all 3 measurements, noting the patient's position and corresponding measurement. Usually, the SBP decreases slightly (less than 10 mm Hg) on standing, while the DBP and pulse increase slightly. **Orthostatic hypotension** occurs when a patient moves from a supine to standing position, and there is a decrease of 20 mm Hg or more in SBP, a decrease of 10 mm Hg or more in DBP, and/or an increase in the HR of 20 beats/min**.** Document any lightheadedness or dizziness during the procedure, which is considered an abnormal finding.[15] Common causes of orthostatic hypotension include dehydration and inadequate

vasoconstrictor mechanisms related to disease or drug therapy.

Some people have a wide gap between the first Korotkoff sound and subsequent beats. This is called the *auscultatory gap.* Failure to inflate the cuff high enough may result in an inaccurate SBP, one that is too low for the patient.

In acute care settings, BP measurement is usually done to assess vital signs, volume status, and effects of drugs, rather than to diagnose hypertension. Trends in BP are more important than a single value. Inform the HCP of any patient with a persistent elevated BP. These patients should be evaluated for hypertension.[5]

Verifying how blood pressures are obtained at home is important when assessing for potential hypertension. Ensure that the home machine has been validated for accuracy and the patient records measurements to review later and measures the pressure at the same time of day for consistency. Confirming office BP readings with blood pressures obtained at home can help determine average BP.

Screening Programs

Screening programs in the community are widely used to identify persons who have a high BP. At the time of the BP measurement, give each person a written, numeric value of the reading. Explain why further evaluation is needed.

Focus efforts on (1) controlling BP in persons already identified as having hypertension; (2) identifying and controlling BP in at-risk groups, such as blacks, obese people, and blood relatives of people with hypertension; (3) screening those with limited access to health care; and (4) connecting persons with a HCP and/or health insurance if needed.

Nursing Management

Caring for the Patient With Hypertension

You will need to collaborate with many health care team members to

deliver, delegate, and coordinate care based on the patient's status.

- Develop and conduct hypertension screening programs.
- Assess patients for hypertension risk factors and develop risk modification plans.
- Teach patients about lifestyle management and drug therapy.
- Monitor for adverse effects of antihypertensive drugs.
- Evaluate the effectiveness of lifestyle management and drug therapy in decreasing BP to acceptable levels.
- Teach about home BP monitoring, including the correct use of automatic BP monitors. Check that the device chosen by the patient meets the Association for the Advancement of Medical Instrumentation standards (*www.dableducational.org/sphygmomanometers/devices_1_clinical.html*
- Make appropriate referrals to other HCPs, such as dietitians or stress management programs.
- Monitor for complications of hypertension, such as CAD, HF, cerebrovascular disease, PVD, and renal disease.
- Assess the patient with a hypertensive crisis for evidence of target organ disease (e.g., encephalopathy, renal insufficiency, cardiac decompensation).
- Manage the patient with hypertensive urgency or emergency, including giving drugs and evaluating for resolution of the crisis.
- Oversee UAP:
- Obtain accurate BP readings in outpatient and inpatient settings.
- Report high or low BP readings at once to RN.
- Check postural BPs as directed.

Collaborate With Other Team Members

Dietitian

- Obtain a diet history from the patient.

- Teach the components of the DASH diet.
- Provide instructions for dietary changes as needed.

Physical Therapist

- Assess patient's current level of fitness.
- Develop an exercise plan with the patient.

Cardiovascular Risk Factor Modification

Teaching about CVD risk factors is appropriate for all persons. Modifiable CVD risk factors include hypertension, obesity, diabetes, tobacco use, and physical inactivity. Discuss lifestyle modifications based on identified risk factors. Table 32.12 discusses general information and health-promoting behaviors for patients with hypertension.

Ambulatory Care

Your primary role in the long-term management of hypertension is to assist the patient to reach the goal BP and adhere to the treatment plan. Your actions include evaluating therapeutic effectiveness, detecting and reporting any adverse treatment effects, assessing and enhancing adherence, and patient and caregiver teaching.

Table 32.12 Patient & Caregiver TeachingHypertension

When teaching the patient and/or caregiver about hypertension, include the following information:

General Instructions

- Give patient the BP reading and explain what it means (e.g., high, low, goal, borderline).

- Encourage patient to monitor BP at home and teach the patient to call the HCP if BP exceeds high or low limits set by HCP.
- Hypertension is usually asymptomatic, and symptoms (e.g., nosebleeds) do not reliably indicate BP levels.
- Long-term therapy and follow-up care are necessary to treat hypertension. Therapy involves lifestyle changes (e.g., weight management, sodium reduction, smoking cessation, regular physical activity) and, in most cases, drugs to regulate the BP.
- Therapy will not cure but should control, hypertension.
- Controlled hypertension usually results in an excellent prognosis.
- Explain the potential dangers of uncontrolled hypertension (e.g., stroke, heart attack).

Instructions Related to Medication Therapy

- Be specific about the names, actions, dosages, and side effects of prescribed drugs.
- Help the patient plan regular and convenient times for taking medications and measuring BP.
- Do not stop drugs abruptly since withdrawal may cause a severe hypertensive reaction.
- Do not double up on a dose when a dose is missed.
- If BP increases or decreases, do not change the dose of the drug without consulting the HCP.
- Do not take any drugs belonging to someone else.
- Supplement diet with foods high in potassium (e.g., citrus fruits, green leafy vegetables) if taking potassium-wasting diuretics.
- Avoid hot baths, excess amounts of alcohol, and strenuous exercise within 3 hours of taking drugs that promote vasodilation.
- Many drugs cause orthostatic hypotension. Reduce the effects of orthostatic hypotension by rising slowly from the bed, sitting on

the side of the bed for a few minutes, standing slowly, and beginning to move if no symptoms develop (e.g., dizziness, lightheadedness). Do not stand still for prolonged periods, do leg exercises to increase venous return, or sleep with the head of the bed raised. Do lie or sit down when dizziness occurs.

- Some drugs cause sexual problems (e.g., erectile dysfunction, decreased libido). Consult with the HCP about changing drugs or dosages if sexual problems develop.
- Some side effects may decrease with time (e.g., fatigue, diarrhea).
- Be careful about taking potentially high-risk OTC drugs, such as high-sodium antacids, NSAIDs, appetite suppressants, and cold and sinus medications. Read warning labels and consult with a pharmacist.

Home BP Monitoring

Most patients with known or suspected hypertension should monitor their BP at home. Home BP monitoring reduces the white coat effect. The readings are often lower than those taken in the office setting and are a better predictor of CVD risk. Home BP readings may help achieve patient adherence by reinforcing the need to remain on therapy. However, some patients become overly concerned with the BP readings. Provide information that will help patients understand what their goal or target BP is and why.

Check Your Practice

You are making a home visit for a 78-yr-old woman who is recovering from a hip replacement after she fractured her femur. She currently takes a combination of lisinopril/hydrochlorothiazide. The patient's daughter (her caregiver) tells you that her BP that morning was 150/88 and then she took it 2 more times and it was the same. They are both worried and anxious that something is wrong because they heard that a BP over 120/80 is very bad.

- What should you do? What teaching would you provide?

Patient teaching is critical to ensure accuracy. Tell patients to buy an oscillometric BP monitor that uses a cuff for the upper arm or wrist. The patient should bring the BP monitor to the office to verify proper cuff size, the accuracy of the device, and the patient's technique.

Teach the patient to obtain a BP according to the steps in Table 32.11. Tell the patient to measure BP in the nondominant arm, or arm with the higher BP if there is a known difference between arms. Tell the patient to measure BP first thing in the morning (if possible, before taking any drugs) and at night before going to bed. Have the patient record all BP measurements and bring the record to office visits.

For clinical decision making (e.g., changes in dosage, starting a new drug), tell patients to take BP readings as described for 1 week. Stable, normotensive patients should measure morning and evening BP for at least 1 week every 3 months. Devices that have memory or printouts of the readings are convenient for reporting.[5]

Informatics in Practice

Monitoring Blood Pressure

- Smartphone and computer applications can help patients manage their care, including BP self-monitoring, medication history, and appointment tracking. Patients can enter a variety of variables including SBP and DBP, HR, time of day, arm or wrist used, and position (e.g., lying, sitting).
- Remote BP monitoring using telehealth technology can be used with those who have limited access to health care services.
- Reports can be used to evaluate BP control.

Patient Adherence

A significant problem in the long-term management of the patient with hypertension is poor adherence to the treatment plan. The reasons for nonadherence are complicated and can include inadequate patient teaching, low health literacy, unpleasant drug side effects, the BP returns to normal range with the therapy, the high cost of drugs, and lack of insurance.

It is important to determine the reasons why a patient is not adhering to treatment. Assess the patient's diet, activity level, and lifestyle as other indicators of adherence. Develop a plan with the patient and caregiver to improve adherence. The plan should be compatible with the patient's habits, cultural beliefs, and lifestyle. Active patient participation increases the chance of adherence to the plan. Measures include involving the patient in choosing drugs that are affordable and involving caregivers to help increase patient adherence.

Substituting combination drugs for multiple drugs once the BP is stable may promote adherence. They reduce the number of pills that the patient must take each day and may reduce costs. Combination drugs are shown in Table 32.8.

It is important to help the patient and caregiver understand that hypertension is a chronic illness that cannot be cured. Stress that it can be controlled with drug therapy, diet changes, physical activity, periodic follow-up, and other relevant lifestyle modifications.

Evaluation

The overall expected outcomes are that the patient with hypertension will

- Achieve and maintain goal BP as defined for the person
- Understand, accept, and implement the treatment plan
- Report minimal side effects of drug therapy

Gerontologic Considerations: Hypertension

The prevalence of hypertension increases with age. The lifetime risk for developing hypertension is around 90% for normotensive men and women over age 55. Older adults are more likely to have white coat hypertension.[5]

The pathophysiology of hypertension in the older adult involves several age-related physical changes: (1) loss of elasticity in large arteries from atherosclerosis, (2) increased collagen content and stiffness of the myocardium, (3) increased peripheral vascular resistance, (4) decreased adrenergic receptor sensitivity, (5) blunting of baroreceptor reflexes, (6) decreased renal function, and (7) decreased renin response to sodium and water depletion.

In the older adult who is taking antihypertensive drugs, absorption of some agents may be altered because of decreased blood flow to the gut. Metabolism and excretion may be prolonged.

Current recommendations for target BP goals in people older than 65 years of age who live independently are no different for other independent living adults under 65 years old. Care should be taken to assess for orthostatic hypotension and acute kidney injury in patients over 65 years old. Older adults who have multiple comorbidities and do not live independently (i.e., skilled facility) should have gradual titrations of antihypertensives to minimize complications.[5]

Orthostatic hypotension often occurs in older adults because of varying degrees of impaired baroreceptor reflexes. Orthostatic hypotension in this age group is often associated with volume depletion or chronic disease states, such as decreased renal and hepatic function or electrolyte imbalance.

Older adults may have postprandial drops in BP. The most significant decrease occurs about 1 hour after eating. BP returns to preprandial levels 3 to 4 hours after eating. Drugs should be started at low doses and increased slowly to reduce the chance of orthostatic hypotension. Measure BP and HR in the supine, sitting, and standing positions at every visit.

After CVD, arthritis is the second most prevalent disease in older adults. Older adults most often take prescription and OTC nonsteroidal antiinflammatory drugs (NSAIDs). Nonselective NSAIDs

(e.g., ibuprofen) and selective NSAIDs (e.g., celecoxib) can cause loss of BP control and HF. There is the potential for adverse renal effects and/or hyperkalemia when NSAIDs are used with ACE inhibitors, ARBs, or aldosterone antagonists.

Hypertensive Crisis

Hypertensive crisis is a term used to indicate either a hypertensive urgency or emergency. A hypertensive crisis occurs at systolic BP greater than 180 mm Hg and/or diastolic BP greater than 120 mm Hg. BPs often can be greater than 220/140 mm Hg. Difference between hypertensive urgency and emergency are the presence of target organ damage and the type of treatment the patient will receive.

Hypertensive emergencies have evidence of target organ disease. It most often requires hospitalization for immediate, controlled reduction of BP. Without prompt treatment, a hypertensive emergency can produce severe problems. These include encephalopathy, intracranial or subarachnoid hemorrhage, HF, MI, renal failure, dissecting aortic aneurysm, and retinopathy.[16] Untreated hypertensive emergencies have a 1-year mortality rate of more than 79%, so prompt recognition and treatment are essential to decrease the threat to organ function and life.

Hypertensive urgency has no clinical evidence of target organ disease. Hospitalization may not be needed to correct the BP. Hypertensive urgency is much more common than hypertensive emergency. It may be associated with chronic, stable complications such as stable angina, chronic HF, or prior MI or cerebrovascular accident with no threat of an acute event.

A hypertensive crisis occurs more often in patients with a history of hypertension who have not adhered to their medication regimens or who have been undermedicated. Rapidly increasing BP can cause shearing of the endothelial surface due to turbulent blood flow within the vessels leading to further vascular damage and the release of more vasoconstricting substances. A vicious cycle of BP elevation follows, leading to life-threatening damage to target organs.

Hypertensive crisis related to cocaine or crack use is a frequent problem. Other drugs, such as amphetamines, phencyclidine (PCP), and lysergic acid diethylamide (LSD), can cause a hypertensive crisis that may be complicated by drug-induced seizures, stroke, MI, or encephalopathy. Table 32.13 lists causes of hypertensive crisis.

Clinical Manifestations

A hypertensive emergency often presents as *hypertensive encephalopathy*, a syndrome in which a sudden rise in BP is associated with a severe headache, nausea, vomiting, seizures, confusion, and coma. The manifestations of encephalopathy are the result of increased cerebral capillary permeability, which can lead to cerebral edema and disruption in cerebral function. On retinal examination, exudates, hemorrhages, and/or papilledema are found (Fig. 32.6).

TABLE 32.13 Causes of Hypertensive Crisis

- Acute aortic dissection
- Exacerbation of chronic hypertension
- Head injury
- Monoamine oxidase inhibitors are taken with tyramine-containing foods
- Pheochromocytoma
- Preeclampsia, eclampsia
- Rebound hypertension (from abrupt withdrawal of some antihypertensive drugs, such as clonidine or β-blockers)

  Recreational drug use (cocaine, amphetamines)
- Renovascular hypertension

Renal insufficiency ranging from minor injury to complete renal failure can occur. Rapid cardiac decompensation ranging from

unstable angina to MI and pulmonary edema is possible. Patients can have chest pain and dyspnea. Aortic dissection can develop and will cause sudden, severe chest and back pain with reduced or absent pulses in the extremities.

Interprofessional and Nursing Management

Hypertensive emergencies require hospitalization, IV administration of antihypertensive drugs, and intensive monitoring. BP level alone is not the major factor in deciding the treatment for a hypertensive crisis. The link between elevated BP and signs of new or progressive target organ disease determines the seriousness of the situation.

When treating hypertensive emergencies, we often use the mean arterial pressure (MAP instead of BP readings to guide and evaluate therapy. Calculate the MAP as follows:

$$MAP = (SBP + 2\,DBP) \div 3$$

The initial goal is to decrease MAP by no more than 20% to 25% or to decrease MAP to 110 to 115 mm Hg. If the patient is clinically stable, drugs can be titrated to gradually lower BP over the next 24 hours. Lowering the BP too quickly or too much may decrease cerebral, coronary, or renal perfusion. A rapid decrease could cause a stroke, MI, or renal failure.

Check Your Practice

A 68-yr-old male patient presents to the emergency department with a BP 210/118 and reporting a severe headache and vomiting. You know that his BP is dangerously high and must be lowered.

- Calculate his MAP.
- What treatments would you expect to be ordered for this patient?

Patients with aortic dissection require special consideration. These patients should have their SBP lowered to less than 100 to 120 mm Hg as soon as possible (if tolerated). Another exception is patients with acute ischemic stroke. Their BP is lowered to allow the use of thrombolytic agents. Last, an elevated BP in the immediate poststroke period may be a compensatory response to improve cerebral perfusion to ischemic brain tissue. There is no evidence supporting the use of antihypertensive drugs in these patients (see Chapter 57).[5]

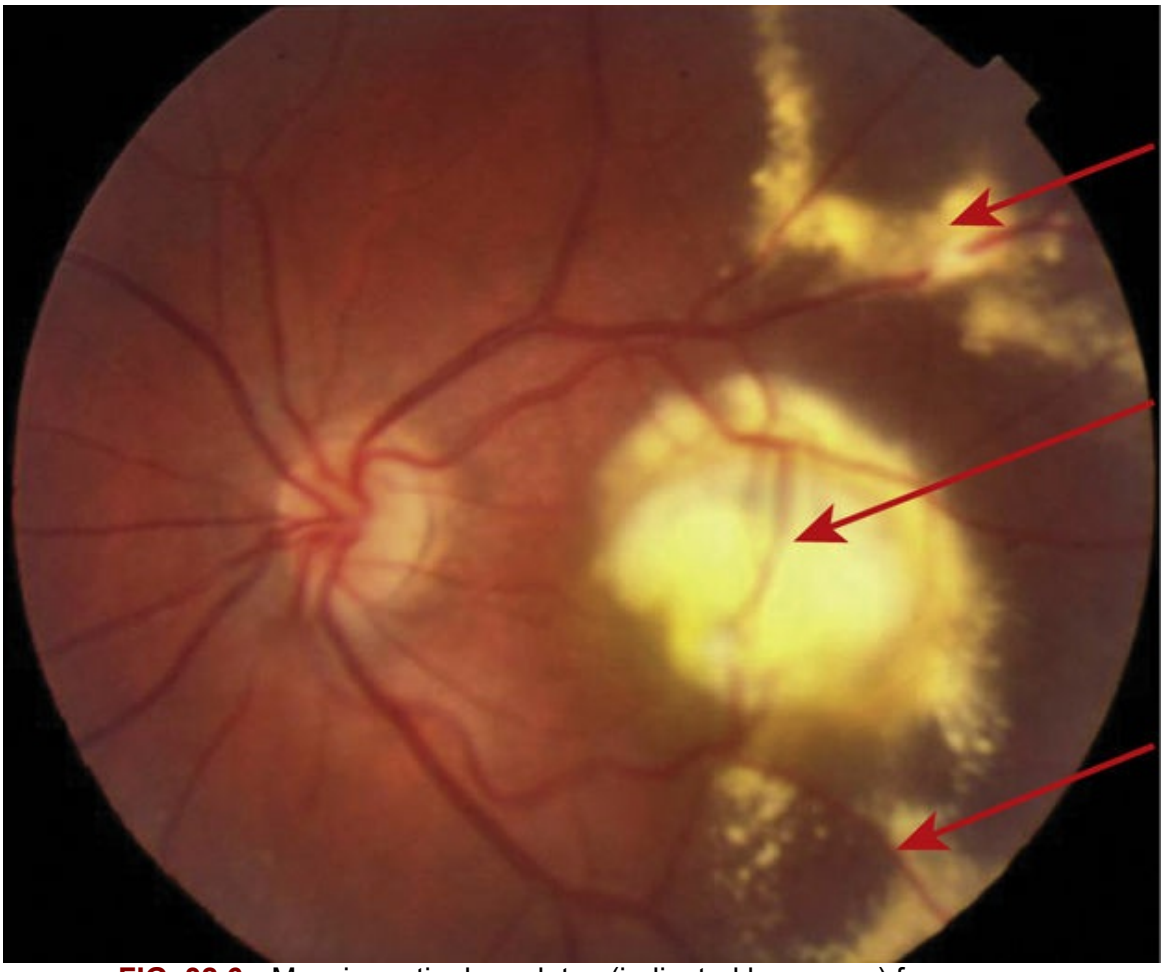

FIG. 32.6 Massive retinal exudates (indicated by *arrows*) from hypertensive retinopathy. To see what a normal retina looks like on

ophthalmoscopic examination, see Fig. 20.7.
From Kliegman RM, Behrman RE, Jenson HB, Stanton B: *Nelson textbook of pediatrics,* ed 18, Philadelphia, 2011, Saunders.

IV agents used for hypertensive emergencies include vasodilators (e.g., sodium nitroprusside, fenoldopam, nicardipine), adrenergic inhibitors (e.g., phentolamine, labetalol, esmolol), and the calcium channel blocker clevidipine (Cleviprex). Sodium nitroprusside is the most effective IV drug to treat hypertensive emergencies. Oral agents may be given along with IV ones to help make an earlier transition to long-term therapy.

Drug Alert

Labetalol

- Teach patient not to stop the drug abruptly.
- Abrupt cessation may precipitate angina or HF.

Antihypertensive drugs given IV have a rapid (within seconds to minutes) onset of action. Assess the patient's BP and HR every 2 to 3 minutes during their initial administration. Use an arterial line (see Chapter 65) or an automated, noninvasive BP machine to monitor the BP. Titrate the drug according to MAP or BP as ordered. Monitor the ECG for dysrhythmias and signs of ischemia or MI. Use extreme caution in treating the patient with CAD or cerebrovascular disease. Measure urine output hourly to assess renal perfusion. Patients receiving IV agents may be on bed rest. Getting up (e.g., to use the commode) may cause severe cerebral ischemia and fainting.

Ongoing assessment is essential to evaluate the effectiveness of and the patient's response to therapy. Monitor cardiac, lung, and renal systems for decompensation caused by the severe elevation in BP (e.g., angina, pulmonary edema, renal failure).

Frequent neurologic checks, including the level of consciousness,

pupillary size and reaction, and movement of extremities, help detect any changes in the patient's condition. The neurologic changes are often like those of a stroke. However, a hypertensive crisis does not show focal or lateralizing signs often seen with a stroke. In a stroke, focal impairments affect a specific region of the body, such as weakness in the left arm or right leg. Lateralizing signs are restricted to one side of the body, such as weakness of an arm or leg.

Hypertensive urgencies usually do not need IV drugs but can be managed with oral agents. The patient with hypertensive urgency may not need hospitalization but will need follow-up. The initial decision for oral antihypertensive agents should be made based on the underlying cause of the hypertensive urgency, the patient characteristics, and comorbidities. Some of the most commonly used oral drugs are captopril, labetalol, clonidine (Catapres), and amlodipine (Norvasc) (Table 32.6).[16] The disadvantage of oral drugs is the inability to regulate the dosage moment to moment, as can be done with IV therapy. A patient with hypertensive urgency who is not hospitalized should have outpatient follow-up care within 24 hours.

Once the hypertensive crisis is resolved, it is essential to determine the cause. The patient will need appropriate management and teaching to avoid future crises.

Drug Alert

Clonidine (Catapres)

- Teach patient to change positions slowly to limit orthostatic hypotension.
- Avoid hazardous activities since the drug may cause drowsiness.
- Do not stop abruptly as this may cause rebound hypertension.

Not every patient with an elevated BP and no target organ disease will need emergent drug therapy or hospitalization. Allowing the

patient to sit for 20 or 30 minutes in a quiet environment may significantly reduce BP. Oral drugs may be started or adjusted. Other interventions include encouraging the patient to share any concerns or fears, answering questions about hypertension, and reducing any adverse stimuli (e.g., excess noise) in the environment.

Case Study

Primary Hypertension

Patient Profile

R.L. is a 45-yr-old black man with no history of hypertension. At a

screening clinic 2 months ago, his BP was 150/95 mm Hg. His HCP has followed him for the past month. During this time, he has been taking hydrochlorothiazide 12.5 mg/day. He is here today for a follow-up visit.

Subjective Data

- Father died of stroke at age 60
- Mother is alive but has hypertension and a history of MI
- States that he feels fine and is not a "hyper" person
- Smokes 1 pack of cigarettes daily for the past 28 yrs
- Drinks "about 2" 6-packs of beer on most Friday and Saturday nights
- Has heard that BP drugs "make you impotent"

Objective Data
Physical Examination

- Mild retinopathy (retinal arteriolar narrowing on ophthalmoscopic examination)
- BP: 166/108 mm Hg (highest of 2 readings, 2 min apart)
- Sustained apical impulse palpable in the 4th intercostal space just lateral to the midclavicular line

Diagnostic Studies

- ECG: mild left ventricular hypertrophy
- Urinalysis: protein 30 mg/dL (0.3 g/L)
- Serum creatinine level: 1.6 mg/dL (141 mmol/L)

Interprofessional Care

- Low-sodium, DASH diet
- Hydrochlorothiazide 25 mg/day oral (dose increase)
- Nicardipine sustained-release 30 mg oral twice daily (second drug added)

Discussion Questions

1. What risk factors for hypertension does R.L. have?
2. What evidence of target organ disease is present?
3. ***Patient-Centered Care:*** What misconceptions about hypertension should be corrected?
4. ***Priority Decision:*** Based on the assessment data, what are the priority nursing diagnoses? What are the collaborative problems?
5. ***Evidence-Based Practice:*** R.L. wants to know the most effective nonpharmacologic strategies to lower his BP. What would you tell him?
6. ***Patient-Centered Care:*** What lifestyle preferences should be addressed in R.L.'s plan of care?
7. ***Collaboration:*** What referrals may be indicated?
8. ***Safety:*** What safety precautions should be considered when changing R.L.'s antihypertensive therapy?
9. ***Quality Improvement:*** What outcomes would indicate that interprofessional care was successful?

Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which BP-regulating mechanism(s) can result in the development of hypertension if defective? *(select all that*

apply)

a. Release of norepinephrine

b. Secretion of prostaglandins

c. Stimulation of the sympathetic nervous system

d. Stimulation of the parasympathetic nervous system

e. Activation of the renin-angiotensin-aldosterone system

2. While obtaining subjective assessment data from a patient with hypertension, the nurse recognizes that a modifiable risk factor for the development of hypertension is

a. A low-calcium diet.

b. Excess alcohol intake.

c. A family history of hypertension.

d. Consumption of a high-protein diet.

3. In teaching a patient with hypertension about controlling the illness, the nurse recognizes that

a. All patients with elevated BP need drug therapy.

b. Obese persons must achieve a normal weight to lower BP.

c. It is not necessary to limit salt in the diet if taking a diuretic.

d. Lifestyle modifications are needed for all persons with elevated BP.

4. A *priority* consideration in the management of the older adult with hypertension is to

a. Prevent primary hypertension from converting to secondary hypertension.

b. Recognize that the older adult is less likely to adhere to

the drug therapy regimen than a younger adult.

c. Ensure that the patient receives larger initial doses of antihypertensive drugs because of impaired absorption.

d. Use precise technique in assessing the BP of the patient because of the possible presence of an auscultatory gap.

5. A patient with newly discovered high BP has an average reading of 158/98 mm Hg after 3 months of exercise and diet modifications. Which management strategy will be a *priority* for this patient?

a. Drug therapy will be needed because the BP is still not at goal.

b. BP monitoring should continue for 3 months to confirm a diagnosis of hypertension.

c. Lifestyle changes are less important since they were not effective, and drugs will be started.

d. More changes in the patient's lifestyle are needed for a longer time before starting drug therapy.

6. A patient is admitted to the hospital in a hypertensive emergency (BP 244/142 mm Hg). Sodium nitroprusside is started to treat the elevated BP. Which management strategies would be *most* appropriate for this patient? *(select all that apply)*

a. Measuring hourly urine output

b. Continuous BP monitoring with an arterial line

c. Decreasing the MAP by 50% within the first hour

d. Maintaining bed rest and giving tranquilizers to lower the BP

e. Assessing the patient for signs and symptoms of heart

failure and changes in mental status

1. a, c, e, 2. b, 3. d, 4. d, 5. a, 6. a, b, e

Coronary Artery Disease and Acute Coronary Syndrome

Rose Shaffer

LEARNING OUTCOMES

1. Relate the etiology and pathophysiology of coronary artery disease (CAD), chronic stable angina, and acute coronary syndrome (ACS) to the clinical manifestations of each disorder.
2. Describe the nursing role in the promotion of therapeutic lifestyle changes in patients at risk for CAD.
3. Distinguish the precipitating factors, clinical manifestations, and interprofessional and nursing care of the patient with CAD and chronic stable angina.
4. Explain the clinical manifestations, diagnostic studies, complications, and interprofessional and nursing care of the patient with ACS.
5. Outline drug therapy used to treat patients with CAD, chronic stable angina, and ACS.
6. Prioritize key components to include in the rehabilitation of patients recovering from ACS and coronary revascularization procedures.
7. Distinguish the precipitating factors, manifestations, and interprofessional and nursing care of patients who are at risk for or have had sudden cardiac death.

KEY TERMS

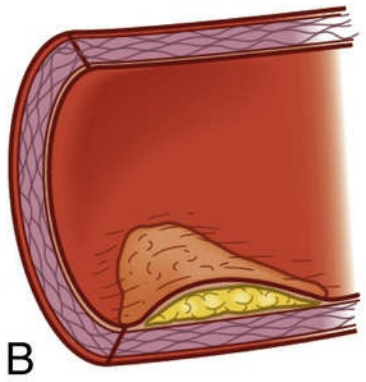
Sexuality

Cardiovascular disease (CVD) is the leading cause of death both globally and in the United States.[1] Coronary artery disease (CAD) is the most common type of CVD. CAD was an underlying cause of death in about 1 of every 7 deaths.[2] Patients with CAD may be asymptomatic or develop chronic stable angina (chest pain). CAD may evolve to more serious conditions of unstable angina (UA) and myocardial infarction (MI), which are referred to as acute coronary syndrome (ACS).

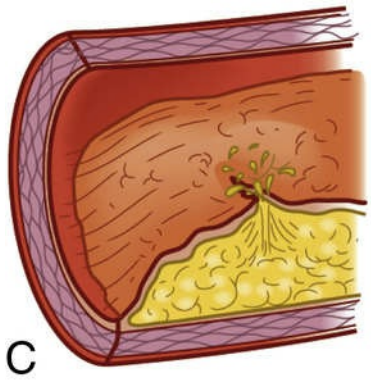
Conceptually, CAD has a profound effect on perfusion. The process of perfusion is based on the heart's ability to generate enough cardiac output (CO) to distribute blood to all body tissues. CAD negatively affects cardiac function, resulting in impaired CO and decreased perfusion. This chapter discusses the care of patients with CAD, chronic stable angina, and ACS and measures to promote optimal perfusion.

Coronary Artery Disease



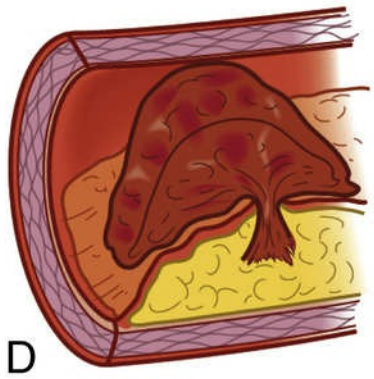
Coronary artery disease (CAD) is a type of blood vessel disorder that we consider in the general category of atherosclerosis. The term **atherosclerosis** comes from 2 Greek words: *athere,* meaning "fatty mush," and *skleros,* meaning "hard."[3] This combination means that atherosclerosis begins as soft deposits of fat that harden with age. That is why many refer to atherosclerosis as "hardening of the arteries." It can occur in any artery in the body. When the *atheromas* (fatty deposits) form in the coronary arteries, the disease is called CAD. The terms *arteriosclerotic heart disease (ASHD), cardiovascular heart disease (CVHD), ischemic heart disease (IHD), coronary heart disease (CHD),* are other terms used to describe CAD. They are often used interchangeably.

Chronic Endothelial Injury



- Hypertension
- Tobacco use
- Hyperlipidemia
- Hyperhomocysteinemia
- Diabetes
- Infections
- Toxins

Damaged endothelium



Fatty Streak

- Lipids accumulate and migrate into smooth muscle cells

Fibrous Plaque

- Collagen covers the fatty streak
- Vessel lumen is narrowed
- Blood flow is reduced
- Fissures can develop

Complicated Lesion

- Plaque rupture
- Thrombus formation
- Further narrowing or total occlusion of vessel

FIG. 33.1 Pathogenesis of atherosclerosis. **A,** Damaged endothelium. **B,** Fatty streak and lipid core formation. **C,** Fibrous plaque covers the lipid core. **D,** Complicated lesion: Plaque rupture with thrombus formation.

Etiology and Pathophysiology

Atherosclerosis is the major cause of CAD. It is characterized by lipid deposits within the intima of the artery. Endothelial injury and inflammation play a key role in the development of atherosclerosis.

The endothelium (inner lining of the vessel wall) is normally nonreactive to platelets and leukocytes, as well as coagulation, fibrinolytic, and complement factors. Damage to the endothelial lining can result from tobacco use, hyperlipidemia, hypertension, toxins, diabetes, high homocysteine levels, and infection causing a local inflammatory response (Fig. 33.1, *A*).[3]

C-reactive protein (CRP), a protein made by the liver, is a nonspecific marker of inflammation. CRP levels rise when there is systemic inflammation, such as rheumatoid arthritis or inflammatory bowel disease. CRP and levels of lipoprotein(a), which has proinflammatory properties, are increased in many patients with CAD (see Table 31.6). CRP and lipoprotein(a) are not a part of a routine risk assessment for CAD. They can be used in patients with an intermediate- or high-risk suspicion of CAD.[4]

Developmental Stages

CAD is a progressive disease that develops in stages over many years. When the patient becomes symptomatic, the disease process usually is well advanced. The stages of development in atherosclerosis are (1) fatty streak, (2) fibrous plaque, and (3) complicated lesion.

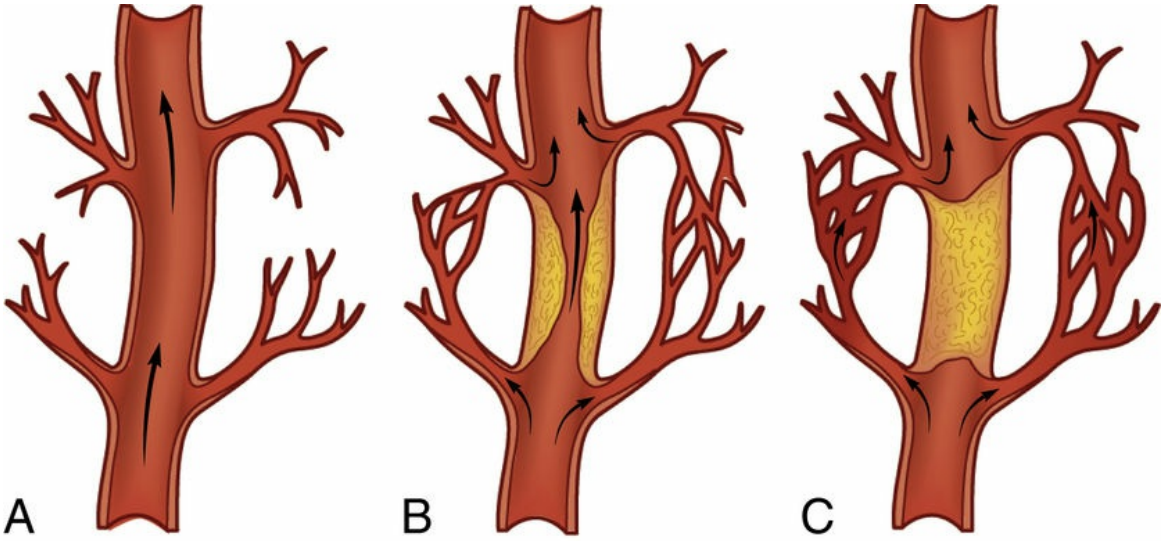


FIG. 33.2 Vessel occlusion with collateral circulation. **A,** Open, functioning coronary artery. **B,** Partial coronary artery closure with collateral circulation being established. **C,** Total coronary artery occlusion with collateral circulation bypassing the occlusion to supply blood to the myocardium.

Fatty Streak

Fatty streaks, the earliest lesions of atherosclerosis, are lipid-filled smooth muscle cells. As streaks of fat develop within the smooth muscle cells, a yellow tinge appears. Fatty streaks can be seen in the coronary arteries by age 20. They involve an increasing amount of surface area as one ages. Treatment that lowers low-density lipoprotein (LDL) cholesterol may slow this process (Fig. 33.1, *B*).

Fibrous Plaque

The *fibrous plaque* stage is the beginning of progressive changes in the endothelium of the arterial wall. These changes can appear in the coronary arteries by age 30 and increase with age.

Normally, the endothelium repairs itself immediately. This does not occur in the person with CAD. LDLs and growth factors from platelets stimulate smooth muscle proliferation and thickening of the arterial wall. Once endothelial injury has taken place, lipoproteins (carrier proteins within the bloodstream) transport cholesterol and other lipids into the arterial intima. Collagen covers the fatty streak and

forms a fibrous plaque with a grayish or whitish appearance. These plaques can form on one side of the artery or in a circular fashion involving the entire lumen. The borders can be smooth or irregular with rough, jagged edges. The result is a narrowing of the vessel lumen and reduced blood flow to the distal tissue (Fig. 33.1, *C*).

Complicated Lesion

The last stage in the development of the atherosclerotic lesion is the most dangerous. As the fibrous plaque grows, continued inflammation can result in plaque instability, ulceration, and rupture. Once the integrity of the artery's inner wall is compromised (plaque rupture), platelets accumulate in large numbers, leading to a thrombus (platelet aggregation and adhesion is the body's attempt to "heal" the ruptured area). The thrombus may adhere to the wall of the artery, leading to further narrowing or total occlusion of the artery. Activation of the exposed platelets causes expression of glycoprotein IIb/IIIa receptors that bind fibrinogen. This, in turn, leads to more platelet aggregation and adhesion, further enlarging the thrombus. At this stage, the plaque is referred to as a *complicated lesion* (Fig. 33.1, *D*).

Collateral Circulation

Normally, some arterial anastomoses or connections, called **collateral circulation**, exist within the coronary circulation. Two factors contribute to the growth and extent of collateral circulation: (1) inherited predisposition to develop new blood vessels *(angiogenesis)* and (2) presence of chronic ischemia (poor blood flow). When plaque blocks the normal flow of blood through a coronary artery and the resulting *ischemia* is chronic, increased collateral circulation may develop (Fig. 33.2). When blockages in coronary arteries occur slowly over a long time, there is a greater chance of collateral circulation developing, so the heart muscle may still receive an adequate amount of blood and oxygen (O_2) except during increased workload on the heart, such as exercise.

TABLE 33.1 Risk Factors for Coronary Artery Disease

Nonmodifiable Risk Factors	Modifiable Risk Factors
• Increasing age • Gender (highest incidence of CAD is among middle-aged men, but for men over age 45 and women over age 55, the risk for CAD increases for both genders) • Ethnicity (more common in white than black men) • Genetic predisposition and family history of heart disease	Major • Serum lipids: • Total cholesterol >200 mg/dL • Triglycerides ≥150 mg/dL* • LDL cholesterol >130 mg/dL • HDL cholesterol <40 mg/dL in men or <50 mg/dL in women* • BP >120/80 mm Hg* • Diabetes* • Tobacco use • Physical inactivity • Obesity: Waist circumference ≥102 cm (≥40 in) in men and ≥88 cm (≥35 in) in women* Contributing • Psychosocial risk factors (e.g., depression, hostility • High homocysteine levels • Substance abuse

*3 or more of these risk factors meet the criteria for metabolic syndrome (discussed in Chapter 40).

However, with rapid-onset CAD (e.g., familial hypercholesterolemia) or coronary spasm, there is not enough time to develop collateral circulation. When this happens, reduced blood flow results in more severe ischemia or infarction.

Risk Factors for Coronary Artery Disease

Many risk factors have been associated with CAD. We group them as nonmodifiable and modifiable (Table 33.1). *Nonmodifiable risk factors* are age, gender, ethnicity, family history, and genetics. *Modifiable risk factors* include high serum lipids, high BP, tobacco use, physical inactivity, obesity, diabetes, metabolic syndrome, psychologic states, and high homocysteine level.

Nonmodifiable Risk Factors

Age, Gender, Ethnicity, and Genetics

The incidence of CAD is highest among middle-aged men, however, the risk for CAD increases for men over age 45 and women over age 55.[4] Heart disease is often diagnosed about 10 years later in women than men. One possible reason for this may be the cardioprotective effects of estrogen. But, interestingly, hormone replacement therapy does not protect women after menopause and may be harmful.[4] Because women are older at the time of CAD diagnosis, they are more likely to have co-morbidities (e.g., hypertension, diabetes). Women are more likely than men to die after their first MI. CAD is present in black women at rates higher than their white or Hispanic counterparts. [4] (See Promoting Health Equity box for more differences in CAD among ethnic groups.)

Most women do not consider CAD their greatest health risk.[4] Despite efforts to increase awareness that more women die from heart disease than from breast cancer (e.g., the American Heart Association's Go Red for Women campaign), heart disease kills almost 10 times more women than breast cancer. It is the leading cause of death in women. When women present to the HCP, their symptoms may be unrecognized as heart related because the symptoms are often atypical. These symptoms include fatigue, shortness of breath, upper back pain, indigestion, weakness, sleep problems, palpitations, and anxiety.[5] These atypical symptoms can relate to many different diseases and syndromes. This lack of recognition of symptoms as a cardiac problem leads to delays in women seeking treatment and HCPs recognizing the symptoms (see the Gender Differences box on p. 701).

Promoting Health Equity

Coronary Artery Disease

Whites

- White men have the highest incidence of CAD.

Blacks

- Blacks have an early age of onset of CAD.
- Deaths from CVDs, including CAD and strokes, are higher for blacks than for the overall population in the United States.
- Black women have a higher incidence and death rate related to CAD than white and Hispanic women.

Native Americans

- Native Americans die from heart disease earlier than expected. Mortality rates for those under age 65 are twice as high as those of other Americans.
- Major modifiable CVD risk factors for Native Americans include tobacco use, hypertension, obesity, and diabetes.

Hispanics

- Hispanics have slightly lower rates of CAD than either non-Hispanic whites or blacks.
- Hispanics have lower death rates from CAD than non-Hispanic whites.

Genetic Link

Genetic predisposition is a key factor in the occurrence of CAD. Family history is a risk factor for CAD and MI. Often patients with angina or MI can name a parent or sibling who died of CAD.

The genetic basis of CAD/MI is complex and poorly understood. We estimate that the genetic contribution to CAD is as high as 40% to 60%. This proportion relates mainly to genes that control known risk factors (e.g., lipid metabolism).[6] (See Genetics in Clinical Practice box.)

Major Modifiable Risk Factors

High Serum Lipids

A high serum lipid level is a major risk factors for CAD (see Table 31.6). The risk for CAD is associated with a total serum cholesterol level greater than 200 mg/dL (5.2 mmol/L), an LDL greater than 130 mg/dL (3.4 mmol/L), a high-density lipoprotein (HDL) level less than 40 mg/dL (1.0 mmol/L) in men and less than 50 mg/dL (1.3 mmol/L) in women, and/or a fasting triglyceride level greater than 150 mg/dL (1.7 mmol/L).

For the body to be able to use and transport lipids, they must become soluble in blood by combining with proteins. Lipids combine with proteins to form lipoproteins. Lipoproteins are vehicles for fat mobilization and transport. They vary in composition. The 3 major lipoproteins are HDLs, LDLs, and very-low-density lipoproteins (VLDLs).[7]

HDLs contain more protein by weight and fewer lipids than any other lipoprotein. HDLs carry lipids away from arteries to the liver for metabolism. This process of HDL transport

Coronary Artery Disease and Acute Coronary Syndrome

Men	Women
• First heart event is more often MI than angina. • Report more typical signs and symptoms of angina and MI. • Receive more evidence-based therapies (e.g., aspirin, statins, diagnostic catheterization, PCI) when acutely ill from CAD (e.g., MI). • Mortality rates from CAD have decreased more rapidly for men than women. • Have larger diameter coronary arteries. Vessel diameter is inversely related to risk for restenosis after interventions.	• First heart event is more often UA than MI. • Fewer women have the "classic" signs and symptoms of UA or MI. • Fatigue is often the first symptom of ACS. • Experience the onset of heart disease about 10 years later than men. • More women with MI die of sudden cardiac death before reaching the hospital. • Before menopause, have higher HDL cholesterol levels and lower LDL cholesterol levels. After menopause LDL levels and risk for MI increase. • Report more disability after a heart event.
• After age 55, the incidence of MI in men and women equalizes. • Develop more collateral circulation. • Standard screening for risk for sudden cardiac death is more predictive in men.	• Seek medical care later in the CAD process, most likely because of lack of recognition of atypical symptoms. • Have more "silent" MIs compared with men. • Those who have an MI are more likely to have a fatal heart event within 1 year than men. • Women who have coronary artery bypass graft surgery have a higher mortality rate and more complications after surgery. • Ae undertreated with guideline-based recommendations, leading to worse outcomes and increased rates of readmission, reinfarction, and death in the first year after MI.

Genetics in Clinical Practice

Familial Hypercholesterolemia

Genetic Basis

- Autosomal dominant disorder
- Exists in both heterozygous (most common) and homozygous forms
- Mutation in low-density lipoprotein receptor (LDLR) gene
- Gene codes for low-density lipoprotein (LDL) receptor that binds to LDLs
- LDLs are the primary carriers of cholesterol in the blood. By removing LDLs from the bloodstream, the LDL receptors play a critical role in regulating cholesterol levels
- High cholesterol levels are a result of defective function of the LDL receptors
- Person has high serum LDLs throughout life

Incidence

- Heterozygotes: 1 in 500
- Homozygotes: rare

Genetic Testing

- DNA testing is available

Clinical Implications

- Develop severe atherosclerosis in early to middle years
- A serum lipid profile measures total cholesterol, triglycerides, LDLs, and high-density lipoproteins (HDLs)
- Homozygous familial hypercholesterolemia is much more severe. Cholesterol levels may exceed 600 mg/dL
- Develop xanthomas (fatty growths on the skin [e.g., around eyes, over joints])
- Treatment includes low-fat diet, exercise, and lipid-lowering drugs (e.g., PCSK9 inhibitors)

prevents lipid accumulation within the arterial walls.[7] Therefore high serum HDL levels are desirable and lower the risk for CAD. Premenopausal women usually have higher HDL levels than men. This may be related to the protective effects of natural estrogen. After menopause, women's HDL levels decrease to levels near those of men. In general, HDL levels are higher in women, decrease with age, and are low in those with CAD. Physical activity, eating more healthy fats, losing excess weight, moderate alcohol intake, and quitting smoking help increase HDL levels.

LDLs contain more cholesterol than any of the lipoproteins and have an attraction for arterial walls. High LDL levels correlate closely

with an increased incidence of atherosclerosis and CAD. This is why low serum LDL levels are desirable. We cannot routinely calculate LDL if the triglycerides are higher than 400 mg/dL (> 4.35 mmol/L). VLDLs have a higher concentration of triglycerides and can deposit cholesterol directly on the walls of arteries.

Triglycerides are the most common type of fat in the blood. A certain amount of triglycerides is needed for bodily function, but high triglyceride levels may increase the risk for CAD. Certain diseases (e.g., type 2 diabetes, chronic kidney disease [CKD]), drugs (e.g., corticosteroids, hormone therapy) and genetic disorders have been associated with high triglyceride levels. Lifestyle factors that can contribute to high levels include high alcohol intake, high intake of refined carbohydrates and simple sugars, and physical inactivity. When a high triglyceride level is combined with a high LDL level, a smaller, denser LDL particle is formed, which favors deposition on arterial walls. People with insulin resistance often have this pattern.

Guidelines for treating high LDL cholesterol are based on a person's 10-year and lifetime risk for having heart disease or stroke. The following data generate a risk score: (1) age, (2) gender, (3) race, (4) use of tobacco, (5) diabetes, (6) systolic BP, (7) diastolic BP, (8) use of BP drugs, (9) total cholesterol level, and (10) HDL cholesterol level. A 10-year risk calculator is available at www.cvriskcalculator.com.

The 2013 American College of Cardiology (ACC)/American Heart Association (AHA) Cholesterol Guideline[8] does not promote treating LDL to target goals as had been recommended in earlier guidelines. However, the 2017 American Association of Clinical Endocrinologists (AACE) guideline endorses treating LDL to specific target goals.[9] The AACE guideline states that those with no cardiac risk factors are considered at low risk for the development of CAD. Their LDL goal is <130 mg/dL. Those with 2 or less risk factors and a 10-year risk of < 10% (moderate risk) should be treated to an LDL target of < 100 mg/dL. Those at high risk (>2 risk factors and a 10-year risk of 10-20%; or diabetes or CKD stage 3 to 4 with no other risk factors) should be treated to an LDL of < 100 mg/dL. Those at very high risk for developing CAD (recent hospitalization for ACS, established CAD,

carotid disease or peripheral vascular disease; diabetes, CKD stage 3 to 4 with 1 or more risk factors) should be treated to an LDL target of < 70 mg/dL.[9]

Hypertension

Hypertension increases the risk for CAD, stroke, peripheral vascular disease, heart failure (HF), and death. In postmenopausal women, hypertension is associated with a higher incidence of CAD than in men and premenopausal women.

According to the most recent published hypertension guidelines, a normal BP is defined as < 120 mm Hg/< 80 mm Hg. BP is classified as elevated (BP 120-129 mm Hg/< 80 mm Hg); stage 1 hypertension (BP 130-139 mmHg/80-89 mm Hg); or stage 2 hypertension (BP >140 mm Hg/ > 90 mm Hg).[10]

The cause of hypertension in 90% of those affected is unknown, but it is usually controllable with lifestyle changes and medications.[11] Lifestyle changes are a part of therapy for all people with elevated BP and hypertension. Those with stage 1 or 2 hypertension usually need drug therapy, often more than 1 drug, to reach therapeutic goals (see Table 32.6).[10] Teach patients the importance of achieving and maintaining target BP goals.

The shearing stress of an elevated BP causes endothelial injury that increases the rate of atherosclerosis. Atherosclerosis, in turn, causes narrowed, thickened arterial walls and decreases the distensibility and elasticity of vessels. More force is needed to pump blood through diseased arteries. This increased force is reflected in a higher BP. This added workload results in left ventricular (LV) hypertrophy and decreased stroke volume with each contraction. See Chapter 32 for a complete discussion of hypertension.

Tobacco Use

A third major risk factor in CAD is tobacco use. The risk for developing CAD is much higher in those who smoke tobacco or use smokeless tobacco than in those who do not. Further, tobacco smoking

decreases estrogen levels, placing premenopausal women who smoke at greater risk for CAD.

Nicotine in tobacco smoke causes catecholamine (i.e., epinephrine, norepinephrine) release. These neurohormones cause an increased heart rate (HR), peripheral vasoconstriction, and increased BP. These changes increase the heart's workload. Tobacco smoke is related to an increase in LDL level, a decrease in HDL level, and release of toxic O_2 radicals. All of these add to vessel inflammation and thrombosis.

Carbon monoxide, found in tobacco smoke, affects the O_2-carrying capacity of hemoglobin by reducing the sites available for O_2 transport. Thus the effects of an increased cardiac workload and the O_2-depleting effect of carbon monoxide significantly decrease the O_2 available to the heart muscle. We also believe that carbon monoxide is a chemical irritant that injures the endothelium.

The benefits of smoking cessation are dramatic and almost immediate. CAD mortality rates drop to those of nonsmokers within 12 months. However, nicotine is highly addictive, and people usually need intensive intervention to quit. Individual and group counseling, nicotine replacement therapy, and smoking cessation drugs (e.g., bupropion, varenicline) are examples of smoking cessation strategies. (See Chapter 10, Tables 10.4 through 10.6 for information on smoking cessation.)

Nonsmokers exposed to secondhand tobacco smoke increase their risk for CAD by 25% to 30%.[1] People who live in the same house as the person who smokes should encourage that person to quit. This reinforces the person's effort and decreases the risk for ongoing exposure to environmental smoke. Pipe and cigar smokers, who often do not inhale, have an increased risk for CAD similar to those exposed to secondhand smoke. The few studies on electronic cigarettes suggest they increase HR and BP through systemic absorption of nicotine.[12]

Physical Inactivity

Physical inactivity is the fourth major modifiable risk factor for CAD. Physical inactivity implies a lack of adequate physical exercise on a

regular basis. The ACC and the AHA recommend 30 to 60 minutes of exercise, such as brisk walking at least 5 days per week.[13]

How physical inactivity predisposes a person to CAD is still unclear. Physically active people have increased HDL levels. Exercise improves thrombolytic activity, thus reducing the risk for clot formation. Exercise may help with the development of collateral circulation in the heart.

Exercise training for those who are physically inactive reduces the risk for CAD through more efficient lipid metabolism, increased HDL production, and more efficient O_2 extraction by the muscles. This decreases the heart's workload. For people with CAD, regular physical activity may reduce symptoms, improve functional capacity, and improve other risk factors, such as insulin resistance and glucose intolerance.

Obesity

The death rate from CAD is higher in obese persons. Obesity is defined as a body mass index (BMI) of greater than 30 kg/m^2 and a waist circumference more than 40 inches for men and more than 35 inches for women. We calculate BMI by dividing a person's weight (in kilograms) by the square of the height in meters (see Fig. 40.6).

The increased risk for CAD is proportional to the degree of obesity. Obese persons may make increased levels of LDLs and triglycerides, which are strongly related to atherosclerosis. Obesity is often linked with hypertension and insulin resistance. People who tend to store fat in the abdomen (an "apple" figure) rather than in the hips and buttocks (a "pear" figure) have a higher incidence of CAD (see Table 40.6).

Contributing Modifiable Risk Factors

Diabetes Mellitus

The incidence of CAD is 2 to 4 times greater among people who have diabetes, even those with well-controlled blood glucose levels. The

patient with diabetes manifests CAD more often and at an earlier age. There is no age difference between males or females with diabetes in the onset of symptoms of CAD.

Undiagnosed diabetes is often discovered when a person has an MI. The person with diabetes has an increased tendency toward endothelial dysfunction. This may account for the development of fatty streaks in the arteries. Patients with diabetes also have changes in lipid metabolism and tend to have high cholesterol and triglyceride levels. Management of diabetes should include lifestyle changes and drug therapy to achieve a glycosylated hemoglobin (A1C or Hb A1C) level of less than 7%.[13]

Metabolic Syndrome

Metabolic syndrome refers to a cluster of risk factors for CAD whose underlying pathophysiology may be related to insulin resistance. These risk factors include central obesity, hypertension, abnormal serum lipids, and a high fasting blood glucose (see Table 40.12). These interrelated risk factors appear to promote the development of CAD. Chapter 40 discusses metabolic syndrome.

Psychologic States

Certain behaviors and lifestyles may contribute to the development of CAD. One type of behavior, referred to as type A, includes perfectionism and a hardworking, driven personality. The type A personality often suppresses anger and hostility, has a sense of time urgency, is impatient, and creates stress and tension. This person may be more prone to MIs than one with a type B personality, who is more easygoing, takes upsets in stride, knows personal limitations, takes time to relax, and is not an overachiever. However, the relationship between behaviors and the risk for CAD/MI is controversial and complex.

Psychologic risk factors thought to increase the risk for CAD include depression, acute and chronic stress (e.g., poverty, serving as a caregiver), anxiety, hostility and anger, and lack of social support.[14] Stressful states contribute to the development and progression of

CAD. Sympathetic nervous system (SNS) stimulation and its effect on the heart are the physiologic mechanisms by which stress predisposes a person to the development of CAD. SNS stimulation causes an increased release of catecholamines (i.e., epinephrine, norepinephrine), which may contribute to endothelial injury, inflammation, and platelet activation.[14] SNS stimulation also increases HR and the force of myocardial contraction, which increases myocardial O_2 demand. Stress-induced mechanisms can cause elevated lipid and glucose levels and changes in blood coagulation, which contribute to the development of atherosclerosis.

Homocysteine

High blood levels of homocysteine are linked to an increased risk for CAD and other CVDs.[13] Homocysteine is made by the breakdown of the essential amino acid methionine, which is found in dietary protein. High homocysteine levels may contribute to atherosclerosis by (1) damaging the inner lining of blood vessels, (2) promoting plaque buildup, and (3) changing the clotting mechanism to make clots more likely to occur. Although folic acid lowers homocysteine levels, research has not shown that reducing homocysteine levels lowers the risk of CAD.[15]

Substance Use

The use of illegal drugs, such as cocaine and methamphetamine, can produce coronary artery spasm resulting in myocardial ischemia and chest pain. Most patients with drug-induced chest pain initially cannot be distinguished from those with CAD. They often have sinus tachycardia, high BP, and chest pain. Chest pain occurs because of increased myocardial O_2 demand from the increased HR and contractility and coronary vasoconstriction.[16] An MI can occur because of coronary spasm. Serum cardiac biomarkers and an electrocardiogram (ECG) help determine if the patient is experiencing ACS. A drug screen may be helpful to identify what precipitated the cardiac event.

Interprofessional and Nursing Care: Coronary Artery Disease

Health Promotion

Management of CAD risk factors may prevent, modify, or slow disease progression. In the United States, there has been a gradual decline in CAD-related deaths over the past 35 years. This relates to people's efforts to become healthier and advances in the treatment of CAD. Prevention and early treatment of heart disease must involve a multifaceted approach and must be ongoing throughout the life span. In fact, healthy lifestyle behaviors should begin in childhood.

Identifying High-Risk Persons

Clinical signs of CAD are not apparent in the early stages of the disease. Therefore it is critical to identify people at risk for CAD. Risk screening involves obtaining a thorough health history. Ask the patient about a family history of heart disease in parents and siblings, especially a premature history of CAD (under age 55 for males and under age 65 for females).[13] Note the presence of any cardiovascular symptoms. Assess environmental factors, such as eating habits, type of diet, and level of exercise, to elicit lifestyle patterns. Include a psychosocial history to determine tobacco use, alcohol intake, recent stressful events (e.g., loss of a spouse), and psychologic state (e.g., anxiety, depression, anger). The place and type of employment provide vital information on the kind of activity performed, exposure to pollutants or toxins, and degree of stress associated with work.

Identify the patient's attitudes and beliefs about health and illness. This gives insight to how disease and lifestyle changes may affect the patient. It also can reveal misconceptions about heart disease. Knowing the patient's educational background and health literacy helps determine teaching needs. If the patient has prescribed drugs, it is important to know the names and dosages and if the patient

adheres to the drug regimen.

Managing High-Risk Persons

Recommend preventive measures for all persons at risk for CAD. The person with nonmodifiable risk factors (e.g., age, gender, ethnicity) can still reduce the risk for CAD by controlling the additive effects of modifiable risk factors. For example, a young person with a family history of heart disease can decrease the risk for CAD by maintaining an ideal body weight, getting adequate physical exercise, reducing intake of saturated fats, and avoiding tobacco and illicit drug use.

Encourage people who have modifiable risk factors to make lifestyle changes to reduce their risk for CAD. You can play a key role in teaching health-promoting behaviors (Table 33.2). For highly motivated persons, just knowing how to reduce their risk may be all the information they need to start.

For people who are less motivated to take charge of their health, the idea of reducing risk factors may be so remote that they are unable to perceive a threat of CAD. Few people want to make lifestyle changes, especially in the absence of symptoms. First, help them to clarify their personal values. Then, discuss risk factors and have them identify their individual risks. This can help them set realistic goals and choose which risk factor(s) to change first. Some people are reluctant to change until they begin to have symptoms or have an MI. Others, having had an MI, may find the idea of changing lifelong habits still unacceptable. Help them review options and respect their decisions.

Physical Activity

A regular physical activity program should be designed and implemented to improve physical fitness by following the FITT formula (Table 33.3): Frequency (how often), Intensity (how hard), Type (isotonic), and Time (how long). Everyone should aim for at least 30 minutes of moderate physical activity on most days of the week. Examples of moderate physical activity include brisk walking, hiking, biking, and swimming. The AHA encourages people to

increase their daily physical activity and lower the chance of developing heart disease simply by walking. Adding weight training to an exercise program 2 days a week can help treat metabolic syndrome and improve muscle strength. Regular physical activity helps with weight reduction, reduces systolic BP, and can help increase HDL cholesterol.

Nutritional Therapy

Dietary recommendations focus on ways to lower LDL cholesterol. They emphasize a decrease in saturated fat and cholesterol and an increase in complex carbohydrates (e.g., whole grains, fruit, vegetables) and fiber (Tables 33.4 and 33.5). Fat intake should be about 25% to 35% of total calories, with most coming from monounsaturated and polyunsaturated fats. Red meat, egg yolks, and whole milk products are major sources of saturated fat and cholesterol. They should be reduced or eliminated from diets. With a high serum triglyceride level, alcohol and simple sugars should be reduced or eliminated.

TABLE 33.2 Patient & Caregiver TeachingReducing Risk Factors for Coronary Artery Disease

Include the following instructions when teaching risk reduction for coronary artery disease:

Risk Factor	Health-Promoting Behaviors
Hypertension	• Monitor home-based BP and obtain regular checkups. • Take prescribed drugs for BP control. • Reduce salt intake. • Stop tobacco use. Avoid exposure to environmental tobacco (secondhand) smoke. • Control or reduce weight. • Perform physical activity daily.
High serum lipids	• Reduce total fat intake. • Reduce saturated fat intake. • Take prescribed drugs for lipid reduction. • Adjust total caloric intake to achieve and maintain ideal body weight. • Engage in daily physical activity. • Increase amount of complex carbohydrates, fiber, and vegetable proteins in diet. • Follow-up with HCP for regular lipid panel assessments.
Tobacco use (see Chapter 10)	• Begin a tobacco cessation program. • Change daily routines associated with tobacco use to reduce desire to smoke. • Substitute other activities for smoking. • Ask caregivers to support efforts to stop smoking. • Avoid exposure to environmental tobacco smoke.
Physical inactivity	• Develop and maintain at least 30 minutes of moderate physical activity daily (minimum 5 days a week). • Increase activities to a fitness level.
Psychologic state	• Increase awareness of behaviors that are harmful to health. • Change patterns that add to stress (e.g., get up 30 min earlier so that breakfast is not eaten on way to work). • Set realistic goals for self. • Reassess priorities in light of identified risk factors. • Learn effective stress management strategies (see Chapter 6). • Seek professional help if feeling depressed, angry, anxious, etc. • Plan time for adequate rest and sleep (see Chapter 7).
Obesity use (see Chapter 40)	• Change eating patterns and habits. • Reduce caloric intake to achieve body mass index of 18.5 to 24.9 kg/m^2. • Increase physical activity to increase caloric expenditure. • Avoid fad and crash diets, which are not effective over time. • Avoid large, heavy meals. Consider smaller, more frequent meals.
Diabetes use (see Chapter 48)	• Follow the recommended diet. • Control or reduce weight. • Take prescribed drugs for diabetes. • Monitor blood glucose levels regularly and follow up with HCP regularly.

TABLE 33.3 Patient & Caregiver TeachingFITT Activity Guidelines for CAD, Chronic Stable Angina, and ACS

Include the following information in the teaching plan for the patient with chronic stable angina and acute coronary syndrome and the caregiver:

Warm-Up/Cool-Down

Perform mild stretching for 3–5 min before the physical activity and 5 min after the activity. Do not start or stop activity abruptly.

Frequency

Perform physical activity on most days of the week.

Intensity

The patient's HR determines the activity intensity. If an exercise stress test has not been performed, the HR of the patient recovering from an MI should not exceed 20 beats/min over the resting HR.

Type of Physical Activity

Select physical activity that is regular, rhythmic, and repetitive, using large muscles to build up endurance (e.g., walking, cycling, swimming, rowing).

Time

Physical activity sessions should be at least 30 min long. Begin slowly at personal tolerance (perhaps only 5–10 min) and build up to 30 min.

Omega-3 fatty acids reduce triglyceride levels and can slow the progression of CAD. They do not affect LDL levels. The AHA recommends eating fatty fish twice a week. Examples of fatty fish include salmon, tuna, and mackerel. Other foods that contain omega-3 fatty acids include soybean oils, canola, walnuts, and flaxseed.[17] Omega-3 fatty acids can be hard to get by diet alone. The HCP may recommend dietary supplements.

Lipid-Lowering Drug Therapy

An estimated 28.5 million American adults over age 20 have cholesterol levels of 240 mg/dL (6.2 mmol/L) or greater.[1] Treatment of high cholesterol focuses mostly on lowering LDL cholesterol. A complete lipid profile should be done every 5 years beginning at age 20.[9] Middle-aged adults should be screened every 1 to 2 years. If multiple risk factors are present, more frequent testing is recommended.[9] Guidelines recommend the following groups of people receive statin therapy: (1) patients with known CVD, (2) patients with primary elevations of LDL cholesterol levels of 190 mg/dL or greater (e.g., familial hypercholesterolemia), (3)

TABLE 33.4 Nutritional TherapyTherapeutic Lifestyle Changes to Diet

Dietary Recommendations	Recommended Daily Intake
Combined total fat calories from: • *Saturated fats:* Limit fats that are usually solid at room and refrigerator temperature (e.g., lard, butter, whole-milk products, fatty cuts of meat, bacon) • *Trans fats:* Mainly in foods made with hydrogenated vegetable oils, such as many hard margarines and shortenings • *Unsaturated fats*: In oils that are usually liquid at room and refrigerator temperature (e.g., olive, corn, sunflower, soybean). There are 2 types of unsaturated fats: • *Monounsaturated fats:* In greatest amounts in foods from plants, including olives, avocadoes, and canola, sunflower, and peanut oils. • *Polyunsaturated fats:* Found mostly in nuts, seeds, fish, seed oils, and oysters. Omega-3 fatty acid is a type of polyunsaturated fat that may help reduce the risk of CAD.	25%–35% of total daily calories (including <7% from saturated fat)
Cholesterol	<200 mg
Plant stanols or sterols (e.g., margarines, nuts, seeds, legumes, vegetable oils)*	2 g
Dietary soluble fiber*	10–25 g of soluble fiber
Total calories	Only enough calories to reach or maintain a healthy weight
Physical Activity	
In addition to diet, teach the patient to get at least 30 min of a moderate intensity physical activity, such as brisk walking, on most, and preferably all, days of the week.	

* Diet options for additional lowering of low-density lipoprotein (LDL).

Complementary & Alternative Therapies

Lipid-Lowering Agents

Agent	Evidence for Use
Berberine	Possibly effective for reducing total cholesterol, low-density lipoproteins (LDLs), triglycerides
Garlic	Conflicting evidence. Possibly effective for reducing total cholesterol and LDL over short periods
Green tea	Possibly effective for reducing total cholesterol
Flaxseed	Conflicting evidence on the efficacy for reducing total cholesterol
Omega-3 fatty acids (fish oil)	Effective for reducing cholesterol and triglyceride levels
Black psyllium	Possibly effective for reducing total cholesterol and LDL
Plant sterols	Likely effective for reducing total cholesterol and LDL

Red yeast rice	Likely effective for reducing total cholesterol, LDL, and triglycerides. Red yeast rice contains a chemical similar to statins.
Soy	Possibly effective for slight reduction in total cholesterol and LDL

Source: Sahebkar A, Serban MC, Gluba-Brzózka A, et al: Lipid-modifying effects of nutraceuticals: an evidence-based approach, *Nutrition* 32:1179, 2016; Siscovick DS, Barringer TA, Fretts AM, et al: Omega-3 polyunsaturated fatty acid (fish oil) supplementation and the prevention of clinical cardiovascular disease, *Circulation*, 2017.

patients 40 to 75 years old with diabetes and LDL cholesterol levels between 70 and 189 mg/dL, and (4) patients 40 to 75 years old with LDL cholesterol levels between 70 and 189 mg/dL and a 10-year risk for CVD of at least 7.5%.[8,18]

Drug therapy should continue for a lifetime unless the patient becomes intolerant. In that case, the patient should switch to another drug. The patient must fully understand the rationale and goals of treatment, as well as the safety and side effects of lipid-lowering drugs.

Concurrent diet change is essential to reduce the need for drug therapy. Treatment also includes weight loss, if overweight, and increased physical activity. Serum lipid levels should be reassessed after 6 weeks of therapy. If they are still high, changes in drug therapy (Table 33.6) and more dietary options (see the Complementary & Alternative Therapies box) may be considered.

TABLE 33.5 Nutritional TherapyTips to Make Diet and Lifestyle Changes

General Tips

1. Know your calorie needs to achieve and maintain a healthy weight.

2. Know the calorie content of the foods and beverages you eat.
3. Track your weight, physical activity, and calorie intake.
4. Prepare and eat smaller, more frequent meals.
5. Track your activities and, whenever possible, decrease sedentary activities (e.g., watching television, computer time).
6. Incorporate physical movement into daily activities (e.g., take stairs and extra steps whenever possible).
7. Do not smoke or use tobacco products.
8. If you drink alcohol, do so in moderation (i.e., no more than 1 drink for women or 2 drinks for men a day).

Tips Related to Food Choices and Preparation

1. Use the Nutrition Facts panel on food labels and ingredients list when choosing foods to buy.
2. Use fresh or frozen vegetables and fruits in place of canned vegetables and fruits.
3. Replace high-calorie foods with fresh fruits and vegetables.
4. Increase fiber intake by eating beans (legumes), whole-grain products, fruits, and vegetables.
5. Use liquid vegetable oils in place of solid fats.
6. Limit beverages and foods high in added sugars (e.g., sucrose, glucose, fructose, maltose, dextrose, corn syrups, concentrated fruit juice, honey).
7. Choose foods made with whole grains (e.g., whole wheat, oats, rye, barley, brown rice, wild rice, buckwheat).
8. Avoid pastries and high-calorie bakery products (e.g., muffins, doughnuts).
9. Select milk and dairy products that are either fat free or low fat.
10. Reduce salt intake by
    - Comparing the sodium content of similar products (e.g., different brands of tomato sauce) and choosing products with less sodium.
    - Choosing versions of processed foods with reduced

salt, including cereals, canned products, and baked goods.
- Limiting condiments (e.g., soy sauce, ketchup).

11. Use lean cuts of meat and remove skin from poultry before cooking or eating.
12. Avoid processed meats that are high in saturated fat and sodium (e.g., deli meats).
13. Grill, bake, or broil fish, meat, and poultry.
14. Incorporate plant-based meat substitutes into recipes (e.g., soy, tofu, quinoa).
15. Consume whole vegetables and fruits in place of juices.

Drugs That Restrict Lipoprotein Production

HMG-CoA Reductase Inhibitors (Statins)

The statin drugs are the most widely used lipid-lowering drugs (Table 33.6). These drugs inhibit the synthesis of cholesterol in the liver. An unexplained result of inhibiting cholesterol synthesis is an increase in hepatic LDL receptors. This allows the liver to remove more LDL from the blood. In addition, statins cause a minor increase in HDL and lower CRP levels. The statins are not equal in reducing LDL levels. Rosuvastatin (Crestor) is the most potent statin currently available. Serious adverse effects of these drugs are rare and include liver damage and myalgia (muscle ache or weakness without breakdown of skeletal muscle) that can progress to rhabdomyolysis (breakdown of skeletal muscle). Liver enzymes are initially monitored and rechecked with any increase in dosage. The creatine kinase isoenzyme, CK-MM (found in skeletal muscle), is assessed if symptoms of myopathy (e.g., muscle aches, weakness) occur.

Drug Alert

Simvastatin (Zocor)

- Increased risk for rhabdomyolysis when used with fibric acid derivatives (e.g., gemfibrozil [Lopid]), niacin (Niaspan), or erythromycin.
- Manifestations of rhabdomyolysis include high creatine kinase levels and muscle pain.
- Prothrombin times may increase in patients taking warfarin (Coumadin).

Niacin

Niacin, a water-soluble B vitamin, is effective in lowering LDL and triglyceride levels by interfering with their synthesis (Table 33.6). Niacin, at high doses, increases HDL levels better than many other lipid-lowering drugs. Unfortunately, side effects are common. They may include severe flushing, pruritus, gastrointestinal (GI) symptoms, and orthostatic hypotension.

Drug Alert

Niacin (Niaspan)

- Teach the patient that flushing (especially of face and neck) may occur within 20 minutes after taking drug and last for 30 to 60 minutes.
- Premedicate with aspirin or NSAID 30 minutes before taking to reduce flushing.
- Use of extended-release niacin may decrease side effects.

Fibric Acid Derivatives

The *fibric acid derivatives* (Table 33.6) work by aiding the removal of VLDLs. They are very effective for lowering triglycerides and increasing HDL levels. They have no effect on LDLs. Although most patients tolerate the drugs well, GI irritability is common. These drugs should be used with caution when combined with statin medications due to increased risk for myopathy.

Drug Alert

Gemfibrozil (Lopid)

- May increase the risk for bleeding in patients taking warfarin (Coumadin)
- Increases the risk of hypoglycemia in patients taking repaglinide (Prandin)

Drugs That Increase Lipoprotein Removal

Bile Acid Sequestrants

Bile-acid sequestrants increase conversion of cholesterol to bile acids in the liver and decrease hepatic cholesterol (Table 33.6). The primary effect is a decrease in total cholesterol and LDL levels. These drugs have been associated with side effects related to taste and a variety of upper and lower GI symptoms. These include belching, heartburn, nausea, abdominal pain, and constipation. Bile-acid sequestrants decrease absorption of many other drugs (e.g., warfarin, thiazides, thyroid hormones, β-adrenergic blockers [β-blockers]). Separating the time of giving these drugs from that of other drugs by at least 2 hours decreases this adverse effect.[7]

Proprotein Convertase Subtilisin/Kexin 9 (PCSK9)

Inhibitors

PCSK9 inhibitors are a newer class of cholesterol-lowering drugs (Table 33.6). PCSK9 reduces the number of receptors on the liver that remove LDL cholesterol from the blood. By blocking PCSK9's ability to work, more receptors are available and can get rid of LDL, thus decreasing circulating LDL levels. Evolocumab (Repatha) and alirocumab (Praluent) are 2 PCSK9 inhibitors. They are given subcutaneously every 2 weeks. Evolocumab may be given every 4 weeks at a higher dose, depending on patient preference. They are not a first-line therapy. They are used in addition to diet and maximum statin therapy for adults with familial hypercholesterolemia and for patients intolerant of statin drugs. They also can be used for patients with CAD who need added LDL lowering because of inadequate treatment with statins.[7]

Drugs That Decrease Cholesterol Absorption

Ezetimibe (Zetia) selectively inhibits the absorption of dietary and biliary cholesterol across the intestinal wall (Table 33.6). It serves as an adjunct to dietary changes, especially for patients with primary hypercholesterolemia. When it is combined with a statin, either as a combination drug (e.g., ezetimibe and simvastatin [Vytorin]) or as 2 separate drugs (ezetimibe and a statin), even greater reductions in LDLs occur.

Antiplatelet Therapy

Low-dose aspirin (81 mg) is recommended for people who have CAD. For people at risk but without known CAD, low-dose aspirin is recommended for adults 50 to 59 years old who have a calculated 10-year CVD risk of 10% or more, are not at increased risk for bleeding (e.g., history of GI bleeding), have a life expectancy of at least 10 years, and are willing to take low-dose aspirin for at least 10 years. For adults 60 to 69 years old who have a calculated 10-year CVD risk of 10% or more, the decision to take low-dose aspirin is an individual one made in conjunction with the HCP. Adults who have no

contraindications (e.g., history of bleeding), have a life expectancy of at least 10 years, and are willing to take low-dose aspirin daily for at least 10 years are more likely to benefit. Currently there is not enough evidence to recommend low-dose aspirin for primary prevention in those younger than 50 or older than 70.[19] Clopidogrel (Plavix) is an option for people who are aspirin intolerant.[15]

Gerontologic Considerations: Coronary Artery Disease

The incidence of heart disease is greatly increased in older adults and the leading cause of death in older persons. In the older adult, CAD is often a result of the complex interaction of nonmodifiable risk factors (e.g., age) and lifelong modifiable risk behaviors (e.g., inactivity, tobacco use). Strategies to reduce CAD risk and to treat CAD are effective in this age-group.

Aggressive treatment of hypertension and hyperlipidemia helps stabilize plaques in the coronary arteries. Tobacco cessation helps to decrease the risk for CAD at any age. Similarly, encourage the older patient to consider a planned program of physical activity. Physical activity improves activity performance, endurance, and ability to tolerate stress. Positive psychologic benefits can include increased self-esteem, emotional well-being, and improved body image. For the older adult who is obese, making modest dietary changes and slowly increasing physical activity (e.g., walking) results in more positive benefits than aiming for a significant weight loss.

TABLE 33.6 Drug TherapyHyperlipidemia

Drug	Mechanism of Action	Side Effects	Nursing Considerations
Restrict Lipoprotein Production			
Fibric Acid Derivatives			
fenofibrate (Tricor) **gemfibrozil (Lopid)**	Decrease hepatic synthesis and secretion of VLDL. Reduce triglycerides by ↓ VLDL ↓ LDL ↓ Triglycerides ↑ HDL	Rashes, mild GI problems (e.g., nausea, diarrhea), high liver enzymes	May ↑ effects of warfarin (Coumadin) and some antihyperglycemic drugs. When used in combination with statins, may increase adverse effects of statins, especially myopathy.
HMG-CoA Reductase Inhibitors (Statins)			
atorvastatin (Lipitor) **fluvastatin (Lescol XL)** **lovastatin** **pitavastatin (Livalo)** **pravastatin (Pravachol)** **rosuvastatin (Crestor)** **simvastatin (Zocor)**	Block synthesis of cholesterol and increase LDL receptors in liver ↓ LDL ↓ Triglycerides ↑ HDL (small amount)	Rash, GI problems, high liver enzymes, myopathy, rhabdomyolysis	Well tolerated with few side effects. Monitor liver enzymes and creatine kinase (if muscle weakness or pain occurs).
Niacin			
Niacin (Niaspan)	Inhibits synthesis and secretion of VLDL and LDL ↓ LDL ↓ Triglycerides ↑ HDL	Flushing and pruritus in upper torso and face, GI problems (e.g., nausea and vomiting, dyspepsia, diarrhea), orthostatic hypotension	Most side effects subside with time. Taking aspirin or NSAID 30 min before drug may prevent flushing. Take drug with food. Decreased liver function may occur with high doses.
Omega-3 Fatty Acid			
icosapent ethyl (Vascepa) (contains eicosapentaenoic acid [EPA])	Inhibits synthesis and/or secretion of triglycerides	Arthralgia	Used for patients with severe hypertriglyceridemia (levels ≥ 500 mg/dL)
omega-3 acid ethyl esters (Lovaza) (contains eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA])	↓ Triglycerides ↑ HDL	Anaphylaxis, rash, taste changes, GI problems (e.g., constipation, vomiting)	Used for patients with high triglycerides. Give with meals and do not open or dissolve capsules
Increase Lipoprotein Removal			
Bile-Acid Sequestrants			
cholestyramine (Prevalite) **colesevelam (Welchol)** **colestipol (Colestid)**	Binds with bile acids in intestine, forming insoluble complex and excreted in feces Binding results in removal of LDL and cholesterol ↓ LDL	Unpleasant quality to taste, GI problems (e.g., indigestion, constipation, bloating)	Effective and safe for long-term use. Side effects lessen with time. Interferes with absorption of many drugs (e.g., digoxin, thiazide diuretics, warfarin, some antibiotics [e.g., penicillins])
Proprotein Convertase Subtilisin/Kexin 9 (PCSK9) Inhibitors			
alirocumab (Praluent) **evolocumab (Repatha)**	Inactivate PCSK9 protein ↓ LDL	Injection-site reactions, muscle pain, limb pain, and fatigue	Used with diet and maximum statin therapy to treat familial hypercholesterolemia and for those who need further LDL lowering or for those who are statin intolerant Drugs are given by injection every 2–4 wks (evolocumab may be given every 4 wks at a higher dose)
Decrease Cholesterol Absorption			
Cholesterol Absorption Inhibitor			
ezetimibe (Zetia)	Inhibits the intestinal absorption of cholesterol ↓ LDL ↑ HDL	Infrequent, but may include headache and mild GI distress	When used with a statin, further reduces LDL. Should not be used by patients with liver impairment

TABLE 33.7 Select Conditions Influencing Myocardial O_2 Needs

Decreased O_2 Supply	Increased O_2 Demand or Consumption
Cardiac	
• Coronary artery atherosclerosis • Coronary artery spasm • Coronary artery thrombosis • Dysrhythmias • Heart failure • Valve disorders	• Aortic stenosis • Cardiomyopathy • Dysrhythmias • Left ventricular hypertrophy • Tachycardia
Noncardiac	
• Anemia • Asthma • Chronic obstructive pulmonary disease • Hypovolemia • Hypoxemia • Pneumonia • Substance (stimulant) abuse (e.g., cocaine, amphetamines)	• Anxiety • Hypertension • Hyperthermia • Hyperthyroidism • Physical exertion • Substance (stimulant) abuse (e.g., cocaine, amphetamines)

When planning a physical activity program, recommend: (1) longer warm-up periods, (2) longer periods of low-level activity, and/or (3) longer rest periods between sessions. Heat intolerance results from a decreased ability to sweat efficiently. Teach the patient to avoid physical activity in temperature extremes and to maintain a moderate pace. The older adult should exercise a minimum of 30 minutes on most days of the week as able.

Encouraging the older patient to adopt a healthy lifestyle may increase the quality of life and reduce the risk for CAD and fatal heart events. Older adults face many of the same challenges as younger persons when it comes to making lifestyle changes. Older adults are more likely to consider change either (1) when hospitalized or (2) when symptoms (e.g., chest pain) are the result of CAD and not normal aging (see Table 31.1). First, assess for the readiness to change and health literacy. Then, help the patient select the lifestyle changes most likely to produce the greatest reduction in risk for CAD.

Chronic Stable Angina

CAD is a chronic and progressive disease. Patients may be asymptomatic for many years but may eventually develop chronic stable chest pain. When the demand for myocardial O_2 exceeds the ability of the coronary arteries to supply the heart with O_2, *myocardial ischemia* occurs. **Angina**, or chest pain, is the clinical manifestation of myocardial ischemia. It is caused by either an increased demand for O_2 or a decreased supply of O_2 (Table 33.7). The most common reason for angina to develop is significant narrowing of 1 or more coronary arteries by atherosclerosis. This leads to insufficient blood flow to the heart muscle. For ischemia to occur from an atherosclerotic plaque, the artery is usually blocked (stenosed) 70% or more (50% or more for the left main coronary artery).[20]

Chronic stable angina refers to chest pain that occurs intermittently over a long period of time with a similar pattern of onset, duration, and intensity of symptoms. It is often provoked by physical exertion, stress, or emotional upset. It is important to get an accurate assessment of the angina symptoms (Table 33.8). When asked, some patients may deny feeling pain, but describe a pressure, heaviness, or discomfort in the chest. This discomfort is often described as a squeezing, heavy, tight, or suffocating sensation. It may be associated with other symptoms, such as dyspnea or fatigue. Chronic angina pain usually does not change with position or breathing.

TABLE 33.8 PQRST Assessment of Angina

Use the following memory aid to obtain information from the patient who has chest pain:

	Factor	Questions to Ask Patient
P	Precipitating events	What events or activities precipitated the pain or discomfort (e.g., argument, exercise, resting)?

Q	Quality of pain	What does the pain or discomfort feel like (e.g., pressure, dull, aching, tight, squeezing, heaviness)?
R	Region (location) and radiation of pain	Can you point to where the pain or discomfort is located? Does the pain or discomfort radiate to other areas (e.g., back, neck, arms, jaw, shoulder, elbow)?
S	Severity of pain	On a scale of 0 to 10, with 0 indicating no pain and 10 being the most severe pain you could imagine, what number would you give the pain or discomfort?
T	Timing	When did the pain or discomfort begin? Has it changed since this time? Have you had pain/discomfort like this before?

Although most angina pain occurs substernally, it may radiate to other locations, including the jaw, neck, shoulders, and/or arms. Many people with angina describe a feeling of indigestion or a burning sensation in the epigastric region. The sensation may be felt between the shoulder blades (Fig. 33.3). Often, people who describe pain between the shoulder blades or indigestion type pain dismiss it as not being heart related. Some patients, especially women and older adults, report atypical symptoms of angina, including dyspnea, nausea, mid-epigastric discomfort, and/or fatigue.[13] We refer to this as an *angina equivalent*.

The pain of chronic stable angina usually lasts for only a few minutes. It often subsides when the precipitating factor is resolved (e.g., by resting, calming down, using sublingual nitroglycerin [SL NTG]) (Table 33.9). Pain at rest is unusual and may indicate UA. With ischemia, the 12-lead ECG often shows ST segment depression and/or T wave inversion. These changes represent inadequate supply of blood and O_2 to the heart muscle. ST depression is significant if it is at least 1 mm (1 small box) below the isoelectric line in at least 2 contiguous (neighboring) leads. In a normal heart, the isoelectric line should be flat (see Fig. 35.10). The ECG changes return to baseline when adequate blood flow is restored, and pain is relieved.

Chronic stable angina is controlled with drugs on an outpatient basis. Because chronic stable angina is often predictable, drugs are timed to provide peak effects during the time of day when angina is likely to occur. For example, if angina occurs when rising, the patient can take medication as soon as awakening and wait 30 minutes to 1 hour before engaging in activity. A comparison of the major types of

angina is outlined in Table 33.10.

Silent ischemia refers to ischemia that occurs in the absence of any subjective symptoms. Patients with diabetes have an increased prevalence of silent ischemia. This is likely due to diabetic neuropathy affecting the nerves that innervate the cardiovascular system. When patients are monitored and silent ischemia occurs, ECG changes are revealed (e.g., ST depression and/or T wave inversion) (Fig. 33.4, *A*). Ischemia with pain or without pain has the same prognosis.

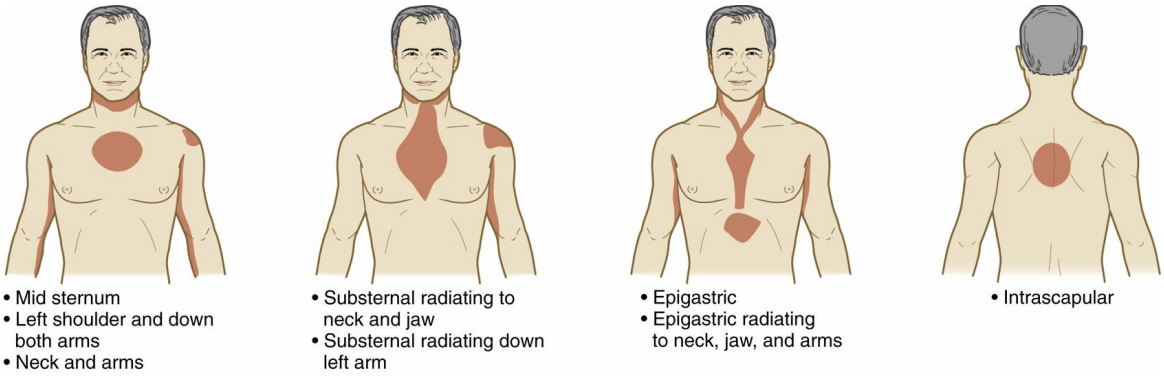

FIG. 33.3 Common locations and patterns of pain during angina or MI.

TABLE 33.9 Precipitating Factors of Angina

Physical Exertion

- Increases HR, reducing the time the heart spends in diastole (the time of greatest coronary blood flow), resulting in an increase in myocardial O_2 demand
- Isometric exercise of the arms (e.g., raking, lifting heavy objects, snow shoveling) can cause exertional angina

Temperature Extremes

- Increase the workload of the heart
- Blood vessels constrict in response to a cold stimulus
- Blood vessels dilate and blood pools in the skin in response to a hot stimulus

Strong Emotions

- Stimulate the sympathetic nervous system, activating the stress response
- Increase the workload of the heart

Consumption of Heavy Meal (e.g., holiday meals)

- Can increase the workload of the heart
- During the digestive process, blood is diverted to the GI system, reducing blood flow in the coronary arteries

Tobacco Use and Environmental Tobacco Smoke

- Decrease available O_2 by increasing the level of carbon monoxide
- Nicotine stimulates catecholamine release, causing vasoconstriction and an increased HR

Sexual Activity

- Increases the cardiac workload and sympathetic stimulation
- In a person with CAD, the extra cardiac workload may precipitate angina

Stimulants (e.g., cocaine, amphetamines)

- Increase HR and BP and increases myocardial O_2 demand
- Stimulate vasoconstriction and decreases myocardial O_2 supply
- May precipitate dysrhythmias

Circadian Rhythm Patterns

- Manifestations of CAD tend to occur in the early morning after awakening

TABLE 33.10 Comparison of Major Types of Angina

Type	Etiology	Characteristics
Chronic stable angina	Myocardial ischemia (usually from CAD) caused by an O_2 supply/demand mismatch	• Episodic pain lasting a few minutes • Provoked by exertion or stress • Relieved by rest or nitroglycerin
Prinzmetal's angina	Coronary vasospasm	• Occurs primarily at rest • Triggered by smoking and increased levels of some substances (e.g., histamine, epinephrine, cocaine) • May occur in presence or absence of CAD • Treatment may include long-acting nitrates and/or calcium channel blockers
Microvascular angina	Myocardial ischemia from microvascular disease affecting the small, distal branches of coronary arteries	• More common in women • Triggered by activities of daily living (e.g., shopping, work) vs. physical exercise (exertion) • Treatment may include nitroglycerin
Unstable angina	Rupture of unstable plaque, exposing thrombogenic surface	• New-onset angina • Chronic stable angina that increases in frequency, duration, or severity • Occurs at rest or with minimal exertion • Lasts more than 10 min

Prinzmetal's Angina

Prinzmetal's angina *(variant angina)* is a rare form of angina that often occurs at rest and not with increased physical demand. It is sometimes seen in patients with a history of migraine headaches, Raynaud's phenomenon, and heavy smoking. It is usually due to spasm of a major coronary artery. Strong contraction (spasm) of smooth muscle

in the coronary artery results from increased intracellular calcium.[21] The spasm may occur in the presence or absence of CAD.

Factors contributing to coronary artery spasm include increased levels of certain substances (e.g., alcohol, cocaine), exposure to medications that narrow blood vessels (e.g. sumatriptan [Imitrex]), or cold weather exposure. When spasm occurs, the patient has angina and transient ST segment elevation (not usually associated with an MI) (Fig. 33.4, *B*). The pain may occur during rapid-eye-movement (REM) sleep when myocardial O_2 consumption increases between midnight and early morning or at rest. The pain may be relieved by moderate exercise, with SL NTG, or it may disappear spontaneously. Cyclic, short bursts of pain at the same time each day may occur with this type of angina. Calcium channel blockers and/or nitrates are an option. Stopping the use of any offending substances is recommended.[22]

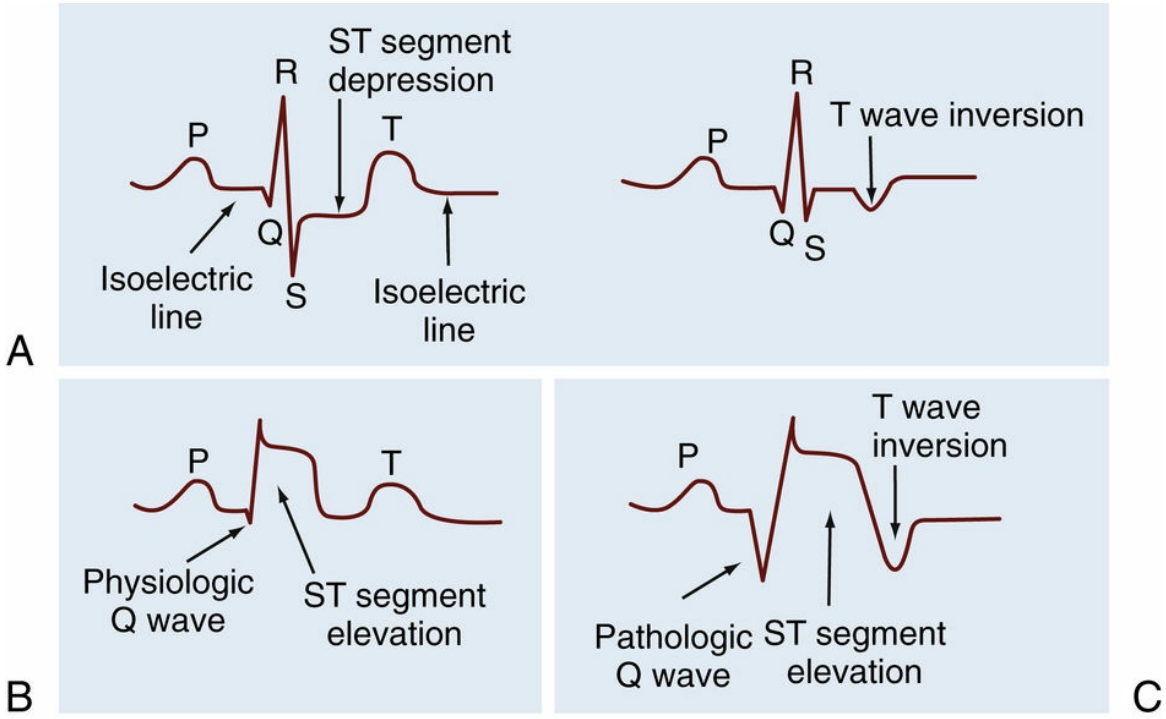

FIG. 33.4 ST segment, T wave, and Q wave changes associated with myocardial ischemia **(A),** injury coronary spasm **(B),** and infarction **(C)**. From Bucher L, Melander S: *Critical care nursing,* Philadelphia, 1999, Saunders.

Microvascular Angina

In *microvascular angina,* chest pain occurs in the absence of significant CAD or coronary spasm of a major coronary artery. In these patients, chest pain is related to myocardial ischemia associated with atherosclerosis or spasm of the small distal branch vessels of the coronary microcirculation. This is known as *coronary microvascular disease* (MVD). MVD is often used interchangeably with the term *syndrome X*. It is more common in women. Often the angina is prolonged and brought on by physical exertion. These patients usually have positive stress test results and an inconsistent response to nitrates.[22] Prevention and treatment of coronary MVD follow the same recommendations as for CAD.

Interprofessional and Nursing Care: Chronic Stable Angina

Chronic stable angina can progress or develop into UA or ACS. Therefore any change in the usual pattern of angina should be evaluated. A patient with chronic stable angina may be admitted with a change in the angina pattern. Until an assessment and diagnostic studies are completed, it may be unclear if the patient is having typical chronic stable angina, UA, or an MI.

The goal of treatment for a patient admitted with angina is to decrease O_2 demand and/or increase O_2 supply. Nursing care focuses on the priority problems of managing acute pain and anxiety while increasing O_2 delivery to the myocardium. The overall goals for a patient who presents with angina include (1) relief of pain, (2) immediate and appropriate treatment, (3) preservation of heart muscle if an MI is suspected, (4) effective coping with illness-associated anxiety, (5) participation in a rehabilitation plan, and (6) reduction of risk factors.

Acute Care

If your patient has angina, perform the following measures: (1) position patient upright unless contraindicated and apply supplemental O_2, (2) assess vital signs, (3) place patient on continuous ECG monitor, (4) obtain a 12-lead ECG, (5) provide prompt pain relief, first with NTG, followed by an IV opioid analgesic, if needed, (6) obtain cardiac biomarkers, (7) assess heart and breath sounds, and (8) obtain a chest x-ray. The patient may be anxious and may have pale, cool, clammy skin. The BP and HR may be high. Auscultation of the heart may reveal an atrial (S_4) or a ventricular (S_3) gallop. A new systolic murmur heard during an angina attack may indicate ischemia of a papillary muscle of the mitral valve, causing mitral regurgitation (the mitral valve does not close properly). The murmur may be

transient and disappear when symptoms resolve.

Ask the patient to describe the pain and to rate it on a scale of 0 to 10 before and after treatment to evaluate the effectiveness of the interventions. It is important to use the same words the patient uses to describe the symptoms (e.g., tightness, pressure). Assess for other signs of pain, such as restlessness; ECG changes; high HR, respiratory rate, or BP; clutching of the bed linens; or other nonverbal cues. Support and reassure the patient. Use a calm approach to help reduce the patient's anxiety during an angina attack. If the chest pain is not related to an ACS, the patient may be discharged within 1 or 2 days. Further testing may be done during the hospitalization or as an outpatient.

Check Your Practice

A visitor finds you in the hallway and tells you that her father is having chest pain. The patient is not assigned to you.

- How would you proceed?

Patient Teaching

Reassure the patient with a history of angina that a long, active life is possible. Preventing angina or at least reducing the frequency of angina is key, so teaching is important. Emphasize the importance of risk factor modification to slow the progression of CAD (Tables 33.1 and 33.11). Give the patient information about CAD, angina, precipitating factors for angina (Table 33.9) and medications to treat angina (Table 33.11).

You can provide patient teaching in a variety of ways. One-on-one contact between you and the patient is often the most effective approach. Time spent providing daily care (e.g., giving drugs) offers many teachable moments. Teaching aids, such as DVDs, heart models, and printed information, are important resources for patient and

caregiver teaching (see Chapter 4).

Help the patient to identify factors that precipitate angina (Table 33.9). Tell the patient how to avoid or control these factors. For example, teach the patient to avoid exposure to extremes of weather and eating large, heavy meals. Tell the patient to rest for 1 to 2 hours after a heavy meal because blood shifts to the GI tract to aid digestion and absorption.

Help the patient to identify personal risk factors for CAD and ways to reduce modifiable risk factors (Table 33.2). Teach the patient and caregiver about diets low in salt and saturated fats (Tables 33.4 and 33.5). Maintaining ideal body weight is important in controlling angina because excess weight increases the heart's workload.

It is important that the patient has a regular, individualized program of physical activity that conditions rather than stresses the heart. For example, tell patients that walking briskly on a flat surface at least 30 minutes a day, most days of the week is recommended.

If needed, arrange for counseling to assess the psychologic adjustment of the patient and caregiver to the diagnosis of CAD and the resulting angina. Many patients feel a threat to identity, self-esteem, and the usual roles in society. These emotions are normal and real.

Drug Therapy

Drug therapy for chronic stable angina aims to reduce symptoms of and the risk for MI and death. The most common medications to optimize myocardial perfusion in chronic stable angina include nitrates, angiotensin-converting enzyme (ACE) inhibitors, β-blockers, and calcium channel blockers (Table 33.11 and Fig. 33.5). Aspirin (previously discussed) is given in the absence of contraindications (Table 33.12).

Short-Acting Nitrates

Short-acting nitrates are first-line therapy for an acute episode of angina. Nitrates produce their principal effects by the following

mechanisms:

Dilating peripheral blood vessels: This results in decreased SVR, venous pooling, and decreased venous blood return to the heart (preload). Therefore myocardial O_2 demand is decreased because of the reduced cardiac workload.

Dilating coronary arteries and collateral vessels: This may increase blood flow to the ischemic areas of the heart. However, when the coronary arteries are severely atherosclerotic, coronary dilation is hard to achieve.

Sublingual Nitroglycerin

SL NTG tablets or translingual spray (Nitrolingual) usually relieves pain in about 5 minutes and lasts about 30 to 40 minutes. The recommended dose of NTG is 1 tablet taken sublingually (SL) or 1 to 2 metered sprays on or under the tongue for symptoms of angina. If symptoms are unchanged or worse after 5 minutes, the patient should repeat NTG every 5 minutes for a maximum of 3 doses. Teach the patient to contact the emergency response system (e.g., 911) if symptoms have not resolved completely after 3 doses.

Teach the patient the proper storage and use of NTG. It should be always easily accessible to the patient. Store the tablets away from light and heat sources, including body heat, to protect them from degradation. Tablets are packaged in light-resistant bottles with metal caps. Once opened, the tablets lose potency. They should be replaced every 6 months.

TABLE 33.11 Treatment of Chronic Stable Angina and Acute Coronary Syndrome

Strategies for the patient with chronic stable angina should address all the treatment elements and related patient teaching in the following mnemonic:

Element	Treatment
A	Antiplatelet/anticoagulant therapy
	Antianginal therapy
	ACE inhibitor/angiotensin receptor blocker
B	β-Blocker
	BP control
C	Cigarette smoking cessation
	Cholesterol (lipid) management
	Calcium channel blockers
	Cardiac rehabilitation
D	Diet (weight management)
	Diabetes management
	Depression screening
E	Education
	Exercise
F	Flu vaccination

Modified from Smith SC, Benjamin EJ, Bonow RO, et al: AHA/ACCF secondary prevention and risk reduction therapy for patients with coronary and other atherosclerotic vascular disease: 2011 update, *J Am Coll Cardiol* 58:2432, 2011.

Tell the patient to sit down and place the NTG tablet under the tongue and allow it to dissolve. If using the spray, the patient should direct it on or under the tongue, not inhale it. SL NTG tablets should cause a tingling sensation when taken; otherwise it may be outdated. Warn the patient that a headache, dizziness, or flushing may occur. Caution the patient to change positions slowly after NTG use because orthostatic hypotension may occur.

Teach the patient and caregiver the proper use of NTG. Patients can use NTG prophylactically before starting an activity that is known to cause angina (e.g., emotionally stressful situation, sexual intercourse). In these cases, the patient can take a tablet or spray 5 to 10 minutes before beginning the activity. Tell the patient to report any changes in the usual pattern of pain, such as increasing frequency, nighttime angina, or angina at rest.

Long-Acting Nitrates

Oral nitrates, such as isosorbide dinitrate (e.g., Isordil) and isosorbide

mononitrate, are longer acting than SL or translingual NTG. They are used to reduce the frequency of angina attacks and to treat Prinzmetal's angina. The main side effect is headache from the dilation of cerebral blood vessels. Tell patients to take acetaminophen (Tylenol) to relieve the headache. Over time, the headaches may decrease, but the antianginal effects are still present.

Orthostatic hypotension is a complication of all nitrates. Monitor BP after the first dose, since the venous dilation that occurs may cause a drop in BP, especially in volume-depleted patients. Finally, tolerance to long-acting NTG can develop. To limit this, patients may have a scheduled 10- to 14-hour nitrate-free period every day. Remind patients that taking a long-acting NTG preparation should not keep them from using translingual or SL NTG if chest pain develops.

Nitroglycerin Ointment

Nitropaste is a 2% NTG topical ointment dosed by the inch. It is placed on the upper body or arm, over a flat muscular area that is free of hair and scars. Once absorbed, it prevents angina for 3 to 6 hours. The ointment should be wiped off each evening to allow for a 10- to 14-hour nitrate-free interval to prevent nitrate tolerance.

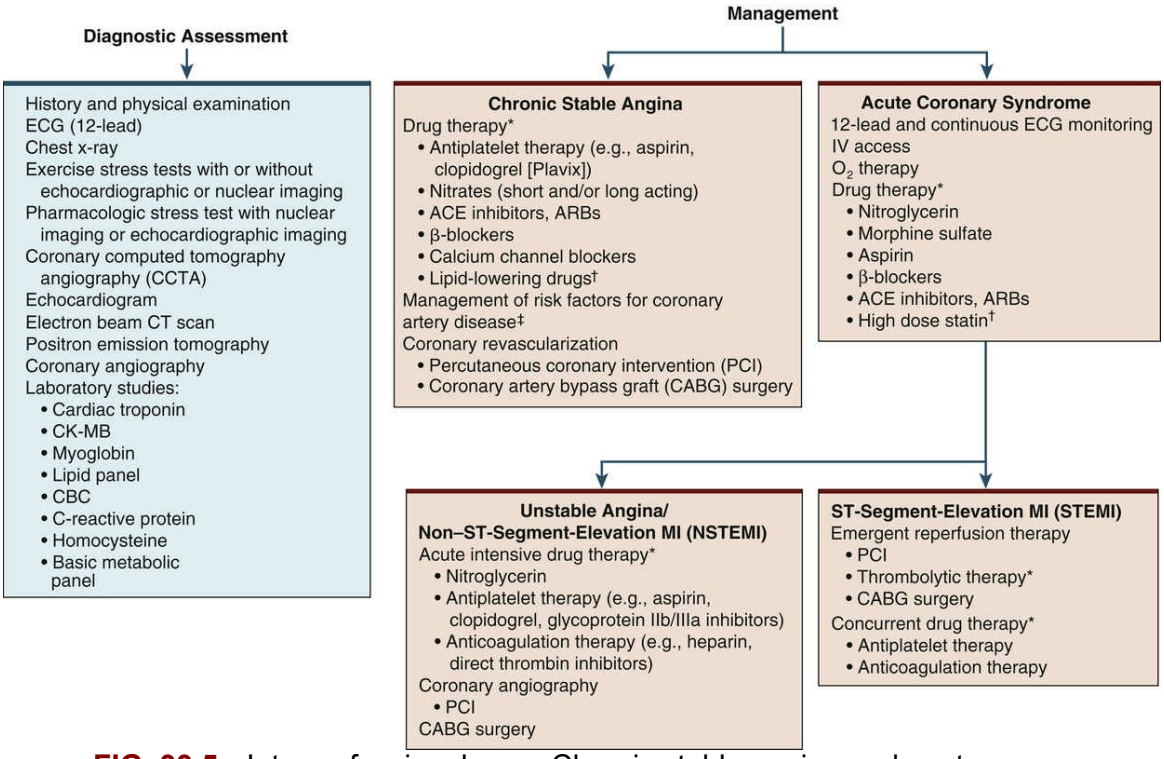

FIG. 33.5 Interprofessional care: Chronic stable angina and acute coronary syndrome.*Table 33.12.†Table 33.6.‡ Tables 33.2, 33.4, and 33.5.

Transdermal Controlled-Release Nitrates

Currently 2 systems are available for transdermal NTG drug delivery: silicone gel and polymer matrix. These systems allow timed release of NTG over a 24-hour period. These preparations may be removed in the evening to allow for a 10- to 14-hour nitrate-free interval to reduce the risk for NTG tolerance.

Drug Alert

Nitrates

- Keep NTG tablets in a dark, airtight container to maintain potency.

- Tell patients to sit down before using short-acting nitrates.
- SL NTG must be placed under the tongue.
- Spray translingual NTG onto or under the tongue.
- Tell patient not to combine NTG with drugs used for erectile dysfunction (e.g., sildenafil [Viagra]) as severe hypotension can occur.
- Monitor for orthostatic hypotension after administration.
- Headaches are common after taking any NTG preparation.
- Caregivers should use gloves to apply and remove NTG ointment or transdermal patches to avoid contact with drug.
- Never cardiovert or defibrillate over NTG ointment or a transdermal patch.
- When using long-acting nitrates, provide a 10- to 14-hour nitrate-free period.
- Remind patient when using long-acting nitrates that short acting nitrates can still be used, if needed.

Angiotensin-Converting Enzyme (ACE) Inhibitors and Angiotensin Receptor Blockers (ARBs)

Patients with chronic stable angina who have an ejection fraction (EF) of 40% or less, diabetes, hypertension, or CKD should take an ACE inhibitor (e.g., lisinopril [Zestril]) indefinitely, unless contraindicated. Patients with chronic stable angina and a normal EF, diabetes, and 1 other CAD risk factor should also take an ACE inhibitor to decrease the risk for MI, stroke, and death.[23]

These drugs result in vasodilation and reduced blood volume. Most important, they can prevent or reverse ventricular remodeling in patients who have had an MI (see p. 725). For patients who are intolerant of ACE inhibitors (e.g., cough, angioedema), angiotensin receptor blockers (ARBs) (e.g., losartan [Cozaar]) are used. ACE inhibitors and ARBs are also discussed later in the chapter and in Chapter 32 and Table 32.6.

β-Adrenergic Blockers

β-Blockers are given for relief of angina symptoms in patients with chronic stable angina. Patients who have LV dysfunction or elevated BP or had an MI should start and continue β-blockers indefinitely, unless contraindicated. These drugs decrease myocardial contractility, HR, SVR, and BP, all of which reduce the myocardial O_2 demand and relieve angina symptoms. β-Blockers that reduce the risk for death in patients with LV dysfunction, HF, or MI include carvedilol (Coreg), metoprolol succinate (Toprol XL), and bisoprolol.[13]

β_1-Receptors are found in the heart. β_2 Receptors are found in blood vessels, lungs, and liver. Some β-blockers are called cardioselective β-blockers because they only block β_1 receptors (e.g., atenolol [Tenormin], metoprolol [Lopressor]). Some β-blockers, referred to as nonselective β-blockers, block both β_1 and β_2 receptors (e.g., nadolol [Corgard], propranolol [Inderal]). Some β-blockers block α_1, β_1, and β_2 receptors (e.g., carvedilol [Coreg], labetalol [Trandate]).

TABLE 33.12 Drug TherapyChronic Stable Angina and Acute Coronary Syndrome

Drug	Mechanism of Action and Comments
Angiotensin-Converting Enzyme (ACE) Inhibitors (See Table 32.6)	
benazepril (Lotensin) **captopril** **enalapril (Vasotec)** **lisinopril (Zestril)** **quinapril (Accupril)** **ramipril (Altace)**	• Prevents conversion of angiotensin I to angiotensin II, resulting in vasodilation • May prevent or limit ventricular remodeling • Decreases endothelial dysfunction • Useful with HF, decreased LV function, tachycardia, MI, hypertension, diabetes, and chronic kidney disease
Angiotensin II Receptor Blockers (See Table 32.6)	
candesartan (Atacand) **irbesartan (Avapro)** **losartan (Cozaar)** **olmesartan (Benicar)** **valsartan (Diovan)**	• Inhibits binding of angiotensin II to angiotensin I receptors, resulting in vasodilation • Used for patients intolerant of ACE inhibitors
Anticoagulant Agents (See Table 37.10)	
Direct Thrombin Inhibitors	
bivalirudin (Angiomax) **argatroban**	• Direct inhibition of the clotting factor thrombin • Used during PCI procedure
Low-Molecular-Weight Heparin†	
dalteparin (Fragmin) **enoxaparin (Lovenox)**	• Binds to antithrombin III, enhancing its effect • Heparin–antithrombin III complex inactivates activated factor X and thrombin. • Prevents conversion of fibrinogen to fibrin
Unfractionated Heparin†	
heparin	• Prevents conversion of fibrinogen to fibrin and prothrombin to thrombin
Vitamin K Antagonist†	
warfarin (Coumadin)	• Interferes with hepatic synthesis of vitamin K–dependent clotting factors • Used for patients with atrial fibrillation or those at risk for thromboembolism (large anterior wall infarctions or ventricular aneurysms) • Closely monitor for bleeding when taking with antiplatelet drugs
Antiplatelet Agents	
aspirin	• Inhibits cyclooxygenase, which in turn produces thromboxane A_2, a potent platelet activator • Should be given as soon as ACS is suspected, unless truly allergic
cangrelor (Kengreal)	• Inhibits platelet aggregation • Given IV • Approved for use in patients having PCI during procedure
clopidogrel (Plavix)	• Inhibits platelet aggregation • Alternative for patients who cannot take aspirin • Used in combination with low-dose aspirin to treat ACS with or without PCI and after elective PCI
prasugrel (Effient)	• Inhibits platelet aggregation • Used as an alternative to clopidogrel in combination with aspirin for patient with ACS who had PCI • Not indicated to treat ACS without PCI or for use after elective PCI
ticagrelor (Brilinta)	• Inhibits platelet aggregation • Alternative for patient who cannot take aspirin • Used in combination with low-dose aspirin to treat ACS with or without PCI • Effectiveness may be decreased by aspirin dosages >100 mg/day
vorapaxar (Zontivity)	• Inhibits platelet aggregation • Increases risk for bleeding, including life-threatening and fatal bleeding (boxed warning) • Must not be used in people who have had a stroke, transient ischemic attack (TIA), or bleeding in the head, because the risk for bleeding in the head is too great
Glycoprotein IIb/IIIa Inhibitors	
abciximab (ReoPro) **eptifibatide (Integrilin)** **tirofiban (Aggrastat)**	• Prevents the binding of fibrinogen to platelets, thereby blocking platelet aggregation • May be used in combination with aspirin for patients with ACS or during PCI
β-Adrenergic Blockers (See Table 32.6)	
atenolol (Tenormin) **carvedilol (Coreg)** **metoprolol (Lopressor)** **nadolol (Corgard)**	• Inhibits sympathetic nervous stimulation of the heart • Reduces heart rate, contractility, and BP • Reduces ischemia • Decreases afterload • Cardioselective β-blockers include atenolol and metoprolol
Calcium Channel Blockers (See Table 32.6)	

Drug	Mechanism of Action and Comments
amlodipine (Norvasc) **diltiazem (Cardizem)** **felodipine** **nicardipine (Cardene)** **verapamil (Calan)** **nifedipine (Procardia)**	• Prevents calcium entry into vascular smooth muscle cells and myocytes (cardiac cells) • May prevent or control coronary vasospasm • Promotes coronary and peripheral vasodilation • Reduces HR, contractility, and BP
Nitrates (See Table 32.6)	
Sublingual nitroglycerin (Nitrostat) **Translingual spray nitroglycerin (Nitrolingual)** **nitroglycerin ointment** **Transdermal nitroglycerin isosorbide dinitrate (Isordil)** **isosorbide mononitrate** **IV nitroglycerin**	• Promotes peripheral vasodilation, decreasing preload and afterload • Promotes coronary artery vasodilation • May prevent or control coronary vasospasm
Opioid	
morphine	• Functions as an analgesic and sedative • Acts as a vasodilator to reduce preload and myocardial O_2 consumption
Thrombolytic Agents	
reteplase (Retavase) **alteplase (Activase)** **tenecteplase (TNKase)**	• Breaks up fibrin meshwork in clots • Used only in ST-segment-elevation MI when access to a hospital with PCI capability is not available

β-Blockers have many side effects that can be poorly tolerated. These include bradycardia, hypotension, wheezing from bronchospasm, and GI effects. Many patients report weight gain, depression, fatigue, and sexual dysfunction. Absolute contraindications to using β-blockers include severe bradycardia and acute decompensated HF. Patients with asthma should avoid β-blockers, especially nonselective ones. They are used cautiously in patients with diabetes since they mask signs of hypoglycemia. β-Blockers should not be stopped abruptly without medical supervision, as this may result in an increase in the number and intensity of angina attacks.

Calcium Channel Blockers

If β-blockers are contraindicated, are poorly tolerated, or do not control anginal symptoms, calcium channel blockers are used. Their main effects are: (1) systemic vasodilation with decreased SVR, (2) decreased myocardial contractility, (3) coronary vasodilation, and (4) decreased HR. They are used to treat Prinzmetal's angina.

There are 2 groups of calcium channel blockers. The dihydropyridines (e.g., amlodipine [Norvasc], nifedipine [Procardia])

have more vasodilatory effects. The nondihydropyridines (e.g., verapamil [Calan], diltiazem [Cardizem]) have a greater effect on decreasing HR and contractility.

Side effects include fatigue, headache, dizziness, flushing and peripheral edema. The nondihydropyridines enhance the action of digoxin by increasing serum digoxin levels. Digoxin levels are closely monitored after starting these agents. Teach the patient the signs and symptoms of digoxin toxicity. Verapamil can cause severe constipation by relaxing GI smooth muscle and slowing peristalsis, especially in older adults.[7]

Lipid-Lowering Drugs

A moderate or high dose of a lipid-lowering drug is given, unless contraindicated (Table 33.6). Patients with chronic stable angina are encouraged to follow a diet low in saturated fat and cholesterol.

Sodium Current Inhibitor

Ranolazine (Ranexa), a sodium current inhibitor, is used to treat chronic angina in patients who have not had an adequate response with other antianginal medications. Although it is approved as a first-line agent, it is usually added to the medication regimen only when the angina is not well controlled. Ranolazine does not affect the BP or HR, but it can prolong the QT interval. Use it very cautiously in patients with a long QT interval or who are taking other QT-prolonging drugs (e.g., fluoxetine [Prozac]).[7] Common side effects include dizziness, nausea, constipation, and headache.

Diagnostic Studies

When a patient describes new-onset chest pain and CAD is suspected or when a patient with chronic stable angina has a change in the angina pattern, a variety of studies are done (Fig. 33.5). After a detailed health history and physical examination, a 12-lead ECG is done and compared with a previous ECG to look for changes that may indicate an ACS. Laboratory tests (e.g., cardiac biomarkers) are used

to determine if the patient is experiencing an ACS. Other laboratory tests may be done (e.g., lipid profile, CRP) to identify risk factors for CAD. A chest x-ray is done to look for cardiac enlargement, aortic calcifications, and pulmonary congestion. An echocardiogram can detect resting LV wall motion abnormalities, which may suggest CAD.

If the ECG and cardiac biomarkers are negative, an exercise stress test with or without echocardiography or nuclear imaging may be done either during the hospitalization or as an outpatient. For patients with physical limitations in walking, a pharmacologic (adenosine [Adenocard]) or dipyridamole stress test with nuclear imaging, or a pharmacologic (dobutamine) stress echocardiogram are options. Stress testing usually does not detect coronary blockages less than 70%.[13] Besides stress testing, other tests may be done if the ECG and cardiac biomarkers are negative. Electron beam computed tomography (EBCT) or coronary computed tomography angiography (CCTA or CTA) testing may be done if there is no evidence of an ACS and the patient remains free of chest pain. See Table 31.7 for more about these studies.

Cardiac Catheterization

For patients with increasing angina symptoms, a cardiac catheterization is the gold-standard test to identify and localize CAD. It is also recommended if the ECG shows ST-T wave changes (not ST elevation) and/or cardiac biomarkers are positive. This procedure should be done only if the patient is a candidate for percutaneous or surgical coronary revascularization.

If a coronary blockage is amenable to treatment, **coronary revascularization** with **percutaneous coronary intervention (PCI)** may be recommended. PCI may be done at the same time as the cardiac catheterization. During PCI, a catheter with a deflated balloon tip is inserted into the blocked coronary artery. The deflated balloon is positioned inside the blockage and inflated. This compresses the plaque against the artery wall, resulting in vessel dilation and a larger vessel diameter. This procedure is called *balloon angioplasty.*

Intracoronary stents are usually placed after a balloon angioplasty. A **stent** is an expandable mesh-like structure designed to keep the vessel open. It provides support to the arterial wall (Figs. 33.6 and 33.7). There are 2 types of stents: bare metal (BMS) and drug-eluting (DES). A DES is coated with a drug (e.g., everolimus, zotarolimus) to reduce the risk for overgrowth of the intimal lining *(neointimal hyperplasia)* within the stent. This is the primary cause of in-stent restenosis (ISR). This risk is lower with the use of a DES.

Because stents are thrombogenic, drugs are used to prevent platelet aggregation within the stent and acute stent thrombosis. Drugs commonly used during PCI are unfractionated heparin (UH) or low-molecular-weight heparin (LMWH), a direct thrombin inhibitor (e.g., bivalirudin [Angiomax]), and/or a glycoprotein IIb/IIIa inhibitor (e.g., eptifibatide [Integrilin]) (Table 33.12). After PCI, the patient receives dual antiplatelet therapy (DAPT) (e.g., aspirin [indefinitely] and ticagrelor or clopidogrel [Plavix]) until the intimal lining grows over the stent and provides a smooth vascular surface.

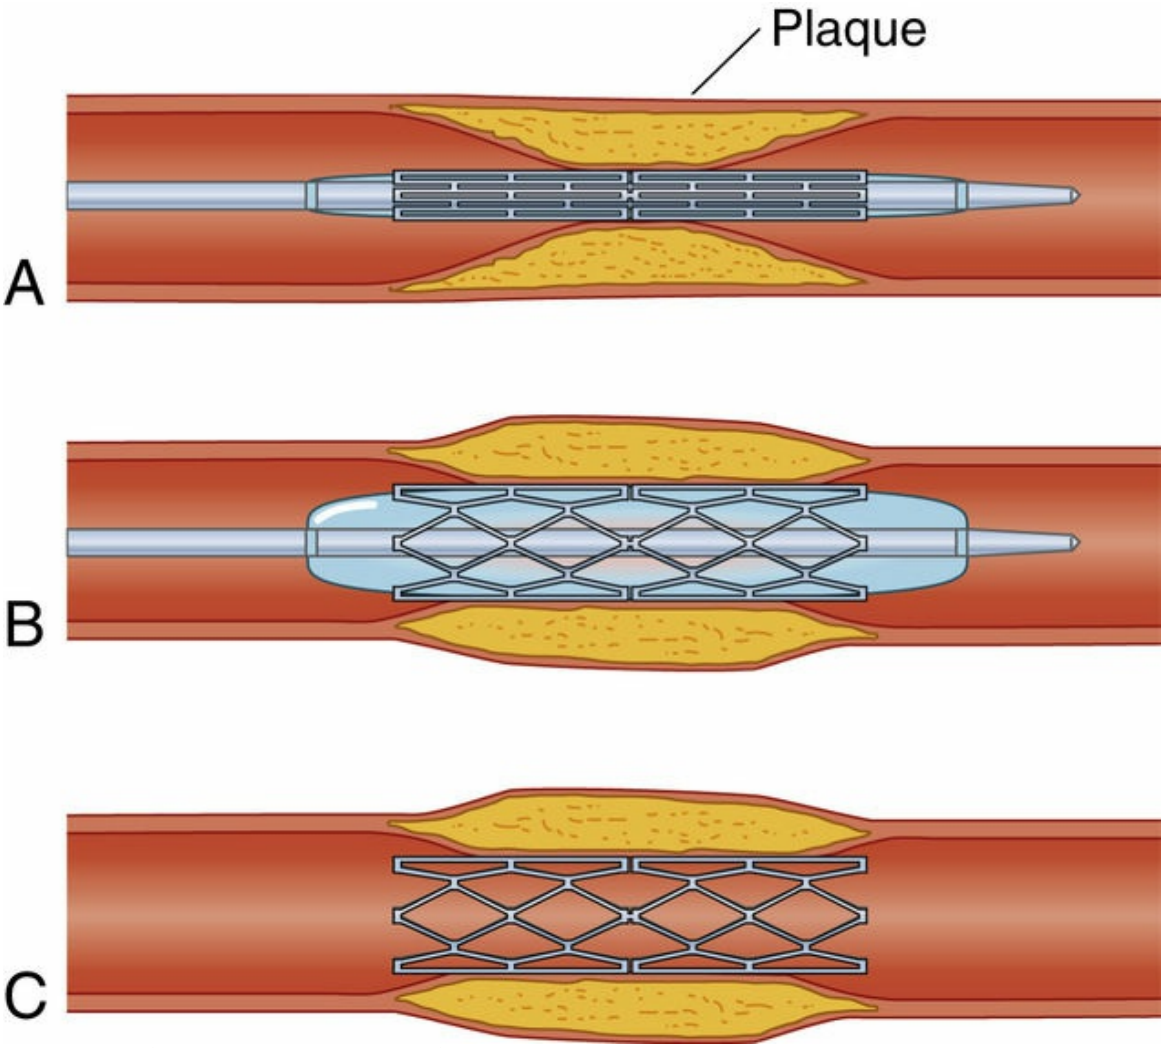

FIG. 33.6 Placement of a coronary artery stent. **A,** The stent is positioned at the site of the lesion. **B,** The balloon is inflated, expanding the stent. The balloon is then deflated and removed. **C,** The implanted stent is left in place.

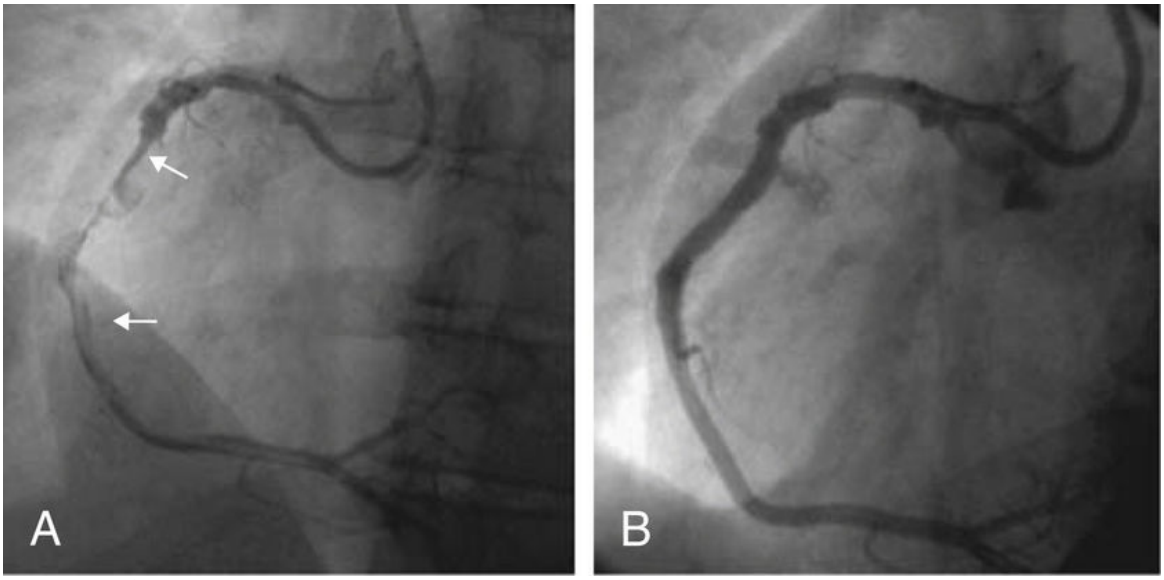

FIG. 33.7 **A,** A thrombotic occlusion of the right coronary artery is seen *(arrows).* **B,** Right coronary artery is opened and blood flow restored following angioplasty and placement of a 4-mm stent.
From Zipes DB, Libby P, Bonow RO, Braunwald E: *Braunwald's heart disease: A textbook of cardiovascular medicine,* ed 7, St Louis, 2005, Saunders.

After DES placement, DAPT is used for a minimum of 12 months. The duration of DAPT for patients with a BMS is a minimum of 1 month after PCI. With the newer generation stents, 3 to 6 months of DAPT is enough to prevent stent thrombosis. Aspirin must continue forever.[24]

Potential complications from cardiac catheterization with PCI include abrupt closure from coronary artery dissection or rupture, vascular injury at the artery access site (e.g., femoral, radial), acute MI from acute stent thrombosis or from plaque dislodging and blocking the vessel distal to the catheter, stent embolization, failure to cross the blockage with a balloon or stent, coronary spasm, dye allergy, renal compromise, bleeding (e.g., retroperitoneal bleeding when the femoral artery is used or vascular access-site bleeding), infection, stroke, and emergent coronary artery bypass graft (CABG) surgery. The risk for dysrhythmias during and after the procedure is always present, so patients should be on a cardiac monitor afterwards.

More PCIs are done in the United States than CABGs.[1] PCI may not be a feasible option for all patients (e.g., patients with 3-vessel CAD [3

different coronary arteries] and/or significant left main coronary artery disease).[25] Coronary revascularization with CABG surgery may be recommended after cardiac catheterization.

Before and after cardiac catheterization and PCI, patients need frequent interventions (see Nursing Management: Cardiac Catheterization and PCI box and Table 31.9). Respiratory therapy may give prescribed therapies (e.g., nebulizer treatments) depending on the patient's past medical history.

Coronary Surgical Revascularization

In patients with chronic stable angina, coronary revascularization with CABG surgery is recommended for patients who (1) fail medical management, (2) have left main coronary artery or 3-vessel disease, (3) are not candidates for PCI (e.g., blockages are long or difficult to access), or (4) have failed PCI and continue to have chest pain. CABG also may be an option for patients with diabetes, LV dysfunction, and/or CKD.[25] CABG surgery and PCI are considered palliative treatment for CAD and not a cure. Lifestyle changes and medications may help slow the progression of the CAD and reduce the risk for recurrent events.

Traditional Coronary Artery Bypass Graft Surgery

CABG surgery consists of the placement of arterial or venous grafts to provide blood from the aorta or a branch of a major artery that originates from the aorta (e.g., internal mammary artery) to the heart muscle distal to blocked coronary arteries. The procedure may involve one or more grafts using the internal mammary (thoracic) artery (IMA or ITA), saphenous vein, and/or radial artery (Fig. 33.8). The gastroepiploic artery, and/or inferior epigastric artery can be used as conduits but are not used as often due to the time and difficulty in harvesting those arteries.

Nursing Management

Percutaneous Coronary Intervention

Preprocedure

- Assess for allergies, especially to contrast dye.
- Perform baseline assessment, including vital signs, pulse oximetry, heart and breath sounds, neurovascular assessment of extremities (e.g., distal pulses, skin temperature, skin color, sensation).
- Assess baseline laboratory values (e.g., cardiac biomarkers, creatinine).
- Give drugs before the procedure and stop drugs not needed for the procedure (e.g., systemic heparin is stopped right before the cardiac catheterization).
- Teach patient and caregiver about procedure and postprocedure care.

Postprocedure

- Perform assessment and compare to baseline: vital signs, pulse oximetry, heart and breath sounds, neurovascular assessment of extremity used for procedure, assessment of catheter insertion site for hematoma, bleeding, and bruit.
- Assess neurovascular status of involved extremity every 15 min for the first hour, then according to agency policy.
- Check for bleeding at catheter insertion site every 15 min for the first hour, then according to agency policy.
- Report changes in neurovascular status of involved extremity or any bleeding.
- Monitor ECG for dysrhythmias or other changes (e.g., ST segment elevation or depression).

- Monitor patient for chest pain and other sources of pain or discomfort (e.g., back, vascular access site).
- Monitor IV infusions of antianginals (e.g., nitroglycerin) and antiplatelet medications (e.g., eptifibatide).
- Teach patient and caregiver about discharge drugs (e.g., aspirin, clopidogrel, lipid lowering drugs).
- Teach patient and caregiver about discharge care, including signs and symptoms to report to HCP (e.g., access site complications, return of chest pain).

Unlicensed Assistive Personnel (UAP)

- Oversee UAP:
    - Take vital signs and report increases or decreases in HR or BP to RN.
    - Report patient descriptions of chest pain, shortness of breath, and/or any other discomfort or distress to RN.
    - Report changes in neurovascular status of the involved extremity or any bleeding to the RN.
    - Help with oral hygiene and hydration, meals, and toileting.
    - Record oral intake and urine output as ordered.

CABG surgery requires a sternotomy (opening of the chest cavity) and *cardiopulmonary bypass* (CPB). During CPB, blood is diverted from the patient's heart to a machine where it is oxygenated and returned (via a pump) to the patient. This allows the HCP to operate on a quiet, nonbeating, bloodless heart while perfusion to vital organs is maintained. CPB is associated with postoperative neurologic dysfunction, renal problems, and systemic inflammatory response syndrome (SIRS).[25]

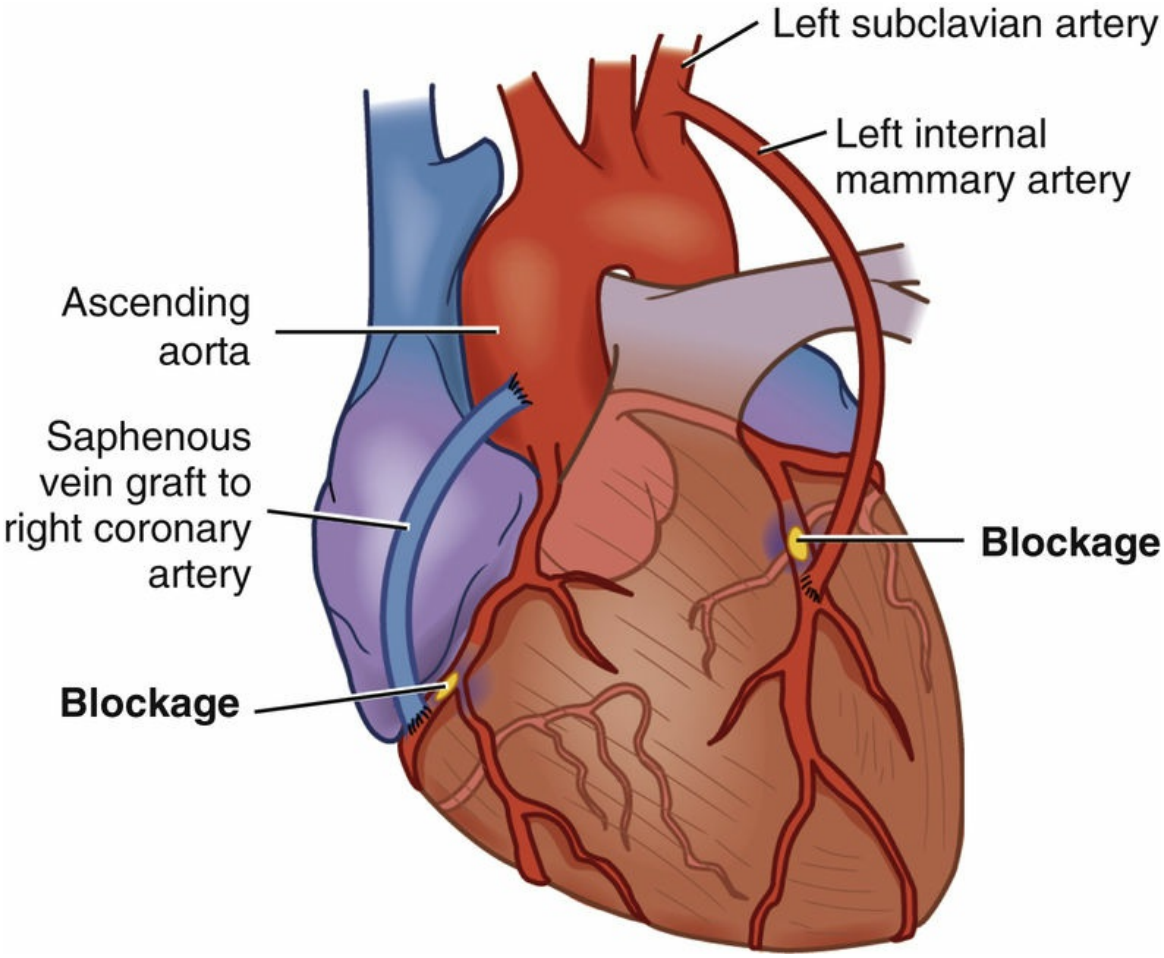

FIG. 33.8 Proximal end of the left internal mammary artery (LIMA) is left attached to the subclavian artery and the distal end of the LIMA is grafted (sutured) into the LAD artery below the blockage. Proximal end of the saphenous vein is grafted (sutured) to the aorta, and the distal end is grafted (sutured) into the right coronary artery below the area of blockage.

The IMA is the most common artery used for bypass graft. The proximal part is left attached to its origin (the subclavian artery). The distal end of the IMA is dissected from the chest wall. Next, it is *anastomosed* (sutured) to the coronary artery distal to the blockage. It usually is used to bypass the left anterior descending (LAD) artery because the LAD supplies blood to the largest part of the heart muscle (anterior wall). The IMA tends to have longer patency rates than saphenous veins (Fig. 33.8).

Saphenous veins can be used for bypass grafts. The HCP endoscopically removes the saphenous vein from one or both legs. A

section is sutured into the ascending aorta near the native coronary artery opening and then anastomosed to the coronary artery distal to the blockage (Fig. 33.8). Saphenous vein grafts are more prone to develop diffuse intimal hyperplasia. This contributes to future stenosis and graft occlusion. The use of antiplatelet and statin therapy after surgery helps maintain vein graft patency.

The radial artery, another potential graft, is a thick muscular artery prone to spasm. Perioperative calcium channel blockers and long-acting nitrates can control the spasms. Patency rates are not as good as the IMA but are better than saphenous veins. Serious extremity complications (e.g., hand ischemia, wound infection) are rare after removal of the radial artery. Paresthesia and impaired sensation are common side effects after radial artery harvest.[26]

Women have higher periprocedural mortality and morbidity rates than men. This has been attributed to the late treatment of CAD in women because women first present with CAD at an older age and have more co-morbidities at the time of surgery. Other factors include smaller diameter coronary vessels, smaller body surface area, and the fact that women are less likely to be referred for catheterization.[25]

Minimally Invasive Direct Coronary Artery Bypass

Minimally invasive direct coronary artery bypass (MIDCAB) offers patients with disease of the LAD or right coronary artery an approach to surgical treatment that does not involve a sternotomy and CPB. The technique requires several small incisions between the ribs or a mini-thoracotomy. A thoracoscope or robotic assistance may be used to dissect the IMA from the chest wall, but usually it is done via direct visualization.[26] A mechanical stabilizer immobilizes the operative site. The IMA is then sutured to the LAD or right coronary artery. Some patients undergo hybrid procedures in which they have a MIDCAB for the LAD artery and undergo a PCI of a second or third artery later.

Off-Pump Coronary Artery Bypass

The *off-pump coronary artery bypass* (OPCAB) procedure uses a median

sternotomy to access all coronary vessels. OPCAB is performed on a beating heart (no CPB) using mechanical stabilizers. OPCAB is associated with less blood loss, less renal dysfunction, less postoperative atrial fibrillation, and fewer neurologic complications.[25] Worldwide, less than 30% of CABG procedures are OPCAB procedures.[26]

Totally Endoscopic Coronary Artery Bypass

Totally endoscopic coronary artery bypass (TECAB) uses a robotic technology to perform CABG surgery. Several instrument ports in the chest are required. This procedure is done without the use of CPB or with the use of CPB using femoral access. TECAB is used for limited bypass grafting. The benefits include smaller incisions, decreased blood loss, less pain, and shorter recovery time.[26]

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization is an indirect revascularization procedure. It is used for patients with advanced CAD who are not candidates for traditional CABG surgery and who have persistent angina despite maximum medical therapy. The procedure involves the use of a high-energy laser to create channels in the heart muscle to allow blood flow to ischemic areas. The procedure can be done using a left thoracotomy approach. It is used as an adjunctive therapy when bypass grafts cannot be placed to help reduce angina symptoms. It also can be used in combination with CABG surgery.[26]

Postoperative Care After CABG Surgery

Care after CABG surgery is provided in the intensive care unit (ICU) for the first 24 to 36 hours. Ongoing and intensive monitoring of the patient's hemodynamic status is critical. The patient will have many invasive lines for monitoring heart status and other vital functions (see Chapter 65). These include (1) hemodynamic monitoring (e.g., CO), (2) an arterial line for continuous BP monitoring, (3) pleural and

mediastinal chest tubes for chest drainage, (4) continuous ECG monitoring, (5) an endotracheal tube connected to mechanical ventilation, (6) epicardial pacing wires for emergency pacing of the heart, (7) a urinary catheter to monitor urine output, and (8) a nasogastric tube for gastric decompression. Most patients are extubated within 6 hours and transferred to a step-down unit within 24 to 48 hours for continued monitoring.

Many of the postoperative complications that develop after CABG surgery relate to the use of CPB. Major complications of CPB are systemic inflammation, bleeding and anemia from damage to red blood cells and platelets, fluid and electrolyte imbalances, infections, and hypothermia (because blood is cooled as it passes through the CPB machine). Focus your care on assessing the patient for bleeding (e.g., chest tube drainage, incision sites), monitoring hemodynamics, checking fluid status, replacing blood and electrolytes as needed, and restoring temperature (e.g., warming blankets).

Postoperative dysrhythmias, especially atrial dysrhythmias (e.g., atrial fibrillation [AF]), are common. The incidence of postoperative AF after CABG surgery is 20% to 40%.[26] β-Blockers should be started or restarted as soon as possible after surgery (unless contraindicated) to reduce the incidence of AF.[25] Discharge may be delayed in patients who develop AF in order to begin anticoagulation therapy, especially if using warfarin. (See Chapter 35 for information on treatment of AF.)

Nursing care for the patient with a CABG includes wound care for the patient's surgical sites (e.g., leg, chest, arm). Chest incisions are often closed with skin adhesive and do not need dressings after 24 hours. Management of the chest wound is similar to that of other chest surgeries (see Chapter 27). Care of the leg incision is minimal since endoscopy is used to harvest the vein.

Care of a radial artery harvest site includes monitoring sensory and motor function of the hand. The patient with radial artery harvest should take a calcium channel blocker and/or a long-acting nitrate for around 3 months to reduce the incidence of arterial spasm at the arm or anastomosis site.

Other nursing interventions include strategies to manage pain and

prevent venous thromboembolism (e.g., early ambulation, sequential compression device) and respiratory complications (e.g., incentive spirometry, splinting during coughing and deep-breathing exercises). (See Chapter 19 for care of the postoperative patient.)

Patients may have some cognitive dysfunction. This includes impairment of memory, concentration, language comprehension, and social integration. Depression and anxiety are common. Patients may cry or become teary. *Postoperative cognitive dysfunction* (POCD) can manifest days to weeks to months after surgery but usually improves within a few months after surgery. However, it may become a chronic disorder.[27] POCD is discussed in Chapter 19.

In the older patient (> age 80), elective CABG is generally well tolerated. Many patients have multiple preoperative co-morbidities, so the incidence of postoperative complications (e.g., dysrhythmias, stroke, POCD, infection) is higher. Although the benefits of treatment may outweigh risks in this group, morbidity and mortality are higher than in younger persons.[25]

Postoperative nursing care of the patient with a MIDCAB, OPCAB, or TECAB procedure is similar to that for CABG surgery patients. The recovery time is shorter with these procedures. Patients often resume routine activities sooner than patients who have CABG surgery. Pain control is important regardless of the procedure. Patients generally report higher levels of pain with a thoracotomy incision than a sternotomy incision.

Alternative Therapies for Refractory Chronic Stable Angina

For patients with refractory angina, *enhanced external counterpulsation* (EECP) may be used. EECP consists of placing inflatable BP cuffs around the legs. The cuffs sequentially inflate during diastole and deflate during systole from the calves to the thighs. This action increases venous return and augments diastolic BP. This increases coronary perfusion, improves LV diastolic filling, and helps with collateral circulation. Patients get treatments 5 days a week for a total

of 35 treatments. EECP is contraindicated in patients with decompensated HF, severe peripheral arterial disease, and severe aortic insufficiency.[13]

Acute Coronary Syndrome

When chest pain from ischemia is prolonged and not immediately reversible, **acute coronary syndrome (ACS)** may develop. ACS includes the spectrum of non-ST elevation acute coronary syndrome (*UA and non–ST-segment-elevation myocardial infarction* [NSTEMI]), and *ST-segment-elevation myocardial infarction* (STEMI) (Fig. 33.9). When patients first present with chest pain, ST-elevations on the 12-lead ECG most likely indicate a STEMI (Fig. 33.4, *B*). The ECG should be compared to a previous ECG whenever possible. ST elevation represents myocardial injury that is potentially reversible, but, if not treated, will likely evolve to permanent necrosis (tissue death) of the myocardium. Patients with UA or NSTEMI may or may not have ST segment depression and/or T wave inversion on the ECG. For patients with chest pain who do not have ST segment elevation or ST-T wave changes on the ECG, it is difficult to distinguish between UA and NSTEMI until we evaluate serum cardiac biomarkers.[15]

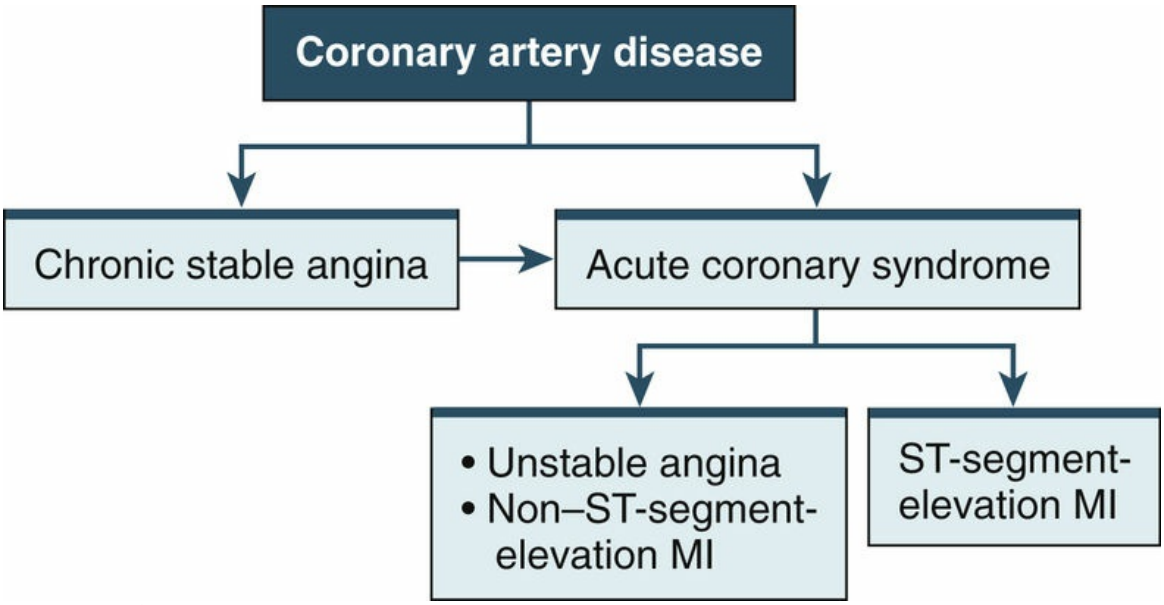

FIG. 33.9 Relationships among coronary artery disease, chronic stable angina, and acute coronary syndrome.

On the cellular level, the heart muscle becomes hypoxic within the first 10 seconds of a total coronary occlusion. Heart cells are deprived of O_2 and glucose needed for aerobic metabolism and contractility. Anaerobic metabolism begins, and lactic acid accumulates. In ischemic conditions, heart cells are viable for about 20 minutes. Irreversible heart damage starts after 20 minutes if there is no collateral circulation (Fig. 33.2).[21] With restoration of blood flow (reperfusion), aerobic metabolism resumes, contractility is restored, and cellular repair begins.

ACS is caused by the decline of a once-stable atherosclerotic plaque. The previously stable plaque ruptures, releasing the lipid core into the vessel. This causes platelet aggregation and thrombus formation. The vessel may be partially blocked by a thrombus (manifesting as UA or NSTEMI) or totally blocked by a thrombus (manifesting as STEMI). We are not sure what causes the plaque to suddenly become unstable. Systemic inflammation (described earlier) may play a role. Patients with suspected ACS need immediate hospitalization.

Unstable Angina

Unstable angina (UA) is chest pain that is new in onset, occurs at rest, or occurs with increasing frequency, duration, or less effort than the patient's chronic stable angina pattern. The pain usually lasts 10 minutes or more.

The patient with chronic stable angina may develop UA, or UA may be the first clinical sign of CAD. Unlike chronic stable angina, UA is unpredictable and must be treated immediately. The patient with previously diagnosed chronic stable angina describes a significant change in the pattern of angina. It occurs with increasing frequency and is easily provoked by minimal exertion, during sleep, or even at rest. The patient without previously diagnosed angina describes chest pain that has progressed rapidly in the past few hours, days, or weeks, often ending in pain at rest. ECG changes that may be seen with UA include ST depression and/or T wave inversion (Fig. 33.4, A). These changes are referred to as ischemic changes.

Myocardial Infarction: St-Elevation and Non–St-Elevation Myocardial Infarction

A **myocardial infarction (MI)** occurs because of an abrupt stoppage of blood flow through a coronary artery with a thrombus caused by platelet aggregation. This causes irreversible myocardial cell death (necrosis) in the heart muscle beyond the blockage (Figs. 33.10 and 33.11). Serum cardiac biomarkers are released into the blood. Most MIs occur in the setting of preexisting CAD.[13]

A STEMI, caused by an occlusive thrombus, results in ST-elevation in the ECG leads facing the area of infarction (Figs. 33.12 and 33.13). ST segment elevation is significant if it is 1 mm or more above the isoelectric line in at least 2 contiguous (neighboring) leads except in V_2 and V_3, where the ST elevation must be 2 mm or more. [28]

A STEMI is an emergency. To limit the infarct size, the artery must be opened within 90 minutes of presentation to restore blood and O_2 to the heart muscle and limit the infarct size. This can be done either by PCI or with thrombolytic (fibrinolytic) therapy. PCI is the first-line treatment, if available. It confirms which artery has the occlusive thrombus so it can be opened with a balloon and stent (Fig. 33.6). Thrombolytic therapy is done in hospitals that do not have a catheterization laboratory for PCI. If the patient does not seek treatment quickly, the STEMI will evolve.

NSTEMI, caused by a nonocclusive thrombus, does not cause ST segment elevation on the 12-lead ECG. The ECG may or may not show ST depression and/or T wave inversion in the leads facing the area of infarction. NSTEMI patients usually undergo catheterization within 12 to 72 hours. Thrombolytic therapy is not indicated for NSTEMI.

With either NSTEMI or STEMI, an echocardiogram may show *hypokinesis* (worsening myocardial contractility) or *akinesis* (absent myocardial contractility) in the necrotic area(s). The degree of LV dysfunction depends on the area of the heart involved and size of the

infarction.

The acute MI process evolves over time, from hours to a few days. The earliest tissue to become ischemic is the subendocardium (the innermost layer of tissue in the heart muscle). If ischemia persists, it takes around 4 to 6 hours for the entire thickness of the heart muscle to necrose. If the thrombus is not completely blocking the artery, the time to complete necrosis may be as long as 12 hours.

Most MIs affect the LV and are usually described based on the location of damage (e.g., anterior, inferior, lateral, septal, or posterior wall infarction). The location of the MI and ECG changes correlate with the involved coronary artery (Table 33.13). For example, in most people, the right coronary artery supplies blood to the inferior and posterior LV walls. Blockage of the right coronary artery results in an inferior wall and/or posterior wall MI. Anterior wall infarctions result from blockages in the LAD artery. Blockages in the left circumflex artery usually cause lateral wall MIs. Damage can occur in more than 1 location, especially if more than 1 coronary artery is involved (e.g., anterolateral MI). Right ventricular MIs are much less common and treated differently from LV MIs. Suspect a right ventricular MI in patients who have a left inferior wall STEMI.[28]

The degree of collateral circulation influences the severity of the MI (Fig. 33.2). Not everyone develops collateral circulation. A person with a long history of CAD may develop good collateral circulation to provide the area surrounding the infarction site with an adequate blood supply. This is one reason why a younger person may have a more serious first MI than an older person with the same degree of blockage.

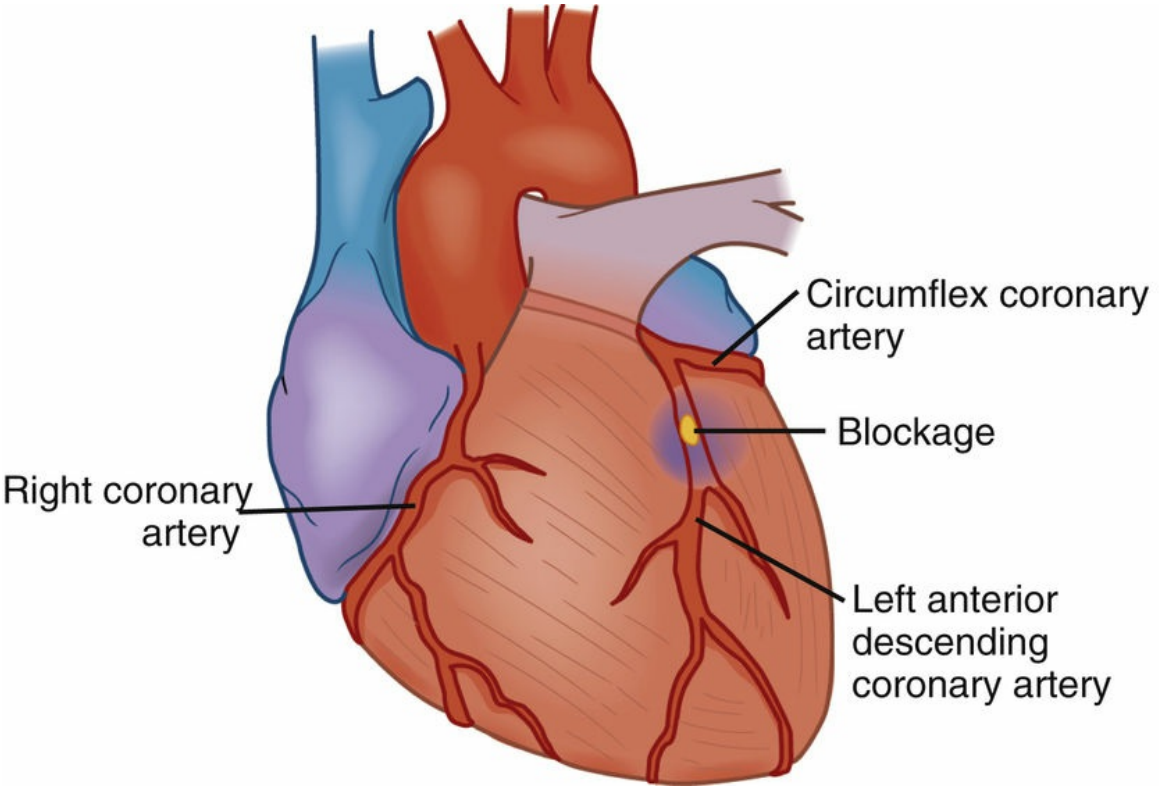

FIG. 33.10 Occlusion of the LAD coronary artery, resulting in acute MI.

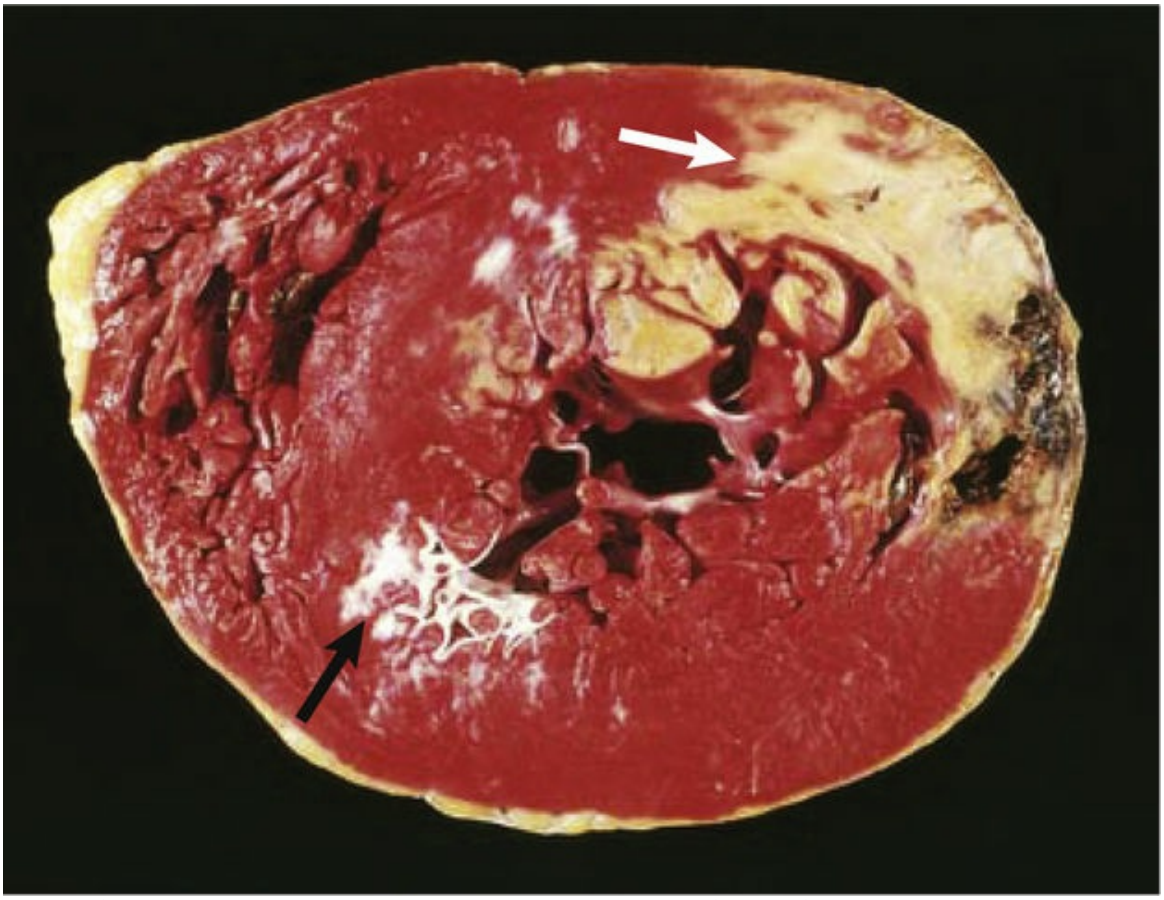

FIG. 33.11 Acute MI in the posterolateral wall of the left ventricle. This is shown by the absence of staining in the areas of necrosis *(white arrow).* Note the scarring from a previous anterior wall MI *(black arrow).*

From Kumar V, Abbas AK, Aster JC, et al: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

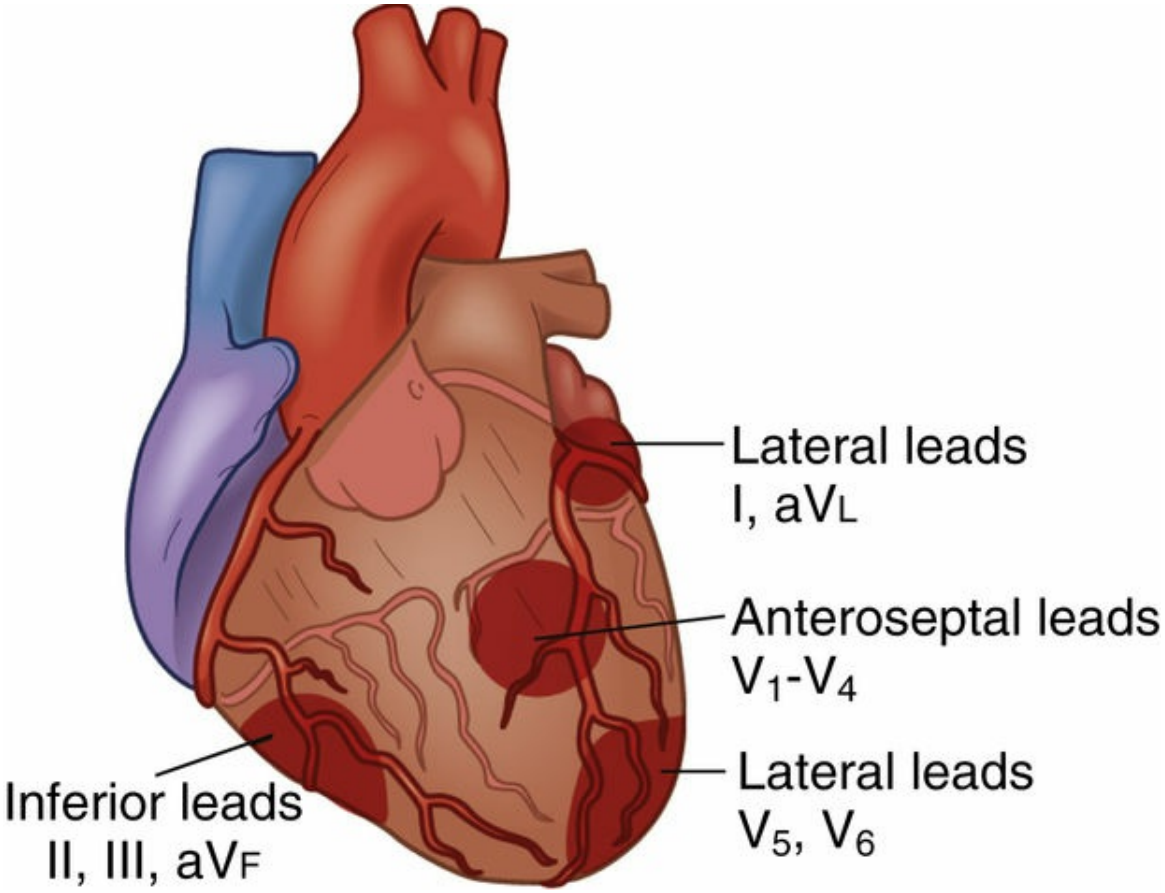

FIG. 33.12 Definitive ECG changes occur in leads that face the area of ischemia, injury, or infarction. Reciprocal changes may occur in leads facing opposite the area of ischemia, injury, or infarction.

Women who have MIs are often undertreated with guideline-based recommendations, leading to worse outcomes and increased rates of readmission, reinfarction, and death in the first year after MI.[5]

FIG. 33.13 ECG findings with anteroseptal lateral wall MI. Normally, leads I, aVL, and V_1 to V_3 have a positive R wave. Note the pathologic Q waves in these leads and the ST segment elevation in leads V_2 to V_6 *(arrows)*.

TABLE 33.13 ECG Evidence in Acute Coronary Syndrome

Left Ventricle Involvement	ECG EVIDENCE		Associated Coronary Artery
	Leads Facing Area	Leads Opposite Area (Reciprocal Changes)	
Septal wall	V_1, V_2	II, III, aVF	LAD
Anterior wall	V_3, V_4	II, III, aVF	LAD
Lateral wall, low	V_5, V_6	II, III, aVF	LAD or circumflex
Lateral wall, high	I, aVL	II, III, aVF	Circumflex
Inferior wall	II, III, aVF	I, aVL, V_5, V_6	Right coronary artery, posterior descending coronary artery

Clinical Manifestations of Myocardial Infarction

Pain

Severe chest pain not relieved by rest, position change, or nitrate

administration may mean the patient is having an MI. Persistent and unlike any other pain, it is usually described as a heavy, pressure, tight, burning, constricted, or crushing feeling. Common locations are the substernal or epigastric area. The pain may radiate to the neck, lower jaw, and arms or to the back (Fig. 33.3). When epigastric pain is present, the patient may relate it to indigestion, take antacids without relief, and therefore delay seeking treatment. It may occur while the patient is active or at rest, asleep, or awake. It often occurs in the early morning hours. It usually lasts for 20 minutes or longer and is more severe than chronic angina pain.

Not everyone who has an MI has classic symptoms. Some patients may not have pain but may have "discomfort," weakness, nausea, indigestion, or shortness of breath. Some women may have atypical discomfort, shortness of breath, or fatigue. Patients with diabetes may have silent (asymptomatic) MIs because of cardiac neuropathy or have atypical symptoms (e.g., shortness of breath). An older patient may have a change in mental status (e.g., confusion), shortness of breath, pulmonary edema, dizziness, or a dysrhythmia.

Sympathetic Nervous System Stimulation

During the initial phase of MI, the ischemic heart cells release catecholamines (norepinephrine and epinephrine) that are normally found in these cells. This results in diaphoresis, increased HR and BP, and vasoconstriction of peripheral blood vessels. On physical examination, the patient's skin may be ashen, clammy, and cool to touch.

Cardiovascular Manifestations

In response to the release of catecholamines, BP and HR may be high initially. Later, the BP may drop because of decreased CO. If severe enough, this may result in decreased renal perfusion and urine output. Crackles, if present, may persist for several hours to several days, suggesting LV dysfunction. Jugular venous distention (JVD), hepatic engorgement, and peripheral edema may mean right ventricular dysfunction.

Examination may reveal abnormally distant heart sounds. Other abnormal sounds suggesting LV dysfunction are S_3 and S_4. A loud holosystolic murmur may occur with a ventricular septal defect, papillary muscle rupture, or mitral valve dysfunction (mitral regurgitation).

Nausea and Vomiting

The patient may have nausea and vomiting. These symptoms can result from reflex stimulation of the vomiting center by the severe pain. They can also result from vasovagal reflexes initiated in the area of the infarcted heart muscle, especially with inferior wall MIs.

Fever

The temperature may increase to 100.4° F (38° C) within 24 to 48 hours. The temperature elevation may last for as long as 4 to 5 days. This increase in temperature is due to a systemic inflammatory process caused by the death of myocardial cells.

Healing Process

The body's response to cell death is the inflammatory process (see Chapter 11). Within 24 hours, leukocytes infiltrate the area. The dead heart cells release enzymes that are important diagnostic indicators of MI (see serum cardiac biomarkers later in this chapter). The proteolytic enzymes of the neutrophils and macrophages begin to remove necrotic tissue by the fourth day. During this time, the necrotic muscle wall is thin.

Once infarction takes place, catecholamine-mediated lipolysis and glycogenolysis occur. These processes allow the increased plasma glucose and free fatty acids to be used by the O_2-depleted myocardium for anaerobic metabolism. For this reason, serum glucose levels are often high after MI.

The necrotic zone of a STEMI is identified by ECG changes (e.g., lowering of the initially elevated ST segments, T wave inversion and/or a pathologic Q wave) within 1 or 2 days. At this point, the

neutrophils and monocytes have cleared the necrotic debris from the injured area, and the collagen matrix that will eventually form scar tissue is laid down.

At 10 to 14 days after MI, the new scar tissue is still weak. The heart muscle is vulnerable to increased stress during this time. At the same time, the patient's activity level may be increasing, so special caution and assessment are necessary. By 6 weeks after MI, scar tissue has replaced necrotic tissue and the injured area is considered healed. Often the scarred area is less compliant than the surrounding area. This condition may be manifested by abnormal wall motion on an echocardiogram or nuclear imaging (e.g., hypokinesis, akinesis), LV dysfunction, altered conduction patterns, dysrhythmias, or HF. The scarred area may become an irritable focus for life-threatening dysrhythmias causing sudden cardiac death (SCD) years later (see section on SCD on pp. 730–731).

These changes in the infarcted heart muscle also cause changes in the unaffected areas. To try to compensate for the damaged muscle, the normal myocardium hypertrophies and dilates. This process is called *ventricular remodeling.* Remodeling of normal myocardium can lead to the development of late HF, especially in the person with atherosclerosis of other coronary arteries and/or an anterior MI. ACE inhibitor drugs are given to limit ventricular remodeling.

Complications of Myocardial Infarction

Dysrhythmias

Any condition that affects the heart cells' sensitivity to nerve impulses (e.g., ischemia, electrolyte imbalances, SNS stimulation) can cause dysrhythmias that adversely affect the damaged heart muscle. Dysrhythmias are the most common complication after an MI. They occur in 80% to 90% of patients. Ventricular tachycardia (VT) and ventricular fibrillation (VF) are the most common cause of death in patients in the prehospital period.

After MI, bradycardias (e.g., complete heart block) develop when key areas of the conduction system are destroyed (e.g., infarction

involves the sinus or atrioventricular node). VT or VF most often occurs within the first 4 hours after the onset of pain. Premature ventricular contractions (PVCs) may precede VT and VF. Life-threatening ventricular dysrhythmias must be treated immediately.

With reperfusion (thrombolytic therapy or PCI), it is common to see PVCs, asymptomatic nonsustained VT, and idioventricular rhythms. These rhythms are not associated with an increased risk for sudden cardiac death (SCD) and are not treated unless the patient is symptomatic.[28] See Chapter 35 for a detailed description of dysrhythmias and their management.

Heart Failure

Heart failure (HF) is a complication that occurs when the right or left ventricle's pumping action is reduced. Depending on the severity and extent of the injury, left-sided HF occurs initially with subtle signs, such as mild dyspnea, restlessness, agitation, or slight tachycardia. Other signs indicating the onset of left-sided HF include pulmonary congestion on chest x-ray, S_3 or S_4 heart sounds, crackles on auscultation of the lungs, paroxysmal nocturnal dyspnea (PND), and orthopnea. Signs of right-sided HF include JVD, hepatic congestion, or lower extremity edema. See Chapter 34 for information about the treatment of acute decompensated HF.

Cardiogenic Shock

Cardiogenic shock occurs when O_2 and nutrients supplied to the tissues are inadequate because of severe LV failure, papillary muscle rupture, ventricular septal rupture, LV free wall rupture, or right ventricular infarction.[28] This occurs less often when STEMI is treated early and rapidly with PCI or thrombolytic therapy. Cardiogenic shock, associated with a high death rate, requires aggressive management. This includes control of dysrhythmias, intraaortic balloon pump (IABP) therapy, and support of contractility with vasoactive drugs. Goals of therapy are to maximize O_2 delivery, reduce O_2 demand, and prevent complications (e.g., acute kidney injury). Cardiogenic shock is

discussed in Chapter 66.

Papillary Muscle Dysfunction or Rupture

Papillary muscle dysfunction may occur if the infarcted area includes or is near the papillary muscle that attaches to the mitral valve (see Fig. 31.2). Suspect papillary muscle dysfunction if you hear a new systolic murmur suggestive of mitral regurgitation at the cardiac apex. An echocardiogram confirms the diagnosis.

Papillary muscle rupture is a rare and life-threatening complication. It causes acute and massive mitral valve regurgitation with no time for the heart to compensate. Dyspnea, pulmonary edema, and decreased CO result from the backup of blood in the left atrium. This condition aggravates an already damaged LV by reducing CO even further. The patient undergoes rapid clinical decline. Treatment includes afterload reduction with nitroprusside (Nipride) and/or IABP therapy and immediate cardiac surgery with mitral valve repair or replacement. (See Chapter 36 for discussion of valve disorders.)

Left Ventricular Aneurysm

Left ventricular aneurysm results when the infarcted heart wall is thin and bulges out during contraction. This can develop within a few days, weeks, or months. It is more common with anterior MIs.[28] The patient with a ventricular aneurysm may develop HF, dysrhythmias, and angina. Besides ventricular rupture, which is usually fatal, ventricular aneurysms can hide thrombi that can lead to an embolic stroke. Anticoagulation therapy is recommended for these patients unless contraindicated.

Ventricular Septal Wall Rupture and Left Ventricular Free Wall Rupture

A new loud systolic murmur heard in patients with acute MI may signal ventricular septal wall rupture. Depending on the size of the defect and degree of right and LV dysfunction, HF and cardiogenic shock may occur. The patient must undergo emergency repair, either

surgically or percutaneously. The defect can quickly expand and lead to hemodynamic compromise.[28]

LV free wall rupture is an emergent clinical situation. Rapid hemodynamic compromise and death ensues if not treated immediately. Although this is a rare complication, death rates are high. Free wall rupture is seen more often in patients after their first MI, patients with anterior MIs, older adults, and women.[28]

Pericarditis

Acute pericarditis, an inflammation of the visceral and/or parietal pericardium, may occur 2 or 3 days after an acute MI. Pericarditis is characterized by mild to severe chest pain that increases with inspiration, coughing, and movement of the upper body. Sitting in a forward position often relieves the pain. The pain is usually different from pain associated with an MI.

Assess the patient with suspected pericarditis for the presence of a friction rub over the pericardium. The sound is best heard with the diaphragm of the stethoscope at the mid to lower left sternal border. It may be persistent or intermittent. Fever may be present. The patient may have hypotension and/or a narrow pulse pressure if it is accompanied by significant pericardial effusion or cardiac tamponade. Asymptomatic pericardial effusions are common after STEMI.[28]

Diagnosis of pericarditis can be made with the 12-lead ECG. Typical ECG changes include diffuse ST segment elevations in many leads (with STEMI, ST elevation occurs in the leads facing the infarcted wall). This reflects the inflammation of the pericardium. Treatment includes pain relief with high doses of aspirin (e.g., 650 mg every 4 to 6 hours). Nonsteroidal antiinflammatory drugs (NSAIDs) and corticosteroids are avoided in the first 4 weeks after MI because they can interfere with myocardial scar formation.[21,28] Pericarditis is discussed in Chapter 36.

Dressler Syndrome

Dressler syndrome is pericarditis and fever that develop 1 to 8 weeks

after MI. Although the cause is unclear, it may be an autoimmune reaction to the necrotic heart muscle. The patient has chest pain, fever, malaise, a pericardial friction rub, and arthralgia. A pericardial effusion may be present. Laboratory findings include a high white blood cell count and sedimentation rate. High-dose aspirin is the treatment of choice.

Diagnostic Studies: Acute Coronary Syndrome

In addition to the patient's history of pain, risk factors, and health history, the primary diagnostic studies used to determine whether a person has UA or an MI (STEMI or NSTEMI) include a 12-lead ECG and serum cardiac biomarkers.

Electrocardiogram Findings

The ECG is one of the primary tools to diagnose UA or an MI (STEMI or NSTEMI). Whenever possible, it should be compared to a previous ECG. Changes in the QRS complex, ST segment, and T wave caused by injury, ischemia, and infarction can develop slowly or quickly with UA and MI. The pattern of ECG changes among the 12 leads provides information on the coronary artery involved in ACS (Table 33.13).

The ECG must be read carefully since changes can be absent or subtle at first. For this reason, serial 12-lead ECGs are done. For diagnostic and treatment purposes, it is important to distinguish between STEMI and NSTEMI/UA. STEMI patients usually have a complete coronary occlusion. ST elevation in the leads facing the infarcted wall is seen first on the 12-lead ECG (Figs. 33.4, *B*, 33.12, and 33.13 and Table 33.13). ST segment elevation is significant if it is 1 mm or more above the isoelectric line in at least 2 contiguous leads. Within a few hours to days, the ST segments begin to lower, with T wave inversion and pathologic Q waves developing in the same leads (Fig. 33.4, *C*). The Q wave is the first negative deflection after a P wave (Fig. 33.4, *A*). A pathologic Q wave is defined as a deep Q wave, greater than or equal to one-third the height of the R wave in the same lead. The pathologic Q wave will remain on the ECG forever. T wave inversion may persist for months after a STEMI. With early reperfusion, Q waves may not develop.

Patients with NSTEMI or UA usually have transient thrombosis or incomplete coronary occlusion. ECG changes with UA or an NSTEMI

include ST depression and/or T wave inversion in the leads facing the area of infarction (Figs. 33.4, 33.12, 33.14, and Table 33.13). Both groups of patients may present with angina and have the same ECG changes. The only way to tell if the patient is experiencing an NSTEMI or UA is by drawing cardiac biomarkers. The biomarkers will be high in the NSTEMI patient but normal in the patient with UA. These patients do not develop pathologic Q waves on the ECG.

Because MI is a dynamic process that evolves over time, serial ECGs are done to show the evolution of ischemia, injury, infarction, and resolution of the infarction.

Serum Cardiac Biomarkers

Serum cardiac biomarkers are proteins released into the blood from necrotic heart muscle after an MI (see Table 31.6). These biomarkers are important in the diagnosis of MI. The onset, peak, and duration of levels of these biomarkers are shown in Fig. 33.15.

Cardiac-specific troponin has 2 subtypes: cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI). These biomarkers are highly specific indicators of MI and have greater sensitivity and specificity for myocardial injury than creatine kinase MB (CK-MB). Serum levels of cTnI and cTnT increase 4 to 6 hours after the onset of MI, peak at 10 to 24 hours, and return to baseline over 10 to 14 days. Sets of serial cardiac biomarkers are drawn over 24 hours (e.g., every 6 hours × 3). The presence of biomarkers helps distinguish between UA (negative biomarkers) and NSTEMI (positive biomarkers). A newer high-sensitivity troponin test is available that provides more rapid detection of cardiac necrosis at an earlier time than traditional troponin assays, allowing for a quicker diagnosis.

CK levels begin to rise about 6 hours after an MI, peak at about 18 hours, and return to normal within 24 to 36 hours. The CK enzymes are fractionated into bands. The CK-MB band is specific to heart muscle cells and helps to quantify myocardial damage. CK-MB is a less sensitive marker for myocardial injury compared to troponin.[15] Therefore troponin is the best biomarker for diagnosis of acute MI.[28]

Myoglobin is released into the circulation within 2 hours after an MI and peaks in 3 to 15 hours. Although it is one of the first serum cardiac biomarkers to appear after an MI, it lacks cardiac specificity. It has a limited role in diagnosing MI.

Cardiac Catheterization

The patient with a STEMI must undergo cardiac catheterization within 90 minutes of presentation or receive thrombolytic therapy within 30 minutes in agencies without PCI capability. The goal is to open the totally occluded artery and limit the infarction size. The patient with UA or NSTEMI usually undergoes cardiac catheterization during the hospitalization to diagnose and evaluate the extent of the disease. Guidelines suggest that it is reasonable to do cardiac catheterization on stable but high-risk patients with UA or NSTEMI within 12 to 72 hours after presentation.[15] If appropriate, a PCI is performed at this time. Depending on the findings and many factors, some patients may be treated with medical therapy and some patients may be referred for CABG surgery.

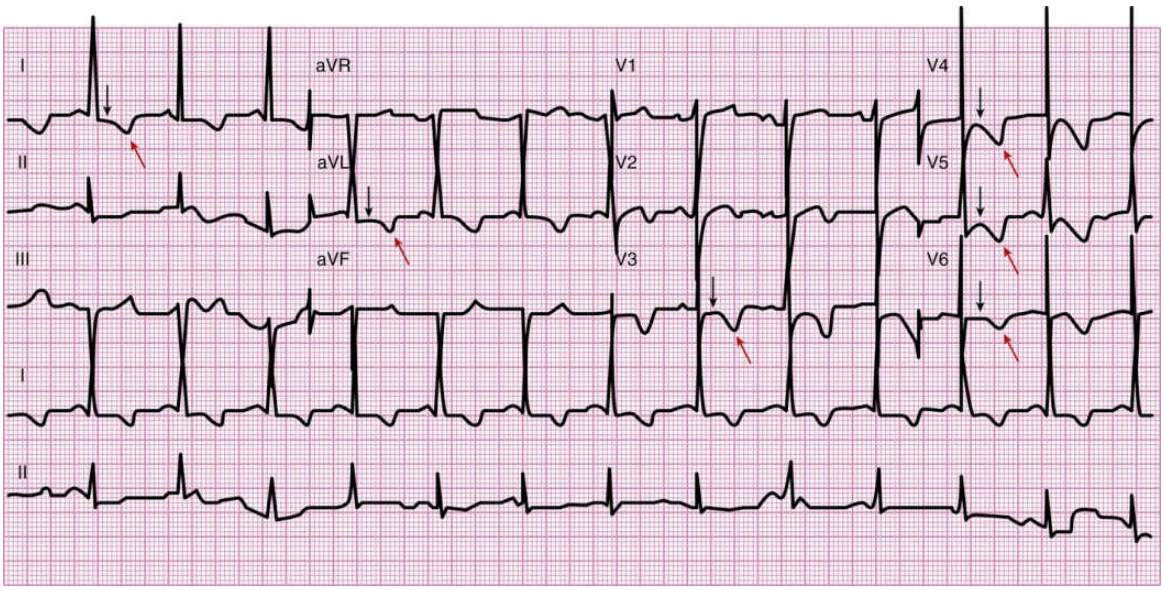

FIG. 33.14 ECG findings with anterior and lateral ischemia or an NSTEMI. Note the ST depression in the lateral leads (lead I, aVL, V5 and V6 [black arrows]) and the T wave inversion in I, aVL, V5 and V6

[red arrows]. These leads face the lateral wall. Note the ST depression in 2 anterior leads (V3 and V4 [black arrows]) and the T wave inversion in V3 and V4 [red arrows]. These leads face the anterior wall.

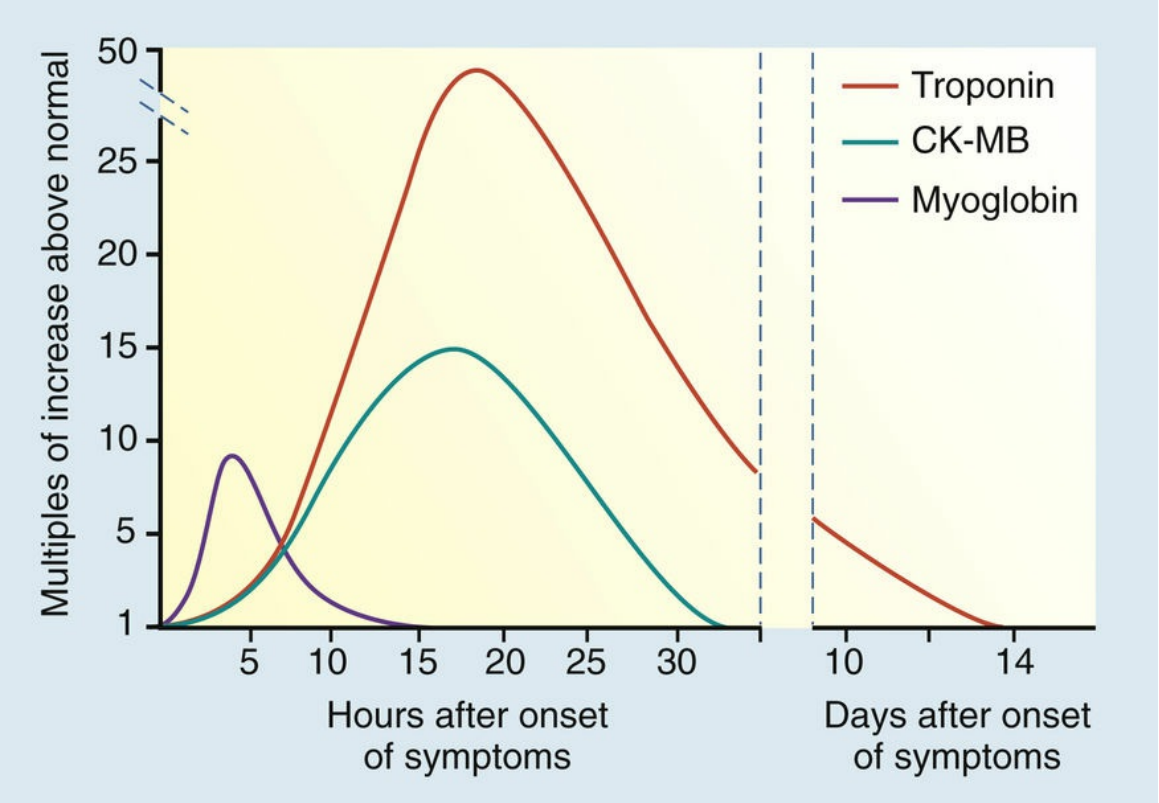

FIG. 33.15 Serum cardiac biomarkers found in the blood after MI.

Interprofessional Care: Acute Coronary Syndrome

It is extremely important to quickly diagnose and treat a patient with ACS to preserve heart muscle. Initial management of the patient with chest pain most often occurs in the ED. Table 33.14 presents the emergency care of the patient with chest pain. Obtain a 12-lead ECG and start continuous ECG monitoring. Position the patient in an upright position unless contraindicated and start O_2 by nasal cannula to keep O_2 saturation above 93%. Obtain IV access for drug administration. Give SL NTG and 162 to 325 mg of chewable aspirin if not given before arrival at the ED. Morphine is given for pain unrelieved by NTG. A high-dose statin (e.g., atorvastatin [Lipitor]) is given.

If the ECG shows ST elevation, the patient is taken directly for cardiac catheterization in PCI-capable hospitals. Thrombolytic therapy is started if the patient is unable to be quickly transported to a PCI-capable hospital. If the ECG shows ST depression and/or T wave inversion, the patient is usually transferred to an ICU or telemetry unit for ongoing care. Dysrhythmias are treated according to agency protocols. Serial cardiac biomarkers are drawn until the peak level drops off. UA and NSTEMI patients are started on heparin. Some patients with UA or NSTEMI start on glycoprotein IIb/IIIa inhibitors (e.g., eptifibatide [Integrilin]) either before catheterization or at the time of PCI. Glycoprotein IIb/IIIa inhibitors may be used during PCI for STEMI patients. Fig. 33.5 shows the interprofessional care of ACS.

Emergent PCI

Emergent PCI is the first line of treatment for patients with confirmed STEMI (i.e., ST-elevation on the ECG and positive cardiac biomarkers). The goal is to open the blocked artery within 90 minutes of arrival to an agency that has an interventional cardiac

catheterization laboratory to limit the infarction size. In this case, the patient undergoes a cardiac catheterization to locate and assess the severity of the blockage(s), determine the presence of collateral circulation, and evaluate LV function. During the procedure, a bare metal stent (BMS) or drug-eluting stent (DES) is inserted into the blocked coronary artery (Figs. 33.6 and 33.7). PCI should not be done on a noninfarct artery during the same urgent procedure if the patient is hemodynamically stable.[28] Patients with severe LV dysfunction may require IABP therapy and/or inotropes (e.g., dobutamine). A small percent of patients may need emergent CABG surgery.

TABLE 33.14 Emergency ManagementChest Pain

Etiology	Assessment Findings	Interventions
Cardiovascular • **Aortic aneurysm** • **Aortic valve disease** • **Dysrhythmia** • **MI** • **Myocardial ischemia** • **Pericarditis** **Respiratory** • **Costochondritis** • **Pleurisy** • **Pneumonia** • **Pneumothorax, hemothorax** • **Pulmonary edema** • **Pulmonary embolus** **Chest Trauma** • **Cardiac tamponade** • **Flail chest** • **Great vessel injury** • **Hemothorax** • **Pulmonary contusion** • **Rib/sternal fracture** **Gastrointestinal** • **Cholecystitis** • **Esophagitis** • **GERD** • **Hiatal hernia** • **Peptic ulcer** **Others** • **Acute anxiety** • **Drugs (e.g., cocaine)** • **Strenuous exercise** • **Stress**	• Pain in chest, neck, jaw, arm, or shoulder • Cold, clammy skin • Diaphoresis • Nausea and vomiting • Epigastric pain • Indigestion, heartburn • Dyspnea, tachypnea • Weakness • Anxiety • Feeling of impending doom • Tachycardia, bradycardia • Irregular HR, murmurs • Palpitations • Dysrhythmias • Decreased or increased BP • Narrowed pulse pressure • Unequal BP readings in upper extremities • Syncope, loss of consciousness • Decreased O_2 saturation • Decreased or absent breath sounds • Pericardial friction rub	Initial • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation (ABC). • Position patient upright unless contraindicated. • Give O_2 by nasal cannula or nonrebreather mask. • Obtain baseline vital signs, including O_2 saturation. • Auscultate heart and breath sounds. • Obtain 12-lead ECG. • Insert 2 IV catheters. • Assess pain using PQRST mnemonic (Table 33.8). • Medicate for pain as ordered (e.g., nitroglycerin, morphine). • Start continuous ECG monitoring and identify underlying rhythm. • Obtain baseline blood work (e.g., cardiac biomarkers, CBC, basic metabolic panel, coagulation studies). • Obtain portable chest x-ray. • Assess for contraindications for antiplatelet, anticoagulant, or thrombolytic therapy, or PCI as appropriate. • Give aspirin for heart-related chest pain unless contraindicated. • Give a high-dose statin. • Give antidysrhythmic drugs for life-threatening dysrhythmias. Ongoing Monitoring • Monitor ABCs, vital signs, level of consciousness, heart and breath sounds, heart rhythm, and O_2 saturation. • Assess and record response to drugs (e.g., decrease in chest pain) and remedicate or titrate drugs (e.g., nitroglycerin) as needed. • Provide reassurance and emotional support to patient and caregiver. • Explain all interventions and procedures to patient and caregiver in simple terms. • Anticipate need for intubation if respiratory distress is evident. • Prepare for CPR and defibrillation if cardiac arrest is evident. • Anticipate need for transcutaneous pacing for symptomatic bradycardia or heart block.

The advantages of PCI (compared to CABG surgery) include (1) it allows for faster reperfusion to limit infarction size; (2) it provides an alternative to surgical intervention; (3) it is performed with local anesthesia; (4) the patient is ambulatory shortly after the procedure; (5) the length of hospital stay is about 3 to 4 days after MI compared with the 4 to 6 days with CABG surgery, thus reducing hospital costs; and (6) the patient can return to work several weeks sooner after PCI, compared with a 6- to 8-week convalescence after CABG.

Complications of PCI that may lead to emergent CABG include dissection or rupture of the coronary artery, abrupt artery closure, acute stent thrombosis, and failure to cross the blockage with a balloon or stent. There is a risk that the infarction could be extended if a part of the plaque dislodges and blocks the vessel distal to the catheter.

In stent restenosis, ISR is a potential problem whenever stents are placed in a coronary artery. ISR is the build-up of scar tissue inside the stent (referred to as neointimal hyperplasia). ISR usually occurs within a few months to a year after stent placement. Stent thrombosis is the other potential problem with stents, so DAPT is required up to 12 months post procedure.

Check Your Practice

Your patient underwent an emergent PCI 2 days ago for a STEMI. You are about to give him his morning medications, which include clopidogrel and aspirin. The patient asks you if he will need to take these medications forever.

- What would you tell the patient?

Thrombolytic Therapy

Thrombolytic (fibrinolytic) therapy is indicated only for patients with a STEMI. Advantages include availability and rapid administration in

agencies that do not have an interventional cardiac catheterization laboratory or when one is too far away to transfer the patient quickly. Patients who are admitted to non–PCI-capable hospitals can be moved to a PCI-capable hospital if the first medical contact to balloon inflation (PCI) time can be done within 120 minutes.[28] Treatment of STEMI with thrombolytic therapy aims to limit the infarction size by dissolving the thrombus in the coronary artery to reperfuse the heart muscle. The goal is to give the thrombolytic within 30 minutes of the patient's arrival to the ED.

TABLE 33.15 Contraindications for Thrombolytic Therapy

Absolute Contraindications

- Active internal bleeding or bleeding diathesis (excluding menstruation)
- History of intracranial hemorrhage
- Intracranial or intraspinal surgery within 2 mo
- Known structural or vascular abnormality (e.g., arteriovenous malformation)
- Known intracranial cancer (primary or metastatic)
- Recent (within past 3 mo) ischemic stroke
- Severe uncontrolled hypertension
- Significant closed-head or facial trauma within past 3 mo
- Suspected aortic dissection
- For streptokinase, prior treatment within the past 6 mo

Relative Contraindications

- Active peptic ulcer disease
- Current use of oral anticoagulants
- Dementia
- History of chronic, severe, poorly controlled hypertension
- Known intracranial pathology not covered in absolute contraindications
- Major surgery (<3 wks)
- Noncompressible vascular punctures
- Pregnancy
- Prior ischemic stroke (>3 mo ago)
- Recent (within 2-4 wks) internal bleeding
- Significant hypertension on presentation (SBP >180 mm/Hg or DBP >110 mm/Hg)
- Traumatic or prolonged (>10 min) cardiopulmonary resuscitation

---

Source: O'Gara PT, Kushner FG, Ascheim DD, et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the ACCF/AHA Task Force on Practice Guidelines, *Circulation* 127:e362, 2013.

Indications and Contraindications

All thrombolytics (e.g., tenecteplase, alteplase) are given IV (Table

33.12). The cost, efficacy, and ease of administration guide the choice of a thrombolytic agent. Although these drugs have different pharmacokinetics, they all open the blocked artery by lysis of the thrombus. Because thrombolytics lyse the pathologic clot, they may also lyse other clots (e.g., a postoperative site). Therefore patient selection is important because minor or major bleeding can be a complication of therapy.

Inclusion criteria for thrombolytic therapy are (1) chest pain less than 12 hours with 12-lead ECG findings consistent with acute STEMI and (2) no absolute contraindications (Table 33.15). Patients with chest pain lasting 12 to 24 hours with ECG changes supporting STEMI may be considered for thrombolytic therapy.[28]

Procedure

Each hospital has a protocol for giving thrombolytic therapy, but 2 steps should be completed before thrombolytic therapy is started: (1) draw blood to obtain baseline laboratory values and (2) start 2 or 3 lines for IV therapy. Perform all other invasive procedures before giving the thrombolytic agent to reduce the risk for bleeding.

Depending on the drug selected, therapy is given in 1 IV bolus or over time (30 to 90 minutes). Note the time at which therapy begins and monitor the patient during and after the thrombolytic. Assess heart rhythm, vital signs, and pulse oximetry. Assess the heart and lungs often to evaluate the patient's response to therapy. Regularly assess for changes in neurologic status that may indicate cerebral bleeding.

When reperfusion occurs (e.g., a blocked coronary artery is opened and blood flow is restored to the heart muscle), several clinical signs can be seen. The most reliable sign is the return of the ST segment to baseline on the ECG. Other signs include resolution of chest pain and an early, rapid rise of the serum cardiac biomarkers within 3 hours of therapy, peaking within 12 hours. These levels increase as the necrotic heart cells release proteins into the circulation after perfusion is restored to the area. The presence of *reperfusion dysrhythmias* (e.g., accelerated idioventricular rhythm) is a less reliable sign of

reperfusion. These dysrhythmias are generally self-limiting and do not require aggressive treatment. (See Chapter 35 for management of dysrhythmias.)

A major concern with thrombolytic therapy is reocclusion of the artery. The site of the thrombus is unstable, and formation of another clot or spasm of the artery may occur. Therefore IV heparin therapy is started. If another clot develops, the patient will describe similar chest pain symptoms and ECG changes will return. Patients receiving thrombolytic therapy should be moved to an agency with PCI capabilities as soon as possible so PCI can be performed if thrombolytic therapy fails.

The major complication with thrombolytic therapy is bleeding. Ongoing nursing assessment is essential. Minor bleeding (e.g., surface bleeding from IV sites or gingival bleeding) is expected and controlled by applying manual pressure followed by a pressure dressing or ice packs.

Safety Alert

Thrombolytic Therapy

- Minor or major bleeding can occur with thrombolytic drugs.
- Place 2 or 3 IV lines before thrombolytic therapy is started.
- If signs and symptoms of major bleeding occur (e.g., drop in BP, increase in HR, sudden change in the patient's mental status, blood in the urine or stool), stop the drug and notify the HCP.

Drug Therapy

When a patient presents with suspected ACS, antiplatelet therapy (e.g., chewable aspirin for UA patients plus clopidogrel or ticagrelor [for STEMI and NSTEMI patients]), IV NTG, and atorvastatin are drug treatments of choice. Since STEMI patients are taken directly to

cardiac catheterization, systemic anticoagulation with either subcutaneous LMWH or IV UH is used only for UA and NSTEMI patients. Glycoprotein IIb/IIIa inhibitors may be given if PCI is anticipated. DAPT should continue for 1 year after an MI whether the patient receives a stent or not. Aspirin should never be stopped. Oral β-blockers are given within the first 24 hours if there are no contraindications (e.g., HF, heart block, hypotension). Calcium channel blockers are used if the patient cannot tolerate β-blockers. These drugs must be used cautiously after MI because they can decrease contractility. ACE inhibitors are added after an MI if there are no contraindications. Nitrates may be used for persistent chest pain.

Table 33.12 and Fig. 33.5 present drug therapy for patients with chronic stable angina and ACS. These drugs are discussed on p. 713. Drugs specifically used to treat ACS are discussed in this section.

IV Nitroglycerin

IV NTG is used in the initial treatment of the patient with ACS. SL NTG can be used until the IV NTG is prepared. The goal of therapy is to reduce angina pain and improve coronary blood flow. IV NTG decreases preload and afterload while increasing the myocardial O_2 supply. The onset of action is immediate. Titrate NTG to eliminate chest pain. Because hypotension is a common side effect, closely monitor BP. Patients who become hypotensive may be volume depleted and may benefit from an IV fluid bolus. Closely assess for volume overload after the bolus (e.g., crackles on lung auscultation).

Morphine

Morphine is the drug of choice for chest pain that is unrelieved by NTG. As a vasodilator, it decreases cardiac workload by lowering myocardial O_2 consumption, reducing contractility, and decreasing BP and HR. In addition, morphine can help reduce anxiety and fear. In rare situations, morphine can depress respirations. Monitor patients for signs of bradypnea or hypotension, which are conditions to avoid in myocardial ischemia and infarction.

β-Adrenergic Blockers

β-blockers decrease myocardial O_2 demand by reducing HR, BP, and contractility. The use of these drugs in patients who are not at risk for complications of MI (e.g., cardiogenic shock, bradycardia, hypotension) reduces the risk for reinfarction and the development of HF. Therapy continues indefinitely.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

ACE inhibitors should be started within the first 24 hours if the BP is stable and there are no contraindications. They are continued indefinitely in patients recovering from STEMI or NSTEMI, with HF, or an EF of 40% or less. The use of ACE inhibitors can help prevent ventricular remodeling and prevent or slow the progression of HF. For patients who cannot tolerate ACE inhibitors (e.g., angioedema, cough), ARBs should be considered.

Antidysrhythmic Drugs

Dysrhythmias are the most common complications after an MI. In general, they are self-limiting and not treated aggressively unless they are life threatening (e.g., sustained ventricular tachycardia). Chapter 35 discusses the drugs used in the treatment of dysrhythmias.

Lipid-Lowering Drugs

A lipid panel is done on all patients with ACS. Patients with ACS or CAD should receive lipid-lowering drugs indefinitely, unless contraindicated (Table 33.6).

Stool Softeners

After an MI, the patient may be predisposed to constipation because of bed rest and opioid drugs. Stool softeners (e.g., docusate sodium [Colace]) prevent straining and the resultant vagal stimulation from the *Valsalva maneuver*. Vagal stimulation produces bradycardia and can provoke dysrhythmias. A laxative may be used, if needed.

Nutritional Therapy

Initially, patients may be NPO (nothing by mouth) except for water until stable (e.g., pain free, nausea resolved). Advance the diet as tolerated to a low-salt, low-saturated-fat, and low-cholesterol diet (Tables 33.4 and 33.5).

Nursing Management: Acute Coronary Syndrome

Nursing Assessment

Table 33.16 presents the subjective and objective data to obtain from a patient with ACS.

Nursing Diagnoses

Nursing diagnoses for the patient with ACS may include:

- Impaired cardiac output
- Acute pain
- Anxiety
- Activity intolerance

More information on nursing diagnoses of patients with ACS is presented in eNursing Care Plan 33.1 available on the website for this chapter.

TABLE 33.16 Nursing AssessmentAcute Coronary Syndrome

Subjective Data

Important Health Information

Past health history: Previous history of CAD, chest pain/angina, MI, valve disease (e.g., aortic stenosis), heart failure, or cardiomyopathy. Hypertension, diabetes, anemia, lung disease, hyperlipidemia

Medications: Use of antiplatelets, anticoagulants, nitrates, ACE

inhibitors, β-blockers, calcium channel blockers, antihypertensive drugs, lipid-lowering drugs, over-the-counter drugs (e.g., vitamin and herbal supplements)

History of present illness: Description of events related to current illness (Table 33.9), including any self-treatments and response

Functional Health Patterns

Health perception–health management: Family history of heart disease. Sedentary lifestyle, tobacco use, exposure to environmental smoke

Nutritional-metabolic: Indigestion, heartburn, nausea, belching, vomiting

Elimination: Urinary urgency or frequency, straining at stool

Activity-exercise: Palpitations, dyspnea, dizziness, weakness

Cognitive-perceptual: Substernal chest pain or pressure (squeezing, constricting, aching, sharp, tingling), radiation to jaw, neck, shoulders, back, or arms (Table 33.8)

Coping–stress tolerance: Stressful lifestyle, depression; anger, anxiety. Feeling of impending doom

Objective Data

General

Anxious, fearful, restless, distressed

Integumentary

Cool, clammy, pale skin

Cardiovascular

Tachycardia or bradycardia, pulsus alternans (alternating weak and strong heartbeats), pulse deficit, dysrhythmias (especially ventricular), murmur, S_3, S_4, ↑ or ↓ BP

Possible Diagnostic Findings

Positive serum cardiac biomarkers, ↑ serum lipids; ↑ WBC count. Positive exercise or pharmacologic stress test and thallium scans. Pathologic Q wave, ST segment elevation, and/or ST-T wave abnormalities on ECG. Cardiac enlargement, calcifications, or pulmonary congestion on chest x-ray. Abnormal wall motion with stress echocardiogram or resting echocardiogram. Positive coronary angiography.

Planning

Nursing care focuses on the priority problems of acute pain and decreased CO. The immediate goals for a patient with ACS include (1) relief of pain, (2) quick and appropriate treatment, and (3) preservation of heart muscle. During the hospitalization, the overall goals include: (1) effective coping with illness-associated anxiety, (2) participation in a rehabilitation plan, and (3) reduction of risk factors. The Joint Commission has identified a core measure set in the management of patients with an acute MI (AMI) to reflect standards of evidence-based care.

Nursing Implementation

Acute Care

When the patient is admitted to the intensive care or telemetry unit, monitor vital signs and pulse oximetry frequently (e.g., every hour) during the first few hours after admission and closely thereafter, according to agency protocol. Start continuous ECG monitoring. Obtain serial 12-lead ECGs, and draw serial cardiac biomarkers

Maintain bed rest and limit activity for 12 to 24 hours, with a gradual increase in activity unless contraindicated.

For patients with UA and NSTEMI, heparin (UH or LMWH) is recommended to prevent microemboli from forming and causing further chest pain. DAPT (e.g., aspirin and clopidogrel or ticagrelor [Brilinta]) (Table 33.12) also is recommended for NSTEMI patients (with or without a stent). UA patients receive aspirin alone unless they have a stent placed; then DAPT is used. Cardiac catheterization is an option for both UA and NSTEMI patients once the patient is stabilized and angina is controlled or if angina returns or increases in severity. Depending on the results, options include medical management, PCI, or CABG surgery.

For patients with STEMI, reperfusion therapy is started as soon as possible. *Reperfusion therapy* includes emergent PCI (preferred, for PCI-capable hospitals) or thrombolytic therapy (in hospitals not capable of performing PCI). The goal in the treatment of STEMI is to save as much heart muscle as possible. Technical advances in PCI technology have almost eliminated CABG surgery as the primary treatment for patients with STEMI unless there is another reason to perform surgery (e.g., ventricular septal rupture, papillary muscle rupture).

Pain

Provide NTG, morphine, and supplemental O_2 as needed to eliminate or reduce chest pain. Ongoing evaluation and documentation of the effectiveness of the interventions is important. Once pain is relieved, some patients interpret the absence of pain as an absence of heart disease. Provide information about the importance of continued therapy to limit myocardial damage.

Monitoring

Maintain continuous ECG monitoring while the patient is in the ED and ICU and after transfer to a step-down unit. Treat life-threatening dysrhythmias quickly. During the initial period after MI, ventricular fibrillation is the most common lethal dysrhythmia. In many patients,

premature ventricular contractions or ventricular tachycardia (VT) precedes this dysrhythmia. Isolated PVCs are not usually treated. VT may or may not be treated depending on whether it is sustained VT or nonsustained VT and depending on the patient's hemodynamic status. Using the bedside ST segment monitor, assess the patient's ST segments for reinfarction or ischemia (ST segments will shift above or below the baseline of the ECG). Silent ischemia, noted only by ST segment changes, can occur without subjective symptoms (e.g., chest pain). Notify the HCP if you see ST segment changes with or without clinical symptoms. (See Chapter 35 for a complete discussion of ECG monitoring.)

Perform a physical assessment to detect changes from the patient's baseline findings. Assess heart and breath sounds and for signs of early HF (e.g., dyspnea, tachycardia, pulmonary congestion, distended neck veins). In addition to routine vital signs, monitor intake and output.

Assessment of the patient's oxygenation status is important. If a nasal cannula is used to deliver O_2, check the nares for irritation or dryness, which can cause considerable discomfort.

Rest and Comfort

It is important to promote rest and comfort for the patient with any degree of heart damage. Bed rest may be ordered for the first few days after a large MI. A patient with an uncomplicated MI (e.g., angina resolved, no signs of complications) may rest in a chair within 8 to 12 hours after the event. Prolonged bed rest is not recommended. The use of the bathroom, a commode, or a bedpan is based on patient preference and hemodynamic status.

TABLE 33.17 Phases of Rehabilitation After Acute Coronary Syndrome

Phase I: Hospital

- Occurs while the patient is still hospitalized
- Activity level depends on severity of angina or MI
- Patient may first sit up in bed or chair, perform range-of-motion exercises and self-care (e.g., washing, shaving), and progress to walking in hallway and limited stair climbing
- Attention focuses on management of chest pain, anxiety, dysrhythmias, and complications

Phase II: Early Recovery

- Begins after the patient is discharged
- Usually lasts from 2-12 weeks and is held in an outpatient facility but may be done in the home
- Activity level is gradually increased under the supervision of the cardiac rehabilitation team and with ECG monitoring
- Team may suggest that physical activity (e.g., walking program) be started at home
- Information about risk factor reduction is provided at this time

Phase III: Late Recovery

- Long-term maintenance program
- Individual physical activity programs are designed and implemented at home, a local gym, or the rehabilitation center
- Patient and caregiver restructure lifestyles and roles
- Therapeutic lifestyle changes should become lifelong habits
- Medical supervision recommended

When sleeping or resting, the body requires less work from the heart than it does when active. It is important to plan nursing and

other interventions to ensure adequate rest periods free from interruption. Comfort measures that can promote rest include a quiet environment, use of relaxation techniques (e.g., music therapy, guided imagery), and assurance that staff is nearby and responsive to the patient's needs.

It is important that the patient understand the reasons why activity is limited. Gradually increase the patient's heart workload through more demanding physical tasks. Before discharge, it is important that the patient achieve an activity level adequate for home care. Cardiac rehabilitation should be discussed and encouraged as an outpatient. Table 33.17 outlines the phases of cardiac rehabilitation.

Anxiety

A degree of anxiety is present in all patients with ACS. Your role is to identify the source of anxiety and assist the patient in reducing it. If the patient is afraid of being alone, allow a caregiver to sit by quietly and check the patient frequently. If a source of anxiety is fear of the unknown, explore these concerns with the patient. For anxiety caused by lack of information, provide teaching based on the patient's stated need and level of understanding. Answer the patient's questions with clear, simple explanations.

Check Your Practice

You are walking in the hallway with a 64-yr-old woman who had an MI 3 days ago. She is scheduled for discharge tomorrow. She is visibly anxious and irritable, wringing her hands, and talking very fast. She tells you, "My heart is pounding." You do not know if she is anxious or about to have another MI.

- What should you do?

TABLE 33.18 Psychosocial Responses to Acute Coronary Syndrome

Anger and Hostility

- Is often expressed as, "Why did this happen to me?"
- May be directed at family, staff, or medical regimen

Anxiety and Fear

- Fears long-term disability and death
- Overtly displays apprehension, restlessness, insomnia, tachycardia
- Less overtly displays increased verbalization, projection of feelings to others, hypochondriasis
- Fears activity
- Fears recurrent chest pain, heart attacks, and sudden death

Denial

- May have history of ignoring signs and symptoms related to heart disease
- Minimizes severity of health condition
- Ignores activity restrictions
- Avoids discussing illness or its significance

Dependency

- Totally reliant on staff
- Unwilling to perform tasks or activities unless approved by HCP
- Always wants to be monitored by ECG

- Hesitant to leave the intensive care or telemetry unit or hospital

Depression

- Mourns loss of health, altered body function, and changes in lifestyle
- Realizes seriousness of situation
- Begins to worry about future implications of health problem
- Shows manifestations of withdrawal, crying, apathy
- May be more evident after discharge

Realistic Acceptance

- Focuses on optimum rehabilitation
- Plans changes compatible with altered cardiac function
- Actively engages in lifestyle changes to address modifiable risk factors

It is important to start teaching at the patient's level rather than to present a prepackaged program. For example, patients generally are not ready to learn about the pathology of CAD. The earliest questions usually relate to how the disease affects perceived control and independence. Examples include:

- When will I leave the intensive care unit?
- When can I be out of bed?
- When will I be discharged?
- When can I return to work?
- How many changes will I have to make in my life?
- Will this happen again?

Tell the patient that more complete teaching will begin once the

patient is feeling stronger. Often the patient may not be able to ask the most serious concern of ACS patients: Am I going to die? Even if a patient denies this concern, it is helpful for you to start a conversation by remarking that fear of dying is a common concern among most patients who have had ACS. This gives the patient "permission" to talk about an uncomfortable and fearful topic.

Emotional and Behavioral Reactions

Patients' emotional and behavioral reactions vary, but often follow a predictable response pattern (Table 33.18). Your role is to understand what the patient is currently experiencing and to support the use of constructive coping styles.

Assess the support structure of the patient and caregiver. Determine how you can help maximize the support system. Often the patient is separated from the most significant support system at the time of hospitalization. Talk with the caregiver(s) about the patient's progress. Allow the patient and caregivers to interact as necessary and support the caregivers who will provide the necessary assistance to the patient. Open visitation is helpful in decreasing anxiety and increasing support for the patient with ACS.[29] It is important for you to help the patient identify additional support systems (e.g., spiritual care, Mended Hearts) that can assist during the hospital stay and/or after discharge.

Patient Teaching

Patient teaching is needed at every stage of the patient's hospitalization and recovery (e.g., ED, telemetry unit, home). Give patients and caregivers the tools they need to make informed decisions about their health. For teaching to be meaningful, the patient must be aware of the need to learn. Careful assessment of the patient's health literacy and learning needs helps you set realistic goals (see Chapter 4).

The timing of the teaching is important. When patients and caregivers are in crisis, they may not be ready to learn new information. Answer the patient's questions in simple, brief terms.

The answers often need repetition. When the shock accompanying a crisis subsides, the patient and caregiver are better able to focus on new and more detailed information.

Limit your use of medical terms. For example, you are caring for a patient with UA who asks you why he has chest tightness when he climbs stairs. Begin by explaining that the heart is a muscle that works as a pump. Like all muscles, it needs O_2 to work (or pump) properly. When blood vessels supplying the heart muscle with O_2 are blocked by fat and cholesterol, less O_2 is available to the muscle. As a result, the pump cannot work well. Tell the patient that the chest tightness (angina) is the heart's message that it is having trouble doing its work. Use a model of the heart to support what you are explaining.

Anticipatory guidance involves preparing the patient and caregiver for what to expect during recovery and rehabilitation. By learning what to expect, the patient gains a sense of control.

The idea of perceived control is operationalized as the process by which the patient makes decisions by cutting back. Cutting back is one way of reducing the psychologic and physiologic losses after ACS (or any other life-changing event). For example, a middle-aged man who smokes 2 packs of cigarettes a day, is 20 lb overweight, and gets no physical exercise may feel overwhelmed. He may decide that he can live with a weight reduction plan and will get more exercise (although perhaps not daily) but that it is not possible for him to quit smoking. He believes that because he is changing 2 of his 3 risk factors, he will be healthier. Ideally, the tobacco risk factor should be a priority for this patient. If the information about risks and effects of tobacco use is not accepted, you must respect the patient's choices.

In addition to teaching the patient and caregiver what they wish to know, several types of information are essential in achieving optimal health. Table 33.19 presents a teaching guide for the patient with ACS and the caregiver.

Physical Activity

Physical activity, an integral part of rehabilitation, is necessary for optimal physiologic functioning and psychologic well-being. It has a

direct, positive effect on maximal O_2 uptake, increasing CO, decreasing blood lipids, decreasing BP, increasing blood flow through the coronary arteries, increasing muscle mass and flexibility, improving the psychologic state, and assisting in weight loss and control. A regular schedule of physical activity, even after many years of sedentary living, is beneficial.

TABLE 33.19 Patient & Caregiver TeachingAcute Coronary Syndrome

Include the following information in the teaching plan for the patient with acute coronary syndrome and the caregiver:

- Signs and symptoms of angina and MI and what to do should they occur (e.g., how to take nitroglycerin)*
- When and how to seek help (e.g., contact 911)*
- Anatomy and physiology of the heart and coronary arteries
- Cause and effect of CAD
- Definition of terms (e.g., CAD, angina, MI, heart failure)
- Identification of and plan to decrease risk factors* (Tables 33.1, 33.2, 33.4, and 33.5)
- Reasons for tests and treatments (e.g., ECG monitoring, blood work, angiography), activity limitations and rest, diet, and drugs*
- Appropriate expectations about recovery (anticipatory guidance)
- Resumption of work, physical activity, sexual activity
- Measures to promote recovery and health (e.g., cardiac rehabilitation)
- Importance of the gradual, progressive resumption of activity*

* Identified by patients as most important to learn before discharge.

One method of identifying levels of physical activity is by using **metabolic equivalent (MET)** units: 1 MET is the amount of O_2 needed by the body at rest—3.5 mL of O_2 per kilogram per minute, or 1.4 cal/kg of body weight per minute. The MET determines the energy costs of various exercises (Table 33.20).

In the hospital, the activity level is gradually increased so that by the time of discharge the patient can tolerate moderate-energy activities of 3 to 6 METs. Many patients with UA or an uncomplicated MI are in the hospital for 3 or 4 days. By day 2, the patient can walk in the hallway and begin climbing a few steps. Because of the short hospital stay, it is critical to give the patient specific guidelines for physical activity so that overexertion will not occur. Tell the patient to always "listen to what your body is saying"—the most important aspect of recovery.

Teach patients that 30 to 60 minutes of moderate-intensity aerobic activity (e.g., brisk walking) at least 5 days a week is recommended by the AHA. For patients who have been hospitalized for a coronary event (e.g., PCI, UA, NSTEMI, STEMI), they must "work up" to 30 minutes of exercise per day. An exercise stress test may be ordered after hospitalization to assess for chest pain with activity and help guide physical activity. The patient who has been physically inactive and just starting an exercise program should do so under supervision whenever possible. Cardiac rehabilitation, either in a group setting or home-based setting, is recommended.[15,28]

Teach patients to check their HR. Some patients may use technology (e.g., cell phone applications, fitness trackers) to check their HR. The patient should know the limits within which to exercise. Tell the patient that the heart rate should return to the resting HR within a few minutes of stopping the exercise. Tell the patient to stop exercising and rest if chest pain or shortness of breath occurs. The key factor is the patient's response to physical activity in terms of symptoms rather than absolute HR, especially since many patients are taking β-blockers and may not be able to reach a target HR. This point cannot be

overstressed. Basic physical activity guidelines for patients after ACS follow the FITT formula (Table 33.3).

TABLE 33.20 Energy Expenditure in Metabolic Equivalents (METs)

Low-Energy Activities (<3 METs or <3 cal/min)

Activities in Hospital

- Eating
- Resting supine
- Washing hands, face

Activities Outside Hospital

- Driving a car
- Painting, seated
- Sewing by machine
- Sweeping floor

Moderate-Energy Activities (3–6 METs or 3–5 cal/min)

Activities in Hospital

- Showering
- Sitting on bedside commode
- Using bedpan

- Walking at 3–4 mph

Activities Outside Hospital

- Cycling at 5.5 mph on level ground
- Going up a flight of stairs
- Golfing
- General gardening
- Ironing, standing
- Painting, standing

High-Energy Activities (6–8 METs or 6–8 cal/min)

- Mowing lawn using walking mower
- Performing carpentry
- Walking 5 mph

Very-High-Energy Activities (>9 METs or >9 cal/min)

- Cross-country skiing
- Cycling at >13 mph
- Running at >6 mph

- Shoveling heavy snow

The basic categories of physical activity are isometric (static) and isotonic (dynamic). Most daily activities are a mixture of the two. *Isometric activities* involve the development of tension during muscular contraction but produce little or no change in muscle length or joint movement. Lifting, carrying, and pushing heavy objects are isometric activities. These activities are associated with the Valsalva maneuver and may cause a vasovagal response. Because the HR and BP change rapidly during isometric work, isometric exercises should be limited.

Isotonic activities involve changes in muscle length and joint movement with rhythmic contractions at relatively low muscular tension. Walking, jogging, swimming, bicycling, and jumping rope are examples of activities that are mostly isotonic. Isotonic exercise can put a safe, steady load on the heart and lungs and improve the circulation to other organs.

Women who have an MI often have poor adherence to a regular physical activity program.[4] Women often are the caregivers for everyone else and do not take good care of themselves. They may prioritize a physical activity program as less important than caring for others. Often women describe continued fatigue. Another factor linked to poor adherence to a physical activity program after MI is depression. Depression is common among patients with CAD, especially in women.[4] Routinely screen for depression in patients with CAD/ACS and recommend referral for treatment as appropriate.

Cardiac Rehabilitation

Cardiac rehabilitation is the restoration of a person to an optimal state of function in 6 areas: (1) physiologic, (2) psychologic, (3) mental, (4) spiritual, (5) economic, and (6) vocational.

Discuss participation in an outpatient cardiac rehabilitation program with patients who have had UA, an MI, a PCI, or CABG surgery (Table 33.17). These programs are helpful, but not all patients choose or are able to take part in them due to cost, location, and travel limitations. Home-based cardiac rehabilitation programs can provide

an alternative. Physical activity guidelines are developed for the patient and staff to maintain ongoing contact (e.g., telehealth, exercise logs, Internet). Maintaining contact with the patient is a key to the success of these programs.

Many patients recover physically from ACS or CABG surgery but do not attain psychologic well-being. All patients should be referred to an outpatient or home-based cardiac rehabilitation program because exercise-based cardiac rehabilitation is a Class I recommendation from the ACC/AHA for any patient with HF or who had a cardiac event.[13,15,20] Despite the proven beneficial effects of cardiac rehabilitation, it is often not recommended, and participation is less than optimal.

In considering rehabilitation, the patient must recognize that CAD is a chronic disease. It is not curable. Therefore basic changes in lifestyle must be made to promote recovery and future health. Tell patients that recovery takes time and resuming physical activity after ACS or heart surgery is slow and gradual. However, with appropriate and adequate supportive care, recovery is more likely.

Resuming Sexual Activity

It is important to include sexual counseling for heart patients and their partners. This often-neglected area of discussion may be difficult for both the patient and HCP to approach. However, the patient's concern about resumption of sexual activity after hospitalization for ACS often produces more stress than the physiologic act. Most patients change their sexual behavior because they are concerned about sexual inadequacy, death during intercourse, and impotence. A concerned and knowledgeable HCP can clarify any misconceptions with specific counseling.

Before providing guidelines on resumption of sexual activity, it is important to know the patient's physiologic status, physiologic effects of sexual activity, and psychologic effects of having an MI. Sexual activity for most middle-aged men and women with their usual partners is considered a moderate-energy activity equivalent to climbing 2 flights of steps or walking briskly.[30]

You may be uncertain of how and when to begin counseling about resumption of sex. It is helpful to consider sex as a physical activity and to discuss or explore feelings in this area when discussing other physical activities. One helpful approach is, "Many people who have had a heart attack wonder when they will be able to resume sexual activity. Has this been of concern to you?" You may also state, "Sexual activity, like other forms of activity, should be gradually resumed after MI. If your ability to perform sexually is concerning you, the energy you use is likely no more than climbing 2 flights of steps or walking briskly." Facilitate discussion by providing the patient with reading material on resumption of sexual activity. Say something such as, "If resuming sexual activity has been of concern to you, this information should be helpful." This type of nonthreatening statement brings up the topic, allows the patient to explore personal feelings, and gives the patient an opportunity to raise questions with you or another HCP. Common guidelines are outlined in Table 33.21.

TABLE 33.21 Patient & Partner TeachingSexual Activity After Acute Coronary Syndrome

Include the following information in the teaching plan for the patient and his/her partner after an acute coronary syndrome:

- Resume sexual activity at a level that relates to sexual activity before experiencing ACS.
- Physical training may improve the physiologic response to intercourse. Encourage daily physical activity during recovery.
- Consumption of food and alcohol should be reduced before intercourse is anticipated (e.g., waiting 3–4 hr after eating a large meal before engaging in sexual activity).
- Familiar surroundings and a familiar partner reduce anxiety.
- Masturbation may be a useful sexual outlet and may reassure the

patient that sexual activity is still possible.

- Avoid hot or cold showers just before and after intercourse.
- Foreplay is desirable because it allows a gradual increase in HR before orgasm.
- Positions during intercourse are a matter of individual choice.
- Orogenital sex places no undue strain on the heart.
- A relaxed atmosphere free of fatigue and stress is optimal.
- Prophylactic use of nitrates to decrease chest pain during sexual activity may be suggested.
- Use of erectile agents (e.g., sildenafil) is contraindicated if taking nitrates in any form.
- Avoid anal intercourse because of the chance of inducing a vasovagal response.

Tell the patient that the inability to perform sexually after MI is common and that sexual dysfunction usually disappears after several attempts. Reinforce the idea that patience and understanding usually solve the problem. However, many male patients may be interested in using drugs to correct erectile dysfunction. Warn the patient that these drugs are not to be used with nitrates because severe hypotension, and even death, have been reported. Tell patients to discuss the use of these drugs with their HCP.

It is common for a patient who has chest pain on physical exertion to have some angina during sexual stimulation or intercourse. The patient may take NTG prophylactically if he is not using erectile dysfunction medications. Tell the patient to delay sex after a heavy meal or excess alcohol intake, when extremely tired or stressed, or with unfamiliar partners. Patients should avoid anal intercourse because of the chance of eliciting a vasovagal response.

Tell the patient that resumption of sex depends on the patient and partner's emotional readiness and on the HCP's assessment of the extent of recovery. It is generally safe to resume sexual activity 7 to 10 days after an uncomplicated MI. However, some HCPs think that the patient should decide when to resume sex. Others think patients must

be asymptomatic during moderate-energy activities before resuming sexual activity.[30]

Evaluation

The expected outcomes are that the patient with ACS will

- Maintain stable signs of adequate cardiac output
- Have relief of pain and/or shortness of breath
- Report decreased anxiety and increased sense of self-control
- Achieve a realistic program of activity that balances physical activity with energy-conserving activities
- Describe the disease process, measures to reduce risk factors, and rehabilitation activities necessary to manage the therapeutic regimen

Evidence-Based Practice

Participating in Cardiac Rehabilitation

You are caring for M.M., a 76-yr-old male who had a NSTEMI and PCI with stent placement 3 days ago. The HCP prescribed cardiac rehabilitation 3 times per week for 12 weeks, to begin in 4 weeks. M.M. and his wife live in a rural area and express concern that it will be hard for M.M. to travel to attend the nearest center-based program 40 minutes from their home. They ask you if M.M. needs to take part in the rehabilitation program or if there are other options they can pursue.

Making Clinical Decisions

Synthesis of Best Available Evidence

Cardiac rehabilitation programs help to aid in recovery and prevent further cardiac events. They typically include exercise, healthy lifestyle education, and/or psychologic interventions, such as stress reduction counseling. Programs are available in supervised centers or

in the home (home-based). Home-based programs have been introduced to increase access and participation in cardiac rehabilitation. The programs are similar in terms of outcomes of mortality, exercise capacity, and health-related quality of life.

Clinician Expertise

You know that taking part in a home-based or center-based cardiac rehabilitation program will help to aid in recovery and prevent further cardiac events after a NSTEMI.

Patient Preferences and Values

M.M. and his wife want him to take part in cardiac rehabilitation but express concern about attending a hospital-based program.

Implications for Nursing Practice

1. What strategies may be useful in encouraging M.M. to take part in a program?
2. Why is it important to reinforce the benefits of adhering to a recommended exercise program?
3. What would you suggest since they are concerned about not being able to travel to a center-based program?

Sudden Cardiac Death

Sudden cardiac death (SCD) is a sudden, unexpected death resulting from a variety of cardiac causes. Around 350,000 adults experience SCD yearly.[1]

Etiology and Pathophysiology

SCD is defined as sudden unexpected death occurring within 1 hour of symptom onset. In SCD, a sudden disruption in heart function from a life-threatening dysrhythmia produces an abrupt loss of CO and cerebral blood flow. The affected person may or may not have a known history of heart disease. CAD is the main cause of SCD in the United States, especially in adults over 35 years of age.[31] Black women have a higher incidence of SCD as the first manifestation of CAD than white women.[5] SCD is the initial manifestation of CAD or structural heart disease in up to 50% of people; however, SCD can occur without evidence of CAD.[31]

Acute ventricular dysrhythmias (e.g., ventricular tachycardia, ventricular fibrillation) cause most cases of SCD. With the use of implantable cardioverter-defibrillators (ICDs), the incidence of SCD from VT and VF is declining.[31] These dysrhythmias may or may not be associated with an acute MI. Many SCD survivors have a history of a prior (old) MI.

Besides patients with CAD, patients with LV dysfunction and structural heart disease are at risk for SCD. Structural heart disease includes LV hypertrophy, myocarditis, and hypertrophic cardiomyopathy. Hypertrophic cardiomyopathy is a risk factor for SCD, especially in young, athletic people.

Some cases of SCD (especially in people less than age 45) occur in the absence of structural heart disease, LV dysfunction or CAD. These involve changes in the conduction system (e.g., prolonged QT syndrome, Wolff-Parkinson-White syndrome complicated by atrial fibrillation, Brugada syndrome).

Clinical Manifestations and Complications

Some people have symptoms within 1 hour of an SCD event, such as angina, palpitations, dizziness, or lightheadedness. People who experience SCD because of CAD fall into 2 groups: (1) those who had a prior (old) MI and (2) those who had an acute MI. SCD is more common in people who had a prior (old) MI. Those who had a prior MI and survive SCD are at risk for another SCD event because of the continued electrical instability from the scarred heart muscle that caused the first event to occur. They are usually referred for an ICD. Patients who have SCD associated with an acute MI undergo at least 40 days of maximal medical therapy to see if there is recovery in the EF before an ICD can be implanted.[32]

Most SCD patients have a lethal ventricular dysrhythmia that is associated with a high incidence of recurrence. It is difficult to know who is at high risk for SCD. However, LV dysfunction (EF < 30%) is the most commonly used tool to help guide decisions about ICD implantation.[31]

Interprofessional and Nursing Care

People who survive an SCD event need a diagnostic workup to determine whether they had an acute MI. Serial analysis of cardiac biomarkers and ECGs are done to rule out ACS. Because some people with SCD have undiagnosed CAD, cardiac catheterization is done to identify if significant CAD (e.g., greater than 70% stenosis in multiple coronary arteries) was the cause of the SCD event. PCI or CABG surgery may be indicated because significant CAD may be a reversible cause of SCD.

If no reversible cause is identified and the EF is low normal, it is useful to know if these patients are likely to have a recurrence. Assessment of dysrhythmias in these patients may include obtaining an electrophysiology study (EPS).[32] EPS is done under fluoroscopy. Pacing electrodes are placed in various intracardiac areas and stimuli are selectively used in an attempt to reproduce life-threatening dysrhythmias. See Chapters 31 and 35 for a discussion of EPS.

For patients with syncope with the suspected cause of ventricular dysrhythmias, an outpatient wearable monitor (e.g., Holter monitor) can be used for up to 48 hours or a Mobile Cardiac Outpatient Telemetry (MCOT) (e.g., CardioNet) may be worn up to 30 days. An implantable cardiac monitor (e.g., LINQ) may be implanted and left in place up to 3 years.

The most common approach to preventing a recurrence of SCD is the use of an ICD. It has been shown that an ICD improves survival.[31,32] (See Chapter 35 for a discussion of ICDs.) Drug therapy with amiodarone may be used with an ICD to decrease episodes of ventricular dysrhythmias if the patient is receiving multiple ICD shocks from the dysrhythmias.

Some patients at risk for SCD (e.g., during the time when a patient with an MI and low EF must wait at least 40 days on maximum medical therapy to see if there is improvement in LV function) are recommended to use a wearable cardioverter-defibrillator (e.g., LifeVest) as a bridge to ICD or heart transplantation.[33] The wearable cardioverter-defibrillator is a personal external defibrillator that has 2 main parts: a garment and monitor. The garment is worn under clothing and has electrodes that continuously record the patient's ECG. The monitor is worn around the waist or from a shoulder strap. If the patient has ventricular tachycardia or ventricular fibrillation, the device sounds an alarm to confirm that the patient is unresponsive. If the patient is conscious, the patient can press 2 buttons to stop the shock. If the patient does not respond, the device warns bystanders that a shock is about to be delivered. If the dysrhythmia continues and the patient still does not respond, a treatment shock is delivered through the electrodes.[33]

Teaching people about the care of SCD victims and the actions to take can save lives. Rapid cardiopulmonary resuscitation (CPR) and defibrillation with an automatic external defibrillator (AED), combined with early advanced cardiac life support, has improved long-term survival rates for a witnessed arrest due to ventricular dysrhythmias.

When caring for these patients, be alert to the patient's psychosocial

adaptation to this sudden “brush with death.” Many patients develop a “time bomb” mentality. They fear the recurrence of cardiac arrest and may become anxious, angry, and depressed. Their caregivers are likely to have the same feelings. Patients and caregivers may need to deal with other issues, such as driving restrictions, role reversal, and change in occupation. The grief response varies among patients and caregivers. Be attuned to the specific needs of the patient and caregiver. Teach them accordingly while providing emotional support.

Case Study

Myocardial Infarction

© iStockphoto/Thinkstock.

Patient Profile

D.M., a 51-yr-old, white, small business owner, is rushed to the ED by ambulance with crushing, substernal chest pain that radiates down

his left arm. He reports dizziness and nausea.

Subjective Data

- Short of breath, nauseous
- History of chronic stable angina and hypertension
- States he is “borderline diabetic”
- Overweight, but recently lost 10 lb
- Rarely exercises
- Has 3 teenage children who are causing “problems”
- Recently lost his best friend and business partner, who died from cancer

Objective Data
Physical Examination

- Diaphoretic
- BP 165/100 mm Hg, pulse rate 120/min, respiratory rate 26/min

Diagnostic Studies

- 12-lead ECG shows sinus tachycardia with occasional premature ventricular contractions and ST elevation in leads II, III, aV_F, V_5, V_6 consistent with an inferolateral wall MI
- High cardiac-specific troponin I level
- Total cholesterol 350 mg/dL (9.1 mmol/L)
- Hb A1C 9.0%

Interprofessional Care

- ED: Notify the cardiac catheterization laboratory of patient with

STEMI:

- O_2 2 L/min via nasal cannula, titrate to keep O_2 saturation above 93%
- Continuous ECG monitoring
- 2 IV access sites
- Aspirin 325 mg (chewable)
- Atorvastatin (Lipitor) 80 mg PO
- Eptifibatide (Integrilin) IV (this should *not* delay the patient getting to the cardiac catheterization laboratory)
- Weight-based heparin IV (only used if the patient does not go directly to cardiac catheterization)
- SL NTG until an IV line is placed, then titrate nitroglycerin IV to relieve chest pain; hold for systolic BP below 100 mm Hg
- Morphine 2 mg IV q5–15 min as needed for chest pain unrelieved by NTG
- Vital signs (including pulse oximetry) every 10 minutes
- Prepare patient for cardiac catheterization with possible PCI

Discussion Questions

1. Which coronary artery(ies) is (are) most likely occluded in D.M.'s coronary circulation?
2. Explain the pathogenesis of CAD. What risk factors contribute to its development? What risk factors were present in D.M.'s life?
3. What is angina? How does chronic stable angina differ from angina associated with acute coronary syndrome?
4. Explain the pathophysiologic basis for the clinical manifestations that D.M. exhibited.
5. Explain the significance of the results of the laboratory tests and the 12-lead ECG findings.
6. Give a rationale for each treatment measure ordered for D.M.

7. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Identify any collaborative problems.
8. ***Priority Decision:*** What are the priority nursing interventions for D.M. before PCI? Immediately after his PCI?
9. ***Collaboration:*** Identify activities that can be delegated to unlicensed assistive personnel (UAP).
10. ***Evidence-Based Practice:*** Two days after an uncomplicated PCI and the placement of 2 stents, D.M. wants to know what the most effective strategies are to prevent another MI. Based on his clinical situation, what would you tell him?
11. ***Quality Improvement:*** What outcomes would show that the interdisciplinary care was successful?
12. Develop a conceptual care map for D.M.

Answers and a corresponding conceptual care map available at http://evolve.elsevier.com/Lewis/medsurg.

Bridge to Nclex Examination

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In teaching a patient about coronary artery disease, the nurse explains that the changes that occur in this disorder include *(select all that apply)*
   a. diffuse involvement of plaque formation in coronary veins.
   b. abnormal levels of cholesterol, especially low-density lipoproteins.
   c. accumulation of lipid and fibrous tissue within the coronary arteries.
   d. development of angina due to a decreased blood supply to the heart muscle.
   e. chronic vasoconstriction of coronary arteries leading to permanent vasospasm.
2. After teaching about ways to decrease risk factors for CAD, the nurse recognizes that further instruction is needed when the patient says
   a. "I can keep my blood pressure normal with medication."
   b. "I would like to add weight lifting to my exercise program."
   c. "I can change my diet to decrease my intake of saturated fats."
   d. "I will change my lifestyle to reduce activities that increase my stress."

3. A hospitalized patient with a history of chronic stable angina tells the nurse that she is having chest pain. The nurse bases his actions on the knowledge that ischemia
   a. will always progress to myocardial infarction.
   b. can be relieved by rest, nitroglycerin, or both.
   c. is often associated with vomiting and extreme fatigue.
   d. indicates that irreversible myocardial damage is occurring.
4. The nurse is caring for a patient who is 2 days post MI. The patient reports that she is experiencing chest pain when she takes a deep breath. Which action would be a *priority*?
   a. Notify the provider STAT and obtain a 12-lead ECG.
   b. Obtain vital signs and auscultate for a pericardial friction rub.
   c. Apply high-flow O_2 by face mask and auscultate breath sounds.
   d. Medicate the patient with as-needed analgesic and reevaluate in 30 minutes.
5. A patient is admitted to the ICU with a diagnosis of NSTEMI. Which drugs(s) would the nurse expect the patient to receive? *(select all that apply)*
   a. Oral statin therapy
   b. Antiplatelet therapy
   c Thrombolytic therapy
   d. Prophylactic antibiotics
   e. Intravenous nitroglycerin
6. A patient is recovering from an uncomplicated MI. Which

rehabilitation guideline is a *priority* to include in the teaching plan?

a. Refrain from sexual activity for a minimum of 3 weeks.

b. Plan a diet program that aims for a 1- to 2-lb weight loss per week.

c. Begin an exercise program that aims for at least 5 30-minute sessions per week.

d. Consider the use of erectile agents and prophylactic NTG before engaging in sexual activity.

7. The most common finding in people at risk for sudden cardiac death is

a. aortic valve disease.

b. mitral valve disease.

c. left ventricular dysfunction.

d. atherosclerotic heart disease.

1. b, c, d, 2. b, 3. b, 4. b, 5. a, b, e, 6. c, 7. c

Heart Failure

Vera Barton-Maxwell

LEARNING OUTCOMES

1. Compare the pathophysiology of heart failure with reduced ejection fraction (HFrEF) and heart failure with preserved ejection fraction (HFpEF).
2. Relate the compensatory mechanisms involved in heart failure (HF) to the development of acute decompensated heart failure (ADHF) and chronic HF.
3. Describe appropriate nursing and interprofessional care to manage the patient with ADHF.
4. Describe appropriate nursing and interprofessional care to manage the patient with chronic HF.
5. Discuss advanced therapeutic options for patients with stage D HF.
6. Describe the indications for heart transplantation and the nursing care of heart transplant recipients.

Heart Failure

Heart failure (HF) is a complex clinical syndrome that develops in response to myocardial insult. It results in the inability of the heart to provide sufficient blood to meet the oxygen (O_2) needs of tissues and organs. The decreased cardiac output leads to decreased tissue perfusion, impaired gas exchange, fluid volume imbalance, and decreased functional ability. This chapter discusses the nursing and

interprofessional care of patients with HF.

The *percentage* of the total blood volume in the left ventricle (LV) at the end of diastole that is pumped out of the LV with the next systole is called the left ventricular ejection fraction (LVEF). HF manifestations occur due to a defect in either ventricular systolic function/LV contraction (**heart failure with reduced ejection fraction [HFrEF]**) and/or a defect in ventricular diastolic function/filling (**heart failure with preserved ejection fraction [HFpEF]**).[1]

HF is associated with many cardiovascular diseases (CVDs), particularly long-standing hypertension (HTN), coronary artery disease (CAD), and myocardial infarction (MI). HF is increasing in incidence and prevalence. This is partially due to better survival after cardiac events and the aging population. HF is primarily a disease of older adults. The incidence is similar in men and women.[2]

HF is a major health problem in the United States. The number of people diagnosed with HF has increased from 5.7 million (2009–2012) to 6.5 million (2011–2014). That number is projected to rise 46% by 2030.[2] HF is the most common reason for hospital admission in adults over the age of 65. This places a significant economic burden on the health care system.[1] The complex, progressive nature of HF often results in poor outcomes, such as hospital readmissions. Around 25% of patients discharged with a primary diagnosis of HF are readmitted within 30 days. The total cost of HF care exceeds $40 billion annually, with over half of these costs spent on hospitalizations.[2]

Etiology

HTN and CAD are the primary risk factors for HF. HTN is a modifiable risk factor that should be aggressively treated and managed. Long-term treatment of HTN reduces the incidence of HF by 50%.[1] Co-morbidities. such as diabetes, metabolic syndrome, advanced age, tobacco use, and vascular disease, contribute to the development of HF. Other causes of HF include congenital abnormalities (e.g., septal defects), infiltrative cardiomyopathies (e.g., sarcoidosis), infections and inflammatory processes (e.g., viral

myocarditis), persistent dysrhythmias, and toxins (e.g., alcohol, drug use, chemotherapy).[3]

Promoting Health Equity

- Black and Hispanic Americans develop HF at an earlier age, are admitted to the hospital more often, and have higher mortality rates related to HF as compared to whites.
- Hispanic Americans have more CVD risk factors but are 25% less likely to die of heart disease than whites.[4]

Any interference with the normal mechanisms regulating cardiac output (CO) may cause HF. CO depends on (1) preload, (2) afterload, (3) myocardial contractility, and (4) HR. These factors affect stroke volume (SV), which is the amount of blood pumped per heartbeat. Thus the equation: CO = SV × HR. Preload and afterload are discussed in Chapter 31. Any changes in these factors can lead to decreased ventricular function and HF.

The major causes of HF are divided into 2 subgroups: (1) primary causes (Table 34.1) and (2) precipitating causes (Table 34.2). Precipitating causes often increase the workload of the heart, resulting in an acute condition and decreased heart function.

Genetic Link

Several different forms of heart disease are passed down in families. Research suggests that 1 form of HF partially depends on a genetic predisposition. Mutations in more than 30 genes can cause the familial form of cardiomyopathy, a group of diseases that weaken the heart muscle. These genes provide the instructions for cardiomyocyte (heart muscle cell) proteins. The body's largest known protein, *titin*, responds to such a mutated gene. Titin mutations impair sarcomere function and disrupt chemical signaling, which negatively affects

ventricular structure and stability.[5] Specific genes and gene mutations are linked to the development of HTN and CAD, known risk factors for HF (see Chapters 32, 33, and 36). Research into the effects of gene mutations on the incidence of HF is ongoing.

Pathophysiology

HF is a complex clinical syndrome that develops in response to myocardial injury and results in decreased heart function. Manifestations of HF are the result of neurohormonal compensatory mechanisms activated in response to myocardial dysfunction, leading to *remodeling* of myocardial structure and function (Fig. 34.1).

TABLE 34.1 Primary Causes of Heart Failure

- Cardiomyopathy (e.g., viral, postpartum, substance use)
- Congenital heart defects (e.g., ventricular septal defect)
- CAD, including MI
- HTN, including hypertensive crisis
- Hyperthyroidism
- Myocarditis
- Pulmonary HTN
- Rheumatic heart disease
- Valvular disorders (e.g., mitral stenosis)

Left-Sided Heart Failure

The most common form of HF, left-sided HF, results either from the inability of the LV to (1) empty adequately during systole or (2) fill adequately during diastole. We can further classify left-sided HF as HFrEF (systolic HF), HFpEF (diastolic HF), or a combination of the two.

Heart Failure With Reduced EF (Systolic Failure)

HFrEF results from an inability of the heart to pump blood effectively. The hallmark of HFrEF is a decrease in the LVEF. Normal LVEF is 55% to 65%. Patients with HFrEF generally have an LVEF < 40%. It can be as low as 5% to 10%. HFrEF is caused by impaired contractile function (e.g., MI), increased afterload (e.g., HTN), cardiomyopathy, and mechanical abnormalities (e.g., valvular heart disorders).[3]

The LV in HFrEF loses the ability to generate enough pressure to eject blood forward through the aorta. Over time, the LV becomes dilated and hypertrophied. The weakened heart muscle cannot generate adequate SV, which impairs CO. Because the LV cannot effectively push blood forward, end diastolic volumes and pressures in the LV increase. When the LV fails, blood backs up into the left atrium (LA). This causes fluid accumulation in the lungs. The increased pulmonary hydrostatic pressure causes fluid leakage from the pulmonary capillary bed into the interstitium and then the alveoli. This results in pulmonary congestion and edema (Fig. 34.2, *A* through *D*). Fortunately, there are many therapies that reduce morbidity and mortality in HFrEF.

Heart Failure With Preserved EF (Diastolic Failure)

HFpEF results from the inability of the ventricles to relax and fill during diastole. About 50% of patients with HF have HFpEF. HTN is the primary cause of HFpEF.[1] Other risk factors include older age, female gender, diabetes, and obesity (see Gender Differences box). In HFpEF, the LV is generally stiff and noncompliant, resulting in high filling pressures. Decreased filling of the ventricles results in decreased SV. The eventual result of HFpEF is the same as that of HFrEF, a reduced CO leading to fluid congestion. The diagnosis of HFpEF is based on (1) signs and symptoms of HF, (2) normal LVEF, and (3) evidence of LV diastolic dysfunction by echocardiography or cardiac catheterization. Therapies are targeted at reducing underlying risk factors, treating co-morbidities, and reducing symptoms.[6]

TABLE 34.2 Common Precipitating Causes of Heart Failure

Cause	Mechanism
Anemia	↓ O_2-carrying capacity of the blood stimulating ↑ in CO to meet tissue demands, leading to increase in cardiac workload and increase in size of LV
Bacterial endocarditis	*Infection:* ↑ metabolic demands and O_2 requirements *Valvular dysfunction:* causes stenosis or regurgitation
Dysrhythmias	May ↓ CO and ↑ workload and O_2 requirements of myocardial tissue
Hypervolemia	↑ Preload causing volume overload on the RV
Hypothyroidism	Indirectly predisposes to ↑ atherosclerosis. Severe hypothyroidism decreases myocardial contractility.
Infection	↑ O_2 demand of tissues, stimulating ↑ CO
Nutritional deficiencies	May ↓ cardiac function by ↑ myocardial muscle mass and myocardial contractility
Obstructive sleep apnea	Frequent nighttime apnea results in ↑ afterload, intermittent hypoxia, and ↑ sympathetic nervous system activity.
Paget's disease	↑ Workload of the heart by ↑ vascular bed in the skeletal muscle
Pulmonary embolism	↑ Pulmonary pressure resulting from obstruction leads to pulmonary HTN, ↓ CO.
Thyrotoxicosis	Changes the tissue metabolic rate, ↑ HR and workload of the heart

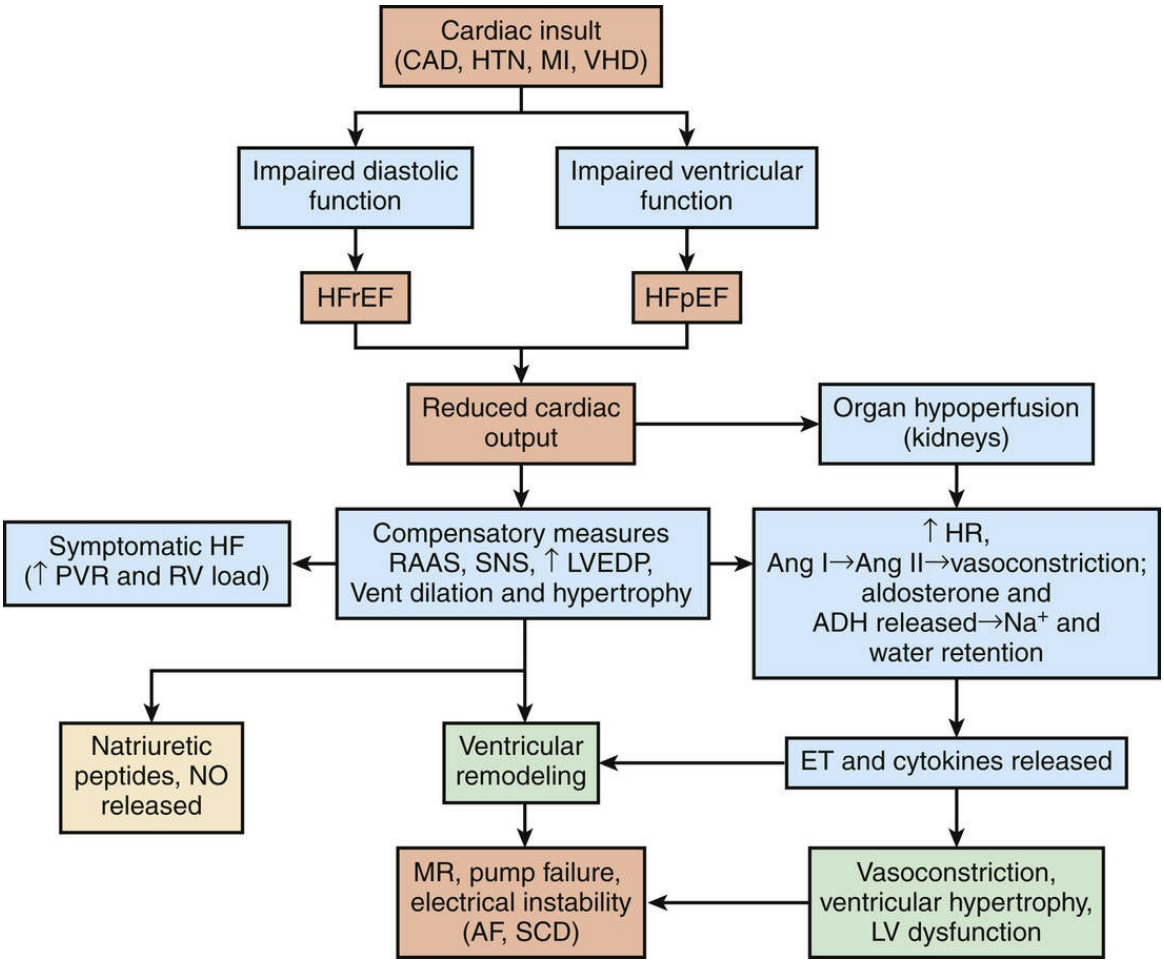

FIG. 34.1 Pathophysiology of HF. *Ang I,* Angiotensin I; *Ang II,* angiotensin II; *ADH,* Antidiuretic hormone; *ET,* endothelin; *HFpEF,* HF with preserved ejection fraction; *HFrEF,* HF with reduced ejection fraction; *LVEDP,* left ventricular end-diastolic pressure; *MR,* mitral regurgitation; *NO,* nitric oxide; *PVR,* pulmonary vascular resistance; *RAAS,* renin-angiotensin-aldosterone system; *SCD,* sudden cardiac death; *SNS,* sympathetic nervous system; *VHD,* valvular heart disease.

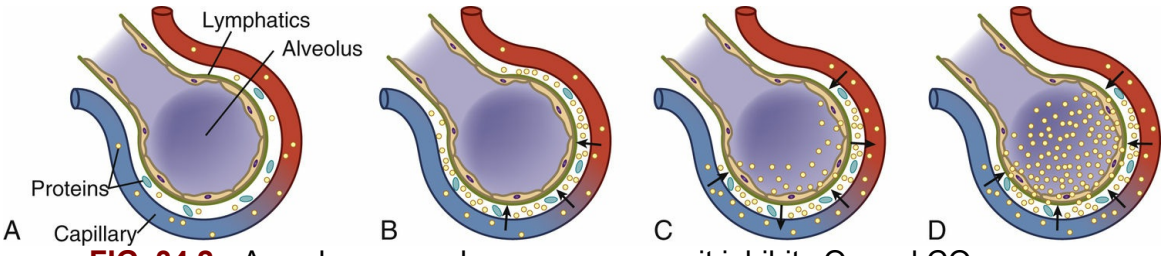

FIG. 34.2 As pulmonary edema progresses, it inhibits O_2 and CO_2 exchange at the alveolar-capillary interface. **A,** Normal relationship. **B,** Increased pulmonary capillary hydrostatic pressure causes fluid to

move from the vascular space into the pulmonary interstitial space. **C,** Lymphatic flow increases to try to pull fluid back into the vascular or lymphatic space. **D,** Failure of lymphatic flow and worsening of left-sided HF result in further movement of fluid into the interstitial space and into the alveoli.
Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: Diagnosis and management,* ed 6, St Louis, 2010, Mosby.

Gender Differences

Heart Failure

Men

- Have HFrEF more often than women.
- Ischemic heart disease (MI, CAD) is the most common cause of HF in men.
- ACE inhibitor therapy reduces mortality more in asymptomatic HFrEF for men than women.

Women

- Underrepresented in major clinical trials about CVD making gender comparison conclusions difficult.
- Have HFpEF more often than men.
- HTN is the most common cause of HF in women.
- Women with HF tend to be older as compared to men.
- Higher risk of ACE inhibitor–related cough than men.[4]

Borderline HFpEF describes HF patients with LVEF 41% to 49%. Characteristics and therapies are like those for patients with HFpEF.[1] The patient with ventricular failure of any type may have low BP, low CO, and poor renal perfusion. Poor exercise tolerance and heart

dysrhythmias are common. The patient may arrive at this point acutely from an MI or chronically from worsening cardiomyopathy or HTN. In both acute and chronic causes of HF, the body's response to low CO is to mobilize its compensatory mechanisms to maintain CO and BP.[3]

Right-Sided Heart Failure

Right-sided HF occurs when the right ventricle (RV) does not pump effectively. When the RV fails, fluid backs up into the venous system. This causes movement of fluid into the tissues and organs (e.g., peripheral edema, abdominal ascites, hepatomegaly, jugular venous distention [JVD]).

The most common cause of right-sided HF is left-sided HF. As the LV fails, fluid backs up into the pulmonary system, causing increased pressures in the lungs. The RV must work harder to push blood to the pulmonary system. Over time, this increased workload weakens the RV and gradually it fails. Other causes of right-sided HF (independent of the function of the LV) include RV infarction, pulmonary embolism, and *cor pulmonale* (RV dilation and hypertrophy caused by pulmonary disease) (see Chapter 27).

Biventricular Failure

Biventricular failure includes both LV and RV dysfunction, the inability of both ventricles to pump effectively. Because of decreased contractility, fluid build-up and systemic venous engorgement occur. Inadequate CO results in decreased perfusion to vital organs.[3]

Compensatory Mechanisms

HF can have an abrupt onset as with acute MI, or it can be a subtle process resulting from slow, progressive changes. The overloaded heart uses compensatory mechanisms to try to maintain adequate CO. The main compensatory mechanisms include (1) neurohormonal responses: renin-angiotensin-aldosterone system (RAAS) and the sympathetic nervous system (SNS); (2) ventricular dilation; and (3)

ventricular hypertrophy.

Neurohormonal Response

Renin-angiotensin-aldosterone system

The renin-angiotensin-aldosterone system (RAAS) is a regulatory system that works to maintain normal homeostasis. The goal of RAAS activation is augmentation of preload and ventricular contractility to maintain CO. RAAS activation promotes retention of fluid and sodium. The juxtaglomerular apparatus in the kidneys senses decreased renal perfusion from a falling CO. In response, the kidneys release renin, which converts angiotensinogen to angiotensin I (see Chapter 44 and Fig. 44.4). Angiotensin I is next converted to angiotensin II by a converting enzyme made in the lungs. Angiotensin II is a potent vasoconstrictor that stimulates renal water and sodium retention and the release of aldosterone from the adrenal gland. Aldosterone acts in the nephron to stimulate sodium retention and potassium excretion and promoting myocardial fibrosis in the failing heart.

Continuous activation of the RAAS and SNS in HF leads to increased levels of antidiuretic hormone (ADH). ADH regulates water retention by stimulating renal tubular reabsorption. It is released in response to arterial low pressure/under filling via baroreceptor signals. It causes vasoconstriction and increases BP and central venous pressure (CVP). The consequences are fluid congestion and hyponatremia.[7] Chronic activation of the RAAS can cause harmful effects, such as cardiac myocyte apoptosis (programmed cell death), hypertrophy, and fibrosis. These cause the burdensome signs and symptoms that develop with HF.[8]

Sympathetic nervous system

Baroreceptors sense low arterial pressure, stimulating the SNS to try to maintain CO. Catecholamines (epinephrine and norepinephrine) are released. Stimulation of β-adrenergic receptors increases HR *(chronotropy)* and ventricular contractility *(inotropy).* Ultimately,

chronic SNS stimulation increases myocardial O_2 demand on the already weakened heart.

Continuous activation of the neurohormonal responses (RAAS and SNS) in HF leads to high levels of ADH, endothelin, and proinflammatory cytokines. Together, these factors further increase in the heart's workload, intensify ventricular dysfunction, and force ventricular remodeling.[3,7]

Peptides and Cytokines

Endothelin, a vasoconstrictor peptide made by the vascular endothelial cells, is stimulated by hypoxia, ischemia, neurohormones, and inflammatory cytokines. Although endothelin stimulates contraction in most smooth muscles, it has the opposite effect on the heart, acting as a negative inotrope. This serves to decrease ventricular contractility in the failing heart.

Proinflammatory cytokines are released by myocytes in response to heart injury (e.g., MI, HF). Two cytokines, tumor necrosis factor (TNF) and interleukin-1 (IL-1), further depress heart function by exerting a negative inotropic effect, causing myocyte hypertrophy and apoptosis. Over time, a systemic inflammatory response also occurs.[9] High levels of endothelin and proinflammatory cytokines result in an increase in the heart's workload, progressive LV dysfunction, myocyte hypertrophy, and *ventricular remodeling*.[3,8]

Ventricular Adaptations

Dilation

Dilation is an enlargement of the heart chambers (Fig. 34.3, *A*). It occurs when pressure in the heart chambers (usually the LV) is elevated over time. The heart muscle fibers stretch in response to the volume of blood in the heart at the end of diastole. According to the *Frank-Starling Law,* the strength of the heart's contraction is directly proportional to its diastolic expansion. The implication is that increased preload (a greater influx of blood into the ventricle during

diastole) will cause a more forceful contraction. This increased contraction initially leads to increased CO and maintains BP and perfusion. Dilation starts as an adaptive mechanism to cope with increasing blood volume. However, excessive preload exhausts the Frank-Starling mechanism, cardiac muscle fibers are overstretched, and further increases in preload no longer increase CO.

Hypertrophy

Hypertrophy is an adaptive increase in the muscle mass and heart wall thickness as a slow response to overwork and strain (Fig. 34.3, *B*). It occurs slowly because it takes time for this increased muscle tissue to develop. Initially, the increased contractile power of the muscle fibers leads to an increase in CO and maintains tissue perfusion. Over time, hypertrophic heart muscle has poor contractility, needs more O_2 to perform work, has poor coronary artery circulation (tissue becomes ischemic more easily), and is prone to dysrhythmias.

Remodeling

Pathologic ventricular *remodeling* is an actual change in the structure (dimensions, mass, shape) of the heart. Ventricular remodeling in HF occurs over time in response to pressure or volume overload and/or cardiac injury and the subsequent compensatory mechanisms. These include neurohormonal, ET, and cytokine activation and ventricular adaptations, including dilatation and hypertrophy. This altered shape of the ventricles eventually leads to increased ventricular mass, increased wall tension, increased O_2 consumption, and impaired contractility. The actual shape of the heart becomes less elliptical and more spherical. Although the ventricles become larger, they become less effective pumps. The LVEF further declines due to loss of mechanical advantage from altered ventricular geometry. Increases in angiotensin II, aldosterone, and cytokines stimulate collagen synthesis leading to fibrosis and further impaired pumping ability.[10] Ventricular remodeling is a risk factor for life-threatening dysrhythmias and sudden cardiac death (SCD). Drug therapies to

prevent or reverse remodeling and decrease mortality are recommended. These include ACE inhibitors, β-adrenergic blockers (β-blockers), and aldosterone antagonists.

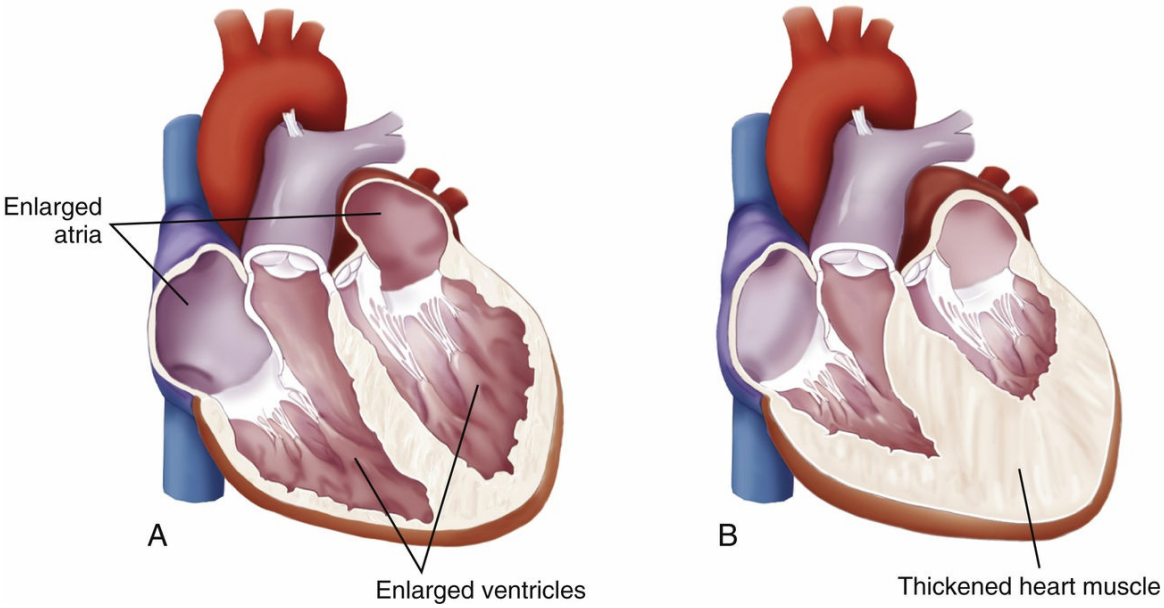

FIG. 34.3 **A,** Dilated heart chambers. **B,** Hypertrophied heart chambers.

Beneficial Counterregulatory Mechanisms

The body tries to maintain balance through several beneficial counterregulatory processes. Natriuretic peptides (atrial natriuretic peptide [ANP] and brain [b-type] natriuretic peptide [BNP]) are hormones made by the heart muscle. ANP is released from the atria and BNP is released from the ventricles in response to increased blood volume and ventricular wall stretching.[11]

The natriuretic peptides have beneficial renal, cardiovascular, and hormonal effects. Renal effects include: (1) increased glomerular filtration rate and diuresis and (2) excretion of sodium (natriuresis). Cardiovascular effects include vasodilation and decreased BP. Hormonal effects include (1) inhibition of aldosterone and renin secretion and (2) interference with ADH release. The combined effects

of ANP and BNP help to counter the adverse effects of the SNS and RAAS.[11] We can measure serum BNP levels. High serum BNP corresponds proportionately with fluid retention and is a predictor of mortality in HF.

Nitric oxide (NO) and prostaglandin are counterregulatory substances released from the vascular endothelium in response to the compensatory mechanisms activated in HF. NO and prostaglandin work to relax the arterial smooth muscle, resulting in vasodilation and decreased afterload.[10]

Compensated HF occurs when compensatory mechanisms succeed in maintaining an adequate CO that is needed for tissue perfusion. *Decompensated HF* occurs when these mechanisms can no longer maintain adequate CO and inadequate tissue perfusion results.

Classifications of Heart Failure

New York Heart Association Classes of Heart Failure

The New York Heart Association (NYHA) Functional Classification places patients in 1 of 4 categories (I–IV) based on physical activity limitation due to symptom burden.[1] NYHA class designation changes based on worsening or improving symptoms.

The Stages of Heart Failure

The American College of Cardiology Foundation and the American Heart Association (ACCF/AHA) more recently developed a staging system (A–D) that emphasizes the evolution and progression of HF as well as treatment strategies.[1] This system identifies people at risk for developing HF who do not currently have heart disease (stage A). This classification encourages clinicians to actively address the patient's risk factors and treat any existing conditions to prevent further disease progression. This staging system is progressive and unidirectional. Patients advance to a higher (worse) stage as the disease progresses. Table 34.3 compares the NYHA classification and ACC/AHA staging system.

Clinical Manifestations: Acute Decompensated Heart Failure

Acute decompensated heart failure (ADHF) is an increase (usually sudden) in symptoms of HF with a decrease in functional status, often requiring rapid escalation of therapy and hospital admission. ADHF is the most common cause of hospitalization for older Americans.[12] The presentation of ADHF typically includes symptoms and signs related to pulmonary congestion and volume overload. Neurohormonal activation leads to impaired regulation of sodium excretion through the kidneys that results in sodium and fluid accumulation. The lungs become less compliant. There is increased resistance in the small airways. To help compensate, the lymphatic system increases its flow to help maintain a constant volume of the pulmonary extravascular fluid (Fig. 34.1, *A* and *B*). This early stage is clinically associated with a mild increase in the respiratory rate (RR) and a decrease in partial pressure of O_2 in arterial blood (PaO_2).

If pulmonary venous pressure continues to increase, the increase in intravascular pressure causes more fluid to move into the interstitial space than the lymphatics can remove resulting in *interstitial edema* (Fig. 34.1, *C*). Tachypnea develops, and the patient becomes symptomatic (e.g., short of breath). If the pulmonary venous pressure increases further, the alveoli lining cells are disrupted, and fluid moves into the alveoli *(alveolar edema).* This is accompanied by a worsening of the arterial blood gas values (i.e., lower PaO_2, increased $PaCO_2$, progressive respiratory acidosis).

TABLE 34.3 Comparison of ACCF/AHA Stages of Heart Failure and NYHA Functional Classifications

ACCF/AHA Stages of Heart Failure (HF)		NYHA Functional Classifications	
A	At high risk for HF, but without structural heart disease or symptoms of HF	None	
B	Structural heart disease, but without signs or symptoms of HF	I	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF.
C	Structural heart disease with prior or current symptoms of HF	I	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF.
		II	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in symptoms of HF.
		III	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes symptoms of HF.
		IV	Unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest
D	Refractory HF requiring specialized interventions	IV	Unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest

ADHF can manifest as **pulmonary edema**. This is an acute, life-threatening situation, in which the lung alveoli become filled with serosanguineous fluid (Fig. 34.1, *D*). The most common cause of pulmonary edema is left-sided HF. Other causes of pulmonary edema are listed in Table 27.24.

Manifestations of pulmonary edema include acute manifestations of left HF, such as dyspnea, *orthopnea*, and *paroxysmal nocturnal dyspnea*. JVD is often present and is the most sensitive and specific sign for elevated LV filling pressures. Coughing may provide an early clue to developing pulmonary edema in patients with chronic HF. The patient is usually anxious and pale and may be cyanotic. The RR is often > 30 breaths per minute. You may see use of accessory respiratory muscles. Pink, frothy sputum may be present in patients with severe disease. Auscultation of the lungs may reveal crackles and wheezes throughout. The absence of crackles does not rule out ADHF as many patients with a history of chronic HF develop increased lymphatic drainage of the alveolar edema. The patient's HR is often rapid, and an abnormal S_3 or S_4 heart sound may be heard (Table 31.4). BP may be high or decreased depending on the severity of the HF. Hypotension indicates severe LV systolic dysfunction and the chance of cardiogenic shock. Cool extremities occur with low CO and poor perfusion. Skin pallor or mottling may be present. They result

from peripheral vasoconstriction and shunting of blood to the central circulation. Sometimes, hoarseness may be present because of compression of the recurrent laryngeal nerve from an enlarged LA (Ortner sign).

TABLE 34.4 Clinical Profile in Acute Decompensated Heart Failure

LOW PERFUSION (COLD)	CONGESTION (WET)	
No	No	Yes
	Dry-Warm	Wet-Warm
	• **PAWP normal** • **CO normal** • **Signs and symptoms: none**	• PAWP ↑ • CO normal • Signs and symptoms: dyspnea, edema, orthopnea
Yes	Dry-Cold	Wet-Cold
	• **PAWP ↓ or normal** • **CO ↓** • **Signs and symptoms: edema, hypotension, cool extremities**	• PAWP ↑ • CO ↓ • Signs and symptoms: altered mental status, decreased O_2 saturation, reduced urine output, shock

PAWP, Pulmonary artery wedge pressure.

Patients with ADHF are categorized into 1 of 4 groups based on hemodynamic and clinical status: dry-warm, dry-cold, wet-warm, and wet-cold (Table 34.4).[1] The most common presentation in patients with ADHF is the wet and warm patient. A patient is "wet" due to volume overload (e.g., congestion, dyspnea) but "warm" due to adequate perfusion (warm skin, positive pulses).

Check Your Practice

You are assigned to a patient with ADHF who was admitted to the HF unit. Your assessment reveals that the patient has bilateral crackles in the mid-lower lung fields and dyspnea on exertion (e.g., moving from the bed to the commode). The patient's skin is warm, and pulses are present in all extremities. Your preceptor asks you to

categorize your patient based on the classification systems in Tables 34.3 and 34.4.

- In what NYHA class would you place your patient?
- In what ACCF/AHA stage would you place your patient?
- What ADHF clinical profile does your patient best fit?

Clinical Manifestations: Chronic Heart Failure

Chronic HF is a progressive syndrome characterized by reduced CO and increased venous pressure, associated with underlying molecular changes that result in the death of cardiac muscle cells. The compensatory mechanisms in response to this reduced CO include neurohormonal and hemodynamic reactions to maintain major organ perfusion through vasoconstriction and SNS stimulation, an inflammatory response involving cytokines, and ventricular remodeling. These physiologic responses are responsible for the manifestations of chronic HF. Many therapies for chronic HF work by counteracting these mechanisms. Table 34.5 lists the manifestations of right-sided and left-sided chronic HF.

Fatigue

Fatigue following usual daily activities can be an early symptom of chronic HF. As the falling CO cannot sustain activities, fatigue eventually limits activities. Anemia, common in HF, is another potential cause of fatigue.

TABLE 34.5 Manifestations of Heart Failure

Right-Sided Heart Failure	Left-Sided Heart Failure
Signs	
• **Right ventricular heaves** • ↑ HR • **Murmurs** • **Jugular venous distention** • **Edema (e.g., pedal, scrotum, sacrum)** • **Weight gain** • **Ascites** • **Anasarca (massive generalized body edema)** • **Hepatomegaly (liver enlargement)**	• Left ventricular heaves • ↑ HR • Pulsus alternans (alternating pulses: strong, weak) • PMI displaced inferiorly and left of the midclavicular line (LV hypertrophy) • ↓ PaO_2, slight ↑ $PaCO_2$ (poor O_2 exchange) • Crackles (pulmonary edema) • S_3 and S_4 heart sounds • Pleural effusion • Changes in mental status • Restlessness, confusion • Shallow respirations up to 32–40/min • Dry, hacking cough • Frothy, pink-tinged sputum (advanced pulmonary edema)
Symptoms	
• **Fatigue** • **Anxiety, depression** • **Right upper quadrant pain** • **Anorexia and GI bloating** • **Nausea**	• Weakness, fatigue • Anxiety, depression • Dyspnea • Paroxysmal nocturnal dyspnea • Orthopnea • Nocturia

$PaCO_2$, Partial pressure of CO_2 in arterial blood; *PaO_2,* partial pressure of O_2 in arterial blood; *PMI,* point of maximal impulse.

Dyspnea

Dyspnea is the most common manifestation of chronic HF. It is caused by increased pulmonary pressures from interstitial and alveolar edema. Dyspnea can occur early in the HF disease process with mild exertion. As HF progresses, dyspnea develops with less exertion until dyspnea occurs at rest.

Orthopnea, or dyspnea in the recumbent position, suggests HF. Orthopnea occurs due to redistribution of fluid from the lower extremities into the lungs while in a supine position. The dyspnea is usually relieved with sitting up. Asking the patient about the number of pillows used under the head while sleeping or about sleeping in a recliner can reveal adaptive behaviors that aid breathing.

Paroxysmal nocturnal dyspnea (PND) is episodic, sudden dyspnea that wakes a patient at night. PND is caused by fluid accumulation in the lungs entering the alveoli while the patient is supine. The patient can awaken in a panic with feelings of suffocation and a strong desire to sit or stand to aid breathing.

Cough

A chronic, nonproductive cough that is worse in the recumbent position is often associated with pulmonary congestion and can be a sign of HF. Other potential causes of cough include gastric conditions, medications (e.g., ACE inhibitors due to increased bradykinin levels), and pulmonary conditions.

Tachycardia

Tachycardia is an early sign of HF. One of the body's first responses to compensate for a reduced CO is to increase the HR via activation of the SNS. At first, this compensatory response has a favorable effect on CO. But over time, persistent tachycardia is harmful and may worsen HF and the accompanying manifestations. Adequate HR control in patients with chronic HF has been associated with better clinical outcomes, including decreased hospitalizations and mortality.[1]

Palpitations

Palpitations, or an irregular heartbeat, can occur due to dysrhythmias that occur with chronic HF. Atrial fibrillation (AF) is the most common of these dysrhythmias. Patients may report a fast or irregular heartbeat, a fluttering sensation, or "skipped beats" that may be intermittent. Palpitations may be accompanied by dyspnea, lightheadedness, or near syncope if the dysrhythmia further decreases CO.

Edema

Edema is a common sign of HF. It may occur in dependent body areas (peripheral edema), liver (hepatomegaly), abdominal cavity (ascites), and lungs (pulmonary edema and pleural effusion). If the patient is in bed, dependent sacral and scrotal edema may develop. Pressing the edematous skin with the finger may leave a depression *(pitting edema).* Accumulation of extravascular fluid in the lower extremities can indicate volume overload and be a sign of ADHF. It is important to note that not all lower extremity edema is a result of HF. Hypoproteinemia, renal insufficiency, cellulitis, venous stasis,

cirrhosis, and certain drugs can cause peripheral edema.

Changes in Urine Output

Urine output may be decreased because of decreased renal perfusion. HF patients often develop resistance to diuretics, which can result in a drop in urinary output. *Nocturia* is the tendency to urinate excessively during the night due to increased renal perfusion in the supine position.

Skin Changes

A low CO can result in decreased perfusion to the skin of the extremities resulting in *mottling,* a blue or gray coloring. A coolness or clammy feeling to touch can occur with poor perfusion. Because tissue capillary O_2 extraction is increased with chronic HF, the skin may appear dusky. Chronic edema can result in pigment changes. The skin can become dry from overdiuresis. It is important to recognize integumentary signs of other conditions, such as venous stasis, peripheral arterial disease, and cellulitis.

Neurologic Manifestations

Dizziness, lightheadedness, near syncope, or syncope can occur due to reduced CO and hypoperfusion to the brain or dysrhythmias that often occur with chronic HF. Hypotension secondary to HF medications and hypovolemia are common causes of neurologic symptoms in chronic HF.

Mental Status and Behavioral Changes

Cerebral hypoperfusion may occur because of hypoxia to the brain from decreased CO. The patient or caregiver may report confusion, forgetfulness, inattentiveness, and restlessness. A thorough assessment is needed to evaluate for possible confounding conditions, including psychologic disorders (especially depression and anxiety) or neurologic disorders, such as stroke or transient ischemic attack (TIA). Around 1 in 5 patients with HF have clinical depression, which

confers a twofold risk of mortality and higher readmission rates.[13] Patients with psychologic disorders have poorer adherence to treatment plans. All HF patients should be screened for depression or coexisting mental health conditions.

Sleep Problems

Snoring and daytime sleepiness can indicate sleep apnea, a common confounding condition with chronic HF. Sleep apnea screening questions include those about daytime sleepiness and falling asleep, feeling rested in the morning, frequent nighttime awakenings, and history and results of a sleep study. Alternatively, insomnia could be due to psychologic issues, including anxiety or depression, or due to excessive daytime napping. The need to void often with nocturia may disturb the patient's rest.

Chest Pain

Chest pain or angina can be the result of the reduced CO associated with HF compounded with CAD. Chest pain in HF can also occur due to myocardial stretch from volume overload. Careful questioning and assessment will help distinguish among the many potential causes for chest pain in the patient with chronic HF.

Weight Changes

Many factors contribute to weight changes. Progressive weight gain in the patient with chronic HF may indicate fluid retention. Renal failure may contribute to fluid retention. Abdominal fullness from ascites and hepatomegaly often causes anorexia and nausea. As HF advances, the patient may have cardiac *cachexia* with muscle wasting and fat loss. This can be masked by the patient's edematous condition and may not be evident until the edema subsides.

Complications of Heart Failure

Pleural Effusion

Pleural effusion, fluid between the 2 tissue layers (pleura) that cover the lung and line the chest wall, is a common complication in HF. Increased capillary hydrostatic pressure in the systemic or pulmonary circulation from HF causes fluid leakage into the pleural space. Pleural effusions may result in symptoms of dyspnea, cough, and chest pain. Pleural effusion is discussed in Chapter 27.

Dysrhythmias and Dyssynchronous Contraction

Both atrial and ventricular dysrhythmias are common in HF. Structural changes, including myocardial stretch, fibrosis, and chamber dilatation, alter the electrical paths of the heart. Early and delayed depolarizations, both common in HF, can trigger dysrhythmias. AF is quite common in patients with HF, and the prevalence increases as the severity of HF increases. AF occurs when numerous sites in the atria fire spontaneously and rapidly, and organized atrial depolarization (contraction) no longer occurs. Loss of "atrial kick" during systole may contribute to decreased CO and worsening HF symptoms.

AF promotes thrombus formation within the atria. Thrombi can break loose and form emboli, placing patients at significant risk for stroke. Treatment with anticoagulation should be a priority if there are no significant contraindications. Treatment with drugs to achieve HR control is important. Restoring normal sinus rhythm with cardioversion and ablation may be considered. Atrial fibrillation is discussed in Chapter 35.

An enlarged LV and very low LVEF also increase the risk for thrombus formation in the LV. Anticoagulant therapy may be considered for patients with these problems.

Patients with HF are at risk for dangerous ventricular dysrhythmias (e.g., ventricular tachycardia [VT], ventricular fibrillation [VF]). SCD (sudden loss of cardiac function due to a fatal ventricular tachyarrhythmia), is a major cause of death in the HF population. Patients with HFrEF are at greatest risk for SCD. Guidelines recommend implantation of a prophylactic implantable cardioverter-defibrillator (ICD) for patients with an LVEF < 35%, who are NYHA

Class II or III.[1] SCD is discussed in Chapter 33. Dysrhythmias are discussed in Chapter 35.

Ventricular remodeling can lead to dyssynchrony in ventricular contractions. One ventricle may contract prior to the other ventricle, leading to suboptimal ventricular filling (preload), reduced force of ventricular contraction (systole), and severe mitral regurgitation (MR). This worsens HF symptoms. **Cardiac resynchronization therapy (CRT)** in the form of implantable cardiac devices can significantly improve morbidity and mortality for these patients. Many HF patients receive a combination ICD and CRT device, discussed later in the chapter.

Hepatomegaly

HF can lead to severe hepatomegaly. The liver becomes congested with venous blood from right HF or ADHF. The hepatic congestion can lead to impaired liver function. Eventually liver cells die, fibrosis occurs, and cirrhosis can develop (see Chapter 43).

Cardiorenal Syndrome

Reduction in CO results in decreased renal perfusion, decreased glomerular filtration rate, and increased serum creatinine. Neurohormonal activation causes sodium and water retention, worsening HF symptoms and renal function. Impaired renal function with HF is an independent risk factor for HF morbidity and mortality.

Anemia

The primary cause of anemia in chronic HF is chronic kidney insufficiency due to the renal vasoconstriction that often occurs with HF. This vasoconstriction results in reduced erythropoietin production in the kidney, leading to anemia. Excessive cytokine production also can reduce erythropoietin secretion. The anemia itself can worsen cardiac function due to increased cardiac workload through tachycardia, fluid retention, and increased SV. Because anemia can reduce renal blood flow, it adds further stress to the heart

and worsens fatigue and other manifestations of chronic HF.

Diagnostic Studies

Diagnosing HF can be challenging. Signs and symptoms are not highly specific and may mimic many other medical conditions (e.g., anemia, lung disease). Diagnostic tests for ADHF and chronic HF are outlined in Table 34.6. A primary goal in diagnosis is to find the underlying cause of HF.

An echocardiogram is a valuable, noninvasive diagnostic tool used in patients with HF. The echocardiogram gives information about chamber size and function, LVEF, heart valve function, wall thickness and motion, presence of effusion or thrombus, and intracardiac and pulmonary pressures. This test helps to distinguish between HFrEF and HFpEF. Other useful tests include 12-lead ECG, ambulatory heart monitors, chest x-ray, 6-minute walk test, multigated acquisition (MUGA) scan, cardiopulmonary exercise stress test, cardiac MRI, and cardiac catheterization/angiogram. Polysomnography studies for obstructive sleep apnea may be done. An endomyocardial biopsy may be done as part of a heart catheterization to evaluate for infective or infiltrative disease in acutely ill patients who develop unexplained, new-onset HF unresponsive to usual care.

Laboratory studies aid in the diagnosis of HF. In general, BNP and N-terminal prohormone of BNP (NT-proBNP) levels correlate positively with the degree of LV failure.[11] Levels are temporarily higher in patients receiving nesiritide (Natrecor) and may be high in patients with chronic, stable HF. So, it is important you know the baseline levels. Increases in BNP or NT-proBNP levels can be caused by conditions other than HF, including pulmonary embolism, renal failure, and acute coronary syndrome.

Interprofessional Care: Acute Decompensated Heart Failure

Mortality and readmission rates for ADHF remain unacceptably high.

Professional HF organizations have developed quality improvement initiatives, such as "Get with the Guidelines" and the Acute Decompensated HF Registry (ADHERE), to help clinicians and agencies improve HF outcomes.[1]

Goals of therapy for the patient hospitalized with ADHF include (1) symptom relief; (2) optimizing volume status; (3) supporting oxygenation, ventilation, CO, and end organ perfusion; (4) identifying and addressing the cause of the ADHF; (5) avoiding complications; (6) providing patient teaching addressing factors that precipitated HF exacerbation; and (7) discharge planning.

TABLE 34.6 Interprofessional CareHeart Failure

Both ADHF and Chronic HF	ADHF	Chronic HF
Diagnostic Assessment		
• History and physical examination • Determine underlying cause • Serum chemistries, cardiac biomarkers, BNP or NT-proBNP level (see Table 31.6), liver function tests, thyroid function tests, CBC, lipid profile, kidney function tests, urinalysis • Chest x-ray • 12-lead ECG • 2-dimensional echocardiogram (see Table 31.7) • Nuclear imaging studies (see Table 31.7) • Cardiac catheterization (see Table 31.8)	• Measure LV function • Hemodynamic monitoring • Endomyocardial biopsy in select patients	• Cardiopulmonary exercise stress test • 6-minute walk test • Sleep studies in select patients
Management		
• Treatment of underlying cause • Drug therapy (Table 34.7) • Circulatory assist devices (e.g., ventricular assist device) • Daily weights • Sodium- and possibly fluid-restricted diet • O_2 by mask or nasal cannula if indicated	• High-Fowler's position • Noninvasive positive pressure ventilation • Circulatory assist device: intraaortic balloon pump • Endotracheal intubation and mechanical ventilation • Vital signs, urine output at least q1hr until stable • Continuous ECG and pulse oximetry monitoring • Hemodynamic monitoring (e.g., intraarterial BP, PAWP, CO) • Cardioversion (e.g., atrial fibrillation) • Ultrafiltration	• Cardiac resynchronization therapy with biventricular pacing and internal cardioverter-defibrillator • Heart transplantation • Rest-activity periods • Dietitian consult • Physical/occupational therapy consult • Cardiac rehabilitation • Home health nursing care (e.g., telehealth monitoring) • Palliative and end-of-life care

BNP, b-type natriuretic peptide; *LVAD,* left ventricular assist

device; *NT-proBNP,* N-terminal prohormone of BNP; *PAWP,* pulmonary artery wedge pressure.

Patients with ADHF need ongoing monitoring and assessment of vital signs, O_2 saturation, weight, mentation, ECGs, and indicators of volume overload and decreased organ perfusion. Assessment findings indicating fluid volume overload include edema, ascites, JVD, a positive hepatojugular reflux test, an S_3 heart sound, crackles, hypoxia, and worsening renal function.

Stable patients with ADHF may be treated in the emergency department (ED) or admitted to a telemetry unit. Assess these patients every 4 hours (e.g., vital signs, pulse oximetry) for adequate oxygenation. Record intake, output, and daily weights to evaluate fluid status. If the patient has dyspnea, place in a high-Fowler's position with the feet horizontal in the bed or dangling at the bedside. This position helps decrease venous return because of the pooling of blood in the extremities. This position also increases the thoracic capacity, allowing for improved breathing.

If unstable, these patients are managed in an intensive care unit (ICU). In addition to continual ECG and O_2 saturation monitoring, vital signs and urine output are assessed at least hourly. Indicators of decreased perfusion include hypotension, decreased urine output, cool extremities, altered mentation, heart murmur, dysrhythmias, and worsening renal and liver function tests. The patient may have hemodynamic monitoring, including arterial BP and pulmonary artery pressures. If a pulmonary artery (PA) catheter is placed, CO and pulmonary artery wedge pressure (PAWP) are routinely monitored. PAWP is an indirect measurement of LA filling pressure measured from the tip of the PA catheter when inflated in a capillary artery. A normal PAWP is 6 to 15 mm Hg. Patients with ADHF may have a PAWP as high as 30 mm Hg. Therapies are adjusted to maximize CO and reduce PAWP. Hemodynamic monitoring is discussed in Chapter 65.

Supplemental O_2 is provided to help increase the PaO_2. O_2 therapy is discussed in Chapter 28. In severe pulmonary edema, the patient

may need noninvasive positive pressure ventilation (e.g., bilevel positive airway pressure [BiPAP]) or intubation and mechanical ventilation. BiPAP also decreases preload. Ventilatory support is discussed in Chapter 65.

Nonpharmacologic Therapies

Ultrafiltration, or *aquapheresis,* is an option for the patient with volume overload when diuretics have not been effective.[1] It can rapidly remove intravascular fluid volume and excess sodium from the patient's blood while maintaining hemodynamic stability. Hemodialysis can be used for volume overload with concomitant renal failure. They are discussed in Chapter 46.

Implantation of CRT, a biventricular pacemaker, may be considered for patients with ADHF who meet specific criteria and do not respond to more traditional therapies.

In the ICU, *mechanical cardiac assist devices* are used temporarily to manage patients with worsening HF. The intraaortic balloon pump (IABP) is a device that increases coronary blood flow to the heart muscle and decreases the heart's workload through a process called *counterpulsation*. The IABP is useful in hemodynamically unstable patients because it can decrease pulmonary artery pressures and systemic vascular resistance (SVR), leading to improved CO. Ventricular assist devices (VADs) can help maintain the pumping action of a weakened heart. A VAD is a surgically implanted mechanical pump. IABPs and VADs are discussed in Chapter 65.

Drug Therapy

Drug therapy is essential in treating ADHF (Table 34.7).

TABLE 34.7 Drug TherapyHeart Failure

Drug	Mechanism of Action
Anticoagulants (see Table 37.10)	
	• Prevent thromboembolism • Recommended for patients with an ejection fraction <20% and/or atrial fibrillation
Antidysrhythmic Drugs (see Table 35.9)	
	• Prevent or treat dysrhythmias
β-Adrenergic Blockers (see Table 32.6)	
bisoprolol (Zebeta) **carvedilol (Coreg)** **metoprolol succinate (Toprol XL)**	• Promote reverse remodeling • Decrease afterload • Inhibit SNS • Reverse cardiac remodeling • Reduce mortality and morbidity in patients with chronic HF
Diuretics (see Table 32.7)	
Loop Diuretics **bumetanide (Bumex)** **furosemide (Lasix)**	• Block absorption of sodium and chloride in the kidneys at the loop of Henle • Increase urine output • Decrease fluid volume • Decrease preload • Decrease pulmonary venous pressure • Relieve symptoms of fluid congestion
Thiazide Diuretics **hydrochlorothiazide** **metolazone (Zaroxolyn)**	• Affect electrolyte reabsorption at the distal renal tubule resulting in sodium and chloride excretion • Increased urine output (milder diuretic effect than loop diuretics) • Decrease blood pressure
Aldosterone Antagonists (Potassium-Sparing Diuretics)	
eplerenone (Inspra) **spironolactone (Aldactone)**	• Inhibit aldosterone that causes sodium and water retention and antiinflammatory responses in HF • Prevent potassium loss by inhibiting sodium and potassium exchange in the distal tubule • Mild diuretic effect • Reduce mortality and HF hospitalizations in patients with chronic HF
Morphine	
morphine (MS Contin, Duramorph, Embeda, Kadian)	• Binds to opioid receptors • May decrease the chemoreceptor response to hypoxia, and/or cause vasodilation reducing pulmonary congestion • Reduces anxiety
Neprilysin-Angiotensin Receptor Inhibitors	
sacubitril/valsartan (Entresto)	• Sacubitril inhibits neprilysin, decreasing natriuretic degradation which promotes diuresis, natriuresis • Valsartan selectively blocks angiotensin II receptors • Lower blood pressure • Dilate venules and arterioles • Improve renal blood flow • May decrease mortality and hospitalizations in patients with chronic HF
Positive Inotropes	
β-Adrenergic Agonists* **dobutamine** **dopamine**	• Increase contractility (positive inotropic effect) • Increase CO • May reduce PAWP • May cause dysrhythmias • Increase myocardial O_2 demand
Digitalis Glycoside **digoxin**	• Weak positive inotrope mostly at higher doses • Reduce effects of RAAS and SNS • May reduce HF symptoms and hospitalization if added to standard therapy for chronic HF
Phosphodiesterase Inhibitor* **milrinone**	• Produce mild vasodilation • Increase SV and CO • Promote vasodilation
Renin-Angiotensin-Aldosterone System Inhibitors (see Table 32.6)	
ACE Inhibitors **benazepril (Lotensin)** **captopril (Capoten)** **enalapril (Vasotec)** ***Angiotensin II Receptor Blockers*losartan (Cozaar)** **valsartan (Diovan)**	• Dilate venules and arterioles • Reduce afterload and SVR • Improve renal blood flow • May relieve HF symptoms • Promote reverse remodeling • May reduce morbidity, mortality, and HF hospitalizations in patients with chronic HF
Selective SA Node Inhibitor	

Drug	Mechanism of Action
ivabradine (Corlanor)	• Selectively inhibits the I *f*-current in the SA node • Decreases heart rate • May reduce CVD death and HF hospitalizations in patients with HFrEF in sinus rhythm with a HR ≥70 bpm • Used only for patients with chronic HF
Vasodilators	
isosorbide dinitrate/hydralazine (BiDil) **neseritide (Natrecor)*** **nitrates (e.g., nitroglycerin [Nitro-Bid], isosorbide dinitrate [Isordil])** **nitroprusside (Nitropress)***	• Reduce afterload • Dilate the arterioles of the kidneys, leading to increased renal perfusion and fluid loss • Decrease BP • Decrease preload • Neseritide may reduce PAWP • May relieve HF symptoms (e.g., dyspnea) • Isosorbide dinitrate/hydralazine, fixed dose, may reduce morbidity and mortality in blacks with HFrEF and NYHA Class III–IV symptoms

* Used for ADHF only.

Diuretics

Diuretics are the first line for treating patients with volume overload. They decrease sodium reabsorption at various sites within the kidneys, enhancing sodium and water loss. Decreasing intravascular volume with diuretics reduces volume returning to the LV (preload). This allows for more efficient LV pumping, decreased pulmonary vascular pressures, and improved alveolar gas exchange. IV administration of loop diuretics (e.g., furosemide) by bolus or infusion is preferred. We evaluate effectiveness by increased urine output, decreased symptoms, and fluid weight loss. Serum potassium and magnesium levels are continually monitored.

Vasodilators

Vasodilators are used to treat ADHF in the absence of hypotension. IV nitroglycerin (NTG) is a primary venodilator that reduces circulating blood volume. It also improves coronary artery blood flow by dilating the coronary arteries. So, NTG reduces preload, slightly reduces afterload (in high doses), and increases myocardial O_2 supply.

Tolerance often develops with continued IV use, requiring higher doses. When titrating IV NTG, monitor BP often (every 5 to 10 minutes) to avoid hypotension. Patients on IV vasodilators may have an indwelling arterial line or continuous noninvasive blood pressure monitoring.

Sodium nitroprusside (Nitropress) is a potent IV arterial vasodilator that reduces both preload and afterload, thus improving myocardial contraction, increasing CO, and reducing pulmonary congestion. Complications of therapy include hypotension and, at high doses, thiocyanate (cyanide) toxicity. It is given in an ICU.

Drug Alert

Sodium Nitroprusside (Nitropress)

- Record baseline BP and continuously monitor during administration.
- Arterial BP monitoring is recommended during drug infusion.
- Too rapid rate of IV infusion can reduce BP too quickly and cause hypotension.
- Headache, dizziness, nausea, agitation, and restlessness can occur.
- Monitor thiocyanate (drug by-product) levels if infusion is greater than 3 mcg/kg/min, as toxicity can occur.

IV nesiritide is a recombinant form of BNP used for short-term treatment of ADHF after a failed response to IV diuretics.[1] As a venous and arterial vasodilator, its main effects include a reduction in PAWP and decrease in dyspnea. Because the primary adverse effect is symptomatic hypotension, BP is carefully monitored.

Morphine

Morphine dilates pulmonary and systemic blood vessels, reducing preload and afterload. It is often given in small IV boluses for the dyspnea associated with ADHF. Cautious use and close monitoring are advised. Morphine has serious adverse effects, including respiratory depression, which can require mechanical ventilation.

Positive Inotropes

Inotropic drugs increase myocardial contractility and are used for patients with evidence of cardiogenic shock or with low CO. Drugs include β-agonists (e.g., dopamine, dobutamine, norepinephrine [Levophed]) and phosphodiesterase inhibitors (milrinone). β-Agonists are used as a short-term treatment of ADHF. In addition to increasing myocardial contractility and SVR, dopamine dilates the renal blood vessels and enhances urine output. Unlike dopamine, dobutamine is a selective β-agonist that works mainly on the β_1-receptors in the heart and does not increase SVR. Effectiveness of inotropes is evaluated by assessing for improved CO, BP, urine output, and reduced filling pressures.

Drug Alert

Dopamine

- Monitor IV site. Tissue necrosis and sloughing can occur with drug extravasation.
- High doses may produce ventricular dysrhythmias.

Milrinone has both inotropic and vasodilator properties. Milrinone improves myocardial contractility, increases CO, and reduces BP (decreases afterload). Like dopamine and dobutamine, this drug is available only for IV use. Adverse effects include dysrhythmias, thrombocytopenia, and hepatotoxicity.

Digitalis is a weaker positive inotrope that can be added if symptoms persist after other medications have been started. Digoxin can mildly increase contractility but also increases myocardial O_2 consumption. It can optimize heart rate, especially in those with atrial fibrillation. We monitor digoxin levels and make dose adjustments based on renal function. Serum potassium and magnesium levels must be maintained.

Current evidence recommends the use of inotropic therapy only for the short-term management of patients with ADHF who have not responded to conventional drug therapy (e.g., diuretics, vasodilators, morphine).[1] Continuous cardiac monitoring is necessary with all positive inotropic drugs as they can cause life-threatening dysrhythmias.

Safety Alert

Infusion Pumps

- To control the rate and assist with titration, use an infusion pump whenever you are giving IV vasodilators and inotropes.
- Ideally, pumps that have drug libraries can help to avoid rates and dosages that are out of the safe range for the drug.

Interprofessional Care: Chronic Heart Failure

The evolution of evidence-based medication and device therapies over the last few decades has dramatically improved the potential for better patient outcomes with chronic HF. The Heart Failure Society of America (HFSA) and the AHA have regularly published and updated guidelines on therapies for HF. Specialized inpatient, transitional, and ambulatory HF units have emerged. These units are staffed with interprofessional HF teams (Table 34.6).

Chronic HF therapies are tailored to the individual patient based on co-morbid conditions. The goals of chronic HF therapies include (1) optimal symptom management, (2) mortality and morbidity benefit, (3) minimizing side effects, and (4) monitoring responses to therapies. Specifically, these therapies treat the underlying cause and contributing factors, maximize CO, improve ventricular function, improve quality of life (QOL), and preserve target organ function.

In a person with HF, the blood may not be adequately oxygenated,

resulting in reduced O_2 saturation. The use of supplemental O_2 improves saturation and helps meet tissue O_2 needs. This helps to relieve patient dyspnea and fatigue. Ongoing pulse oximetry monitors the need for and effectiveness of O_2 therapy.

Physical and emotional rest allows the patient to conserve energy and decreases the need for more O_2. The degree of rest recommended depends on the severity of HF. A patient with severe HF may be on bed rest. A patient with mild to moderate HF can be ambulatory with restricted activity. Urge the patient to take part in prescribed activities, allowing for adequate recovery periods. A structured exercise program, such as cardiac rehabilitation, should be considered for all patients with chronic HF. These programs are associated with decreased hospitalizations, reduced mortality, improved QOL, and less depression.[1,14]

Drug Therapy

The cornerstone of drug therapy in chronic HF is neurohormonal blockade. The result of neurohormonal blockade is decreased plasma aldosterone levels, decreased SNS activity, vasodilation, and sodium and water excretion. Each class of evidence-based medications has been shown to decrease mortality and morbidity in patients with chronic HFrEF. Recommendations for HFpEF primarily address symptoms and co-morbid conditions. Drug therapy for chronic HF is outlined in Table 34.7.

Evidenced-Based Medications for HFrEF

ACE inhibitors

ACE inhibitors are first-line drugs for chronic HFrEF. They decrease mortality, morbidity, hospitalizations, and symptoms in patients with HFrEF.[1] ACE inhibitors block the RAAS by inhibiting the conversion of angiotensin I to angiotensin II. They reduce afterload and SVR and inhibit the development of ventricular remodeling by inhibiting ventricular hypertrophy.

Major side effects include symptomatic hypotension, intractable cough, hyperkalemia, angioedema (allergic reaction involving edema of the face and airways), and renal insufficiency (when used in high doses). Aging and renal insufficiency slow the metabolism of ACE inhibitors and may lead to increased serum drug levels. We monitor renal function and serum potassium levels. Examples of ACE inhibitors are listed in Table 34.7. More information about ACE inhibitors is found in Chapter 32.

Drug Alert

Captopril

- Severe hypotension and hyperkalemia may occur.
- Monitor patient for first-dose hypotension (first-dose syncope).
- Skipping doses or discontinuing the drug can result in rebound HTN.
- Angioedema, a rare adverse effect, can develop suddenly and be life-threatening.

Angiotensin II receptor blockers

For patients who are unable to tolerate ACE inhibitors, angiotensin II receptor blockers (ARBs) (see Table 32.6) are recommended.[1] They prevent the vasoconstrictor and aldosterone-secreting effects of angiotensin II by binding to the angiotensin II receptor sites. ARBs promote afterload reduction and vasodilation. The side effects are similar to those of ACE inhibitors except that ARBs do not typically cause a cough. Angioedema is less common. Monitoring is similar to that for ACE inhibitors.

Neprilysin-angiotensin receptor inhibitors

Sacubitril/valsartan (Entresto) is a combination of a neprilysin inhibitor (sacubitril) and an ARB (valsartan). This drug provides dual

blockade of the RAAS and the natriuretic peptide system. Sacubitril, a recombinant form of BNP, inhibits neprilysin, an enzyme that degrades natriuretic peptides. Sacubitril inhibition allows for more available circulating BNP. This results in decreased SVR, afterload, and CVP and increased natriuresis and diuresis. This drug is an alternative to ACE inhibitors and ARBs in patients meeting criteria with symptomatic HFrEF and reduces death and hospitalization. Patients are monitored for hypotension, renal insufficiency, and angioedema.[15]

Aldosterone antagonists

Spironolactone (Aldactone) and eplerenone (Inspra) are potassium-sparing diuretics that inhibit aldosterone activation. These drugs work by binding to receptors at the aldosterone-dependent sodium-potassium exchange site in the distal renal tubule, where they have a mild diuretic effect. They may prolong survival in patients with HFrEF.[1] It is critical to carefully monitor serum potassium levels and renal function in patients taking aldosterone antagonists.

Drug Alert

Spironolactone (Aldactone)

- Monitor potassium levels during treatment.
- Use with caution in patients taking digoxin, since hyperkalemia may reduce the effects of digoxin.
- Teach patient to avoid foods high in potassium (e.g., bananas, oranges).
- Assess male patients for gynecomastia, a common side effect of long-term use of spironolactone.

β-adrenergic blockers

β-Blockers directly block the negative effects of the SNS (e.g., increased HR) on the failing heart. Three β-blockers decrease mortality in patients with HFrEF: metoprolol succinate (Toprol XL), bisoprolol (Zebeta), and carvedilol (Coreg). These β-blockers may also increase LVEF. The improvement in LVEF is dose-related, so the highest tolerated dose should be given.[1] However, because β-blockers can reduce myocardial contractility, care must be taken in patients with volume overload. They are usually started at low dose, then the dosage is increased every 2 weeks as tolerated. Major side effects include worsening of HF symptoms, hypotension, fatigue, and bradycardia.

Drug Alert

Carvedilol (Coreg)

- Obtain standing BP 1 hr after dosing to assess tolerance.
- Overdose can cause profound bradycardia, hypotension, bronchospasm, and cardiogenic shock.
- Abrupt withdrawal may result in sweating, palpitations, and headaches.

Ivabradine (Corlanor)

Ivabradine selectively inhibits a particular sodium/potassium current in the SA node, resulting in a decreased HR. It can decrease hospitalizations in patients with HFrEF who are in sinus rhythm with an HR greater than 70 bpm and have symptoms despite optimal doses of other medications. Monitor patients for bradycardia and lightheadedness.[15]

Hydralazine/isosorbide dinitrate combination (Bidil)

This drug is a fixed combination of the vasodilator hydralazine and isosorbide dinitrate. It can significantly reduce mortality and improve

LVEF and exercise tolerance by reducing afterload through blood vessel vasodilation. The drug is specifically effective in blacks with HFrEF already receiving optimal doses of other evidence-based medications.[1] Although non-black patients do not see the same benefit, it may be used in any patient with HFrEF already on evidence-based medication. Major side effects include hypotension and headache. Like other nitrates, it should not be used with phosphodiesterase inhibitors, such as sildenafil (Viagra).

Digitalis

Digitalis (digoxin), a weak positive inotrope, acts primarily as a neurohormonal modulator that reduces the effects of the SNS and suppresses renin secretion from the kidneys. Low-dose digitalis decreases HF hospitalizations and symptoms in patients who are still symptomatic despite standard HF therapies.[1,12] No mortality benefit has been found. Better outcomes occur with digoxin serum levels of <0.9 ng/ml. Higher serum doses are associated with increased mortality rate and digoxin toxicity. Dose should be based on body mass, renal function, and concomitant medications. The usual maintenance dose in HF is 0.125 mg daily. Monitor renal function and serum potassium levels of all patients taking digitalis. Concerns about digoxin toxicity are abated by the subtherapeutic dosing in HF.

Medications for Symptom Management

Diuretics
