Notice
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

VOLUME ONE

SECTION ONE: Overview of Basic Science

0 Basic Principles of Dermatology 1
Whitney A High, Carlo Francesco Tomasini, Giuseppe Argenziano and Iris Zalaudek

1 Anatomy and Physiology 43
Travis W Vandergriff and Paul R Bergstresser

2 Skin Development and Maintenance 55
Maranke I Koster, Cynthia A Loomis, Tamara Koss and David Chu

3 Molecular Biology 65
Jonathan Vogel, Carole Yee and Thomas N Darling

4 Immunology 81
Thomas Schwarz

SECTION TWO: Pruritus

5 Cutaneous Neurophysiology 99
Gil Yosipovitch and Alexandru DP Papoiu

6 Pruritus and Dysesthesia 111
Elke Weisshaar, Alan B Fleischer Jr, Jeffrey D Bernhard and Thomas G Cropley

7 Psychocutaneous Diseases 127
Chai Sue Lee and John YM Koo

SECTION THREE: Papulosquamous and Eczematous Dermatoses

8 Psoriasis 135
Peter CM van de Kerkhof and Frank O Nestlé

9 Other Papulosquamous Disorders 157
Gary S Wood and George T Reizner

10 Erythroderma 171
Wolfram Sterry and Matthias Steinhoff

11 Lichen Planus and Lichenoid Dermatoses 183
Tetsuo Shiohara and Yoko Kano

12 Atopic Dermatitis 203
Thomas Bieber and Caroline Bussmann

13 Other Eczematous Eruptions 219
Norbert Reider and Peter O Fritsch

14 Allergic Contact Dermatitis 233
Christen M Mowad and James G Marks Jr

15 Irritant Contact Dermatitis 249
David E Cohen and Aieska de Souza

16 Occupational Dermatoses 261
S Mark Wilkinson

17 Dermatoses Due to Plants 273
Thomas W McGovern

SECTION FOUR: Urticarias, Erythemas and Purpuras

18 Urticaria and Angioedema 291
Clive EH Grattan

19 Figurate Erythemas 307
Agustín España

20 Erythema Multiforme, Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis 319
Lars E French and Christa Prins

21 Drug Reactions 335
Jean Revuz and Laurence Valeyrie-Allanore

22 Purpura: Mechanisms and Differential Diagnosis 357
Warren W Piette

23 Cutaneous Manifestations of Microvascular Occlusion Syndromes 369
Warren W Piette

24 Cutaneous Vasculitis 385
Kanade Shinkai and Lindy P Fox

25 Eosinophilic Dermatoses 411
Cloyce L Stetson and Kristin M Leiferman

26 Neutrophilic Dermatoses 423
Samuel L Moschella and Mark DP Davis

27 Pregnancy Dermatoses 439
Christina M Ambros-Rudolph and Jeff K Shornick

SECTION FIVE: Vesiculobullous Diseases

28 The Biology of the Basement Membrane Zone 449
Kim B Yancey

29 Pemphigus 461
Masayuki Amagai

30 Pemphigoid Group 475
Philippe Bernard and Luca Borradori

31 Dermatitis Herpetiformis and Linear IgA Bullous Dermatosis 491
Christopher M Hull and John J Zone

32 Epidermolysis Bullosa 501
Jo-David Fine and Jemima E Mellerio

33 Other Vesiculobullous Diseases 515
José M Mascaró Jr

34 Vesiculobullous and Erosive Diseases in the Newborn 523
Deborah S Goddard, Amy E Gilliam and Ilona J Frieden

SECTION SIX: Adnexal Diseases

35 Structure and Function of Eccrine, Apocrine and Sebaceous Glands 539
Martin Schaller and Gerd Plewig

36 Acne Vulgaris 545
Andrea L Zaenglein and Diane M Thiboutot

37 Rosacea and Related Disorders 561
Frank C Powell and Síona Ní Raghallaigh

38 Folliculitis and Other Follicular Disorders 571
Amy McMichael, Ashley R Curtis, Daniela Guzman-Sanchez and A Paul Kelly

39 Diseases of the Eccrine and Apocrine Sweat Glands 587
Jami L Miller

SECTION SEVEN: Rheumatologic Dermatology

40 Autoantibodies Encountered in Patients with Autoimmune Connective Tissue Diseases 603
Heidi T Jacobe, Richard D Sontheimer and Stephanie Saxton-Daniels

41 Lupus Erythematosus 615
Lela A Lee and Victoria P Werth

42 Dermatomyositis 631
Joseph L Jorizzo and Ruth Ann Vleugels

43 Systemic Sclerosis (Scleroderma) and Related Disorders 643
M Kari Connolly

44 Morphea and Lichen Sclerosus 657
Martin Röcken and Kamran Ghoreschi

45 Other Rheumatologic Diseases 671
Jennie T Clarke

SECTION EIGHT: Metabolic and Systemic Diseases

46 Mucinoses 687
Franco Rongioletti and Alfredo Rebora

47 Amyloidosis 699
Richard W Groves and Martin M Black

48 Deposition Diseases 709
Jennifer Quist, Sven Quist and Harald Gollnick

49 Porphyria 717
Jorge Frank and Pamela A Poblete-Gutiérrez

50 Calcifying and Ossifying Disorders of the Skin 729
Janet A Fairley

51 Nutritional Diseases 737
Stephanie McLeish Schaefer and Chad M Hivnor

52 Graft-versus-Host Disease 753
Edward W Cowen

53 Dermatologic Manifestations in Patients with Systemic Disease 761
Kathryn Schwarzenberger and Jeffrey P Callen

SECTION NINE: Genodermatoses

54 Basic Principles of Genetics 783
Maija Kiuru, Amalia Martinez-Mir and Angela M Christiano

55 Genetic Basis of Cutaneous Diseases 799
Vered Molho-Pessach and Julie V Schaffer

56 Biology of Keratinocytes 825
Meral J Arin, Dennis R Roop, Peter J Koch and Maranke I Koster

57 Ichthyoses, Erythrokeratodermas and Related Disorders 837
Gabriele Richard and Franziska Ringpfeil

58 Keratodermas 871
Alfons L Krol and Dawn Siegel

59 Darier Disease and Hailey-Hailey Disease 887
Daniel Hohl

60 Primary Immunodeficiencies 899
Julie V Schaffer and Amy S Paller

61 Neurofibromatosis and Tuberous Sclerosis 925
Hensin Tsao and Su Luo

62 Mosaicism and Linear Lesions 943
Celia Moss

63 Other Genodermatoses 963
Disorders Featuring Tumorigenesis 963
Susan J Bayliss and David R Berk
Enzyme Deficiency Diseases 970
Barbara K Burton
Premature Aging Syndromes and Poikilodermas 975
Bernard A Cohen
Ectodermal Dysplasias 982
Alanna F Bree and Virginia P Sybert

64 Developmental Anomalies 993
Richard Antaya and Julie V Schaffer

SECTION TEN: Pigmentary Disorders

65 Melanocyte Biology 1011
Jean L Bolognia and Seth J Orlow

66 Vitiligo and Other Disorders of Hypopigmentation 1023
Jean-Paul Ortonne and Thierry Passeron

67 Disorders of Hyperpigmentation 1049
Mary Wu Chang

SECTION ELEVEN: Hair, Nails and Mucous Membranes

68 Biology of Hair and Nails 1075
David de Berker, Claire A Higgins, Colin Jahoda and Angela M Christiano

69 Alopecias 1093
Leonard C Sperling, Rodney D Sinclair and Laila El Shabrawi-Caelen

70 Hypertrichosis and Hirsutism 1115
Francisco M Camacho-Martinez

71 Nail Disorders 1129
Antonella Tosti and Bianca Maria Piraccini

72 Oral Disease 1149
Carl M Allen and Charles Camisa

73 Anogenital (Non-venereal) Disease 1171
Susan M Cooper and Fenella Wojnarowska

VOLUME TWO

SECTION TWELVE: Infections, Infestations and Bites

74 Bacterial Diseases 1187
Christian R Millett, Analisa V Halpern, Annette C Reboli and Warren R Heymann

75 Myobacterial Infections 1221
Marcia Ramos-e-Silva and Maria Cristina Ribeiro de Castro

76 Rickettsial Diseases 1243
David H Walker

77 Fungal Diseases 1251
Boni E Elewski, Lauren C Hughey, Jenny O Sobera and Roderick Hay

78 Cutaneous Manifestations of HIV Infection 1285
Armin Rieger, T Minsue Chen and Clay J Cockerell

79 Human Papillomaviruses 1303
Reinhard Kirnbauer and Petra Lenz

80 Human Herpesviruses 1321
Natalia Mendoza, Vandana Madkan, Karan Sra, Beau Willison, L Katie Morrison and Stephen K Tyring

81 Other Viral Diseases 1345
Anthony J Mancini and Ayelet Shani-Adir

82 Sexually Transmitted Infections 1367
Angelika Stary and Georg Stary

83 Protozoa and Worms 1391
Steven A Nelson and Karen E Warschaw

84 Infestations 1423
Craig N Burkhart, Craig G Burkhart and Dean Scott Morrell

85 Bites and Stings 1435
Dirk M Elston

SECTION THIRTEEN: Disorders Due to Physical Agents

86 Ultraviolet Light 1455
Thomas M Rünger

87 Photodermatologic Disorders 1467
Henry W Lim and John LM Hawk

88 Environmental and Sports-Related Skin Diseases 1487
Mary Beth Cole and Michael L Smith

89 Signs of Drug Abuse 1511
Josep L Genebriera de Lamo, Mark R Pittelkow and Miguel Sanchez

90 Skin Signs of Abuse 1521
Sharon S Raimer, Lauren Raimer-Goodman and Ben G Raimer

SECTION FOURTEEN: Disorders of Langerhans Cells and Macrophages

91 Histiocytoses 1529
Warren T Goodman and Terry L Barrett

92 Xanthomas 1547
W Trent Massengale, Kafele T Hodari, Erin E Boh and Lee T Nesbitt Jr

93 Non-infectious Granulomas 1557
Amy Reisenauer, Kevin P White, Veselina Korcheva and Clifton R White Jr

94 Foreign Body Reactions 1573
MA Abdallah, MMA Abdallah and Marwa A-R Abdallah

SECTION FIFTEEN: Atrophies and Disorders of Dermal Connective Tissues

95 Biology of the Extracellular Matrix 1585
Leena Bruckner-Tuderman

96 Perforating Diseases 1599
Ronald P Rapini

97 Heritable Disorders of Connective Tissue 1607
Franziska Ringpfeil and Jouni Uitto

98 Dermal Hypertrophies 1621
Marco Romanelli, Valentina Dini, Mariya Miteva and Paolo Romanelli

99 Atrophies of Connective Tissue 1631
Catherine Maari and Julie Powell

SECTION SIXTEEN: Disorders of Subcutaneous Fat

100 Panniculitis 1641
James W Patterson

101 Lipodystrophies 1663
Suat Hoon Tan, Priya Sen and Mark Tang

SECTION SEVENTEEN: Vascular Disorders

102 Vascular Biology 1679
Michael Detmar and Satoshi Hirakawa

103 Infantile Hemangiomas 1691
Anita N Haggstrom and Maria C Garzon

104 Vascular Malformations 1711
Odile Enjolras

105 Ulcers 1729
Ariela Hafner and Eli Sprecher

106 Other Vascular Disorders 1747
Robert Kelly and Christopher Baker

SECTION EIGHTEEN: Neoplasms of the Skin

107 Principles of Tumor Biology and Pathogenesis of BCCs and SCCs 1759
Edel A O'Toole, Fredrik Pontén, Joakim Lundeberg and Anna Asplund

108 Actinic Keratosis, Basal Cell Carcinoma and Squamous Cell Carcinoma 1773
H Peter Soyer, Darrell S Rigel and Elisabeth MT Wurm

109 Benign Epidermal Tumors and Proliferations 1795
Luis Requena, Celia Requena and Clay J Cockerell

110 Cysts 1817
Mary S Stone

111 Adnexal Neoplasms 1829
Timothy H McCalmont

112 Benign Melanocytic Neoplasms 1851
Harold S Rabinovitz and Raymond L Barnhill

113 Melanoma 1885
Claus Garbe and Jürgen Bauer

114 Vascular Neoplasms and Neoplastic-like Proliferations 1915
Paula E North and Jay Kincannon

115 Neural and Neuroendocrine Neoplasms (Other than Neurofibromatosis) 1943
Zsolt B Argenyi

116 Fibrous and Fibrohistiocytic Proliferations of the Skin and Tendons 1961
Hideko Kamino, Vijaya B Reddy and John Pui

117 Muscle, Adipose and Cartilage Neoplasms 1979
Steven Kaddu and Sabine Kohler

118 Mastocytosis 1993
Michael D Tharp

119 B-Cell Lymphomas of the Skin 2003
Lorenzo Cerroni

120 Cutaneous T-Cell Lymphoma 2017
Rein Willemze

121 Other Lymphoproliferative and Myeloproliferative Diseases 2037
Harry L Winfield and Bruce R Smoller

122 Cutaneous Metastases 2049
Matthew B Zook, Hong Wu and Stuart R Lessin

SECTION NINETEEN: Medical Therapy

123 Public Health and Dermatology 2057
Sarah Nakib and Abrar A Qureshi

124 Skin Barrier and Transdermal Drug Delivery 2065
Mark R Prausnitz, Peter M Elias, Thomas J Franz, Matthias Schmuth, Jui-Chen Tsai, Gopinathan K Menon, Walter M Holleran and Kenneth R Feingold

125 Glucocorticosteroids 2075
Scott M Jackson and Lee T Nesbitt Jr

126 Retinoids 2089
Anne-Marie Thielen and Jean-Hilaire Saurat

127 Antimicrobial Drugs 2105
Jack L Lesher Jr and R Carol McConnell

128 Immunomodulators 2131
J Mark Jackson and Jeffrey P Callen

129 Other Topical Medications 2153
Matthew Fox, Yolanda Helfrich and Sewon Kang

130 Systemic Drugs 2165
Julia R Nunley and Stephen E Wolverton

131 Drug Interactions 2183
Lori E Shapiro, Sandra R Knowles and Neil H Shear

132 Sunscreens 2197
Vincent A DeLeo

133 Complementary and Alternative Medicine 2205
Amy Geng and Raymond G Dufresne Jr

SECTION TWENTY: Physical Treatment Modalities

134 Ultraviolet Therapy 2219
Herbert Hönigsmann and Thomas Schwarz

135 Photodynamic Therapy 2237
Harvey Lui and Rolf-Markus Szeimies

136 Lasers and Other Energy Technologies – Principles and Skin Interactions 2251
Fernanda H Sakamoto, Mathew M Avram and R Rox Anderson

137 Laser Therapy 2261
Christopher B Zachary and Rana Rofagha

138 Cryosurgery 2283
Emanuel G Kuflik and Julianne H Kuflik

139 Radiotherapy 2291
Michael Veness and Shawn W Richards

140 Electrosurgery 2303
Sheldon V Pollack

SECTION TWENTY-ONE: Surgery

141 Biology of Wound Healing 2313
Sabine A Eming

142 Surgical Anatomy of the Head and Neck 2327
Franklin P Flowers and Thomas S Breza Jr

143 Anesthesia 2343
George J Hruza

144 Wound Closure Materials and Instruments 2353
Christie Travelute Ammirati and Glenn Goldman

145 Dressings 2365
Gregg M Menaker, Stephanie L Mehlis and Sarah Kasprowicz

146 Biopsy Techniques and Basic Excisions 2381
Suzanne Olbricht

147 Flaps 2399
David G Brodland and David B Pharis

148 Grafts 2421
Désirée Ratner

149 Nail Surgery 2435
Phoebe Rich

150 Mohs Surgery 2445
Stephen N Snow and Juliet Gunkel

151 Surgical Complications and Optimizing Outcomes 2459
Anna S Clayton and Thomas Stasko

SECTION TWENTY-TWO: Cosmetic Surgery

152 Evaluation of Beauty and the Aging Face 2473
Thomas E Rohrer, Naissan O Wesley, Richard Glogau and Jeffrey S Dover

153 Cosmetics and Cosmeceuticals 2479
Zoe Diana Draelos

154 Chemical and Mechanical Skin Resurfacing 2493
Gary D Monheit and Mark A Chastain

155 Phlebology and Treatment of Leg Veins 2509

159 Botulinum Toxin 2561
Alastair Carruthers and Jean Carruthers

Index to volumes one and two I-1

Preface

The practice of dermatology is based upon a visual approach to clinical disease, with the development of an appreciation of recurrent patterns and images. The entire spectrum of our discipline, from the generation of clinicopathologic differential diagnoses to the orientation of rotational flaps, relies upon imagery. As a result, visualization also plays a critical role in how we integrate new information into pre-existing frameworks that serve as the hard drives of our medical memory.

In the textbook *Dermatology* there is a strong emphasis on visual learning. This commitment is reflected in the use of schematic diagrams to convey the principles of skin biology as well as cutaneous surgery, and the inclusion of algorithms, which provide a logical as well as practical approach to commonly encountered clinical problems. The majority of the basic science is integrated throughout the book and appears as introductory chapters to the various sections. In this edition, there are more photomicrographs demonstrating key histologic findings interspersed within the clinical chapters. These chapters also contain tables that attempt to provide weighted differential diagnoses and a "ladder" approach to therapeutic interventions. Lastly, color-coding of sections allows an easy and rapid access to required information.

The ultimate goal of *Dermatology* is for it to never make its way to the bookshelf because it is being used on a weekly, or perhaps even daily, basis. Hopefully, this book will function as a colleague, albeit a non-verbal one, who is easily approachable and possesses the necessary expertise to provide succinct, up-to-date information that is both precise and practical. It is also our hope that the organization is intuitive and information can therefore be quickly retrieved. Realizing this goal required the time and energy of our contributors who have unselfishly shared their knowledge and experience with literally thousands of patients from around the world, and we thank them.

JB, JJ and JVS

Columbia University
College of Physicians & Surgeons
New York, NY, USA

David Chu MD PhD
Scripps Health
San Diego, CA, USA

Jennie T Clarke MD
Assistant Professor of Dermatology
Department of Dermatology
Penn State College of Medicine
Penn State Milton S. Hershey Medical Center
Hershey, PA, USA

Anna S Clayton MD
Assistant Professor
Division of Dermatology
Department of Medicine
Vanderbilt University Medical Center
Nashville, TN, USA

Clay J Cockerell MD
Clinical Professor
Department of Dermatology and Pathology
University of Texas Southwestern Medical Center
Cockerell and Associates
Dallas, TX, USA

Bernard A Cohen MD
Director
Department of Pediatric Dermatology
Johns Hopkins University School of Medicine
Baltimore, MD, USA

David E Cohen MD MPH
Vice Chairman and Associate Professor of Dermatology
Department of Dermatology
New York University School of Medicine
New York, NY, USA

Mary Beth Cole MD
Resident Physician
Department of Dermatology
Vanderbilt University
Nashville, TN, USA

Kyle M Coleman MD
Private Practice
Austin, TX, USA

William P Coleman III MD
Clinical Professor of Dermatology, and Adjunct Professor of Surgery (Plastic Surgery)
Tulane University Health Sciences Center
New Orleans, LA, USA

M Kari Connolly MD
Professor of Dermatology and Medicine
Department of Dermatopathology
University of California in San Francisco
San Francisco, CA, USA

Susan M Cooper MD MBChB MRCGP FRCP
Consultant Dermatologist
Honorary Senior Clinical Lecturer
Department of Dermatology
Churchill Hospital
Oxford, UK

Edward W Cowen MD MHSc
Staff Clinician
Dermatology Branch
Center for Cancer Research
National Cancer Institute
National Institutes of Health
Bethesda, MD, USA

Thomas G Cropley MD
Professor and Chairman
Department of Dermatology
University of Virginia Health System
Charlottesville VA, USA

Ashley R Curtis MD
Department of Dermatology
Wake Forest University School of Medicine
Medical Center Boulevard
Winston-Salem, NC, USA

Thomas N Darling MD PhD
Assistant Professor
Department of Dermatology
Uniformed Services University
Bethesda, MD, USA

Mark DP Davis MD
Professor of Dermatology
Department of Dermatology
Mayo Clinic
Rochester, MN, USA

David de Berker MD
ASWCS Skin Cancer
Lead Consultant Dermatologist and Senior Clinical Lecturer
Bristol Dermatology Centre
Bristol Royal Infirmary
Bristol, UK

Vincent A DeLeo MD
Chairman
Department of Dermatology
St Luke's Roosevelt Hospital Center and Beth Israel Medical Center
New York, NY, USA

Aieska de Souza MD
Dermatopharmacology Fellow
Langone Medical Center
New York University
New York, NY, USA

Michael Detmar MD
Professor of Pharmacogenomics
Institute of Pharmaceutical Sciences
Swiss Federal Institute of Technology, ETH Zurich
Zurich, Switzerland

Valentina Dini MD
Wound Healing Research Unit
Department of Dermatology
University of Pisa
Pisa, Italy

Jeffrey S Dover MD FRCPC
Associate Professor of Clinical Dermatology
Yale University School of Medicine
Adjunct Professor of Surgery (Dermatology)
Dartmouth Medical School
SkinCare Physicians of Chestnut Hill
Chestnut Hill, MA, USA

Zoe Diana Draelos MD
Consulting Professor
Department of Dermatology
Duke University School of Medicine
Durham NC, USA

Raymond G Dufresne Jr MD
Professor of Dermatology
University Dermatology, Inc.
Rhode Island Hospital
Brown University School of Medicine
Providence, RI, USA

Boni E Elewski MD
Professor of Dermatology
Department of Dermatology
University of Alabama at Birmingham
Birmingham, AL, USA

Peter M Elias MD
Professor of Dermatology,
UCSF and Staff Physician
Dermatology Service
VA Medical Center
San Francisco, CA, USA

Dirk M Elston MD FAAD
Director
Department of Dermatology
Geisinger Medical Center
Danville, PA, USA

Sabine A Eming MD
Professor of Dermatology
Department of Dermatology
University of Cologne
Cologne, Germany

The late Odile Enjolras MD
Consultant in Dermatology, Pediatric Dermatology, and Vascular Anomalies
Department of Dermatology
Hôpital Tarnier
Department of Plastic Surgery
Hôpital d'enfants Armand Trousseau
Paris, France

Agustín España MD
Professor of Dermatology
Department of Dermatology
School of Medicine
University Clinic of Navarra
Navarra, Spain

Janet A Fairley MD
Professor and Head of Dermatology
Department of Dermatology
University of Iowa Hospitals and Clinics
Iowa City, IA, USA

Kenneth R Feingold MD
Professor of Medicine and Dermatology,
Department of Medicine,
University of California in San Francisco,
Chief of the Endocrine-Metabolism Clinic
Department of Veterans Affairs Medical Center
San Francisco, CA, USA

Jo-David Fine MD MPH FRCP
Professor of Medicine (Dermatology) and Pediatrics and Head,
National Epidermolysis Bullosa Registry
Division of Dermatology
Vanderbilt University School of Medicine
VMG Patterson Dermatology
Nashville, TN, USA

Alan B Fleischer Jr MD
Professor and Former Chair
Department of Dermatology
Wake Forest University School of Medicine
Winston-Salem, NC, USA

Franklin P Flowers MD
Professor of Dermatology
Division of Dermatology
University of Florida
School of Medicine
Gainesville, FL, USA

Timothy C Flynn MD
Clinical Professor
Department of Dermatology
University of North Carolina at Chapel Hill
Medical Director
Cary Skin Center
Cary, NC, USA

Lindy P Fox MD
Assistant Professor of Clinical Dermatology
Director
Hospital Consultation Service
University of California at San Francisco
San Francisco, CA, USA

Matthew Fox MD
Procedural Dermatology Fellow
Department of Dermatology
University of Michigan
Ann Arbor, MI, USA

Jorge Frank MD
Professor of Dermatology
Department of Dermatology
Maastricht University Medical Center
Maastricht, The Netherlands

Thomas J Franz MD
Executive Medical Director
Clinical Dermatology
PRACS Institute, Ltd.
Portland, OR, USA

Lars E French MD
Chairman
Department of Dermatology
Zurich University Hospital
Zürich, Switzerland

Ilona J Frieden MD
Professor of Dermatology and Pediatrics,
Director of Pediatric Dermatology
University of California at San Francisco
San Francisco, CA, USA

Peter O Fritsch MD
Professor and Chairman
Department of Dermatology and Venereology
Innsbruck Medical University
Innsbruck, Austria

Claus Garbe MD
Professor of Dermatology,
Head, Dermato-oncology Section
Department of Dermatology
Eberhard Karls University Tübingen
Tübingen, Germany

Maria C Garzon MD
Professor of Clinical Dermatology and Clinical Pediatrics,
Columbia University
Director
Pediatric Dermatology
Morgan Stanley Children's Hospital of New York
Department of Dermatology
New York Presbyterian Hospital
New York, NY, USA

Josep L Genebriera de Lamo MD
Dermatologist
North Florida Dermatology
Jacksonville, FL, USA

Amy Geng MD
President
Todd Park and Amy Geng Foundation
Canton, MA, USA

Kamran Ghoreschi MD
Senior Resident
Department of Dermatology
Eberhard Karls University Tübingen
Tübingen, Germany

Amy E Gilliam MD
Assistant Clinical Professor
University of California San Francisco
Staff Physician
Department of Dermatology
Palo Alto Medical Foundation
Palo Alto, CA, USA

Richard Glogau MD
Clinical Professor of Dermatology
University of California at San Francisco
San Francisco, CA, USA

Deborah S Goddard MD
Staff Physician
Department of Dermatology
Kaiser Permanente Medical Group
San Jose, CA, USA

User Guide

VOLUMES, SECTIONS AND COLOR CODING

Dermatology is divided into two volumes. The book is divided into 22 sections, which are color-coded as follows for reference:

VOLUME ONE

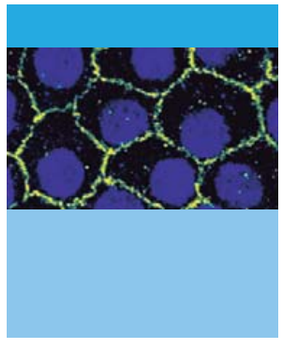
- Section 1 Overview of basic science
- Section 2 Pruritus
- Section 3 Papulosquamous and eczematous dermatoses
- Section 4 Urticarias, erythemas and purpuras
- Section 5 Vesiculobullous diseases
- Section 6 Adnexal diseases
- Section 7 Rheumatologic dermatology
- Section 8 Metabolic and systemic diseases
- Section 9 Genodermatoses
- Section 10 Pigmentary disorders
- Section 11 Hair, nails and mucous membranes

VOLUME TWO

- Section 12 Infections, infestations and bites
- Section 13 Disorders due to physical agents
- Section 14 Disorders of Langerhans cells and macrophages
- Section 15 Atrophies and disorders of dermal connective tissues
- Section 16 Disorders of subcutaneous fat
- Section 17 Vascular disorders
- Section 18 Neoplasms of the skin
- Section 19 Medical therapy
- Section 20 Physical treatment modalities
- Section 21 Surgery
- Section 22 Cosmetic surgery

Basic Science Chapters

Basic science chapters in the book are highlighted on the upper corner of each page with the following skin biology symbol:



Therapeutic Ladders

Therapeutic ladders have been standardized for measuring levels of evidence.

Key to evidence-based support:

(1) prospective controlled trial
(2) retrospective study or large case series
(3) small case series or individual case reports.

Dermatology Website

Additional 'e' references in Chapters 8 and 24 can be found in full at http://www.expertconsult.com, which includes all of the book's content plus supplementary images in a searchable format.

Expert CONSULT

Dedication

This book is dedicated to our families, in particular Dennis Cooper, MD, Andrew Schaffer and Irene Carros, who endured our work on this project and who unwittingly were part of the team, and to all the rest of the team at Elsevier who made it all happen.

Acknowledgments

We are grateful to the authors for sharing their expertise and putting forth their best efforts to bring up-to-date educational material to the readers. In addition, we wish to acknowledge the contributions of Russell Gabbedy, who was there in the early days of the first edition and who has rejoined us for the third edition; the London team, initially led by Sven Pinczewski and then Rachael Harrison with the assistance of Emma Cole; and the Oxford team, led by Anne Collett, with Susan Stuart and Elaine Leek.

We would also like to thank the following people for their help during this project: Kalman Watsky, MD, Louis A. Fragola, Jr, MD, Lisa Rao, Henry Votava, MD, PhD, Donald J. Baker, MD, Caterina Catricalà, MD, Misty Godwin, and Evan, Henry and Samuel Schaffer.

Introduction to clinical dermatology....1
The role of dermatopathology in clinicopathologic correlation....11
Introduction to the use of dermoscopy (dermatoscopy)....33

INTRODUCTION TO CLINICAL DERMATOLOGY

The skin represents the largest organ of the human body. The average adult has 1.75 m^2 (18.5 ft^2) of skin that contains a variety of complex adnexal structures, including hair, nails, glands and specialized sensory structures, all of which function in protection, homeostasis and the transmission of sensation. Dermatology is the field of medicine that deals with the macroscopic study of skin, adjacent mucosa (oral and genital) and cutaneous adnexa, while dermatopathology deals with the microscopic study of the same structures. The two fields are closely allied, as they are complementary and requisite to one another.

Multiple studies have shown that a dermatologist is the most effective diagnostician with regard to skin disease[1,2]. This enhanced acumen reflects experience in recognizing distribution patterns and configurations as well as subtle variations in morphology and colors, in addition to appreciating associated histopathologic findings. This chapter will not only serve as an introduction to the classification schemes, descriptive terminologies and diagnostic tools utilized in dermatology, it will also highlight additional means for studying the skin, including dermoscopy (dermatoscopy) and dermatopathology, with clinicopathologic correlation between macroscopic and microscopic findings.

Etiologic Premises

All students of dermatology, whether beginners or advanced scholars, require a basic conceptual framework upon which to organize thousands of skin diseases. A useful arrangement is one that is analogous to a tree, with a trunk, major branches, minor branches, twigs and, ultimately, leaves (Fig. 0.1). Instead of memorizing thousands of leaves, a logical, progressive movement along the limbs will allow for a more complete and sophisticated differential diagnosis.

Inflammatory versus neoplastic

An early and major "branch point" in classifying skin diseases is deciding simply if a skin condition is "neoplastic" (either benign or malignant) or "inflammatory" (either infectious or non-infectious) (see Fig. 0.1). However, an experienced clinician knows that one must consider possible diagnoses along multiple limbs before narrowing the differential diagnosis, because both overlap and mimicry can occur. For example, mycosis fungoides, the most common form of cutaneous T-cell lymphoma, is a clonal lymphoproliferative disorder (a "neoplasm"), yet its clinical presentation resembles an inflammatory disorder (Fig. 0.2), especially in its early stages. Conversely, sarcoidosis is an inflammatory condition, but it may present as an isolated infiltrated plaque that may mimic a neoplasm (Fig. 0.3).

Morphology

To an engineer or material scientist, the word "*morphology*" refers to the structure and appearance of a material without regard to function. In dermatology, this term is used analogously to refer to the general appearance of a skin lesion or lesions, irrespective of the etiology or underlying pathophysiology. For example, a small cutaneous blister is referred to as a "vesicle", regardless of whether it is due to an infectious process, such as herpes zoster, or an autoimmune process, such as

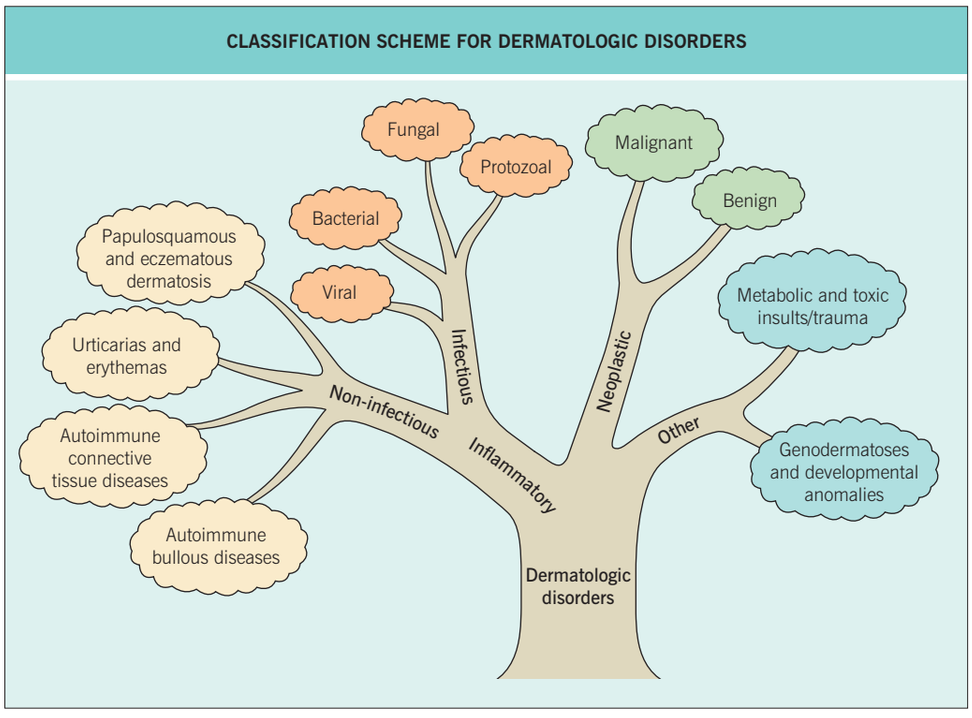

Fig. 0.1 Classification scheme for dermatologic disorders. This scheme is analogous to the structure of a tree with multiple branch points terminating in leaves.

Fig. 0.2 Mycosis fungoides, the most common form of cutaneous T-cell lymphoma. Mycosis fungoides represents a neoplastic proliferation of monoclonal lymphocytes, but it presents clinically in a manner akin to that of inflammatory conditions.

Fig. 0.3 Sarcoidosis. It is an inflammatory disorder of uncertain etiology, most prevalent in African-Americans from the southern United States, but sarcoidosis can present as a papulonodule or infiltrated plaque, mimicking a neoplastic disorder.

Fig. 0.4 Herpes zoster (A), an infectious disease, and bullous pemphigoid (B), an autoimmune disease. While disparate in etiology, both can result in a similar morphology – namely, cutaneous vesicles and bullae.

bullous pemphigoid (Fig. 0.4). Therefore, the proper use of morphological terms establishes a structural framework for grouping skin diseases based upon their macroscopic appearance.

In essence, morphologic terms become a "native language" by which dermatologists, and other health professionals, communicate with each other to *describe* skin lesions. As such, they are key elements of a lexicon. Without a basic working knowledge of morphology, it is impossible to describe cutaneous observations in a consistent manner. Therefore, one of the initial steps in studying dermatology is to learn basic morphologic definitions inherent to the specialty.

There exist both primary morphologic terms (Table 0.1), which refer to the most characteristic, representative or native appearance of skin lesions (such as a "papule"), and secondary morphologic terms (Table 0.2), which can augment or even supplant primary morphologic terms. Secondary morphologic terms often reflect the effects of exogenous factors or temporal changes (such as "scales" or "crusts") that evolve during the course of a skin disease.

Secondary changes must be considered when performing, or examining histologically, a biopsy of a skin lesion. An astute clinician will generally attempt to biopsy a well-developed but "fresh" lesion that demonstrates the expected primary pathology, free of secondary changes such as erosions, ulcers and scars. This allows the dermatopathologist to evaluate the histologic features of the lesions in their native state, without potentially confounding alterations.

Palpation and appreciation of textural changes

Any discussion of morphology must include textural change, and palpating a lesion often provides important diagnostic clues. In dermatology, palpation can prove useful in several ways. Firstly, it helps in making a distinction amongst primary morphologies (see Table 0.1). For example, the key difference between macules and patches, as opposed to papules and plaques, is that the former are flush with the surrounding skin and cannot be appreciated by palpation. On the other hand, the latter, by definition, must be palpable (Table 0.3). Secondly, palpation may augment the examination and appreciation of a disease process for which visual changes are absent, unimpressive or nonspecific. For example, in morphea, an autoimmune connective tissue disease that leads to sclerotic collagen within the dermis, the skin feels indurated (very firm) while only nonspecific hyperpigmentation may be evident with visual inspection. The same is true for other fibrotic disease processes, such as nephrogenic systemic fibrosis and scleroderma. Lastly, purpura is often classified as palpable or non-palpable, and this division implies different underlying etiologies (e.g. small vessel vasculitis aligned more with palpable purpura than macular purpura).

PRIMARY LESIONS – MORPHOLOGICAL TERMS

	Term	Clinical features		Clinical example	Clinical disorders
← Related by size →	**Macule**	• Flat, circumscribed • <1 cm in diameter • Often hypo- or hyperpigmented • Also other colors (e.g. pink, red, violet)		 Solar lentigines	• Ephelid (freckle) • Lentigo • Idiopathic guttate hypomelanosis • Petechiae • Flat component of viral exanthems
	Patch	• Flat, circumscribed • >1 cm in diameter • Often hypo- or hyperpigmented • Also other colors (e.g. blue, violet)		 Vitiligo	• Vitiligo • Melasma • Dermal melanocytosis (Mongolian spot) • Café–au–lait macule • Nevus depigmentosus • Solar purpura
← Related by size →	**Papule**	• Elevated, circumscribed • <1 cm in diameter • Elevation due to increased thickness of the epidermis and/or cells or deposits within the dermis • May have secondary changes (e.g. scale, crust) • Need to distinguish from vesicle or pustule		 Seborrheic keratoses	• Seborrheic keratosis • Cherry hemangioma • Compound or intradermal melanocytic nevus • Verruca or molluscum contagiosum • Lichen nitidus • Elevated component of viral exanthems • Small vessel vasculitis
	Plaque	• Elevated, circumscribed • >1 cm in diameter • Elevation due to increased thickness of the epidermis and/or cells or deposits within the dermis • May have secondary changes (e.g. scale, crust)		 Psoriasis	*Primarily epidermal* • Psoriasis • Lichen simplex chronicus • Nummular dermatitis
				 Acne scarring	*Dermal* • Granuloma annulare • Sarcoidosis • Hypertrophic scar, keloid • Morphea • Lichen sclerosus

PRIMARY LESIONS – MORPHOLOGICAL TERMS				
	Term	**Clinical features**	**Clinical example**	**Clinical disorders**
	Nodule	• Elevated, circumscribed • Larger volume than papule, often >2 cm in diameter • Involves the dermis and may extend to the subcutis • Greatest mass may be beneath the skin surface	 Epidermoid inclusion cysts	• Epidermoid inclusion cyst • Lipoma • Metastases • Neurofibromas • Panniculitis, e.g. erythema nodosum • Lymphoma cutis
← Related by size →	**Vesicle**	• Elevated, circumscribed • <1 cm in diameter • Primarily filled with clear fluid • May become pustular, umbilicated or an erosion	 Herpes zoster	• Herpes simplex • Varicella or zoster • Dermatitis herpetiformis • Dyshidrotic eczema
	Bulla	• Elevated, circumscribed • >1 cm in diameter • Filled with clear fluid	 Bullous fixed drug eruption	• Friction blister • Bullous pemphigoid • Linear IgA bullous dermatosis • Bullous fixed drug eruption • Coma bullae • Edema bullae
	Pustule	• Elevated, circumscribed • Usually <1 cm in diameter • Filled primarily with purulent fluid	 Steroid folliculitis	*Follicularly centered* • Folliculitis • Acne vulgaris *Non-follicularly centered* • Pustular psoriasis • Acute generalized exanthematous pustulosis • Subcorneal pustular dermatosis

Table 0.1 Primary lesions – morphological terms (cont'd).

SECONDARY FEATURES – MORPHOLOGICAL TERMS			
Feature	**Description**		**Disorders**
Crust	• Dried serum, blood or pus on the surface • May include bacteria (usually *Staphylococcus*)	 Secondarily infected hand dermatitis	• Eczema/dermatitis (multiple types) • Impetigo • Later phase of herpes simplex, varicella or zoster • Erythema multiforme
Scale	• Hyperkeratosis • Accumulation of stratum corneum due to increased proliferation and/or delayed desquamation	 Psoriasis	• Psoriasis (micaceous scale) • Tinea (leading scale) • Erythema annulare centrifugum (trailing scale) • Actinic keratoses (gritty scale) • Pityriasis rosea (peripheral collarette of scale and central scale)

Table 0.2 Secondary features – morphological terms. *Photos courtesy, Louis A Fragola, Jr, MD and Jeffrey C Callen, MD.*

Continued

SECONDARY FEATURES – MORPHOLOGICAL TERMS			
Feature	**Description**		**Disorders**
Fissure	• Linear cleft in skin • Often painful • Results from marked drying, skin thickening, and loss of elasticity	 Hand dermatitis	• Angular cheilitis • Hand dermatitis • Sebopsoriasis (intergluteal fold) • Irritant cheilitis
Erosion	• Partial loss of the epidermis (epithelium)	 Pemphigus foliaceus	• Impetigo • Friction • Trauma • Pemphigus, vulgaris and foliaceus
Ulceration	• Full-thickness loss of the epithelium (epidermis) • May have loss of the dermis or even subcutis	 Pyoderma gangrenosum	• Ecthyma gangrenosum • Pyoderma gangrenosum • Stasis ulcer • Ecthyma • Neuropathic ulcer
Excoriation	• Exogenous injury to all or part of the epidermis (epithelium)	 Neurotic excoriations	• A secondary feature of pruritic conditions, including arthropod bites and atopic dermatitis • Neurotic excoriations • Acne excoriée
Atrophy	• Epidermal atrophy – thinning of the epidermis, leading to wrinkling and a shiny appearance • Dermal atrophy – loss of dermal collagen and/or elastin, leading to a depression (see Table 0.3)	 Striae secondary to potent corticosteroids	• Lichen sclerosus • Poikiloderma • Anetoderma • Focal dermal hyoplasia (Goltz syndrome) • Striae
Lichenification	• Thickening (acanthosis) of the epidermis, and accentuation of natural skin lines	 Lichen simplex chronicus	• Lichen simplex chronicus, isolated or superimposed on a pruritic condition, e.g. atopic dermatitis

Table 0.2 Secondary features – morphological terms (cont'd). *Photos courtesy, Louis A Fragola, Jr, MD and Jeffrey C Callen, MD.*

Color

The color of skin lesions can provide important clues as to the nature of the disease process. Sometimes our perception of color may be modified by palpation (see above). For example, while many dermatological processes appear red–purple in color, it is important to ascertain whether this is a blanchable erythema (i.e. it disappears with pressure), which suggests the color is due to vasodilation, or whether it is due to extravasation of red blood cells into the tissue (purpura), which does not blanch. Also, it is not uncommon for exogenous sources of pigment, such as topical medicaments, oral drugs and other ingestants, to be implicated in producing discoloration of the skin. Table 0.4 lists the more frequently observed colors of skin lesions and examples of associated disorders.

Variation in skin color within the human population

Many racial and ethnic descriptors are used in common parlance, including African, African-American, Asian, Middle Easterner, Northern European, Southern European, Native American, Pacific Islander, and Hispanic, to describe individuals with similar cutaneous characteristics as well as heritage. Yet even within racial and ethnic groups, gradations exist with regard to skin pigmentation. Sometimes the term "skin of color" is used to describe all skin tones darker than those of

USE OF PALPATION IN DEFINING CUTANEOUS LESIONS		
Types of lesion		**Examples**
Macules & patches (non-palpable)		• Solar lentigines • Idiopathic guttate hypomelanosis • Melasma • Vitiligo • Petechiae • Dermal melanocytosis
Papules & plaques (palpable)		• Psoriasis • Lichen planus • Dermatitis • Intradermal or compound melanocytic nevus • Hypertrophic scar, keloid • Morphea
Atrophy – dermal & subcutaneous		**(A)** • Anetoderma **(B)** • Focal dermal hypoplasia (Goltz syndrome) **(C)** • Lipoatrophy due to corticosteroid injections • Lipoatrophy due to panniculitis

Table 0.3 Use of palpation in defining cutaneous lesions.

COLOR AS A CLUE TO THE CLINICAL DIAGNOSIS		
Color	**Clinical example**	**Examples of diseases with this color**
Erythema (pink to red–brown, depending upon the skin phototype)	 Morbilliform (exanthematous) drug eruption	• Dermatitis • Psoriasis • Morbilliform drug eruption • Viral exanthems • Any insult that causes vasodilation

Black	
	Necrosis secondary to vasculopathy from levamisole-contaminated cocaine
		• Necrosis of the skin:
		  • Vasculitis (Wegener's granulomatosis)
		  • Thrombosis (e.g. DIC, monoclonal cryoglobulinemia)
		  • Emboli (e.g. ecthyma gangrenosum)
		  • Vasospasm (e.g. severe Raynaud's phenomenon)
		  • Vascular compromise (e.g. atherosclerosis, calciphylaxis)
		  • Eschar (e.g. anthrax)
		• Cutaneous melanoma
		• Traumatic tattoos (e.g. asphalt)

Table 0.4 Color as a clue to the clinical diagnosis. DIC, disseminated intravascular coagulation.

Continued

COLOR AS A CLUE TO THE CLINICAL DIAGNOSIS		
Color	**Clinical example**	**Examples of diseases with this color**
Blue (ceruloderma)	Dermal melanocytosis	• Dermal melanocytosis (e.g. Mongolian spot, nevus of Ota) • Dermal melanocytomas (e.g. blue nevi) • Cyanosis • Ecchymoses • Venous congestion (e.g. venous malformations) • Drugs/deposits (e.g. minocycline, traumatic tattoos)

Brown	Phytophotodermatitis due to lime juice	• Pigmented lesions
		  • Lentigines
		  • Seborrheic keratoses
		  • Junctional, compound and congenital melanocytic nevi
		  • Café-au-lait macules
		  • Dermatofibromas
		  • Melanoma
		  • Pigmented AKs, Bowen's disease
		• Postinflammatory hyperpigmentation – epidermal (see Ch. 67)
		• Melasma
		• Phytophotodermatitis
		• Drug-induced hyperpigmentation (e.g. cyclophosphamide)
		• Metabolic (e.g. Addison's disease, hemochromatosis)

Gray	Argyria	• Postinflammatory hyperpigmentation – dermal (e.g. erythema dyschromicum perstans; see Ch. 67) • Drugs/deposits (e.g. argyria, chrysiasis) • Combined melanocytic nevus • Traumatic tattoos • See Blue (above)
Purple (violaceous)	Purpura	• Purpura, non-palpable (e.g. solar purpura) • Purpura, palpable (e.g. small vessel vasculitis) • Vascular neoplasms (e.g. angiokeratoma, angiosarcoma) • Lichen planus • Lymphoma cutis • Pyoderma gangrenosum – border • Morphea - border
White	Calcinosis cutis (systemic sclerosis)	• Absence of melanocytes or melanin production (e.g. vitiligo, piebaldism, OCA1A) • Scarring (e.g. scarring in discoid lupus erythematosus) • Vasospasm (e.g. Raynaud's phenomenon, nevus anemicus) • Deposits (e.g. calcinosis cutis, gouty tophi) • Macerated stratum corneum – mucosal surfaces (e.g. leukoplakia)
Green	Onycholysis with secondary *Pseudomonas* infection	• *Pseudomonas* infection • Tattoo • Chloroma • Green hair due to copper deposits
Orange–red (salmon)	Pityriasis rubra pilaris with islands of sparing	• Pityriasis rubra pilaris • Mycosis fungoides (sometimes)
Yellow	Xanthelasma	• Solar elastosis • Carotenemia • Xanthomas (e.g. xanthelasma, eruptive) • Xanthogranulomas • Adnexal tumors and hyperplasias with sebaceous differentiation • Necrobiosis lipoidica • Capillaritis (yellow–brown background) • Deposits/drugs (e.g. tophi, quinacrine)

Table 0.4 Color as a clue to the clinical diagnosis (cont'd). AK, actinic keratosis; OCA1A, oculocutaneous albinism, type 1A.

FITZPATRICK SCALE OF SKIN PHOTOTYPES		
Skin phototype	**Skin color**	**Response to UV irradiation**
I	White	Always burns, does not tan
II	White	Burns easily, tans with difficulty
III	Beige	Mild burns, tans gradually
IV	Brown	Rarely burns, tans easily
V	Dark brown	Very rarely burns, tans very easily
VI	Black	Never burns, tans very easily

Table 0.5 Fitzpatrick scale of skin phototypes.

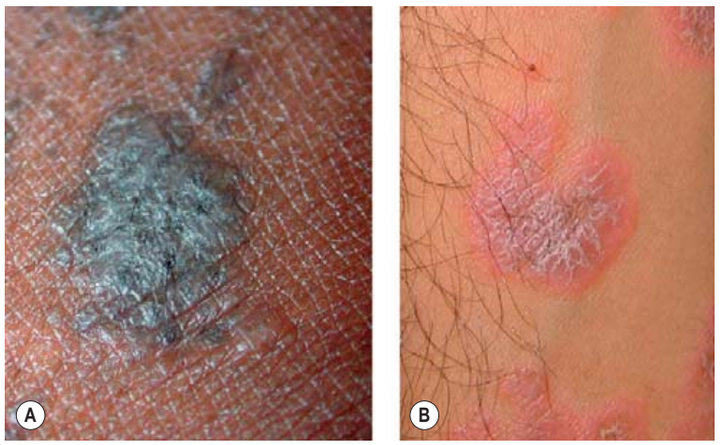

Fig. 0.5 Lichen planus presents differently in darkly pigmented (A) versus lightly pigmented (B) skin. The violaceous hue seen in **B** is more muted in **A** and these lesions appear brown–black in color. Wickham's striae (lacy white pattern) are more easily seen in **B**.

white (Caucasian) skin[3]. However, this term encompasses more than skin color and its response to ultraviolet irradiation, as is assessed by the Fitzpatrick Scale (skin phototypes I–VI; Table 0.5). It also refers to other shared characteristics, such as hair color, hair texture, and a tendency toward certain reaction patterns in the skin as a response to an insult. The practice of dermatology requires a solid understanding of the differences in clinical features (e.g. hues of red) amongst individuals with different levels of skin pigmentation.

Variations in skin color are due to differences in the amount and distribution of melanin within epidermal melanocytes and keratinocytes[4], rather than the number of melanocytes (see Ch. 65). In addition, the ratio of eumelanin (brown–black) to pheomelanin (yellow–red) influences skin color, with pheomelanin the predominant pigment in those with freckles and red hair. Exposure to ultraviolet radiation also significantly impacts melanin production (tanning).

Pigmentation of the skin clearly influences the prevalence of certain cutaneous findings and disorders. For example, individuals with darkly pigmented skin are more likely to develop multiple streaks of longitudinal melanonychia (see Ch. 71)[5,6], pigmentation of the oral mucosa[7], persistent postinflammatory hyperpigmentation (see Ch. 67), and obvious pigmentary demarcation lines[8] (Futcher's lines or Voigt's lines; see Fig. 67.10). Whether postinflammatory hypopigmentation[9] is more common or just more clinically apparent is a matter of debate. In addition, discoid lupus erythematosus and keloids are seen more often in patients with darkly pigmented skin and African ancestry, but the relationship of these disorders to melanocyte function is not clear.

There can also be differences in the physiologic properties of the skin. For example, the stratum corneum of black skin often retains more layers and is more compact and cohesive than that of white skin. In addition, darker skin produces less vitamin D_3 in response to equivalent amounts of sunlight, and this is postulated to have been a driving force in the evolution of paler skin as early humans migrated away from the equator[10].

Perhaps the most important point to remember is that erythema (redness) can be difficult to appreciate in darkly pigmented skin. Erythema is caused by vasodilation and/or increased blood flow in the dermis, and if the epidermis is deeply pigmented, the red hues of oxyhemoglobin are often less obvious. For this reason, diseases that are classically described as erythematous (e.g. dermatitis) or violaceous (e.g. lichen planus) may present more subtly in darker skin types (Fig. 0.5)[11]. Diagnostic procedures that depend upon the development of erythema, such as patch testing for the evaluation of allergic contact dermatitis, can be more challenging to interpret in dark skin. Lastly, cyanosis (blue hues indicative of poor oxygenation and a critical clinical sign) is also more difficult to appreciate when the skin is darkly pigmented.

Configuration and Distribution

After carefully considering the morphology and color of skin lesions, the dermatologist must next analyze two closely related properties – configuration and distribution – in order to hone in on the correct diagnosis. For example, pruritic and fragile vesicles on the elbows and knees would prompt consideration of dermatitis herpetiformis, whereas grouped vesicles on an erythematous base confined to a single dermatome would mandate consideration of herpes zoster (Fig. 0.6) or zosteriform herpes simplex.

Fig. 0.6 The dermatomal pattern of herpes zoster. Note the midline demarcation.

Configuration

Appreciation of the configuration or arrangement of skin lesions can provide important clues as to the diagnosis. Examples include *annular* (e.g. tinea corporis, granuloma annulare; see Ch. 19), *serpiginous* (e.g. cutaneous larva migrans), *clustered* (e.g. piloleiomyomas, herpetiform vesicles), *reticulated* (e.g. erythema ab igne), and *retiform* (e.g. purpura fulminans, purpura due to calciphylaxis [Fig. 0.7]; see Ch. 22). The latter pattern reflects occlusion of the cutaneous vasculature[12].

It also important to note if the cutaneous lesions are in a *linear* array. The lesions may follow Blaschko's lines, which reflect patterns of embryonic development (see Fig. 62.1)[13], or they may be confined to a dermatome, which represents an area of skin whose innervation is from a single spinal nerve (see Fig. 80.14). Irrespective of whether the lesions are along Blaschko's lines (e.g. epidermal nevi) or in a dermatomal pattern (e.g. herpes zoster [see Fig. 0.6]), there is often a characteristic midline demarcation. In addition to these two patterns, a linear arrangement can result from a trauma-induced Koebner phenomenon (an isomorphic response), as in vitiligo, lichen planus (Fig. 0.8) and psoriasis[14,15], or be due to trauma-induced autoinoculation, as in verrucae vulgares or verrucae planae. Lastly, linear lesions are frequently seen in acute allergic contact dermatitis due to plants (e.g. poison ivy), reflecting brushing of the branches and leaves against the skin.

Fig. 0.7 Retiform purpura and cutaneous necrosis secondary to calciphylaxis. Note the irregular shape of the purpura. *Courtesy, Amanda Tauscher, MD.*

Fig. 0.8 Koebernization (isomorphic response) of lichen planus secondary to trauma. As a result, the lesions have a linear configuration.

On occasion, lesions have an unusual, even "unnatural", shape that corresponds to an external (exogenous) insult, such as allergic or irritant contact dermatitis (Fig. 0.9), an accidental or purposeful injury (see Ch. 90)[16], or even ritualistic medicinal practices (e.g. "cupping" or "coining"; see Ch. 133).

Distribution

Stepping back and observing the anatomic distribution pattern of skin lesions can also prove very helpful. For example, plaques of psoriasis often favor *extensor* surfaces (e.g. elbows and knees) while lichenified plaques of atopic dermatitis favor *flexural* surfaces in older children and adults (e.g. the antecubital and popliteal fossae). However, to complicate matters a bit, there is an "inverse" form of psoriasis in which lesions are present in major body folds, i.e. in flexural areas (see Ch. 8). Langer's cleavage lines refer to natural skin tension lines that are often used to guide the orientation of surgical excisions (see Fig. 142.7). The long axis of oval lesions of pityriasis rosea[17] and erythema dyschromicum perstans follows these cleavage lines, and this pattern is most obvious on the posterior trunk.

A *seborrheic* distribution pattern includes the head and neck as well as the upper trunk, and it reflects areas rich in sebaceous glands; seborrheic dermatitis, acne vulgaris and pityriasis versicolor are dermatoses

Fig. 0.9 Allergic contact dermatitis to a para-phenylenediamine-based ("black henna") temporary tattoo. The shape of the lesion clearly suggests an exogenous insult/etiology. *Courtesy, Colby Evans, MD.*

that favor these sites. The term "*photodistribution*" describes lesions that are accentuated in areas exposed to ultraviolet irradiation, and photodermatoses include polymorphic light eruption, phototoxic drug reactions (e.g. to doxycycline), and subacute cutaneous lupus erythematosus. Of note, sometimes a disorder will display a combination of distribution patterns; for example, in dermatomyositis, lesions can be both photodistributed and involve extensor surfaces (e.g. elbows, knees). Table 0.6 lists common diagnoses that occur in different anatomic sites.

In addition to differences in the color of inflammatory lesions, individuals with darkly pigmented skin also have an increased frequency of several cutaneous disorders (see section on Color) and certain types of reaction and distribution patterns[18]. Examples of these reaction patterns include papular eczema and a follicular accentuation of atopic dermatitis and pityriasis versicolor, as well as an annular configuration of seborrheic dermatitis and facial secondary syphilis. An example of a favored distribution pattern is inverse pityriasis rosea in which lesions occur primarily in the axillae and groin rather than on the trunk. Although a sound explanation for these phenomena is not currently available, it is still important to be aware of their occurrence[18].

Temporal Course

Central to any medical history, including that of cutaneous disorders, is the temporal course. The patient should be queried as to duration and relative change in intensity or distribution over time. For example, there are some dermatoses that have a cephalocaudal progression over time, such as measles and pityriasis rubra pilaris. Of course, the time course is more prolonged in the latter as compared to the former.

However, the dermatologist is at an advantage because the skin is so accessible, and information provided by the patient can be readily compared to what is seen in the physical examination. With experience, the dermatologist can usually determine by observation whether the cutaneous lesions are acute, subacute or chronic. Examples of helpful signs include scale (not to be confused with crusts), which often reflects parakeratosis that requires 2 weeks to develop, and intact tense bullae, which are rarely more than a week old. Lichenification, i.e. thickening of the skin with accentuation of normal skin markings, takes weeks to months to develop. Therefore, if lichenification is present, the lesion has not appeared acutely, despite what the patient may believe.

In an otherwise generally healthy patient, there are several diseases whose cutaneous manifestations are often acute in nature (Table 0.7). This is not to indicate that these diseases necessarily require immediate or emergent management, but rather that they present to the dermatologist abruptly and are distinguished, particularly from neoplasms or chronic dermatoses, by their temporal acuity.

Finally, although emergencies are unusual in dermatology, there are a few illnesses, particularly those that present with a rash and fever, which are true emergencies and must be recognized promptly and treated appropriately. Examples include Stevens–Johnson syndrome, toxic epidermal necrolysis, Kawasaki disease, meningococcemia (including purpura fulminans), Rocky Mountain spotted fever, necrotizing

COMMON DIAGNOSES FOR PAPULES, PLAQUES AND SMALL NODULES OCCURRING ON SELECT ANATOMICAL SITES		
Anatomic location		**Common**
Scalp	Inflammatory	• Seborrheic dermatitis • Psoriasis • Folliculitis • Prurigo simplex • Tinea capitis (children)
	Neoplastic	• Cherry hemangioma • Melanocytic nevus (compound, dermal, blue) • Seborrheic keratosis • Actinic keratosis (bald scalp) • Squamous cell carcinoma > basal cell carcinoma
Face/ears	Inflammatory	• Acne vulgaris • Rosacea, including periorificial dermatitis • Seborrheic dermatitis • Irritant and allergic contact dermatitis • Vitiligo (periorificial) • Verruca • Molluscum contagiosum (primarily children) • Chondrodermatitis nodularis helicis (ear) • Keloid (ear)
	Neoplastic	• Epidermoid inclusion cyst • Seborrheic keratosis • Melanocytic nevus • Cherry hemangioma } Set 1 • Sebaceous gland hyperplasia • Milium • Lentigines • Dermatosis papulosa nigra (blacks) • Fibrous papule (nose) • Pilomatricoma • Actinic keratosis • Basal cell carcinoma • Squamous cell carcinoma } Set 2
Neck	Inflammatory	• Lichen simplex chronicus
	Neoplastic	• Acrochordons • Set 1 and set 2
Elbow	Inflammatory	• Psoriasis • Verruca • Lichen simplex chronicus • Granuloma annulare • Rheumatoid nodule
	Neoplastic	• Set 1 and set 2
Hand/wrist	Inflammatory	• Irritant and allergic contact dermatitis • Atopic dermatitis • Psoriasis • Tinea • Verruca • Vitiligo • Scabies • Dyshidrotic eczema • Granuloma annulare • Lichen planus (flexural wrist)
	Neoplastic	• Lentigines • Seborrheic keratoses • Actinic keratosis • Squamous cell > basal cell carcinoma
Chest/shoulders	Inflammatory	• Folliculitis • Seborrheic dermatitis (central chest) • Pityriasis (tinea) versicolor • Grover's disease • Miliaria rubra • Pityriasis rosea (trunk) • Subacute cutaneous lupus erythematosus
	Neoplastic	• Solitary lichenoid keratosis • Lipoma • Supernumerary nipple • Paget's disease (periareolar) • Set 1 and set 2

Table 0.6 Common diagnoses for papules, plaques and small nodules occurring on select anatomical sites.

Continued

COMMON DIAGNOSES FOR PAPULES, PLAQUES AND SMALL NODULES OCCURRING ON SELECT ANATOMICAL SITES		
Anatomic location		**Common**
Abdomen/umbilicus	Inflammatory	• Folliculitis • Psoriasis vulgaris • Grover's disease • Eczema craquelé (flanks) • Nummular dermatitis
	Neoplastic	• Set 1 • Lipoma • Metastatic carcinoma (umbilicus)
Genitalia/groin	Inflammatory	• Seborrheic dermatitis • Cutaneous candidiasis • Tinea cruris (may include buttocks) • Inverse psoriasis • Irritant and allergic contact dermatitis • Herpes simplex viral infection • Condyloma acuminatum • Molluscum contagiosum (primarily sexually active individuals) • Scabies • Lichen sclerosus • Lichen simplex chronicus • Vitiligo
	Neoplastic	• Acrochordon • Angiokeratoma • Seborrheic keratosis • Anogenital lentiginosis • Bowenoid papulosis • Squamous cell carcinoma • Extramammary Paget's disease
Lower extremity	Inflammatory	• Folliculitis • Nummular dermatitis • Psoriasis vulgaris (knee) • Verruca (especially knees)
	Neoplastic	• Dermatofibroma • Lipoma • Set 1 and set 2
Ankles/feet	Inflammatory	*Ankles:* • Eczema craquelé • Stasis dermatitis • Lichen simplex chronicus • Lichen planus • Lipodermatosclerosis • Stasis ulcer *Feet:* • Tinea pedis • Verruca • Psoriasis • Pernio • Atherosclerotic ulcer • Neuropathic ulcer (plantar surface) *Both:* • Irritant and allergic contact dermatitis • Vitiligo • Scabies • Granuloma annulare
	Neoplastic	• Stucco keratosis • Actinic keratosis • Squamous cell carcinoma

Table 0.6 Common diagnoses for papules, plaques and small nodules occurring on select anatomical sites (cont'd).

fasciitis, and endocarditis with cutaneous manifestations. An approach to critical dermatologic emergencies that present with a fever and rash is outlined in Fig. 0.10.

The next two sections of this introductory chapter focus on the basic principles of dermatopathology and dermoscopy, respectively, and it is important to remember that all the diagnostic techniques (unaided clinical examination, histological examination, dermatoscopic examination) discussed herein are complementary. In other words, synergistic strength and clinicopathologic correlation are achieved when the techniques are used in combination. As a corollary, using any one technique, to the exclusion of the others, may be misleading and potentially result in misdiagnosis.

THE ROLE OF DERMATOPATHOLOGY IN CLINICOPATHOLOGIC CORRELATION

With the introductory elements of clinical dermatology firmly in mind, we next turn to dermatopathology, the microscopic examination and assessment of both normal and diseased skin. It is noteworthy that

ACUTE CUTANEOUS ERUPTIONS IN OTHERWISE HEALTHY INDIVIDUALS	
Disorder	**Characteristic findings**
Urticaria (see Ch. 18)	• Pathogenesis involves degranulation of mast cells with release of histamine • Primary lesion: edematous wheal with erythematous flare • Widespread distribution • Very pruritic* • Individual lesions are transient (<24 h in duration) • May become chronic (>6 weeks)
Acute allergic contact dermatitis (see Ch. 14)	• Immune-mediated and requires prior sensitization • Primary lesion: dermatitis, with vesicles, bullae and weeping when severe • Primarily in sites of exposure; occasionally more widespread due to autosensitization • Pruritus, often marked • Spontaneously resolves over 2–3 weeks if no further exposure to allergen (e.g. poison ivy, nickel)
Acute irritant contact dermatitis (see Ch. 15)	• Direct toxic effect • Primary lesion: ranges from erythema to bullae (e.g. chemical burn) • At sites of exposure • Burning sensation • Spontaneously resolves over 2–3 weeks if no further exposure to irritant (e.g. strong acid, strong alkali)
Exanthematous (morbilliform) drug eruptions (see Ch. 21)	• Immune-mediated and requires prior sensitization • Pink to red–brown, blanching macules and papules; may become purpuric on distal lower extremities • Widespread distribution • May be pruritic • Spontaneously resolves over 7–10 days if no further exposure to inciting drug
Pityriasis rosea (see Ch. 9)	• May follow a viral illness • Primary lesion: oval-shaped, pink to salmon-colored papule or plaque with fine white scale centrally and peripheral collarette; occasionally vesicular • Initial lesion is often largest (herald patch) • Favors trunk and proximal extremities; may have inverse pattern (axillae & groin); long axis of lesions parallel to skin cleavage lines • Spontaneously resolves over 6–10 weeks; exclude secondary syphilis
Viral exanthems (see Ch. 81)	• Due to a broad range of viruses, including rubeola, rubella, enteroviruses, parvovirus, adenovirus (see Fig. 81. 2) • Often associated with fever, malaise, arthralgias, myalgias, nausea, upper respiratory symptoms • Primary lesions vary from blanching pink macules and papules to vesicles or petechiae • Distribution varies from acral to widespread; may have an enanthem • Spontaneously resolves over 3–10 days
*May have burning rather than pruritus with urticarial vasculitis, and lesions can last longer than 24 hours.	

Table 0.7 Acute cutaneous eruptions in otherwise healthy individuals.

very few other medical specialties place as much emphasis on *both* the clinical and the histological features of diseases within their realm[19]. This natural union between dermatology and dermatopathology exists because the domains are essential to one another, and, practically speaking, both rely heavily upon the powers of observation and classification.

With experience, clinicians can visualize the most likely associated histologic findings as they examine a cutaneous lesion or eruption – e.g. hyperkeratosis and/or parakeratosis when there is scale, or dermal hemorrhage when there are petechiae. As a result, a more sophisticated differential diagnosis accompanies the biopsy specimen. Once the histopathologic features are delineated, then the dermatologist performs a clinicopathologic correlation in order to arrive at the most likely diagnosis.

The Skin Biopsy

In no other field of medicine is tissue for histologic examination so easily accessible. As a result, the skin biopsy has become an integral component of dermatologic diagnoses. Skin biopsies are performed for a multitude of reasons, including:

- uncertainty about the clinical diagnosis
- to investigate a poor response to therapy
- to exclude or investigate the evolution of one condition into another
- to investigate symptoms in the absence of clinically recognizable disease.

Regardless of the rationale for performing a skin biopsy, it is important to realize that the process of securing appropriate tissue involves more than the mere mechanical removal of a specimen. It is a multistep process, executed with forethought, precision and care in order to obtain the maximum amount of useful information[20,21]. Pitfalls that can limit the diagnostic value of a skin biopsy are many and include inappropriate site selection, biopsy technique or tissue handling. Regardless of the specific limitation, the end result can be the same – lack of a diagnosis, an inaccurate diagnosis or a clinicopathologic disconnect.

Site selection

In general, the first step in performing a biopsy is to identify an unadulterated *primary lesion* (see above). Lesions with secondary changes, such as those resulting from rubbing or traumatic injury (e.g. lichenification, excoriations) or superimposed processes (e.g. crusting due to impetiginization), are generally avoided (unless the purpose of the biopsy is to prove their presence), as these secondary changes may alter or obscure the primary pathology.

A well-developed but "fresh" lesion is usually chosen for biopsy, based upon the assumption that it will exhibit the most characteristic, and therefore diagnostic, histopathology. The concern regarding lesions deemed too immature or too old is that they may demonstrate nonspecific histopathologic features. As to be expected, there are exceptions to this general principle, such as the need to biopsy early lesions of small vessel (leukocytoclastic) vasculitis (<24 hours old), especially when performing direct immunofluorescence.

Another commonly accepted rule is that a biopsy specimen is usually obtained from the central aspect of a primary lesion. Again, exceptions exist (Fig. 0.11), especially in the case of ulcers and when the histopathologic changes are subtle, even when compared to uninvolved skin. An example of the latter is atrophoderma, where a thin wedge biopsy that begins in involved skin and ends in normal-appearing skin (and includes the border) is recommended (see Ch. 99). In the case of ulcers, secondary changes beneath the ulcer bed, including nonspecific vasculitis, may be misinterpreted leading to misdiagnosis. For this reason, the wedge biopsy should include the ulcer, its edge and surrounding inflamed skin. Lastly, selection of a proper biopsy site may also be influenced by knowledge of the underlying pathology and pathophysiology of the most likely diagnoses.

Biopsy techniques

A wide range of biopsy techniques exists (see Ch. 146). Those most commonly performed include superficial/tangential shave, deep shave (also known as "saucerization"), punch and incisional/excisional (Fig. 0.12). For optimal results, the technique selected must obtain tissue from the level of the skin or subcutaneous tissue where the pathologic changes are expected, while simultaneously balancing concerns of cosmesis and morbidity. For example, if panniculitis (inflammation of the subcutaneous fat) is suspected, the shave technique would not provide the proper tissue required to establish or exclude this diagnosis (Table 0.8). Similarly, in the case of a benign-appearing exophytic lesion such as a verruca or skin tag, it would not be expedient, economical, or even cosmetically savvy to remove the lesion via an excision with sutured closure.

- ***Superficial shave biopsy*** **–** often employed when the pathologic process is primarily epidermal (e.g. pigmented actinic keratosis or Bowen's disease versus macular seborrheic keratosis) or when removing exophytic benign lesions such as intradermal melanocytic nevi. If the diagnostic histopathologic findings are

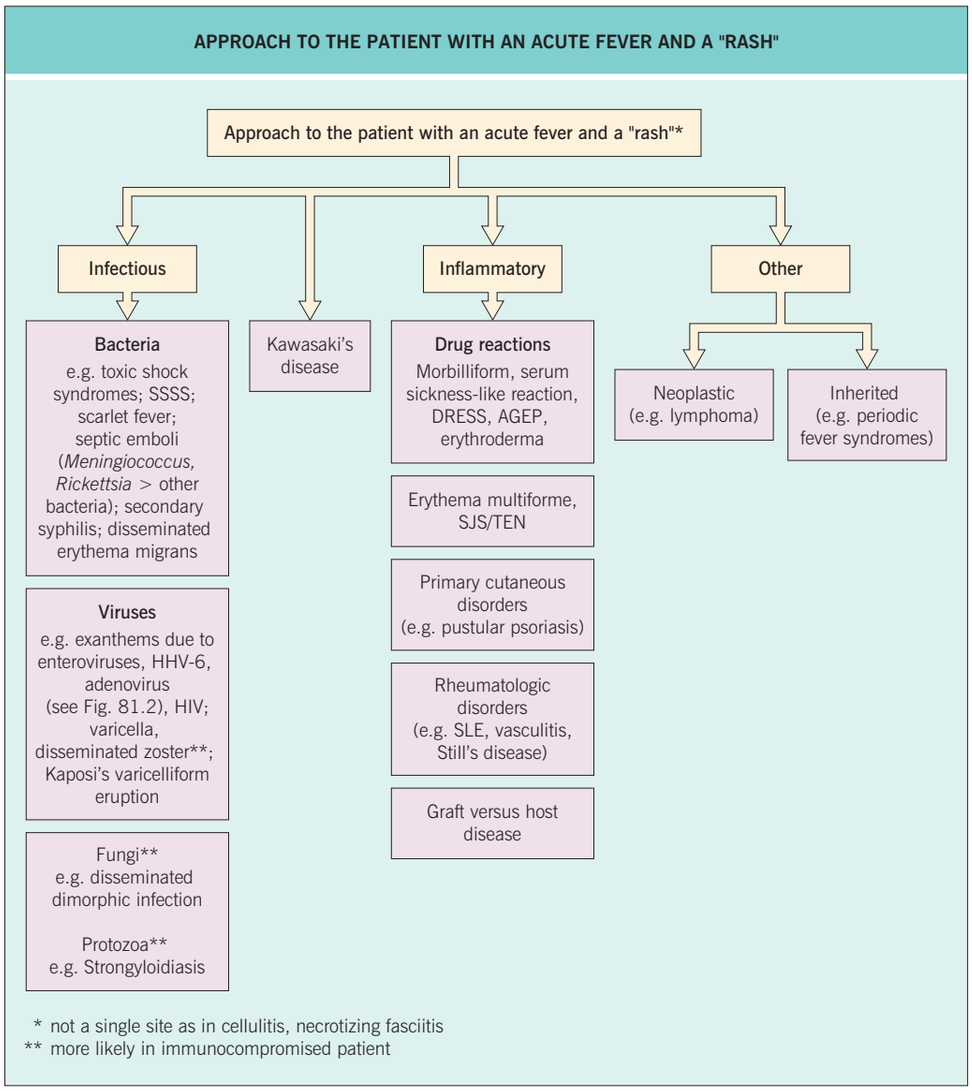

Fig. 0.10 Approach to the patient with an acute fever and a "rash". AGEP, acute generalized exanthematous pustulosis; DRESS, drug reaction with eosinophilia and systemic symptoms (also referred to as drug-induced hypersensitivity syndrome [DIHS]); HHV, human herpes virus; HIV, human immunodeficiency virus; SJS, Stevens-Johnson syndrome; SLE, systemic lupus erythematosus; SSSS, staphylococcal scalded skin syndrome; TEN, toxic epidermal necrolysis.

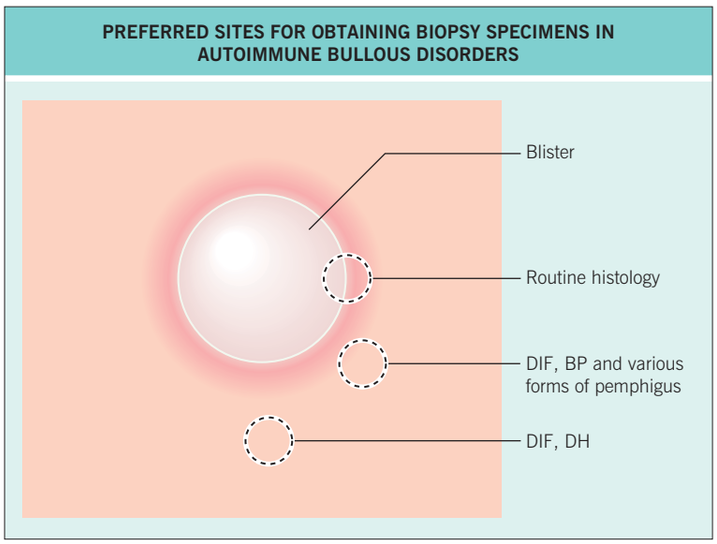

Fig. 0.11 Preferred sites for obtaining biopsy specimens in autoimmune bullous disorders. If the edematous papule or vesicle is small enough, it can be removed in its entirety for routine histology. Otherwise, a biopsy specimen that includes the inflammatory rim as well the edge of a fresh vesicle or bulla is appropriate. In bullous pemphigoid (BP) and pemphigus vulgaris a perilesional biopsy is done for direct immunofluorescence (DIF), whereas in dermatitis herpetiformis (DH), nearby normal skin is preferred for DIF.

present in the mid to deep dermis (e.g. discoid lupus erythematosus versus lichen planus, Spitz nevus versus melanoma), a superficial shave biopsy will often fail to provide all the information necessary to establish the diagnosis.

- ***Deep shave/saucerization biopsy*** – a deeper variant of the superficial shave biopsy. In the latter, the path of the blade is nearly parallel to the surface of the skin, whereas in a saucerization, the greater angle of the blade can lead to removal of the mid to deep dermis (see Fig. 0.12B). This technique is often used to biopsy neoplasms (e.g. squamous cell carcinoma versus hypertrophic actinic keratosis), and there is evidence to suggest that, when properly performed, its diagnostic value is nearly equal to that of most incisional/excisional procedures[22]. Clearly, many factors are considered when choosing between these two techniques.
- ***Punch biopsy*** – preferred for skin conditions in which the suspected pathology is within the dermis and when it is thought that a partial sampling will be representative of the entire lesion or process. The diameters of commercially available punch biopsy instruments range from 1.5 to 8.0 mm, and when the entire lesion is removed, then the issue of sampling error is rendered moot. It is controversial whether punch biopsies, even when performed in a stacked fashion, can provide adequate tissue for assessment of deeply infiltrating tumors or the full thickness of the subcutaneous fat. There are multiple studies that have shown that *partial* punch biopsies of melanocytic neoplasms can lead to erroneous diagnoses.

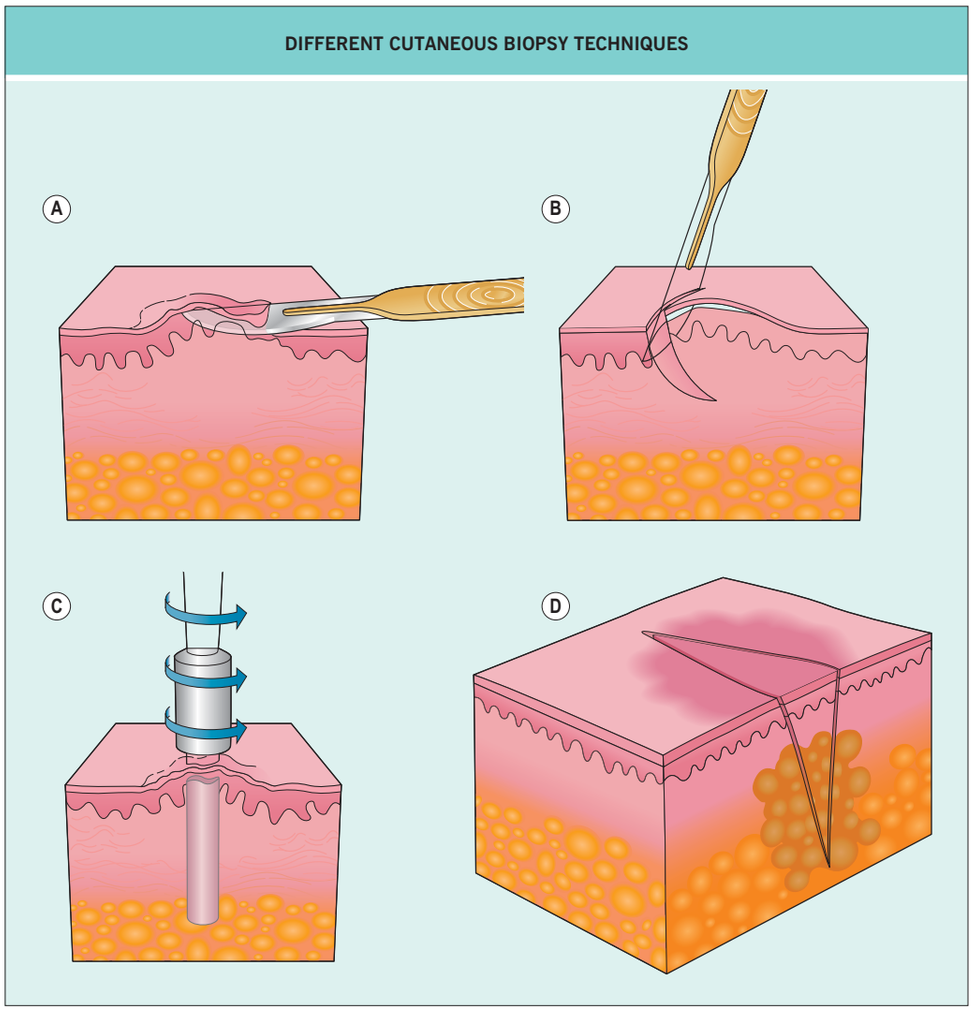

Fig. 0.12 Different cutaneous biopsy techniques. The size, topography, depth and site of the lesion, as well as the clinical differential diagnosis, influence the type of biopsy technique that is performed. **A** Superficial shave biopsy. **B** Deep shave biopsy (saucerization). **C** Punch biopsy. **D** Incisional biopsy. For more details, see text and Chapter 146. *Courtesy, Suzanne Olbricht, MD.*

OPTIMIZING INFORMATION OBTAINED FROM A SKIN BIOPSY SPECIMEN (BASED UPON PRESUMED DIAGNOSIS)

INFLAMMATORY DISEASES				
Disorders (presumed)	**Where and when to biopsy**	**Preferred technique**	**Pitfalls**	**Ancillary techniques to consider**
Vasculitides	• Center of an early lesion • Prefer sites above the knee to avoid poor wound healing or background features due to venous hypertension	Punch or incisional biopsy (depending on the size of affected vessels)	Necrotic or ulcerated lesions may be non-diagnostic	Direct immunofluorescence (early lesions, not older than 24 h)
Livedo reticularis	• Center of the pale areas defined by the surrounding venous plexus network • Corresponds to the site of the ascending arteriole (see Fig. 106.1)	Punch or incisional biopsy	Biopsy of the venous plexus or a biopsy that is too superficial can lead to false-negative results	
Autoimmune connective tissue diseases	• Fully developed lesion • In DLE, biopsy areas of inflammation, not scarred areas	Primarily punch biopsy, unless panniculitis is suspected	• In DLE, biopsies of non-inflammatory scarred areas are often non-diagnostic • Changes of acute LE may be subtle	Direct immunofluorescence of lesional skin
Panniculitides	Early evolving to fully developed lesion	Large and deep incisional biopsy (must include subcutaneous fat)	• Failure to include enough fat • Late-stage lesions often have nonspecific findings	• Fresh tissue culture and/or PCR (if infectious etiology suspected) • Direct immunofluorescence (if vasculitis suspected)

Table 0.8 Optimizing information obtained from a skin biopsy specimen (based upon presumed diagnosis). DLE, discoid lupus erythematosus; h, hour; LE, lupus erythematosus; PCR, polymerase chain reaction. *Table created with the assistance of Dr Stefano Titli.* *Continued*

OPTIMIZING INFORMATION OBTAINED FROM A SKIN BIOPSY SPECIMEN (BASED UPON PRESUMED DIAGNOSIS)

INFLAMMATORY DISEASES

Disorders (presumed)	Where and when to biopsy	Preferred technique	Pitfalls	Ancillary techniques to consider
Autoimmune blistering disorder	• An edematous papule/plaque or an early vesicle is preferred • If only large bullae are present, biopsy the edge of the bulla plus surrounding inflamed skin	Punch biopsy (e.g. 4 mm) or saucerization of: edematous papule/plaque, entire small vesicle, or edge of fresh, intact vesicle/bulla plus surrounding inflamed skin	• Biopsy of late-stage bullae undergoing re-epithelialization may lead to erroneous diagnosis • Late-stage, purulent, crusted or ulcerated lesions may be non-diagnostic	Direct immunofluorescence of perilesional skin (Fig. 0.11) or nearby skin (if dermatitis herpetiformis)
Alopecias	• Active advancing edge • Areas of perifollicular inflammation	• 4–6 mm punch biopsy oriented parallel to the direction of hair • Include subcutaneous fat	Scarred areas show only end-stage fibrosis	Vertical and horizontal sectioning of biopsy Direct immunofluorescence
Infectious diseases	• Prefer mature lesions • If ulcerated, include inflammatory border	Punch biopsy or incisional biopsy (for deep-seated infections)	• Organisms may not be appreciated in histologic sections • Fresh tissue culture and/or PCR may be necessary	Fresh tissue culture and/or PCR
Ulcerative dermatoses	Active edge of the ulcer or early lesion if the spectrum of lesions includes a pre-ulcerative stage (e.g. pyoderma gangrenosum)	Punch or incisional biopsy	Avoid center of ulcer where nonspecific changes or possible misleading secondary changes such as vasculitis	Fresh tissue culture and/or PCR (if infectious etiology suspected)
Pigmentary disorders	Include the edge of the lesion as well as normal skin for comparison	Punch biopsy, rarely incisional biopsy	Subtle findings require clinicopathologic correlation	Special stains and/or immunohistochemistry may be necessary
Urticaria	Include the edge of the lesion as well as normal skin for comparison	Punch biopsy	Small-diameter punch biopsies may lead to false-positive results as retraction of collagen bundles may simulate interstitial edema	Direct immunofluorescence (if urticarial vasculitis is suspected)

NEOPLASTIC PROCESSES

Disease	Preferred technique*	Pitfalls
Melanocytic neoplasms	Excisional biopsy (preferred when melanoma is reasonably suspected) Saucerization that includes the entire lesion When major differential diagnosis is macular seborrheic keratosis vs lentigo maligna, broad shave technique Other techniques may be appropriate depending upon the circumstances and the degree of suspicion	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process
Keratinocytic neoplasms	Punch, saucerization, or excisional biopsies	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process or allow assessment for possible dermal invasion
Dermal neoplasms	Punch or excisional biopsy	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process
Deep-dermal and/or subcutaneous neoplasms	Excisional biopsy	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process
Lymphoma and leukemia cutis	Punch or excisional biopsy When major differential diagnosis is patch-stage mycosis fungoides vs parapsoriasis, broad saucerization may be performed	Partial (subtotal) punch biopsy or superficial shave biopsy may not be representative of the entire process Crush artifact is common when lymphocytic infiltrates are sampled via a small-diameter punch biopsy

*On occasion, surgical/clinical/cosmetic constraints may, in the patient's best interest, require consideration and performance of an alternative technique, or even a subtotal biopsy, with acceptance of limitations upon the diagnostic result.

Table 0.8 Optimizing information obtained from a skin biopsy specimen (based upon presumed diagnosis) (cont'd). PCR, polymerase chain reaction. *Table created with the assistance of Dr Stefano Titli.*

- ***Incisional/excisional biopsy –*** removal of either a portion of a lesion (incisional) or the entire lesion (excisional) via a scalpel and standard surgical techniques (see Ch. 146; see Fig. 0.12D). The former is often used for disorders in which assessment of the subcutaneous fat is critical (e.g. panniculitis), while the latter is employed when the leading clinical diagnosis is invasive cutaneous melanoma and the size of the lesion allows for this procedure.

Methods for optimizing the amount of critical information one can obtain from a biopsy specimen, based on the suspected cutaneous disease, are outlined in Table 0.8.

Post-procedure handling of the skin biopsy

Even after the specimen has been obtained, it must be handled carefully. For example, if there is excessive lateral pressure, especially when exerted on small punch biopsy specimens, by forceps, a distortion of cellular infiltrates can occur ("crush" artifact). Lymphocytes are particularly susceptible to crush artifact, and when present, it may be impossible to render an accurate diagnosis.

For routine histologic study, the specimen is fixed in a buffered 10% formalin solution, with a volume 10–20 times that of the tissue itself, to prevent underfixation. For microbial tissue culture, the specimen is instead placed in a sterile container with a small amount of non-bacteriostatic saline (simply a few drops to keep it moist) and routed immediately to the laboratory. Specimens must be flash-frozen or placed in specialized transport medium (Michel's solution at room temperature) for direct immunofluorescence microscopy, while fixation in paraformaldehyde and glutaraldehyde in a cacodylate buffer is required for electron microscopy. To obtain the most information from the histologic examination, the biopsy should be accompanied by data

regarding the age and sex of the patient, anatomic site, pertinent and precise physical findings, and the differential diagnosis. Any treatments that might influence the histologic findings, as well as special instructions, such as inking eccentric pigmentation in a melanocytic neoplasm or sectioning longitudinally, should also be included. Addition of drawings or clinical photographs, especially when the case is difficult or complex, may prove useful.

Diagnosis of Inflammatory Skin Diseases by Pattern Analysis

First conceived by Dr Hermann Pinkus, but more firmly established by Dr A Bernard Ackerman[23–25], histopathologic assessment via pattern analysis has become the primary classification scheme for inflammatory skin diseases (Fig. 0.13). While the number of patterns and their

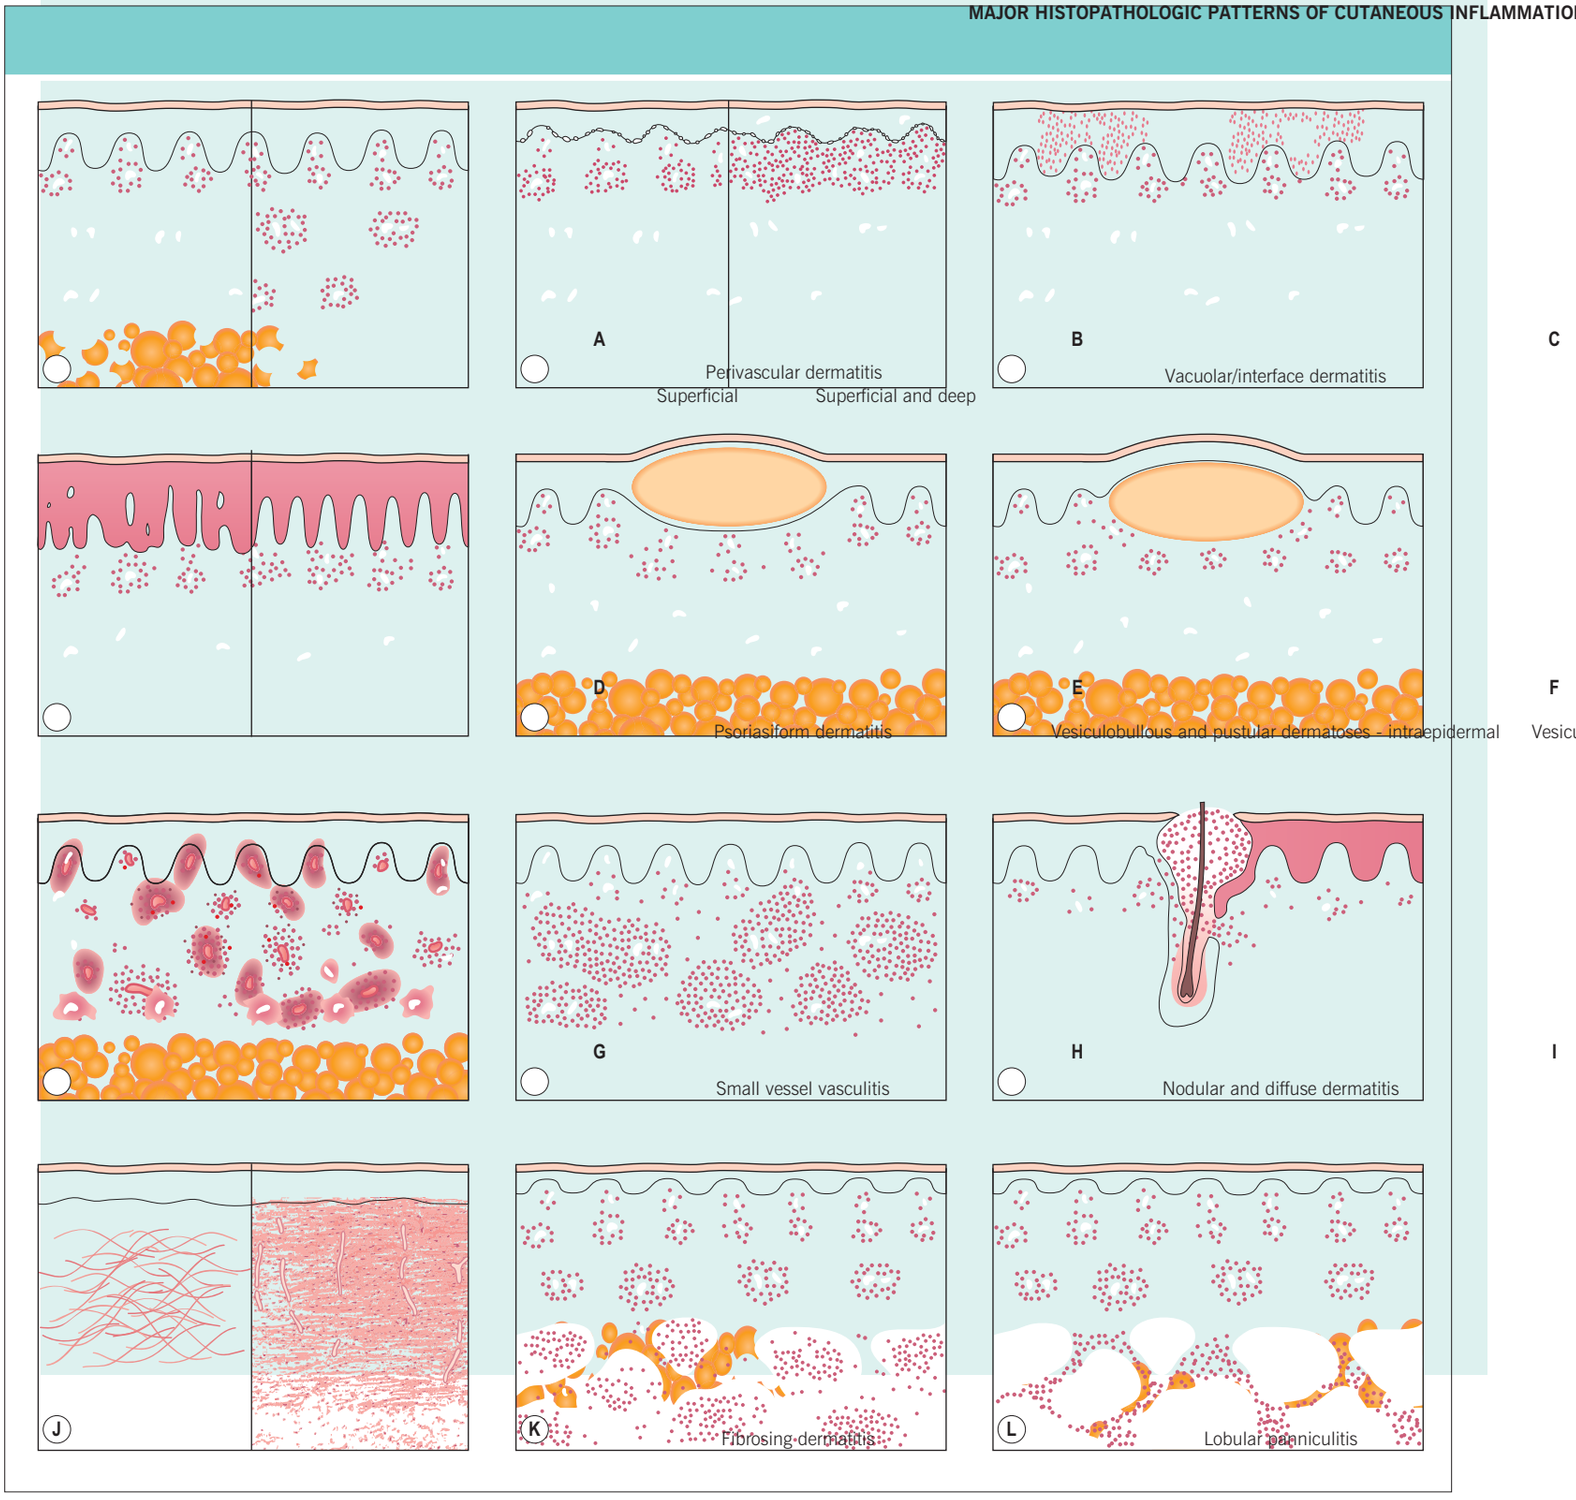

Fig. 0.13 Basic histopathologic patterns of cutaneous inflammation (based upon Ackerman's classification). Basic patterns of inflammation result primarily from the distribution of the inflammatory cell infiltrate within the dermis and/or the subcutaneous fat (e.g. nodular, perivascular). It also reflects the character of the inflammatory process itself (e.g. pustular), the presence of injury to blood vessels (e.g. vasculitis), involvement of hair follicles (e.g. folliculitis), abnormal fibrous dermal and/or subcutaneous tissue, and formation of vesicles and bullae. *Adapted from Ackerman AB. Histologic Diagnosis of Inflammatory Skin Diseases: A Method by Pattern Analysis. Philadelphia: Lea & Febiger, 1978.*

descriptors may vary, the basic principle is generally the same – once a major pattern has been identified, further histologic details are used to progressively, and more specifically, subcategorize the disease process until a final diagnosis is rendered.

The principal advantages of pattern analysis are that it is algorithmic and reproducible and serves to minimize personal subjectivity. However, the method has two important limitations; namely, it is based on artificial disease categories and does not include every single possible pattern. Furthermore, while pattern analysis clearly narrows the differential diagnosis, the final diagnosis may require clinical correlation or ancillary laboratory testing.

Ten patterns defined

Over the past several decades, a number of classification schema based upon pattern analysis have been proposed, with the number of patterns varying from as few as 9 up to 28 or even more. In this introductory chapter, 10 major patterns will be discussed.

Perivascular dermatitis

This common pattern is defined and recognized by the presence of an inflammatory infiltrate that is arranged primarily around dermal blood vessels (Fig. 0.14). Traditionally, perivascular dermatitis has been subdivided into "superficial" and "superficial and deep" variants, and while this division has some diagnostic value, histologically there is considerable overlap. In addition, inflammatory skin diseases can exhibit a spectrum of findings, depending in part on severity, duration and stage (acute vs chronic) of an individual lesion.

Once a perivascular pattern is identified (see Fig. 0.13A), the next step in the algorithm is to determine: (1) if there are accompanying epidermal changes; and (2) the types of inflammatory cell(s) present within the infiltrate, e.g. lymphocytes, neutrophils, eosinophils, plasma cells. There are disorders in which classically no detectable changes are seen within the epidermis, e.g. deep gyrate erythemas (see Ch. 19). Also, when an inflammatory process is just beginning or is resolving, epidermal changes may be subtle. A search is then required to detect a hint of *spongiosis* (intercellular edema of the epidermis), *parakeratosis* (aberrant retention of nuclei in the stratum corneum), extravasated erythrocytes, or subtle *interface* and *vacuolar changes* (see below), in an attempt to refine the diagnosis.

Interface dermatitis

This pattern is characterized by the presence of inflammation and/or degenerative change(s) at the dermal–epidermal junction (see Fig. 0.13B). Morphologically, this pattern may be subdivided into primarily *vacuolar* (degeneration of basilar keratinocytes with little or no inflammation; Fig. 0.15) versus primarily *lichenoid* (with lymphocytes directly engaged in the destruction of basilar keratinocytes; Fig. 0.16), but frequently there is overlap between these two categories.

It is important to remember that even though an entity has lichenoid features histologically (e.g. fixed drug eruption), that does not mean it must resemble lichen planus clinically. Also, some degree of lichenoid inflammation can be associated with a variety of benign and malignant neoplasms of the skin – e.g. solitary lichenoid keratosis and melanoma,

respectively. In these instances, it appears to represent an attempted immunological response to the tumor.

Spongiotic dermatitis

A large number of inflammatory skin diseases have histologic evidence of *spongiosis* (intraepidermal edema) that manifests as widened spaces between keratinocytes with elongation of intercellular bridges (see Fig. 0.13C), usually in association with *exocytosis* of lymphocytes (exit of inflammatory cells from the vasculature with migration into the epidermis). The degree of spongiosis may vary from microscopic foci to grossly visible vesicles and even intraepidermal bullae.

Spongiotic dermatoses may be further subdivided into acute, subacute and chronic forms. In acute spongiotic dermatitis, the spongiosis is often severe, sometimes resulting in microvesicles within the stratum corneum (Fig. 0.17). Parakeratosis often overlies subacute spongiotic dermatitis, while in chronic spongiotic dermatitis, spongiosis may actually be difficult to appreciate, being overshadowed by epidermal *acanthosis* (thickening of the epidermis). Also, a predominance of other types of inflammatory cells, such as eosinophils or neutrophils, in association with a spongiotic dermatitis may serve as a clue to a hypersensitivity component or infectious aspect to the disease, respectively.

Lastly, it is important to recognize that many dermatologic disorders with eczematous features, such as allergic contact dermatitis, atopic dermatitis, nummular dermatitis and seborrheic dermatitis, may have histologic evidence of spongiosis, but this pattern is not exclusive to those diseases. In other words, spongiosis may also be seen as a reactive epidermal component of other disorders that would be better classified as having another pattern (see Fig. 0.13).

Psoriasiform dermatitis

The term "psoriasiform" refers to a regular pattern of *epidermal hyperplasia* (elongation of the rete ridges; see Fig. 0.13D) that is observed not just in psoriasis, but also in a wide spectrum of longstanding conditions. Clinically, this group of disorders is characterized by thickened, scaly papules and plaques (Fig. 0.18). Psoriasiform dermatoses may be subdivided into those diseases that are exclusively psoriasiform, as well as those that are associated with another pattern (e.g. psoriasiform *and* lichenoid; psoriasiform *and* spongiotic).

Pseudoepitheliomatous hyperplasia represents a related, but exaggerated, irregular hyperplasia of the epidermis. It may occur in response to a range of insults to the skin, such as chronic rubbing or scratching in lichen simplex chronicus and prurigo nodularis, as well as various inflammatory, neoplastic and infectious skin diseases (e.g. hypertrophic lupus erythematosus, halogenodermas, chromoblastomycosis). As with spongiotic dermatitis, psoriasiform dermatitis is a histologic concept,

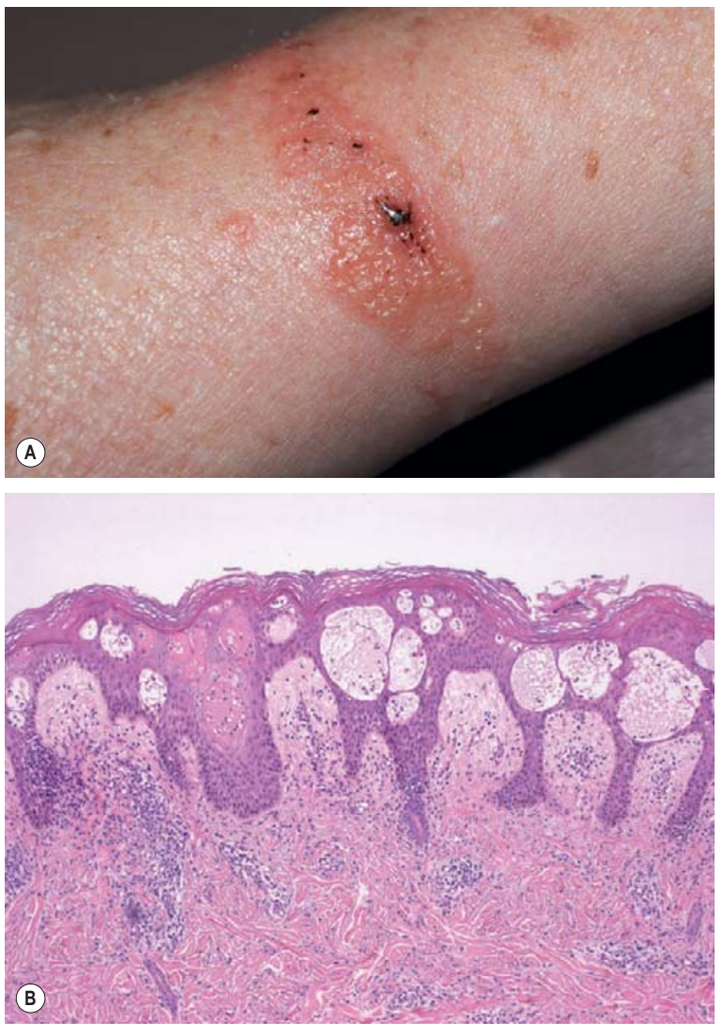

Fig. 0.17 Spongiotic dermatitis. A Acute allergic contact dermatitis to *Toxicodendron radicans* (poison ivy). The central black discoloration is due to the plant's resin. **B** Intercellular edema (spongiosis) and vesicle formation within the epidermis. Lymphocytes are also seen in both the epidermis and dermis. *A, Courtesy, Kalman Watsky, MD, B, Courtesy, James Patterson, MD.*

not a specific clinical diagnosis. Its presence mandates consideration of a variety of skin diseases that share this constellation of histopathologic findings.

Vesiculobullous and pustular dermatoses

Intraepidermal (see Fig. 0.13E)

The concept of intraepidermal vesiculation due to spongiosis has been addressed above, but there exist other disease mechanisms that may lead to intraepidermal vesicles or bullae, e.g. acantholysis, ballooning degeneration. *Acantholysis* refers to discohesion of keratinocytes as a consequence of the disruption of desmosomes (intercellular connections) and this can lead to an intraepidermal vesicle or bulla (Fig. 0.19). Although acantholysis may occur at any level of the epidermis, the location of the blister is often used as a clue to the underlying disorder; for example, superficial (subcorneal) acantholysis favors pemphigus foliaceus, while acantholysis in the deeper aspects of the epidermis is more characteristic of pemphigus vulgaris. Cytotoxic events such as herpes virus infection may also yield an intraepidermal vesicle secondary to ballooning degeneration.

An intraepidermal accumulation of neutrophils may be seen in a variety of infectious and non-infectious skin diseases, and this pustule formation is viewed as a subcategory of vesiculobullous dermatoses. In early pustule formation, neutrophils are scattered within the lower portion of the epidermis, whereas later, an accumulation is noted in the upper epidermis (Fig. 0.20). In a resolving pustule, the neutrophils may even appear within scale-crust in the cornified layer.

In both vesiculobullous and pustular dermatoses, autoimmune and non-autoimmune mechanisms may be indistinguishable histopathologically, e.g. subcorneal pustular dermatosis versus IgA pemphigus. As a result, direct and indirect immunofluorescence studies are often of great utility in determining the precise diagnosis.

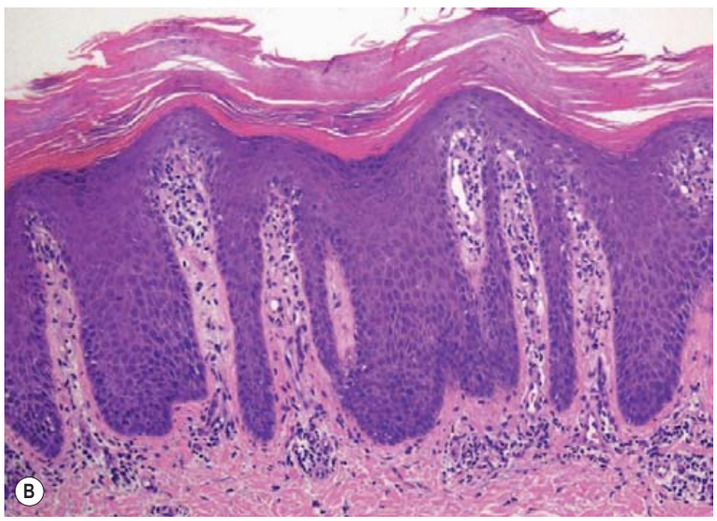

Fig. 0.18 Psoriasiform pattern. A Plaque of psoriasis vulgaris with silvery scale. **B** Regular epidermal hyperplasia and elongated dermal papillae with thin suprapapillary plates and confluent parakeratosis. The parakeratosis represents the histologic correlate of the visible scale. *A, Courtesy, Julie V Schaffer, MD.*

Subepidermal (see Fig. 0.13F)

In this subcategory, vesicle or bulla formation occurs at the junction between the epidermis and dermis (Fig. 0.21), or between the mucosa and submucosa of mucous membranes. Such clefting can be the result of autoantibodies targeting specific components of the dermal–epidermal junction (e.g. collagen XVII in bullous pemphigoid or linear IgA bullous dermatosis) or a dermal inflammatory or toxic/metabolic insult, such as in bullous cellulitis and porphyria cutanea tarda, respectively.

Within subepidermal blister cavities, the number of inflammatory cells can vary from very few, which is more characteristic of toxic insults such as porphyria cutanea tarda, to numerous, as in the majority of cases of inflammatory bullous pemphigoid. The findings often reflect the nature and mechanism of the blistering process. It is also helpful to identify the type of inflammatory cell present, e.g. eosinophil versus neutrophil, as this can serve as a clue to the diagnosis.

However, because there is considerable histologic overlap amongst the underlying disorders, the final diagnosis must depend upon cumulative information, including direct and indirect immunofluorescence microscopy, ELISA, immunoblotting, and, of course, clinicopathologic correlation.

Vasculitis/pseudovasculitis

Vasculitis refers to inflammatory damage to and destruction of blood vessels, leading to the deposition of fibrin and/or thrombus formation (see Fig. 0.13G). The histopathologic classification of vasculitides is based on the size of the vessel involved (small, medium-sized or large vessel vasculitis; see Ch. 24) and the predominant inflammatory cell mediating the damage (neutrophils or lymphocytes more often than eosinophils or histiocytes).

In dermatopathology, the most common form of vasculitis is *leukocytoclastic vasculitis* (Fig. 0.22), a process mediated by neutrophils and primarily affecting the post-capillary venule. Leukocytoclastic vasculitis is initiated by the deposition of circulating immune complexes within and around vessel walls, with neutrophils later recruited to the site of deposition. This is followed by *leukocytoclasia* (nuclear fragmentation) and the deposition of fibrin during the ensuing vessel destruction. In some longstanding disorders that feature leukocytoclastic vasculitis, such as erythema elevatum diutinum, concentric fibrosis may evolve over time.

The concept of *lymphocytic vasculitis* is less well defined, but it is a term used to denote an inflammatory process in which there may be some fibrinoid necrosis of the vessel wall but the mediating cell is a lymphocyte. It is postulated as a mechanism chiefly in disorders such as pernio, Sneddon syndrome, and pityriasis lichenoides et varioliformis acuta, although the latter lacks fibrinoid necrosis.

Granulomatous vasculitis is defined by the presence of histiocytes (macrophages) within and around blood vessel walls in association with fibrin and/or degenerative and necrotic changes. Like lymphocytic vasculitis, it is a pattern observed in a restricted spectrum of diseases, often in association with autoimmune connective tissue diseases, and it may very well represent a later evolutionary stage of another form of vasculitis, either leukocytoclastic or lymphocytic.

In *medium-sized vessel cutaneous vasculitis*, there is involvement of the blood vessels at the dermal–subcutaneous junction and within the septa of the subcutaneous fat (Fig. 0.23). For dermatopathologists, polyarteritis nodosa is the most commonly encountered entity in this category. Temporal arteritis represents a form of large vessel vasculitis, but biopsies of this artery are rarely done by dermatologists.

Pseudovasculitis refers to a group of heterogeneous, non-inflammatory conditions that are broadly classified into disorders that primarily cause hemorrhage (*non-inflammatory purpuras*) and those that primarily occlude vessels (*occlusive vasculopathies*) (see Chs 22 & 23). Many of these disorders involve dermal hemorrhage and/or occlusion of vessels by emboli, thrombi, vasospasm, fibro-intimal-medial hyperplasia secondary to vessel trauma, or non-inflammatory

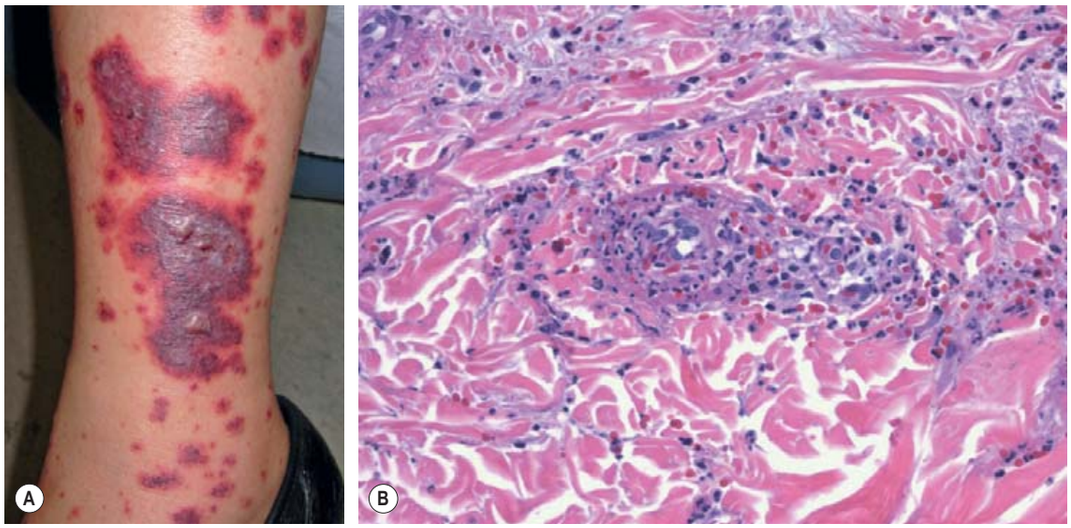

Fig. 0.22 Small vessel vasculitis. **A** Inflammatory palpable purpura of the leg. **B** Perivascular and interstitial infiltrate of neutrophils with nuclear dust (leukocytoclasia). Fibrin within the vessel wall and extravasation of erythrocytes is also seen. *B, Courtesy, James Patterson, MD.*

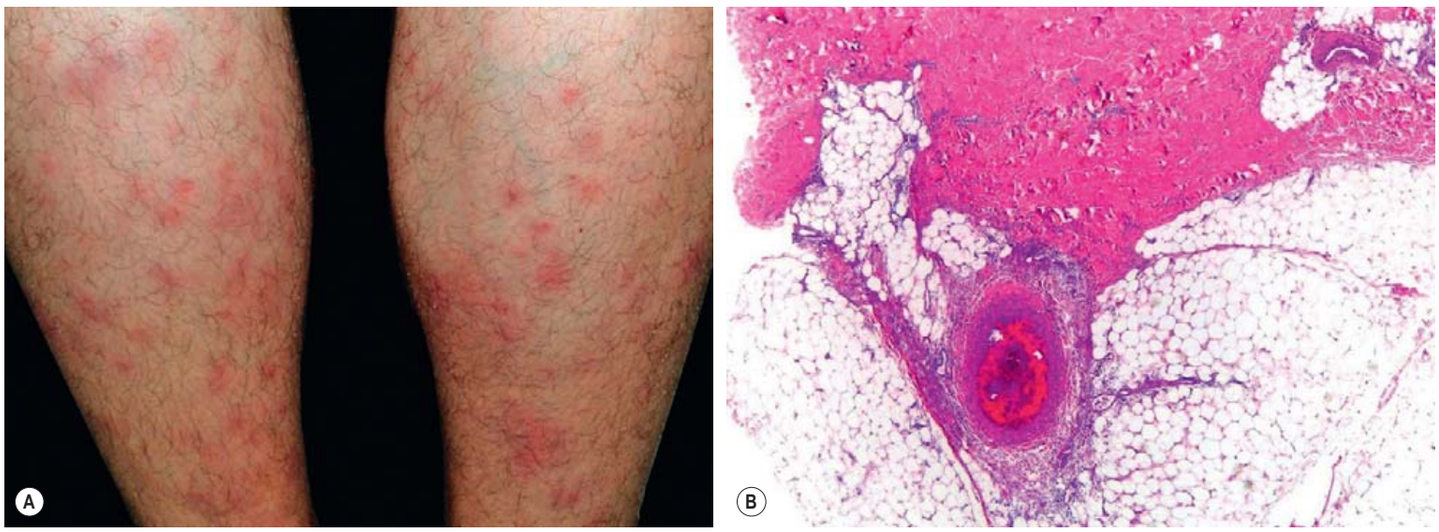

Fig. 0.23 Medium-sized vessel vasculitis. **A** Nodules of cutaneous periarteritis nodosa. **B** Inflammation and destruction of a subcutaneous arteriole.

vessel wall pathology such as calcification, cholesterol emboli, and amyloid deposition.

Nodular and diffuse dermatitis

Nodular dermatitis is somewhat similar to perivascular dermatitis, but the inflammatory infiltrate has enlarged and coalesced to form one or multiple nodules within the dermis (see Fig. 0.13H). Further expansion of the nodules can essentially fill the entire dermis, yielding the diffuse pattern (Fig. 0.24).

The nodular and diffuse pattern of dermatitis may be further subdivided, based chiefly upon the predominant inflammatory cell type. When *histiocytes* (macrophages) predominate in a nodular or diffuse infiltrate in one or more foci, the pattern is defined as *granulomatous*. Typically, in *foreign body granulomas*, the macrophages, over time, tend to fuse and multinucleate rather than divide, leading to foreign body giant cells. Two other forms of multinucleated macrophages (i.e. giant cells) are frequently observed in granulomatous dermatitides, namely the *Langhans type* and the *Touton type* of giant cells. Although none of these giant cells is pathognomonic or exclusive to just one disease, some disorders are characterized by the conspicuous presence of one or more of these three types of giant cells (e.g. Touton giant cells in juvenile xanthogranuloma).

Based on the constituent cells and other distinctive features, four major histopathologic types of granulomas can be identified (Fig. 0.25):

- *Tuberculoid* granulomas (see Fig. 0.25A) – comprised of epithelioid histiocytes, including multinucleate forms, surrounded by a dense infiltrate of lymphocytes and plasma cells; caseation may be present centrally. The *Langhans type* of multinucleated giant cell, with a horseshoe-like arrangement of nuclei, may be observed within tuberculoid granulomas. This type of granuloma is associated with cutaneous infections (e.g. *Mycobacterium tuberculosis*) and is seen in lupus miliaris disseminatus faciei.
- *Sarcoidal* granulomas (see Fig. 0.25B) – composed of discrete collections of epithelioid macrophages with only a sparse number of peripheral lymphocytes or plasma cells (i.e. a "naked" granuloma). While multinucleated cells may be identified, no particular type is associated with sarcoidal granulomas.
- *Palisaded ("necrobiotic")* granulomas (see Fig. 0.25C) – characterized by an infiltrate of epithelioid macrophages aligned in a rim around a central area of *necrobiosis* (altered connective tissue with different tinctorial qualities such as increased basophilia or eosinophilia). Of note, not all palisaded granulomas

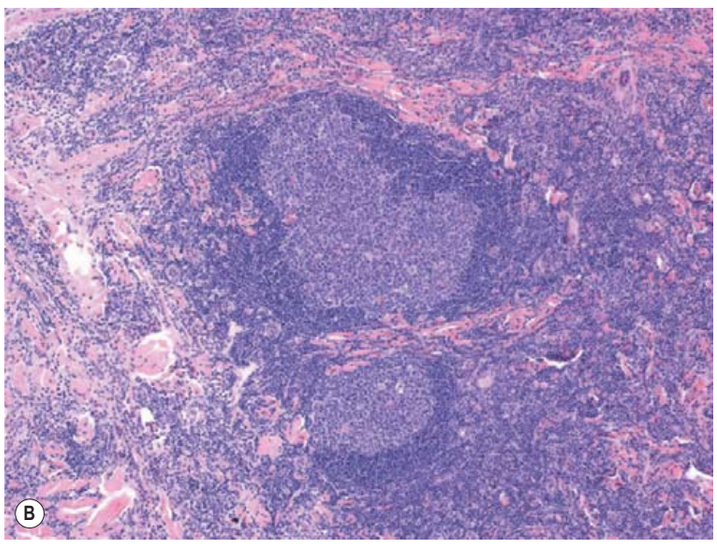

Fig. 0.24 Nodular and diffuse dermatitis, lymphocytic. A Cutaneous lymphoid hyperplasia. **B** Dense dermal infiltrate containing lymphoid follicles with formation of germinal centers. *B, Courtesy, James Patterson, MD.*

are truly *palisaded* (with a rim of aligned histiocytes), and in fact, the histiocytes may also be distributed interstitially, in strands or cords between and amongst collagen bundles (*interstitial granuloma*).

- *Suppurative* granulomas (see Fig. 0.25D) – typified by collections of neutrophils within, and sometimes among or surrounding, aggregates of epithelioid macrophages. Suppurative granulomas may be induced by infectious agents and foreign body material.

In general, all granulomatous infiltrates, but particularly tuberculoid, sarcoidal and suppurative forms, require exclusion of infectious agents and/or foreign material by special stains, immunohistochemical stains, fresh tissue culture and/or PCR, and polarization microscopy.

Nodular and diffuse infiltrates composed predominantly of histiocytes may also be further subcategorized into *Langerhans cell* and *non-Langerhans cell histiocytoses* (see Ch. 91). In Langerhans cell histiocytosis, the primary cells have the classic reniform (kidney bean-shaped) nuclei and characteristic immunohistochemical staining pattern, i.e. $S100^+$ and $CD1a^+$. Non-Langerhans histiocytes, on the other hand, have a range of both cytologic features (vacuolated, spindle-shaped, foamy, scalloped, and oncocytic) and types of admixed multinucleated giant cells (Touton type, Langhans type, foreign body type); sometimes, the histiocytes and giant cells display a homogenous "ground glass" cytoplasm. These cells are generally $S100^-$,$CD1a^-$, and $CD68^+$ (a nonspecific marker of histiocyte lineage). The varying histopathologic features of the non-Langerhans histiocytoses may possibly be related to the actual physiologic function of histiocytes within the granuloma[26].

Lastly, *xanthomas* are characterized by the accumulation of lipophages, or foamy histiocytes filled with lipid, within the dermis (see Ch. 92). It is the lipid content that imparts the yellowish hue to the lesions (Fig. 0.26). Cutaneous xanthomas may take various forms, including widespread papules (eruptive), nodules (tuberous or tendinous), and planar (xanthelasma, palmar).

Folliculitis/perifolliculitis

Folliculitis (inflammation of a hair follicle) is defined by the presence of inflammatory cells within the wall and lumen of a hair follicle (see Fig. 0.13I); perifolliculitis refers to the presence of similar cells in the adjacent dermis. Folliculitis may be due to infections (bacterial, fungal, viral, *Demodex*), drugs, occlusion, or unknown etiologies (e.g. eosinophilic folliculitis).

The classification of folliculitis (and perifolliculitis) can be made on the basis of the primary inflammatory cell (lymphocytes, neutrophils or eosinophils), the nature of the underlying pathologic process (e.g. dermatophyte infection), the temporal course (acute versus chronic), and the site of involvement along the length of the hair follicle. If the inflammatory process is severe and/or irreversibly damages epithelial stem cells located in the bulge region destruction of the hair follicle will invariably ensue with resultant scarring ("scarring alopecia"; Fig. 0.27).

Fibrosing/sclerosing conditions

Fibrosing conditions include a wide spectrum of disorders that result from altered collagen production or destruction (or both), typically related to injury or an autoimmune connective tissue disease (see Fig. 0.13J). Histopathologically, the pattern is characterized by either: (1) abnormal fibrous dermal (and sometimes subcutaneous) tissue with an increased number of fibrocytes and increased, but rather unremarkable, collagen (*fibrosis*); or (2) homogenized, abnormally enlarged and eosinophilic collagen with a paucity of admixed fibroblasts (*sclerosis*). An example of the former is nephrogenic systemic fibrosis, and the latter, morphea (Fig. 0.28) and scleroderma. Obviously, overlap between the two ends of the spectrum may occur.

Panniculitis

Panniculitis represents inflammation of the subcutis (see Fig. 0.13K,L) and it encompasses a wide range of disease processes (see Ch. 100). The diagnosis of panniculitides is difficult for both clinicians and dermatopathologists because the clinical presentation is often nonspecific and the histopathologic changes vary markedly over time and may also be rather nonspecific, especially in later stages. Adding to the challenge, biopsy specimens are often inadequate, commonly being too superficial in nature, too narrow in breadth, or too badly crushed by forceps to render a diagnosis with certainty.

An important first step in the subdivision of panniculitides is determination of the predominant location of the cellular infiltrate (Figs 0.29 & 0.30). That is, does it affect primarily the fat lobules versus the septa between the lobules versus both (mixed)? Secondly, there should be an assessment as to whether a coexisting vasculitis is present or not, and if vasculitis is detected, the size and type of the vessels involved must be determined.

With panniculitides, one must be keenly aware of the type and quality of the inflammatory infiltrate, as well as peculiarities in the pattern of fat necrosis. Early in the course of the most common form of panniculitis, erythema nodosum, the infiltrate may contain a significant number of acute inflammatory cells (neutrophils in particular), but in later stages, the infiltrate is composed chiefly of chronic inflammatory cells (lymphocytes, histiocytes and plasma cells; see Fig. 0.29). If mononuclear cells are present, the degree of cytologic atypia should be assessed, as subcutaneous panniculitis-like T-cell lymphoma may mimic an inflammatory panniculitis. Lastly, peculiarities of fat necrosis, such as the hyaline quality of the necrosis in lupus panniculitis, the basophilic saponification in pancreatic panniculitis (see Fig. 0.30), or the pseudomembranous degeneration of lipodermatosclerosis, should be appreciated.

INVISIBLE DERMATOSES		
Microanatomic site	**Abnormality**	**Example dermatoses**
Stratum corneum, granular cell layer	Superficial infections	Pityriasis (tinea) versicolor Dermatophytosis
	Keratinization disorders	Ichthyosis Disseminated superficial actinic porokeratosis
Basilar layer of epidermis	Pigmentation disorders	Vitiligo Café-au-lait macule
Superficial dermis	Infestations	Onchocerciasis
	Mast cell infiltration	Telangiectasia macularis eruptiva perstans
	Deposition of endogenous substances	Macular amyloidosis
Superficial and deep dermis	Deposition of exogenous substances	Argyria (basement membrane of epithelial structures)
	Deposition of endogenous substances	Dermal melanocytosis
	Collagen abnormalities	Collagenoma Atrophoderma
	Elastic tissue abnormalities	Nevus elasticus Anetoderma (non-inflammatory)
Absence of normal epithelial structure	Deficiency of eccrine sweat glands	Hypohidrotic ectodermal dysplasia

Table 0.9 Invisible dermatoses.

As is the case for granulomatous infiltrates, panniculitis requires a low threshold for performing special stains to exclude an infectious etiology and for using polarized light examination to identify foreign material.

Invisible dermatoses

Occasionally, one encounters a subcategory of dermatoses that actually lack a pattern of histopathology, and these conditions are often referred to collectively as "invisible dermatoses" (Table 0.9). From the perspective of the dermatopathologist, invisible dermatoses represent a group of skin diseases where a compelling case for disease exists clinically, but for which the histologic examination is rather unremarkable, i.e. the microscopic findings differ minimally from those of normal skin[27,28].

Among the "invisible dermatoses" are: (1) diseases with subtle pathologic changes and diseases requiring special stains to visualize diagnostic pathology (e.g. disorders of elastic and collagen tissue without significant fibrosis or sclerosis); (2) diseases with focal pathologic processes requiring serial tissue levels to identify diagnostic features (e.g. polyarteritis nodosa); and (3) diseases that require precise clinical information and/or strict clinical correlation to make the diagnosis (e.g. vitiligo, melasma, telangiectasia macularis eruptiva perstans [a form of mastocytosis]).

Because the histopathologic changes in "invisible dermatoses" are subtle and vexing, upon recognition a methodical analysis is recommended that includes: careful searching for diagnostic pathology at all levels of the skin (cornified layer, epidermis, papillary dermis, reticular dermis, hypodermis, adnexa); use of special stains where appropriate and necessary (e.g. markers for melanocytes and stains for melanin in suspected vitiligo); and comparison of the specimen with normal skin.

Deposition of Materials within the Skin

Occasionally, materials not normally present in the skin are deposited, either by exogenous or metabolic insult, and this can be appreciated histologically. In some patients, there is aberrant deposition of endogenously produced materials, such as uric acid in gouty tophi or light chain-derived amyloid due to an underlying plasma cell dyscrasia, whereas in others, exogenous material has been purposefully or accidentally inoculated into the skin (e.g. cosmetic filler material, tattoo pigment). These materials may accumulate within the dermis, the subcutaneous fat, or both. Deposits of some materials, such as the silver in patients with argyria, may be limited to cutaneous adnexa. Use of polarized light or darkfield microscopy (where light enters tissue at an angle that is not perpendicular to the slide) may be of use in identifying foreign material.

Some deposits engender a granulomatous inflammatory reaction (see Ch. 94), while others evoke no appreciable reaction at all. Deposited material is usually visualized during microscopic examination, but it may be removed during processing (e.g. siliconosis), leaving only characteristic "empty spaces" to suggest its clinical presence. Special stains may be helpful for precise identification, depending upon the suspected nature of the material.

Histologic Stains

The standard stain in dermatopathology is *hematoxylin and eosin*, ubiquitously referred to as "H&E". H&E staining yields a predictable pattern of staining, with the hematoxylin marking basophilic structures, such as cellular nuclei and the granular layer of the epidermis, a characteristic blue–purple, and eosinophilic structures, such as cytoplasm, collagen, muscle, nerve and fibrin, pink–red.

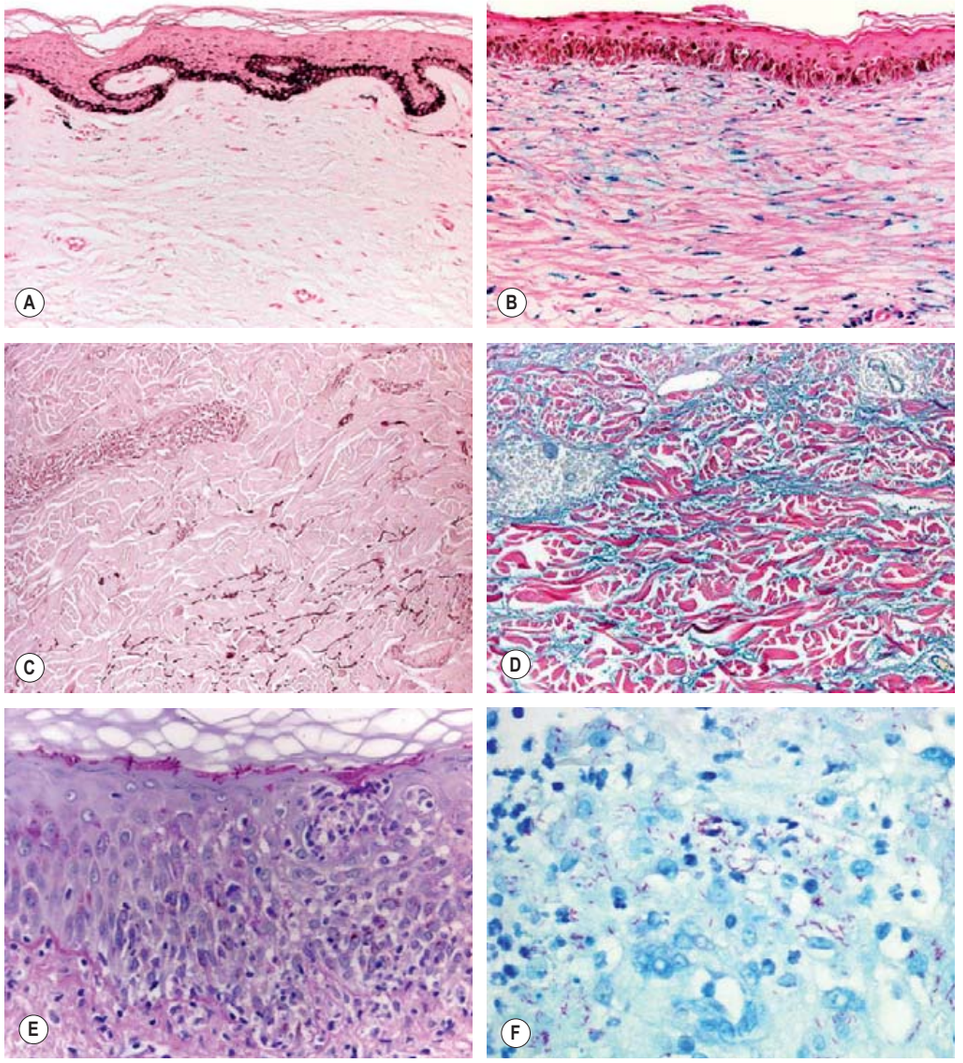

Fig. 0.31 Examples of histochemical stains. Often, histochemical stains reveal structures or substances (e.g. pigments, connective tissue elements, microorganisms) that cannot be clearly seen on H&E-stained sections. **A** Enhancement of increased *melanin* within the basal layer of the epidermis in genital melanosis (black color) – Fontana–Masson stain. **B** Demonstration of *iron* (hemosiderin) within dermal macrophages in purpura (blue color) – Prussian blue (Perls' iron) stain. **C** A near absence of dermal *elastic fibers* (upper left), compared to normal elastic fibers in the lower right, in anetoderma (black color) – orcein elastic tissue stain. **D** Increased *mucin* in the dermis in reticular erythematous mucinosis (blue color) – colloidal iron stain. **E** *Fungal hyphae* within the stratum corneum in dermatophytosis (red color) – PAS stain (also note the staining of the basement membrane zone). **F** *Mycobacteria* within a granulomatous infiltrate in cutaneous tuberculosis (red–violet color) – Fite stain (modified acid-fast stain). *A–E, Courtesy, Lorenzo Cerroni, MD. F, Courtesy, Karen Warschaw, MD.*

Although H&E staining alone enables the histopathologic diagnosis of many skin diseases, some disorders require additional "special stains" to facilitate a diagnosis[29]. For example, elastic tissue, unless significantly altered by ultraviolet radiation or calcium deposits, does not stain with H&E, and special stains such as Verhoeff–van Gieson are required to identify alterations in these fibers (e.g. in anetoderma; Fig. 0.31). Similarly, special stains exist to screen for the presence of infectious agents, such as the Brown–Brenn stain (a modified tissue Gram stain) for bacteria, the periodic acid–Schiff (PAS) or Gomori methenamine silver stain for fungus, and the Ziehl–Neelsen or Fite stain for mycobacteria (see Fig. 0.31). Additional special stains may be utilized to determine the type of infiltrating cell, such as the Giemsa or chloroacetate esterase stain for mast cells. Table 0.10 lists the more commonly employed histochemical ("special") stains used in dermatopathology.

Immunohistochemical Testing

Immunohistochemistry (IHC) is the use of immunologic techniques to identify cellular antigens (proteins) not visible on routine H&E-stained sections. It exploits the principle of antibodies binding specifically to antigens in biological tissues. Visualizing this antibody–antigen interaction may be accomplished in a number of ways. Most commonly, the antibody is conjugated to an enzyme that can catalyze a color-producing reaction when the antibody–enzyme conjugate is bound to the appropriate antigen within tissue; the enzyme is often peroxidase, hence the older terminology, immunoperoxidase technique.

While IHC is most often used to characterize the cellular lineage of neoplasms, it is also helpful in assessing the biological behavior of tumors and in identifying specific infectious agents that are not discernible or are difficult to detect in routine H&E-stained sections (Fig. 0.32)[30]. IHC is also used as a research tool to determine the distribution and localization of specific biomarkers and proteins within biological tissue.

When used rationally and appropriately, IHC is a formidable tool in diagnostic dermatopathology, but if used without insight or excessively, it can be misleading and economically wasteful. Important factors to consider when using IHC include the following: (1) practically no antibody is specific for a certain cell type, and therefore a panel of antibodies should be employed to avoid premature, incomplete or erroneous conclusions; (2) a differential diagnosis must be constructed prior to ordering an antibody panel so that the requested antibodies are appropriate; and (3) no antibody can differentiate irrefutably between a benign and malignant neoplasm (although, on occasion, evidence of an increased proliferative index or the aberrant expression of certain proteins may *support* such a conclusion).

A list of antibodies used most often in dermatopathology, the corresponding antigens, and the disease processes suggested by positive reactions is provided in Table 0.11. When reading about specific disease processes in other sections of this book, pay particular attention to the use of IHC techniques.

COMMONLY EMPLOYED SPECIAL STAINS IN DERMATOPATHOLOGY			
Stain	**Structures identified**	**Color**	**Application**
Alcian blue (pH 2.5)	Acid mucopolysaccharides (glycosaminoglycans)	Light blue	Mucinoses Lupus erythematosus Extramammary Paget's disease Mucopolysaccharidoses
Alcian blue (pH 0.5)	Sulfated mucopolysaccharides (heparin sulfate, chondroitin sulfate)	Blue	
Chloroacetate esterase (Leder)	Myeloid cells and mast cells	Red	Neutrophilic dermatoses Malignant hematopoietic infiltrates Mastocytosis
Colloidal iron	Acid mucopolysaccharides	Blue	Mucinoses Lupus erythematosus Extramammary Paget's disease
Congo red	Amyloid	Red; green in polarized light	Amyloidosis
Crystal violet	Acid mucopolysaccharides and amyloid	Metachromatically purple with blue background	Mucinoses Amyloidosis
Fite–Faraco	*Mycobacterium leprae*	Red	Leprosy (Hansen's disease)
Fontana–Masson (argentaffin)	Melanin	Black	Distinction between iron and melanin Discoloration due to drugs (e.g. minocycline) Evaluation of vitiligo
Giemsa	Nuclei of cells, microorganisms	Blue	Leishmaniasis Histoplasmosis Granuloma inguinale
	Mast cell granules	Metachromatically purple	Urticaria Mastocytosis
Gomori methenamine silver	Fungal cell walls	Black	Mycotic infections
Gram (Brown–Brenn)	Gram-positive bacteria	Blue	Bacterial infections
	Gram-negative bacteria	Red	Bacterial infections
Masson's trichrome	Smooth muscle	Pink	Useful for distinguishing leiomyomas from dermatofibromas and neural tumors
	Collagen	Blue/green	Useful in evaluating the characteristics of dermal collagen, e.g. perforating disorders
Mucicarmine	Epithelial mucin (acid or neutral mucopolysaccharides)	Red	Usually used for sialomucin (e.g. adenocarcinoma, Paget's disease) and the capsule of *Cryptococcus neoformans*
Myeloperoxidase	Immature myeloid cells	Orange	Leukemic infiltrates
Orcein (acid orcein-Giemsa)	Collagen	Pink	Elastic tissue disorders (e.g. PXE, anetoderma)
	Elastic tissue	Dark brown	
	Muscle and nerves	Yellow	
Pagoda	Amyloid	Orange	Amyloidoses
Periodic acid–Schiff (PAS)	Glycogen, fungal walls, neutral mucopolysaccharides, fibrin, basement membranes, many clear cell neoplasms	Red	Used for diagnosis of fungal infections; also to identify a thickened epidermal basement membrane in lupus erythematosus and the thickened vascular walls in porphyria cutanea tarda
Perls' iron (Prussian blue)	Hemosiderin Ferric ions	Blue	Useful for identifying iron as the source of pigment
Sudan black	Lipids (in frozen sections or formalin-fixed, unprocessed tissue)	Black	Xanthomatoses Storage diseases (e.g. Fabry disease)
Sudan orange	Lipids (in frozen sections or formalin-fixed, unprocessed tissue)	Orange	Xanthomatoses Storage diseases
Thioflavin T	Amyloid	Yellow–green by fluorescence microscopy	Amyloidoses
Truant (auramine-rhodamine)	Acid-fast organisms	Reddish-yellow by fluorescence microscopy	Mycobacterial infections
Toluidine blue	Acid mucopolysaccharides and mast cell granules	Metachromatically purple	Mastocytosis

Table 0.10 Commonly employed special stains in dermatopathology. In parentheses are alternative names or variations of the stain. PXE, pseudoxanthoma elasticum.

Continued

COMMONLY EMPLOYED SPECIAL STAINS IN DERMATOPATHOLOGY			
Stain	**Structures identified**	**Color**	**Application**
Verhoeff–Van Gieson or Weigert	Collagen	Pink to red	Elastic tissue disorders (e.g. PXE, anetoderma, mid-dermal elastolysis)
	Elastic tissue	Black	
	Muscle and nerves	Yellow	
Von Kossa	Calcium salts	Black	Pseudoxanthoma elasticum (oxalate salts may not stain with this method)
Warthin–Starry (modified Steiner)	Bacteria	Black	Granuloma inguinale Syphilis (and other diseases caused by spirochetes) Rhinoscleroma Bacillary angiomatosis
Ziehl–Neelsen	Acid-fast bacteria	Red	Mycobacterial infections

Table 0.10 Commonly employed special stains in dermatopathology (cont'd). In parentheses are alternative names or variations of the stain. PXE, pseudoxanthoma elasticum.

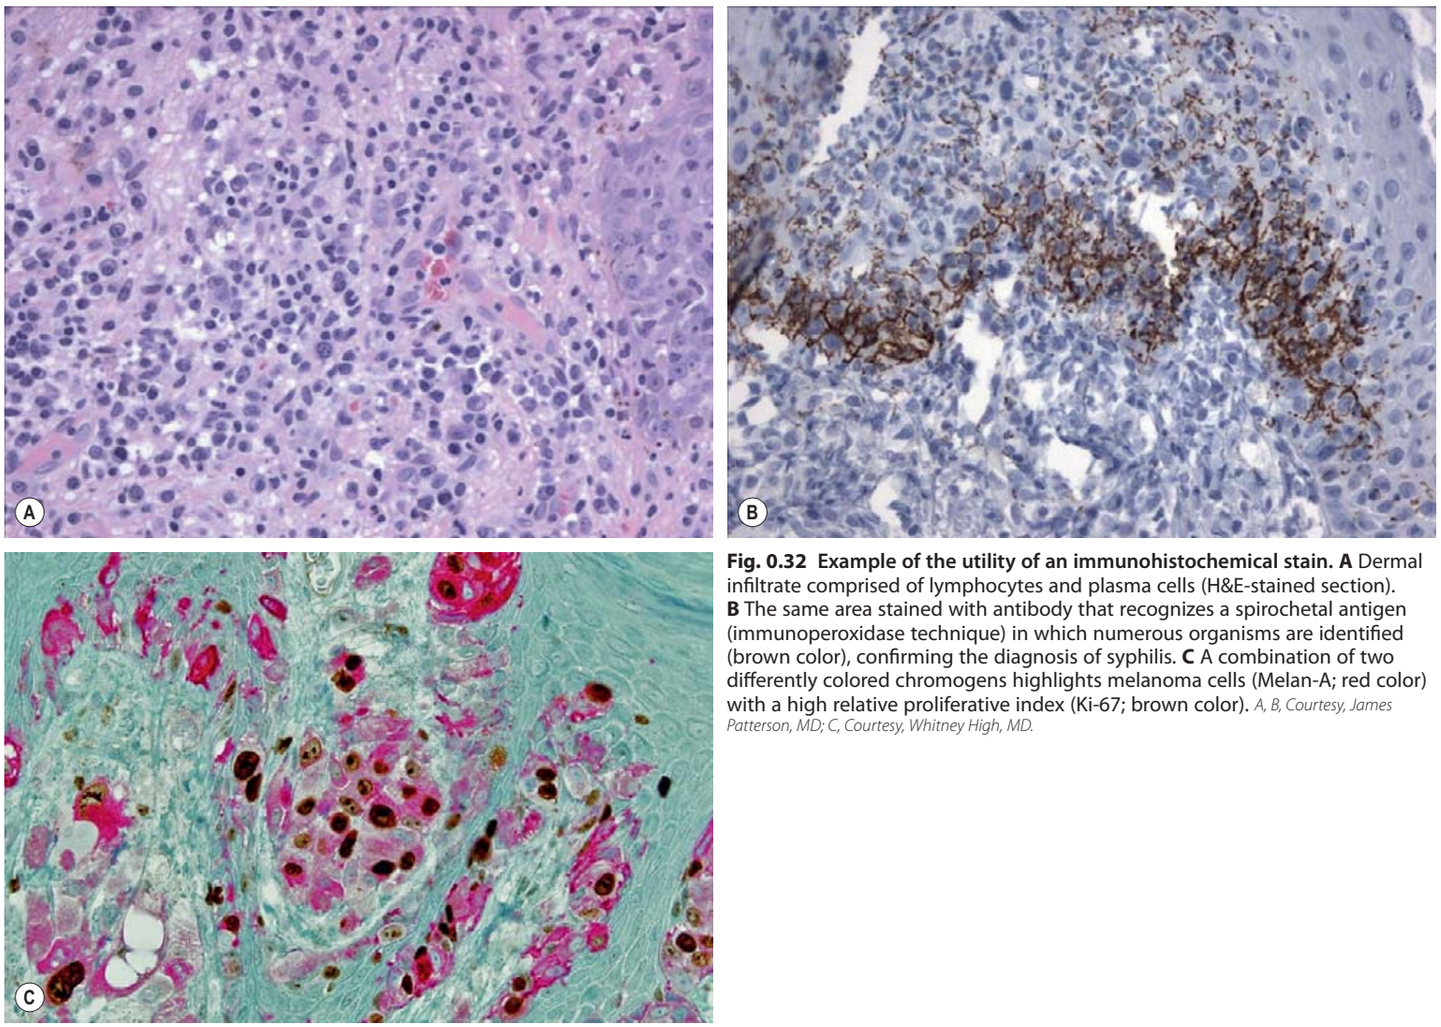

Fig. 0.32 Example of the utility of an immunohistochemical stain. A Dermal infiltrate comprised of lymphocytes and plasma cells (H&E-stained section). **B** The same area stained with antibody that recognizes a spirochetal antigen (immunoperoxidase technique) in which numerous organisms are identified (brown color), confirming the diagnosis of syphilis. **C** A combination of two differently colored chromogens highlights melanoma cells (Melan-A; red color) with a high relative proliferative index (Ki-67; brown color). *A, B, Courtesy, James Patterson, MD; C, Courtesy, Whitney High, MD.*

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
	EPITHELIAL MARKERS	
Bcl-2	• Protein product of an oncogene that negatively regulates programmed cell death (apoptosis) • Expressed in the basal layer of the epidermis and in lymphoid cells (see below)	• Sometimes useful in distinguishing basal cell carcinoma from trichoepithelioma • Sometimes useful in suggesting a systemic form of B-cell lymphoma when there is cutaneous involvement
CEA (carcinoembryonic antigen)	• A protein expressed by a variety of tissues, from gastrointestinal cells to skin adnexa	• Expressed in eccrine and apocrine epithelium • Paget's disease (mammary and extramammary), although somewhat supplanted by CK 7 stain
CK 5/6	• Intermediate-sized basic keratins • Expressed in the basal layer of stratified squamous epithelia	• Spindle cell squamous cell carcinoma • May aid in distinguishing primary carcinomas of the skin from metastatic carcinoma
CK 7	• Low-molecular-weight cytokeratin	• Expressed in eccrine and apocrine epithelium • Paget's disease (mammary and extramammary) • Cutaneous metastases of breast carcinoma
CK 20	• Low-molecular-weight cytokeratin • Expressed in simple epithelia and Merkel cells	• Sometimes expressed (along with CK 7) in metastatic transitional cell carcinoma
EMA (epithelial membrane antigen)	• High-molecular-weight transmembrane glycoprotein expressed in many epithelial cells	• Often stains malignant eccrine and apocrine tumors • Stains most sebaceous glands
GCDFP-15 (gross cystic disease fluid protein-15)	• Expressed by apocrine glands, eccrine glands (variable), minor salivary glands, bronchial glands, metaplastic epithelium of the breast, benign sweat gland tumors of the skin, and the serous cells of the submandibular gland	• Breast carcinoma • Sweat gland carcinoma with apocrine differentiation
P53	• Protein product of the tumor suppressor gene *TP53* that is involved in regulation of the cell cycle	• Aberrant nuclear expression may be seen in: sun-damaged skin (confined to the basilar layer); actinic keratoses (some suprabasilar staining); squamous cell carcinoma *in situ* (full-thickness staining); and some invasive squamous cell carcinomas
P63	• P53 homolog that acts as a transcription factor, with roles in regulating differentiation and development of epithelia as well as the cell cycle • Expressed in the basal layer of the epidermis and cutaneous adnexa	• Spindle cell squamous cell carcinoma • Undifferentiated carcinomas • Adnexal carcinomas
Pancytokeratins AE1/AE3	• Mixture of low- and high-molecular-weight cytokeratins	• Screening tumors for an epithelial origin • Useful for squamous cell carcinomas
CK903 (34βE12)	• High-molecular-weight cytokeratin	• Spindle cell squamous cell carcinoma • May aid in distinguishing primary cutaneous carcinomas from metastases
	MELANOCYTIC AND NEURAL MARKERS	
HMB45	• Glycoprotein present in premelanosomes and melanosomes (Pmel17/gp100) • Matrix protein expressed in melanocytes that are synthesizing melanin	• Melanocytic nevi and melanomas (highly specific) • PEComas • Diminished staining with dermal descent favors benign tumors
MART-1/Melan-A	• Protein involved in melanosome structure and maturation • An antigen present on melanocytes and melanoma cells • Recognized by cytotoxic T lymphocytes	• Melanocytic nevi and melanomas (highly specific) • PEComas
MITF-1 (microphthalmia-associated transcription factor)	• Necessary for the development of melanocytes during embryogenesis • Regulator of multiple proteins involved in melanogenesis	• Melanocytic nevi and melanoma • Exclusive nuclear staining may be advantageous in some situations (e.g. lentigo vs lentigo maligna)[40]
P16	• One of two protein products of the tumor suppressor gene *CDKN2A* • Expressed in some melanocytic and epithelial neoplasms	• Melanocytic nevi and Spitz nevi • Strong nuclear and cytoplasmic expression may favor benignity in melanocytic processes
P75	• Common receptor for members of the neurotrophins (NT) family • Involved in programmed cell death • Marker of Schwannian differentiation	• Helpful for establishing the diagnosis of desmoplastic and neurotropic melanoma when S100 staining is weak or absent
S100	• Family of low-molecular-weight, calcium-binding proteins • Expressed in neural crest-derived cells (melanocytes, Schwann cells, glial cells), chondrocytes, fat cells, macrophages, Langerhans cells, dendritic cells, some breast epithelial cells and sweat glands	• Most sensitive marker for melanoma and spindle cell/desmoplastic melanoma • Malignant peripheral nerve sheath tumors (stains weakly in comparison to melanoma) • Clear cell sarcoma
Tyrosinase	• Enzyme involved in melanin biosynthesis	• Higher sensitivity than HMB45 • Sensitivity decreases with increased clinical stage and in metastases

Table 0.11 Most commonly employed immunohistochemical stains in dermatopathology. CDKN2A, cyclin-dependent kinase inhibitor 2A; CD, cluster of differentiation; CK, cytokeratin; CTLA-4, cytotoxic T-lymphocyte antigen-4; HTLV-1, human T-cell leukemia virus 1 (human T-cell lymphotropic virus 1); IL, interleukin; LFA-3, lymphocyte function-associated antigen-3; MAdCAM-1, mucosal addressin cell adhesion molecule-1; MART-1, melanoma antigen recognized by T cells; Melan-A, melanocyte antigen; MHC, major histocompatibility complex; NK, natural killer; PEC, perivascular epithelioid cell. *Table created with the assistance of Dr Stefano Titli.*

Continued

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
	NEUROENDOCRINE MARKERS	
CD57 (Leu-7)	• Adhesion molecule • T cells, NK cells, Schwann cells	• Myelinated areas of neuromas and neurofibromas
Chromogranin	• Granules of neuroendocrine cells and sympathetic nerves	• Merkel cell carcinoma
CK 20	• Low-molecular-weight cytokeratin • Expressed in simple epithelia and Merkel cells	• The most sensitive stain for Merkel cell carcinoma (especially when used in combination with TTF-1; when the latter is negative, cutaneous metastases of small cell lung carcinoma are excluded)
Neurofilament	• Intermediate filaments within neuronal processes of central and peripheral nervous tissue	• Merkel cell carcinoma • Neural tumors
NSE (neuron-specific enolase)	• A protein originally found in neurons and neuroendocrine cells, but also demonstrated within melanocytes, striated and smooth muscle cells, megakaryocytes, T cells and some platelets	• Often humorously referred to as "non-specific enolase", the antibody is not of great utility due to the large number of tissues it stains, but it is occasionally used as a screen and supportive evidence for Merkel cell carcinoma
Synaptophysin	• Glycoprotein of presynaptic vesicles found in neurons and neuroendocrine cells	• Merkel cell carcinoma • Neural tumors
TTF-1 (thyroid transcription factor-1)	• Expressed in the epithelia of the thyroid and lung as well as some neural tissues	• Thyroid carcinoma • Small cell lung carcinoma • Visceral neuroendocrine tumors [negative in Merkel cell carcinoma]
	MESENCHYMAL CELL MARKERS	
Caldesmon	• Actin and protomyosin binding protein involved in regulation of muscle and non-muscle contraction	• Smooth muscle neoplasms
CD10	• A cell-surface enzyme with neutral metalloendopeptidase activity • Present on some fibrohistiocytic cells as well as lymphoid cells (see below)	• Dermatofibroma (strong and diffuse), atypical fibroxanthoma, renal cell carcinoma • Renal cell carcinoma, neurothekeoma
CD99 (MIC2)	• Transmembrane protein expressed on most hematopoietic cells	• Ewing sarcoma, peripheral neuroectodermal tumor
Desmin	• Intermediate filament protein expressed predominantly by striated and smooth muscle cells	• Smooth and striated muscle cell neoplasms
Factor XIIIa	• Human coagulation factor XIII • Expressed in a subset of dermal dendrocytes, monocytes and macrophages	• Non-Langerhans cell histiocytoses • Dermatofibroma; negative in dermatofibrosarcoma protuberans (DFSP)
Smooth muscle actin	• Present in smooth muscle around blood vessels, arrector pili muscle and myofibroblasts	• Benign and malignant smooth muscle tumors, myofibroblastic tumors and pseudotumors
Vimentin	• Intermediate filaments in mesenchymal cells	• All mesenchymal cells/tumors, sarcomatoid (spindle cell) carcinoma
	ENDOTHELIAL MARKERS	
CD31	• Platelet–endothelial cell adhesion molecule-1 (PECAM-1) • Highly sensitive for endothelial cells, but poor specificity	• Benign and malignant vascular neoplasms
CD34	• Surface glycoprotein involved in cell–cell adhesion • Highly sensitive for endothelial cells, but poor specificity	• Benign and malignant vascular neoplasms • DFSP; negative in dermatofibroma
Human herpesvirus-8 (HHV-8)	• HHV-8 latent nuclear antigen	• Kaposi sarcoma (earliest stage may be negative)
Podoplanin (D2-40)	• Mucin-type transmembrane glycoprotein • Expressed by lymphatic, but not vascular, endothelial cells	• Kaposi sarcoma, angiosarcomas with lymphatic differentiation • Lymphangiomas • Schwannomas
	HISTIOCYTIC MARKERS	
CD1a	• Transmembrane glycoprotein structurally related to the MHC proteins; functions in antigen presentation • Expressed in Langerhans cells and precursor T cells	• Langerhans cell histiocytoses • Some T-cell lymphoblastic lymphomas
CD68	• Glycoprotein that binds to low-density lipoprotein • Expressed in monocytes and macrophages • With some anti-CD68 monoclonal antibodies (e.g. KP1), also detected in mast cells, neutrophils and myeloid precursors	• Blastic NK cell lymphoma (some cases), myeloid leukemias • Some soft tissue tumors • Non-Langerhans cell histiocytoses • Atypical fibroxanthoma
CD163	• Protein expressed by monocytes and macrophages that functions in endocytosis and clearance of materials	• Cells of histiocytic lineage • Some cells of fibrohistiocytic lineage (dermatofibromas)
CD207 (Langerin)	• Transmembrane cell surface receptor produced by Langerhans cells and localized in the Birbeck granules (involved in internalization of antigen into Birbeck granules)	• Langerhans cell histiocytoses

Table 0.11 Most commonly employed immunohistochemical stains in dermatopathology (cont'd). CDKN2A, cyclin-dependent kinase inhibitor 2A; CD, cluster of differentiation; CK, cytokeratin; CTLA-4, cytotoxic T-lymphocyte antigen-4; HTLV-1, human T-cell leukemia virus 1 (human T-cell lymphotropic virus 1); IL, interleukin; LFA-3, lymphocyte function-associated antigen-3; MAdCAM-1, mucosal addressin cell adhesion molecule-1; MART-1, melanoma antigen recognized by T cells; Melan-A, melanocyte antigen; MHC, major histocompatibility complex; NK, natural killer; PEC, perivascular epithelioid cell. *Table created with the assistance of Dr Stefano Titli.*

Continued

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
S100	• Family of low-molecular-weight, calcium-binding proteins • Expressed in Langerhans cells, activated macrophages and other cells (see melanocytic section above)	• Langerhans cell histiocytoses
	MAST CELL MARKERS	
CD117 (c-KIT)	• Stem cell factor (KIT ligand) receptor • Tyrosine kinase receptor expressed on the surface of hematopoietic stem cells, myeloid progenitor cells, mast cells and melanocytes	• Mastocytosis, mast cell neoplasms • Myeloid leukemia • Junctional component in melanocytic nevi, some melanomas • Gastrointestinal stromal tumors (GIST) • The efficacy of imatinib, a c-KIT inhibitor, is affected by the mutation status of the gene that encodes this receptor
Tryptase	• Serine protease in mast cell granules	• Mastocytosis, mast cell neoplasms
	METASTASES (See Ch. 122)	
CDX2 (caudal-type homeobox 2)	• Transcription factor expressed in all but the most distal portions of the intestinal tract during development	• Gastrointestinal and carcinoid tumors
PSA (prostate-specific antigen)	• Glycoprotein produced almost exclusively by the prostate gland	• Prostate carcinomas, benign prostatic hyperplasia
Uroplakin	• Protein of urothelial surface membrane	• Bladder carcinomas
	LYMPHOID MARKERS	
ALK (anaplastic lymphoma kinase)	• Membrane-associated tyrosine kinase receptor • Probable role in nervous system development and maintenance	• Systemic anaplastic large cell lymphoma (nodal and extranodal) • Negative in primary cutaneous T-cell lymphomas and other types of anaplastic lymphoma (especially B-cell lymphomas) with CD30 positivity
Bcl-2	• Antiapoptosis factor for T and B cells • Expressed in non-germinal center B cells and most T cells	• Diffuse large B-cell lymphoma, leg type • Most follicular lymphomas (excluding primary cutaneous follicle center lymphoma)
Bcl-6	• Nuclear protein expressed in mature B cells within normal germinal centers	• Primary cutaneous follicle center lymphoma • Reactive lymphoid follicles
Immunoglobulin light chains (kappa and lambda)	• Small polypeptide subunits of immunoglobulin • Expressed in B cells and plasma cells	• Plasma cell and plasmacytoid neoplasms • Monotypic expression (all kappa or all lambda) in clonal neoplasms
LMP1	• EBV latent membrane antigen	• AIDS-related non-Hodgkin lymphomas, post-transplant lymphoproliferative disorders, some NK/T-cell lymphomas
TdT	• Terminal deoxynucleotidyl transferase • Expressed in immature pre-B and pre-T cells	• Lymphoblastic lymphoma/leukemia • $CD4^+/CD56^+$ hematodermic neoplasm
CD3	• Complex of transmembrane proteins in the immunoglobulin superfamily involved in signal transduction to the T-cell interior following antigen recognition • Pan T-cell marker • Also expressed in NK cells (cytoplasmic staining for CD3ε)	• T-cell lymphomas • HTLV-1-associated adult T-cell leukemia/lymphoma
CD4	• Transmembrane glycoprotein involved in T-cell activation (class II MHC restricted) • Expressed in helper and regulatory T cells, monocytes, granulocytes, macrophages and Langerhans cells	• Some T-cell lymphomas, including classic mycosis fungoides
CD5	• Transmembrane glycoprotein • Expressed in mature T cells, thymocytes and a subset of mature B cells	• T-cell lymphomas, B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma, mantle cell lymphoma
CD7	• Transmembrane protein in the immunoglobulin superfamily with a role in T-cell interactions with other T cells and B cells • Expressed throughout T-cell differentiation	• T-cell lymphomas, myeloid leukemias, NK-cell neoplasms, T-cell lymphoblastic lymphoma/leukemia • Expression often lost in mycosis fungoides
CD8	• Transmembrane glycoprotein involved in T-cell activation (class I MHC restricted) • Expressed in cytotoxic T cells, NK cells, thymocytes	• Primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic cutaneous T-cell lymphoma, most subcutaneous panniculitis-like T cell lymphomas • Some peripheral T-cell lymphomas
CD10 (common acute lymphoblastic leukemia antigen; CALLA)	• Cell-surface enzyme with neutral metalloendopeptidase activity • Expressed in precursor and germinal center B cells	• Follicle center lymphoma, • B-cell lymphoblastic lymphoma/leukemia
CD15 (LeuM1; Lewis X)	• Membrane protein • Sulfated sialyl Lewis X (a component of adhesion molecules such as MAdCAM-1) binds selectins (CD62L, E and P) and mediates leukocyte rolling on activated endothelium • Expressed in monocytes and granulocytes • Absent on normal lymphocytes	• Classic Hodgkin disease (Reed Sternberg cells) • Acute myeloid leukemia

Table 0.11 Most commonly employed immunohistochemical stains in dermatopathology (cont'd). CDKN2A, cyclin-dependent kinase inhibitor 2A; CD, cluster of differentiation; CK, cytokeratin; CTLA-4, cytotoxic T-lymphocyte antigen-4; HTLV-1, human T-cell leukemia virus 1 (human T-cell lymphotropic virus 1); IL, interleukin; LFA-3, lymphocyte function-associated antigen-3; MAdCAM-1, mucosal addressin cell adhesion molecule-1; MART-1, melanoma antigen recognized by T cells; Melan-A, melanocyte antigen; MHC, major histocompatibility complex; NK, natural killer; PEC, perivascular epithelioid cell. *Table created with the assistance of Dr Stefano Titli.*

Continued

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
CD20	• Unglycosylated phosphoprotein expressed only on B cells • Plays a role in B-cell activation and proliferation	• B-cell lymphomas
CD21 (complement receptor 2)	• Receptor for the C3d fragment of complement and EBV in B cells and epithelial cells • Expressed in follicular dendritic cells, mantle B cells and marginal zone B cells	• Follicular dendritic cell neoplasms • Mantle and marginal zone B-cell lymphomas
CD25 (IL-2 receptor α chain)	• Component of the high-affinity receptor for IL-2 • Expressed in activated T cells (including regulatory T cells), B cells, and macrophages	• Adult T-cell leukemia/lymphoma (associated with HTLV-1) • Targeted by denileukin diftitox (used to treat mycosis fungoides) as well as daclizumab and basiliximab (used to prevent rejection in solid organ transplant recipients)
CD30	• Member of the tumor necrosis factor (TNF) receptor family • Expressed in activated T and B cells	• Anaplastic large T-cell lymphoma, lymphomatoid papulosis, Hodgkin lymphoma • Non-neoplastic skin diseases (e.g. herpesvirus infections, poxvirus infections)
CD34	• Surface glycoprotein involved in cell–cell adhesion • Expressed in hematopoietic cell precursors	• Acute lymphoblastic lymphoma/leukemia, acute myeloblastic leukemia
CD40 and CD154 (CD40 ligand)	• Interaction between CD40 ligand on T cells and CD40 on B cells mediates immunoglobulin class switching	• Mutations in the genes encoding CD40 and CD40 ligand can lead to hyper-IgM syndrome
CD43	• Membrane glycoprotein with regulatory functions • Expressed in T cells, a subset of B cells, monocytes, mast cells and other granulocytes	• T-cell lymphomas, some B-cell lymphomas (aberrant expression), myeloid leukemias, mast cell neoplasms • B-cell chronic lymphocytic leukemia when CD20 is coexpressed
CD45 (leukocyte common antigen)	• Family of high-molecular-weight glycoproteins (all products of a single complex gene) present on the surface of leukocytes • Protein tyrosine phosphatase that functions in cellular signaling	• Most B- and T-cell lymphomas
CD45RA	• High-molecular-weight isoform of leukocyte common antigen • Found on naive T cells and B cells	• Primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic T-cell lymphoma, some subcutaneous panniculitis-like T-cell lymphomas, • Mantle cell lymphoma
CD45RO	• Low-molecular-weight isoform of leukocyte common antigen • Found on memory T cells	• T-cell lymphomas
CD52	• Glycosylphosphatidylinositol-anchored surface protein • Expressed on T cells, B cells, monocytes and dendritic cells	• Targeted by the drug alemtuzumab for the treatment of chronic lymphocytic leukemia and T-cell lymphomas
CD56	• Neural cell adhesion molecule • Expressed on NK cells, a subset of $CD3^+$ cytotoxic T cells, a subset of $CD4^+$ T cells and monocytes as well as neural cells	• Extranodal NK/T-cell lymphoma (nasal type), primary cutaneous γ/δ T-cell lymphoma (including with subcutaneous involvement), $CD4^+/CD56^+$ hematodermic neoplasm, rarely in primary cutaneous anaplastic large cell lymphoma • Some leukemias, most myelomas • Neural neoplasms
CD58 (LFA-3)	• Adhesion molecule on antigen-presenting cells that binds to CD2 on T cells and strengthens the interaction between these cells	• The drug alefacept is an LFA-3/IgG1 fusion protein
CD79a	• Surface glycoprotein associated with immunoglobulin in the B-cell membrane; involved in signal transduction after antigen binding • Appears before the pre-B-cell stage • Found on B cells (immature and mature) and plasma cells	• B-cell lymphomas (may be positive in cases where CD20 is negative) • Plasma cell neoplasms
CD80 (B7-1), CD86 (B7-2) and CD28	• Binding of CD80 or CD86 on activated B cells and antigen presentation cells to the CD28 receptor on T cells delivers a costimulatory signal for T-cell activation	
CD95 (Fas) and CD178 (Fas ligand)	• Fas ligand-expressing cytotoxic T cells induce apoptosis in Fas-expressing target cells, which can include activated B and T cells, keratinocytes and fibroblasts	
CD99	• Surface glycoprotein with roles in cellular adhesion, activation and migration • Expressed in thymocytes, T cells, other hematopoietic cells and endothelial cells	• Lymphoblastic lymphoma/leukemia • Various non-lymphoid tumors, e.g. Ewing's sarcoma, peripheral primitive neuroectodermal (PNET) tumors and Merkel cell carcinoma
CD138 (syndecan-1)	• Surface glycoprotein involved in cell–cell and cell–matrix adhesion • Expressed in plasma cells, plasmacytoid cells and activated T and B cells	• Marginal zone B-cell lymphoma, myeloma, plasmablastic lymphoma
CD152 (CTLA-4)	• Transmembrane protein on the surface of T cells that transmits an inhibitory signal • Binding to CD80 or CD86 leads to negative regulation of T-cell activation	• A CTLA-4/IgG1 fusion protein (abatacept) that inhibits T-cell costimulation is used as anti-inflammatory treatment for rheumatoid arthritis • A monoclonal antibody (ipilimumab) that *blocks* the effects of CTLA-4 activates the immune system; used to treat melanoma

Table 0.11 Most commonly employed immunohistochemical stains in dermatopathology (cont'd). CDKN2A, cyclin-dependent kinase inhibitor 2A; CD, cluster of differentiation; CK, cytokeratin; CTLA-4, cytotoxic T-lymphocyte antigen-4; HTLV-1, human T-cell leukemia virus 1 (human T-cell lymphotropic virus 1); IL, interleukin; LFA-3, lymphocyte function-associated antigen-3; MAdCAM-1, mucosal addressin cell adhesion molecule-1; MART-1, melanoma antigen recognized by T cells; Melan-A, melanocyte antigen; MHC, major histocompatibility complex; NK, natural killer; PEC, perivascular epithelioid cell. *Table created with the assistance of Dr Stefano Titli.*

MOST COMMONLY EMPLOYED IMMUNOHISTOCHEMICAL STAINS IN DERMATOPATHOLOGY		
Marker	**Definition/primary cellular expression**	**Applications/comments**
Granzyme B	• Serine protease expressed specifically by activated cytotoxic T cells	• Cytotoxic T-cell lymphomas
MUM1 (multiple myeloma oncogene 1)	• Member of the interferon regulatory factor family of transcription factors • Expressed in plasma cells, late B cells and activated T cells	• Some B-cell neoplasms • $CD30^+$ lymphoproliferative disorders, anaplastic $CD30^+$ lymphoma
Myeloperoxidase	• Lysosomal protein • Most abundant in neutrophils and monocytes	• Myeloid leukemias
Perforin	• Cytolytic protein stored in cytoplasmic granules and then released from cytotoxic T cells	• Cytotoxic T-cell lymphomas
TIA-1	• Granule-associated RNA-binding protein that defines a subset of $CD8^+$ lymphocytes with cytotoxic potential	• Cytotoxic T-cell lymphomas
	MICROORGANISMS	
Cytomegalovirus (CMV)	• Glycoproteins expressed during the immediate-early and early stages of CMV replication within infected cells	• CMV infection
Epstein-Barr virus (EBV)	• EBV membrane protein encoded by *BNLF*	• Post-transplantation lymphoproliferative disorders, Hodgkin disease
Herpes simplex virus (HSV)	• Glycoproteins present within the viral envelope and core	• HSV-1 or -2 infection
Human herpesvirus-8 (HHV-8)	• HHV-8 latency-associated nuclear antigen	• Kaposi sarcoma, primary effusion lymphoma, Castleman's disease
Varicella-zoster virus (VZV)	• Glycoprotein I of VZV	• Varicella or herpes zoster
BCG	• Anti-Bacillus Calmette-Guérin	• Mycobacterial infections • Mycotic infections • Bacterial infections
Borrelia burgdorferi	• Reacts against various antigens (e.g. flagellin) of *Borrelia burgdorferi* • Cross-reacts against *Treponema pallidum*, *B. hermsii,* and *B. parkeri*	• Lyme disease • Syphilis
Treponema pallidum	• Specific for all *Treponema pallidum* antigens	• Syphilis
	PROLIFERATION MARKERS	
Ki-67	• Prototypic antigen for cell cycle-related nuclear proteins, expressed by proliferating cells during the active phases of the cell cycle, but not during the resting phase (G0)	• Assessment of proliferative activity of tumors (with malignancy generally possessing an elevated proliferative index)
MIB-1	• Peptides from recombinant fragments of the gene for Ki-67 antigen	

CD (cluster differentiation) molecules exist as markers on the cell surface and are recognized by specific sets of antibodies used to identify the cell type, stage of differentiation and activity of a cell.

Table 0.11 Most commonly employed immunohistochemical stains in dermatopathology (cont'd). CDKN2A, cyclin-dependent kinase inhibitor 2A; CD, cluster of differentiation; CK, cytokeratin; CTLA-4, cytotoxic T-lymphocyte antigen-4; HTLV-1, human T-cell leukemia virus 1 (human T-cell lymphotropic virus 1); IL, interleukin; LFA-3, lymphocyte function-associated antigen-3; MAdCAM-1, mucosal addressin cell adhesion molecule-1; MART-1, melanoma antigen recognized by T cells; Melan-A, melanocyte antigen; MHC, major histocompatibility complex; NK, natural killer; PEC, perivascular epithelioid cell. *Table created with the assistance of Dr Stefano Titli.*

INTRODUCTION TO THE USE OF DERMOSCOPY (DERMATOSCOPY)

In the prior two sections, we reviewed the basic principles of clinical dermatology and then dermatopathology, with particular emphasis on clinicopathologic correlations. We now turn to an increasingly utilized ancillary examination technique known as dermoscopy (dermatoscopy). It is a non-invasive diagnostic technique that allows for the observation of morphologic features that are not visible to the naked eye, thus forming a link between macroscopic clinical dermatology and microscopic dermatopathology. This "sub-macroscopic" observation of colors and structures (Figs 0.33–0.37) enhances clinical assessment by providing new diagnostic criteria for the differentiation of melanoma from other melanocytic and non-melanocytic, benign and malignant neoplasms[31].

The technique of dermoscopy classically involves applying a liquid or gel to the skin surface and then inspecting the lesion using a hand-held, illuminated microscope (also called a dermatoscope), a stereomicroscope, a camera or a digital imaging system. The magnification of these instruments ranges from 6× to 40× and even up to 100×.

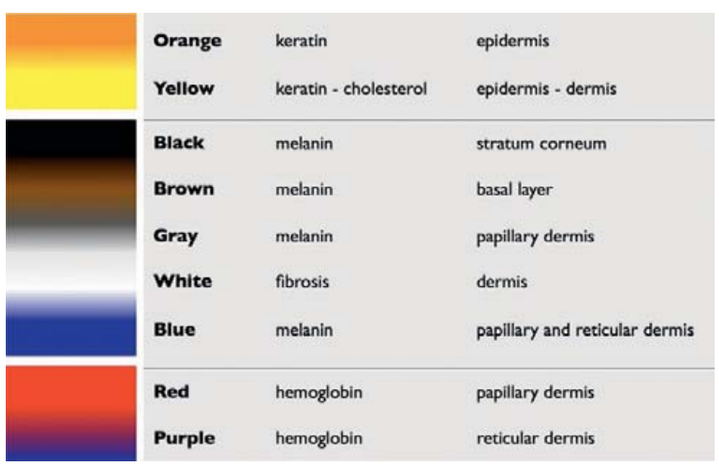

Fig. 0.33 Dermoscopy colors of keratinizing, melanocytic, and vascular tumors.

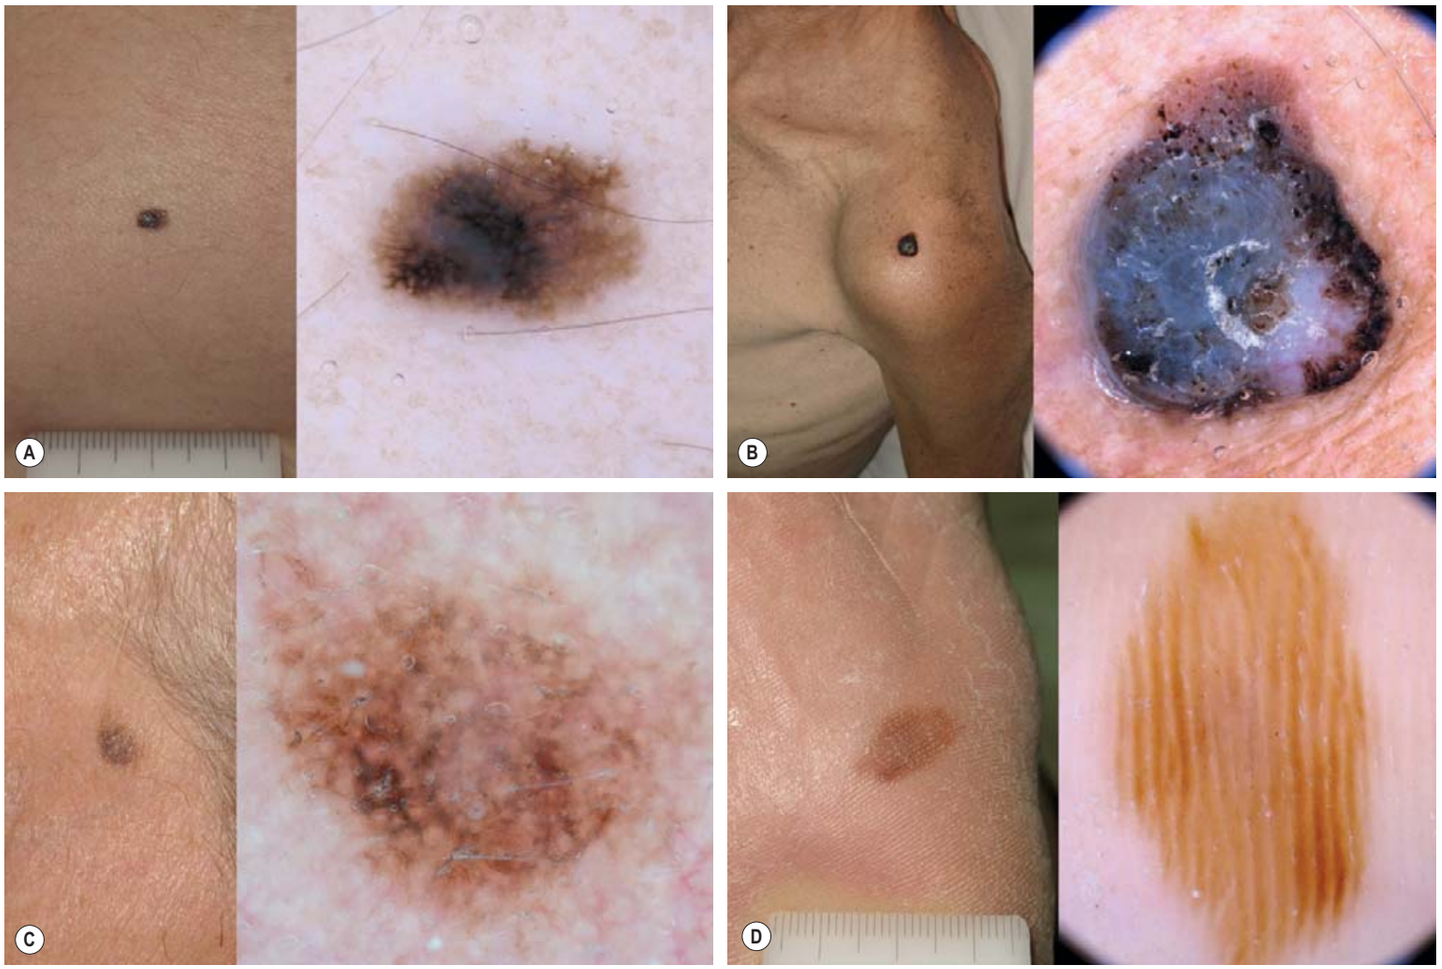

Fig. 0.34 The four most common types of melanoma. A Small superficial melanoma typified dermoscopically by asymmetry of color and structure, atypical network, blue–white structures, and irregular streaks at the periphery. **B** Large thick melanoma with predominant blue–white veil. The combination of blue color with irregular black to brown dots, globules, and blotches (as seen here) is highly specific for the diagnosis of thick melanoma. **C** Small facial melanoma *in situ* (lentigo maligna) typified by gray color and rhomboidal structures in dermoscopy. **D** Acral melanoma *in situ* typified by the characteristic parallel-ridge pattern.

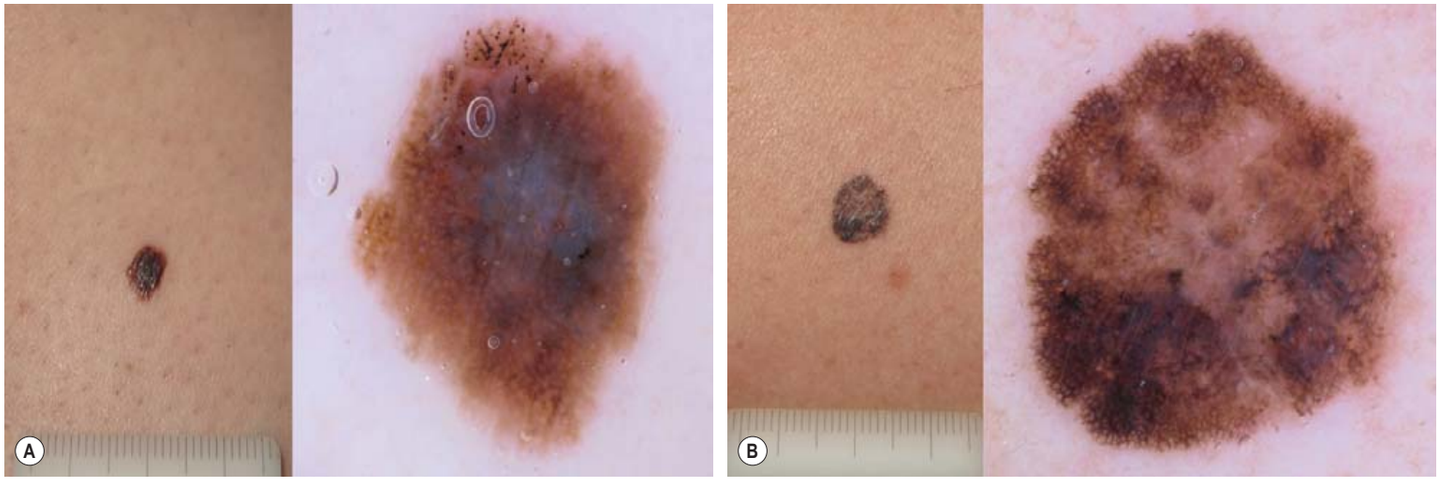

Fig. 0.35 Four examples of superficial melanomas of increasing tumor thickness. A Melanoma *in situ* typified dermoscopically by asymmetry of color and structure, atypical network, blue–white structures, and irregular black dots and globules (at the upper side of the lesion). **B** Melanoma 0.5 mm thick typified predominantly by atypical pigment network and regression structures. The latter are composed by areas of pigment loss (in the center of the lesion) and bluish pepper-like granules corresponding to melanophages.

Continued

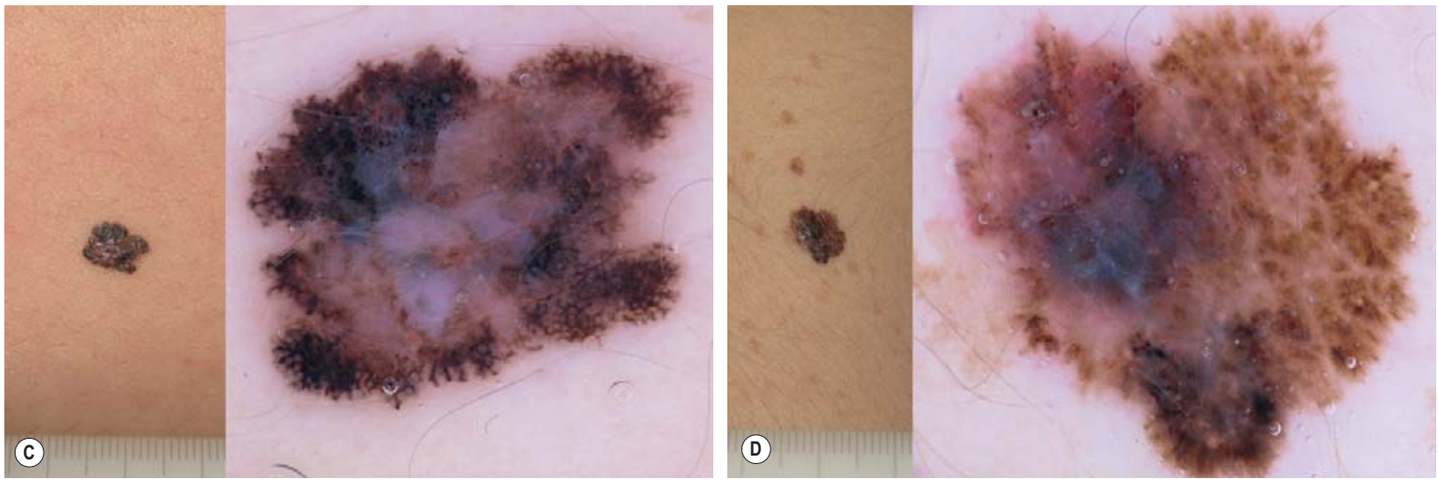

Fig. 0.35 Four examples of superficial melanomas of increasing tumor thickness (cont'd). **C** Melanoma 0.75 mm thick typified by multiple melanoma-specific criteria including asymmetry of color and structure, atypical network, irregular streaks at the periphery, irregular dots and globules (upper side of the lesion), and blue–white structures especially in the center. **D,** Melanoma 0.9 mm thick. Clinically, a palpable area is visible, corresponding dermoscopically to the presence of blue–white veil, a sign of increased tumor thickness. Irregular dots and globules (at the upper side), irregular streaks at the periphery, and uneven brown to black pigmented areas (blotches) are also observed.

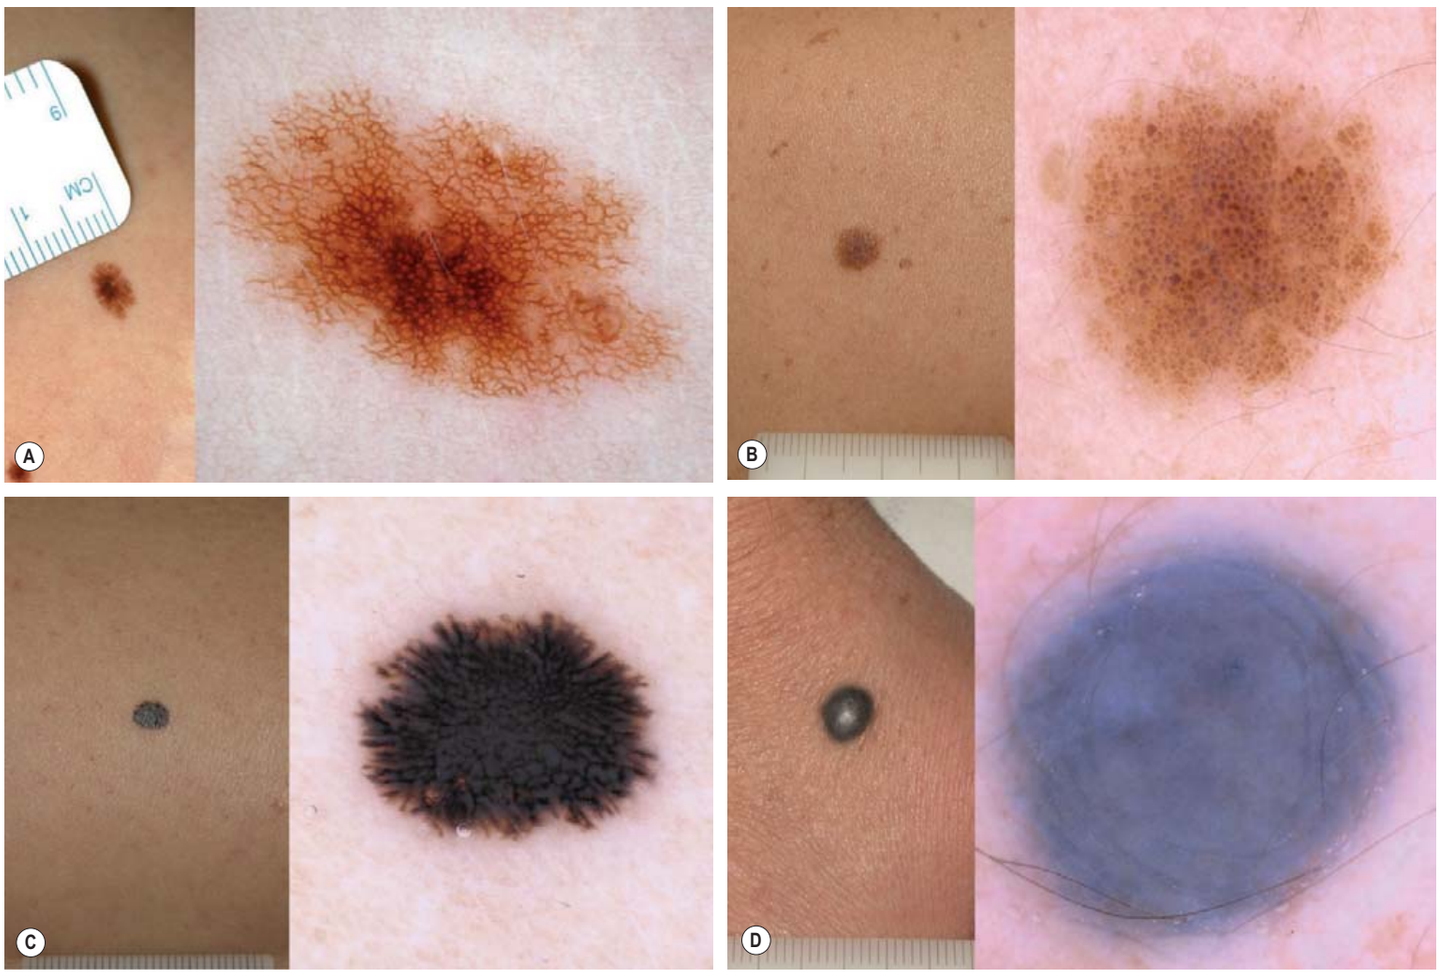

Fig. 0.36 The four most common types of melanocytic nevi – clinical and dermoscopic findings. **A** Typical acquired nevus with reticular pattern in dermoscopy. **B** Small congenital nevus with globular pattern. **C** Reed nevus typified dermoscopically by the classic starburst pattern (regular streaks at the periphery of a heavily pigmented and symmetric small macule). **D** Classic blue homogenous color typically found in blue nevi.

The widely used dermatoscope has a 10-fold magnification, sufficient for routine assessment of skin tumors. The fluid placed on the lesion eliminates surface reflection and renders the cornified layer translucent, thus allowing a better visualization of pigmented structures within the epidermis, the dermal–epidermal junction and the superficial dermis. Moreover, the size and shape of vessels of the superficial vascular plexus are better visualized with this procedure (Figs 0.38 & 0.39). More recently, hand-held devices have been introduced that utilize polarized light which renders the epidermis translucent. With these latter devices, use of a liquid medium is no longer required in order to visualize subsurface structures.

Nowadays, the dermatoscope is increasingly being used by dermatologists as a stethoscope equivalent. This is because it not only facilitates the diagnosis of pigmented and non-pigmented skin tumors, but it also

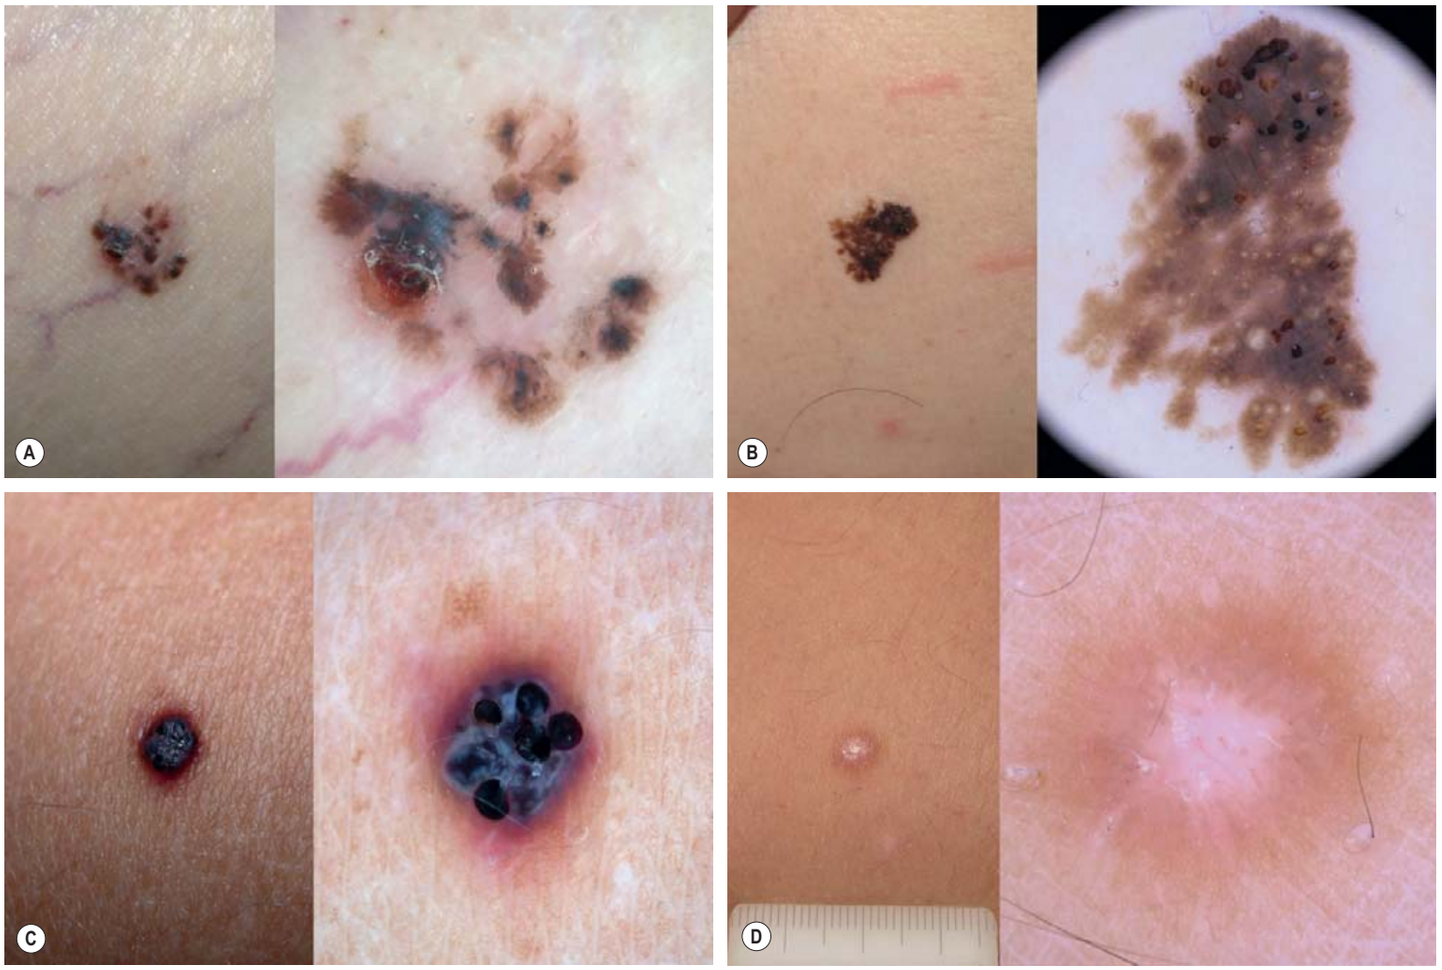

Fig. 0.37 Four non-melanocytic pigmented tumors – clinical and dermoscopic findings. A Pigmented basal cell carcinoma with leaf-like areas (islands of blue–gray color) at the periphery and a small erosion of reddish color at the left side of the lesion. **B** Seborrheic keratosis with typical milia-like cysts (white shining globules) and comedo-like openings (black targetoid globules). **C** Angiokeratoma with red–black lacunas clearly visible as well-demarcated roundish structures. **D** A dermatofibroma with characteristic central white patch and peripheral delicate pseudo-network.

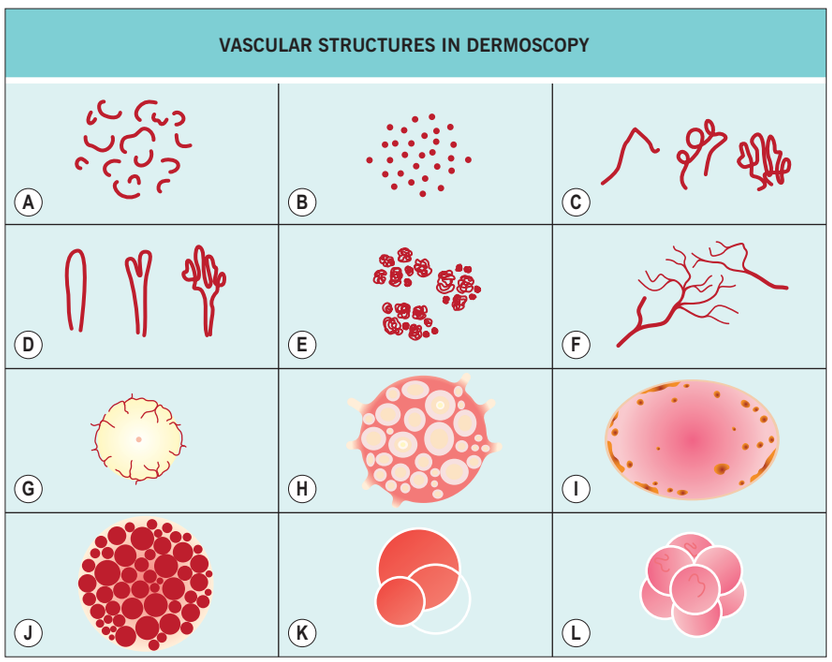

Fig. 0.38 Vascular structures in dermoscopy. (See also Table 0.13 for definitions and diagnostic significance). **A** Comma vessels (typical of dermal and congenital nevi). **B** Dotted vessels (often found in melanoma and Spitz nevi). **C** Linear-irregular vessels (typical of melanoma). **D** Hairpin vessels (most common in keratinizing tumors, such as seborrheic keratosis and squamous cell carcinoma). **E** Glomerular vessels (found in Bowen's disease). **F** Arborizing vessels (typical of basal cell carcinoma). **G** Crown vessels (common finding in sebaceous hyperplasia). **H** Strawberry pattern (typical of facial actinic keratosis). **I** Multiple blood crusts over a red background (typical finding in superficial basal cell carcinoma). **J** Red lacunas (typical finding in hemangiomas). **K** Red homogenous areas intersected by whitish lines (most common in pyogenic granuloma). **L** Milky-red areas (typical of melanoma).

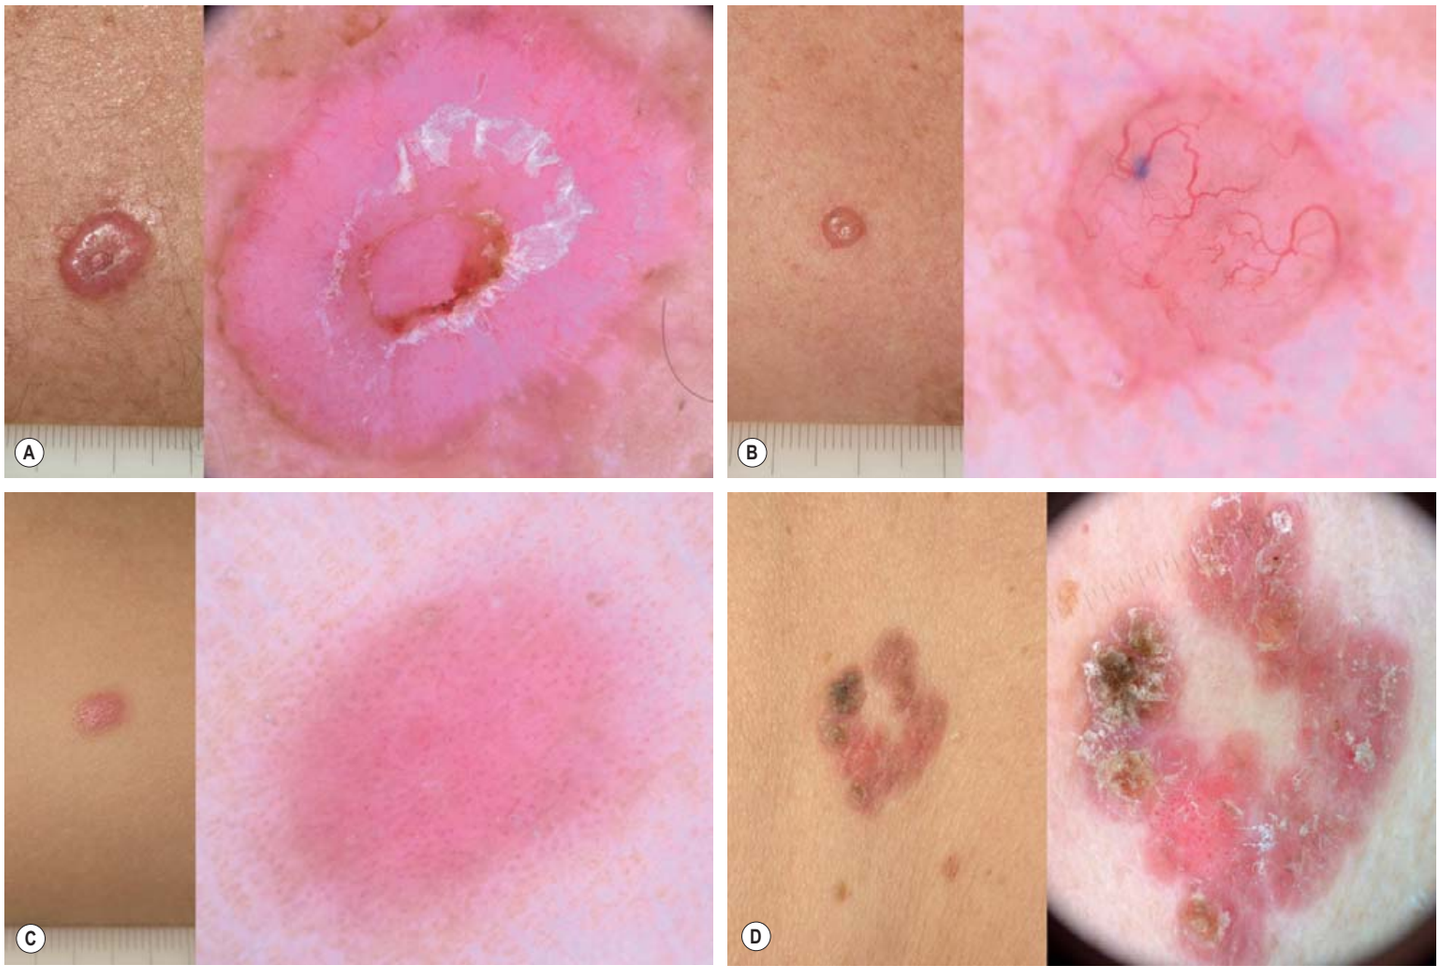

Fig. 0.39 Four non-pigmented skin tumors – clinical and dermoscopic findings. A This amelanotic melanoma is typified by a central ulceration, polymorphic vascular structures (combination of dotted and linear-irregular vessels), and milky-red color in the background. **B** Nodular basal cell carcinoma with striking arborizing vessels. **C** A Spitz nevus with dotted vessels and typical negative pigment network (reticular depigmentation) at the periphery. **D** An example of Bowen's disease with clusters of glomerular vessels that in combination with superficial scales are highly specific for the diagnosis.

improves recognition of a growing number of non-pigmented skin conditions. For example, dermoscopy can facilitate the diagnosis of scabies due to the presence of the pathognomonic "jet with contrail" sign[32] (Fig. 0.40A). Additional skin infections and infestations that may be differentiated with increased confidence include pediculosis, phthiriasis, tungiasis, tinea nigra and molluscum contagiosum. For two of the more common inflammatory skin disorders – psoriasis and lichen planus – the use of dermoscopy allows for the visualization of specific submacroscopic features, including the "red dots" pattern in psoriasis and the "whitish striae" pattern in lichen planus (Fig. 0.40B,C). Scalp psoriasis and seborrheic dermatitis may also be differentiated via dermoscopy. The most notable scalp psoriasis features are red dots and globules, twisted red loops and glomerular vessels, whereas seborrheic dermatitis is characterized by the presence of arborizing vessels and atypical red vessels, as well as featureless areas with no particular vascular pattern and no red dots or globules. In a recent review of the indications for dermoscopy, more than 35 different inflammatory and infectious skin diseases were listed[33]. One of the newest applications of this technique is trichoscopy, namely the dermoscopic observation of the scalp, which may prove helpful in the differential diagnosis of hair and scalp diseases[34] (Fig. 0.40D).

The aim of dermoscopy in melanoma screening is to maximize early detection while minimizing the unnecessary excision of benign skin tumors. Over the past few years, three meta-analyses and two randomized studies have proven definitively that dermoscopy improves the sensitivity for melanoma detection as compared to just the naked eye[35–39]. In a meta-analysis of dermoscopy studies performed in a clinical setting, the relative odds ratio for dermoscopic diagnosis of cutaneous melanoma (compared to naked eye examination) was 15.6 ($p = 0.016$). The average sensitivities for melanoma detection by naked eye versus dermoscopic examinations were 74% and 90%, respectively. Furthermore, this improved sensitivity came about without a decrease in specificity, suggesting that better melanoma detection (16% improvement) occurred without increasing the number of unnecessary excisions of benign lesions[39]. A randomized study found that combining eye and dermoscopic examinations led to a significant reduction in the percentage of patients referred for biopsy (9% vs 15.6%; $p = 0.013$)[37]. In summary, the use of dermoscopy is associated with a significant increase in the number of excised melanomas, as well as a significant reduction in the number of excised benign pigmented skin lesions.

Pattern analysis is the most well-known and reliable method for differentiating pigmented skin tumors. This is based on a two-step algorithm, where first there is recognition of basic criteria for melanocytic and non-melanocytic tumors (first step; Table 0.12) and then benign and malignant features of melanocytic nevi and melanoma, respectively (second step; Tables 0.13 & 0.14)[31]. Recent attempts to simplify the dermoscopic approach to diagnosing melanocytic nevi and melanoma include the ABCD rule, the Menzies method, and the 7-point checklist[31] (Tables 0.15–0.17).

In a virtual "Consensus Net Meeting on Dermoscopy"[31], 40 experts were able to correctly classify more than 95% of melanocytic lesions and more than 90% of non-melanocytic lesions, with pattern analysis producing the best diagnostic performance. The alternative algorithms (ABCD rule, Menzies method, and 7-point checklist) revealed similar sensitivities as compared to pattern analysis but ~10% less specificity. The favorable results of pattern analysis were not unexpected, as this method probably best reflects the workings of the human brain when categorizing morphologic images and is similar to the pattern analysis

Fig. 0.40 Four non-neoplastic skin disorders – clinical and dermoscopic findings. A A 6-month-old boy with scabies. By dermoscopy, a characteristic "jet with contrail" structure can be identified corresponding to the anterior part of the mite (arrow) and the burrow behind it. **B** By dermoscopy, classic psoriasis plaques exhibit regular dotted vessels. **C** The dermoscopic pattern of lichen planus is definitely different from the previous one. Here, dotted vessels are seen at the border of typical whitish lines and clods, which closely resemble the Wickham striae found in lichen planus of the oral mucosa. **D** Typical yellow dots seen dermoscopically in scalp patches of alopecia areata.

PATTERN ANALYSIS: FIRST-STEP ALGORITHM FOR DIFFERENTIATION BETWEEN MELANOCYTIC AND NON-MELANOCYTIC LESIONS		
Dermoscopic criterion	**Definition**	**Diagnostic significance**
Pigment network – pseudo-network[†]	Network of brownish interconnected lines over a background of tan diffuse pigmentation. In facial skin, a peculiar pigment network, also called a pseudo-network, is typified by round, equally sized network holes corresponding to the pre-existing follicular ostia	Melanocytic lesion
Aggregated globules	Numerous, variously sized, more or less clustered, round to oval structures with various shades of brown and gray–black. They should be differentiated from multiple blue–gray globules	Melanocytic lesion
Streaks	These have been previously described separately as pseudopods and radial streaming, but are now combined into the one term. They are bulbous and often kinked or finger-like projections seen at the edge of a lesion. They may arise from network structures but more commonly do not. They range in color from tan to black	Melanocytic lesion
Homogeneous blue pigmentation[‡]	Structureless blue pigmentation in the absence of pigment network or other distinctive local features	Melanocytic lesion
Parallel pattern	Seen in melanocytic lesions of palms/soles and mucosal areas. On palms/soles, the pigmentation may follow the sulci or the cristae (i.e. furrows or ridges) of the dermatoglyphics. Rarely arranged at right angles to these structures	Melanocytic lesion
Multiple milia-like cysts	Numerous, variously sized, white or yellowish, roundish structures	Seborrheic keratosis
Comedo-like openings	Brown–yellowish to brown–black, round to oval, sharply circumscribed keratotic plugs in the ostia of hair follicles. When irregularly shaped, comedo-like openings are also called irregular crypts	Seborrheic keratosis
Light-brown fingerprint-like structures	Light-brown, delicate, network-like structures with the pattern of a fingerprint	Seborrheic keratosis
Cerebriform pattern	Dark-brown furrows between ridges typifying a brain-like appearance	Seborrheic keratosis
Arborizing vessels	Tree-like branching telangiectasias	Basal cell carcinoma*

Table 0.12 Pattern analysis: first-step algorithm for differentiation between melanocytic and non-melanocytic lesions. Adapted from ref. 31.

Continued

PATTERN ANALYSIS: FIRST-STEP ALGORITHM FOR DIFFERENTIATION BETWEEN MELANOCYTIC AND NON-MELANOCYTIC LESIONS		
Dermoscopic criterion	**Definition**	**Diagnostic significance**
Leaf-like structures	Brown to gray/blue discrete bulbous structures forming leaf-like patterns. They are discrete pigmented nests (islands) never arising from a pigment network and usually not arising from adjacent confluent pigmented areas	Basal cell carcinoma*
Large blue–gray ovoid nests	Well-circumscribed, confluent or near confluent, pigmented, ovoid or elongated areas, larger than globules, and not intimately connected to a pigmented tumor body	Basal cell carcinoma*
Multiple blue–gray globules	Multiple globules (not dots) that should be differentiated from multiple blue–gray dots (melanophages)	Basal cell carcinoma*
Spoke-wheel areas	Well-circumscribed radial projections, usually tan in color but sometimes blue or gray, meeting at an often darker (dark brown, black or blue) central axis	Basal cell carcinoma*
Ulceration§	Absence of the epidermis, often associated with congealed blood, not due to a well-described recent history of trauma	Basal cell carcinoma*
Red–blue lacunas	More or less sharply demarcated, roundish or oval areas with a reddish, red–bluish, or dark-red to black coloration	Vascular lesion
Red–bluish to reddish-black homogeneous areas	Structureless homogeneous areas of red–bluish to red–black coloration	Vascular lesion
None of the listed criteria	Absence of the above-mentioned criteria	Melanocytic lesion

*To diagnose a basal cell carcinoma, the negative feature of pigment network must be absent and one or more of the positive features listed here must be present.
†Exception 1: Pigment network or pseudo-network is also present in solar lentigo and rarely in seborrheic keratosis and pigmented actinic keratosis. A delicate, annular pigment network is also commonly seen in dermatofibroma and accessory nipple (clue for diagnosis of dermatofibroma and accessory nipple: central white patch).
‡Exception 2: Homogeneous blue pigmentation (dermoscopic hallmark of blue nevus) is also seen (uncommonly) in some hemangiomas and basal cell carcinomas and (commonly) in intradermal melanoma metastases.
§Exception 3: Ulceration is also seen less commonly in invasive melanoma.

Table 0.12 Pattern analysis: first-step algorithm for differentiation between melanocytic and non-melanocytic lesions (cont'd). Adapted from ref. 31.

PATTERN ANALYSIS: SECOND-STEP ALGORITHM FOR DIFFERENTIATION BETWEEN MELANOCYTIC NEVI AND MELANOMA		
Dermoscopic criterion	**Definition**	**Diagnostic significance**
	GLOBAL FEATURES	
Reticular pattern	Pigment network covering most parts of the lesion	Melanocytic nevus
Globular pattern	Numerous, variously sized, round to oval structures with various shades of brown and gray–black	Melanocytic nevus
Cobblestone pattern	Large, closely aggregated, somehow angulated globule-like structures resembling a cobblestone	Dermal nevus
Homogeneous pattern	Diffuse, brown, gray–blue to gray–black pigmentation in the absence of other distinctive local features	Melanocytic (blue) nevus
Starburst pattern	Pigmented streaks in a radial arrangement at the edge of the lesion	Spitz/Reed nevus
Parallel pattern	Pigmentation on palms/soles that follows the sulci or the cristae (furrows or ridges), rarely arranged at right angles to these structures	Acral nevus/melanoma (see below)
Multicomponent pattern	Combination of three or more of the above patterns	Melanoma
Nonspecific pattern	Pigmented lesion lacking above patterns	Possible melanoma
	LOCAL FEATURES	
Pigment network	Typical pigment network: light- to dark-brown network with small, uniformly spaced network holes and thin network lines distributed more or less regularly throughout the lesion and usually thinning out at the periphery	Benign melanocytic lesion
	Atypical pigment network: black, brown or gray network with irregular holes and thick lines	Melanoma
Dots/globules	Black, brown, round to oval, variously sized structures regularly or irregularly distributed within the lesion	If regular, benign melanocytic lesion If irregular, melanoma
Streaks	These have been previously described separately as pseudopods and radial streaming. Streaks are bulbous and often kinked or finger-like projections seen at the edge of a lesion. They may arise from network structures but more commonly do not. They range in color from tan to black	If regular, benign melanocytic lesion (Spitz/Reed nevus) If irregular, melanoma
Blue–whitish veil	Irregular, structureless area of confluent blue pigmentation with an overlying white "ground-glass" film. The pigmentation cannot occupy the entire lesion and usually corresponds to a clinically elevated part of the lesion	Melanoma
Regression structures	White scar-like depigmentation and/or blue pepper-like granules usually corresponding to a clinically flat part of the lesion	Melanoma
Hypopigmentation	Areas with less pigmentation than the overall pigmentation of the lesion	Nonspecific
Blotches	Black, brown, and/or gray structureless areas with symmetrical or asymmetrical distribution within the lesion	If symmetrical, benign melanocytic lesion If asymmetrical, melanoma

Table 0.13 Pattern analysis: second-step algorithm for differentiation between melanocytic nevi and melanoma. Adapted from ref. 31.

Continued

PATTERN ANALYSIS: SECOND-STEP ALGORITHM FOR DIFFERENTIATION BETWEEN MELANOCYTIC NEVI AND MELANOMA		
Dermoscopic criterion	**Definition**	**Diagnostic significance**
	SITE-RELATED FEATURES	
Face	Typical pseudo-network (round, equally sized network holes corresponding to the pre-existing follicular ostia)	Benign melanocytic lesion
	Annular-granular structures (multiple blue–gray dots surrounding the follicular ostia with an annular-granular appearance)	Melanoma
	Gray pseudo-network (gray pigmentation surrounding the follicular ostia, formed by the confluence of annular-granular structures)	Melanoma
	Rhomboidal structures (gray–brown pigmentation surrounding the follicular ostia with a rhomboidal appearance)	Melanoma
	Asymmetric pigmented follicles (eccentric annular pigmentation around follicular ostia)	Melanoma
Palms/soles	Parallel-furrow pattern (pigmentation following the sulci superficiales)	Acral nevus
	Lattice-like pattern (pigmentation following and crossing the furrows)	Acral nevus
	Fibrillar pattern (numerous, finely pigmented filaments perpendicular to the furrows and ridges)	Acral nevus
	Parallel-ridge pattern (pigmentation aligned along the cristae superficiales)	Melanoma

Table 0.13 Pattern analysis: second-step algorithm for differentiation between melanocytic nevi and melanoma (cont'd). Adapted from ref. 31.

VASCULAR STRUCTURES SEEN IN VARIOUS SKIN TUMORS		
Pattern	**Definition**	**Diagnostic significance**
Comma	Coarse vessels that are slightly curved and barely branching	Congenital and dermal nevi
Dotted	Tiny red dots densely aligned next to each other	Melanocytic lesion (often Spitz nevus and melanoma)
Linear-irregular	Linear, irregularly shaped, sized and distributed red structures	Melanoma
Hairpin	Vascular loops sometimes twisted and bending. They can be surrounded by a whitish halo	With white halo: keratinizing proliferation (seborrheic keratosis, squamous cell carcinoma, keratoacanthoma, viral wart) Without white halo: melanoma
Glomerular	Variation on the theme of dotted vessels. They are tortuous capillaries often distributed in clusters mimicking the glomerular apparatus of the kidney	Bowen's disease
Arborizing	Stem vessels of large diameter branching irregularly into finest terminal capillaries. The color is bright red, being sharply focused in dermoscopic images due to their location immediately beneath the surface of the tumor	Basal cell carcinoma
Crown	Groups of orderly bending, scarcely branching vessels located along the border of the lesion	Sebaceous hyperplasia
Strawberry	Pink-to-red "pseudo-network" around hair follicles of the face, frequently intermingled with fine, linear-wavy vessels. Often hair follicles are filled with yellowish keratotic plugs	Actinic keratosis
Corkscrew	Linear vessels twisted along a central axis	Thick melanoma or melanoma metastasis
Milky-red color	Globules and/or larger areas of fuzzy or unfocused milky-red color often corresponding to an elevated part of the lesion	Melanoma
Polymorphous	Any combination of two or more different types of vascular structures. The most frequent is linear-irregular and dotted vessels	Malignant tumor (melanoma, basal cell carcinoma, squamous cell carcinoma, etc.)

Table 0.14 Vascular structures seen in various skin tumors. See also Figs 0.38 & 0.39.

ABCD RULE FOR THE DERMOSCOPIC DIFFERENTIATION BETWEEN BENIGN MELANOCYTIC LESIONS AND MELANOMA			
Dermoscopic criterion	**Definition**	**Score**	**Weight factor**
Asymmetry	In 0, 1, or 2 perpendicular axes; assess not only contour, but also colors and structures	0–2	× 1.3
Border	Abrupt ending of pigment pattern at the periphery in 0–8 segments	0–8	× 0.1
Color	Presence of up to six colors (white, red, light brown, dark brown, blue–gray, black)	1–6	× 0.5
Dermoscopic structures	Presence of network, structureless (homogeneous) areas, branched streaks, dots, and globules	1–5	× 0.5

Table 0.15 ABCD rule for the dermoscopic differentiation between benign melanocytic lesions and melanoma. Formula for calculating total score: (A score × 1.3) + (B score × 0.1) + (C score × 0.5) + (D score × 0.5). Interpretation of total score: <4.75, benign melanocytic lesion; 4.75–5.45, suspicious lesion (close follow-up or excision recommended); >5.45, lesion highly suspicious for melanoma. Adapted from ref. 31.

MENZIES SCORING METHOD FOR THE DERMOSCOPIC DIFFERENTIATION BETWEEN BENIGN MELANOCYTIC LESIONS AND MELANOMA	
Dermoscopic criterion	**Definition**
NEGATIVE FEATURES	
Symmetry of pattern	Symmetry of pattern is required across all axes through the lesion's center of gravity (center of the lesion). Symmetry of pattern does not require shape symmetry
Presence of a single color	The colors scored are black, gray, blue, dark brown, tan and red. White is not scored as a color
POSITIVE FEATURES	
Blue–white veil	An area of irregular, structureless confluent blue pigmentation with an overlying white "ground-glass" haze. It cannot occupy the entire lesion and cannot be associated with red–blue lacunas
Multiple brown dots	Focal areas of multiple brown (usually dark brown) dots (not globules)
Pseudopods	Bulbous and often kinked projections that are found at the edge of a lesion, connected either directly to the tumor body or to the pigmented network. They can never be seen distributed regularly or symmetrically around the lesion. When connected directly to the tumor body, they must have an acute angle to the tumor edge or arise from linear or curvilinear extensions. When connected to the network, the width of the bulbous ending must be greater than the width of any part of the surrounding network and at least double that of its directly connected network projection
Radial streaming	Finger-like extensions at the edge of a lesion which are never distributed regularly or symmetrically around the lesion
Scar-like depigmentation	Areas of white distinct irregular extensions (true scarring), which should not be confused with hypo- or depigmentation due to simple loss of melanin
Peripheral black dots/globules	Black dots/globules found at or near the edge of the lesion
Multiple (5–6) colors	The colors scored are black, gray, blue, dark brown, tan and red. White is not scored as a color
Multiple blue/gray dots	Foci of multiple blue or gray dots (not globules) often described as "pepper-like" granules in pattern
Broadened network	A network made up of irregular thicker "cords" of the net, often seen focally thicker

Table 0.16 Menzies scoring method for the dermoscopic differentiation between benign melanocytic lesions and melanoma. For melanoma to be diagnosed, a lesion must have neither of both negative features and one or more of the nine positive features. Adapted from ref. 31.

SEVEN-POINT CHECKLIST FOR THE DERMOSCOPIC DIFFERENTIATION BETWEEN BENIGN MELANOCYTIC LESIONS AND MELANOMA		
Dermoscopic criterion	**Definition**	**Score**
1. Atypical pigment network	More than one type of network (in terms of color and thickness of the meshes) irregularly distributed within the lesion	2
2. Blue–whitish veil	Irregular, structureless area of confluent blue pigmentation with an overlying white "ground-glass" film. The pigmentation cannot occupy the entire lesion and usually corresponds to a clinically elevated part of the lesion	2
3. Atypical vascular pattern	Linear-irregular or dotted vessels not clearly seen within regression structures	2
4. Irregular streaks	Brown to black, bulbous or finger-like projections irregularly distributed at the edge of a lesion. They may arise from network structures but more commonly do not	1
5. Irregular dots/globules	Black, brown, round to oval, variously sized structures irregularly distributed within the lesion	1
6. Irregular blotches	Black, brown, and/or gray structureless areas asymmetrically distributed within the lesion	1
7. Regression structures	White scar-like depigmentation and/or blue pepper-like granules usually corresponding to a clinically flat part of the lesion	1

Table 0.17 Seven-point checklist for the dermoscopic differentiation between benign melanocytic lesions and melanoma. By simple addition of the individual scores, a minimum total score of 3 is required for the diagnosis of melanoma, whereas a total score of less than 3 is indicative of non-melanoma. Adapted from ref. 31.

DEFINITIONS OF DERMOSCOPIC CRITERIA FOR THE 3-POINT CHECKLIST	
Criterion	**Definition**
Asymmetry	Asymmetrical distribution of colors and dermoscopic structures
Atypical network*	More than one type of network (in terms of color and thickness of the meshes) irregularly distributed within the lesion
Blue–white structures†	Presence of any type of blue and/or white color
*Usually found in early melanoma. †Usually found in both melanoma and pigmented basal cell carcinoma.	

Table 0.18 Definitions of dermoscopic criteria for the 3-point checklist. The presence of more than one criterion suggests a suspicious lesion. Adapted from ref. 38.

utilized in general clinical dermatology and dermatopathology (see above). That is, there is a subjective perception of the "gestalt" of a given lesion and its integration into an internalized knowledge base, which is the result of expertise on the subject; in contrast, "simplified" algorithms were designed to keep non-experts from failing to detect melanomas, even at the cost of decreased specificity.

Results of the virtual consensus study showed that three criteria (asymmetry, atypical network, and blue–white structures) were especially important in distinguishing malignant from benign pigmented skin tumors (Table 0.18). Using this 3-point dermoscopy rule as a screening test, general physicians previously inexperienced in the use of dermoscopy were able to perform better triage of skin lesions suggestive of skin cancer as compared to examination with the naked eye (referral sensitivity of 79% and 54%, respectively), without increasing the number of unnecessary expert consultations[38].

While the continued, skilled use of dermoscopy will undoubtedly aid in the early recognition of melanoma as well as the diagnosis of inflammatory disorders and other cutaneous neoplasms, there are additional technologies that may also have a significant impact on our specialty over the next decade.

CONCLUSION

In conclusion, this chapter has sought to provide an introduction and basic structural framework to the study of dermatology by addressing terminology, morphology, pattern recognition, and a number of techniques that will all serve to enhance the practice of clinicopathologic correlation. The desired end results are more accurate diagnoses and better care of patients.

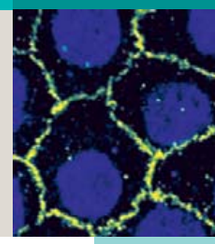
1 Anatomy and Physiology



Travis W Vandergriff and Paul R Bergstresser

Key features

- The function and structure of skin is not demonstrated best by diagrams and figures, but rather by presenting the diseases that illustrate how skin can fail. Thus, function is revealed by disease, and disease illustrates structure
- The primary function of skin is to maintain an internal environment that allows an organism to protect its DNA and to reproduce it faithfully
- Cutaneous structures include an epidermis that serves as a barrier (e.g. to prevent fluid loss and infection) and a dermis that provides circulation and nutrition. Other functions provided by the cells that reside in the skin include immune recognition, a capacity to repair damage, thermoregulation and communication
- Evidence that skin has failed may be found in barrier disruption, infection, autoimmunity, cancer and an undesirable appearance

INTRODUCTION

Most reviews of the anatomy and physiology of skin begin with detailed descriptions of cellular composition, structural proteins, and extrafibrillar matrix ("ground substance"). Because each of these subjects, with relevant documentation, is presented in subsequent sections of this textbook, such aspects of cutaneous function will be introduced only briefly, using references to appropriate chapters. Following this, the conventional approach is reversed by examining diseases that illustrate cutaneous function in the context of the cells and structures that sustain it. This method is derived from the assertion that the structure and function of skin is revealed best through disease. The validity of this alternative methodology may be seen in five short clinical vignettes easily recognized by those who care for patients with skin disease:

- an albino Native American from Panama develops numerous squamous cell carcinomas at an early age
- a 15-year-old boy with hypohidrotic ectodermal dysplasia suffers heat stroke while competing in outdoor athletics in Texas
- toxic epidermal necrolysis leading to dehydration and sepsis develops in a 40-year-old woman treated with phenytoin
- painful leg ulcerations incapacitate a 60-year-old woman with rheumatoid arthritis
- widespread herpes simplex virus infection occurs in a young man who has atopic dermatitis unrecognized by his primary care physician.

These patients and their diseases illustrate at least five of the functions of skin: photoprotection, thermoregulation, barrier formation, cutaneous circulation, and immunologic protection. Each function is supported by the cells and structural elements that reside there.

STRUCTURE AND FUNCTION

Conventional Concepts of the Structure of Skin

Epidermis

Consistent with conventional introductory chapters on cutaneous structure and function, we begin with a histologic section through normal skin. The anatomic structures observed by light microscopy are similar in most regions of the body (Fig. 1.1). However, specialized regions of skin, including the palms (Fig. 1.2), soles, genitalia and scalp, have modified forms of these structures.

As seen in Figures 1.1 and 1.2, the outer layer of skin (epidermis) consists of a thin matrix of cells. In humans, the epidermis contains three major resident populations of cells[1]: keratinocytes (Ch. 56), melanocytes (Ch. 65) and Langerhans cells (Chs 4 & 14). In conventional H&E-stained sections, these cells are nearly indistinguishable, but substantial differences become apparent when specialized immunohistochemical techniques are employed. Keratinocytes, the major population, originate in bottom-most stem-cell pools; cells that leave this pool then undergo maturation as they move toward the stratum corneum (Ch. 56). The human epidermis averages 50 microns in thickness, with a surface density of approximately 50 000 nucleated cells/mm^2[2]. Under basal conditions, differentiated keratinocytes require about 2 weeks to exit the nucleated compartment and an additional 2 weeks to move through the stratum corneum[3]. It should be noted that keratinocytes have the capacity to increase rates of proliferation and maturation to levels far greater than this, when stimulated to do so by injury, inflammation or disease (Ch. 8).

Melanocytes, as noted in a DOPA-stained whole mount of epidermis (Fig. 1.3), have the capacity to elaborate the light-absorbing pigment melanin, which plays a major role in protecting the skin from UV radiation (Ch. 65). Melanosomes, with their complement of melanin, are produced by melanocytes and then transferred by excretion and phagocytosis into nearby keratinocytes, where they assume their preferred location above the nucleus. Members of the third major resident epidermal population, Langerhans cells, have the capacity to metabolize complex antigenic materials into peptides, some of which are immunogenic (Fig. 1.4). After activation, these cells traffic out of the epidermis toward regional lymph nodes, where they play a critical role in antigen presentation during the induction of immunity (Chs 4 & 14). Merkel cells, which contain neuroendocrine peptides within intracytoplasmic granules, are also found in the basal layer of the epidermis.

The most obvious function of epidermis lies in the stratum corneum, a semipermeable laminated surface aggregate of differentiated (keratinized) squamous epithelial cells, which serve as a physiologic barrier to chemical penetration and microbiologic invasion from the environment, as well as a barrier to fluid and solute loss from within[4] (Ch. 124).

Dermis

Beneath the epidermis, a vascularized dermis provides structural and nutritional support. It is composed of a mucopolysaccharide gel held together by a collagen- and elastin-containing fibrous matrix (Ch. 95). Vascular structures, accompanied by nerves and mast cells (Ch. 118), course through the dermis to provide nutrition, recirculating cells, and cutaneous sensation. Three additional cells, fibroblasts, macrophages and dermal dendritic cells, complete the list of dermal residents. In pathologic conditions such as acute inflammation, the functions and types of dermal cells change substantially, with a variety of infiltrating leukocytes arriving via vascular routes. In fact, the composition of cutaneous infiltrates differs depending on the disease entity, which provides students of dermatopathology useful diagnostic clues.

Dermal–epidermal interface

The boundary between epidermis and dermis consists of a specialized aggregation of attachment molecules, collectively known as the basement membrane[5] (Ch. 28). This structure is of considerable interest, because a variety of diseases originate from genetic defects in its composition; it also may serve as a target of autoimmune attack.

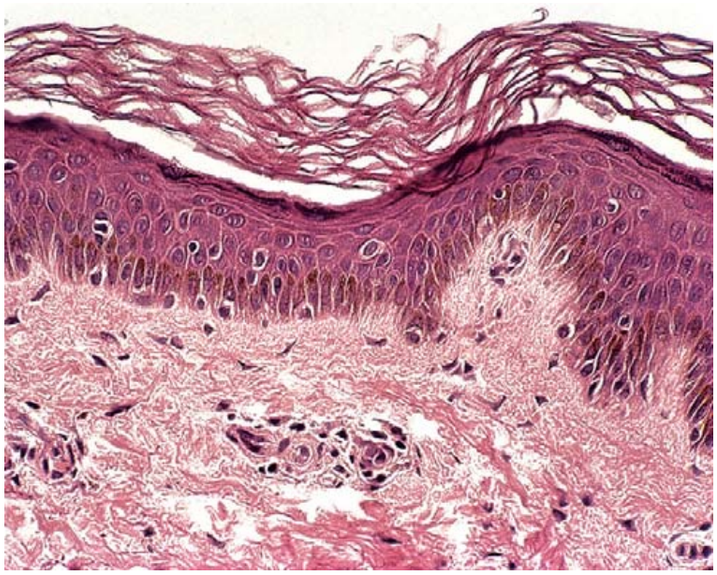


Fig. 1.1 Normal skin: trunk. Note epidermal layers from the surface: stratum corneum, stratum granulosum, stratum spinosum and stratum basale. Tightly packed dermal collagen is seen near the epidermal–dermal junction, and more loosely arranged collagen is found deeper in the dermis. A cluster of small blood vessels and nerves is seen in the dermis.

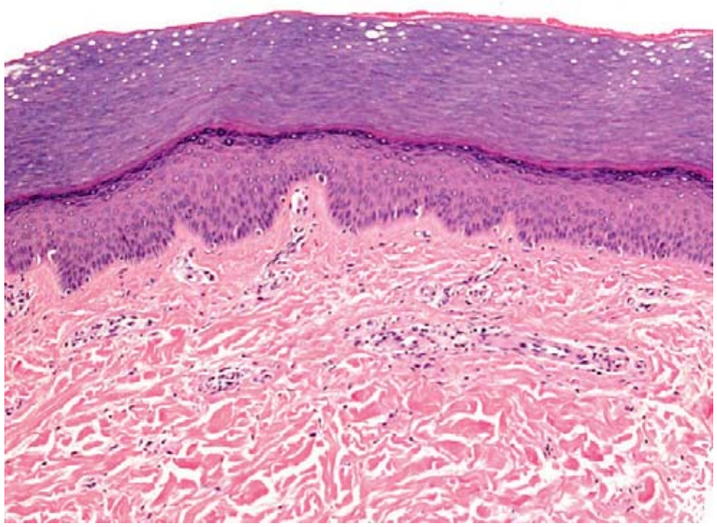

Fig. 1.2 Normal skin: palm. Note that the epidermis is thicker than that seen in Figure 1.1. The compact and thick stratum corneum is typical of skin on the palms and soles. *Courtesy, Lorenzo Cerroni, MD.*

Fig. 1.3 Normal melanocyte. A whole mount of epidermis has been stained for the presence of the enzyme tyrosinase, which typifies melanocytes. Note that the surrounding keratinocytes are virtually invisible. An adjacent hair shaft passes through the specimen. Melanocytes contain long dendritic processes that deliver protective melanosomes to nearby keratinocytes.

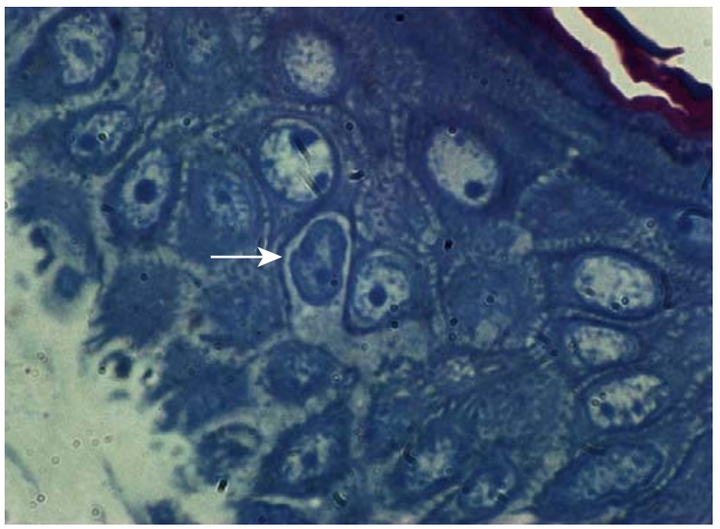

Fig. 1.4 Epon-embedded section of human epidermis. Note the pale cytoplasm and extended dendritic process of a central Langerhans cell (arrow), which resides above the basal cell layer of the epidermis.

Knowledge of the Function and Structure of Skin Begins with Skin Disease

We have chosen to present in the remainder of this chapter a conceptual framework into which the other chapters of this textbook may be placed. This framework is derived from the assertion that knowledge of cutaneous function begins with disease. One corollary of this assertion is that there may be unrecognized functions of skin, either because there is no corresponding disease or because the disease is fatal. For example, no one would have guessed that incontinentia pigmenti was lethal in males had it not been for the survival of heterozygous females with this X chromosome-linked disease[6,7]. Overwhelming apoptosis is thought to explain the death of male fetuses *in utero*.

Two other prejudices color the picture we choose to paint. First, we deviate from the concept that physicians should invariably attempt to develop a single diagnosis for an illness. Rather, we believe that it is possible and even likely that two or more disease processes and/or susceptibilities underlie an illness and that such simultaneous occurrences may alter the clinical presentation. In fact, practicing dermatologists are quite aware of the unusual morphologic features of pityriasis rosea when it occurs in a patient with underlying psoriasis or when a patient with atopic dermatitis improves substantially following treatment with an antibiotic, even in the absence of obvious infection. A growing array of genetic factors and infectious agents are known to modulate the course of otherwise conventional skin diseases. Witness the presence of numerous viral warts or tumors of molluscum contagiosum in patients with immunodeficiency from occult HIV infection or from iatrogenic immunosuppression. Thus, dermatologists have an extra assignment: to find otherwise hidden genetic, infectious and environmental factors that modify the appearance and severity of cutaneous disease.

All plants and animals possess limiting membranes that define an internal space and at the same time protect against external insults. In mammals, these membranes, which may be described functionally as "barriers", occur primarily in three organs: the lung, gastrointestinal

tract and skin (Ch. 124). Although similar in concept, the barrier properties of these organs are fundamentally different. Pulmonary and gastrointestinal barriers, by virtue of their internal location, are protected from many environmental influences, and at the same time they promote rather than retard the transfer of gases, nutrients and wastes. By contrast, and with the possible exception of UV radiation-facilitated vitamin D_3 production[8], there is no obvious benefit to skin penetration, or, at least, there are as yet no recognized diseases attributed to the failure of any material or form of energy to penetrate the skin. It should be noted, however, that biomedical scientists now try to subvert the cutaneous barrier, as skin has become a target of novel therapies based upon percutaneous penetration[9] (Chs 124–129). In addition to serving as a useful portal of entry for pharmaceutical agents, plans are underway for skin to serve as a site for immunization with gene-based materials and as a gene-driven cutaneous factory[10].

The Central Role of Protecting DNA as a Function of Skin

Although we begin with the common rhetorical question: "What are the functions of skin?", it is followed by a second and perhaps more complicated question: "What are the requirements of skin that allow it to serve those functions?". We propose that the primary function of skin is to maintain an internal environment that allows an organism to protect DNA and to reproduce it faithfully. In short, preservation and reproduction of DNA sustains the species. A second and highly related process in a changing world is the generation of useful changes in DNA that accommodate new environmental circumstances. This results in evolution of the species, which may include genetically programmed changes in the skin. Ultimately, all biologic activities serve these functions.

Although the permanent repository of DNA lies in the gonads, the protection of DNA in all sites, including the skin, is also essential for biologic success. This concept of the centrality of DNA has been developed by Reg Morrison in his monograph *The Spirit in the Gene: Humanity's Proud Illusion and the Laws of Nature*, which reviews how life-form competition may be modeled as a method of protecting DNA[11]. Morrison makes the striking observation that human DNA has in the last 300 years come to dominate all life on the earth.

The requirements of skin are identified in its failings

So, what are the requirements of skin for the protection and duplication of DNA? In fact, these requirements have not been identified through logical considerations; rather, as noted above, they have been identified through the various failures that result in skin disease. For this reason, we begin our survey with a listing of failures of skin (Table 1.1).

SELECTED REQUIREMENTS AND FAILINGS OF SKIN	
Requirement	**Selected failings**
Prevent infection via innate and adaptive immunity	Fungal, bacterial and viral infections; autoimmunity, cancer
Maintain a barrier	Infection, dehydration
Repair injury	Cancer, leg ulcers
Provide circulation	Infarction (due to embolization, vasculitis, or other forms of occlusion)
Communicate	Sensory neuropathy, pruritus
Provide nutrition	Vitamin D deficiency
Regulate temperature	Hypothermia, hyperthermia
Attract attention	Photoaging, vitiligo, alopecia

Table 1.1 Selected requirements and failings of skin.

Fig. 1.5 Verrucae vulgaris (warts). Human papillomavirus infections in humans can affect virtually any cutaneous surface. Periungual infections, as seen in this photograph, are both common and difficult to treat. *Courtesy, Louis A Fragola, Jr, MD.*

Preventing Infection: Skin as an Immunologic Organ

An intricate system of immunologic recognition, both innate and adaptive, protects skin (and underlying tissues) from infection[12] (Ch. 4). The cornerstone of adaptive immunity lies in recirculating lymphocytes and antibodies that are specifically recruited and "tuned" to recognize "foreign" materials, primarily peptides derived from infectious agents. Initial recognition occurs when sentinel dendritic cells in the epidermis (Langerhans cells) or dermis (dermal dendritic cells) are activated. Prior to activation, these cells acquire the capacity to engulf particles of many sizes and to metabolize complex proteins into small immunogenic fragments. Once activated, motility is induced, allowing these cells to travel out of their cutaneous residence, and, via draining lymphatics, move to regional lymph nodes. Thus, these residents of normal skin have the capacity to travel to a distant location where reactive lymphocytes are selected and then expanded greatly in number. Within a lymph node, activated helper T lymphocytes assist B lymphocytes to generate antibodies, while helper T lymphocytes and cytotoxic T lymphocytes begin to recirculate preferentially to and from skin. For a further discussion of innate and adaptive immunity, the reference by Janeway is highly useful[12].

Failure of immunity: infection

The diagnosis and treatment of infection constitutes a substantial portion of dermatology (Chs 74–83). Examples of chronic and recurrent infectious skin diseases illustrate the extent to which mechanisms of resistance to infection are lost or defective in some patients. In each example that follows, initial resistance depends upon the structural integrity of the stratum corneum.

Warts

Trauma to the stratum corneum interrupts a physical barrier that is ordinarily not susceptible to viral infection (Ch. 79). In addition, trauma allows implantation of infectious particles among the underlying keratinocytes, which are viable and less resistant. Following this structural failure, immunologic recognition of infected keratinocytes is ordinarily followed by a cytotoxic cellular response, destruction and cure. When this fails, chronic infection may ensue (Fig. 1.5). It is of interest that many therapies for warts, other than physical destruction, rely on modulating the immune response. On the other hand, few problems are more vexing than chronic and recurrent warts, particularly in patients who are immunosuppressed. Especially important are the viral serotypes associated with squamous cell carcinoma and the genetic disorder epidermodysplasia verruciformis[13] (Ch. 79). It is instructive that protective immunity against warts often appears to be balanced precariously, so that minor shifts in responsiveness may lead to their elimination in many sites simultaneously. This has been attempted therapeutically by the use of oral cimetidine, topical applications of imiquimod, elicitation of contact sensitivity reactions, and intralesional injection of recall antigens such as *Candida* or mumps[14,15].

Dermatophytosis

The diagnosis and treatment of infections with dermatophytes remain largely the responsibility of dermatologists (Ch. 77). Perhaps this is because dermatophyte infections are almost invariably limited to the skin, hair and nails, inasmuch as one or more serum factors (e.g. transferrin) may prevent growth where serum can reach[16] (Figs 1.6 & 1.7). As yet unidentified genetic factors protect some individuals from infection, because it is not uncommon to encounter families in which several individuals are chronically infected, whereas other family members, in the face of obvious exposure, are seemingly never infected. On the other hand, experience from tropical climates indicates that individuals who are relatively resistant in a dry environment may lose that resistance as the ambient humidity increases or when occlusive military shoes are worn[17]. Obviously, dermatophyte infection and resistance include a complicated interplay among genetic susceptibilities, immune responsiveness and environmental circumstances.

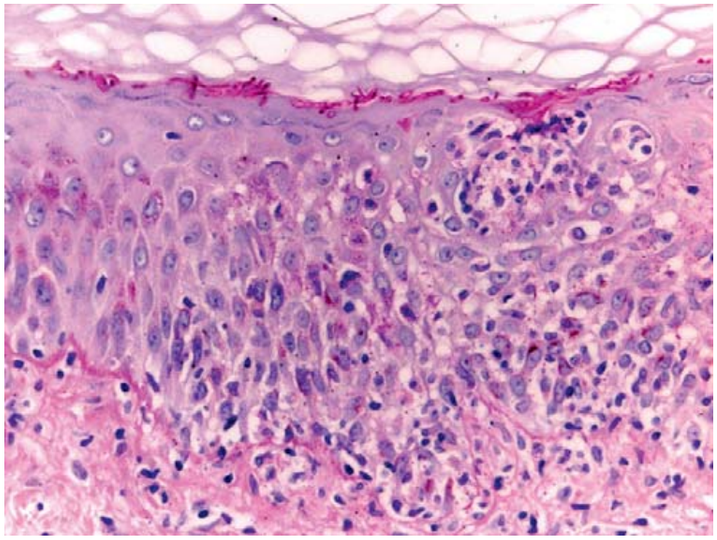

Fig. 1.6 Dermatophytosis. PAS staining for neutral mucopolysaccharides reveals branching red–purple fungal hyphae within the stratum corneum in a patient with tinea corporis. If diastase enzyme is not added, glycogen within keratinocytes also stains with PAS. *Courtesy, Lorenzo Cerroni, MD.*

Fig. 1.7 Dermatophytosis. This annular presentation of tinea corporis typifies cutaneous dermatophyte infections.

Opportunistic infections in the setting of human immunodeficiency virus infection

An enormous body of biomedical knowledge has accrued during the 30-year epidemic of HIV infection (Ch. 78). As a beginning, it appears that HIV penetrates through small tears in genital and rectal mucosae. Once infection has occurred, the virus has been impossible to delete, despite a panoply of relatively effective therapies. With the eventual loss of immunologic integrity, patients develop AIDS and thereby demonstrate the relevance of effective cellular immunity to protection against infections with a wide variety of agents, including *Mycobacterium tuberculosis, Pneumocystis jiroveci*, varicella zoster (Figs 1.8 & 1.9) and herpes simplex viruses. What more evidence would one want to demonstrate the relevance of cellular immune protection of skin than the diseases that are described in Chapter 78?

Hansen's disease (leprosy)

Hansen's disease is instructive in that the majority of humans exposed to its causative organism, *Mycobacterium leprae*, develop an effective immune response that is seemingly curative (Ch. 75). On the other hand, a small percentage of exposed individuals develop chronic infection that may take any one of several forms, based on immunologic resistance. In fact, observations made in patients with Hansen's disease have been important in formulating the Th1/Th2 paradigm (Ch. 4), with each patient's clinical response falling along a spectrum from tuberculoid to lepromatous[18]. Importantly, Hansen's disease also illustrates the relevance of cutaneous sensation to protection against traumatic injury, as will be presented later.

Warts, dermatophytosis, opportunistic infections in the setting of HIV infection, and Hansen's disease all illustrate important aspects of

Fig. 1.8 Herpes zoster. Unilateral grouped vesicles and serous crusts on an erythematous background. Note the associated edema of the eyelid and lip. *Courtesy, Louis A Fragola, Jr, MD.*

cutaneous function, ranging from a structural barrier provided by the stratum corneum to immunologic recognition and protective immunity.

Faulty immunity: autoimmunity

We have made a case for the concept that the primary task of immunity is to recognize and destroy infectious organisms. Having stated this, autoimmunity may then be modeled as a failure in distinguishing "self" from infection, i.e. autoimmunity is a misidentification and destruction of portions of the host, as if it were dangerous or "foreign". Autoimmune diseases are legion, with components of the epidermal basement membrane and desmosomes serving as important targets (Fig. 1.10). Moreover, cutaneous cellular elements serve as both regulators and targets of autoimmune injury. Table 1.2 lists several common autoimmune diseases that affect the skin, each with a different target. These diseases have different sets of genetic factors and environmental insults that promote their development. Subsequent chapters detail their relevant elements.

We know a substantial amount about molecular targets in these diseases, and we also know much about how immunity works in protecting against infectious diseases. However, we are only now learning about how errors in recognition lead to immune responses that target self antigens inappropriately and damage indigenous structures. It has also become apparent that autoimmunity to skin antigens may impact other organ systems. Bullous pemphigoid antigen 1, for example, has distinct isoforms in the skin and in the central nervous system, and patients with bullous pemphigoid have a higher incidence of dementia, Parkinson's disease and multiple sclerosis[19].

Failure of immunity: cancer

Data to support the concept that immune responses also protect against malignancy is strongest for those malignancies that arise in skin and lymphatic tissues[20,21], especially cutaneous melanoma and squamous cell carcinoma (SCC). Cutaneous SCC is a well-known complication of immunosuppression in solid organ transplant recipients. Additionally, we include a photomicrograph of a thick melanoma, without inflammation (Fig. 1.11). Many developments in melanoma therapy are based on attempts to enhance immune responsiveness (Ch. 113).

Maintaining a Barrier: Skin as a Protective Organ

From the outset, the most obvious function of skin is to maintain a barrier that prevents the loss of fluids, electrolytes and other molecules from within the body and, at the same time, prevents penetration by microorganisms, toxic materials and UV radiation[22,23] (Ch. 86). For all but UV radiation, the stratum corneum is the central element in that function. By contrast, protection against UV radiation occurs through several independent phenomena, including photon scattering in the stratum corneum and photon absorption by underlying melanin.

Failure of protection against toxic chemicals

The analysis of barrier failure begins with the observation that the stratum corneum is defective in disorders of keratinization[24], as it is less resistant to chemical penetration. Two diseases typify this defect: epidermolytic hyperkeratosis (Fig. 1.12) and Darier disease (keratosis follicularis)[25,26]. An instructive set of circumstances arose with the problem that patients with these diseases commonly have recurrent bacterial infections. In an attempt to treat and to prevent such infections, dermatologists and other physicians have recommended for decades the prophylactic use of topical antibacterial agents to decrease bacterial carriage and, at the same time, the associated odor.

In an article published in 1960, Medansky and Woloshin[27] described an extraordinarily high frequency of neuropsychiatric disorders in

COMMON AUTOIMMUNE SKIN DISEASES		
	Target antigen	**Chapter**
DISEASES WITH IDENTIFIED AUTOANTIGENS		
Pemphigus foliaceus	Desmoglein 1	29
Pemphigus vulgaris (Fig. 1.10)	Desmoglein 3 and 1	29
Bullous pemphigoid	Collagen XVII (BPAG2), BPAG1*	30
Epidermolysis bullosa acquisita	Collagen VII	30
Dermatitis herpetiformis	Transglutaminase-3	31
DISEASES WITH UNKNOWN OR MULTIPLE AUTOANTIGENS		
Subacute cutaneous lupus erythematosus	Unknown	41
Chronic cutaneous lupus erythematosus	Unknown	41
Psoriasis	Unknown	8

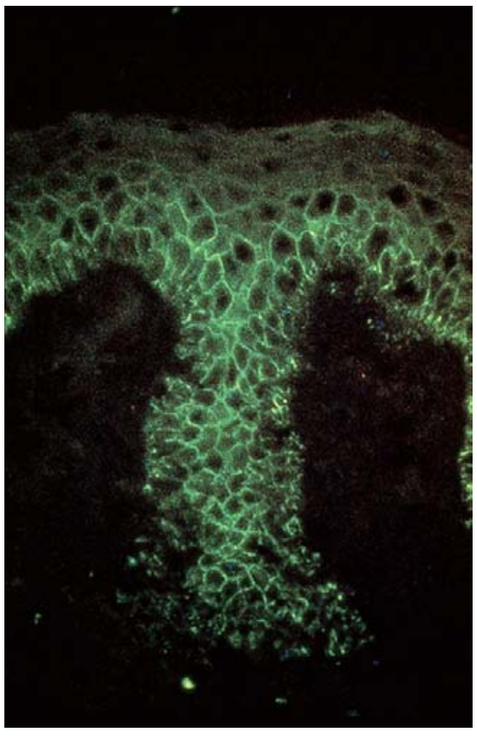

Fig. 1.10 Pemphigus vulgaris (immunofluorescence). Intercellular staining of epidermal keratinocytes reveals the *in vivo* deposition of antibodies to desmoglein 3.

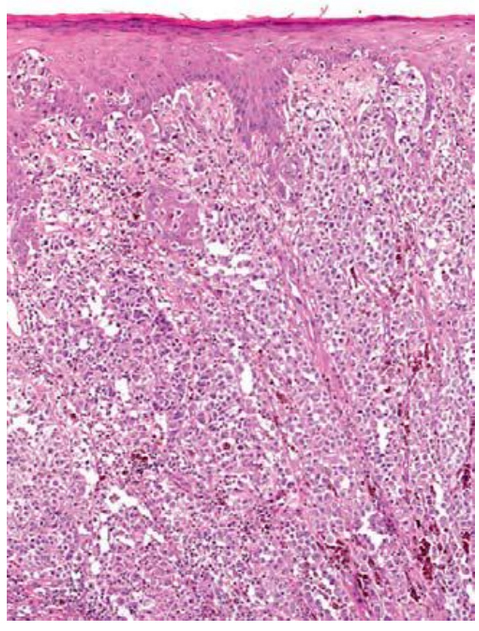

Fig. 1.11 Melanoma. This thick melanoma has virtually no associated inflammatory cells histologically. The thickness and lack of a host response indicate a poor prognosis for the patient. *Courtesy, Lorenzo Cerroni MD.*

patients with keratosis follicularis, even though no mechanism could be imagined that would link keratin function with CNS function. In retrospect, however, hexachlorophene had been recommended as a useful antibacterial agent soon after its introduction in 1944. Several decades later, it was recognized that it was potentially neurotoxic, with use eventually curtailed in the 1970s[28]. Since that time, there have been fewer reports of neuropsychiatric findings in keratosis follicularis. Our conclusion is that hexachlorophene penetrates a defective barrier in toxic amounts. However, an alternative explanation proposed by others is that dysfunction of SERCA2 within the brain may potentially lead to neuropsychiatric findings[29]. In contrast, there is no debate about the more recently reported enhanced absorption of topical tacrolimus in patients with Netherton syndrome.

In sum, the barrier for chemical penetration is invested in the stratum corneum (Ch. 124), and this barrier is defective in diseases of keratinization.

Failure to protect against dehydration and infection: toxic epidermal necrolysis

The most dramatic form of epidermal failure occurs in patients with toxic epidermal necrolysis (TEN; Ch. 20). In this drug-induced disease, rapidly progressive keratinocyte death leads to detachment of the epidermis over large areas of the body. There is a complete loss of barrier function (Figs 1.13 & 1.14). TEN is most often associated with sulfonamides, anticonvulsants and nonsteroidal anti-inflammatory drugs. It has a mortality rate that depends upon the area of skin involved, but death is not uncommon. There is as yet no specific treatment for TEN. However, there is evidence that drug-induced triggering of massive keratinocyte apoptosis may underlie the disease[30], and inhibition of the apoptosis signaling pathway (e.g. by administration of intravenous immunoglobulin) may improve survival. However, the point of this discussion is that the complications that accompany loss of the epidermis reveal all of its functions. Despite intensive treatment with similar techniques as those employed for burns, complications are common and can include enormous fluid and electrolyte losses leading to dehydration as well as infections with bacteria and yeast.

Failure to protect against UV radiation: albinism

UV radiation induces a myriad of changes in the skin, ranging from acute toxicity and immunosuppression to carcinogenesis and premature aging (Chs 86, 87, 107 & 108). However, there is an apparent contradiction in the recommendations of dermatologists: effective therapies for a number of skin diseases are based on the use of UV radiation of various wavelengths (Ch. 134), while protection from the sun's rays is in general highly recommended to prevent adverse effects from UV radiation (Ch. 132). In addition to wearing clothing and using topical preparations that include UV-absorbing or UV-blocking molecules, several characteristics of the skin itself limit UV radiation-induced damage. Due to its optical characteristics, the stratum corneum tends to reflect and scatter photons, and those that penetrate the stratum corneum are usually absorbed by molecules such as melanin. Additional mechanisms are the scavenging of reactive oxygen species by antioxidants and repair of damage with DNA repair enzymes.

The importance of cutaneous pigment in protecting the skin against UV damage is demonstrated in patients with oculocutaneous albinism (OCA)[31]. The impact of melanin in limiting UV penetration may be seen unequivocally in patients who have type 1 OCA due to an absence or reduction in tyrosinase activity and, as a result, melanin production (Fig. 1.15)[31]. Striking amongst the evidence is the experience of the Cuna Indians, residents of islands near Panama, in whom there is an extraordinarily high frequency of type 1 OCA and little relief from year-long intense exposure to sunlight. In the context of this high background genetic frequency (approximately 1%), there is a parallel high frequency of skin cancer. Likewise, acute toxicity, photosensitivity diseases and premature photoaging (Ch. 87) are known complications for these patients.

Maintaining the Integrity of Skin: Repair Mechanisms

Physical injury occurs commonly in the skin, including many small breaks from blunt and sharp objects that are repaired almost without notice. A special type of injury is caused by the penetration of UV radiation. This includes a variety of effects that range from sunburn to immune suppression, accelerated aging and carcinogenesis. Thermal injury occurs upon exposure to a hot object or radiant energy, e.g. from fire, that heats the skin excessively (see below, Thermoregulation). Injury also occurs when there is interruption of the underlying vascular supply. Each episode of injury is followed by a sequence of repair processes that eliminate foreign objects and cover defects. This "wound

healing" response has been studied in considerable detail (Ch. 141), because delays in wound healing are both incapacitating and expensive.

Failure to effectively repair injury

Delayed wound healing

Delayed and incomplete wound healing have been associated with diabetes mellitus and aging. The treatment of chronic leg ulcers, especially in the elderly, is an important part of dermatology and rehabilitation medicine (Ch. 105). The Wound Healing Society (www.woundheal.org) is a consortium of clinical and basic science investigators that includes physicians, scientists, industrial representation and governmental agencies. Only in recent years have these investigators begun to address the issues of chronic cutaneous ulceration.

Keloids

The formation of hypertrophic scars and keloids may be seen as an exuberant response to injury. It combines a unique mix of genetic and environmental factors. The most reasonable explanation of pathogenesis may be seen in studies showing that transforming growth factor β (TGF-β) activity is excessively high in fibroblasts derived from keloids[32]. Despite preliminary evidence that TGF-β may play a role in the establishment of an environment that favors overgrowth of dermal elements to form hypertrophic scars and keloids, the discipline of wound healing remains in its infancy.

Xeroderma pigmentosum

An important failure occurs when UV radiation-induced DNA damage is not repaired effectively. The prototype for this deficiency is the disease xeroderma pigmentosum[33]. The high incidence of skin cancers of many types in these patients supports the assertion that UV radiation-induced injury is an important cause of skin cancer in humans. Thus, it is necessary for the skin is to protect itself against the detrimental effects of UV radiation. This illustrates two points: first, UV radiation is dangerous; and second, when DNA repair mechanisms are defective, cancers arise much more quickly.

Providing Circulation: Skin as a Nutritive Organ

The movement of cells and soluble elements to and from skin is mediated by two circulatory systems: (1) a two-way hematologic system that conducts blood flow; and (2) a one-way lymphatic system that returns leukocytes and interstitial fluids, first to draining lymph nodes and then, via the thoracic duct, into the central venous system. Hematologic circulation, the most obvious because of the red and blue colors of blood, serves three major functions: nutritional support, the delivery of leukocytes, and thermoregulation. Although the movement of oxygen and solutes from blood into interstitial tissues occurs largely by passive diffusion, the emigration of cellular elements from the vascular space occurs by a highly ordered sequence of signaling, attachment, and migratory processes that are described in Chapter 102.

The hematologic system includes two types of vessels: (1) nutritive vessels (arteries, capillaries and veins); and (2) anastomosing arteries and veins that participate in heat regulation. This latter system includes an extensive subcutaneous venous plexus, which can hold large quantities of blood (to dissipate heat from the surface of the skin), and arteriovenous anastomoses, which are large direct connections between arterial and venous plexuses. These anastomoses are prominent in areas often exposed to maximal cooling, such as the volar surfaces of the hands and feet, lips, nose and ears.

Cutaneous lymphatic drainage begins in microscopic blind-ended dermal vessels called lymphatic capillaries. These collect both cells and interstitial substances that are then directed toward regional lymph nodes. Lymphocytes, macrophages and dendritic cells all have the capacity to exit the skin via lymphatic drainage. Stoitzner and colleagues[34] have provided an exquisite photographic description of Langerhans cells in their travels from epidermis to draining lymphatic vessels.

Failure of circulation: arteries and veins

Embolic occlusion of arteries

The most dramatic form of blood vessel occlusion occurs with embolimediated blockage, which can produce changes within hours. This is followed rapidly by necrosis of all cutaneous structures distal to that blockage. The extent of necrosis depends on the size of the vessel occluded, and occlusion due to non-infectious cholesterol emboli is usually associated with generalized arteriosclerotic cardiovascular disease. Occlusion followed by cutaneous necrosis demonstrates in vivid fashion the complete dependence of skin on arterial circulation.

Vasculitis

Cutaneous inflammation centered in the blood vessel wall is responsible for a spectrum of cutaneous findings that vary depending upon the size of vessel affected. Vasculitis is commonly associated with rheumatic skin disorders (Chs 24, 41, 42 & 45). They include inflammation associated with dermato- and polymyositis, rheumatoid arthritis, lupus erythematosus, and immune complex-mediated small vessel vasculitis (Fig. 1.16). The critical element in terms of cutaneous structure is that, once again, the survival of skin is highly dependent upon an intact circulation.

Occlusive vasculopathy

Other disorders characterized by vascular occlusion result from aberrant coagulation or cold-related "gelling" (Ch. 23). This can be precipitated by antibodies directed against regulators of coagulation, which may develop in patients with rheumatic diseases.

Venous insufficiency

Although listed last, venous insufficiency through partial occlusion and valvular incompetence contributes to the most common vascular problem, the development of venous stasis ulcers of the legs (Ch. 105).

Failure of circulation: lymphatic blockage

Blockage of lymphatic drainage may also occur in certain inflammatory skin conditions. The inflammation associated with recurrent streptococcal and staphylococcal infections may lead to scarring and loss of

lymphatic drainage, resulting in distal edema. With chronic infection, permanent edema may develop, associated with widespread verrucous change at the skin surface, a condition described as elephantiasis nostras verrucosa (Ch. 105). Likewise, blockage of lymphatic drainage in parasitic infections is known to cause deforming patterns of lymphatic blockage (Ch. 83). It is also relevant that, many years ago, Frey and Wenk[35] demonstrated that ligation of lymphatic drainage caused a back-up of leukocytes unable to return from tissue sites as well as a failure to immunize against antigens that penetrated skin affected in this way.

Interfacing with External and Internal Environments: Skin as a Communicating Organ

Communication in skin occurs by three mechanisms: conventional nerve conduction via cutaneous fibers; intercellular signaling mediated by cytokines and hormones (endocrine, paracrine and autocrine effects); and the physical movement of "message-carrying" cells from one site to another. The roles and importance of these mechanisms have been revealed through various defects in their execution.

Skin is "wired" with afferent and efferent nerve fibers that accompany vascular structures, forming an intricate network within the dermis. They envelop the pilosebaceous apparatus (Ch. 68), blood vessels and sweat glands. Although the head and distal extremities are innervated most densely, all skin contains nerves. Within the dermis, larger fibers are surrounded by a myelin sheath, but as diameters diminish, many fibers run free. In fact, most nerve fibers appear to end in the dermis, although there is clear evidence that some small endings penetrate the basement membrane and travel into the epidermis, where they have the capacity to modulate immune responsiveness[36].

Nerves control vascular tone, as demonstrated in blushing responses, and they mediate the sensations of heat, cold, itch, touch and pain (Chs 5 & 6). Defects in sensation and neurologic function occur commonly, and they may be seen in patients with chronic pain following varicella–zoster virus infection, uncontrolled itching, neurologic syndromes (e.g. trigeminal trophic syndrome), and excessive sweating. A highly useful therapeutic development has been the intradermal injection of botulinum toxin to uncouple cholinergic nerve fibers. This technique has at least two dermatologic applications: (1) to decrease muscle tone, leading to a loss of facial lines for cosmetic purposes; and (2) to inhibit the excessive sweating that characterizes disabling axillary and palmar hyperhidrosis[37] (Ch. 159).

Abnormality of neurologic communication: excessive sensitivity

Itch is a major problem for patients with skin disease (Chs 5 & 6). We presume that modest levels of itching confer some beneficial effect, but, most certainly, excessive itching can be devastating to both personal and social activities. On the other hand, there is at present little evidence for structural abnormalities that predispose to excessive itching. Postherpetic neuralgia is similarly important[38] (Ch. 80), although, once again, there is no obvious structural defect in this exquisitely painful disorder.

Abnormality of neurologic communication: excessive sweating

Hyperhidrosis is a potentially debilitating disorder of sweating, which commonly involves intertriginous areas as well as the palms and soles. Accumulated evidence favors a neurologic abnormality rather than a structural abnormality[39]. Moreover, injection of botulinum toxin now offers considerable potential for relief (Ch. 159).

Abnormality of neurologic communication: decreased sensitivity

The most obvious and devastating effects of altered touch and pain sensation may be found in patients with the peripheral neuropathies that accompany Hansen's disease[40] (Ch. 75) and diabetes mellitus[41] (Ch. 105). Similar problems may occur in patients under the influence of narcotic anesthesia. In each of these settings, the loss of sensory function leads to the failure of patients to recognize, and therefore avoid, cutaneous trauma. For patients with Hansen's disease, numerous injuries over months and years lead to a gradual loss of tissue. In a similar fashion, a loss of cutaneous sensory function in patients with longstanding diabetes mellitus leads to unappreciated pressure ulcers in weight-bearing areas of the feet. In both of these conditions, a profound loss of sensation leads to unrecognized trauma to the skin, with consequent ulcer formation and loss of tissue. What we can learn from patients with these diseases is the exquisite vulnerability of skin to traumatic injury in the absence of appropriate sensation.

Communication via hormones and cytokines

Hormones

A relevant model for indirect hormonal influences on skin is adrenocorticotropic hormone (ACTH), which was recognized in classic studies as having systemic effects through the induced secretion of adrenal corticosteroids. This, in turn, had temporarily beneficial effects on inflammatory skin disorders such as psoriasis (Ch. 8) and atopic dermatitis (Ch. 12). On the other hand, a model for pathologic changes induced by inappropriate secretion of hormones is seen in the effects of the catecholamine hormones and their precursors (norepinephrine, epinephrine or dopamine) in patients with vascular instability caused by pheochromocytomas. Likewise, several of the clinical signs of Cushing's disease (altered fat distribution, vascular dilation and striae) result from excessive secretion of corticosteroids. In contrast, diminished production of adrenocortical hormones causes excessive secretion of ACTH, which, in turn, gives rise to the hyperpigmentation seen in patients with Addison's disease (Ch. 67).

Skin also plays a unique hormonal role in calcium metabolism. Vitamin D_3 (cholecalciferol) is produced in the epidermis by the action of UV radiation on 7-dehydrocholesterol[8]. It then leaves the skin and is hydroxylated in the liver and kidneys to the active form of vitamin D (1,25-dihydroxycholecalciferol).

Cytokines

In the last 30 years, a new field of cutaneous knowledge has evolved, beginning with the recognition that keratinocytes contain large amounts of the biologically active cytokine interleukin-1 (IL-1)[42,43]. This was followed in rapid succession by the recognition that cells within skin are able to produce an array of biological response modifiers. Most prominently, keratinocytes produce IL-1, IL-8 and TGF-β[44]. The capacity of these substances to exert important physiologic functions is demonstrated by the beneficial effect TGF-β has on wound healing[45]. Looking at other cutaneous cells, Langerhans cells produce a unique spectrum of cytokines and chemotactic factors related to their immunologic properties[46]. Vascular endothelial cells produce IL-1β, IL-6 and IL-8[47]. In fact, cytokine-mediated communication within the skin is an active area of research[45,48–51], and the interplay between cytokines and cells is often reciprocal[52,53]. For example, mast cells produce tumor necrosis factor (TNF), which affects cutaneous immunity[54], but, at the same time, mast cell function is regulated by other cytokines[55]. Unraveling the complex relationships among cutaneous cells, their own hormones (autocrine), hormones from adjacent cells (paracrine), and hormones from distant cells (endocrine) will occupy the attention of skin biologists and skin pharmacologists for the next generation.

Cellular communication

We have only recently begun to appreciate that certain resident cutaneous cells, in the course of their normal function, depart from the skin while in possession of information that ultimately has direct impact on the function of the skin. Chief among these cells are dendritic cells, which, after activation, leave the skin and traffic to regional lymph nodes. In this location, they select and prime naive and resting T lymphocytes (Chs 4 & 14). The processes of activation, outward migration, and repopulation have been areas of intense investigation, with the prospect of developing methods by which immunity may be modulated.

Failure of cytokine and cellular communication

Knowledge about the roles of cytokines and cell traffic in cutaneous communication is as yet in its infancy, meaning that defects are only now being recognized. Stemming from an improved understanding of the role of cytokines in keratinocyte biology, major developments in

dermatologic therapy have been achieved during the last decade in the management of inflammatory skin diseases, most notably psoriasis. Aberrant levels of TNF-α and IL-23 have emerged as critical targets of immunobiologic agents used to treat psoriasis. As our understanding of cytokine biology increases, new developments in targeted therapy will continue to expand our therapeutic armamentarium.

Regulating Temperature: Skin as a Thermoregulatory Organ

Regulation of core temperature is a characteristic of all mammals, which, by definition, are euthermic. For humans, core temperature is maintained at approximately 37°C (98–99°F). Because environmental influences tend to change that temperature, there exists an intricate system of regulation in which skin plays a decisive role as both radiator and insulator. Temperature regulation by the skin is effected primarily through evaporative cooling after eccrine sweating (Ch. 39) and through vasodilation and vasoconstriction.

Human skin includes several million eccrine sweat glands distributed over most of its surface, with the total mass of eccrine glands approximately that of one kidney. Under neurologic control, the secretory activity of eccrine sweat glands consists of two major activities: (1) secretion of an ultrafiltrate of a plasma-like fluid; and (2) reabsorption of sodium by the duct to produce hypotonic sweat.

Failure of thermoregulation: effects of excessive heat

Excessive heating may be local or systemic, and, when this occurs, skin plays a cooling role to prevent injury. Cooling may be required under two non-exclusive circumstances: (1) in response to central heating, which occurs when heat enters skin from an external source or when energy is generated through muscular exertion in amounts sufficient to increase core temperature; and (2) in response to sustained local heating, which occurs when a portion of skin is heated to a temperature at which critical proteins begin to denature, i.e. in the neighborhood of 45–50°C (113–122°F; Ch. 88). The subsequent physiologic responses that lower temperature to prevent injury require innervation, circulation and successful sweating. Dispersion of local heat takes place by direct radiation into the environment and by heat transfer to other body locations via circulating blood. In contrast, the elimination of central heat occurs through radiation from the skin surface and from the evaporative cooling that follows sweating.

The relevance of sweating to the elimination of heat, and, ultimately, to survival may be found in the vignette of hyperthermia found at the beginning of this chapter. In this patient with the X-linked genetic disorder hypohidrotic ectodermal dysplasia, the defining defect is a nearly complete absence of sweat glands, in association with other features such as hypotrichosis and abnormal teeth (Ch. 63)[56]. This disease demonstrates the importance of sweating, as death from overheating during exercise is known to occur, especially when the environmental temperature is high. It is of interest that since evaporative cooling normally plays no role in these patients, there is virtually no effect of environmental humidity on core temperature, because all heat loss occurs through radiation. On the other hand, heat loss may be increased substantially by a relatively simple measure that allows patients with this disease to engage in vigorous outdoor activities in hot climates. Exogenous "sweat" may be created by spraying water over the body repeatedly throughout an exercise or event[56].

Heat injury as therapy

The production of local heat injury may also have a beneficial side, as electrocautery is a time-honored method of therapy in cutaneous medicine (Ch. 140). Additionally, heat therapy has been used in the management of cutaneous infection, including sporotrichosis and leishmaniasis.

Failure of thermoregulation: effects of excessive cold

In contrast to heat injury, individuals exposed to cold temperatures require heating to prevent injury. This also occurs under two related circumstances: (1) in response to heat loss to the environment in amounts that cool the body centrally (hypothermia); and (2) in response to exposure locally to sustained temperatures below freezing, which otherwise would lead to direct freezing injury ("frostbite"). With extreme exposure, of course, both may occur together.

Extreme examples of excessive core and surface cooling in association with limited central heat generation were described vividly by Jon Krakauer in his report of the Mount Everest climbing disasters of 1996[57]. Unfortunately, aside from vascular constriction to reduce radiation of heat from the skin surface and shivering (or exercise) to increase central heating, there are no intrinsic cutaneous mechanisms to protect against excessive cooling. However, humans have become quite adept at creating artificial methods to prevent cold or heat injury through clothing and shelter. These have enabled humans, and consequently human DNA, to survive successfully in geographic areas of extreme temperature. Perhaps the most obvious are the mountain climbers who scale the Himalayan mountains and the firefighters who wear insulated clothing as they enter burning buildings.

Cold injury as therapy

When properly applied, local cold injury (e.g. cryosurgery) has been used successfully as a therapeutic tool for decades (Ch. 138).

Interpersonal Communication: The Skin Conveys Beauty, Attracts Attention and Contributes to Self-Identity

An important function of skin begins with the need for humans to communicate with each other so that personal and societal goals can be met. The skin plays an important role in interpersonal communication by conveying beauty to others, attracting attention, and contributing to the development and expression of self-identity.

The presence of beauty, as seen in photographs or paintings, tends to attract attention, which is sometimes intense. It is easy to imagine that these responses are coded genetically, because high attractiveness would seem to increase the likelihood that DNA survives and also, therefore, that the species survives. In sum, without any confirming data, we assert that the desire to be attractive helps to insure the selective survival of human DNA.

Virtually all attraction that occurs at a distance beyond that of touch and smell is mediated by vision, and, thus, the skin assumes overwhelming importance as a visual target for humans. Having said this, it should not be surprising that in every society, the physical appearance and condition of the skin seems to have assumed fundamental importance. In Figure 1.17 we have included portraits of Mr Frederick H Hemming and his fiancée, Miss Mary Anne Bloxam, painted in 1824–25 by the English portrait artist Thomas Lawrence. The intrinsic "beauty" of these individuals prompts one to examine their features with interest. More recently, modern artists such as Andy Warhol have challenged us to reconsider the relationship between appearance and beauty.

There is not sufficient space to list the physical features that are considered beautiful, but let us assert that the loss of these features has much to do with the anxiety that often characterizes patients with acne, vitiligo, alopecia, aging and photoaging, as well as virtually all other skin diseases. During the past decade, increasing attention has been given by both researchers and clinicians to the effect of skin disease on quality of life. Myriad reports have been published defining the extent to which chronic skin diseases, including psoriasis, eczema, and pigmentary disorders, affect the way in which patients perceive themselves. As dermatologists become more aware of the psychosocial impact of chronic skin disease, we are better able to treat patients with these conditions.

Finally, the skin represents a "canvas" onto which individuals may make modifications in order to communicate with each other and to display aspects of self-identity. Tattoos, ritual scarification, and piercings have long been seen as expressions of self-identity. Dermatologists can participate in skin modification by interventions meant to improve the attractiveness of the patient. Many dermatologists now practice cosmetic surgery and procedures, repairing a variety of defects and moving fat from one site to another. During the last 25 years, increasing amounts of discretionary money have been diverted into procedures that improve appearance (Chs 152–159). Dermatologists and their patients have played major roles in this transition.

Failures to present an attractive appearance

Appropriately proportioned, symmetric, unblemished skin seems to be preferred in the majority of societies. Our question at this point

Fig. 1.17 Mr Frederick H Hemming and his fiancée, Miss Mary Anne Bloxam. These portraits were painted in 1824–25 by the English artist Thomas Lawrence. Fig. 1.18 Vitiligo. This African-American man has vitiligo on the distal portions of his fingers. Pigmentary disorders of this sort are much more obvious in patients with substantial natural pigmentation.

concerns the types of changes that are considered to be "defective". The defects that are most disagreeable do vary from culture to culture, so that one cannot assume that what is unattractive in one culture is necessarily unattractive elsewhere.

Pigmentary turmoil

Pigmentary disorders tend to be more pronounced, and thus more important, in populations with greater amounts of natural pigmentation. For this reason, Western cultures, which until recently have been derived primarily from European immigrants, may underestimate the critical role of pigmentation throughout the world. Although dermatologists care for patients who have many different disorders of pigmentation, two diseases predominate: vitiligo (Fig. 1.18; Ch. 66)[58] and melasma (Ch. 67).

The preference for unblemished skin is exceedingly important in cultures in which altered pigmentation may be confused with Hansen's disease (Ch. 75) or viewed as hereditary. In Indian culture, for example, it is not uncommon for the discovery of vitiligo to invalidate a marriage contract[59]. The defect in vitiligo is the absence of epidermal melanocytes after physical destruction guided by autoimmune influences. Not only is vitiligo an important disease in its own right, the associated autoimmune phenomena have profound implications for melanoma therapy (Ch. 113).

Likewise, melasma has a high frequency in Hispanic individuals in the Americas, and it is often extraordinarily distressing[60] (Ch. 67). It is not uncommon to observe that money for necessities may be diverted to this seemingly inconsequential problem.

Inappropriate hair distribution

Hair performs no vital function for humans in the twenty-first century, as body hair can be removed without any physiologic disadvantage. By contrast, the psychologic contributions of hair for many humans cannot be underestimated. Scalp hair is a major social and sexual display feature for humans. The biology of hair and hair growth is detailed in Chapter 68, and additional information may be found in other useful references[61,62]. A discussion regarding excessive hair may be found in Chapter 70 and elsewhere[63]. Two phenomena predominate in concerns about hair: (1) too much hair in the wrong place; and (2) not enough hair in the right place. Too much hair in the wrong place occurs in congenital and acquired forms of hypertrichosis, in response to therapy with minoxidil and certain immunosuppressive agents, and as an effect of androgen excess (Ch. 70). However, the vast majority of patients who seek help for excessive hair do so primarily for cultural reasons.

In terms of insufficient hair (Ch. 69), three diseases predominate: (1) androgenetic alopecia in men; (2) female pattern alopecia in women[64]; and (3) alopecia areata (Fig. 1.19). Hair transplantation has become a popular procedure performed by dermatologists (Ch. 157).

Undesirable fat distribution

With the possible exception of hemifacial atrophy and lipodystrophy syndromes, indications for the absolute removal and for the movement of fat are based on psychologic needs rather than on abnormalities in the structure of the skin and subcutaneous tissues. Nevertheless, the movement of fat is becoming a fairly common procedure and, once again, dermatologists are playing increasingly important roles in this arena[65] (Ch. 156).

The next steps

We could go on at length about dermabrasion for acne scars, rejuvenation protocols, blepharoplasties, and other techniques to reverse the effects of aging. However, the point has been made. What we propose is that anxiety about appearance is genetically programmed. The discipline of cosmetic dermatology has arisen to address that anxiety, with the important goals of alleviating scars, hiding defects and preventing photoaging.

An Important Corollary, with an Eye to the Future

In this introductory chapter, we have asserted that the structure and function of skin is revealed through careful study of skin disease. An important corollary to this statement becomes apparent when we apply our knowledge of skin disease to patient care: the structure and function of skin is also revealed by observing the outcomes of our specific interventions. Whether the outcomes are anticipated or completely unexpected, much can be learned by studying the way skin responds to our attempts at manipulation through medicine and surgery. This

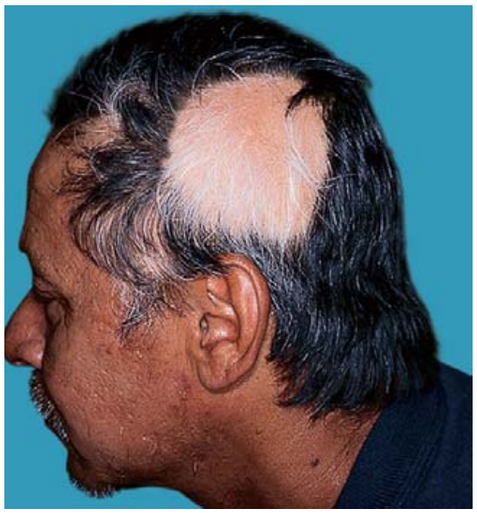

Fig. 1.19 Alopecia areata. The detrimental social impact of hair loss in patients with diseases such as alopecia areata cannot be underestimated. The disease process targets pigmented hairs, and the initial cycle of regrowth may consist of depigmented hairs.

point has been recently illustrated by the observation that keratoacanthomas may erupt in patients being treated with molecular inhibitors of mutated BRAF, which is found in approximately 40% of melanomas[66,67]. In patients with the characteristic V600E activating mutation in BRAF, molecular inhibitors of BRAF arrest melanoma growth[68]. However, when wild-type BRAF is inhibited, especially in the presence of mutated RAS, signaling pathways are enhanced and cellular proliferation ensues[66,67]. Keratoacanthomas and squamous cell carcinomas are the clinical consequence. Our understanding of the molecular pathways of keratinocyte biology has been expanded by observing the outcomes of our intervention on melanoma. Many more such observations are bound to follow as we continue to develop new ways of treating skin disease.

Prenatal diagnosis of genodermatoses 63
Significance of skin development in postnatal life 63

INTRODUCTION

Development of the human embryo is a complex process involving highly orchestrated cell movements, proliferation, death and differentiation. This chapter focuses on key events and regulatory mechanisms that result in skin morphogenesis, maintenance and regeneration. The spectrum of cutaneous abnormalities that can result from mutations in genes with critical roles in skin development is discussed. Ultimately, improved understanding of the pathways and signaling cascades that are disrupted in genetic skin disorders will aid in the development of therapeutic approaches for patients with acquired as well as inherited skin disorders.

EMBRYONIC ORIGIN OF THE SKIN

The skin is composed of diverse cell types of both ectodermal (e.g. keratinocytes, melanocytes, Merkel cells, neurons) and mesodermal (e.g. fibroblasts, hematopoietic cells such as Langerhans cells, endothelial cells) lineages. To understand the origins of these cells, it is important to review the early stages of embryogenesis. Immediately after fertilization, cells divide rapidly, and by the end of the first week, the embryo begins to implant into the uterine wall. During the third week, the embryo undergoes gastrulation, a complex process resulting in the formation of the three embryonic germ layers: endoderm, mesoderm and ectoderm.

During the next stage of embryogenesis, ectodermal cells commit to either a surface ectodermal or neuroectodermal fate. The surface ectodermal cells eventually differentiate into the keratinocytes of the embryonic epidermis, whereas the neuroectodermal cells invaginate to create the neural tube in a process called neurulation. As the neural tube forms, cells in its dorsal portion separate to form the neural crest. An important neural crest-derived cell in the skin is the melanocyte. Although Merkel cells were once believed to be neural crest derivatives, it was recently established that they descend from the epidermal lineage. The lineage of the dermis depends on its location. Whereas the dermis (and other mesenchymal structures) of the face and frontal scalp are derived from the neural crest, the dermis elsewhere is derived from the mesoderm. Knowing from which germ layer and lineage different cell types in the skin derive helps one to understand the pathophysiology of cutaneous disorders ranging from congenital melanocytic nevi (where "neurotization" is explained by the derivation of both melanocytes and peripheral nerve sheath cells from the neural crest) to Waardenburg syndrome (where craniofacial dysmorphism and hearing impairment as well as pigmentary abnormalities reflect disrupted migration and survival of neural crest-derived cells).

An overview of key events in the development of skin and its specialized structures is shown in Figure 2.1.

EPIDERMAL DEVELOPMENT

The ectoderm that covers the developing embryo after gastrulation is a single-layered epithelium (Fig. 2.2A). The first step in epidermal development occurs when cells of the surface ectoderm adopt an epidermal fate[1]. Although this process does not result in major morphologic changes, it is marked by dramatic alterations in gene expression that result in the formation of the embryonic epidermis, which initially consists of only a basal layer (Fig. 2.2B). Basal keratinocytes subsequently generate cells of the periderm, a single cell layer that covers the developing epidermis until the cornified cell layer is formed (Figs 2.2C–F & 2.3A,B). Although the precise function of the periderm is not known, it is believed to participate in the exchange of substances across fetal skin and protects the developing epidermis from the amniotic fluid.

The embryonic epidermis begins to stratify at approximately 8 weeks' estimated gestational age (EGA)[2]. At this time, basic organogenesis is complete and bone marrow hematopoiesis commences, marking the transition from embryo to fetus. During the first stage of epidermal stratification, an intermediate cell layer is formed between the basal layer and periderm (Figs 2.2D & 2.3B). Unlike suprabasal keratinocytes in the postnatal epidermis, the intermediate layer consists of actively proliferating cells. As a consequence, it is able to expand to accommodate the rapid growth of the embryo as well as create additional layers of intermediate cells over the next several weeks (Fig. 2.2E). However, the intermediate cell layer only exists temporarily during epidermal development, as it is eventually replaced by layers of postmitotic keratinocytes undergoing terminal differentiation.

Terminal differentiation, the process resulting in the formation of mature keratinizing epidermal cells, begins during the second trimester. Early cornification can be observed within the hair canal at approximately 15 weeks' EGA[2a], but it does not commence in the interfollicular epidermis until 22–24 weeks' EGA, occurring first in the skin on the head, palms and soles. Expression of the *p63* gene is required for the process of epidermal stratification. The process begins when cells in the intermediate layer permanently withdraw from the cell cycle and differentiate into spinous and granular cells (Fig. 2.2F). The cornified cell layer, which is composed of "dead" keratinocytes (corneocytes) held together by a matrix of proteins and lipids (see Ch. 56), subsequently starts to form and is several cells thick by 24–26 weeks' EGA. The corneocytes are a reflection of the closely regulated process of terminal differentiation that is required for normal functioning of the skin. At the same time, the periderm detaches from the underlying epidermis and is sloughed off into the amniotic fluid, with remnants contributing to the vernix caseosa that coats newborns. During the third trimester, the number of keratohyalin and lamellar granules as well as stratum corneum layers increase. By the mid third trimester, the epidermis is morphologically similar to adult skin (Figs 2.2G & 2.3C), although it does not acquire full barrier function until a few weeks after birth.

Clinical Relevance

Genetic abnormalities affecting various stages of epidermal morphogenesis have been found to underlie inherited skin disorders in humans. However, generalized abnormalities in epidermal specification, the process through which the surface ectoderm adopts an epidermal fate, have not been identified, and it is likely that such defects would be incompatible with survival past the first trimester. Mosaic

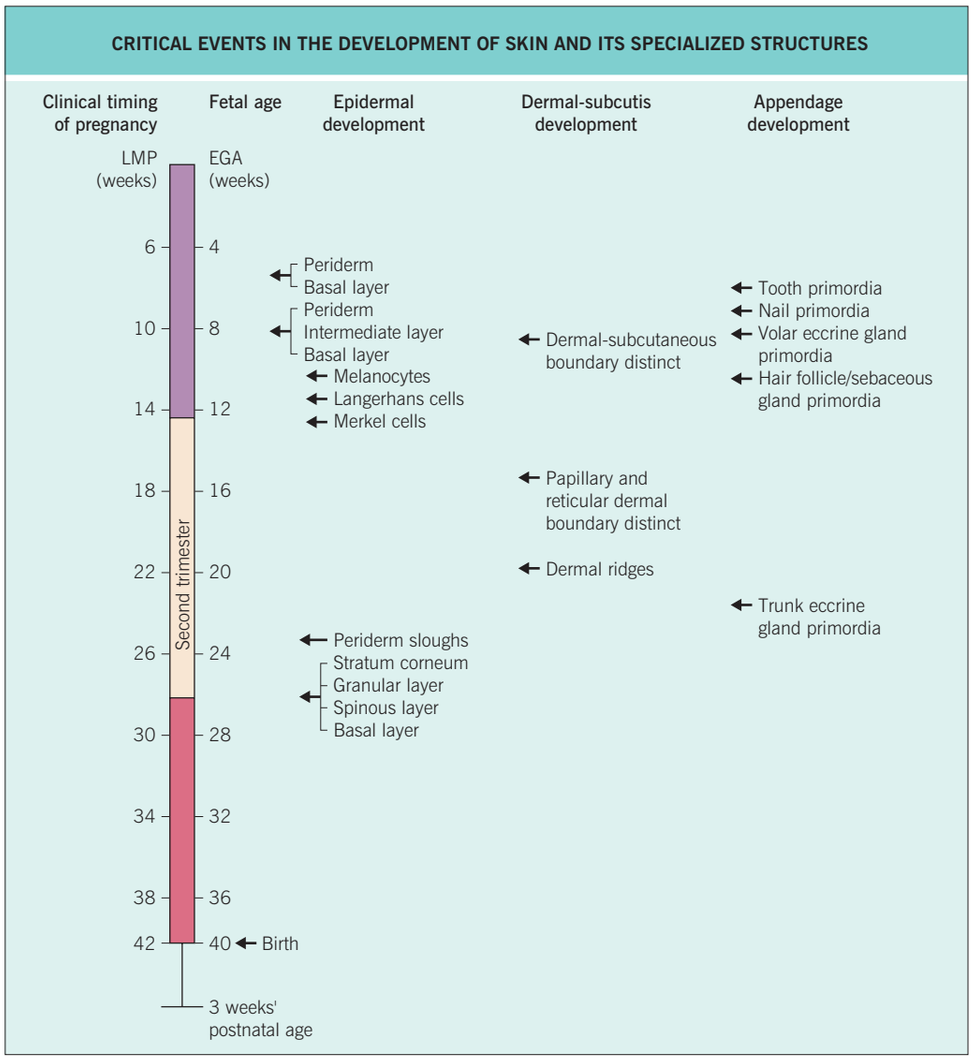

Fig. 2.1 Critical events in the development of the skin and its specialized structures. The timeline indicates the time of initiation defined by estimated gestational age (EGA) and duration of pregnancy (by last menstrual period [LMP]). Refers to skin on the back unless otherwise noted.

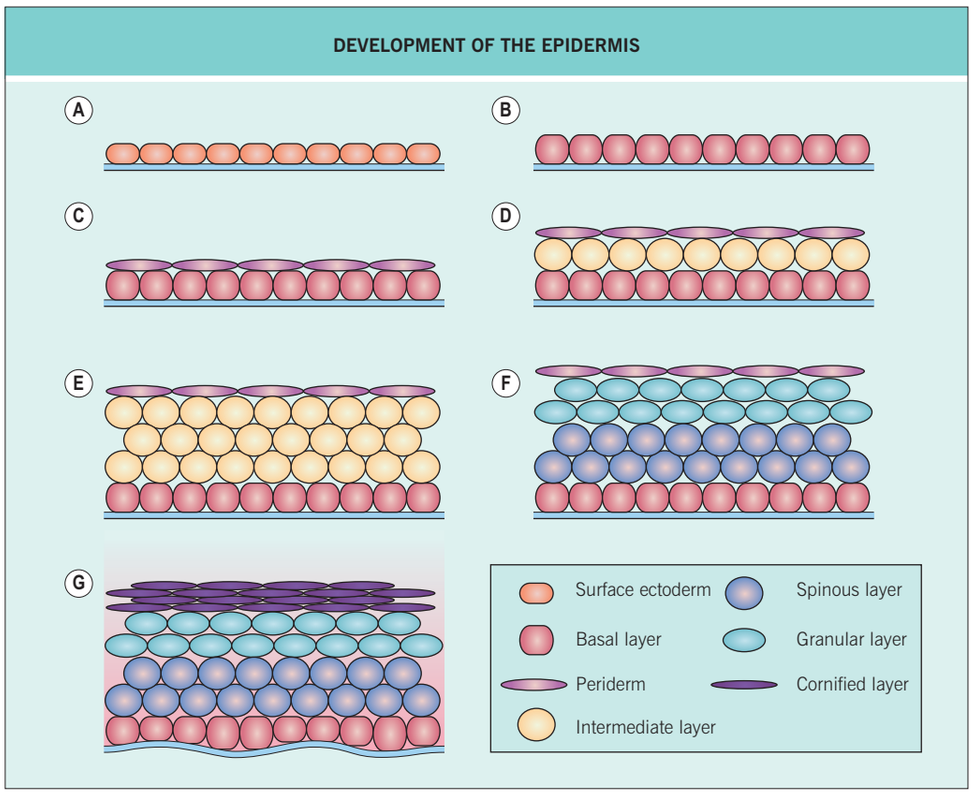

Fig. 2.2 Development of the epidermis. A The epidermis develops from the surface ectoderm, a single-layered epithelium that initially covers the developing embryo. **B** Through changes in gene expression, cells of the surface ectoderm adopt an epidermal fate, resulting in the formation of the basal layer of the epidermis. **C** Basal cells subsequently give rise to the periderm, a cell layer that covers the developing epidermis until cornification occurs. **D** Epidermal stratification begins with the formation of a highly proliferative intermediate layer between the basal layer and the periderm. **E** The intermediate layer becomes several cells thick over the next few weeks. **F** Intermediate cells ultimately withdraw from the cell cycle and differentiate into spinous and granular keratinocytes. **G** The periderm is replaced by the cornified cell layer.

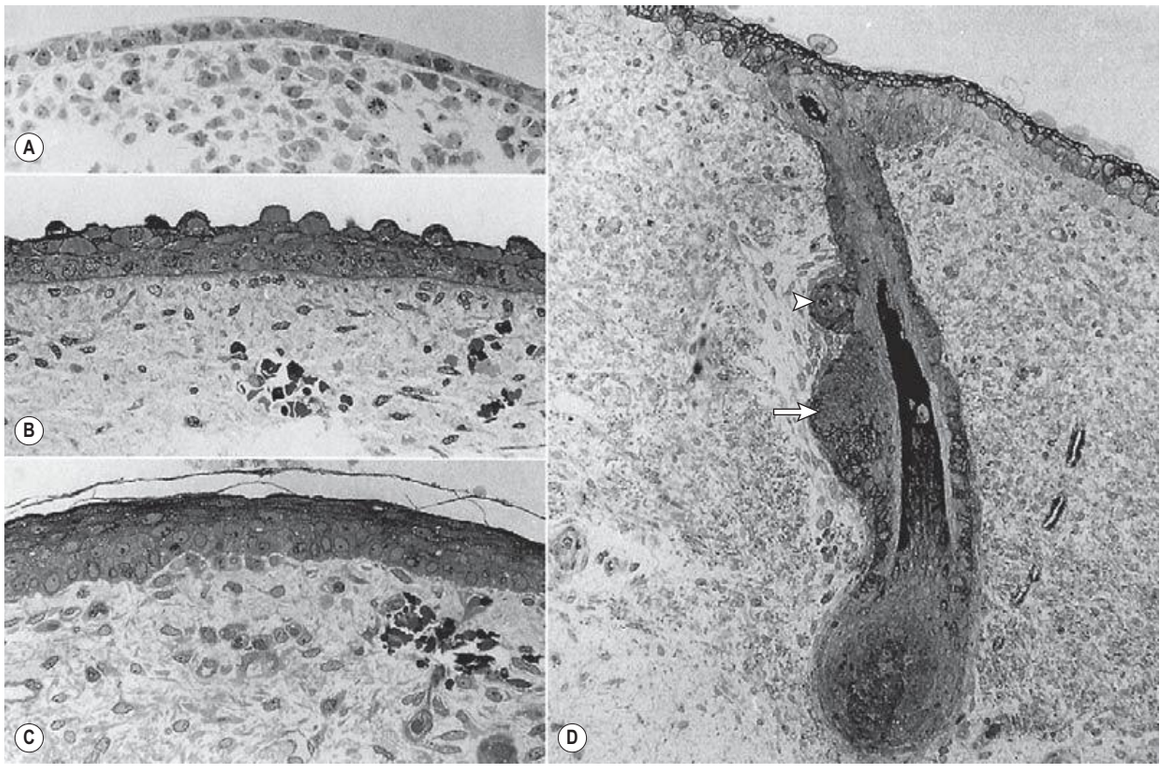

Fig. 2.3 Development of the skin. A At 36 days' estimated gestational age, the embryonic epidermis consists of two layers – a superficial periderm layer overlying a basal layer. **B** By 72 days, the basal layer has given rise to the highly proliferative intermediate cell layer. **C** A distinct granular cell layer and stratum corneum are seen in neonatal skin. **D** An early peg-stage follicle from a mid second trimester fetus. The more superficial bulge consists of the developing sebaceous gland (arrowhead), whereas the deeper bulge represents the insertion point of the future arrector pili muscle and the location of the presumptive follicular stem cells (arrow). *Photomicrographs courtesy of Dr Karen Holbrook, from Loomis CA, Koss T, Chu D. Fetal skin development. In: Eichenfield LF, Frieden IJ, Esterly NB (eds). Textbook of Neonatal Dermatology, 2nd edn. Philadelphia: WB Saunders, 2007:1–17.*

skin conditions that result in abnormalities of the epidermis (e.g. of keratinocytes or melanocytes) and/or its appendages often have a distribution pattern that follows Blaschko's lines, which are thought to represent the migration pathways of epidermal cells during embryonic development. Classic examples include epidermal nevi (with underlying defects including mosaicism for mutations in genes encoding the fibroblast growth factor receptor 3, keratin 1 or keratin 10) and sebaceous nevi (where the underlying genetic defect remains unknown but is thought to be lethal if present in all the cells of the body) (see Ch. 62).

There are a number of genetic disorders that result in abnormal epidermal differentiation and barrier formation. One clinical presentation of such conditions is a "collodion baby" born encased in a taut, shiny, transparent membrane that is formed by aberrant stratum corneum. After shedding the membrane, most of these infants manifest with lamellar ichthyosis (LI) or congenital ichthyosiform erythroderma (CIE), two forms of autosomal recessive ichthyosis that exist on a spectrum[3]. However, the phenotypes that can develop following a collodion membrane include not only the large, plate-like brown scales of LI and the erythroderma with fine white scales of CIE, but also completely normal appearing skin. Referred to as a "self-healing" collodion baby, the latter is an example of a dynamic epidermal phenotype that depends on environmental conditions. All of these outcomes can result from mutations in the same set of genes that encode proteins essential for formation of the epidermal barrier, including transglutaminase-1 (an enzyme that cross-links lipids to the cornified cell envelope; *TGM1*), lipid processing enzymes (*ALOXE3*, *ALOX12B*) and lipid transporters (*ABCA12*) (see Ch. 57).

More deleterious mutations in the *ABCA12* gene represent the cause of harlequin ichthyosis (HI), an especially severe and often fatal disorder of cornification characterized by aberrant epidermal maturation. Patients with HI are born with a tremendously thick, armor-like shell of hyperkeratosis, severe ectropion and eclabium, and underdevelopment of the nose and ears. The extreme phenotype of HI highlights the importance of lipid transport into lamellar bodies for epidermal formation and function.

Abnormalities in the stratum corneum are present not only in infants with ichthyosis, but also in premature infants, especially those born before 28 weeks' EGA. The immaturity of the stratum corneum results in impaired barrier function, which leads to an increased risk of infection, dehydration, and excessive absorption of topical medications or chemicals[4]. Even healthy full-term infants do not attain full skin barrier function until 3 weeks of age. The structural features of premature skin and adult skin are summarized in Table 2.1.

DEVELOPMENT OF SPECIALIZED CELLS WITHIN THE EPIDERMIS

Two populations of specialized cells – melanocytes and Langerhans cells – migrate to the epidermis during early embryonic development. Melanocytes are derived from the neural crest that forms along the dorsal neural tube. Melanocyte precursors migrate away from the neural tube within the mesenchyme beneath the primitive epidermis. They follow a characteristic trajectory, moving dorsolaterally and then ventrally around the trunk to the ventral midline, anteriorly over the scalp and face, and distally along the extremities. Cutaneous melanocytes can also arise from Schwann cell precursors located along nerves in the skin, which originate from the neural crest via the distinct ventral pathway[5].

Melanocytes are present in the epidermis by the middle of the first trimester, but they are not fully functional until the second trimester. Melanocytes can be first identified within the embryo's epidermis at approximately 50 days' EGA, based on their positive reactivity with the HMB45 monoclonal antibody and their dendritic morphology. Epidermal melanocyte density is high early in embryonic development (1000 cells/mm^2), and it increases further (~3000 cells/mm^2) as the epidermis stratifies (80–90 days' EGA) and the appendages begin to develop; later in gestation, the density decreases and becomes similar to that of young adults (800–1500 cells/mm^2). However, epidermal melanin production does not begin until 3–4 months' EGA, and melanosome transfer to keratinocytes is not seen until 5 months' EGA. Even though all melanocytes are functional and in place at birth, newborn skin is not fully pigmented and subsequently darkens over the first few months of life; this process is most pronounced in more darkly pigmented infants.

Active melanocytes are also present throughout the dermis during embryonic development. Eventually, most of these dermal melanocytes migrate to the epidermis or undergo apoptosis. By the time of birth, dermal melanocytes have disappeared, with the exception of certain

COMPARATIVE FEATURES OF PREMATURE, NEWBORN, AND ADULT SKIN			
	Premature	**Newborn**	**Adult**
Skin thickness	0.9 mm	1.2 mm	2.1 mm
Epidermal surface	Vernix (gelatinous)	Vernix	Dry
Epidermal thickness	~20–25 microns	~40–50 microns	~50 microns
Stratum corneum thickness	4–5 microns	9–10 microns	9–15 microns
	5–6 cell layers	>15 cell layers	>15 cell layers
Spinous cell glycogen content	Abundant	Little or none	Little or none
Melanocytes	High number of cells; few mature melanosomes	Similar number of cells to young adult; low melanin production	Numbers decrease with age; melanin production dependent on skin type, body area
Dermal–epidermal junction	All known adult antigens expressed; fewer and smaller desmosomes	Structural features and antigens similar to those of the adult	Well-developed adhesive structures; large number of antigens expressed
Papillary dermis			
• Boundary with reticular dermis	Present but not marked	Present but not marked	Marked
• Size of collagen fiber bundles	Small	Small	Small
• Cellular density	Abundant	Abundant	Moderately abundant
Reticular dermis			
• Boundary with the subcutis	Marked	Marked	Marked
• Size of collagen fiber bundles	Small	Small to intermediate	Large
• Cellular density	Abundant	Moderately abundant	Sparse
Elastic fibers	Sparse; tiny with immature structure	Small size and immature structure; distribution similar to adult	Large in reticular dermis, small and immature in papillary dermis; form network
Hypodermis	Well-developed fatty layer	Well-developed fatty layer	Well-developed fatty layer

Table 2.1 Comparative features of premature, newborn, and adult skin. *Reproduced with permission from Schachner LA, Hansen RC (eds). Pediatric Dermatology, 4th edn. London: Mosby, 2010.*

anatomic sites (head and neck, dorsal aspects of the distal extremities and presacral area), which correspond to the most common locations for dermal melanocytoses and blue nevi (see Ch. 112).

Langerhans cell precursors appear within the epidermis during the first trimester and are first detectable in this site as early as 40 days' EGA. These cells can be distinguished by their characteristic dendritic morphology; expression of CD45, HLA-DR and CD1c; and high levels of ATPase activity. Langerin expression precedes CD1a acquisition, which first occurs at 13 weeks' EGA, and the production of Birbeck granules[6]. The density of Langerhans cells in fetal skin remains low early in gestation and increases to typical adult levels during the third trimester.

Merkel cells, highly innervated neuroendocrine cells involved in mechanoreception, are initially identified within the epidermis during the first trimester. These cells are detected as early as 8–12 weeks' EGA in palmoplantar epidermis, and slightly later in interfollicular skin. Merkel cells are identified by the presence of cytoplasmic dense core granules, cytokeratin 20 and neuropeptides. They are found in the basal layer of the epidermis, are often associated with appendages and nerve fibers, and are particularly dense on volar skin. The developmental origin of Merkel cells has been the subject of longstanding controversy, but recent studies have demonstrated that mammalian Merkel cells are derived from an epidermal rather than neural crest lineage[7].

Clinical Relevance

Several inherited pigmentary disorders result from genetic defects that lead to abnormal migration and proliferation of neural crest-derived melanocyte precursors (melanoblasts). Piebaldism and Waardenburg syndrome are characterized by achromic patches of skin on the central forehead, central abdomen and extremities, a distribution pattern that reflects the failure of melanocyte precursors to survive, proliferate or travel to the distal points of their embryonic migration pathway. A number of different causative genes leading to this phenotype have been identified, including those encoding transcription factors (e.g. microphthalmia-associated transcription factor [MITF], PAX3, SOX10, SNAI2) as well as membrane receptors and their ligands (e.g. endothelin-3, endothelin B receptor, KIT receptor)[8] (see Ch. 66). The endothelin B receptor is found on melanoblast–ganglion cell precursors in the developing neural crest, explaining the Hirschsprung disease (as well as pigmentary abnormalities) that is associated with defects in this receptor or its ligand.

DEVELOPMENT OF THE DERMIS AND SUBCUTIS

The specification of dermal mesenchymal cells is a complex process that is incompletely understood. Unlike the epidermis, which is derived exclusively from the ectoderm, the origin of the dermis varies depending on the body site. As noted above, the dermal mesenchyme of the face and anterior scalp (as well as the underlying muscle and bone) is derived from neural crest ectoderm, thereby explaining the facial dysmorphia in the neurocristopathy Waardenburg syndrome. On the other hand, the dermal mesenchyme of the back originates from the dermomyotome of the embryonic somite, and the dermal mesenchyme of the extremities and ventral trunk is thought to arise from the lateral plate mesoderm.

By 6–8 weeks' EGA, presumptive dermal fibroblasts are situated under the developing epidermis[9]. However, at this developmental stage, there is no distinct demarcation between the cells that will give rise to the dermis and those that will give rise to musculoskeletal components. Although embryonic dermal cells are capable of synthesizing collagens (e.g. types I, III and IV) and some microfibrillar components, these proteins are not yet assembled into complex fibers. Of note, the ratio of collagen III to collagen I is 3:1, the reverse of what is seen in the adult dermis.

The demarcation between the dermis and underlying skeletal condensations becomes distinct at approximately 9 weeks' EGA. By 12–15 weeks' EGA, progressive changes in matrix organization and cell

morphology distinguish the fine weave of the papillary dermis located directly beneath the epidermis from the thicker, deeper reticular dermis. At this stage, the collagen proteins produced by the fibroblasts start to assemble into collagen fibers, which continue to accumulate in the reticular dermis during the second and third trimesters. Electron microscopy can first detect definitive elastic fibers at approximately 22–24 weeks' EGA. As development progresses, the watery, proteoglycan-rich, cellular dermis of the embryo is modified to the more rigid, fibrous, acellular dermis characteristic of adult skin. By the end of the second trimester, the dermis shifts from a non-scarring to a scarring form of wound repair. At birth, the dermis is still thinner and more cellular than the adult dermis.

The basic pattern of the dermal vasculature is discernible by the end of the first trimester. This pattern, however, undergoes extensive remodeling *in utero* and is not fully mature until after birth. Numerous molecular controls are involved in the regulation of angiogenesis, including the vascular endothelial growth factor (VEGF) family as well as the tyrosine kinase receptors Tie-1 and Tie-2 and their stimulatory (Ang-1) and inhibitory (Ang-2) angiopoietin ligands (see Ch. 102).

Nerve networks are formed by the mid to late first trimester, and they tend to follow the vascular pattern. Accumulation of subcutaneous fat begins during the second trimester and continues through the third trimester, when distinct lobules separated by fibrous septae are formed.

Clinical Relevance

Mutations in the genes that encode a variety of dermal structural proteins (e.g. collagens, components of elastic fibers) and the enzymes that process them underlie multiple forms of Ehlers–Danlos syndrome (characterized by skin hyperextensibility and fragility with poor wound healing) and cutis laxa (featuring lax, redundant skin). Genetic defects in regulatory proteins important for extracellular matrix development can lead to abnormalities in the skin and other organs. For example, mutations in the latent transforming growth factor-β (TGF-β) binding protein-4 gene (*LTBP4*) were recently found to underlie a form of cutis laxa associated with severe pulmonary, gastrointestinal and genitourinary malformations. The absence of LTBP4, an extracellular matrix protein that binds to fibrillin and controls the bioavailability of TGF-β, leads to aberrant TGF-β activity and defective elastic fiber assembly in many types of tissues.

Another disorder characterized by abnormal dermal development is Goltz syndrome (focal dermal hypoplasia), an X-linked dominant disorder characterized by areas of dermal hypoplasia (with fat herniation/hamartomas) in a distribution following Blaschko's lines, skeletal defects and mucosal papillomas. Goltz syndrome is caused by mutations in PORCN, an effector of the Wnt signaling pathway that is critical for normal dermal development[10]. Blaschko's lines are thought to represent pathways of epidermal development, and in a mouse model, PORCN expression and resultant Wnt signaling originating from the ectoderm have been shown to regulate development of the dermis.

DEVELOPMENT OF THE DERMAL–EPIDERMAL JUNCTION

The dermal–epidermal junction (DEJ) mediates adhesion between the basal keratinocytes and the dermis and provides resistance against shearing forces on the skin (see Ch. 28). The DEJ develops from a simple, generic basement membrane in the embryo to a highly complex, multilayered structure in the second-trimester fetus.

The embryonic DEJ consists of a lamina densa and a lamina lucida, and it is composed of molecules that are common to all basement membrane zones (e.g. type IV collagen, laminin, heparan sulfate, proteoglycans)[11]. The DEJ becomes progressively more complex, and skin-specific components of the DEJ start to appear after the embryonic–fetal transition at 8 weeks' EGA, coincident with the onset of epidermal stratification. By 12 weeks' EGA, almost all of the structures characteristic of the mature DEJ are in place (see Ch. 28). Hemidesmosomes, anchoring filaments and anchoring fibrils are synthesized by basal keratinocytes, with the type VII collagen-containing anchoring fibrils localizing to the sub-lamina densa; laminin 5 and the bullous pemphigoid antigens are also expressed. As development progresses, the flat embryonic DEJ acquires the rete ridges and dermal papillae that characterize the adult DEJ.

Clinical Relevance

Epidermolysis bullosa (EB) is a heterogeneous group of genetic disorders characterized by blister formation due to mechanical fragility of the skin. EB can result from mutations in genes that encode several different components of the DEJ[12]. The specific protein affected (and the degree to which it is altered) largely determines disease severity, depth of bulla formation, and involvement of extracutaneous tissues (see Ch. 32).

DEVELOPMENT OF SKIN APPENDAGES

Skin appendages (hair, nails, and eccrine, apocrine and sebaceous glands) have both epidermal and dermal components that are critical in embryogenesis. Normal development of skin appendages depends on tightly regulated interactions between the early dermis and epidermis (e.g. signaling molecules that are sent back and forth between these tissues), and a failure in either component (or in communication between them) leads to aberrant development. Despite the differences in the structure and function of the various types of cutaneous appendages, the developmental processes that regulate their formation are remarkably similar[13].

Hair Follicle Development

The complex dermal–epidermal interactions and genetic control mechanisms that occur in appendage development are best understood in the formation of the hair follicle. Follicle formation is initiated by signals from the dermis that direct the embryonic epidermis to form focal thickenings, called placodes (see Figs 68.2 & 68.3)[14]. Placodes are first seen on the scalp and face between 10 and 11 weeks' EGA; they subsequently develop in a caudal and then in a ventral direction. The epidermal placodes instruct the underlying dermal cells to condense and form the presumptive dermal papilla. The dermal papilla then directs the keratinocytes of the placode to proliferate and extend deeper into the dermis, thereby forming the hair germ (see Figs 68.2 & 68.3). By 12–14 weeks' EGA, the base of the developing hair follicle surrounds the presumptive dermal papilla, forming the hair peg (see Figs 68.2 & 68.3). The superficial portion of the developing hair follicle has two distinct bulges. The more superficial bulge consists of the developing sebaceous gland, whereas the deeper bulge represents the insertion point of the future arrector pili muscle and the location of the presumptive follicular stem cells.

Hair follicles undergo further maturation during the second trimester, forming seven concentric cell layers (from outer to inner): outer root sheath; inner root sheath, composed of Henley's and Huxley's layers and a cuticle; and then the hair shaft cuticle, cortex and medulla (see Fig. 68.2). The hair canal is fully formed by 18–21 weeks' EGA, and hairs are visible shortly thereafter. The hairs continue to grow until 24–28 weeks' EGA, when they leave the active growing phase (anagen) and enter the short-lasting degenerative phase (catagen) and subsequently the resting phase (telogen). The follicles then start the second hair cycle by re-entering anagen; new hairs grow and push out the first group of telogen hairs, which are shed into the amniotic fluid.

Hair cycling through anagen, catagen and telogen continues throughout life, but the hair cycles for individual hair follicles become asynchronous after birth. The third hair cycle is initiated perinatally, leading to the shedding of the second wave of fine lanugo hair follicles. Most hairs become thicker and coarser with subsequent growth cycles, leading to vellus and then adult-like terminal hairs on the scalp and in the eyebrows.

Many genes important for hair follicle development and cycling have been identified (see Ch. 68). Sonic hedgehog (SHH), a signaling molecule secreted by cells of the developing hair follicle, is required for the maturation of the dermal papilla and for the progression of the follicle placode to the peg hair stage. SHH also appears to be critical in mediating the transition from telogen to anagen during postnatal hair cycling. Members of the Wnt, bone morphogenetic protein (BMP) and fibroblast growth factor (FGF) families of signaling molecules are also important in hair follicle development and cycling. Transcription factors with roles

in follicular differentiation have also been identified, including HOXC13 and FOXN1.

Sebaceous gland development parallels follicular development. The presumptive sebaceous gland is first seen at around 13–16 weeks' EGA as the most superficial bulge on the developing hair follicle. The outer proliferative layer of the sebaceous gland generates lipogenic cells that progressively accumulate lipid/sebum until they are terminally differentiated, at which time they disintegrate and release their products into the upper portion of the hair canal. Maternal hormones contribute to sebaceous gland hypertrophy and increased synthesis and secretion of sebum during the second and third trimesters. The neonatal adrenal gland also has a disproportionately large zone of androgen production (referred to as the "fetal zone"), which involutes over the first year of life.

Nail Development

Nail development begins at 8–10 weeks' EGA and is completed by the fifth month of intrauterine development. The flat, rectangular surface of the future nail bed on the dorsal digital tips is first demarcated by folds visible at 8–10 weeks' EGA. A wedge of ectoderm invaginates obliquely into the mesenchyme along the proximal end of the early nail field, forming the proximal nail fold by 13 weeks' EGA. The presumptive nail matrix cells, which will later produce the differentiated nail plate, are found ventral to the proximal nail fold. The nail bed on the dorsal digit is the first skin structure to keratinize, at around 11 weeks; keratinization begins distally and then continues over the nail bed toward the proximal nail fold. The first, preliminary nail is shed easily and replaced by the hard, differentiated nail plate that emerges from under the proximal nail fold during the fourth month of gestation and completely covers the nail bed by the fifth month.

Eccrine and Apocrine Sweat Gland Development

Like hair and nails, palmoplantar eccrine sweat glands begin to develop during the first trimester and are fully developed by the second trimester. Sweat gland development starts with the formation of large mesenchymal bulges or pads (analogous to the paw pads of other mammals) on the palms and soles between 55 and 65 days' EGA. Parallel ectodermal ridges are induced in the epidermis overlying these pads between 12 and 14 weeks' EGA. The curves and whorls formed by these ridges result in characteristic dermatoglyphics (fingerprints), which can be seen on the digit tips by the fifth month of gestation. Unlike most other animals, the mesenchymal pads in the human fetus regress by the third trimester.

Beginning between 14 and 16 weeks' EGA, individual eccrine gland primordia bud along the ectodermal ridges at regularly spaced intervals. The buds elongate as cords of cells that enter the pad mesenchyme. By 16 weeks' EGA, glandular structures form at the terminal portion of the buds and secretory and myoepithelial cells are visible. Canalization of the dermal component of the eccrine duct is also complete by 16 weeks' EGA; this occurs via a loss of the desmosomal adhesions along the innermost ectodermal surfaces, with concomitant maintenance of the adhesion between duct cells and the gland walls. Canalization of the epidermal component of the duct is not complete until 22 weeks' EGA.

Unlike volar eccrine sweat glands, interfollicular eccrine glands and apocrine glands do not begin to form until the fifth month of gestation. Like sebaceous glands, apocrine glands typically arise from the upper portion of a hair follicle. Interfollicular eccrine glands, on the other hand, originate independently. The glandular cords of cells elongate during the ensuing weeks, and by 7 months' EGA the clear cells and mucin-secreting dark cells characteristic of apocrine glands can be visualized. Apocrine glands function transiently during the third trimester and subsequently become quiescent in the neonate. Eccrine glands, however, do not function *in utero* but mature and begin functioning postnatally.

Clinical Relevance

Ectodermal dysplasias are a large, heterogeneous group of genetic disorders that are characterized by developmental abnormalities in two or more major ectodermal appendages (hair, teeth, nails, and sweat glands); other ectodermal structures (e.g. sebaceous glands) can also be affected[15] (see Ch. 63). Hypohidrotic ectodermal dysplasia (HED) is a relatively common type of ectodermal dysplasia that affects the sweat glands (hypohidrosis), hair (hypotrichosis) and teeth (hypodontia). HED is caused by mutations in genes encoding components of the ectodysplasin A (EDA) signaling pathway, which is critical for the initiation of sweat gland, hair follicle and tooth morphogenesis. Underlying mutations can occur in the genes encoding the EDA ligand, EDA receptor (EDAR), or EDAR-associated death domain (an intracellular adaptor protein that functions in EDAR signaling). Mutations in EDA are responsible for the X-linked variety of HED (XLHED), which leads to "full-blown" disease in affected males and areas of involved skin following Blaschko's lines in heterozygous females. Because the underlying defect is in a soluble ligand that is only required for a brief period during the initiation of appendage formation, XLHED is a prime target for protein therapy. Encouragingly, studies in mice and dogs have demonstrated an almost complete correction of the XLHED phenotype upon prenatal or neonatal treatment with recombinant EDA protein[16,17]. Clinical trials with recombinant EDA protein for the treatment of infants with XLHED are planned.

In addition to mutations in genes that are required for appendage development, ectodermal dysplasias can also be caused by mutations in genes that are required for epidermal development[18]. In these instances, abnormal appendages result from disruption of cross-talk between the developing epidermis and dermis. Mutations in *p63*, a gene that is required for epidermal morphogenesis, can cause several types of ectodermal dysplasia, including the ankyloblepharon–ectodermal dysplasia–cleft lip/palate (AEC) and ectrodactyly–ectodermal dysplasia–cleft lip/palate (EEC) syndromes (see Ch. 63). The phenotypic differences between AEC and EEC are explained by underlying mutations in separate regions of the *p63* gene, which affect different functions and isotypes of the p63 protein.

Wnt signaling is critical for the development of epidermal appendages, and genetic defects in this pathway underlie conditions ranging from hereditary hypotrichosis simplex to onycho-odonto-dermal dysplasia and Schöpf–Schulz–Passarge syndrome[19]. The nevoid basal cell carcinoma syndrome (Gorlin syndrome) is caused by mutations in the *PTCH* tumor suppressor gene that result in overactivation of the sonic hedgehog (SHH) signaling pathway, which has important roles in neurologic and anterior–posterior axis development as well as hair follicle formation[20]. This explains the broad range of developmental anomalies, including craniofacial and skeletal defects, and the propensity for medulloblastomas, odontogenic keratocysts and multiple basal cell carcinomas to arise (see Ch. 108).

SKIN STEM CELLS

Stem cells are present in each self-renewing tissue and are responsible for maintaining and repairing the tissue they reside in. The epidermis, dermis, appendages, and melanocytes are each maintained by different stem cell compartments. Stem cells are self-renewing and divide infrequently during periods of homeostasis, with the latter feature believed to protect them from acquiring mutations during cell cycle progression. Under homeostatic conditions, stem cells are believed to undergo asymmetric division, generating one new stem cell and one daughter transit amplifying (TA) cell. Unlike stem cells, TA cells divide frequently and ultimately differentiate into lineage-specific cell types. Within the skin, stem cells that maintain the epidermis and hair follicles have been most extensively studied. The properties of stem cells, TA cells and terminally differentiated cells are listed in Table 2.2.

Epidermal Stem Cells

The human epidermis renews itself every 40–56 days[21]. This constant turnover is mediated by epidermal stem cells, which reside in the basal layer together with TA cells[22]; the latter constitute the majority of basal keratinocytes. Ultimately, TA cells withdraw from the cell cycle and move suprabasally, which initiates the keratinocyte terminal differentiation program. In non-acral human skin, epidermal stem cells are scattered within the basal layer, where they give rise to epidermal proliferative units (EPUs), columns of cells composed of one stem cell and its progeny (Fig. 2.4)[23]. The location of epidermal stem cells in human palmoplantar skin is less clear, but there is some evidence that they are found at the base of the rete ridges, where they are physically protected from environmental stress. However, other

PROPERTIES OF STEM CELLS, TRANSIT AMPLIFYING CELLS AND TERMINALLY DIFFERENTIATED CELLS			
	Stem cells	**Transit amplifying cells**	**Terminally differentiated cells**
Self-renewal*	Unlimited	Limited	No
Potential for differentiation*	Multipotent	Limited	None
Cycling in normal epidermis	Slow†	Rapid	None
Proliferative potential (e.g. during fetal development and wound healing)	High	Limited‡	None
Growth in culture	Sustained clonal growth	Small abortive clones‡	None
Maintenance of tissue homeostasis	Yes	Limited	No

*In order to maintain both the stem cell and differentiating cell compartments, upon division a stem cell gives rise to another stem cell and a cell that is destined to terminally differentiate (transit amplifying cell); this is referred to as asymmetry of fate.
†Retention of a DNA label (e.g. 5-bromo-2-deoxyuridine or tritiated thymidine) is utilized as an *in vivo* marker of stem cells based on their slowly cycling nature.
‡The proliferative potential of transit amplifying cells of the matrix is higher than those of the interfollicular epidermis, but still finite; the former cells can be serially passaged in culture.

Table 2.2 Properties of stem cells, transit amplifying cells and terminally differentiated cells.

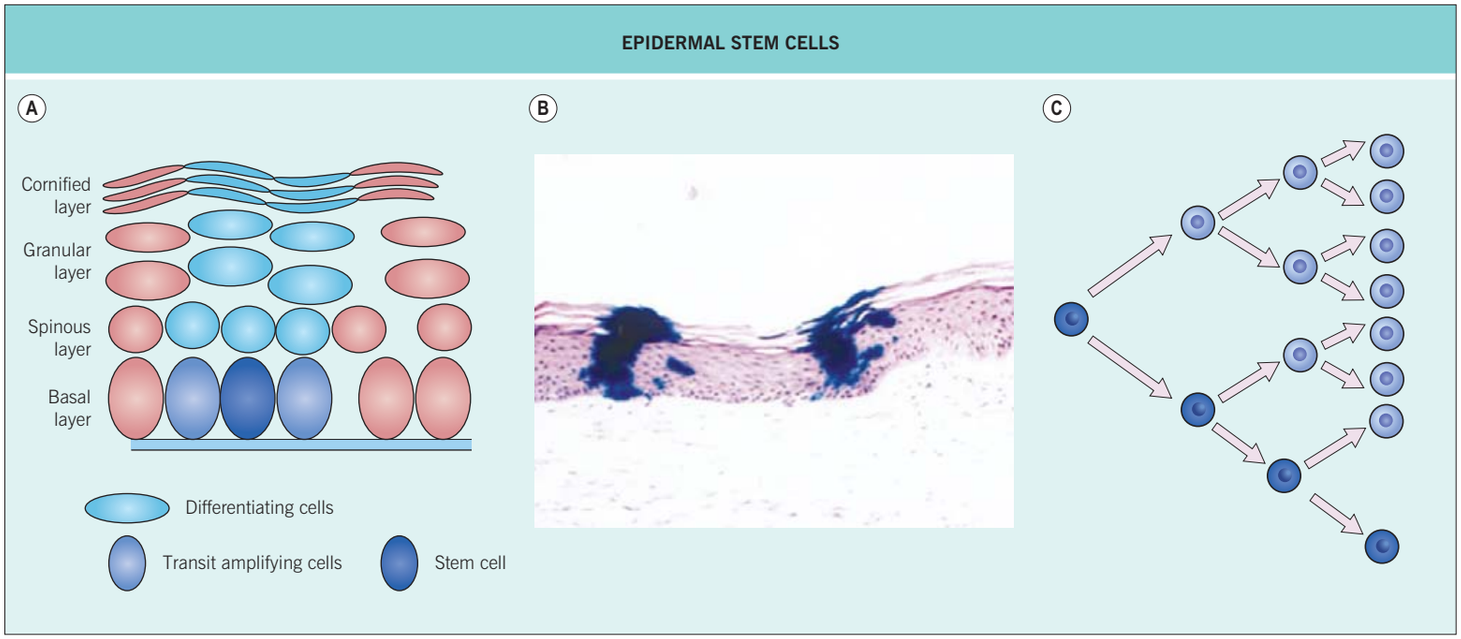

Fig. 2.4 Epidermal stem cells. A Epidermal stem cells are located in the basal layer of the epidermis. Each epidermal stem cell and its progeny forms a vertical column of progressively differentiating cells, which is known as the epidermal proliferation units (EPU) (blue). **B** EPUs in human skin grafted onto the back of a nude mouse. A subset of epidermal keratinocytes was transduced with a β-galactosidase-expressing virus. Forty weeks after grafting these cells onto nude mice, EPUs were visible. Since only epidermal stem cells and not TA cells or differentiated cells are able to persist for this length of time, the presence of EPUs indicates that they are derived from and maintained by epidermal stem cells. **C** With each cell division, another stem cell and a transit amplifying (TA) cell are generated (asymmetry of fate). The TA cells undergo a few rounds of cell division before they permanently withdraw from the cell cycle and initiate the terminal differentiation program. *Reprinted with permission from Kolodka TM, Garlick JA, Taichman LB (1998), Evidence for keratinocyte stem cells in vitro: Long term engraftment and persistence of transgene expression from retrovirus-transduced keratinocytes Proceedings of the National Academy of Sciences of the United States of America 95:4356-4361, © 1998 National Academy of Sciences, U.S.A.*

data suggest that palmoplantar epidermal stem cells are located at the top of deep rete ridges.

One distinguishing feature of stem cells is that they can be maintained in culture virtually indefinitely. A subset of epidermal basal cells forms highly proliferative colonies that can be passaged long term *in vitro*; referred to as holoclones, they presumably represent stem cells[24]. Holoclones can reconstitute epidermis *in vitro*, and they have been utilized for the treatment of burns and inherited skin disorders (see below). The properties of cutaneous stem cells, including their molecular markers, are summarized in Table 2.3.

Hair Follicle Stem Cells

The hair follicle bulge, which is located in the mid portion of the follicle (just deep to the sebaceous gland and adjacent to the arrector pili muscle attachment site), is thought to harbor hair follicle stem cells (Fig. 2.5). The bulge represents the lowest permanent portion of the hair follicle, and it contains morphologically undifferentiated cells[25]. Hair follicle bulge cells are slow-cycling and have a high proliferative potential as well as being self-renewing and multipotent. *In vivo*, they proliferate only when the hair follicle re-enters the active growing phase of anagen, in which the bottom two-thirds of the follicle must be regenerated. Such appendageal stem cells provide an important ectodermal reserve, allowing temporary reconstitution of the surface epidermis after severe wounds such as second-degree burns.

In addition to bulge cells, other cell populations in the hair follicle display stem cell characteristics. One of these populations is located in the lower outer root sheath in anagen hair follicles and is marked by the expression of Lgr5[26]. Whether these cells represent a separate stem cell population or whether they are derived from bulge stem cells (or vice versa) remains to be determined.

Stem Cell Plasticity

Under homeostatic conditions, epidermal and hair follicle stem cells only contribute to their respective tissues of origin. However, bulge-derived keratinocytes can also contribute to the repair of the interfollicular epidermis in response to injury[25]. Within the healing

CUTANEOUS STEM CELLS				
Stem cell	**Location (niche)**	**Tissue regeneration in homeostasis**	**Tissue regeneration in injury repair**	**Markers**
Keratinocyte				
Interfollicular epidermis	Basal layer	Interfollicular epidermis	Hair follicle Sebaceous gland Interfollicular epidermis	Delta 1, MCSP, α_6* and β_1 integrins, LRIG1; *low* levels of CD71
Hair follicle**	Bulge†	Hair follicle	Hair follicle Sebaceous gland Interfollicular epidermis	Keratin 15, α_6 and β_1 integrins, CD200, PHLDA1, follistatin, frizzled homolog 1, LGR5; *low* levels of CD24, CD34‡, CD71, CD146
Sebaceous gland§	At or near the bud of the sebaceous gland	Sebaceous gland	Sebaceous gland	Blimp1
Merkel cell	Touch domes of hairy skin	Interfollicular epidermis	Interfollicular epidermis	α_6 integrin*, SCA1, CD200
Melanocyte§	Lower bulge and sub-bulge region¶	Hair matrix and epidermal melanocytes	Hair matrix and epidermal melanocytes	Pax3, TYRP2; *negative* for KIT, tyrosinase, TYRP1
"Neural crest-like"	Bulge† (form spheres)	?	*In vitro*: melanocytes, neurons, smooth muscle, adipocytes, chondrocytes	Twist, SLUG, SOX10, BMI-1, Notch1
"Dermal"	Dermis (form spheres)	?	*In vitro:* melanocytes, neurons, Schwann cells, smooth muscle adipocytes, chondrocytes	NGFRp75, nestin, OCT4, SLUG
"Skin-derived precursors"	Dermal papilla (form spheres)	?	*In vitro:* neurons, Schwann cells, smooth muscle adipocytes	Nestin, OCT4, SLUG, Twist

*Also expressed by epidermal transit amplifying cells.
**Additional stem cell populations identified within the hair follicle in mice include LGR6-positive cells in the central isthmus and LRIG1-positive cells in the upper isthmus, both of which contribute to the interfollicular epidermis and sebaceous glands during homeostasis.
†Within the outer root sheath just below the sebaceous gland, at or near the site of insertion of the arrector pili muscle.
‡Upregulated in mouse bulge cells.
§Studied primarily in mice; sebaceous gland stem cells have thus far been shown to be unipotent progenitor cells.
¶Lowest permanent portion of the hair follicle.

Table 2.3 Cutaneous stem cells. CD24, glycoprotein involved in cell adhesion and signaling; CD34, marker of hematopoietic progenitor cells and endothelial cells; CD71, transferrin receptor; CD146, melanoma cell adhesion molecule/MUC18/S-Endo-1 antigen; CD200, transmembrane glycoprotein that delivers a negative immunoregulatory signal (may be involved in maintaining immune tolerance); LGR5/6, leucine-rich repeat-containing G protein-coupled receptor 5/6; LRIG1, leucine-rich repeats and immunoglobulin-like domains 1 (epidermal growth factor receptor antagonist and regulator of stem cell quiescence); MCSP, melanoma-associated chondroitin sulfate proteoglycan; NGFR, nerve growth factor receptor; PHLDA1, pleckstrin homology-like domain, family A, member1; SCA1, stem cell antigen 1; TYRP, tyrosinase-related protein.

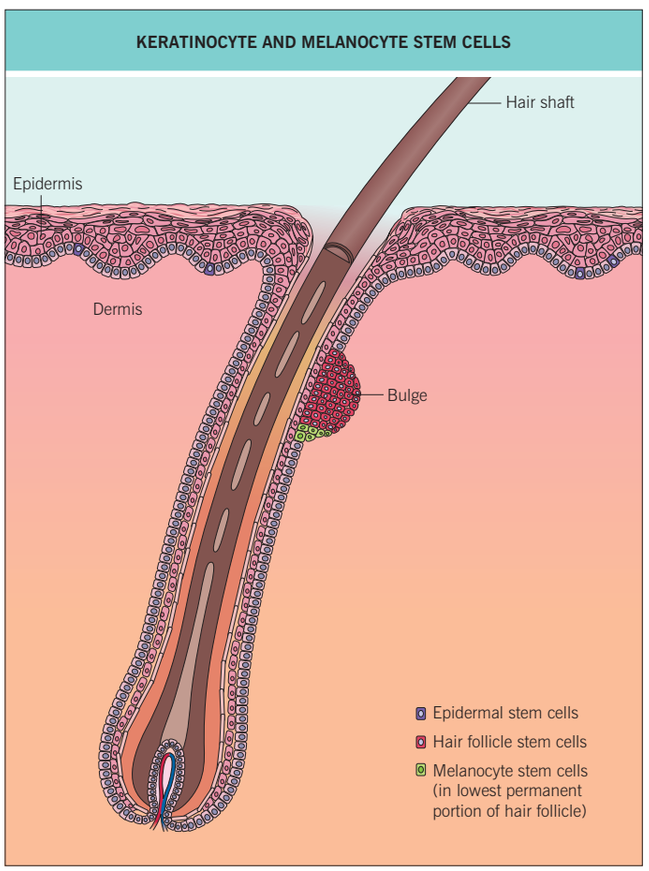

Fig. 2.5 Keratinocyte and melanocyte stem cells. Note that the bulge is continuous with the outer root sheath.

epidermis, bulge-derived cells survive only transiently, as they are rapidly replaced by progenies of epidermal stem cells. Similarly, epidermal stem cells can contribute to hair follicle formation in the center of large wounds[27].

Furthermore, emerging data indicate that cells in adult mammals are far more "flexible" in their potential to form other cell types than was previously thought. Some cell types, particularly bone marrow cells, are able to incorporate themselves into diverse tissues (such as the epidermis or heart) and to adopt the fates of resident cells, contributing progeny to the tissue. Induced pluripotent stem cells (iPS) are somatic cells (e.g. fibroblasts) that have been reprogrammed into an embryonic stem cell-like state[28]; these cells can be stimulated to differentiate into a variety of cell types, including keratinocytes. Thus, many adult cells, including different skin cell types, may be capable of dedifferentiating into pluripotent stem cells.

Stem Cell-Based Therapy for Genetic Skin Disease

Stem cells have been utilized in several strategies for gene therapy of heritable skin diseases (Fig. 2.6). Treatment via delivery of gene-corrected stem cells has the advantage of continuous protein synthesis in the skin, but it may carry a risk of oncogenesis (especially with retroviral vectors). In a pilot study, laminin-β3-deficient skin from a man with junctional EB was corrected by transplantation of stem cell-enriched epidermal grafts transduced *ex vivo* with a retroviral vector encoding normal *LAMB3* cDNA. The treatment resulted in expression of functional laminin 332 and an absence of blistering in the corrected epidermis, both sustained over several years of follow-up. Clinical trials are also ongoing to investigate the value of bone marrow-derived stem cell transplantation as a systemic treatment for the extremely severe recessive dystrophic form of EB (RDEB). In an initial report[29], bone marrow transplantation after total or partial myeloablation resulted in substantial proportions of donor cells in the skin, increased collagen VII deposition at the dermal–epidermal junction and variably decreased

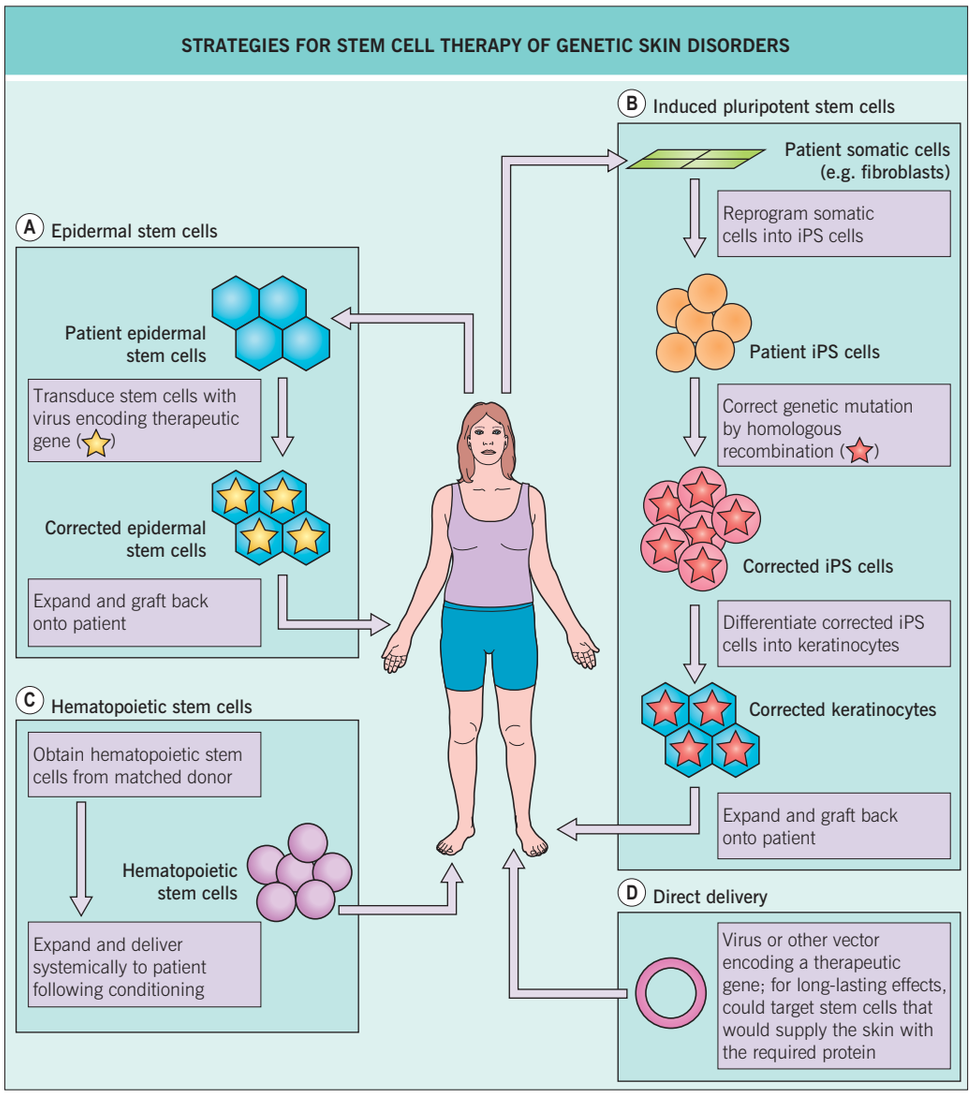

Fig. 2.6 Strategies for stem cell therapy of genetic skin disorders. A One strategy is to isolate epidermal stem cells from a patient, correct the genetic defect *in vitro* (e.g. using a viral vector), and graft epithelial sheets containing the corrected stem cells back onto the patient. **B** Gene therapy could also potentially utilize induced pluripotent stem (iPS) cells, which are generated from somatic cells (e.g. fibroblasts). The genetic defect could be corrected via homologous recombination in these cells, which would then be differentiated into keratinocytes and grafted onto the patient. **C** A third strategy involves the use of hematopoietic stem cells (HSC). Upon systemic administration (following conditioning), allogeneic HSC cells have the capacity to home to the skin (e.g. to sites of injury in patients with epidermolysis bullosa) and produce differentiated progeny cells that provide the needed skin protein (e.g. collagen VII). **D** Finally, therapeutic genes could be directly administered to patients via a virus or another vector. To achieve permanent correction, the vector must target stem cells that could supply the protein to the skin.

blistering in children with RDEB. Other investigators are studying alternative sources of stem cells for the treatment of EB.

PRENATAL DIAGNOSIS OF GENODERMATOSES

Many genodermatoses are incompatible with survival to term or are associated with significant morbidity or even mortality after birth, making prenatal diagnosis desirable. In the early 1980s, fetal skin biopsy became the first technique available for prenatal diagnosis of inherited skin diseases. Fetal biopsies are typically obtained between 19 and 22 weeks' EGA using ultrasound guidance and then analyzed via light and electron microscopy for the characteristic morphologic changes associated with the disease in question. The Herlitz form of junctional EB and epidermolytic hyperkeratosis were the first diseases diagnosed prenatally using this technique.

As the causative genes for many genodermatoses have been discovered, DNA-based testing using material obtained from chorionic villus sampling (10–12 weeks after the last menstrual period/8–10 weeks' EGA) or amniocentesis (14–16 weeks after the last menstrual period/12–14 weeks' EGA) has largely replaced fetal skin biopsy, as these techniques can be performed earlier and pose less risk to the mother and fetus. The pathogenic mutation(s) must be identified in family members prior to prenatal testing.

Preimplantation genetic diagnosis is a recently introduced technique that allows for prenatal diagnosis before the embryo is implanted and pregnancy begins. This technique requires the use of *in vitro* fertilization. One or two cells are taken from the embryo at the blastocyst (6- to 10-cell) stage. The cellular DNA is amplified using PCR and analyzed for the known family mutation(s); unaffected embryos are then selected for uterine implantation. For X-linked disorders, sex determination has been utilized both in conjunction with specific genetic analysis and to identify embryos of a particular sex for selective transfer. Preimplantation genetic diagnosis obviates the need to terminate a pregnancy with an affected fetus. However, it has several disadvantages compared to chorionic villus sampling or amniocentesis, including higher cost, technical difficulties (e.g. contamination by extraneous DNA), and a low rate of completed pregnancies.

SIGNIFICANCE OF SKIN DEVELOPMENT IN POSTNATAL LIFE

Understanding skin development is essential for the appropriate diagnosis and management of congenital skin disorders. This knowledge is useful far beyond the neonatal period, however, as many of the regulatory pathways central to development are recapitulated in postnatal life. For example, PTCH is essential for postnatal hair cycling as well as hair follicle development. In addition to the germline *PTCH* mutations that result in the nevoid basal cell carcinoma syndrome, somatic *PTCH* mutations represent a pathogenic factor in sporadic basal cell carcinomas. Elucidation of the mechanisms controlling angiogenesis during intrauterine development holds promise for improving wound healing and developing new anticancer therapies. Furthermore, delineating the factors involved in wound healing in embryos may point to interventions that may decrease scarring in children and adults. Thus, advancing the understanding of skin embryology may lead to life-saving or life-enhancing therapies.

Molecular Biology 3

Jonathan Vogel, Carole Yee and Thomas N Darling

INTRODUCTION

Advances in molecular biology are rapidly changing our understanding of skin biology and disease. Increased knowledge is being translated into new molecular diagnostic tests that are transforming the clinical practice of dermatology[1,2]. In order to use these tests in a prudent manner, dermatologists today have an even greater need to understand basic concepts in molecular biology. This knowledge is also leading to the development of new targeted therapies, many of which require determination of the molecular basis for disease in order to appropriately implement treatment[3]. In addition, the language and concepts of molecular biology are increasingly found in the lay media, and they are being brought into our offices by a well-educated public. The goal of this chapter is to outline basic concepts and methodologies of molecular biology and to give practicing dermatologists a fundamental appreciation of what their colleagues are doing in the laboratory and how their own clinical practice may change as molecular approaches are implemented into patient care.

In this chapter we will imagine a dermatologist confronting a representative dermatologic disease, melanoma. This dermatologist will utilize a range of techniques to elucidate the molecular basis for melanoma and then develop an effective treatment. In the first section we will begin at the bedside, as the dermatologist considers ways to examine the tissue. The next sections are divided into molecular biology techniques for analyzing DNA, RNA and protein from the melanoma cells. The dermatologist will then move on to develop animal models of melanoma, and utilize these animal models to study the pathogenesis of melanoma and develop new targeted therapies. Throughout, the use of melanoma is meant to provide a real-life construct for the discussion of scientific approaches and techniques in molecular biology; it is not intended to present data on the pathogenesis of melanoma, for which a vast literature already exists.

EXPERIMENTAL TECHNIQUES

At the Bedside

Dr A looks at a pigmented lesion on Mr B and suspects that this represents a melanoma. She plans an excisional biopsy, knowing that analyzing the histologic features of the lesion will likely determine the diagnosis. This will also lead to information important for assessment of prognosis, guidance of therapy, and future monitoring. Her inquisitive mind rapidly generates additional questions regarding melanoma. What molecular changes cause melanoma? Can the identification of these molecular changes assist in the diagnosis? What molecular differences exist between different types of melanoma? Can the molecular profiles be used to discriminate between melanomas that have a similar appearance histologically, but differ in prognosis? Can treatments be designed that target specific molecular alterations? Not content simply

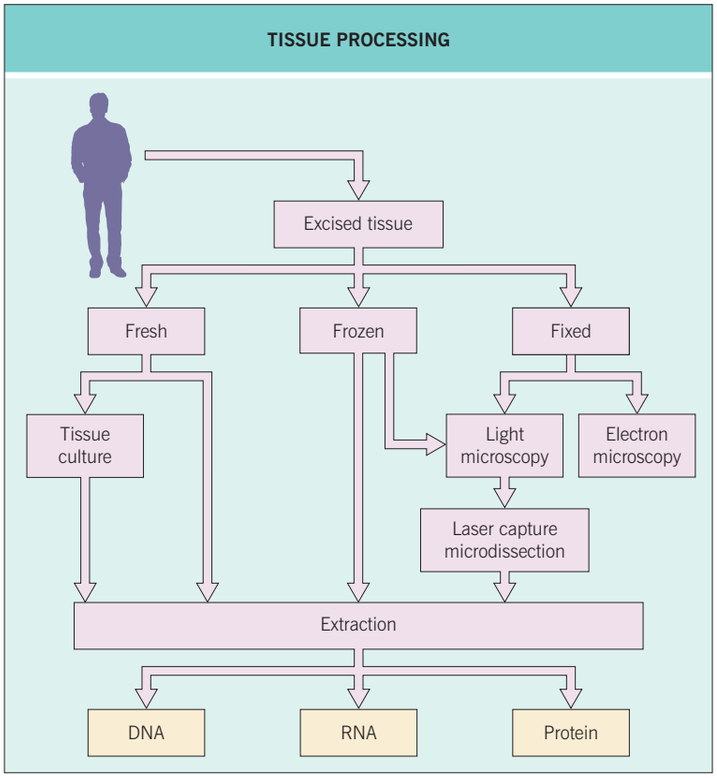

Fig. 3.1 Tissue processing. The biopsy from the melanoma tumor can be processed in four different ways, each with distinct advantages and disadvantages.

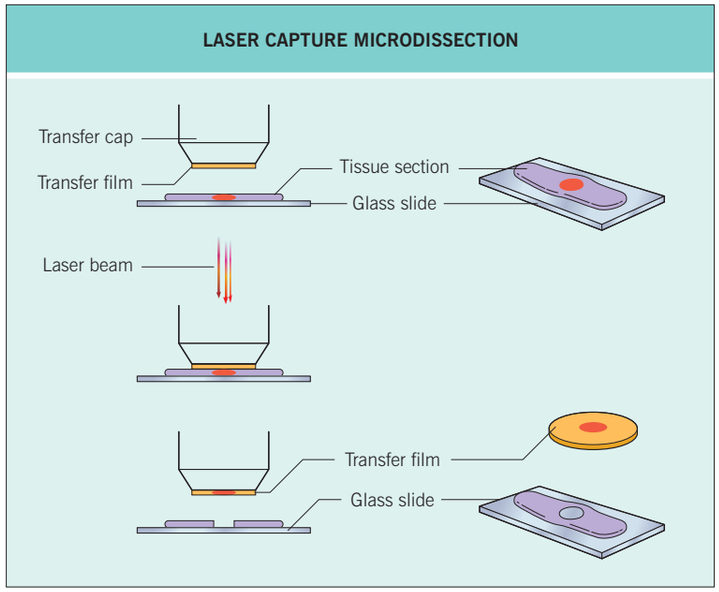

Fig. 3.2 Laser capture microdissection (LCM). LCM is used to selectively procure individual cells or clusters of cells from tissue sections. A glass slide with a section of paraffin-embedded or cryopreserved tissue is stained and placed on the microscope stage. A cap coated with a thermoplastic transfer membrane is placed directly over the tissue section. The operator identifies the cells of interest by looking through the eyepiece of the microscope or by looking at a monitor. A low-energy infrared laser is then pulsed that melts the transfer film onto the cells of interest. The cap is then lifted from the section to separate the selected cells from the remainder of the tissue section. Molecules of interest, including DNA, RNA and protein, can be extracted from the microdissected cells present on the cap[5].

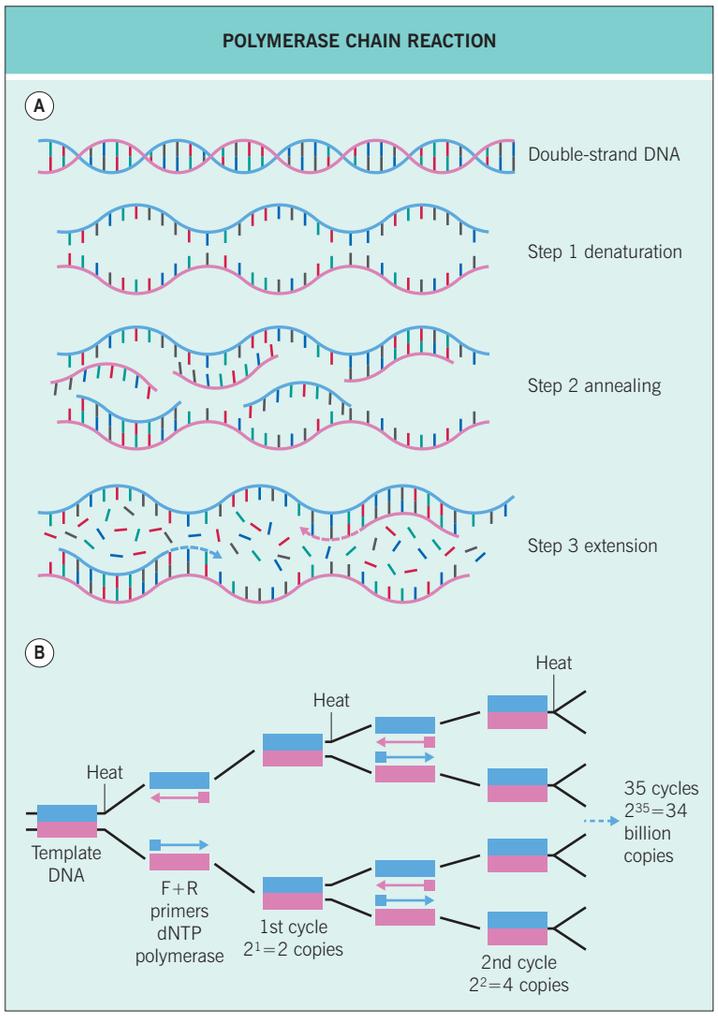

Fig. 3.3 Polymerase chain reaction. A Each cycle contains the following steps: (1) denaturation – separate the two strands of DNA by heating to >90°C; (2) primer annealing or primer hybridization – allow the oligonucleotide primers to bind to the template DNA by cooling to 50–65°C; (3) primer extension – DNA polymerase catalyzes the addition of nucleotides (A, G, C, T) that are complementary to the DNA template, beginning with the primer and extending 3′ at the optimal temperature of 72°C; and (4) repeat the complete cycle 30–40 times. **B** Each cycle increases the number of PCR products twofold. The total number of PCR products after *n* cycles will be 2^n times the original amount. F+R, forward and reverse.

to think about these things, Dr A obtains IRB approval to study melanoma and performs the excision, retaining a portion for further study in her laboratory. The immediate question is, how can this tissue be utilized?

Tissue Processing

The melanoma that Dr A has excised can be processed in four different ways, each with distinct advantages and disadvantages (Fig. 3.1). First, fresh tissue can be placed in culture medium and melanoma cells could be grown in an incubator. Culturing cells allows one to obtain more cells than in the original sample, and allows one to expose the cells to various conditions. The disadvantage of this approach is that the culturing process may change fundamental characteristics of the cells, so that they do not accurately represent the melanoma in the patient.

A second approach is to directly process the fresh tissue with buffers and reagents in order to extract DNA, RNA and protein from the whole mass of tumor cells. The advantage of this approach is that the DNA, RNA and protein will be fresh and of high quality. The disadvantage is that the extracts will not be from a pure population of cells.

In the third approach, the tumor specimen could be placed in a preservative buffer such as formalin (for light microscopy) or glutaraldehyde (for electron microscopy) for processing and sectioning, and then

POLYMERASE CHAIN REACTION
PURPOSE
• Amplify a specific piece of DNA from a complex mixture
REQUIREMENTS
• Need to know sequence of the DNA of interest (at least of its ends)
UNDERLYING CONCEPTS
• Double-stranded DNA can be melted or unwound to single strands with increased temperature (Fig. 3.3A); when cooled, the single strands come back together to form double strands (hybridize) if the nucleotide sequences are complementary* • During the hybridization process, when two complementary strands bind to each other, the A nucleotides on one strand bind to T nucleotides on the complementary strand, whereas C nucleotides of one strand bind to G nucleotides on the complementary strand, and vice versa • In PCR, short DNA strands called oligonucleotide primers are designed for hybridization to specific sequences in the template DNA
OUTLINE OF METHOD (FIG. 3.3)
• Oligonucleotide primers are designed to hybridize to specific sequences at each end of the DNA of interest. These primers are added to a reaction vessel mixture containing the template DNA along with a thermostable DNA polymerase, the nucleotides dATP (A), dTTP (T), dGTP (G) and dCTP (C), and buffer • The reaction vessel is placed in a thermal cycler, which controls the temperature of the reaction through many cycles • Each cycle contains the following steps: (1) denaturation; (2) primer annealing or primer hybridization; (3) primer extension; and (4) repeat of the complete cycle of PCR 30–40 times (see legend to Fig. 3.3 for more details)
BENEFITS
• PCR is simple and rapid • Because the PCR product is exponentially increased, it is extremely sensitive in amplifying low amounts of DNA. Each cycle increases the number of PCR products twofold. The total number of PCR products after *n* cycles will be 2^n
LIMITATIONS/ERRORS
• Because of its high degree of sensitivity, laboratory contamination of a DNA sample by trace amounts of the PCR product can cause misleading results • Primers used for PCR can anneal to sequences that are similar, but not identical, to the sequence of interest. This can be countered with "hot start" techniques (DNA polymerase prevented from acting until after first denaturation step) or nested PCR (after the PCR amplification, repeat the PCR amplification using a second set of primers that hybridize to sequences inside first set of primers). In nested PCR, the second set of primers will only hybridize to correct PCR products resulting from the first PCR amplification • DNA polymerase occasionally incorporates incorrect nucleotides. For sequencing by PCR, polymerases that possess proofreading enzymatic activity can be used. This also allows the generation of even longer PCR products, up to approximately 50 kb long
EXPERIMENTAL APPLICATIONS
• DNA can be amplified either for detection of a specific sequence or for cloning that sequence • PCR can be used to label DNA with radioactive nucleotides • PCR can be used for rapid haplotype analysis
MODIFICATIONS/ALTERNATIVES
• Quantitative PCR – the amount (number of copies) of a specific piece of DNA can be quantified by a variety of methods utilizing PCR. A relatively simple and high-throughput method, called real-time quantitative PCR, uses a specially designed thermal cycler that measures the amount of PCR product formed after each cycle (see Fig. 3.5). The higher the level of DNA, the earlier the product can be detected. This can be used to measure genetic changes in cancer such as gene amplification, to quantify the amount of residual cancer following treatment, or to quantify the amount of a pathogen in a sample. Modifications of this procedure can allow discrimination of gene polymorphisms • Southern blot, *in situ* hybridization, comparative genomic hybridization
*Hybridization actually forms the basis of several techniques in molecular biology, as the two strands can be DNA:DNA (PCR, Southern blotting), DNA:RNA (Northern blotting, **in situ** hybridization), or RNA:RNA.

Table 3.1 Polymerase chain reaction.

DNA SEQUENCING
PURPOSE
• Determine the sequence or order of nucleotides (A, G, C, T) in a stretch of DNA
REQUIREMENTS
• The piece of DNA to be sequenced can be either a PCR product or a cloned piece of DNA present in a plasmid, but it should be pure
UNDERLYING CONCEPTS
• Chain termination, or a variation thereof, is the preferred method for DNA sequencing • In chain termination, the extension of a new strand of DNA is stopped by the addition of an analogue of dATP, dCTP, dGTP or dTTP (ddATP, ddCTP, ddGTP or ddTTP, respectively) to the sequencing mixture (Fig. 3.4). When the DNA polymerase incorporates the analogue nucleotide instead of the correct normal nucleotide, DNA synthesis is terminated because the polymerase is no longer able to link to the next nucleotide • Gel electrophoresis is used to separate the different sizes of DNA fragments that result from chain termination synthesis (Fig. 3.4). The DNA fragments are forced to travel through a gel using an electric current; the smaller molecules are less impeded by the gel and travel faster than larger molecules*
OUTLINE OF METHOD (FIG. 3.4)
• An oligonucleotide primer hybridizes to the DNA to be sequenced and DNA polymerase synthesizes a second complementary strand • The synthesis of the second strand is interrupted randomly by the incorporation of the fluorescent nucleotide analogues (ddATP, ddGTP, ddCTP, ddTTP), and the DNA fragments containing this final nucleotide analogue can be identified because each of the four ddNTPs is labeled with a different color fluorochrome • The different DNA fragments are electrophoresed through a polyacrylamide gel or capillary tubes • The different-length DNA strands terminating with different fluorochrome-labeled nucleotide analogues pass a fluorescence detector and indicate the order of the DNA sequence
BENEFITS
• The fluorescent chain termination method is able to rapidly sequence large amounts of DNA with automated analysis of results
LIMITATIONS/ERRORS
• Routinely sequence only approximately 500 bases per run • Difficulty with G+C-rich regions • DNA must be high-quality
EXPERIMENTAL APPLICATIONS
• Determine previously unknown sequence • Confirm sequence following the cloning of a DNA fragment of interest and other manipulations
MODIFICATIONS/ALTERNATIVES
• Pyrosequencing • Sequencing by oligonucleotide ligation and detection • Solid-phase amplification followed by sequencing by synthesis of randomly fragmented DNA
*Gel electrophoresis is used in many molecular biologic techniques to separate DNA, RNA or protein molecules of differing sizes.

Table 3.2 DNA sequencing.

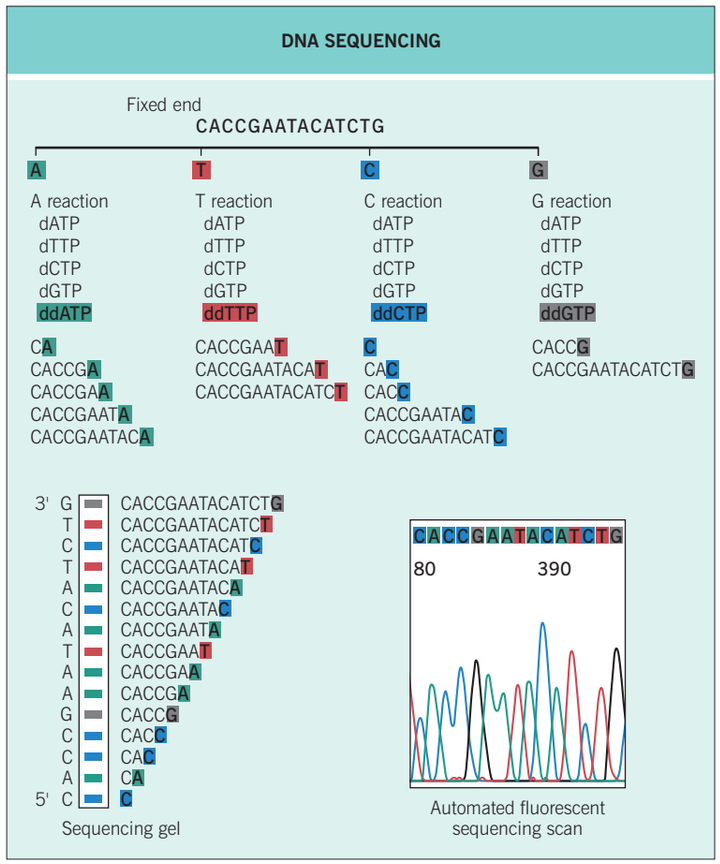

Fig. 3.4 DNA sequencing. An oligonucleotide primer hybridizes to the DNA to be sequenced and DNA polymerase synthesizes a second complementary strand. The synthesis of the second strand is interrupted randomly by the incorporation of fluorescent nucleotide analogues (ddATP, ddGTP, ddCTP, ddTTP). The DNA fragments containing this final nucleotide analogue can be identified because each of the four ddNTPs is labeled with a different color fluorochrome. Gel electrophoresis is used to separate the different sizes of DNA fragments. The different-length DNA strands terminating with different fluorochrome-labeled nucleotide analogues pass a fluorescence detector and indicate the order of the DNA sequence (see Table 3.2 for more details).

analyzed histologically in a variety of ways, including routine staining, immunohistochemistry or *in situ* hybridization. The advantage of this approach is that the cells are preserved in a very stable fashion, with well-preserved architecture, for later analysis. One disadvantage is that the cells are no longer living, and the fixation procedure places limits on the methods that can be used to analyze DNA, RNA and protein from the tumor.

Finally, the specimen could be snap-frozen, with DNA, RNA and protein being extracted at a later time[4]. The histology of the frozen melanoma tumor could also be analyzed by obtaining cryosections of the tumor for histologic analysis.

Dr A may also decide to use laser capture microdissection (LCM) to isolate individual melanoma cells for subsequent analysis (Fig. 3.2). LCM uses a laser to retrieve individual cells from a section on a slide while the specimen is viewed with a microscope[5]. The biggest advantage of this approach is that a very pure population of cells is obtained that has been precisely identified under the microscope. The disadvantage is that the total number of cells isolated is relatively low, as each cell has to be individually captured by the laser. Consequently, the procedures to extract DNA, RNA and protein from these pure (but few) cells have to be robust.

Assessing the DNA, RNA and Protein of Individual Genes that may be Responsible for Melanoma

After Dr A has extracted DNA, RNA or protein from the melanoma tumor specimen, she is ready to proceed with her analysis. Dr A knows that cancer is caused by mutations in proto-oncogenes and tumor suppressor genes (see Chs 107 & 113). She would like to identify the gene(s) mutated in her patient's melanoma, to find out what effects these mutations have on melanocytes, and to potentially use this information to design a better treatment for melanoma.

Dr A has read the literature about a new proto-oncogene, *toomuchsun*, that is normally expressed in cells and regulates cell growth but which can induce cancer when mutated. She decides to begin her studies by analyzing the tumor DNA and determining whether the gene *toomuchsun* is present in a mutated form. She knows that one can extract DNA from tumors, but her gene of interest is just a tiny fraction of the total amount of DNA. How can she obtain sequence information on just her gene of interest?

REVERSE TRANSCRIPTION PCR
PURPOSE
• To amplify mRNA by PCR, the mRNA is first converted to DNA (called complementary DNA or cDNA) (Fig. 3.5A), followed by PCR amplification of a specific region of the cDNA to detectable levels
REQUIREMENTS
• Starting material can be total cellular RNA (including ribosomal, transfer and messenger RNA [mRNA]) or purified mRNA
UNDERLYING CONCEPT
• In order to facilitate studies of RNA, many techniques that study RNA first convert the RNA to cDNA with an enzyme called reverse transcriptase, an RNA-dependent DNA polymerase
OUTLINE OF METHOD (FIG. 3.5A)
• Reverse transcriptase can convert mRNA to cDNA by three different methods, depending on the primer used for the initial RT step*. (1) Random hexamer primers contain six nucleotides (6-mer) that have all possible sequence combinations of the dA, dG, dC and dT nucleotides (4^6 possible combinations). These random hexamers will hybridize to the corresponding complementary sequences in the sample RNA. (2) Oligo dT primers contain only dT nucleotides and hybridize to the complementary string of dA nucleotides that are present at the end of mRNA molecules (poly A tail). (3) The third choice is a primer that will only hybridize to a specific mRNA sequence • After the mRNA has been converted to cDNA, primers that can hybridize to specific sequences are added and PCR amplification is performed as described in Table 3.1
BENEFITS
• As for PCR, RT-PCR is simple and rapid • RT-PCR is extremely sensitive in detecting low levels of mRNA transcripts
LIMITATIONS/ERRORS
• If the RNA sample is contaminated with DNA (that contains the gene of interest), a PCR product may be amplified from the DNA even though the corresponding mRNA for the gene is not present. To control for this, RT-PCR of RNA samples can be done with and without reverse transcriptase† • RNA is fragile and the absence of a specific mRNA transcript may result from RNA degradation during and following extraction. RNA quality can be tested by gel electrophoresis and/or by RT-PCR of housekeeping genes (genes expressed by all cells)
EXPERIMENTAL APPLICATIONS
• The mRNA gene transcripts can be amplified for subsequent cloning or sequencing • The mRNA gene transcripts (instead of the gene) could be analyzed for the presence of mutations
MODIFICATIONS/ALTERNATIVES
• Quantitative RT-PCR – by adding a reverse transcription step to quantitative PCR (see Table 3.1), the levels of mRNA transcripts from genes of interest can be quantified. This is very important because it allows us to precisely measure and compare the number of mRNA transcripts in different types of cells or cells grown under different conditions • Correspondingly, samples that contain less mRNA transcripts will require more PCR cycles before the exponential phase. Therefore, different RNA samples can be precisely compared by measuring the number of PCR cycles (x axis) needed to produce a defined amount of PCR product (y axis) (Fig. 3.5B) • By carefully designing the primers, quantitative RT-PCR can be used to measure the amounts of alternatively spliced forms of a gene • Alternative methods to measure RNA levels, not based on RT-PCR, include Northern blots and ribonuclease protection assays • Differential display – this is used to find differences in gene expression in several samples. It is an RT-PCR-based system that uses short arbitrary primers that amplify numerous genes in a sample. By comparing the complex banding pattern of PCR products observed after gel electrophoresis, bands can be observed that are present in some samples but not others. With further study, these differing bands can be identified as corresponding to known or novel genes
*In addition to the RNA, the reaction mixture contains the reverse transcriptase enzyme, an oligonucleotide primer, dNTPs and buffer. †If DNA contamination is not present, PCR products will not be amplified from RNA that has not been reverse transcribed, and PCR products will be present only in RNA samples that have been reverse transcribed into cDNA.

Table 3.3 Reverse transcription PCR (RT-PCR).

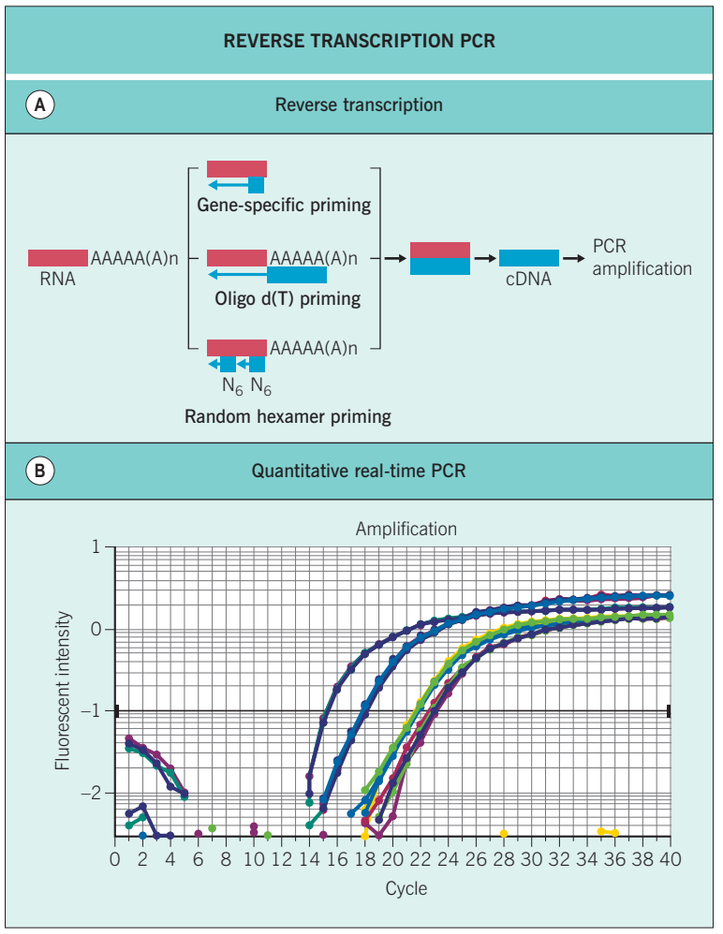

Fig. 3.5 Reverse transcription PCR (RT-PCR). A Reverse transcriptase can convert mRNA to cDNA in three different ways, depending on the primer used for the initial RT step: (1) random hexamer primers; (2) oligo dT primers; and (3) gene-specific primers (see Table 3.3 for more details). After the mRNA has been converted to cDNA, primers that can hybridize to specific sequences are added and PCR amplification is performed as described in Table 3.1. **B** Real-time PCR is able to precisely measure the amount of PCR product continuously (*y* axis) after each cycle (*x* axis). Each plotted line represents the amount of PCR product present in a different sample. In samples that initially contain more mRNA gene transcripts, real-time PCR will demonstrate an exponential increase in PCR product earlier, after fewer PCR cycles.

Although Dr A initially finds the terminology confusing, she soon discovers that the concepts behind molecular biology are simple and unifying[6]. Most of it comes down to extracting the molecules of interest, amplifying them to measurable amounts, and detecting them. Dr A chooses PCR amplification as the best technique to obtain and isolate sufficient amounts of pure DNA containing the proto-oncogene *toomuchsun* (Table 3.1; Fig. 3.3)[7]. The PCR-amplified DNA containing the gene can be sequenced using automated fluorescence sequencing techniques (Table 3.2; Fig. 3.4). Based on the sequencing results, Dr A will know whether mutations are present in the *toomuchsun* gene in these melanomas. This simple and relatively inexpensive approach is still widely used. However, it is being succeeded by rapidly evolving techniques for ultra-high-throughput sequencing[8], yielding, for example, a comprehensive catalogue of mutations in melanoma cell lines and tumors[9].

Dr A's discovery that the melanomas have mutations in the proto-oncogene *toomuchsun* has potential clinical significance. By analyzing large numbers of melanomas, nevi and normal melanocytes, she can determine whether the presence of these mutations correlates with a certain type of lesion or a melanoma with a particular prognosis. For example, it is known that activating mutations in the *BRAF* proto-oncogene can be found in the majority of superficial spreading melanomas (as well as banal and atypical melanocytic nevi), whereas *KIT* mutations characterize a subset of melanomas arising from acral sites,

WESTERN BLOT
PURPOSE
• Western analysis can measure the size and the amount of protein present in a sample (Fig. 3.6)
REQUIREMENTS
• Western analysis requires an antibody that is specific for the protein of interest (i.e. does not cross-react with other proteins)
UNDERLYING CONCEPTS
• Polyclonal antibodies that react to several epitopes on a protein antigen are obtained by injecting a protein into an animal and later isolating the antibodies from the serum immunoglobulin fraction • Monoclonal antibodies that react to only one epitope of a protein antigen are obtained by immunizing mice (or rats, rabbits, or chickens) with the antigen, then fusing the animal's reactive lymphocytes with an immortal myeloma cell line to create cells that are able to provide antibodies indefinitely • A secondary antibody is used to detect the protein or the primary antibodies bound to the protein. These detection antibodies can be visualized by attaching a fluorescent probe or by attaching an enzyme that can produce either light or a color by enzymatic action on a substrate
OUTLINE OF METHOD (FIG. 3.6)
• A solubilized protein mix is separated on a polyacrylamide gel and transferred electrophoretically to a membrane. The membrane is then soaked in a buffer containing the antibody. Bound antibody is detected by a chromogenic or chemiluminescent assay
BENEFITS
• Western analysis is a simple and sensitive method to detect and quantify proteins present in a complex mixture • Western analysis can determine the molecular weight of a specific protein relative to standard controls
LIMITATIONS/ERRORS
• Proteins are subject to degradation during extraction. The use of protease inhibitors in the extraction buffer helps to prevent degradation • To perform a Western analysis, one must possess a highly specific antibody that can recognize denatured proteins • Western blots may contain a high background of nonspecific staining. To correct this, blocking agents such as bovine serum albumin or milk protein are used • Large proteins transfer poorly from the gel to the membrane, and small proteins may transfer through the membrane without binding. Adequate transfer to the membrane can be accomplished by controlling the duration of the transfer procedure
EXPERIMENTAL APPLICATIONS
• Detection, quantification and characterization of a specific protein • Identification of antibody activity to a known antigen
MODIFICATIONS/ALTERNATIVES
• Dot blot – a drop of the protein mixture is placed on a paper membrane and the protein of interest detected with antibodies, as in the Western blot. The disadvantage of this technique is that, owing to the elimination of size separation by gel electrophoresis, specific binding to the protein of correct size cannot be distinguished from nonspecific background binding to proteins • Immunoprecipitation (IP) – in immunoprecipitations, the specific antibody is added to the protein mixture and the resulting antibody–protein complexes are then isolated. Because proteins are not first denatured in immunoprecipitation, they can be detected in a more native configuration • IP–Western – protein–protein interactions can be studied by first immunoprecipitating the protein with one antibody, bringing down a protein complex. The protein complex is then separated on a polyacrylamide gel, followed by Western blotting to detect members of the protein complex • Enzyme-linked immunosorbent assay (ELISA) – this is a sensitive and specific method for quantifying the amount of a protein. The protein of interest is captured on a plate coated with a monoclonal antibody and other proteins are washed away. The protein is then detected using a second antibody that has been modified for detection using a colorimetric or luminescent assay • Immunohistochemistry – this is used to visualize the cellular localization of a protein. An antibody to the protein of interest is applied to a tissue section. The antibody is detected using a secondary antibody coupled to an enzyme that reacts with a substrate to produce a colored precipitate

Table 3.4 Western blot.

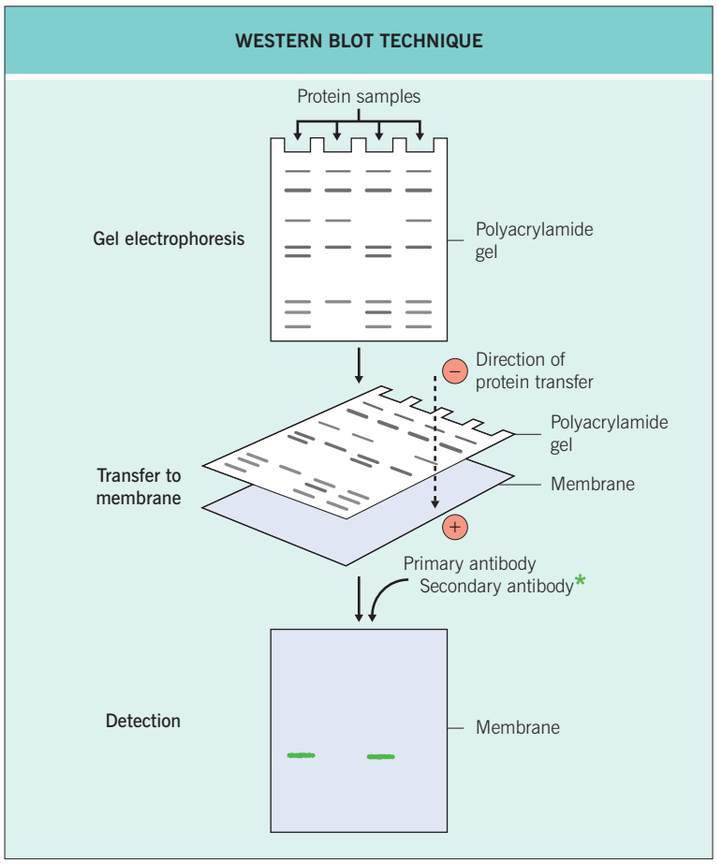

Fig. 3.6 Western blot technique. A solubilized protein mix is separated on a polyacrylamide gel and transferred electrophoretically to a membrane. The membrane is soaked in a buffer containing antibody. The bound antibody is detected by a chromogenic or chemiluminescent assay utilizing a labeled secondary antibody (green asterisk).

the mucous membranes or chronically sun-damaged skin. Knowing whether or not these mutations are present can help to direct targeted therapy, such as use of a *BRAF* inhibitor (e.g. vemurafenib) for advanced melanomas with activating BRAF mutations or a *KIT* inhibitor (e.g. imatinib) for those with KIT alterations.

Before embarking on a large study, Dr A decides to gather some information indicating whether *toomuchsun* mutations have significant consequences. She would like to determine whether these mutations influence the level of *toomuchsun* mRNA and protein inside cells.

As mutations in proto-oncogenes are frequently activating mutations that increase the amount and/or activity of the gene product, Dr A would like to determine whether these mutations increase the level of *toomuchsun* mRNA inside the melanocytes, possibly contributing to melanoma development. Although, like DNA, RNA is easy to purify, it is much more readily degraded than DNA. Therefore, a typical first step in the analysis of RNA is to convert it into DNA using reverse transcription (RT; Table 3.3; Fig. 3.5A). Following RT, the complementary DNA (cDNA) can be amplified by PCR, as described above. The technique of RT-PCR has also been modified to allow accurate quantitation of very low levels of mRNA[10]. Because the amount of PCR product is monitored throughout each cycle of amplification, this technique is referred to as "real-time" quantitative PCR (Fig. 3.5B).

Dr A observes that in cultures of melanomas, levels of *toomuchsun* mRNA are increased compared to those in normal melanocytes, and she would like to know whether these changes are also reflected in the levels of protein. The amount of protein is a complex balance of synthesis and degradation controlled at multiple steps, including efficiency of protein translation and post-translational modifications that affect protein stability. To measure the levels of *toomuchsun* protein, she decides to use a procedure called a Western blot (Table 3.4; Fig. 3.6), also known as an immunoblot, as it employs an antibody to detect the

protein of interest. In addition to measuring protein levels, Western blot analysis can determine the size of proteins and can reveal whether there are different forms of the protein[11].

Measuring and Profiling RNA and Protein Expression from Multiple Genes that may be Responsible for Melanoma

At this point, Dr A has identified mutations in the *toomuchsun* gene in melanoma, and has found that this mutation increases the levels of *toomuchsun* mRNA and protein in cells. She does not know the function of *toomuchsun* protein, but expects that the mutant protein may alter the expression patterns of many other genes inside melanoma cells and melanocytes. To better understand how melanocytes transform into melanoma cells, Dr A would like to compare the patterns of gene expression in these cells. How can Dr A investigate changes in gene expression of all the genes (i.e. the transcriptome) that occur inside melanoma cells compared with normal melanocytes? Knowing which genes are abnormally expressed in melanoma cells (either increased or decreased) will allow her to investigate the role of these genes in the development of melanoma.

Dr A decides to use gene expression profiling to quantitatively analyze the expression levels of nearly the entire genome in melanoma cells compared with normal melanocytes (Table 3.5; Fig. 3.7)[12]. Several approaches are available to accomplish this, but most are based on the hybridization of labeled sample mRNA to known oligonucleotide or cDNA sequences (representing thousands of genes) placed on chips, beads, or glass slides. The level of hybridization to the nucleotide sequence of a given gene indicates how much mRNA of that gene is present. The advantage of this approach is that it allows Dr A to quantitatively analyze the expression levels of thousands of genes at one time. In addition to using this method to profile mRNAs (the transcriptome), modified approaches allow the measurement of differences in microRNAs or changes in genomic DNA copy number. Changes in copy number can be determined by array comparative genomic hybridization (CGH) or single nucleotide polymorphism (SNP) arrays[12] (see Ch. 54). The use of these techniques for clinical purposes is expanding, such as utilization of array CGH to help classify melanocytic lesions with ambiguous histologic features (e.g. atypical spitzoid tumors).

The comparative analysis of so many different genes would be impossible for Dr A without the help of powerful software that can compare results from multiple experiments and cluster results according to changes in gene expression. The field of bioinformatics allows Dr A to analyze thousands of genes simultaneously, and it helps her to characterize the sequence, genomic location, protein structure, and related genes for any gene of interest (Fig. 3.8). This work is enhanced by the availability of large public databases of gene expression arrays as well as data-mining applications[12].

From these studies, Dr A is able to find a number of candidate genes that may contribute to the development of melanoma. All of these candidate genes are either overexpressed or underexpressed in melanoma cells compared to normal melanocytes (see Fig. 3.7). Some of the genes appear promising based on their known function. For example, a subset of the *overexpressed* genes are known to be involved in stimulating cell growth, whereas several of the *underexpressed* genes are known to inhibit cell growth. Moreover, some of the melanomas show very similar patterns of gene expression, whereas others have different patterns.

Microarray experiments similar to those portrayed in this hypothetical situation have actually been carried out. These have shown that different patterns of gene expression profiles may serve to distinguish melanomas with different biologic behaviors and prognoses.

In addition to using microarrays to analyze mRNA, Dr A would also like to analyze the proteins expressed by the melanoma cells. The term "proteome" refers to all of the proteins produced inside a cell at any point in time. A quantitative technique that is able to determine which proteins are produced by pure populations of cells in a high-throughput manner would, in theory, be more valuable than the data generated by microarray analysis. This is because the mRNA levels determined by microarray analysis do not always correspond to the protein levels inside a cell, and it is the expression level of proteins encoded by different genes that is of greatest relevance.

Technologies that allow measurement of the proteome are rapidly being developed. One technique relies on mass spectrometry, which can provide extremely accurate measurements of protein mass by ionizing the protein and measuring the "time-of-flight" through a tube to a detector on the opposite end (Table 3.6; Fig. 3.9)[13]. In most instances, the proteins are separated prior to mass spectrometry, using two-dimensional gel electrophoresis or capillary electrophoresis. This can be technically difficult and time-consuming, so mass spectrometry analysis of proteins continues to be optimized for high-throughput and quantitative analysis of proteins. One approach, called multidimensional protein identification (MudPIT), is a non-gel-based "shotgun" proteomic technique. Quantitation is accomplished

NUCLEIC ACID ARRAYS
PURPOSE
• To profile the mRNA expression of thousands of genes in one experiment
REQUIREMENTS
• Total RNA or mRNA from samples (larger amounts than required for RT-PCR)
UNDERLYING CONCEPTS
• Hybridization to DNA – the same principle of hybridization applies as in PCR (described in Table 3.1), except that many different genes are being evaluated simultaneously. DNA is attached to beads, chemically synthesized on a surface at thousands of specific locations, or spotted onto glass slides (Fig. 3.7). If cells are expressing mRNA of the corresponding gene, labeled cRNA prepared from mRNA in those cells will hybridize and generate a signal intensity related to its level of expression
OUTLINE OF METHOD (FIG. 3.7)
• RNA is reverse transcribed to generate cDNA. *In vitro* transcription of the cDNA in the presence of biotinylated nucleotides yields biotin-labeled cRNA (see Fig. 3.7). Labeled cRNA molecules are then hybridized to small DNA fragments attached to beads or on a chip. The samples are stained with streptavidin phycoerythrin, the streptavidin binding the biotin on the cRNA and the phycoerythrin generating a fluorescent signal. Usually, the patterns of gene expression of two samples are compared, such as normal versus tumor or treated versus untreated • Alternatively, oligonucleotide arrays can be used (see Fig. 3.7). Using this approach, the RNA is directly labeled with either fluorescent or radioactive nucleotides, and hybridized to oligonucleotides on a slide or membrane. When using radioactive probes, the samples are hybridized to separate microarrays. If the mRNA samples to be compared are labeled with differently colored fluorescent probes, the two samples can be hybridized to the same array simultaneously • A scanner measures the intensity of the signals at each spot and computer software determines those genes over- and underexpressed in one sample compared to the other
BENEFITS
• Thousands of genes can be rapidly and quantitatively profiled in one experiment
LIMITATIONS/ERRORS
• Genes expressed at low levels may not be detected • For some genes, the cRNA may not hybridize under the conditions used • The RNA must be of very high quality
EXPERIMENTAL APPLICATIONS
• Microarray analysis can be used to profile changes in gene expression • The patterns of gene expression can be used to group samples
MODIFICATIONS/ALTERNATIVES
• Subtractive hybridization • Serial analysis of gene expression (SAGE) • Deep sequencing • MicroRNA arrays • Comparative genomic hybridization (CGH) to detect differences in DNA copy number • Single nucleotide polymorphism (SNP) arrays to assess markers of genetic variation; useful for linkage analysis, including genome-wide association studies (GWAS; see Ch. 54)

Table 3.5 Nucleic acid arrays.

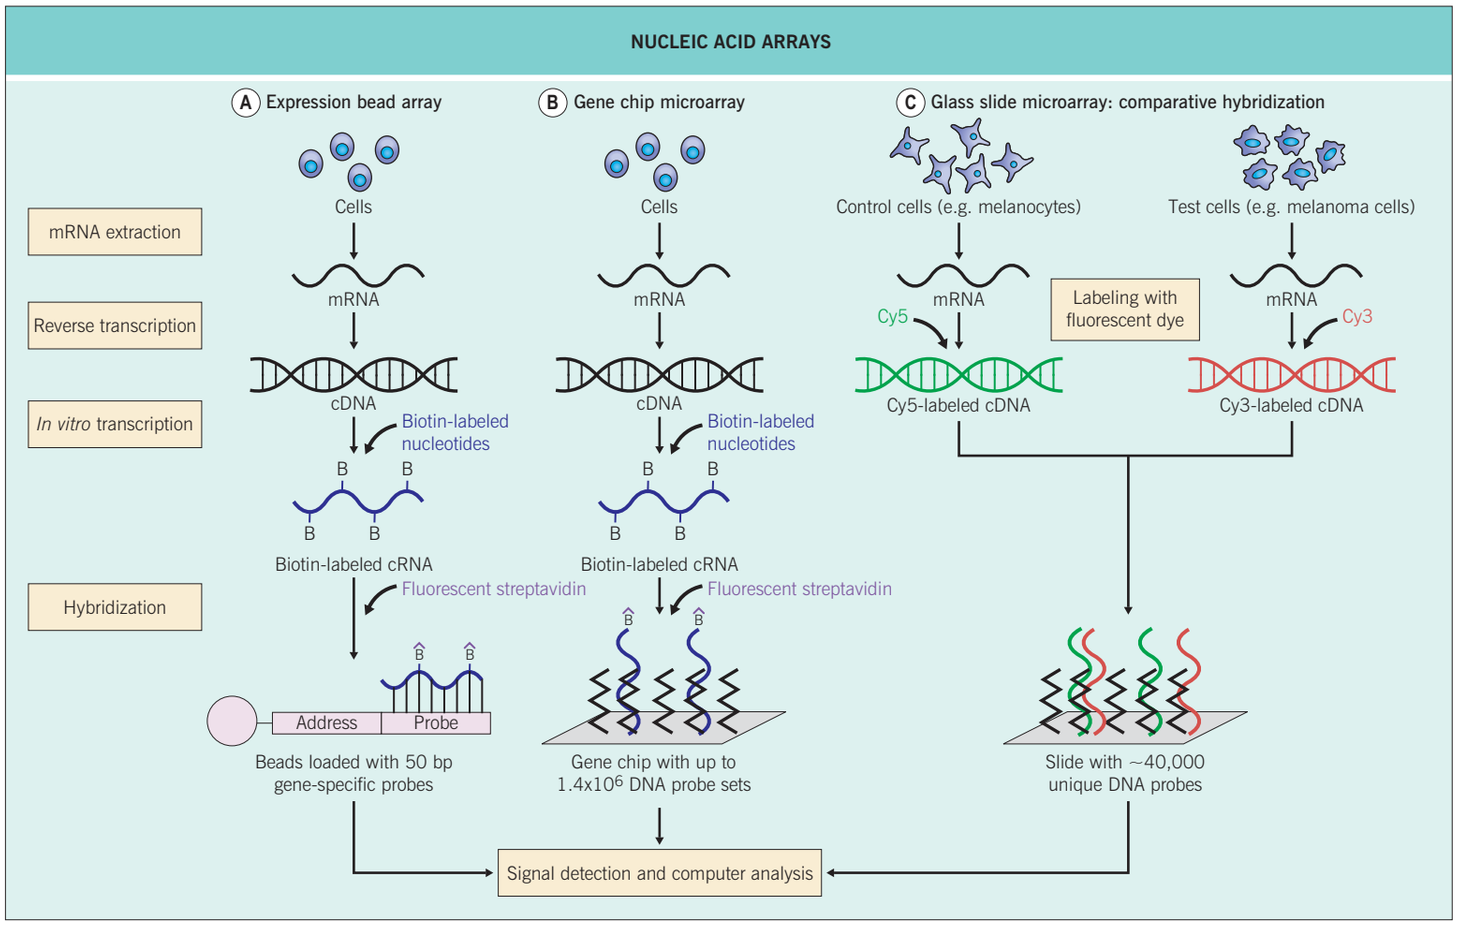

Fig. 3.7 Nucleic acid arrays. A In the expression bead array, RNA is extracted from cells and reverse transcribed to generate cDNA (see Fig. 3.5, Table 3.3). *In vitro* transcription of the cDNA in the presence of biotinylated nucleotides yields biotin-labeled cRNA. Labeled cRNAs bind to their respective 50-base probes that are linked to separate beads using additional nucleotides as an address to decode the gene. Fluorescent streptavidin is added which strongly binds to biotin. The fluorescent intensities on different beads are related to the amount of cRNA and the latter is a reflection of the level of expression of mRNA by specific genes. Usually, the patterns of gene expression of two samples are compared, such as normal versus tumor or treated versus untreated. **B** In the gene chip microarray, labeled cRNA molecules are hybridized to small DNA fragments chemically synthesized on a surface, with the surface containing thousands of specific sequences at different locations. **C** In a third approach using glass slides, two samples can be labeled with differently colored fluorescent probes (e.g. Cy5, Cy3) that are hybridized to an oligonucleotide array simultaneously (see Table 3.5 for more details). Arrays can also be used to analyze DNA rather than RNA; examples include single nucleotide polymorphism (SNP) arrays and array comparative genomic hybridization (CGH) (see Ch. 54).

by labeling proteins using stable isotopes to provide internal standards, or by label-free shotgun proteomic approaches that are being developed for greater speed and lower costs[14]. Another technique is the use of protein arrays, where, for example, antibodies to specific proteins are immobilized on a slide or membrane. These arrays can analyze complicated mixtures of proteins by capturing and detecting specific proteins[15]. If Dr A could use mass spectrometry or protein arrays, in addition to nucleotide microarray analysis, to determine and compare the precise amounts of all cellular proteins in melanoma cells versus melanocytes, she would have a much clearer picture of how melanoma cells differ from normal melanocytes, and which genes may be responsible for cancer development.

Transgenic Animal Models

After completing all these studies, Dr A has now identified a number of different genes that she believes are important in causing melanoma. In the next major phase of her research, she will begin to test these genes in animal models to see if they cause cancer. These animal model studies will allow her to investigate the mechanisms of carcinogenesis (see Ch. 107), enabling her to demonstrate that mutations in a particular gene are able to cause cancer. Although a variety of animal models have been used to study cancer, our discussion will be limited to transgenic mice, including "knockout" and conditional "knockout" mice.

As commonly used experimental models, transgenic mice are normal in all respects except that every cell contains a new gene of interest. The gene to be studied is microinjected into a fertilized mouse egg, randomly integrates into the mouse genome, and is present in every cell as the egg divides and develops into a mouse (Table 3.7; Fig. 3.10)[16,17]. Although the gene is present in every cell, the expression of the gene can be limited or targeted to specific tissues or cell types by using a promoter/enhancer that is only expressed in a given cell. Promoters/enhancers are the portion of a gene – usually on the 5′ end of the gene or upstream of its coding region – that initiates and regulates the level of mRNA expression. The promoters/enhancers that would ensure genes are only expressed in melanocytes would include the promoters of genes involved in melanin biosynthesis, such as tyrosinase.

In order to specifically express the mutated *toomuchsun* gene in melanocytes of transgenic mice, Dr A designed a gene construct that contained a promoter/enhancer from tyrosinase connected to the mutated *toomuchsun* gene, and then injected this gene construct into fertilized mouse eggs (see Fig. 3.10). Although every mouse cell will contain a randomly integrated copy of this new gene, it will be expressed only in melanocytes because of the melanocyte-specific promoter/enhancer. In the same manner, Dr A could express other candidate genes in the melanocytes of transgenic mice. Conversely, if she wanted to express a gene only in keratinocytes, she would design a gene

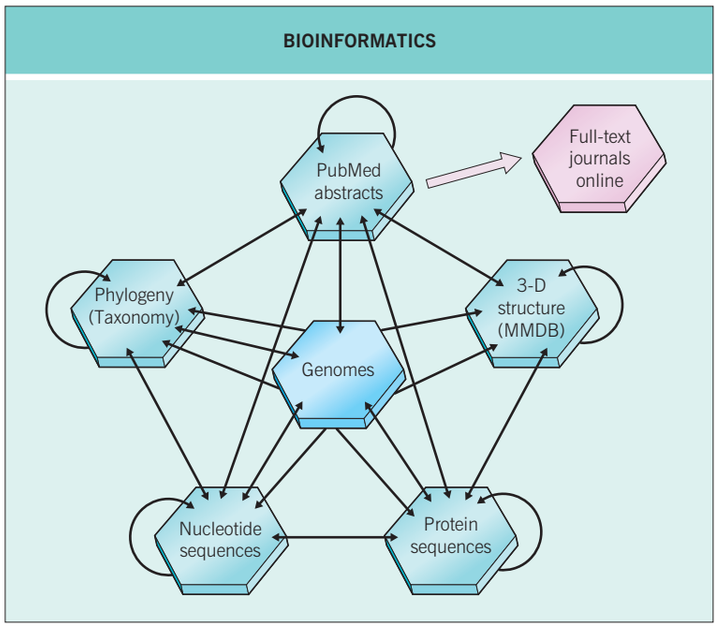

Fig. 3.8 Bioinformatics. A goal of bioinformatics is to give users access to huge amounts of biologic information in a way that is easy to use and analyze. One example is Entrez produced by the National Center for Biotechnology Information (NCBI), available at http://www.ncbi.nlm.nih.gov. This retrieval system allows the user to search the biomedical literature (PubMed), nucleotide sequence database (GenBank), protein sequence database, three-dimensional macromolecular structures, and complete genome assemblies and organisms in GenBank (taxonomy). As indicated by arrows, users may access information from a single database and also integrated information from several NCBI databases. MMDB, molecular modeling database.

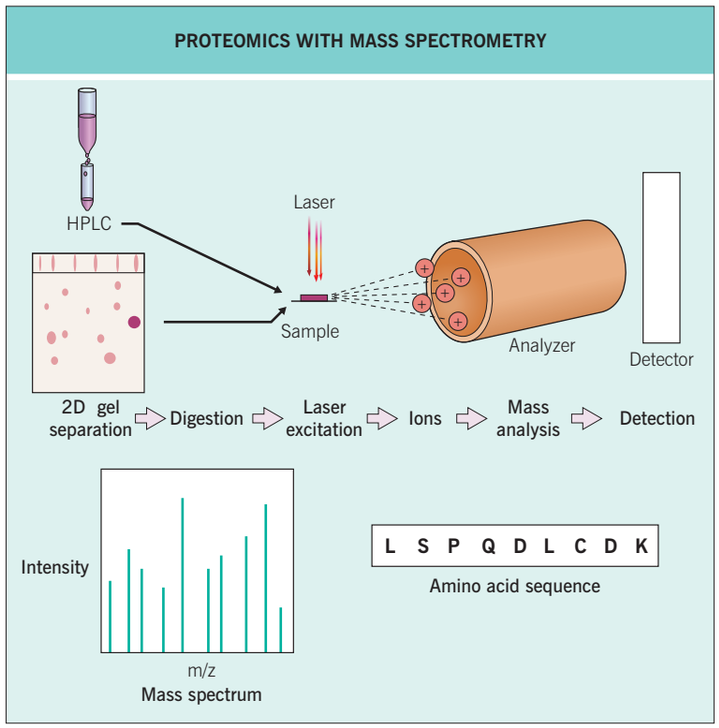

Fig. 3.9 Proteomics with mass spectrometry. The first step is to reduce the complexity of the mixture of cellular proteins or peptides to be analyzed. The two main methods to separate proteins/peptides from each other are two-dimensional gel electrophoresis and/or liquid chromatography columns. Mass spectrometry analysis is then performed by first ionizing the separated proteins/peptides into positively charged ions using lasers. Based on the time-of-flight of the charged ion, mass spectrometry can measure, record and print out the mass/charge ratio of every peptide along with signal intensity.

construct containing a promoter/enhancer from a gene that is only expressed in keratinocytes, such as a keratin promoter.

After these transgenic mice are born, Dr A will carefully examine their skin. She will first check to make sure that the transgene, such as the mutated *toomuchsun*, is expressed in melanocytes by isolating mRNA from the skin and using a RT-PCR assay to determine whether mutated *toomuchsun* mRNA transcripts are present. Alternatively, histologic sections of skin could be analyzed by immunostaining with an antibody against *toomuchsun* in order to confirm that transgenic mice were expressing the transgene in the correct location or cell type (melanocytes).

Next, Dr A will analyze the skin and take random punch biopsy specimens at different time points for histology to determine whether melanoma develops in these transgenic mice. She can determine the time course and frequency of tumor development and can investigate whether external or environmental agents, such as UV light, contribute to the development of the tumors. Finally, if melanomas develop, she can assess their metastatic potential and ability to spread to other organs, such as the lungs.

Based on her initial microarray analysis and proteomic studies, Dr A may decide that melanoma is not caused by expression or aberrant overexpression of a protein (including mutated proteins), but rather is due to the lack of a gene product or protein. In other words, the genetic basis for melanoma may be the result of a protein that normally protects a cell from cancerous growth not being expressed. Her microarray analysis and RT-PCR studies may demonstrate that certain genes which are normally expressed in melanocytes are not expressed in melanoma cancer cells. Such genes are referred to as tumor suppressor genes, and when they are missing or non-functional, the cell is more likely to become cancerous. There are a number of reasons why a tumor suppressor gene may not be expressed and contribute to cancer, including: (1) genetic alterations that delete the tumor suppressor gene from the genome; (2) significant mutations in the coding region of the gene that prevent production of a normal protein; and (3) alterations or mutations of the promoter/enhancer of the tumor suppressor gene that prevent gene expression.

Dr A is fortunate that the functional loss of tumor suppressor genes can also be studied in transgenic mouse models. In order to study the role of a suspected tumor suppressor gene in melanoma development, she can design and create mice in which the tumor suppressor gene is completely deleted and not expressed in any cells of the 'knockout' transgenic mouse (Table 3.8; Fig. 3.11)[18,19]. After these knockout mice are developed, demonstrating that gene expression is lost and assessing tumor development will be similar to the analysis described above for transgenic mice.

Technology now exists to selectively knock out or delete a gene (e.g. a tumor suppressor gene) in a specific cell type or tissue (such as melanocytes), rather than deleting the gene from all cells in the mouse (Fig. 3.12). Furthermore, this technology will also allow Dr A to delete the gene from a specific tissue at any point in time during development. One advantage of this selective approach, compared to gene deletion in all mouse cells, is that it may more faithfully mimic how gene deletion occurs in a specific tissue of a patient and contributes to tumors in those tissues. Another advantage is that gene deletion in all mouse cells may prevent normal mouse development, and selective gene deletion after development is complete will avoid this problem. Finally, selective gene deletion limited to specific target tissues provides a less complicated and cleaner animal model with fewer secondary effects resulting from gene deletion in tissues not being targeted.

Gene Therapy for Cancer

The *in vivo* transgenic mouse models are very important for demonstrating whether a candidate gene or genetic change is responsible for melanoma development. Another important function of melanoma transgenic mouse models is to develop and test novel new therapies

PROTEOMICS WITH MASS SPECTROMETRY
PURPOSE
• The proteome of a cell represents all the cellular proteins that are being expressed under a particular set of conditions. High-throughput analysis that allows investigators to rapidly and quantitatively assess the complex mixtures of proteins present in a cell at a given point in time is under development
REQUIREMENTS
• A mixture of cellular proteins, or peptides derived from these proteins, is purified from a defined population of cells. The protein mixture may represent total cellular proteins or a subcellular fraction of proteins, depending on the isolation procedure
UNDERLYING CONCEPTS
• Mass spectrometry is able to measure very precisely the size or mass of proteins, peptides, or peptide fragments by giving these peptides a positive charge (ionization) and then measuring the time required for the positively charged peptide ions to move through a tube to a detector (time-of-flight) (Fig. 3.9) • The mass of the peptide ion precisely correlates to the time-of-flight, with smaller peptides moving faster (shorter time-of-flight) than larger peptide ions (longer time-of-flight)
OUTLINE OF METHOD (FIG. 3.9)
• The first step is to reduce the complexity of the mixture of cellular proteins or peptides to be analyzed, prior to mass spectrometry analysis. The two main methods to separate proteins/peptides from each other are two-dimensional gel electrophoresis and/or liquid chromatography columns • In two-dimensional gel electrophoresis, proteins are first separated (first dimension) by isoelectric focusing in a gel containing a pH gradient. The pH gradient (acidic to basic) influences the overall charge on the protein, and in isoelectric focusing, proteins migrate through the different pH levels until they reach their isoelectric point (no charge), at which point the electrical current no longer induces their migration • Following first-dimensional separation by isoelectric focusing, these proteins are then further separated by size through a second polyacrylamide gel (second dimension), with smaller proteins moving through the gel faster than the larger ones • After the second-dimension separation, each unique protein will be present in a distinct "spot" on the gel. This protein spot can be physically cut out of the gel and analyzed by mass spectrometry • Liquid chromatography can be also used to separate proteins (or peptides derived from the proteins) as they flow through columns that contain different types of resins. These resins differentially bind the cellular proteins/peptides based on their ionic strength (ion exchange columns) or their relative hydrophobicity (reverse phase columns) • After the protein mixture is bound to the liquid chromatography columns, the proteins/peptides can be eluted from the column into different fractions or aliquots and then analyzed by mass spectrometry. Many high-throughput approaches for protein analysis utilize liquid chromatography • Mass spectrometry analysis is then performed on the separated proteins/peptides by first ionizing them into positively charged ions using lasers or the processes of electrospray ionization and nanospray ionization. Based on the time-of-flight of the charged ion, mass spectrometry can measure, record and print out the mass/charge ratio of every peptide along with signal intensity of that peptide • With the help of powerful computers and bioinformatics software, the peptide mass/charge ratio measurement may allow the identification of the peptide sequence and the protein that contained this peptide (Fig. 3.8) • Mass spectrometry machines are now available (tandem mass spectrometry [MS/MS]) that can "ion trap" a given peptide ion and then sequence the peptide by fragmenting it into its component amino acids. Bioinformatics software can use this sequence information to search protein databases for rapid protein identification
BENEFITS
• Mass spectrometry is extremely sensitive and able to detect very small amounts of proteins/peptides • The field of proteomics promises to provide a tremendous amount of information regarding cell biology and disease
LIMITATIONS/ERRORS
• Better technology to reduce the complexity of protein/peptide mixtures and differentially separate the proteins/peptides in a high-throughput manner is being developed • Although mass spectrometry can measure the mass of proteins/peptides very precisely, it is more difficult to measure the amount of protein/peptide quantitatively, and more robust techniques for quantification by mass spectrometry are being developed
EXPERIMENTAL APPLICATIONS
• Mass spectrometry can be used to determine the complete set of proteins present in a defined population of cells (e.g. melanoma cells) or cells that are being subjected to experimental conditions • Mass spectrometry can differentially compare the proteins in one population of cells (e.g. melanocytes) to those in a distinct group of cells (e.g. melanoma tumor cells) • Because of the sensitivity of mass spectrometry analysis, it holds promise as a sensitive diagnostic tool. For example, mass spectrometry could be used for early detection of small amounts of serum proteins that are characteristic of a particular cancer or systemic disease
MODIFICATIONS/ALTERNATIVES
• Liquid chromatography can be also used to separate proteins (or peptides derived from the proteins) as they flow through columns that contain different types of resins (see Outline of method described above) (Fig. 3.9). Many high-throughput approaches for protein analysis utilize liquid chromatography • Multidimensional protein identification (MudPIT) • Isotope labeling approaches for quantitative mass spectrometry, including isotope-coded affinity tag (ICAT), stable isotope labeling by amino acids in cell culture (SILAC), tandem mass tags (TT), and isobaric tags for relative and absolute quantification (iTRAQ) • Label-free quantitative proteomics, including peak intensity-based comparative liquid chromatography-mass spectrometry (LC-MS) and spectral count-based liquid chromatography-tandem mass spectrometry (LC-MS/MS) • Antibody protein arrays • Reverse-capture protein microarrays • Tissue microarrays

Table 3.6 Proteomics with mass spectrometry.

that Dr A may someday use in clinical trials against melanoma. Gene therapy is one important therapeutic approach that holds future promise as a treatment for cancers such as melanoma. In gene therapy, a gene or genes are introduced into the cells of a target tissue in order to achieve a therapeutic effect. Gene therapy may be used to treat cancer even if the genetic basis or cause of the cancer has not been established.

Two different types of transgenic animal models were described above. In the first, melanoma resulted when an oncogene or tumor-causing gene (mutated) was overexpressed in melanocytes of mice. To treat these tumors with gene therapy, gene(s) that would counteract or oppose the effects of the tumor-causing genes, and thereby inhibit or prevent tumor growth, would be introduced into the melanoma cells[20–25]. For example, tumor suppressor genes (discussed earlier) could

TRANSGENIC MICE
PURPOSE
• Transgenic mouse models allow investigators to study the effects of a transgene (the gene of interest) on a cellular, tissue and whole animal level. The transgene can be selectively expressed in a particular cell type or tissue by using a promoter/enhancer regulatory region that is specific for that cell type
REQUIREMENTS
• A transgene or gene of interest, whose biologic function is to be characterized (e.g. *toomuchsun*) in an animal model • A regulatory region (promoter/enhancer) that will selectively express the transgene in a specific tissue (e.g. melanocytes) • The facilities and technologies to create transgenic mice
UNDERLYING CONCEPTS
• After injection of a transgene into a fertilized mouse egg or single-cell embryo, the transgene randomly integrates into the genome, usually at a single site (Fig. 3.10). As the embryo undergoes many cell divisions and develops into a mouse, the integrated transgene will be present in every cell type, tissue and organ in the mouse. Transgene expression only occurs in cells and tissues where the promoter/enhancer regulatory region is active. Any phenotypes that develop in mice expressing the transgene in the desired tissue can help us understand the biologic effects of the transgene
OUTLINE OF METHOD (FIG. 3.10)
• A transgene construct, defined as the transgene and a regulatory region (promoter/enhancer), is prepared for injection • The transgene is microinjected into fertilized eggs (single-cell stage) and the transgene integrates into the genome, usually at a single site • These injected eggs are then implanted into a recipient mother, who then gives birth to a heterozygous "founder" mouse that can be either male or female. The founder mouse is referred to as a transgenic mouse because it only contains the transgene on one of the two paired chromosomes (e.g. only one copy of chromosome 7 contains the transgene, whereas the other chromosome 7 does not) • The founder mice are bred with normal non-transgenic mice of the same strain. The progeny mice will be both heterozygous transgenic and non-transgenic, according to Mendelian genetics • In order to derive homozygous transgenic mice that contain the transgene on both of the paired chromosomes (e.g. both copies of chromosome 7 contain the transgene), two heterozygous transgenic mice are mated. Homozygous transgenic mice will have a double dose of the transgene, which may lead to different phenotypes and biologic effects from those present in the heterozygous transgenic mice
BENEFITS
• Transgenic mouse models can help us understand the *in vivo* biologic effects of an unknown gene when expressed in a specific tissue
LIMITATIONS/ERRORS
• The precise regulation of the level of transgene expression as well as the timing of gene expression during development (turning the transgene on or off during development) have been relatively difficult. Advancements in transgenic design, including inducible promoters, have improved the regulation of transgene expression • When expressed in mouse tissues, a human transgene may have different biologic effects compared to its effects in human tissues • Classic transgenic mice models do not allow investigators to study the biologic effects of gene mutations or deletions that result in loss of gene expression, because the technique of creating transgenic mice does not alter endogenous genes, it only adds a new transgene to each cell
EXPERIMENTAL APPLICATIONS
• Transgenic mouse models of disease can be used to test the effectiveness of new therapeutic agents
MODIFICATIONS/ALTERNATIVES
• More precise control of transgene expression can be achieved with promoters/enhancers that are inducible and can be regulated (i.e. turned off and on at different time points)[16,17] • "Knockout" transgenic mouse models (Table 3.8) allow investigators to understand the biologic effects of gene mutations and deletions that cause a loss of specific proteins

Table 3.7 Transgenic mice.

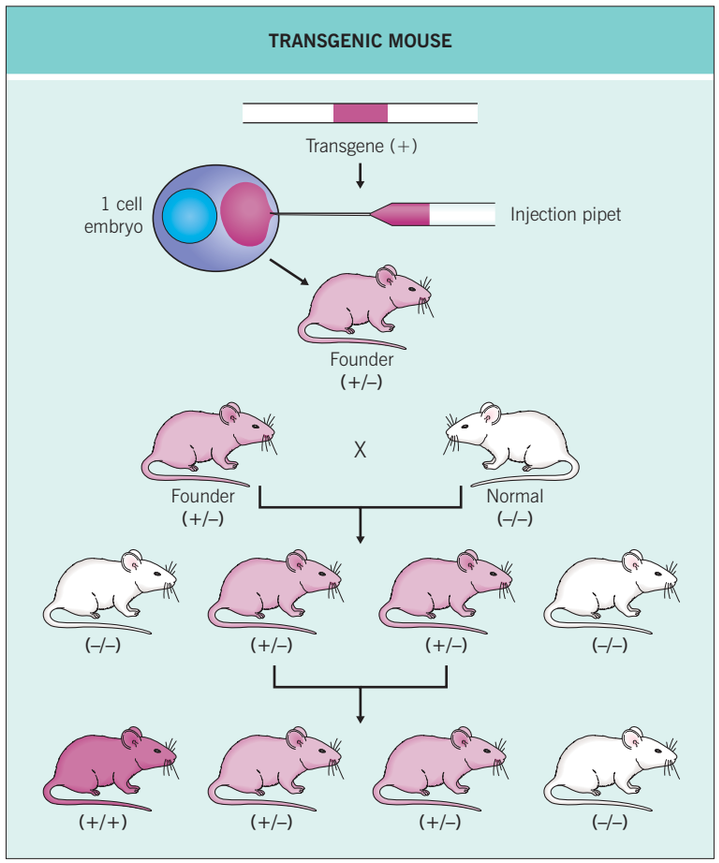

Fig. 3.10 Transgenic mouse. A transgene construct, defined as the transgene and regulatory region (promoter/enhancer), is prepared for injection. The transgene is microinjected into fertilized eggs (single cell stage) and the transgene integrates into the genome, usually at a single site. These injected eggs are then implanted into a recipient mother, who then gives birth to a heterozygous "founder" mouse. The founder mice are bred with normal non-transgenic mice of the same strain, and then two heterozygous transgenic mice are mated.

be introduced into melanomas in order to suppress tumor growth, regardless of which oncogene was stimulating growth. In knockout transgenic mice that develop melanoma, gene therapy could be used to introduce the missing tumor suppressor gene into the melanoma cells. Restoring the deleted tumor suppressor gene should inhibit the proliferation and growth of the melanoma cells.

Another effective type of cancer gene therapy is to introduce gene(s) that are capable of stimulating the immune response against the melanoma cancer cells[26]. Genes encoding cytokines or other immune-modulating proteins would be introduced into the melanoma in order to stimulate an immune response against the tumor cells. The goal here would be to develop a broad systemic immune response against the melanoma cells so that even those not expressing the introduced gene(s) will be targeted and destroyed by the immune system.

Dr A can administer these gene therapies either by introducing the gene directly into the tumor cells or by first putting the gene into a viral vector and injecting the viral vector into the melanoma (Table 3.9; Fig. 3.13). Introducing genes via viral vectors has the advantage of efficiently introducing the desired gene into a high percentage of tumor cells, often in a stable manner[27–29] (Table 3.10). The disadvantage is the additional work of constructing the viral vectors. In contrast, introducing the gene directly without first placing it in a viral vector is simpler and more straightforward. However, the percentage of tumor cells containing and expressing the introduced gene will probably be lower. As noted above, for gene therapy of cancer, it may not be necessary to introduce the gene into every tumor cell in order to elicit an immune response against the tumor cells.

An alternative and perhaps even more promising approach could be, instead of manipulating cancer cells to produce immunostimulatory

KNOCKOUT TRANSGENIC MICE
PURPOSE
• Knockout transgenic mice have both alleles of a normal endogenous gene modified, mutated, or deleted in all cells (whole animal or targeted tissue) so that protein can no longer be produced by that gene. Therefore, knockout transgenic mice allow investigators to understand what happens to a cell or tissue when a particular gene can no longer be expressed
REQUIREMENTS
• Murine embryonic stem cells (ES cells) that are totipotent and capable of forming and reconstituting all tissues and organs of a mouse • A targeting construct defined as a defective gene that can hybridize to the normal endogenous gene in ES cells and modify or delete the targeted gene so that it is no longer able to express a functional protein
UNDERLYING CONCEPTS
• In knockout transgenic mice, all cells (whole animal or targeted tissue) lack the gene that has been "knocked out" and do not express any functional protein from that gene • Technology is available to selectively target and delete an endogenous gene in its normal chromosomal location in ES cells
OUTLINE OF METHOD (FIG. 3.11)
• A targeting vector that contains some sequences of the gene to be targeted is created and introduced into ES cells. This targeting vector is able to selectively hybridize to one of the endogenous alleles of a gene, and through a process known as homologous recombination, the targeting vector modifies or deletes the endogenous gene so that no normal protein is produced. ES cells that contain this defective endogenous gene can be selected for and isolated • The ES cells containing the "knocked out" gene are introduced into early mouse embryos, known as blastocysts, which are then implanted into recipient mothers. The progeny will be chimeric mice; all tissues and organs, including testes and ovaries, will contain a mixture of normal cells and cells that lack the "knockout" gene allele • The chimeric mice are next mated to normal mice. Depending on the degree of chimerism, a certain percentage of the offspring will be heterozygous, containing one normal allele and one allele that has been modified or deleted (knocked out). As described for the mating procedure in transgenic mice (see Table 3.7), the genotypes of all progeny will follow the rules of Mendelian genetics • To obtain completely "knocked out" mice, two heterozygous mice are mated. Approximately 25% of the offspring will lack a normal endogenous gene in every cell and tissue
BENEFITS
• This approach yields mice that completely lack the gene product in all cells of the whole animal or targeted tissues
LIMITATIONS/ERRORS
• Investigators have to ascertain that no normal gene product is being produced. It is possible that the homologous recombination process used to knock out a gene may result in a gene that encodes a mutant protein that still has biologic effects. This would make it difficult to understand the biologic effects of the gene
EXPERIMENTAL APPLICATIONS
• Unlike regular transgenic mice, knockout transgenic mice allow investigators to study the biologic effects of losing gene expression. This is particularly useful in the study of genes that may normally suppress cancer development (tumor suppressors); the tumor suppressor gene can be knocked out in all mouse cells *in vivo*, and the mechanisms of cancer development in different tissues can be studied
MODIFICATIONS/ALTERNATIVES
• In order to more accurately mimic *in vivo* situations, the gene of interest can be selectively deleted in only one organ or tissue (e.g. melanocytes). These *conditional* knockout mice allow investigators to study the effects of gene loss in a particular tissue without the complications of losing gene expression in all the other tissues (Fig. 3.12) • A similar technology is also available to delete a gene of interest at a particular time during development. Initially, the endogenous gene will be expressed normally in the knockout mice and then deleted at a later time, either during intrauterine development or after birth. This is advantageous if investigators want to study the effects of a gene that, if knocked out, would prevent embryo development

Table 3.8 Knockout transgenic mice.

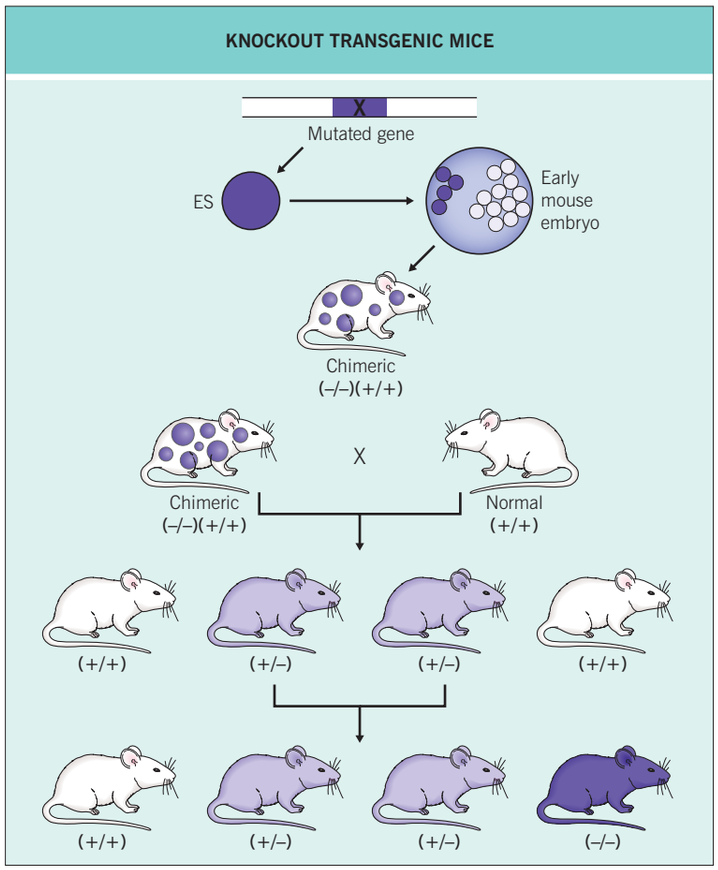

Fig. 3.11 Knockout transgenic mice. A targeting vector that contains some sequences of the gene to be targeted is created and introduced into cells. This targeting vector is able to hybridize selectively to one of the endogenous alleles of a gene, and modifies or deletes the endogenous gene so that no normal protein is produced. The embryonic stem (ES) cells containing the "knocked out" gene are introduced into early mouse embryos, which are then implanted into recipient mothers. The progeny will be chimeric mice. These chimeric mice are then mated to normal mice. To obtain completely knocked out mice, two heterozygous mice are mated.

molecules, to express tumor-associated antigens in dendritic cells for effective presentation to T cells. The feasibility of such a procedure has been demonstrated in several murine cancer models. When injected into the skin, plasmid DNA encoding a tumor-associated antigen finds its way to, among others, cutaneous dendritic cells (Langerhans cells, dermal dendritic cells), where it becomes expressed. This event also results in the activation and maturation of dendritic cells (probably because of the presence of immunostimulatory CpG sequences in plasmid DNA), allowing them to leave the skin and to migrate via the afferent lymphatics to the draining lymphoid tissue, where they induce protective anticancer immune responses.

At this point, Dr A is ready to perform gene therapy clinical trials on patients with melanoma. She has taken melanoma specimens from patients, identified several genes in melanomas that are overexpressed (oncogenes), underexpressed (tumor suppressor genes) or mutated, utilized transgenic animal models to confirm that these genes play a causative role in melanoma development, and developed a gene therapy that is effective in treating melanoma in these animal models.

Gene Therapy that Targets Keratinocyte Stem Cells

Alternatively, instead of using skin gene therapy to treat melanoma, Dr A may want to use skin gene therapy to treat a genetic skin disease by expressing a gene in keratinocytes to correct the keratinocyte genetic

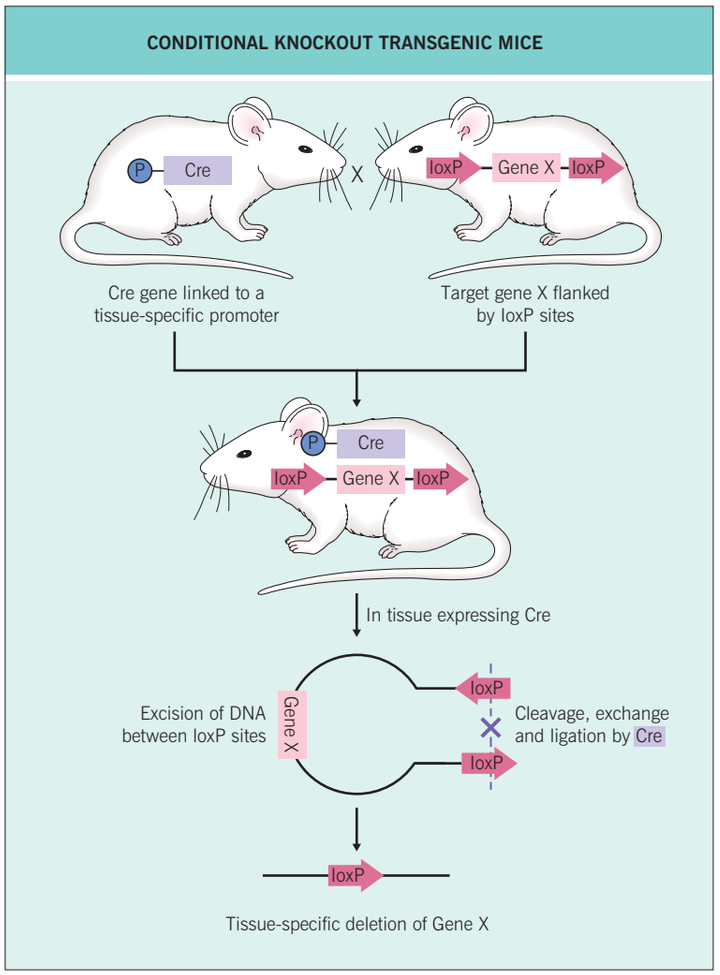

Fig. 3.12 Conditional knockout transgenic mice. In the conditional knockout model using the Cre-lox system, a target gene can be selectively deleted in a particular organ or tissue. Cre is a site-specific DNA recombinase that catalyzes recombination between two loxP sites, resulting in cleavage, exchange and ligation; this leads to excision (and subsequent degradation) of the DNA between the loxP sites. A transgenic mouse with the Cre gene linked to a tissue-specific promoter is mated to a transgenic mouse with two loxP sites flanking the target gene. Progeny inherit both of these constructs, and the target gene is knocked out only in cells that activate the tissue-specific promoter. By adding a ligand-binding domain to the Cre recombinase, such as one that binds tamoxifen, investigators can achieve temporal control of Cre expression in these cells. The target gene can be temporally deleted, inverted or translocated, depending on the orientation of the loxP sites.

SKIN GENE THERAPY
PURPOSE
• In skin gene therapy, genes are introduced and expressed in the skin for therapeutic purposes. Diseases that could be treated by this approach include both skin diseases and systemic diseases where skin is used as a vehicle for the systemic delivery of a needed factor or substance
REQUIREMENTS
• A gene that is able to achieve the desired therapeutic effect when expressed in keratinocytes or other skin cells such as fibroblasts and melanocytes • A delivery vector that can efficiently introduce the desired gene into cells. Both viral vectors and non-viral vectors can be used to deliver a desired gene to a target cell type. With viral vectors, the desired gene is incorporated into the genetic material of a modified virus that is able to efficiently infect target cells but is no longer able to cause disease and spread to other cells (Table 3.10)
UNDERLYING CONCEPTS
• Skin gene therapy is a promising field that has the potential to provide new treatments for both skin and systemic diseases • There are two general approaches for introducing genes into the skin: a direct *in vivo* approach (Fig. 3.13) and an *ex vivo* approach (Fig. 3.14), as described below • The viral vectors that have most often been used to deliver genes to skin cells are retroviral vectors and adenoviral vectors (Table 3.10). Adeno-associated viral vectors and lentiviral vectors (which are related to retroviral vectors and are derived from HIV) have also been described in association with skin gene therapy • Many issues need to be considered when choosing a vector and determining the best approach to deliver the desired gene to the skin. These include: (1) how many cells (what percentage) need to contain the gene in order to have a therapeutic effect; (2) how long the gene needs to be expressed in order to be therapeutic. In some situations, short-term or transient expression is sufficient; in other cases, long-term expression is preferable
OUTLINE OF METHOD (FIGS 3.13 & 3.14)
• In the direct *in vivo* approach, the desired gene is introduced directly into the skin as shown, either directly injected intradermally (Fig. 3.13A) or biolistically discharged into the epidermis and dermis (Fig. 3.13B). Both approaches can be made even more efficient when the skin is concomitantly exposed to an electrical charge in a process known as electroporation. Both viral vectors and non-viral vectors can be delivered to the skin using these *in vivo* approaches • In the *ex vivo* approach, keratinocytes are removed from the donor and, during *ex vivo* culture, the desired gene is efficiently introduced, usually with viral vectors (Fig. 3.14). Skin equivalents or raft cultures containing these genetically modified keratinocytes (along with a dermal portion containing fibroblasts) are constructed and then grafted back onto the donor in the correct anatomic location • The principal advantage of the *in vivo* approaches is their simple straightforward nature. A disadvantage is that expression is usually transient and not long-term because selective targeting of keratinocyte stem cells is usually not feasible with *in vivo* approaches. Another disadvantage is that the percentage of cells containing the desired transgene may be lower than desired • In contrast, the *ex vivo* approaches (Fig. 3.14) are superior at achieving long-term expression of a desired gene in a high percentage of skin cells. During the *ex vivo* culture period, the desired gene could be targeted to keratinocyte stem cells • The disadvantage of the *ex vivo* approach is that it is much more complicated and technically demanding than the *in vivo* approaches

Table 3.9 Skin gene therapy.

Continued

SKIN GENE THERAPY
BENEFITS
• Genes are the therapeutic agent in this approach to treatment of cutaneous and systemic disease. As our understanding of the molecular basis of disease increases, genetic therapies will become more important • The effectiveness of skin gene therapy can be assessed in animal models
LIMITATIONS/ERRORS
• Successful skin gene therapy with long-term expression of a desired gene in a high percentage of cells has been difficult to achieve in animal models • Skin gene therapy for recessive genetic skin diseases is problematic because of the development of an unwanted immune response against the normal protein • Risk of oncogenesis, especially with retroviral vectors
EXPERIMENTAL APPLICATIONS
• Treatment of genetic skin diseases • Treatment of non-genetic skin diseases if a sufficient understanding of the molecular basis of the disease exists • Systemic delivery of cytokines, hormones and growth factors • Genetic immunization • Suicide gene therapy
MODIFICATIONS/ALTERNATIVES
• Use of short (small) interfering RNA (siRNA) that specifically targets and silences expression of dominant negative mutant genes • Protein replacement therapies • Cellular therapies (see Fig. 2.6)

Table 3.9 Skin gene therapy (cont'd).

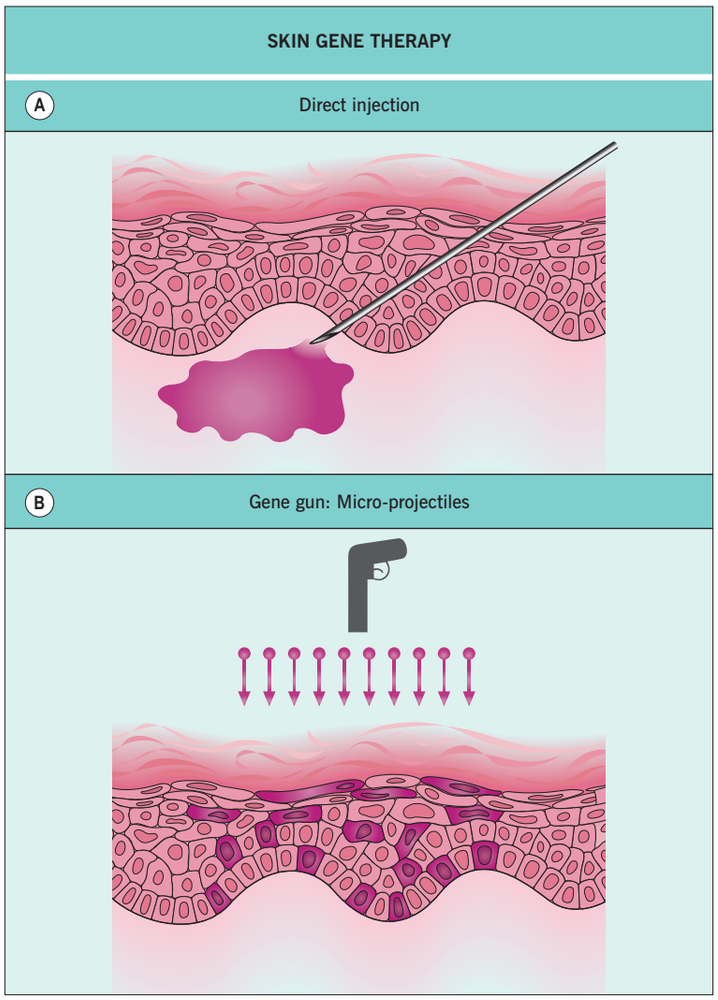

Fig. 3.13 Skin gene therapy. In the direct *in vivo* approach, the desired gene is introduced directly into the skin as shown, either directly injected intradermally (**A**) or biolistically discharged into the epidermis and dermis (**B**). Both viral and non-viral vectors can be delivered to the skin using these *in vivo* approaches

VIRAL VECTORS FOR SKIN GENE THERAPY			
	Retrovirus	**Adenovirus**	**Adeno-associated virus**
Duration of expression	Long term (integration)	Transient (no integration)	Long term possible (some integration)
Efficient gene	Replicating cells only	Replicating and non-replicating cells	Replicating and non-replicating cells
Gene cargo capacity	8–9 kb	>8–9 kb	Around 4.5 kb
Antigenicity	+ (re-administration possible)	++++	+ (not associated with human pathology)

Table 3.10 Viral vectors for skin gene therapy.

defect, or to treat a systemic disease by introducing a gene into keratinocytes and having its gene product secreted into the bloodstream for systemic effect. For these applications of skin gene therapy, Dr A will want to express the gene in the skin for a long period of time. Because skin is a renewable tissue, Dr A may need to insert the gene into keratinocyte stem cells in order to achieve long-term expression in the skin, using an *ex vivo* approach to deliver the gene (Fig. 3.14) (see Ch. 2). Keratinocyte stem cells are located in the hair follicle and scattered along the basal layer of the skin. In the hair follicle, stem cells are highly concentrated in the bulge area where the arrector pili muscle attaches (see Ch. 2). These keratinocyte stem cells are believed to divide very slowly and represent approximately 1–3% of all keratinocytes.

Molecular Therapy that Targets RNA

Another therapeutic approach is to target specific mRNAs for degradation, using short interfering RNA (siRNA) (Fig. 3.15). Double-stranded RNAs, 21–23 nucleotides in length, are designed complementary to the mRNA of interest. These are delivered to the cell, where they mediate sequence-specific mRNA degradation using an endogenous complex of proteins called the RNA-induced silencing complex (RISC).

Ribozymes also target specific sequences based on short complementary oligonucleotides, but the catalyst for target degradation is provided by the RNA enzyme without the need for protein cofactors. These approaches, and variations thereof, have been useful experimentally, but their therapeutic use has thus far been limited by difficulties with stability, efficient delivery to cells, and minimization of unwanted effects[30].

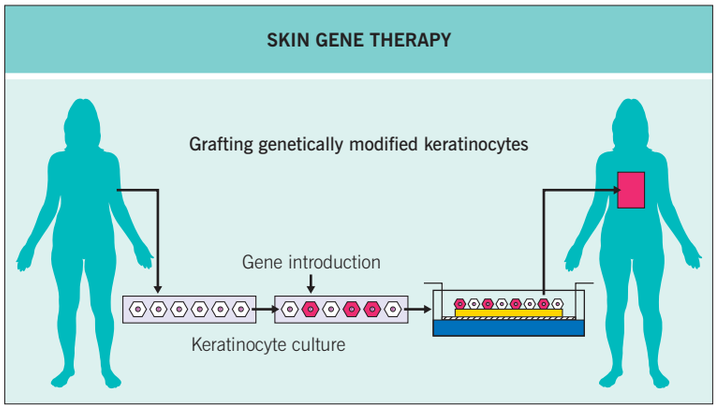

Fig. 3.14 Skin gene therapy. In the *ex vivo* approach, keratinocytes are removed from the donor and, during *ex vivo* culture, the desired gene is efficiently introduced, usually with viral vectors. Skin equivalents or raft cultures containing these genetically modified keratinocytes (along with a dermal portion containing fibroblasts) are constructed and then grafted back onto the donor.

CONCLUSIONS

In this chapter, we have presented a variety of techniques used in dermatology research and clinical practice. Some of these are new, whereas others are long established and still widely used. New technologies continue to appear and change the way research is done. These technologic advances allow experiments to be done faster and with less and less starting material. They allow the measurement of thousands of different genes or proteins in single experiments. They also automate experiments that used to require time-consuming step-by-step human involvement. To handle all the information currently produced by biologic research, advances in computers and bioinformatics are progressing along with the technologic advances. The outcome is that the pace of scientific inquiry proceeds at an increasing rate.

Advances in our scientific understanding translate into new developments in disease diagnosis and management. For dermatology, this provides hope that diseases can be diagnosed more rapidly and more reliably, and that individualized prognostic information can be provided. Therapies have been and will continue to be developed that specifically target the genetic abnormality causing the disease. In the future, therapies may be tailored to the individual, taking into consideration the genetic make-up of the individual and his or her disease process. These future possibilities are exciting.

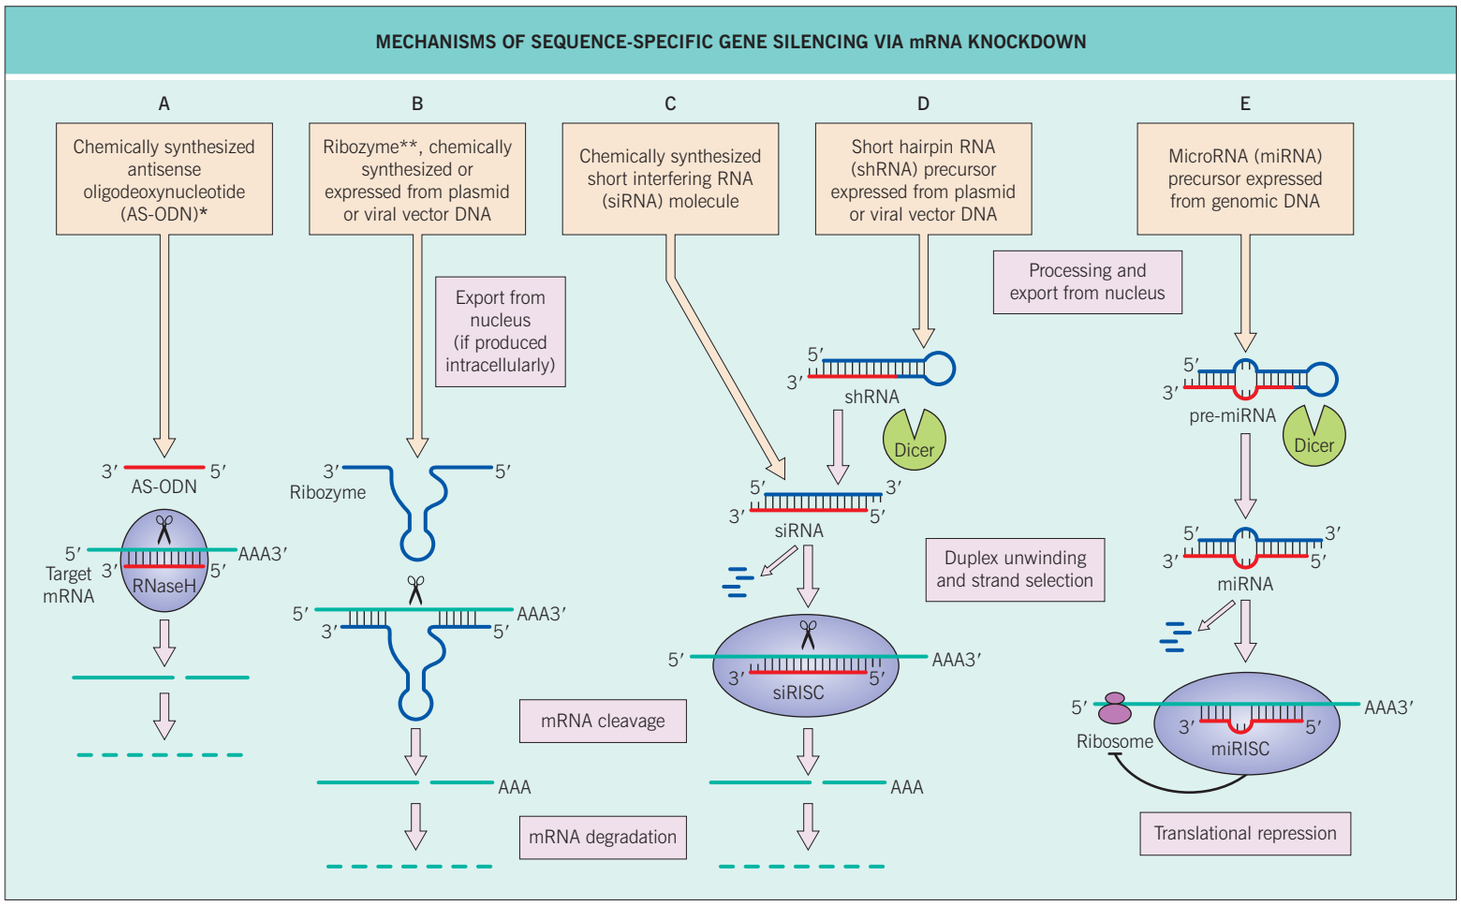

Fig. 3.15 Mechanisms of sequence-specific gene silencing via mRNA knockdown. A Antisense oligodeoxynucleotide (AS-ODN) hybridizes to target mRNA, which is subsequently cleaved by the intracellular enzyme RNase H and degraded. Some chemically modified antisense molecules prevent mRNA splicing or inhibit translation via steric hindrance. **B** Ribozymes have intrinsic catalytic activity and cleave target mRNA directly. **C** Short (small) interfering RNA (siRNA) is unwound and the "guide" antisense strand incorporated into a RNA-induced silencing complex (RISC) that degrades a specific target mRNA sequence. Processing of short hairpin RNA (shRNA; **D**) and pre-microRNA (miRNA; **E**) by the Dicer enzyme can generate siRNA and miRNA, respectively. **E** Endogenously produced miRNA regulates up to a third of human genes and tends to have less complementarity with target mRNA; it recruits RISC proteins and typically inhibits mRNA translation (rather than decreasing mRNA levels). *May also be composed of DNA and/or nucleic acid analogues. **Translocated from the nucleus via exportin-5.

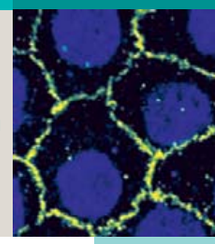
4 Immunology

Thomas Schwarz



Key features

- The major purpose of the immune system is protection against harmful organisms, which is achieved by a rapid "primitive" reaction, called the innate immune response, and a more highly developed specific reaction, called the adaptive immune response
- The characteristics of an adaptive immune response are specificity and the accumulation of memory, thus enabling improvement with each successive encounter with a particular antigen
- The key event in an adaptive immune response is antigen presentation, yielding either a cell-mediated or a humoral response. The cellular response involves primarily T cells, whereas the humoral response involves B cells that ultimately mature into antibody-secreting plasma cells
- Immune responses are not always protective and can even be pathogenic if the response induces severe tissue destruction or is directed against an autoantigen
- As a barrier organ to the outside environment, the skin is endowed with the capacity and the necessary cellular components to mount an immune response

INTRODUCTION

The skin is in a sense a defense organ, since it represents a major barrier against the outside environment. As such, it is constantly confronted with microbial, chemical and physical insults. Within the past three decades, there has been a greater appreciation for the fact that the skin not only functions as a mechanical barrier to the outside world, but also uses the immune system for protection. Accordingly, the skin is endowed with the capacity to generate an immune response, which gave rise to the term "skin-associated lymphoid tissues" (SALT)[1].

The classical immune response, also referred to as the adaptive immune response, is characterized by specificity that is due to immunologic memory (specific immunity)[2]. Innate immunity is a more primitive defense system that acts in a rapid but less specific manner. Both types of responses can be generated in the skin. Adaptive immune responses in the skin, however, are not always protective but can also be harmful in nature, e.g. allergic or autoimmune reactions. Numerous skin diseases are caused by T lymphocytes and are therefore immunologically mediated. Consequently, many dermatoses respond favorably to immunosuppressive therapy administered either systemically or topically.

INNATE IMMUNE RESPONSE

Innate immune responses are characterized by a lack of immunologic memory. These immune reactions are less complicated than adaptive responses and developed earlier in evolution[3]. Nevertheless, failures in these "primitive" immune responses may be associated with severe, even fatal, health problems. Essential components of the innate response are neutrophils, eosinophils, natural killer cells, mast cells, cytokines, complement and antimicrobial peptides. The innate response is more rapid and less controlled than the adaptive immune response.

Complement

The complement system plays an important role in innate immunity. It consists of at least 20 serum glycoproteins that are activated by an enzymatic amplifying cascade (see Ch. 60)[4]. Three pathways can trigger this cascade. The classical pathway is stimulated by antigen–antibody complexes, the alternative pathway by polysaccharides derived from microbial cell walls, and the more recently identified lectin pathway by the interaction of microbial carbohydrates with mannose-binding proteins. All three pathways lead to activation of the central C3 component and, finally, the generation of a number of immunologically active substances. For example, C3b, the cleavage product of C3, binds to the surface of microbes. Since phagocytic cells express receptors for C3b, phagocytosis of the microorganisms is enhanced. In addition, complement components bind to antigen–antibody immune complexes, which helps complement receptor-bearing antigen-presenting cells to target these immune complexes.

C5a is a powerful attractant for neutrophils. C3a, C4a and C5a, also called anaphylatoxins, induce the release of inflammatory mediators from mast cells. This increases vascular permeability, thereby enabling proteins (e.g. antibodies) to enter the tissue. Assembly of the complement components C5b, C6, C7, C8 and C9 forms the membrane-attack complex (MAC), which generates pores in cell membranes, causing death by osmotic lysis. Human cells are much less susceptible to killing by complement than are microbes, since human cells express the complement receptor type 1 (CR1, CD35), decay-accelerating factor (DAF, CD55) and membrane cofactor protein (MCP, CD46), which inhibit C3 convertase and thereby block progression of the complement cascade. CD59 is a protein that binds to C8 and inhibits insertion of C9 into the cell membrane.

Toll-Like Receptors

Innate immunity serves to recognize invading microorganisms and then induce a host defense response. Several families of pattern recognition receptors (PRRs) mediate responses to pathogen-associated molecular patterns (PAMPs) that are conserved among microorganisms. Toll-like receptors (TLRs; the mammalian homologues of the Toll receptors identified in *Drosophila*) are one such family of PRRs. Ten TLRs have been identified to date[5] (Fig. 4.1), with the following specificities: TLR2 (in association with either TLR1 or TLR6), recognition of lipoproteins and peptidoglycans; TLR4, lipopolysaccharide; TLR5, flagellin (a component of bacterial flagella); and TLR9, bacterial CpG DNA sequences. TLRs may also be involved in the recognition of viral components.

The signaling pathway of TLRs is highly homologous to that of the receptor for interleukin-1 (IL-1). Upon interaction with myeloid differentiation factor 88 (MyD88), IL-1 receptor-associated kinase (IRAK) is recruited, ultimately leading to activation of the transcription factor NF-κB (see Fig. 4.1). Activation of TLRs can also result in the release of interferons (IFNs) via activation of interferon regulatory factor 3 (IRF-3).

Dendritic cells express several types of TLRs. Upon activation of these receptors by microbial components, the dendritic cells mature and migrate to the lymph nodes, where they present pathogen-derived antigens to naive T cells and induce an adaptive immune response. TLRs thereby bridge the gap between the innate and adaptive immune systems[6]. These two systems constantly interact in the skin, and the innate immune system represents a potential target for modulating adaptive immune responses[7]. Cutaneous dendritic cells that are stimulated by the innate immune system not only instruct T cells to respond but also tell them how and where. Different PAMPs and danger signals polarize dendritic cells, giving them the ability to produce certain cytokines and to induce T cells to differentiate into particular subtypes. Many of these danger signals are provided by keratinocytes, which also express PRRs. In addition, TLRs expressed in the skin direct control of pathogens by the epithelium.

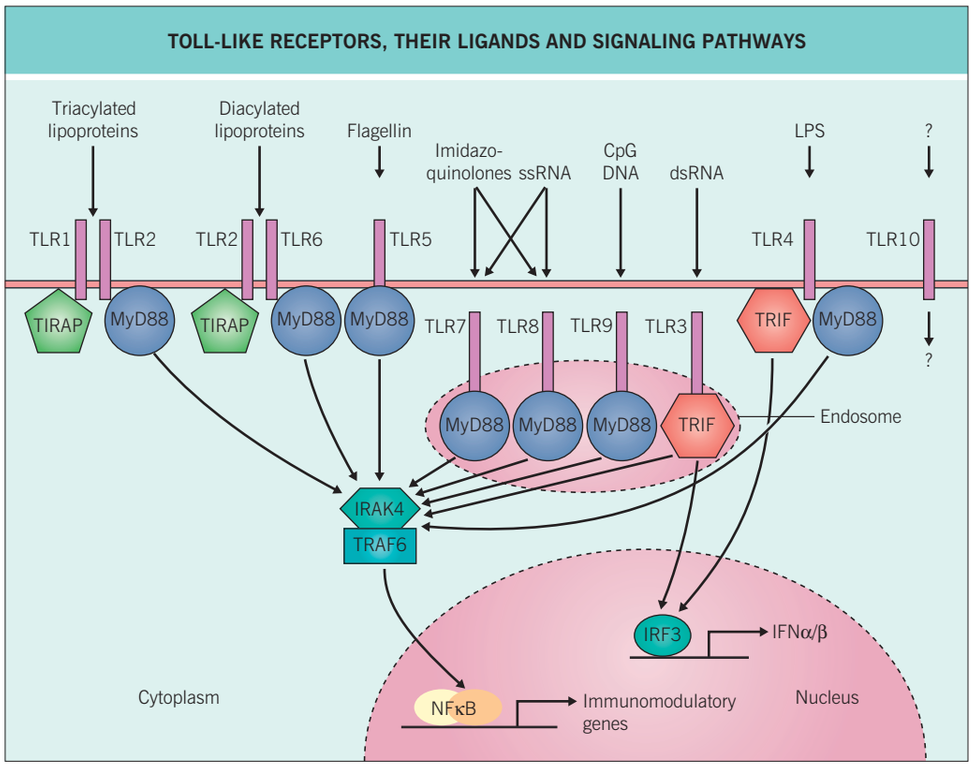


Fig. 4.1 Toll-like receptors, their ligands and signaling pathways. Toll-like receptors (TLRs) recognize pathogen-associated molecular patterns and/or synthetic compounds in a specific fashion. A TLR2/TLR1 dimer recognizes triacylated lipoproteins, and a TLR2/TRL6 dimer interacts with diacylated lipoproteins. TLR5 recognizes flagellin and TLR4 recognizes lipopolysaccharide (LPS). These TLRs are located on the cell membrane and are internalized upon ligand interaction. TLR3, TLR7, TLR8 and TLR9 are located on intracellular membranes of endosomes and lysosomes. TLR3 recognizes viral double-stranded RNA (dsRNA); TLR7 and TLR8 viral single-stranded RNA (ssRNA); and TLR9 bacterial and viral hypomethylated DNA (CpG motifs). TLR7 and TLR8 also bind to synthetic compounds (imidazoquinolones). All TLRs except TLR3 utilize myeloid differentiation factor 88 (MyD88) for signaling, while TLR2 and TLR4 also require Toll-interleukin-1 receptor domain-containing adaptor protein (TIRAP). MyD88 signaling via IL-1 receptor-associated kinase-4 (IRAK-4) and tumor necrosis factor receptor-activated factor-6 (TRAF-6) mostly results in activation of nuclear factor κB (NF-κB), ultimately inducing transcription of genes encoding immunomodulatory and proinflammatory molecules. TLR3 and TLR4 signal via TIR-domain-containing adapter-inducing interferon-β (TRIF). The TRIF pathway induces the production of interferons (IFNs) via interferon regulatory factor-3 (IRF3). Both the ligand and signaling pathway of TLR10 are still unknown. *Adapted from Miller LS. Toll-like receptors in skin. Adv Dermatol. 2008;24:71–87 and from McInturff JE, et al. The role of toll-like receptors in the pathogenesis and treatment of dermatological disease. J Invest Dermatol. 2005;125:1–8.*

Antimicrobial Peptides

To cope with an environment that is full of microorganisms, plants and invertebrates produce a variety of highly effective antimicrobial proteins. Human epithelia, including the epidermis, secrete such antimicrobial peptides as a mechanism of innate defense. The first antimicrobial peptide to be found in human skin (specifically from psoriatic scales) was human β-defensin-2 (hBD-2)[8]. A number of other antimicrobial peptides have subsequently been isolated (Table 4.1). In addition to antibacterial properties, some of these peptides possess antimycotic and likely antiviral activities. As demonstrated for psoriasin, which prevents *Escherichia coli* infection[9], these peptides may protect the skin from bacterial infections. Expression of antimicrobial peptides can be induced by bacteria, bacterial products or proinflammatory cytokines via TLRs and other mechanisms. Enhanced and decreased production of these peptides in psoriasis and atopic dermatitis, respectively, may explain why superinfections are so rare in the former disease and common in the latter[8,10]. However, others have found enhanced expression of antimicrobial peptides in atopic skin, which may reflect disruption of the epidermal barrier[11]. Ultraviolet (UV) B radiation has been shown to induce expression of antimicrobial peptides, potentially explaining the lack of UVB-related bacterial infections despite its immunosuppressive effects (see Ch. 86)[12].

Beta-defensins can also attract immature dendritic cells and memory T cells via the chemokine receptor (CCR)-6, illustrating another link between innate epithelial defense and adaptive immunity[13]. The antimicrobial peptide LL-37 (also known as cathelicidin antimicrobial peptide [CAMP]) mediates dendritic cell activation in psoriasis by binding self-DNA and forming structures that stimulate TLR9 and thereby induce IFN production[14].

Cytokines

Cytokines are a large, heterogeneous family of low-molecular-weight messenger substances that play a crucial role in intercellular communication. Cytokines can be secreted by almost any cell type, and they may act in an autocrine, paracrine or endocrine manner. Cytokines exert their biologic activities by binding to specific cell surface receptors[15]. Although the vast majority of cytokines occur in a soluble form, some can be membrane-bound, making the differentiation between cytokine and receptor difficult. Cytokines influence the proliferation, differentiation and activation of cells. Each cytokine exhibits multiple activities, a fact that complicates strict categorization.

Cytokines that are produced by leukocytes and exert effects preferentially on other white blood cells are called interleukins (IL). Colony-stimulating factors (CSFs) are mediators that induce differentiation and proliferation of hematopoietic progenitor cells, while IFNs interfere with viral replication. Cytokines that have chemoattractant activity are termed chemokines, and they play a crucial role in leukocyte migration. The main subgroups of chemokines are differentiated according to the position of two cysteine (C) residues compared with the other amino acid residues (X), CXC (α-chemokines) and CC (β-chemokines)[16]. Chemokines that recruit leukocytes are termed inflammatory chemokines, whereas those that regulate trafficking within lymphoid tissues are called lymphoid chemokines.

Early *innate* immune responses are dominated by cytokines with inflammatory (e.g. IL-1, IL-6, IL-18, tumor necrosis factor-α [TNF-α], inflammatory chemokines) and antiviral (e.g. IFN-α, IFN-β) capacities. Induction of *adaptive* immune responses is critically dependent on cytokines with immunomodulatory capacities (e.g. IL-2, IL-4, IL-12, IL-13, IL-17, IL-22, IL-23, IFN-γ). However, since most of these mediators exhibit multiple and sometimes overlapping activities, a strict separation into inflammatory and immunomodulatory cytokines is not possible. Due to structural similarities, some cytokines are grouped into families, e.g. the IL-6 family (IL-6, IL-11, oncostatin M, leukemia inhibitory factor [LIF]), the IL-10 family (IL-10, IL-19, IL-20, IL-22, IL-24, IL-26) and the IL-12 family (IL-12, IL-23, IL-27).

Macrophages and Neutrophils

Macrophages, phagocytic cells derived from blood-borne monocytes, carry receptors for carbohydrates that are usually *not* expressed on vertebrate cells (e.g. mannose). Through this mechanism, macrophages can discriminate between "foreign" and "self" molecules. Furthermore, macrophages possess receptors for antibodies and complement. Hence, microorganisms that are coated with antibodies and/or complement are more readily phagocytosed[17]. After phagocytosis, the microorganisms are exposed to a variety of toxic intracellular molecules, including

superoxide anions, hydroxyl radicals, hypochlorous acid, nitric oxide, lysozyme and antimicrobial cationic proteins. Macrophages can also present processed antigens to T and B cells. However, their T-cell stimulatory capacity is less effective than that of dendritic cells.

Activated macrophages release granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF). These two cytokines induce the division of myeloid precursors in the bone marrow, releasing millions of neutrophils into the circulation. Under normal conditions, neutrophils circulate in the bloodstream, some rolling along the vascular endothelium[18]. To enter the site of an infection, neutrophils utilize a complex process that involves proinflammatory mediators, adhesion molecules, chemoattractants and chemokines (see Ch. 26). The recruited neutrophils phagocytose organisms and kill them within phagolysosomes by using oxygen-dependent and oxygen-independent mechanisms. The former, called the respiratory burst, involves the production of hydrogen peroxide, hydroxyl radicals and singlet oxygen. The oxygen-independent method utilizes highly toxic cationic proteins and enzymes, such as myeloperoxidase and lysozyme. Organisms that are coated with antibodies or complement components bind to Fc and complement receptors, respectively, on neutrophils (as well as macrophages) and are more effectively phagocytosed and killed.

Eosinophils

The major function of eosinophils is most likely to protect the host from infections by parasites, particularly nematodes. Infections with these organisms are associated with the production of antigen-specific IgE antibodies that coat the parasite. Via their low-affinity receptors (FcεRII, CD23), eosinophils bind to IgE antibodies and become activated. In contrast to macrophages and neutrophils, eosinophils are only weakly phagocytic. They harbor large granules that contain major basic protein, eosinophilic cationic protein, eosinophil peroxidase and eosinophil-derived neurotoxin (see Ch. 25). Upon activation, eosinophils release these toxic products, which can kill parasites, together with prostaglandins, leukotrienes and various cytokines[19]. Eosinophils also play an important role in the pathogenesis of allergic reactions.

Basophils and Mast Cells

Basophils (found in the blood) and mast cells (located within tissues) exhibit similar functional and morphologic characteristics[20]. At least two populations of mast cells exist, which can be differentiated by the enzymes they contain and by their tissue location. Mucosal mast cells contain only trypsin, while connective tissue mast cells contain both trypsin and chymotrypsin (see Ch. 118). In contrast to pulmonary, uterine and tonsillar mast cells, cutaneous mast cells express the receptor for C5a (CD88), which implies that triggering of mast cells through the anaphylatoxin C5a results in cutaneous, but not systemic, reactions[21]. Basophils and mast cells express high-affinity receptors for IgE (FcεRI) that avidly bind IgE (see Ch. 18).

When a specific antigen binds to mast cell-bound IgE, the FcεRI becomes activated, which leads to degranulation and release of preformed mediators, including histamine and serotonin. Other mediators such as prostaglandins, leukotrienes (B_4, C_4, D_4 and E_4), and platelet-activating factor are also released, and they enhance vascular permeability, bronchoconstriction and induction of an inflammatory response (see Ch. 18). Hence, basophils and mast cells play an important role in immediate-type allergic reactions such as urticaria and angioedema. There is also increasing evidence that mast cells are involved in contact hypersensitivity reactions.

Natural Killer Cells

The major task of natural killer (NK) cells is to eliminate virally infected or malignant cells[22]. NK cells can recognize their targets in two ways. Since they express Fc receptors that bind IgG (FcγRIII, CD16), NK cells can adhere to and kill target cells that are coated with IgG. This killing process is referred to as *antibody-dependent cellular cytotoxicity* (ADCC), the biological value of which remains unclear.

The second recognition system involves killer-activating and killer-inhibitory receptors. Killer-activating receptors recognize molecules that are expressed by nucleated cells. This provides a signal for the NK cell to kill the target cell by secretion of perforins, which make holes in the cell membrane through which granzymes are injected. Granzymes lyse target cells by activating the apoptotic caspase cascade. In addition, NK cells carry inhibitory receptors (KIR) on their surface

that recognize major histocompatibility complex (MHC) class I self-molecules. KIRs shut off the killer signal and thus prevent autolysis of the host. Tumor cells and viruses often down-regulate MHC class I molecules to escape recognition by cytotoxic T cells. Paradoxically, this mechanism renders "MHC class I-low" cells susceptible to recognition by NK cells and can even result in stimulation of specific cytotoxic T cells by dendritic cells.

ADAPTIVE IMMUNE RESPONSE

The characteristic features of an adaptive immune response are its specificity and enhancement with each successive antigen encounter owing to the accumulation of "memory"[2,23]. A crucial event during the generation of an adaptive immune response is antigen presentation.

Antigen-Presenting Cells

Various cells can present antigens, depending on how and where the antigen first encounters cells of the immune system. Interdigitating dendritic cells (DCs) located in the T-cell areas of the spleen and lymph nodes are the most effective antigen-presenting cells (APCs). Within the epidermis, Langerhans cells (LCs) are key APCs. Therefore, the following section will focus primarily on LCs.

Langerhans cells

In 1868, Paul Langerhans[24] first described Langerhans cells as DCs located within the epidermis[24]. Because of their dendritic shape, Langerhans thought that these cells might be of neural origin. More than 100 years later, it was shown that LCs are derived from bone marrow[25]. However, in the 1990s it was observed that LCs are intimately associated with nerve fibers and that nerves, through the release of neuropeptides such as calcitonin gene-related peptide (CGRP), can modulate LC function[26].

Morphology of Langerhans cells

LCs cannot be identified in routinely fixed and stained histologic sections; their recognition requires electron microscopy or histochemical analysis. Ultrastructurally, LCs have rod-shaped organelles termed Birbeck granules (Fig. 4.2). A Ca^{2+}-dependent lectin with mannose-binding specificity called langerin is associated with and responsible for the formation of Birbeck granules[27]. Birbeck granules are thought to result from the antigen-capture function of langerin, which routes antigen into these organelles and provides access to a non-classical antigen-processing pathway. However, langerin is not completely specific for LCs and can also be expressed by a certain type of dermal DC[28].

Histochemically, human LCs can be visualized by staining for adenosine triphosphatase (ATPase), a membrane-bound, formalin-resistant, sulfhydryl-dependent enzyme. In addition to langerin, antigenic moieties present on human LCs include the panhematopoietic marker CD45, MHC class II antigens (HLA-DR), CD1a, the S100 protein and vimentin. CD1a is a useful marker for LCs, since within the epidermis (normal or inflamed) it is exclusively expressed on LCs, whereas HLA-DR antigens are expressed on keratinocytes in inflamed skin (Table 4.2). Since CD1a does not exist in the murine system, staining for MHC class II antigens is often used for detection of murine LCs in non-perturbed skin[29] (Fig. 4.3). In addition, human LCs express the high-affinity IgE receptor (FcεRI)[30], which was initially thought to be exclusively expressed on mast cells and basophils.

The density of murine LCs is dependent on a variety of factors, including strain, age, sex and anatomic location. LCs are almost absent in the tail region, the pouch and the cornea. In humans, the numbers of LCs are reduced on the palms and soles, genitalia and buccal mucosa. In addition, the density of LCs decreases with age and is reduced in chronically UV-exposed skin[29].

PHENOTYPIC MARKERS OF RESIDENT VERSUS MIGRATING HUMAN LANGERHANS CELLS VERSUS HUMAN LANGERIN⁻ DERMAL DENDRITIC CELLS

	Resident LC	Migrating LC	Langerin⁻ dermal DC

Ontogeny of Langerhans cells

Bone marrow chimera experiments showed that LCs are derived and constantly replenished from the bone marrow[25]. However, according to a recent hypothesis[28], murine LCs are derived from radioresistant hematopoietic precursor cells that reside in the skin during embryonic development (Fig. 4.4). The formation of LCs depends on transforming growth factor-β1 (TGF-β1) and macrophage colony-stimulating factor receptor (M-CSFR) ligands (M-CSF, IL-34), which are provided in an autocrine fashion. LCs that are depleted during the steady state or after minor injuries are repopulated locally, independent of circulating precursor cells. In lethally irradiated mice reconstituted with congenic bone marrow cells, half of the LCs are eliminated in the first week after transplantation, but LCs repopulate locally within 3 weeks. After UVB irradiation, which does not affect the dermis or the hair follicle, LC appear to repopulate from the hair follicle[28].

As noted above, langerin is not an exclusive marker for epidermal LCs but can also be expressed by dermal DCs (see Fig. 4.4)[28]. Langerin$^+$ dermal DCs differentiate from radiosensitive circulating precursor cells independently of TGF-β1 and M-CSFR ligands but dependent on CC-chemokine receptor 2 (CCR2), E-selectin and P-selectin. LCs that emigrate from the epidermis to the lymph nodes in a CCR7-dependent manner can also be detected in the dermis but can be distinguished from langerin$^+$ dermal DCs by the differential expression of CD11b, epithelial-cell adhesion molecule (EpCAM) and CD103 (see Fig. 4.4). Two additional types of APCs can be found in the dermis, langerin$^-$ dermal DCs and dermal macrophages with particular surface marker expression.

In humans, the situation is less clear than in mice, since only studies with tissue explants are available. Subtle differences in the surface marker expression of resident LCs, migrating LCs and langerin$^-$ dermal DCs have been described (see Table 4.2).

Other dendritic cells

Since LCs are confined to the epidermis, other DCs are responsible for antigen presentation in other sites. DCs are defined as professional APCs that display an extraordinary capacity to stimulate naive T cells and initiate a primary immune response[31]. This capacity was initially described for the interdigitating DCs in the spleen. It has become apparent that the DC system is very complex, and many questions still remain unanswered.

This complexity is based on the fact that DCs can arise from several types of progenitor cells, and a variety of functional phenotypes of DCs can also be generated from the same precursor cell[32]. In addition, differences exist between experimental systems used to study human and murine DCs. In the murine system, DCs are primarily obtained from the bone marrow or spleen, while human DCs are almost exclusively generated from peripheral blood. Furthermore, many markers/antibodies exist in the human but not the murine system, and vice versa. Whether each of the different types of DCs has a distinct immune function is still a matter of debate[32].

Concerning DC function, there is evidence in the murine system that spleen-derived CD8α$^+$ DCs induce T helper 1 (Th1) responses, while CD8α$^-$ DCs favor T helper 2 (Th2) responses[33]. In contrast, in the human system, lymphoid/plasmacytoid DCs were found to induce Th2 responses, and myeloid DCs generated Th1 reactions[34]. Consequently, myeloid DCs were referred to as DC1 and lymphoid/plasmacytoid DCs as DC2.

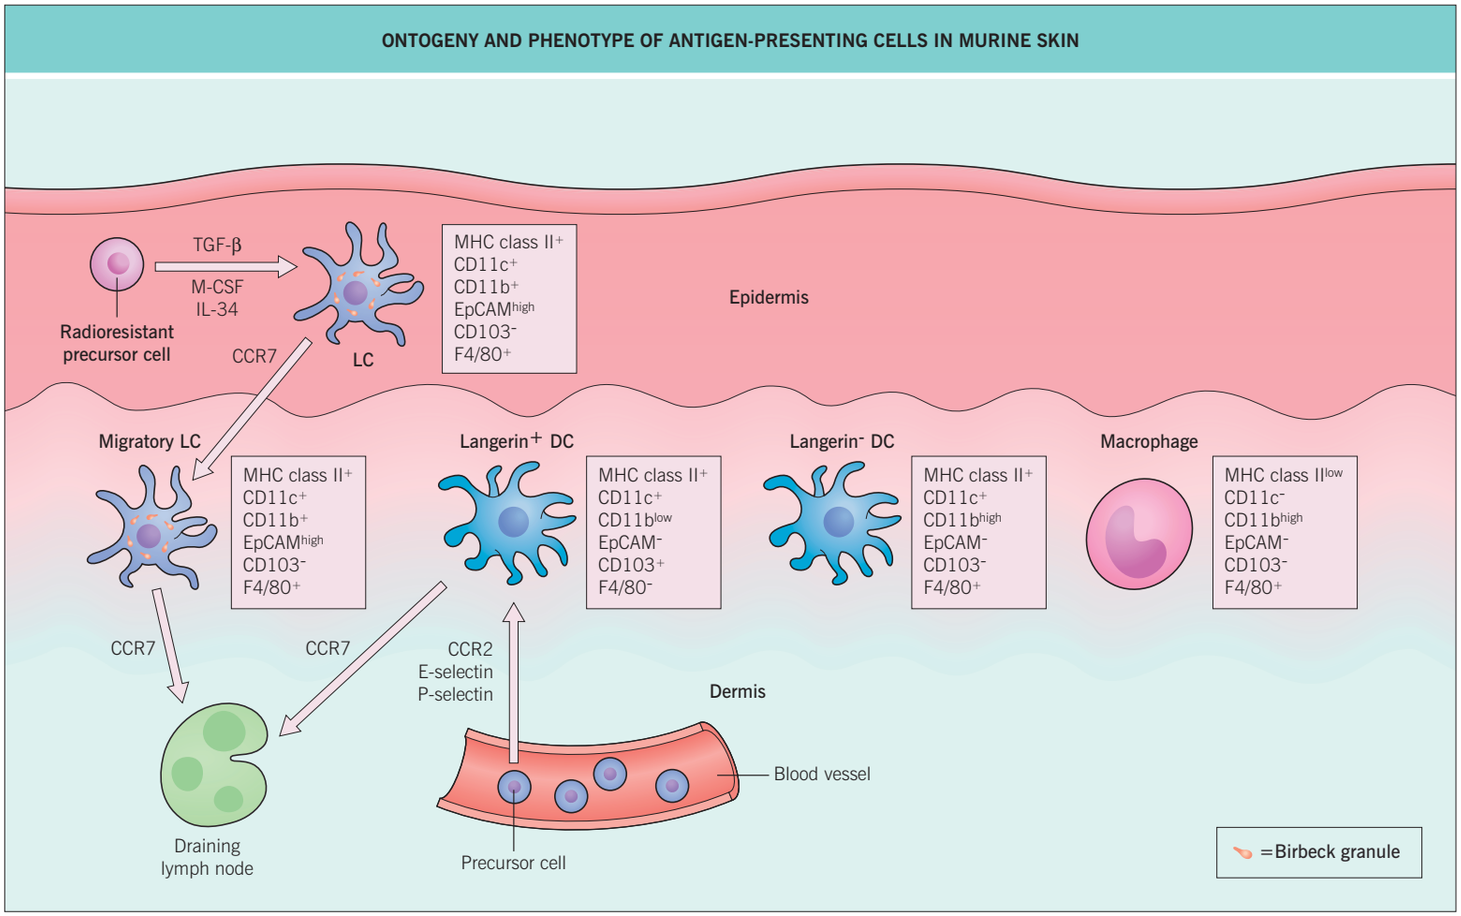

Fig. 4.4 Ontogeny and phenotype of antigen-presenting cells in murine skin. Langerhans cells (LCs) are derived from radioresistant hematopoietic precursor cells in the skin in the presence of transforming growth factor-β (TGF-β), macrophage colony-stimulating factor (M-CSF) and interleukin (IL)-34. LCs migrate to the draining lymph nodes in a CC-chemokine receptor 7 (CCR7)-dependent fashion. The dermis harbors dermal langerin$^+$ dendritic cells (DCs), which differentiate from radiosensitive circulating precursor cells in a CCR2-, E-selectin- and P-selectin-dependent manner. LCs on the way to the lymph nodes can be distinguished from dermal langerin$^+$ DCs by the differential expression of CD11b, epithelial cell adhesion molecule (EpCAM) and CD103. Two additional types of APCs are present in the dermis, dermal langerin$^-$ DCs and dermal macrophages exhibiting peculiar surface marker expression. *Adapted from Merad M, et al. Origin, homeostasis and function of Langerhans cells and other langerin expressing dendritic cells. Nat Rev Immunol. 2008;8:935–47.*

However, the type of immune response that is generated also critically depends on the state of maturation of the stimulating DC at the time of antigen presentation. For the induction of Th1 responses, the presence of IL-12 is crucial. DCs tend to produce IL-12 directly after an activating step in their maturation, driving T cells into a Th1 phenotype if they meet the DCs at this stage[35]. At later time points, the production of IL-12 decreases, thereby favoring the development of a Th2 response. This process is also heavily influenced by the innate immune system (e.g. stimulation by TLRs; see above).

Taken together, the parameters that are responsible for the type of Th cell differentiation that is induced by DCs remain to be fully defined. On the other hand, there is agreement that immature DCs induce tolerance due to incomplete T-cell activation, resulting in T cells of the regulatory type that suppress immune responses[36].

Antigen presentation

Antigen presentation cells: activation and migration

To initiate sensitization, antigens must be presented to T cells by APCs. For many years, LCs were thought to be the most important APC in the skin. It was found that contact sensitization could not be induced in areas of skin that were naturally devoid of LCs (e.g. the murine tail) or in which LCs had been depleted (e.g. by UV radiation)[37]. However, transgenic mice in which LCs are completely depleted via the diphtheria toxin receptor technique (i.e. short-term, inducible ablation) demonstrate variably diminished but not completely abrogated sensitization responses[38]; in one such model, the sensitization response was completely normal[39]. In a different knockout mouse model characterized by constitutive and durable absence of epidermal LCs[40], an enhanced sensitization response was actually observed, suggesting that LCs may have regulatory functions. This "LC paradigm" proposes that LCs may be tolerogenic when they present antigens under steady-state noninflammatory conditions, but sensitizing upon stimulation by inflammatory mediators. Which of these activities is the main function of LCs remains to be determined, and there is accumulating evidence that dermal DCs are equally if not even more important than LCs in presenting antigens.

Antigen presentation to lymphocytes takes place in the regional lymph nodes, while cutaneous APCs actively take up antigens in the skin. In the presence of inflammation, the APCs become activated and leave the skin, migrating to the draining lymph nodes. During emigration, they change their phenotypic and functional behavior and develop into mature DCs. For example, molecules involved in antigen uptake and processing (Birbeck granules, Fc receptors) are down-regulated on activated LCs[41]. In addition, expression of E-cadherin, which mediates the attachment of LCs to neighboring keratinocytes, is reduced, thereby enabling the emigration of LCs.

CD44, a hyaluronic acid receptor involved in the tissue homing of leukocytes, is upregulated on activated LCs. The splice variant CD44v6 supports binding of LCs to T-cell-rich areas of lymph nodes[42]. Furthermore, the integrins $\alpha_6\beta_1$ and $\alpha_6\beta_4$, which exhibit affinity to the basement membrane zone, are induced on the surface of emigrating LCs[43]. The release of proteolytic enzymes like matrix metalloproteinase-9 (type IV collagenase) may enable their penetration through the basement membrane. Their dendricity becomes more pronounced, and surface molecules necessary for antigen presentation and T-cell priming are upregulated (e.g. MHC class I, MHC class II, CD40, CD54, CD58, CD80, CD86). At this stage, LCs emigrating from the epidermis are almost indistinguishable from DCs obtained from lymphoid organs[41]. The same phenotypic and functional changes may occur in other APCs of the skin that have important roles in antigen presentation.

Antigen presentation to T cells

In contrast to B cells, T cells cannot recognize soluble protein antigens per se; instead, the T-cell receptor (TCR) recognizes antigen-derived peptides bound to MHC locus-encoded molecules expressed on APCs. $CD4^+$ T cells recognize antigens in association with MHC class II molecules, while $CD8^+$ T cells, the majority of which become cytotoxic, recognize antigens in association with MHC class I molecules[23] (Fig. 4.5).

Two pathways exist by which antigens can be "loaded" onto MHC molecules. If the antigen has been produced *endogenously* within the cell (e.g. viral or tumor proteins), it is complexed with *MHC class I* molecules through intracellular processing pathways (Fig. 4.6)[44]. The proteasome degrades cytosolic antigens produced by the cell. The resulting peptides (which consist of 8 to 12 amino acid residues) are imported into the endoplasmic reticulum (ER) in a TAP (transporter associated with antigen processing)-dependent manner and loaded onto MHC class I molecules[45]. After binding to the MHC class I–β_2 microglobulin complex, these peptides are transported to the cell

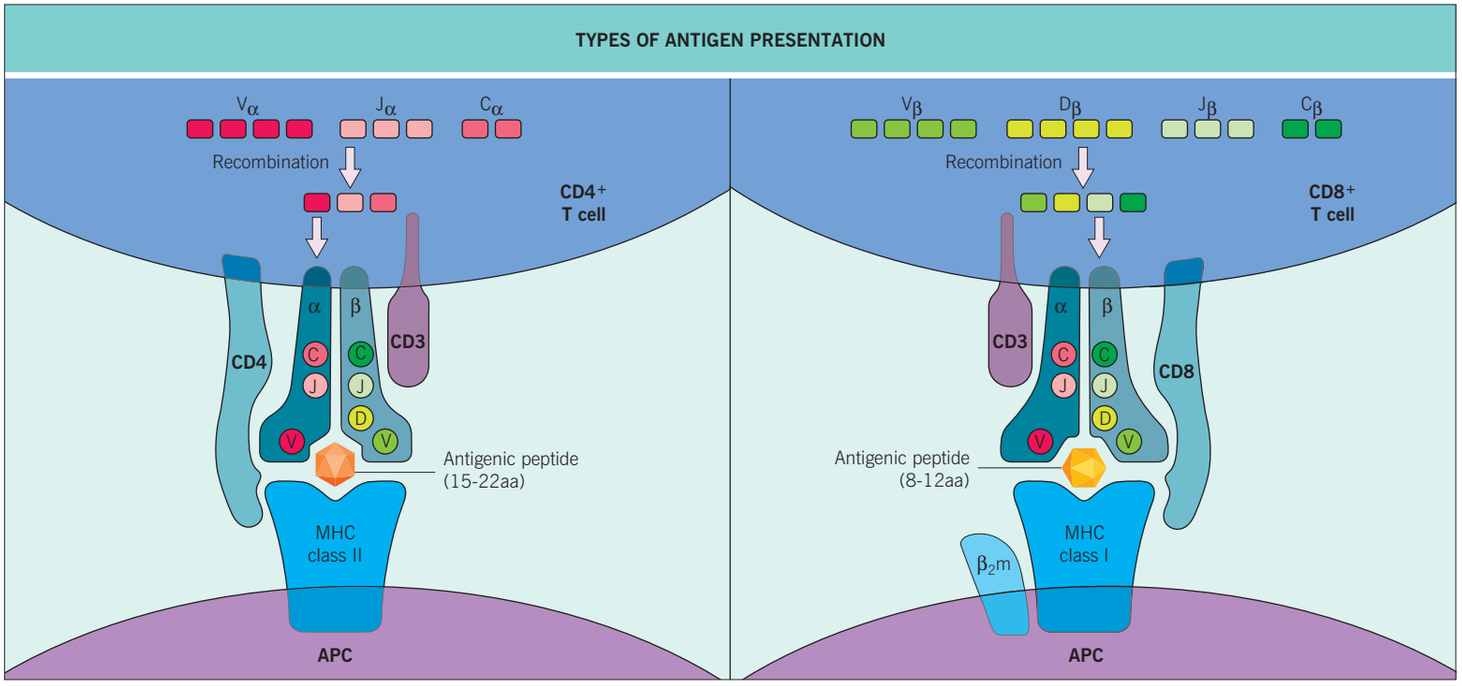

Fig. 4.5 Types of antigen presentation. Antigens are presented by antigen-presenting cells to the T-cell receptor of $CD4^+$ or $CD8^+$ T cells in association with either MHC class II or MHC class I molecules. The diversity of the T-cell receptors is generated by gene rearrangement. For reasons of clarity, the simplified gene rearrangement of the α-chain is shown only in the $CD4^+$ T cell, that of the β-chain in the $CD8^+$ T cell. aa, amino acids; β_2m, β_2-microglobulin; V, variable; D, diversity; J, joining; C, constant. *Adapted from Modlin RL. Lymphocytes. In: Freedberg IM, Eisen AZ, Wolf K, et al. (eds). Fitzpatrick's Dermatology in General Medicine, vol. 1. New York: McGraw-Hill, 1999;32:400–5.*

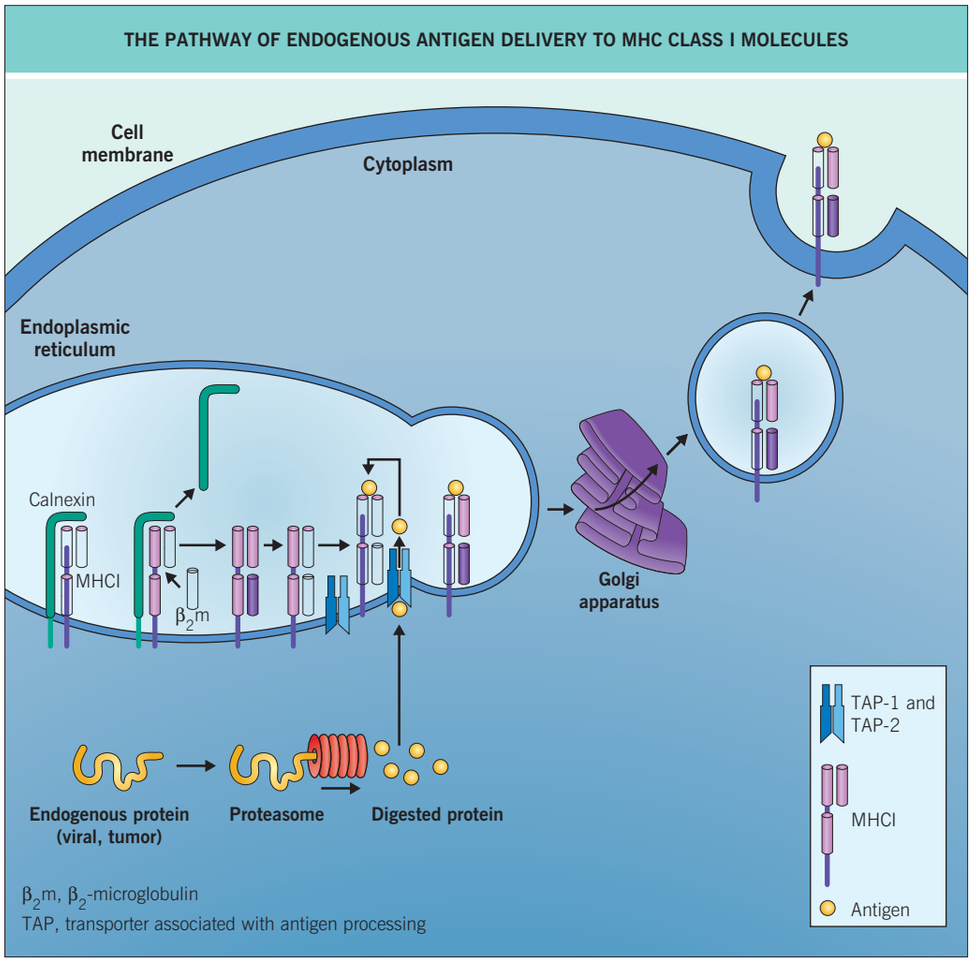

Fig. 4.6 The pathway of endogenous antigen delivery to class I MHC molecules. Newly synthesized MHC class I molecules are stabilized by calnexin. When β_2-microglobulin (β_2m) binds to the complex, calnexin dissociates. This complex associates with the TAP (transporter associated with antigen processing) protein waiting for a suitable peptide. Endogenous antigens are degraded by the proteasome and transported via TAP into the endoplasmic reticulum (ER), where they bind to the MHC class I/β_2m complex. Finally, the peptide/MHC complex is transported through the Golgi apparatus to the cell surface. Not pictured is a possible alternate pathway in which exogenous proteins are phagocytosed and the phagosome fuses to the ER. The proteins are then retransported out of the ER into the cytoplasm and degraded by proteasomes. The degraded peptides can now enter the normal pathway via the TAP protein. *Adapted from Parkin J, Cohen B. An overview of the immune system. Lancet. 2001;357:1777–89. With permission from Elsevier.*

surface via the Golgi apparatus. Alternative pathways by which exogenous proteins are phagocytosed and the phagosome fuses to the ER may also exist. The proteins are subsequently retransported out of the ER into the cytoplasm (by an as yet unclear mechanism) and then degraded by the proteasome. The degraded peptides can now enter the pathway that is normally used for endogenous proteins via the TAP protein. As the vast majority of nucleated cells express MHC class I molecules, many cell types can serve as APCs for MHC class I-restricted antigen presentation in a secondary immune response.

In contrast, MHC class II-dependent antigen presentation is critically dependent on DCs, B cells and monocytes/macrophages. *MHC class II*-associated antigen presentation targets primarily *exogenous* (Fig. 4.7) and less frequently endogenous antigens[46]. Exogenous antigens are taken up via macro- or micropinocytosis or by receptor-mediated endocytosis. One example of the latter is the DEC-205 receptor (CD205), which guides antigens into endocytic vesicles that reside deeper inside the cell and contain MHC class II molecules. As a consequence of this unique intracellular targeting, antigens endocytosed by the DEC-205 receptor stimulate respective T cells up to 500-fold greater than antigens taken up by pinocytosis or other receptors. Protein degradation eventually takes place in the endo-/lysosomes, yielding peptides with a typical length of 15 to 22 amino acid residues. These peptide fragments enter specialized endosomal compartments containing MHC class II molecules that are generated in the ER[47].

Newly synthesized MHC class II molecules are associated with an invariant chain, which inhibits dissociation of empty MHC class II molecules and transports the MHC class II complex from the ER to the specialized endosomal compartments where the molecules can interact with antigen peptide fragments (see Fig. 4.7). In this compartment, the invariant chain is cleaved by proteases, leaving a small fragment called CLIP (class II-associated invariant peptide) that binds to the class II molecule. Upon interaction with the antigenic peptides, the CLIP fragment is released from the complex. The MHC class II molecule with the bound antigen peptide is subsequently expressed on the cell surface, allowing antigen recognition by T cells carrying the appropriate TCR.

Classically, MHC class I molecules present self- or pathogen-derived antigens that are synthesized within the cell to $CD8^+$ T cells (see Fig. 4.6), whereas exogenous antigens derived via endocytic uptake are loaded onto MHC class II molecules for presentation to $CD4^+$ T cells (see Fig. 4.7). However, it has become evident that some DCs are also able to process exogenous antigens into the MHC class I pathway for presentation to $CD8^+$ T cells. This mechanism, referred to as cross-presentation[48], allows DCs to induce either tolerance (to self-antigens) or immunity (to exogenous pathogens).

T Cells

T-cell precursors continuously migrate from the bone marrow to the thymus, where T cells develop[49]. In the thymus, T cells bearing the α/β TCR are subjected to a complex selection process. In contrast to antibodies, which represent the antigen receptor on B cells and recognize antigens in their naive form, the α/β TCR recognizes only short peptide fragments that are generated during antigen processing within APCs (see above). These processed antigens are presented to the TCR by MHC molecules on the cell surface. The amino acid sequences recognized by the TCR include those from both the MHC molecule and the antigenic peptide. Consequently, the TCR recognizes a combination of "self" MHC molecules (which are highly polymorphic) and "foreign" peptides. T cells that recognize "self" MHC molecules but not "self" peptides are useful for immune defense but do not lead to undesirable autoimmunity. This requirement is achieved by a complex process that involves both positive and negative selection within the thymus.

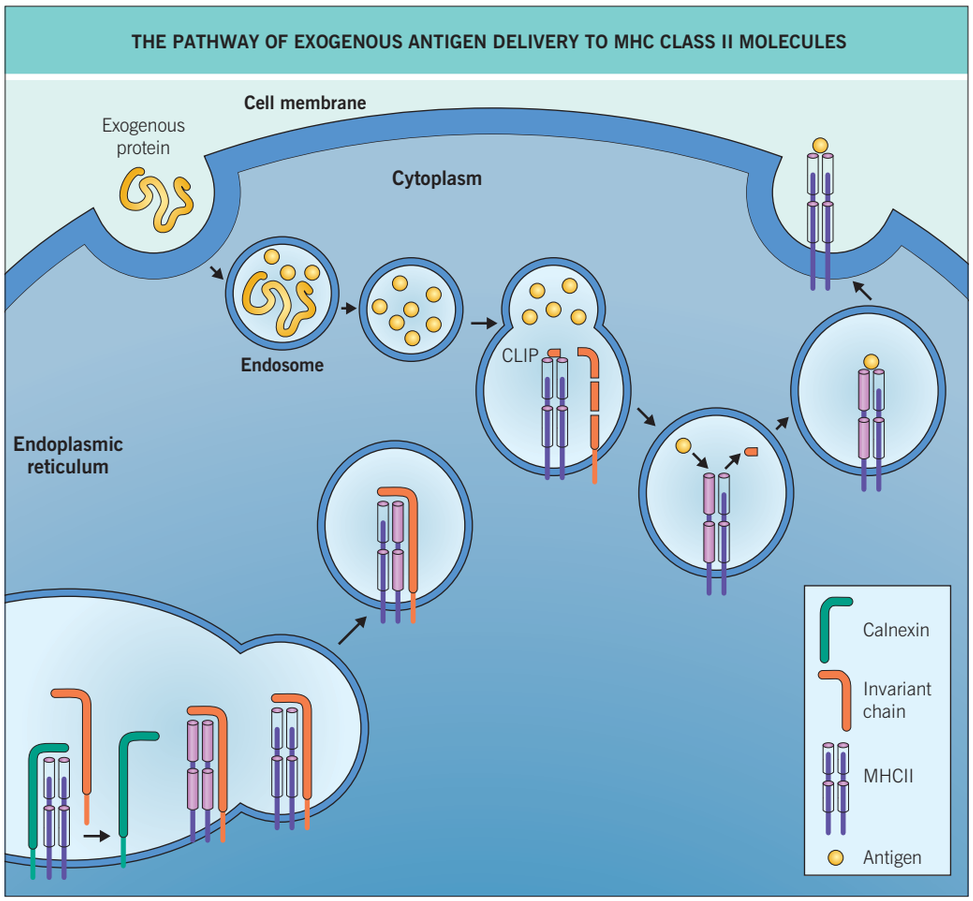

Fig. 4.7 The pathway of exogenous antigen delivery to class II MHC molecules. Exogenous antigens are taken up into the cell by endosomes. The protein is cleaved into peptides within the endosomes, which become increasingly acidic. In the endoplasmic reticulum (ER), newly synthesized MHC class II molecules bind to an invariant chain, which inhibits their disassociation while empty. During this assembly, the complex is stabilized by calnexin. The invariant chain transports the MHC class II molecule from the ER (via the Golgi apparatus) into the endosomal compartment, where the MHC class II complex meets the peptides. The invariant chain is cleaved, leaving a small fragment (CLIP) in the groove of the MHC class II molecule. Finally, CLIP is replaced by the antigenic peptide. The complex is transported to the cell membrane and expressed on the cell surface. CLIP, class II-associated invariant peptide.

T-cell development

Developing T cells within the cortex of the thymus engage MHC complexes on thymic DCs. When the T cells are able to recognize these MHC molecules via their TCR, they receive a survival signal (*positive selection*). Otherwise, the T cells undergo apoptotic cell death[50]. At this stage, more than 95% of the developing T cells die in the thymus because they are not selected due to their uselessness (i.e. inability to recognize "self" MHC molecules)[51]. In addition, T cells that express a TCR with a very high affinity for the complex of a "self" peptide plus a "self" MHC molecule are eliminated by apoptosis, since they are potentially harmful. This process, called *negative selection*, takes place in the thymic medulla and involves DCs and macrophages that process and present a spectrum of "self" antigens. Positive and negative selection allow the survival of just those T cells that recognize foreign (but not "self") peptides in the context of "self" MHC molecules and thus are useful for immune defense without causing auto-attack[52].

During thymic education, a variety of surface molecules are switched on and off. Components of the CD3/TCR complex, together with CD4 or CD8 molecules, have roles in this process. In general, $CD4^+$ T cells function as helper T cells and recognize antigens presented by MHC class II molecules, whereas $CD8^+$ T cells are usually cytotoxic and recognize antigens in association with MHC class I molecules (see Fig. 4.5). In their early stage of development within the thymus, T cells express both CD4 and CD8[53]. Upon expression of an appropriate TCR, these immature T cells exhibit the capacity to recognize antigenic peptides associated with either MHC class I or MHC class II molecules, since they still express both CD4 and CD8 (double-positive stage). During the subsequent process of maturation, one of these surface markers is lost, resulting in single-positive T cells expressing either CD4 or CD8. These cells are specialized for peptides presented only by MHC class II or MHC class I molecules, respectively.

T-cell receptor

One major feature of an adaptive immune response is the recognition of specific antigens. This is achieved either by the TCR during a T-cell-mediated response or by antibodies during a B-cell response. TCRs are transmembrane molecules consisting of α/β (vast majority of T cells) or γ/δ (<10% of T cells) heterodimers[54]. Antigen recognition by γ/δ T cells appears to be independent of classic MHC molecules, instead utilizing other MHC molecules (e.g. CD1) that preferentially present certain lipid and glycolipid antigens[55].

T-cell receptor diversity

An amazing feature of the immune system is that it provides specific receptors for every possible antigen. B cells are capable of producing approximately 10^{15} different antibody variable regions, and T cells generate a comparable number of TCR variable regions. Remarkably, these numerous proteins are encoded by fewer than 400 genes. This tremendous diversity is created via a unique recombination process that cuts, splices and modifies genes in the variable region[56].

Four segments of genes are involved in TCR formation: the variable (V), diversity (D), joining (J) and constant (C) regions (see Fig. 4.5). In contrast to the TCRβ and TCRδ loci (both on chromosome 7), the TCRα and TCRγ loci (both on chromosome 14) do not contain D segments. The segments are cut out by nucleases and spliced together by ligases, ultimately forming the final gene sequence that encodes the receptor molecule. The tremendous diversity is explained by the multiplicity of all these regions within the genome (e.g. ~70–80 V genes and ~60 J genes for the TCRα alone), but only one of each type is used for a particular TCR.

Each lymphocyte utilizes a different combination of V, D and J gene segments to form the genetic code of its antigen receptor. Any one of the genes can join with any other one to form the final VDJ region, thereby creating tremendous diversity. In addition, the recombination process is subject to inaccuracies during splicing, which cause slight variations at the VDJ junctions, and additional nucleotides can be inserted by the enzyme deoxyribonucleotidyl-transferase at the spliced regions. These two events increase the diversity even further. Of note, only a tiny minority of these cells will become functional over a lifetime, with the vast majority dying without ever having met their antigen.

Defects in the *r*ecombination-*a*ctivating *g*enes *RAG1* and *RAG2*[57], which encode two of the enzymes that mediate the recombination of variable-region genes in both B cells and T cells, cause a form of severe combined immunodeficiency (see Ch. 60). Affected individuals are unable to produce lymphocytes bearing functional antigen receptors[58].

T-cell receptor signaling

TCRs are associated with the CD3 complex, which transmits signals upon antigen binding. CD3 consists of CD3γ, CD3δ, two molecules of CD3ε and a disulfide-linked CD3ξ homodimer[59]. Upon binding to the peptide–MHC complexes, TCRs become cross-linked. Aggregation of the TCRs causes phosphorylation of tyrosines in the cytoplasmic tails of the CD3 complex, which contain *i*mmunoreceptor *t*yrosine-based *a*ctivation *m*otifs (ITAMs). Phosphorylation involves kinases such as $p56^{lck}$ (which also binds to the cytoplasmic tails of CD4 and CD8), $p59^{fyn}$ and ZAP-70[60] (Fig. 4.8). These events ultimately lead to the transcriptional activation of genes that encode cytokines and induce cellular proliferation and differentiation.

Costimulatory signals

Signaling through the TCR complex alone does not suffice to activate T cells. The presence of costimulatory signals is needed for T cells to undergo antigen-specific clonal expansion[61]. Hence, development of a productive T-cell immune response requires exposure of these cells to at least two types of stimuli. The *first signal* is the interaction of the TCR with peptide–MHC complexes presented by APCs, which determines the specificity of the immune response. The *second signal* involves surface molecules and cytokines, which determine the clonal expansion of specific T cells and their differentiation into effector and memory cells. Without these costimuli, signaling by the antigen receptors alone will either cause anergy (non-reactivity) or apoptotic cell death (Fig. 4.9). The major receptors and ligands expressed on APCs and T cells that play a role in activation are listed in Table 4.3.

The best-investigated costimulators for T cells are two members of the B7 family, B7-1 (CD80) and B7-2 (CD86)[62]. Both molecules are induced on immature, resting APCs by various TLR ligands or by cytokines (e.g. TNF-α, IL-1). The CD28 receptor on T cells recognizes the B7 molecules and delivers activating signals, including the expression of antiapoptotic genes and the production of cytokines such as IL-2. Cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4 [CD152]) also binds to the B7 molecules, with even higher avidity. Unlike CD28 binding, cross-linking of CTLA-4 to B7 down-regulates IL-2 production and cell cycle progression, whereas blockade of CTLA-4 signaling prolongs T-cell activation. Hence, CTLA-4 is regarded as a T-cell-associated co-receptor with negative regulatory effects[63].

COSTIMULATORY MOLECULES AND THEIR LIGANDS*

Receptor molecule	Expression†	Co-receptor molecule	Expression†
CD80 (B7-1)	APC	CD28, CD152 (CTLA-4)	T
CD86 (B7-2)	APC	CD28, CD152 (CTLA-4)	T
CD275 (ICOS-L, B7H2, B7h, B7RP1)	APC	CD278 (ICOS)	T
CD274 (PDL1, B7H1)	APC	CD279 (PD1)	T, B
CD273 (PDL2, B7DC)	APC	CD279 (PD1)	T, B
CD40	APC, B	CD154 (CD40L)	T
CD134 (OX40)	T	CD252 (OX40L)	APC, B
CD27	APC, T	CD70 (CD27L)	T, B
CDw137 (4-1BB)	T, B	4-1BBL	APC, B
CD265 (RANK)	APC	CD254 (RANKL, TRANCE)	APC, T
CD30	T, B	CD153 (CD30L)	T, B, APC
CD58 (LFA-3)	APC	CD2	T

*Only important costimulatory molecules and those with known ligands are included.
†Expression refers only to T cells (T), B cells (B) and antigen-presenting cells (APC) including DC and LC.

Table 4.3 Costimulatory molecules and their ligands. APC, antigen-presenting cell; CTLA-4, cytotoxic T-lymphocyte-associated antigen-4; ICOS, inducible costimulator; LFA-3, lymphocyte function antigen-3; PDL1, programmed death ligand 1; TNF, tumor necrosis factor.

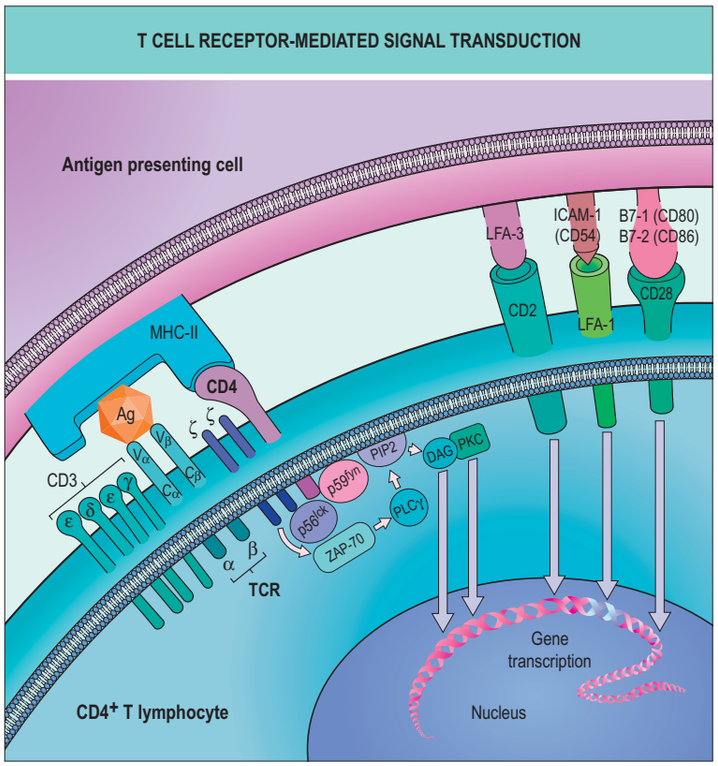

Fig. 4.8 T-cell receptor-mediated signal transduction. Activation of the T-cell receptor by presentation of the appropriate antigen by antigen-presenting cells in association with MHC molecules induces a complex signal transduction cascade. The T-cell receptor-associated signal transduction is primarily mediated by the CD3 complex and the ξ chain. Upon activation, the cytoplasmic tails of these molecules become phosphorylated by protein kinases ($p56^{lck}$, $p59^{fyn}$, ZAP70). This causes downstream signaling which ultimately leads to transcriptional activation of particular genes. Additional stimuli are provided by the signaling of costimulatory molecules (CD2, ICAM-1, CD28). DAG, diacylglycerol; PIP2, phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; PLC, phospholipase C.

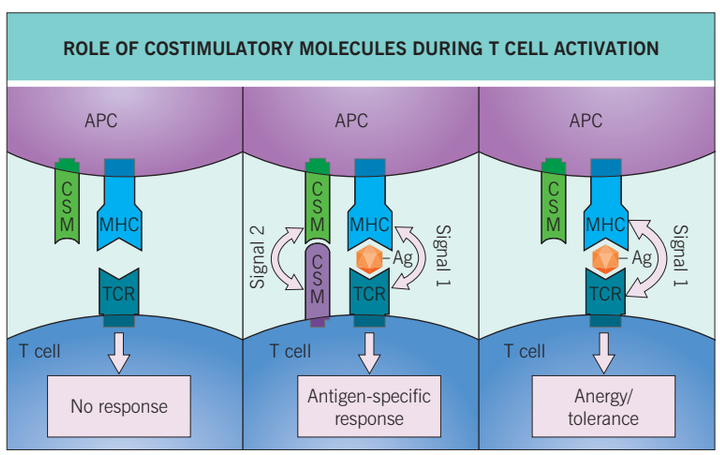

Fig. 4.9 Role of costimulatory molecules during T-cell activation. Presentation of the antigen by antigen-presenting cells to the T-cell receptor in association with MHC molecules delivers the first signal necessary for T-cell activation. The second signal is provided by the interaction of costimulatory molecules present on antigen-presenting cells and T cells. An antigen-specific response is only induced when signal 1 and signal 2 are provided. Presentation of the antigen in the absence of signal 2 does not lead to an antigen-specific response but induces anergy and tolerance, respectively. APC, antigen-presenting cell; CSM, costimulatory molecule; MHC, major histocompatibility complex; TCR, T-cell receptor.

Cytokines, especially inflammatory mediators like IL-1, IL-6 and TNF-α, also provide costimulatory signals by themselves and, in addition, upregulate costimulatory molecules. Hence, a T cell is much more likely to be activated if it meets its specific antigen via an APC that has been exposed to an inflammatory environment.

Clonal expansion

If a T cell recognizes its specific antigen peptide in association with the appropriate MHC molecules and becomes activated by costimulatory signals, division and clonal expansion take place. Memory T cells have a much longer lifespan than effector cells and are characterized by the expression of the surface molecule CD45RO, while naive T cells express CD45RA. Two functionally distinct subsets of human memory T cells have been described. *CCR7⁺ memory T cells* (*central memory T cells* [*TCM*]) express lymph node homing receptors and thus stay in the lymph nodes. These cells lack immediate effector function; however, they efficiently stimulate DCs to produce IL-12 and can differentiate into CCR7⁻ effector cells upon secondary stimulation. In contrast, *CCR7− memory T cells* (*effector memory T cells* [*TEM*]) express receptors for migration to inflamed tissues and have immediate effector functions[64].

Memory T cells react in a more rapid fashion upon re-exposure to their specific antigen. The vast majority of these progenitor cells represent effector cells with upregulated receptors that enable them to leave the lymphoid tissue. Organ-specific adhesion molecules guide these cells to various locations, including the skin[18,64]. Most of the T cells found in human skin reside in the dermis, with a minority in the epidermis (2% to 3% of all CD3⁺ cells present in normal human skin). The majority of human epidermal T cells express the α/β TCR and are either CD8- or CD4-positive. In addition, skin-homing T cells express CD2, CD5 and the skin-homing receptor cutaneous lymphocyte antigen (CLA), and they are of the memory phenotype CD45RO⁺/CD45RA⁻[65].

Effector functions of T cells

Two major types of effector T cells have been identified: T helper (Th) cells, which are CD4⁺, and cytotoxic T (Tc) cells, which are CD8⁺. CD4⁺ Th cells recognize foreign antigen peptides bound to MHC class II and activate/modulate important components of the cell-mediated immune response, mainly through cytokine production. One essential function of CD4⁺ Th cells is the activation of B cells. CD8⁺ Tc cells are crucial to antiviral and antitumor responses[66].

T helper cells

CD4⁺ Th cells recognize "their" antigenic peptides in association with MHC class II molecules. Based primarily on differences in their cytokine secretion patterns, several types of Th cells have been described[67]. Naive precursor Th cells only produce IL-2. Subsequently, preactivated precursor cells, called Th0, can release a wide variety of cytokines (e.g. IL-2, IFN-γ, TNF-β, IL-3, IL-4, IL-5, IL-6, IL-9, IL-10, IL-13, GM-CSF, TNF-α). As they develop into Th1, Th2 or Th17 cells, the cytokine secretion pattern becomes more restricted and specific (see below), leading to generation of different responses. The recently described Th22 cells may represent a separate type. Morphologically, the cells in the various Th subsets are almost indistinguishable, although surface differences (especially in chemokine receptors) have been described[68].

Th1 cells: Typical Th1 cytokines are IFN-γ, TNF-β, and IL-2. Production of IL-2 by Th1 cells induces proliferation of CD4⁺ cells in an autocrine manner and affects the cytokine differentiation pattern; however, it also stimulates CD8⁺ T-cell division and cytotoxicity, thereby providing "help" for CD8⁺ Tc cells.

The major Th1-derived cytokine is IFN-γ, which activates macrophages to kill intracellular pathogens (e.g. mycobacteria, fungi, protozoa) and stimulates NK-cell cytotoxicity. Therefore, Th1 cytokines preferentially induce a cell-mediated inflammatory response, such as the granulomatous lesions of tuberculosis or leprosy. Macrophages stimulated by IFN-γ release huge amounts of IL-12, the major cytokine that drives Th0 cells towards a Th1 phenotype (Fig. 4.10)[69]. The second most important cytokine in promoting Th1 differentiation is IFN-α.

A Th1 response is crucial for the host to control the replication of intracellular pathogens. In addition, Th1 cells promote the isotype switch of B cells to produce complement-binding antibodies. Augmenting the antitumor response of Th1 cells represents a potential target of cancer immunotherapy. On the other hand, Th1 cells contribute to the pathogenesis of autoimmune diseases such as rheumatoid arthritis, multiple sclerosis, allergic contact dermatitis and, perhaps, psoriasis.

Th2 cells: Th2 cells produce primarily IL-4, IL-5, IL-6 and IL-10. These cytokines favor production of non-complement-binding antibodies. IL-4 switches B cells to produce IgE, and IL-5 promotes

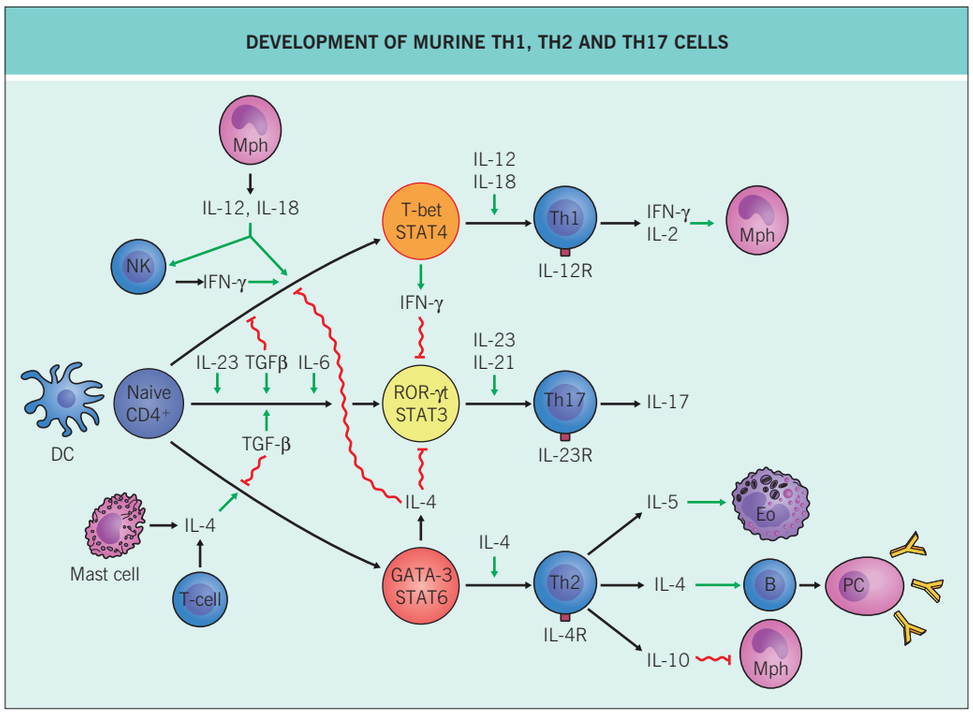

Fig. 4.10 Development of murine Th1, Th2 and Th17 cells. Th1, Th2 and Th17 cells differentiate under the influence of cytokines, which are secreted by various bystander cells and can act in a stimulatory (→) and inhibitory (⇝) fashion. The interaction of dendritic cells (DC) with naive CD4⁺ T cells in the various cytokine milieus induces certain transcription factors in the T cells (T-bet, STAT4, ROR-γt, STAT3, GATA3, STAT6), which direct differentiation. Th1 cells are crucial for T-cell-mediated immunity, Th2 cells support the development of humoral immunity, and Th17 cells are involved in chronic inflammatory and autoimmune reactions. Eo, eosinophil; IL, interleukin; IFN-γ, interferon-γ; MC, mast cell; Mph, macrophage; NK, natural killer cell; PC, plasma cell; ROR-γt, *r*etinoid acid receptor-related *o*rphan *r*eceptor-γt; STAT3/4/6, *s*ignal *t*ransducer and *a*ctivator of *t*ranscription 3/4/6; TGF-β, transforming growth factor-β.
Adapted from Miossec P, et al. Interleukin-17 and type 17 helper T cells. N Engl J Med. 2009;361:888–98.

the growth of eosinophils. Therefore, Th2 responses are often associated with allergic diseases. Comparable to the role of IL-12 in inducing Th1 responses, IL-4 is the key cytokine in driving Th2 responses. In addition, IL-4 suppresses Th1 and Th17 differentiation (see Fig. 4.10). However, IL-4 seems to exert opposing effects on $CD4^+$ T cells and DCs, since it can stimulate DCs to produce IL-12 and thus paradoxically promote Th1 development[70]. IL-10, another characteristic Th2 cytokine, also inhibits the development of a Th1 response.

Immune responses generally tend to drift into a Th1, Th2 or Th17 (see below) pattern. The Th1/Th2 decision is crucial for effective immunity and thus is regulated by a variety of factors[71]. The cytokine profile and balance induced by the antigen is critical. For example, IL-12 is a potent priming stimulus for $CD4^+$ T cells to produce IFN-γ and, thus, for Th1 cellular differentiation[72]. Many TLR signals and infections are strong inducers of IL-12 and therefore favor a Th1 response. Other TLR signals to DCs and early production of IL-4 favor the generation of Th2 cells. Additional factors that influence the Th1/Th2 decision include the dose of the antigen, the APCs involved[32], the cytokines secreted (by APCs and bystander cells), the genetic background of the host, and the presence of costimulatory molecules. Of note, many immune responses are not strongly polarized in the Th1 or Th2 direction.

Th1 and Th2 responses differ greatly in their protective roles, and the same applies with regard to their contribution to immunopathology. Acute allograft rejection, allergic contact dermatitis and multiple sclerosis are characterized by dominant Th1 responses, and Th1 clones have been isolated from patients suffering from these diseases. On the other hand, T-cell clones isolated from patients suffering from atopic dermatitis or systemic lupus erythematosus typically exhibit a Th2 profile.

Th3 cells: Th3 cells are a poorly characterized type of $CD4^+$ Th cell that primarily secretes TGF-β, provides help for IgA production, and has suppressive properties against both Th1 and Th2 cells[73].

Th17 cells: $CD4^+$ T cells that produce IL-17, but neither IFN-γ nor IL-4 (and therefore do not fit into the Th1–Th2 spectrum), are referred to as Th17 cells[74]. Besides IL-17A, these cells also secrete IL-17F, IL-21 and IL-22. Whereas the heterodimeric cytokine IL-12 (consisting of a p35 chain and a p40 chain) is crucially involved in the development of Th1 cells, the IL-12-related cytokine IL-23 (consisting of a p19 chain and the same p40 chain) is essential for the generation of Th17 cells. Naive T cells do not express the IL-23 receptor. In mice, a combination of TGF-β and IL-6 induces expression of the transcription factor *r*etinoid acid receptor-related *o*rphan *r*eceptor-γt (ROR-γt), which stimulates transcription of the IL-17 gene and expression of the IL-23 receptor (see Fig. 4.10). Of note, in the absence of IL-6, TGF-β drives naive T cells into the regulatory phenotype by inducing the transcription factor forkhead box P3 (FoxP3; see below). IL-6 and IL-23 enhance the expression of IL-17 and IL-22 and suppress production of IL-10 and IFN-γ, thereby stabilizing the Th17 phenotype. IL-21 is also produced in large amounts by mature Th17 cells and amplifies Th17-cell differentiation[74]. In human T cells, combinations of TGF-β plus IL-21, TGF-β plus IL-6 and IL-23, or IL-6 plus IL-21 appear to be involved in the differentiation of Th17 cells by inducing the expression of ROR-c, the human analogue of murine ROR-γt.

Th17 cells are rapidly induced in response to infectious agents – in particular, bacteria and fungi. Patients with a defective Th17 response due to mutations in the gene encoding *s*ignal *t*ransducer and *a*ctivator of *t*ranscription 3 (STAT3), another transcription factor involved in Th17 cell development (see Fig. 4.10), have hyperimmunoglobulin E (hyper-IgE) syndrome and suffer from recurrent *Candida albicans* and *Staphylococcus aureus* infections of the skin and lung (see Ch. 60)[75]. Th17 responses have important roles in chronic inflammation and in mediating autoimmune reactions. There is evidence that Th17 cells are involved in rheumatoid arthritis, psoriasis, multiple sclerosis and inflammatory bowel diseases[74]. Genetic studies have linked variants of the IL-23 and IL-23 receptor genes to susceptibility for psoriasis and psoriatic arthritis[76]. Since IL-23 enhances IL-17 production, inhibition of IL-23 is a target for therapeutic intervention. Indeed, a monoclonal antibody (ustekinumab) directed against the common p40 chain, thereby blocking signaling by both IL-12 and IL-23, represents an effective treatment for psoriasis[77]. Since IL-23 appears to be a more potent driving force in autoimmune reactions than IL-12, blocking IL-23 signaling by targeting the p19 chain represents another promising therapeutic strategy.

Th22 cells: Recently, a subset of human $CD4^+$ Th cells characterized by the secretion of IL-22 and TNF-α (in the absence of IFN-γ, IL-4 or IL-17) was identified, and they have been referred to as Th22 cells[78]. These cells infiltrate the epidermis in inflammatory skin disorders including psoriasis. They express proteins involved in tissue remodeling (e.g. fibroblast growth factors) and chemokines involved in angiogenesis and fibrosis.

Cytotoxic T cells

Cytotoxic T (Tc) cells are $CD8^+$, recognize "their" antigenic peptides in association with MHC class I molecules, and can directly lyse their targets (e.g. virally infected or tumor cells). For example, virally infected cells present peptides derived from intracellular viral proteins on MHC class I molecules, and Tc cells that recognize this viral peptide–MHC complex are stimulated to kill the infected cell. Tc cells have at least three different pathways of killing[79], two of which involve direct contact with the target cell. In one method, Tc cells insert perforins into the membrane of the target cell; this creates pores in the membrane, through which granzymes are released from the Tc cell into the target cell. Granzymes then activate caspases, proteolytic enzymes that induce apoptosis in the target cell. In a second mechanism, Tc cells activate the death receptor Fas (CD95) on the target cell by expressing the cognate death ligand FasL (CD95L). The activated Fas also triggers apoptosis in the target cell. The third pathway is mediated by cytokines, including TNF-α and IFN-γ, which are released as long as TCR stimulation continues. These mediators can affect distant cells as well as the target cell[79].

Naive $CD8^+$ T cells (Tc0 cells) can develop into Tc1 and Tc2 cells[80]. Comparable to Th1 and Th2 cells, Tc1 and Tc2 cells are differentiated based on their different cytokine secretion patterns. However, their functional roles still remain to be determined. Even though there is evidence that some $CD8^+$ T cells exhibit suppressor functions[81], most $CD8^+$ T cells develop a cytotoxic phenotype.

Regulatory T cells

More than three decades ago, it was postulated that a subpopulation of T cells could suppress immune responses. Consequently, these cells were designated as T suppressor cells. The most convincing evidence for their existence was provided by adoptive transfer experiments in which suppression could be transferred in an antigen-specific manner. However, the phenotype of these hypothetical cells and the molecular mechanisms underlying suppressive phenomena were poorly characterized. Consequently, the term "T suppressor cells" was almost banned and the entire concept of suppression drawn into question. Passive mechanisms such as clonal deletion, clonal anergy and immunologic ignorance were evoked to explain immunologic unresponsiveness and peripheral tolerance[82].

Nevertheless, the concept of T suppressor cells was persistently pursued in the field of photoimmunology. Application of contact allergens onto the skin of mice exposed to UV radiation not only resulted in a failure of sensitization but also actually induced antigen-specific tolerance, since at a later time these animals could not be resensitized to the same allergen[37] (see Ch. 86). Adoptive transfer of splenocytes from animals tolerized in such a manner rendered naive recipients unresponsive to the specific allergen. Depending on the model used (local or systemic immunosuppression, type of allergen, UV dose), different subtypes of T cells appeared to be responsible for the transfer of suppression[83]. Due to the lack of specific surface markers, to date these cells have not been isolated or cloned; nevertheless, the adoptive transfer experiments clearly indicated that active suppression exists.

Interest in the entire field was rekindled by the observation that chronic activation of both human and murine $CD4^+$ T cells in the presence of IL-10 induced $CD4^+$ T-cell clones with a low proliferative capacity that produced high levels of IL-10, low levels of IL-2, and no IL-4[84]. These antigen-specific T-cell clones suppressed the proliferation of $CD4^+$ T cells in response to antigen and prevented T-cell-mediated colitis in SCID mice. This $CD4^+$ T-cell subset was designated T regulatory cells 1 (Tr1).

Another subset of $CD4^+$ regulatory T cells (Tregs) is characterized by the constitutive expression of the α-chain of the IL-2 receptor (CD25). Some $CD4^+CD25^+$ Tregs are generated in the thymus and become

activated upon re-encountering their antigen in the periphery. Thymectomized mice that do not develop $CD4^+CD25^+$ T cells develop autoimmune diseases[85]. In turn, reinjection of such cells prevents the development of the autoimmune phenomena, indicating that the $CD4^+CD25^+$ cells prevent autoimmunity and thus can act in a suppressive fashion. FoxP3, a transcription factor whose inherited dysfunction leads to an autoimmune and inflammatory syndrome in humans (IPEX: *i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked) and mice (*Scurfy* strain), is specifically expressed in naturally arising $CD4^+CD25^+$ Tregs[86]. Retroviral gene transfer of *Foxp3* converts naive T cells toward a Treg phenotype. Thus, *Foxp3* is a key regulatory gene in the development of Tregs.

Natural Tregs (*nTregs*) are produced in the thymus as a functionally mature subpopulation of T cells[87]. These $CD4^+CD25^+$ T cells constitute approximately 10% of all murine peripheral $CD4^+$ T cells. However *induced Tregs* (*iTregs*) can also develop from naive T cells in the periphery through several mechanisms (Fig. 4.11). Immature DCs appear to be involved in the generation of human iTregs. Upon repeated stimulation by immature DCs, allogeneic $CD4^+$ T cells have been shown to express the negative regulatory molecule CTLA-4; lose their capacity to produce IFN-γ, IL-2 or IL-4; and differentiate into non-proliferating, IL-10-producing T cells[36]. In co-culture experiments, these T cells inhibited the antigen-driven proliferation of Th1 cells in a cell contact-dependent manner. The same may apply for damaged APCs, since the migration of UV-damaged LCs is required for the generation of Tregs by UV radiation[88].

Together, these findings show that immature and mature DCs induce different types of T-cell responses: (1) mature, IL-12-producing DCs result in inflammatory Th1 cells; (2) less well-defined "DC2s" result in Th2 cells; and (3) immature or damaged DCs result in IL-10-producing iTregs. These observations provide evidence for constant control of peripheral tolerance to self-antigens[89]. In this scenario, immature DCs constantly take up proteins from normal cells as they undergo regular cell turnover. In the absence of inflammatory signals, DCs do not mature and therefore enter the regional lymph nodes in an immature stage. Self-antigens expressed on immature DCs lead to the development of Tregs, which then migrate to the respective organ where they exhibit suppressive effects. During an infection, immature DCs take up self-antigens but mature in the presence of TLR and inflammatory signals. In the regional lymph nodes, the mature DCs prime naive $CD4^+$ or $CD8^+$ T cells, which become effector T cells. These cells re-migrate to the initial site of inflammation, where they encounter the inhibitory effects of Tregs that are already present. This process normally prevents the development of autoimmunity under both normal and inflammatory conditions.

Tregs exert their suppressive functions in several ways[87] (see Fig. 4.11). They release inhibitory cytokines (e.g. IL-10, IL-35, TGF-β) and can induce apoptosis of target effector T cells via perforin and granzymes. Tregs also interfere with metabolic functions in their target T cells by depriving them of IL-2 (which results in apoptosis), increasing their intracellular levels of cAMP (which inhibits T-cell proliferation and IL-2 production), and increasing pericellular levels of adenosine (which is cytotoxic). The latter is achieved by the conversion of ATP to adenosine via CD39 and CD73, two ectonucleotidases expressed on the Treg membrane. Furthermore, negative regulation of the maturation and function of APCs occurs through the interaction of CTLA-4 and lymphocyte-activation gene-3 (LAG-3) on Tregs with CD80/CD86 and MHC class II ligands, respectively, on APCs. Induction of the tryptophan-degrading enzyme indoleamine 2,3-dioxygenase (IDO) in DCs has been suggested as another mechanism by which Tregs exert suppression.

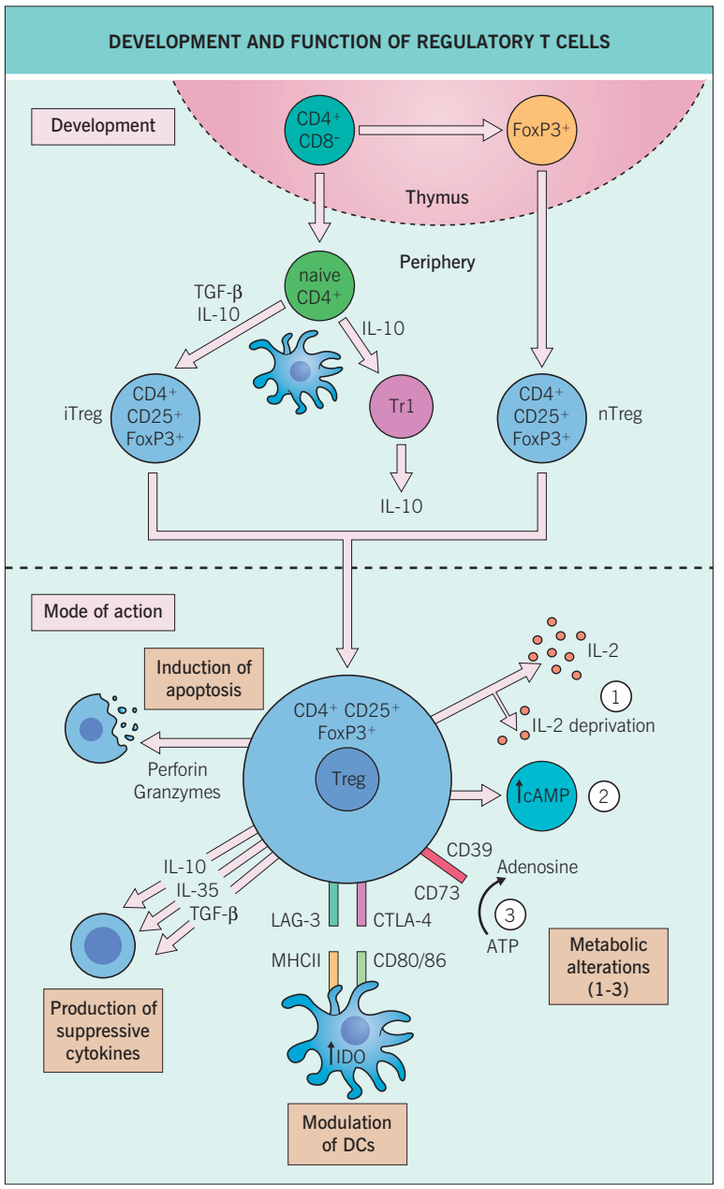

Fig. 4.11 Development and function of regulatory T cells. Natural regulatory T cells (nTregs), which express CD4, CD25 and FoxP3, develop from $CD4^+CD8^-$ T cells in the thymus. In the periphery, naive conventional $CD4^+$ T cells (in the presence of interleukin [IL]-10 and/or transforming growth factor-β [TGF-β]) can develop into $FoxP3^-$ regulatory type 1 cells (Tr1) or induced regulatory T cells (iTreg) that express CD24, CD25 and FoxP3. Tregs exert their inhibitory functions in several ways. They release inhibitory cytokines (e.g. IL-10, IL-35, TGF-β), induce apoptosis of their target effector T cells via release of granzymes and perforin, and interfere with metabolic functions of their target T cells. The latter can be accomplished by: (1) IL-2 deprivation, which triggers apoptosis; (2) transferring cAMP, which inhibits proliferation and IL-2 production, into target cells; and (3) increasing pericellular levels of cytotoxic adenosine via conversion of ATP to adenosine by CD39 and CD73, two ectonucleotidases expressed on the surface of Tregs. Tregs also modulate dendritic cell (DC) maturation and function via interaction of cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4) and lymphocyte-activation gene-3 (LAG-3) on Tregs with their ligands CD80/CD86 and MHC class II, respectively, on DCs and induction of the tryptophan-degrading enzyme indoleamine 2,3-dioxygenase [IDO] in DCs. *Adapted from Workman CJ, et al. The development and function of regulatory T cells. Cell Mol Life Sci. 2009;66:2603–22 and from Sakaguchi S, et al. Regulatory T cells and immune tolerance. Cell. 2008;133:775–87.*

Natural killer T cells

NK T cells are a distinct subset of thymocytes and peripheral T cells that have characteristics of both T cells and NK cells[90]. They express the NK marker NK1.1 and an invariant TCR restricted to CD1d. NK T cells produce large amounts of various cytokines, including IFN-γ, IL-4 and IL-10. Since they are present at the early stages of ontogeny in the thymus, they are thought to be involved in the differentiation of various T-cell subsets, especially Th2 cells. They may also play a role in the control of autoimmunity, since NK T cells are numerically and functionally deficient in mice with autoimmune diseases. NK T cells also seem to contribute to UV-induced immunosuppression, and they down-regulate immune responses to UV-induced tumors[91].

γ/δ T Cells

A small proportion of T cells carry a TCR composed of γ and δ (rather than α and β) protein chains. Under normal conditions, the great majority of T cells detected in the skin belong to the α/β type. However, in certain infectious diseases such as leprosy and leishmaniasis, γ/δ T cells can account for almost one-third of the T cells infiltrating the

skin. The exact functional role of γ/δ T cells remains to be determined, but they may be involved in the recognition of non-peptide moieties expressed by microbial pathogens[92].

Dendritic epidermal T cells

$CD3^+$ lymphocytes found in murine epidermis are dendritic in shape and are therefore designated as dendritic epidermal T cells (DETCs)[93]. These murine DETCs express a γ/δ type of TCR with limited diversity. The same TCR configuration is detected in early thymocytes, giving rise to speculation that fetal thymocytes are the progenitors of DETCs. Alternatively, maturation could take place in the skin. Despite extensive studies, the functional role of DETCs could not be clarified completely. It was proposed that DETCs protect stressed keratinocytes and exhibit NK function, but also down-regulate T-cell responses. To date, a human equivalent of the rodent DETC has not been identified.

Lymphocyte recruitment

A major challenge for lymphocytes is to be at the right place at the right time to meet "their" antigen. Naive lymphocytes encounter their antigens for the first time in lymphoid organs, while memory cells have their encounters in the periphery. There is continuous recirculation of naive T cells between the blood and lymphoid organs[94]. Expression of the surface molecule L-selectin (CD62L) allows naive T cells to attach to and roll on the inner surface of the high endothelial venules, specialized postcapillary venules within the lymph nodes. The venules express a chemokine, called the secondary lymphoid-tissue chemokine (SLC/CCL21)[95], which activates T cells via interaction with the chemokine receptor CCR7. Subsequently, T cells adhere tightly to the venules via interaction of endothelial intercellular adhesion molecule-1 (ICAM-1, CD54) with lymphocyte function antigen-1 (LFA-1, CD11a). Finally, T cells extravasate through the high endothelial venules into the lymph node and accumulate in the T-cell-rich areas. They can return into the bloodstream by leaving the lymph node via the efferent lymphatics. Since naive T cells lack the necessary expression of a specific combination of adhesion molecules and chemokine receptors, they cannot enter extranodal tissues from the blood, forcing them back into the lymph nodes.

Upon activation by APCs presenting specific antigenic peptides, T cells start to proliferate and begin to express activation molecules, thereby developing into memory T cells. During this process, they express new surface molecules that allow them to exit the blood vessels and enter extranodal tissues[96]. A hallmark of memory T cells is their ability to "remember" the anatomic location that the lymph node was draining. Due to the expression of specific adhesion molecules, they exhibit the capacity to migrate primarily into the sites where the antigen was first encountered by the host. Hence, lymph nodes draining different organs generate distinct, "tissue-specific" memory T cells. Approximately 10% to 20% of all memory T cells are skin-homing due to their expression of a glycoprotein called cutaneous lymphocyte antigen (CLA)[65].

CLA is generated by modification of the pre-existing P-selectin glycoprotein ligand-1 (PSGL-1, CD162) by glycosylation enzymes[97]. Memory T cells entering the skin express CLA, whereas memory T cells found in other tissues are primarily CLA-negative. The function of CLA (recognized by the antibody HECA-452) is to allow the early tethering of T cells to the endothelium of cutaneous postcapillary venules. This step leads to the subsequent slowing, arrest and extravasation of the T cells. The endothelial ligand for CLA is E-selectin (CD62E), which is constitutively expressed at low levels on cutaneous microvessels. Its expression is strongly upregulated by inflammatory stimuli. Although interaction between CLA and E-selectin is an important initial step, it does not suffice for transmigration. Interactions of LFA-1 and the β-integrin very late antigen-4 (VLA-4) on T cells with ICAM-1 (CD54) and VCAM-1 (CD106), respectively, on endothelial cells produces the firm adhesion that is required for extravasation of T cells from the blood into the skin (see Ch. 102).

B Cells

The major task of B cells is the production of immunoglobulins (antibodies) that bind to specific antigens. Antibodies also interact with components of the innate immune system by preventing foreign organisms from adhering to mucosal surfaces, activating complement and opsonizing bacteria for phagocytosis. Immunoglobulins are secreted products of mature B cells. However, during early B-cell development, immunoglobulins function as antigen-specific B-cell receptors on the cell membrane, equivalent to the TCR on T cells. CD19, CD20 and CD22 are the main markers currently used to detect B cells. Activation of B cells results in cell division and maturation into plasma cells, which secrete the specific antibodies.

Immunoglobulins

Immunoglobulins consist of two identical heavy chains and two identical light chains, linked together by disulfide bonds[98] (Fig. 4.12). The N-terminus of each chain contains a variable domain that binds the antigen through three hypervariable complementarity-determining regions (CDRs). The C-terminal domains of the heavy and light chains form the constant regions. Five classes of immunoglobulin (IgG, IgA, IgM, IgD and IgE) are defined by the amino acid sequences of the constant regions of the heavy chains, and the designation of κ or λ depends on the constant region of the light chain. The class/subclass and titer of the antibody that is formed depend on the physical and chemical properties of the antigen; the site, duration, repetition and amount of antigen exposure; and the individual's propensity to recognize the antigen as foreign.

Digestion of immunoglobulins with the enzyme papain yields an antigen-binding fragment termed Fab and a fragment that spontaneously crystallizes with time and thus is called the Fc portion. Immunoglobulins are divalent, since twice as many Fab fragments than Fc portions are obtained upon cleavage with papain. Digestion of immunoglobulins with pepsin provides Fab fragments that are disulfide bond-linked and thus called F(ab) fragments.

Through their CDRs, antibodies recognize the conformational structure of their epitopes. No antigen processing is required. As for the TCR, extensive gene rearrangement involving V, D and J regions allows the generation of a nearly infinite variety of immunoglobulins specific for any putative antigen[56] (see T-cell receptor diversity above). An even greater repertoire of B-cell receptors than TCRs is produced, since further

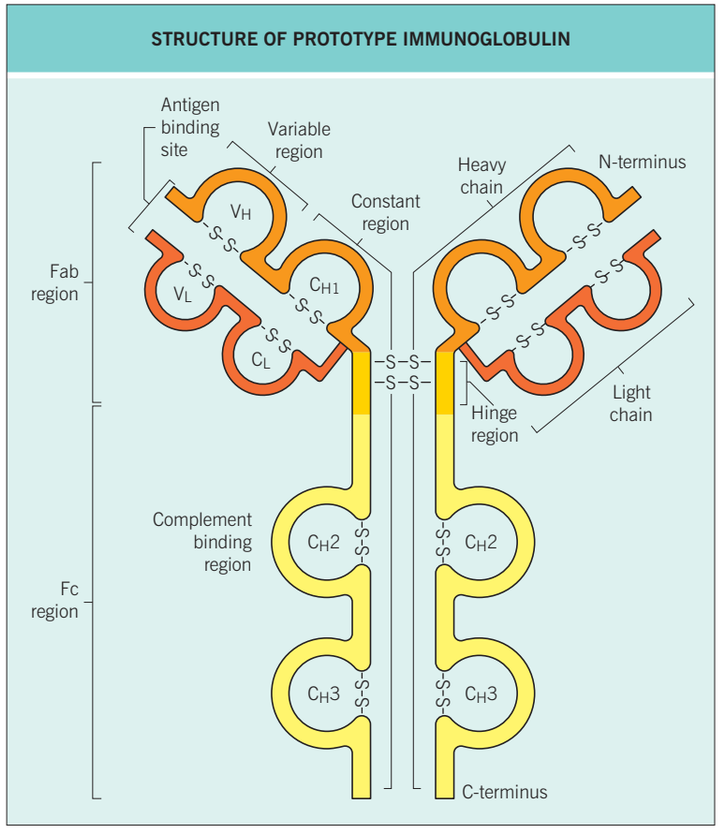

Fig. 4.12 Structure of a prototype immunoglobulin. The basic immunoglobulin structure consists of two identical light polypeptide chains and two identical heavy polypeptide chains, which are linked together by disulfide bonds. The antigen-binding site is at the N-terminal end.

gene rearrangement of immunoglobulins occurs during B-cell division after antigen stimulation, a process called somatic hypermutation.

The ability to induce effector functions resides in the Fc portion of the heavy chain. The Fc portion of IgG contains domains called C_H1, C_H2 and C_H3 for IgG. Complement activation is mediated via the C_H2 domain, while binding to macrophages or monocytes is mediated via the C_H3 domain. Binding of the Fc portion of IgG to phagocytic cells via their Fcγ receptors promotes phagocytosis of antibody–antigen complexes. Three receptors for human IgG exist. FcγRI (CD64) binds monomeric IgG with a high degree of affinity. FcγRII (CD32) is broadly distributed on cells and binds only complexed IgG with a low degree of affinity. FcγRIII (CD16) is expressed on macrophages, NK cells and some T cells, and it interacts with monomeric as well as complexed IgG. IgA binds only to the FcαR (CD89), while IgE can bind to three surface molecules: FcεRI, FcεRII (CD23) and the IgE-binding protein.

Immunoglobulin M

With a size of approximately 900 Da, IgM is the largest immunoglobulin. IgM molecules are pentamers that (in addition to light and heavy chains) contain one J chain. IgM is the major immunoglobulin produced in the primary immune response. Upon binding to its antigen, IgM induces agglutination and activates the classical complement pathway.

Immunoglobulin G

IgG is the most abundant immunoglobulin, accounting for approximately 75% of the total amount of serum immunoglobulin, and the major immunoglobulin of the secondary immune response. Four subclasses (IgG1, IgG2, IgG3, IgG4) are defined by the amino acid sequences of their constant region. They differ in their ability to activate complement. While IgG1 and IgG3 are potent activators of the classical complement pathway, IgG2 is less effective and IgG4 lacks such ability. In addition, IgG1 and IgG3 bind more avidly to mononuclear cells, i.e. they are more cytophilic. Most of the autoimmune dermatoses caused by autoantibodies are mediated by IgG, most often IgG4.

Immunoglobulin A

IgA is the predominant immunoglobulin present in mucosal surfaces, where it protects the host from invasion of microorganisms. IgA can activate the complement system via the alternative (but not the classical) pathway. Two subclasses of IgA exist, IgA1 and IgA2. IgA molecules can be joined by a J chain; this dimer form is mostly found in secretions, while in the serum, IgA circulates primarily as a monomer. IgA molecules can be involved in the pathogenesis of bullous autoimmune diseases.

Immunoglobulin E

IgE is the classic anaphylactic antibody that mediates most immediate allergic and anaphylactic reactions. Although in normal serum IgE is present in only very small amounts (10–70 microg/100 ml), just a few molecules appear to be required for sensitization. Mast cells and basophils express high-affinity receptors for the Fc portion of IgE (FcεRI). Antigens, anti-IgE antibodies or other substances that cross-link at least two IgE molecules bound on mast cells induce the release of mediators such as histamine, serotonin, leukotrienes and prostaglandins (see Ch. 18). The second IgE receptor, FcεRII (CD23), exhibits weaker binding affinity and is expressed on macrophages, eosinophils, platelets, and particular subtypes of T and B cells. Macrophages stimulated via activation of FcεRII exhibit increased phagocytic and cytotoxic activity; secrete prostaglandins, leukotrienes and lysosomal enzymes; and generate superoxides.

In the past, it was believed that mast cells and basophils were the only cells that express the high-affinity FcεRI receptor. However, it became clear that LCs[30], dermal DCs and peripheral blood DCs as well as monocytes from atopic individuals can bind monomeric IgE via the high-affinity FcεRI[99]. FcεRI, both quantitatively and qualitatively, is the crucial serum IgE-binding structure on APCs of atopic individuals and functions as an allergen-focusing molecule. Allergens are more efficiently taken up, processed and presented to T cells following targeting to APCs via the FcεRI. Thus, FcεRI-IgE-dependent allergen presentation may lower the threshold to elicit allergen-specific T-cell responses in atopic individuals[95]. This may perpetuate allergen-specific IgE production and even modulate T-cell-mediated delayed-type hypersensitivity reactions in allergen-exposed tissues.

Immunoglobulin D

The function of IgD still remains mysterious. Recent evidence suggests that IgD participates in respiratory immune defense[100]. It binds to basophils and mast cells, stimulating their production of antimicrobial factors. IgD may also exert proinflammatory functions, as illustrated by the hyperimmunoglobulinemia D with periodic fever syndrome (HIDS; see Table 45.2).

B-cell activation

B cells can respond to some antigens in a T-cell-independent manner[101]. Such antigens have numerous repeating epitopes (mainly polysaccharides), which bind and cross-link multiple B-cell receptors and activate the B cells directly to secrete IgM. However, this response is limited to IgM and is of short duration and poor specificity due to the lack of germinal center formation, affinity maturation, Ig class switching and memory.

Most B-cell responses are activated in a T-cell-dependent manner. Upon recognition by the specific IgM on the B-cell surface, the antigen is internalized, processed, and re-expressed within the MHC class II molecule on the surface. As a result, the B cell can present the antigen to a specific T cell. Primed Th cells, in turn, secrete cytokines (IL-2, IL-4, IL-5, IL-6, IFN-γ) that function as B-cell growth factors, inducing proliferation, isotype switch and maturation to plasma cells. Activation of CD40 (which is expressed on B cells) by CD40 ligand (CD154) expressed on T cells is needed for isotype switching from the initial IgM to an IgG response (Fig. 4.13). Once the switch from IgM to another isotype has occurred, some of the activated cells become long-lived memory cells that can rapidly produce antibodies upon re-challenge with the same antigen. Mutations in the genes encoding CD40 ligand and CD40 are associated with forms of primary immunodeficiency known as hyper-IgM syndromes, which are characterized by low or undetectable levels of IgG, IgA and IgE but elevated levels of IgM (see Ch. 60).

Upon subsequent antigen exposure, B cells become activated by follicular DCs, which are located in the germinal centers of the lymph nodes. Follicular DCs bear Fc and complement receptors and bind immune complexes. In contrast to "conventional" DCs, follicular DCs do not endocytose and process antigens. Instead, they trap antigen–antibody complexes and provide intact antigen for interaction with the

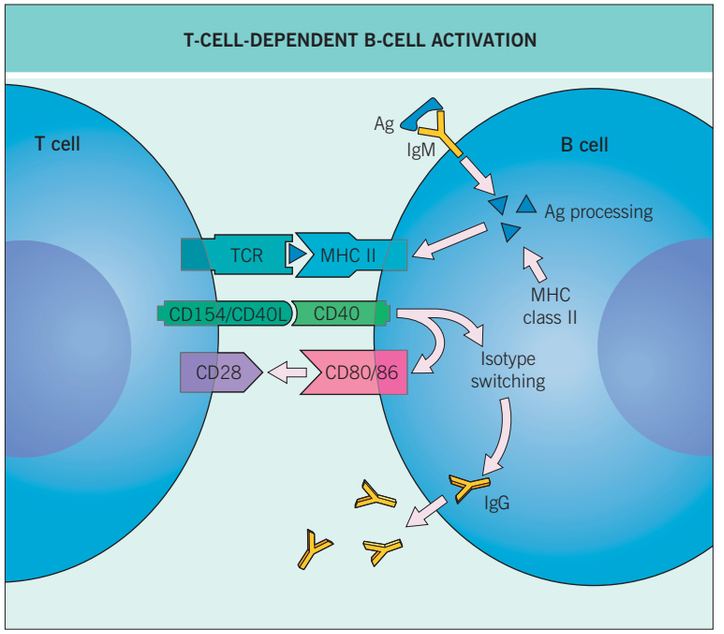

Fig. 4.13 T-cell-dependent B-cell activation. B cells present the antigen in association with MHC II molecules to $CD4^+$ T cells. This results in the upregulation of CD154/CD40 ligand which interacts with CD40 expressed on B cells. CD40–CD40 ligand interaction causes isotype switching of immunoglobulins and upregulation of CD80/86 which interacts with CD28 expressed on T cells. This results in further activation of T cells. Ag, antigen; CD40L, CD40 ligand; Ig, immunoglobulin; MHC II, major histocompatibility complex II.

B-cell receptor. This interaction stimulates B-cell activation and differentiation. In addition, follicular DCs form immune complex-coated bodies (iccosomes) that are taken up by B cells. Upon processing, B cells present this follicular DC-derived antigen to T cells and thus may obtain T-cell assistance[102].

Allergic Contact Hypersensitivity

Allergic contact hypersensitivity (CHS) is highly relevant for dermatologists, since it is the pathogenic basis for allergic contact dermatitis, a frequent inflammatory dermatosis. In addition, important basic immunologic discoveries have been made utilizing the model of CHS[103].

Induction of CHS

Most contact allergens are low-molecular-weight chemicals that, after penetrating the skin, have to couple with host proteins to be able to act as full antigens. This process is called haptenization, and the low-molecular-weight allergens are referred to as haptens. Upon epicutaneous application of a hapten in a naive host, APCs in the skin take up the hapten, migrate to the regional lymph nodes and present it to naive T cells (Fig. 4.14). Although this was previously thought to be done only by LCs, it has been established that other cutaneous APCs (e.g. dermal DCs) can present antigens, and the role of LCs as the primary APC in the skin is currently under debate (see Antigen presentation above).

During the emigration from the skin, APCs convert from a "resting" into an "activated" functional state. This process is initiated by keratinocytes, which secrete inflammatory cytokines as a result of hapten application; triggering of TLRs and direct effects of haptens on the APCs may also be involved. APC activation is associated with induction of cytokine secretion (e.g. IL-1β, IL-6, IL-12, chemokines); enhanced cell surface molecule expression (e.g. MHC class I and II molecules, adhesion molecules, costimulatory molecules); and altered antigen uptake, processing and presenting capacity[103].

Activation and induction of emigration of APCs seems to be dependent on the capacity of haptens to stimulate elaboration of IL-1β by APCs. IL-1β secretion can be immediately induced by epicutaneous hapten application and appears to be specific for haptens, since it is not observed with irritants or tolerogens. In addition, other cytokines, including chemokines, TNF-α and GM-CSF, may also contribute to APC activation and migration. Hence, the hapten itself, through its capacity to provoke a specific cytokine pattern, seems to be the initial trigger that activates APCs and induces sensitization (see Fig. 4.14).

Presentation of the hapten by APCs in the regional lymph nodes causes activation of naive T cells carrying the appropriate TCR and results in the generation of effector cells. In contrast to other types of delayed-type hypersensitivity responses, which are mediated by $CD4^+$ T cells, most haptens induce a T-cell response of predominantly $CD8^+$ effector T cells[103]. In addition, Treg populations that inhibit the CHS response are induced. The balance between effector T cells and Tregs seems to depend on the dose of the antigen applied, since application of extremely low doses of the hapten does not result in sensitization, but rather in tolerance[81].

Elicitation of CHS

T cells that have been primed in the draining cutaneous lymph nodes express the skin-homing marker CLA and thereby exhibit the capacity to enter the skin[65]. These T cells become activated when they encounter their relevant hapten presented by APCs within the skin. However, in contrast to the sensitization phase, antigen presentation can now be effectively performed by other cells (including keratinocytes, dermal mast cells and macrophages) that are capable of presenting antigen at least in a MHC class I-restricted fashion[103]. Alternatively, inflammatory cells that infiltrate the site of hapten application very early during the response may function as APCs.

The earliest histopathologic findings during a CHS response are mast cell degranulation, vasodilation and an influx of neutrophils, which is followed by infiltration of monocytes and T cells (Fig. 4.15). However, the pathophysiologic events that result in allergic contact dermatitis are clearly T-cell-dependent, since T-cell-deficient mice are unable to mount a CHS response. Furthermore, low doses of hapten that are sufficient to stimulate hapten-specific T cells are insufficient to elicit a CHS response. This indicates that the elicitation of a CHS response

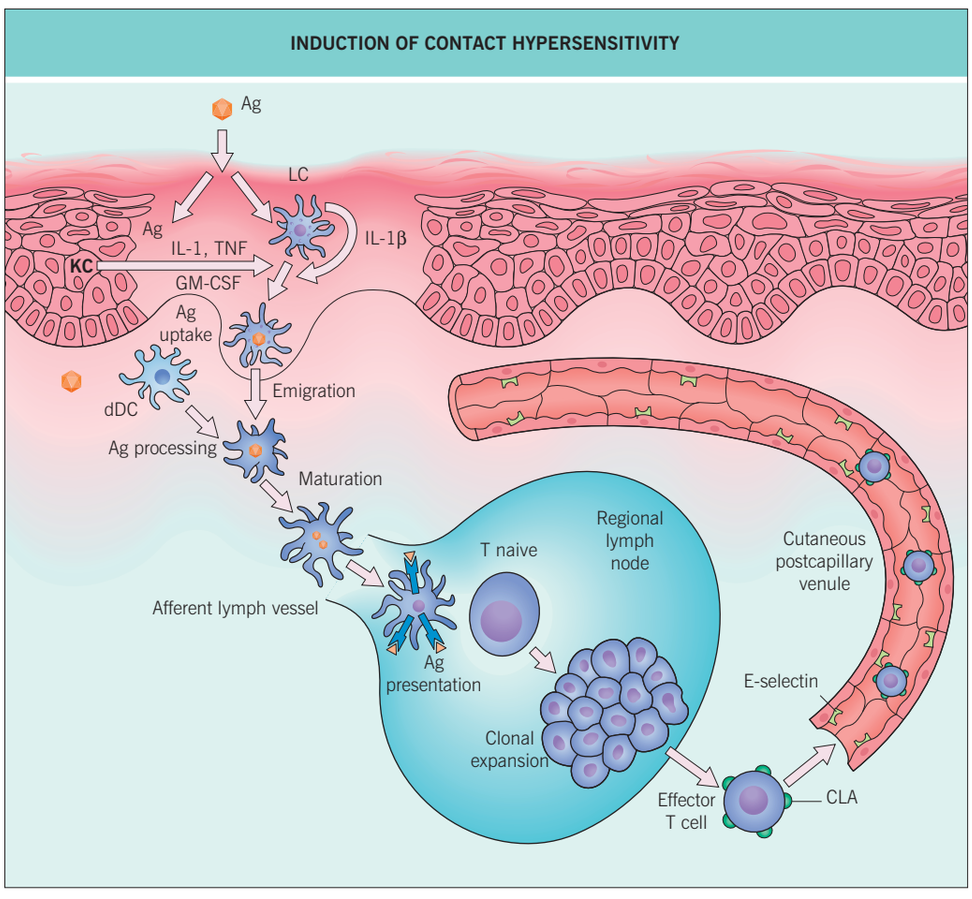

Fig. 4.14 Induction of contact hypersensitivity. Application of contact allergens (Ag) induces the release of cytokines by keratinocytes (KCs), Langerhans cells (LCs) and other cells within the skin. These cytokines in turn activate LCs and/or dermal dendritic cells (dDCs), which uptake the antigen and emigrate into the regional lymph nodes. During this process, they develop into mature antigen-presenting cells. In addition, the antigen is processed, re-expressed on the surface, and, finally, presented to naive T cells in the regional lymph node. Upon antigen presentation, T cells bearing the appropriate T-cell receptor clonally expand and become effector T cells. These alter their migratory behavior due to the expression of specific surface molecules like cutaneous lymphocyte antigen (CLA). Effector T cells recirculate into the periphery, where they may later meet the antigen again.

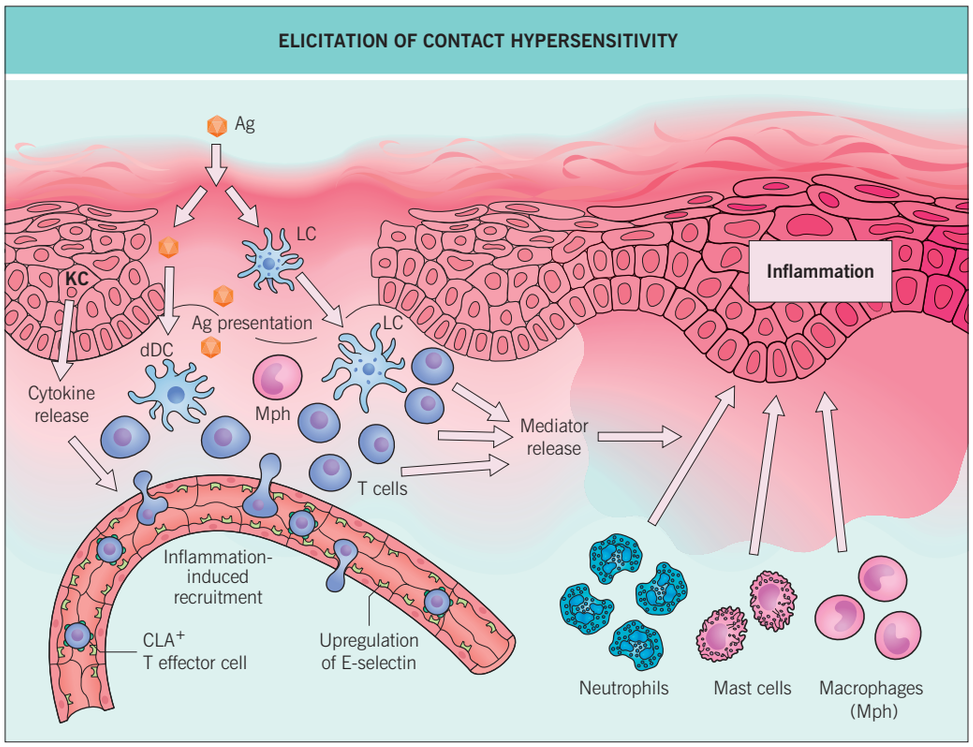

Fig. 4.15 Elicitation of contact hypersensitivity. Application of contact allergens (Ag) into a sensitized individual causes the release of cytokines by keratinocytes (KCs) and Langerhans cells (LCs). These cytokines induce the expression of adhesion molecules and activation of endothelial cells, which ultimately attracts leukocytes to the site of antigen application. Among these cells, T effector cells are present, which are now activated upon antigen presentation either by LCs, dermal dendritic cells (dDCs) or infiltrating macrophages (Mphs). Antigen-specific T-cell activation again induces the release of cytokines by T cells. This causes the attraction of other inflammatory cells, including granulocytes and macrophages, which ultimately cause the clinical manifestation of contact dermatitis. CLA, cutaneous lymphocyte antigen.

requires, in addition to hapten-specific recognition, a proinflammatory stimulus that can be provided in a dose-dependent manner by the hapten itself[104].

The Role of Keratinocytes in Skin Immune Responses

Keratinocytes are also vital contributors to the generation of a cutaneous immune response. Due to their close physical proximity, keratinocytes can affect LCs by the expression of specific surface molecules. In addition, keratinocytes are able to provide signals to LCs and other APCs in a contact-independent manner via the release of soluble mediators, particularly cytokines, eicosanoids and neurohormones.

Secretory capacity of keratinocytes

For decades, keratinocytes were regarded as primitive cells endowed only with the capacity to produce keratins and provide a mechanical barrier to the outside world. Therefore, it was quite surprising when it was discovered in the early 1980s that keratinocytes could secrete immunologic and inflammatory mediators. The first cytokine identified as being released from keratinocytes was IL-1. Subsequently, keratinocytes were shown to have the capacity to secrete a multitude of soluble mediators. These included pro- and anti-inflammatory, immunomodulatory and immunosuppressive cytokines[105]. The inflammatory mediators released by keratinocytes include IL-1, IL-6, TNF-α, IL-8 and other members of the chemokine family. Anti-inflammatory and immunosuppressive activity can be mediated by keratinocytes via the release of IL-10, the IL-1 receptor antagonist and TGF-β. Keratinocyte-derived immunomodulatory mediators also include IL-7, IL-12, IL-15, IL-18, IL-19, IL-20, IL-23, GM-CSF, G-CSF and M-CSF. Other cytokines are clearly *not* produced by keratinocytes, e.g. IL-2, IL-4 and IFN-γ.

Although some cytokines are produced in tiny quantities by keratinocytes, even low concentrations may exert an effect on the local microenvironment. Any perturbation of the skin can induce the release of mediators by the keratinocytes. For example, UV radiation is a potent inducer of cytokine production and release (see Ch. 86). Chemicals with the potential for inducing either irritant or allergic reactions also cause cytokine release from keratinocytes. In addition to cytokines, keratinocytes elaborate prostaglandins (PG) and leukotrienes. Leukotriene B_4 is a potent neutrophil chemoattractant, and PGE_2 possesses both inflammatory and immunosuppressive properties. For example, the erythema caused by UV radiation is partially mediated by PGE_2. There is additional evidence that the skin, and especially keratinocytes, can function as a source of neuropeptides, particularly substance P and pro-opiomelanocortin (POMC)-derived peptides (e.g. α-melanocyte-stimulating hormone)[105].

Keratinocytes as immune targets and initiators

In addition to the secretion of cytokines, keratinocytes express a variety of immunologically relevant surface molecules. Thus, keratinocytes function not only as effectors, but also as targets for immune reactions. Like other nucleated cells, keratinocytes express MHC class I molecules and therefore can be attacked by $CD8^+$ Tc cells, particularly after viral infection. MHC class I-restricted T-cell-mediated cytolysis appears to be involved in CHS, lichen planus, fixed drug eruptions, cutaneous GVHD, and herpes simplex virus infections.

Although keratinocytes do not express MHC class II molecules under normal conditions, they can be induced to do so in inflammatory settings[106]. The major inducer of MHC class II expression on keratinocytes is IFN-γ. Accordingly, MHC class II expression by keratinocytes is frequently observed in association with pronounced lymphocytic infiltrates. Several studies have shown that MHC class II-bearing keratinocytes can induce proliferation of allogeneic $CD4^+$ T-cell lines, but not of resting T cells. Nevertheless, it is important to note that despite their capacity to express MHC class II molecules, keratinocytes are not able to induce a primary T-cell response, a major difference from APCs.

On the other hand, upon overexpression of immunologically relevant molecules, keratinocytes may play a pathogenic role. Transgenic mice that overexpress IFN-γ (a cytokine not derived from keratinocytes) within the basal layer of the epidermis develop an autoimmune phenotype[107]. Autoimmunity is also induced when LCs are constantly activated by keratinocytes through CD40/CD40L interactions. Transgenic mice overexpressing CD40L in the basal epidermis demonstrate a dramatic decrease in the number of LCs within the epidermis that may be due to emigration of CD40-activated LCs[108]. These mice suffer from chronic inflammation of the skin and, over time, develop systemic lupus-like features (e.g. lymphadenopathy, antinuclear antibodies, proteinuria). These models indicate that keratinocytes not only serve as targets of the immune system, but under certain conditions also directly modulate the initiation and course of immune responses.

Pruritus pathways 99
Mediators of pruritus 101
Treatment of pruritus 105

Key features

- Two subsets of pruritoceptive C neurons (responding to histamine and cowhage, respectively) have been identified, and these parallel pathways activate distinct spinothalamic tract neurons
- Itch mediators act both peripherally (e.g. histamine, proteases, interleukin-31) and centrally (e.g. opioids, gastrin-releasing peptide receptors) via several mechanisms
- There is an overlap between chronic itch and chronic pain, including activation of multiple brain areas and associated neuromediators and receptors (e.g. nerve growth factor, neurotrophin 4, *t*ransient *r*eceptor *p*otential *v*anilloid [TRPV] receptor)
- Significant cross-talk between cutaneous nerve fibers and the stratum corneum is a possible mechanism for pruritus associated with impaired barrier function (e.g. xerosis, atopic dermatitis)
- Combination therapies with typical and systemic drugs that reduce itch sensitization by counteracting the responsible mediators represent promising treatment strategies

INTRODUCTION

The skin is a sensory organ with a dense network of highly specialized afferent sensory nerves that convey sensations such as pain, itch, touch, temperature, vibration and pressure (Table 5.1); efferent autonomic nerve branches are also present. Neuropeptides such as nerve growth factor (NGF) and substance P are secreted from nerve fibers, with multiple effects that include immune modulation. Itch (pruritus) is the dominant symptom of many cutaneous diseases. Almost all inflammatory skin disorders can result in pruritus, which is often perceived by the patient as the most unendurable symptom of his or her condition. Pruritus can also occur in association with systemic disease (e.g. renal failure or cholestasis; see Ch. 6), psychiatric conditions (see Ch. 7) and damage to nerve fibers[1,2]. Itch is a multidimensional phenomenon with sensory discriminative, cognitive, evaluative and motivational components. In most instances, itch results from interactions that involve the brain–skin axis.

Pruritus has many similarities to pain. Both are unpleasant sensory experiences that can impair quality of life in affected individuals. However, the behavioral reaction patterns differ – pain elicits a reflex withdrawal, whereas itch leads to a scratching response. Despite being an extremely common complaint[3] and a sensation so rudimentary that almost every two- or four-footed creature experiences it, medical science is still struggling to understand the mechanisms of itch and how it can be inhibited.

The connection between itch and scratching is so close that in some languages the same word refers to both itch and scratch. Itch is restricted to the skin, tracheal mucous membrane and several mucocutaneous junctions (e.g. conjunctivae). Interestingly, the nerves in the deeper layer of the reticular dermis and subcutaneous fat do not transmit itch.

PRURITUS PATHWAYS

Significant advances in our understanding of itch neurophysiology have been achieved in the past decade. Examples include identification of specific nerve fibers that transmit itch peripherally and centrally, as well as the discovery of new itch mediators[4]. While the concept of pruritus as a sensory modality entirely separate from pain was not generally appreciated until the mid-twentieth century, studies have clearly identified individual histamine-sensitive and non-histaminergic C nerve fibers that transmit itch[5,6]. C nerve fibers that transmit itch have exceptionally slow conduction velocities (2–8 cm/second), innervate unusually wide territories, and represent ≤5% of the total C fibers.

Histamine-sensitive C fibers are sensitive to thermal as well as pruritogenic stimuli but not to mechanical stimuli; in contrast, the vast majority of C fibers are sensitive to mechanical and heat stimuli but are entirely insensitive to histamine[7]. The co-responsiveness of itch-transmitting C neurons to temperature changes is clinically relevant, as raising the temperature of the skin lowers the threshold of these receptors to pruritogenic stimuli[8]; this provides an explanation for aggravation of pruritus in a warm environment. However, the fact that oral antihistamines are ineffective in the treatment of most types of pruritus suggests that other fibers have important roles in the sensation of itch[9].

Indeed, a distinct parallel pathway of non-histaminergic C nerve fibers that transmit itch was recently discovered in the peripheral nervous system of humans and the spinothalamic tract of primates[10,11]. These fibers are activated by spicules of the ubiquitous tropical legume cowhage (*Mucuna pruriens*), which is known to induce an intense sensation of itch when rubbed, inserted or injected into the skin, without producing a histaminergic axon reflex[12]. The mechanism by which cowhage induces itch involves the release of a protease (mucunain; contained within the spicules) that activates proteinase-activated receptor (PAR)-2 and PAR-4[13]. Cowhage-sensitive fibers are not itch-specific, transmitting a burning sensation together with itch and also sensitive to mechanical and other stimuli. PAR-2 receptors have a major role in mediating itch in patients with atopic dermatitis[14] (see Ch. 12), explaining the hypersensitivity to mechanical stimuli (e.g. contact with wool) in these individuals. The non-histaminergic, polymodal C nerve fibers stimulated by mucunain may also have clinical relevance in chronic itch.

Gastrin-releasing peptide receptor (GRPR)-positive neurons that transmit itch but not pain are found in the spinal cord of mice; their role in itch pathophysiology in humans remains to be determined[15,16]. Toll-like receptor 7 (TLR-7) was recently found to be expressed in C fibers and to have a role in itch (especially that elicited by non-histaminergic pruritogens) but not pain sensations in mice[17].

Another important observation is that the perceived sensation of pruritus can vary greatly in quality[18–22]. Patients may describe burning, pricking, "insects crawling" on the skin, or even a tickle, but the neurophysiologic and psychologic correlates of these qualitative differences have not yet been elucidated. Recent information obtained from itch questionnaires has enabled a better understanding of the different characteristics of itch and awaits translation into biologic explanations.

PRIMARY AFFERENT NEURONS THAT INNERVATE THE SKIN				
Fiber	**Diameter**	**Myelination**	**Conduction velocity**	**Responds to**
A-beta (Aβ)	Large	+	>30 m/s	Light touch Moving stimuli
A-delta (Aδ)	Small	+	2–30 m/s	Pain (nociceptors) Thermal Mechanical Chemical, including pruritogens
C	Small	–	<2 m/s	Pain (nociceptors) Itch*, histamine-sensitive† Itch*, cowhage-sensitive‡ Thermal† Mechanical

*~5% of total C fibers transmit itch.
†Separate C fibers carry both pruritogenic and thermal stimuli, but not mechanical stimuli.
‡Transmit pruritus accompanied by a burning sensation; also sensitive to mechanical stimuli.

Table 5.1 Primary afferent neurons that innervate the skin.

Central Pathways to Higher Nervous System Centers

In the spinal cord, nociceptor C neurons synapse with secondary transmission neurons in the gray matter of the dorsal horn (Fig. 5.1). These neurons then cross over and ascend in the lateral spinothalamic tract to the thalamus. Studies using microneurography identified a subclass of lamina I spinothalamic tract neurons that are excited by iontophoretically administered histamine[23]. Later studies have found that these nerve fibers are also able to transmit pain upon stimulation by capsaicin and bradykinin[7]. Neurophysiology experiments in primates have discovered that cowhage-induced itch stimulates a distinct population of spinothalamic tract neurons that are not involved in the transmission of histamine-mediated itch[11].

Much of our current understanding of supraspinal processing of itch and the corresponding scratch response is derived from studies in human subjects utilizing positron emission tomography (PET) and functional MRI during stimulation with histamine and (more recently) cowhage[24–28]. In healthy individuals, induction of itch in this manner can elicit co-activation of the anterior and posterior cingulate cortex, precuneus, somatosensory areas I and II, supramarginal gyrus, inferior parietal lobe and insula-claustrum complex[28]. In one study, atopic dermatitis patients exhibited significantly more activation of the posterior cingulate cortex and precuneus (a cortical area involved in integrative tasks such as visuospatial imagery, episodic memory retrieval and self-awareness) than did healthy controls[29]. This highlights the emotional and affective processing of itch experience in atopic individuals, in whom the degree of brain activation correlated with itch intensity and the severity of the atopic disease[29]. In healthy subjects, scratching has been found to inhibit the activation of the cingulate cortex and to activate the prefrontal cortex and cerebellum. The cerebellum may have a role in coordination of the itch–scratch cycle[30,31]. Scratching inhibits histamine-evoked activity of spinothalamic neurons in primates, but not spontaneous activity or that stimulated by pain[32].

Activation of multiple brain areas suggests a lack of a single "itch center", emphasizing the multidimensionality of the itch sensation. Pain demonstrates a similar pattern of brain activation involving many of the same cortical regions[33].

Seeing other people scratching can induce sensations of itch and an urge to scratch[34]. However, the central nervous mechanisms of this transmission, which appear to be beyond conscious control, are poorly understood. Psychophysical studies have shown that the perception of itch intensifies in atopic dermatitis patients when they are exposed to visual cues of itch, which also trigger a scratching response[34]. More studies are needed to verify the working hypothesis that itch "contagion" involves processing in associative cortical networks such as "mirror neurons" of the prefrontal cortex.

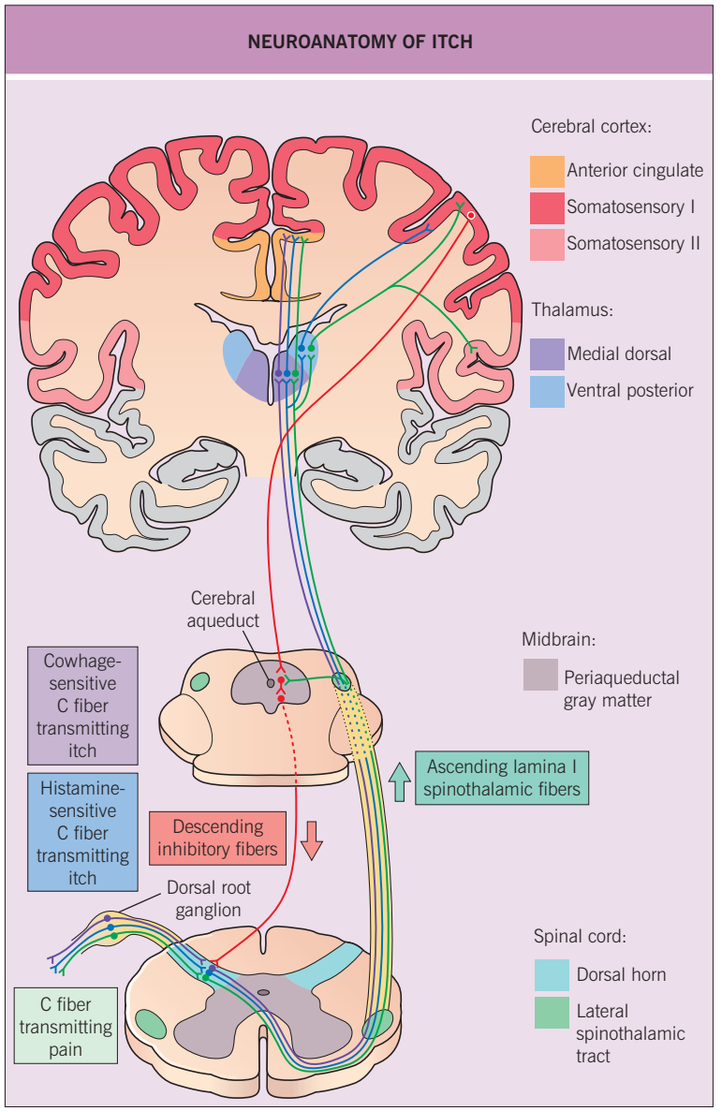

Fig. 5.1 Neuroanatomy of itch. Itch and pain transmission occur via unmyelinated C nerve fibers that excite lamina I neurons in the dorsal horn of the spinal cord. Two subsets of pruritoceptive C-fiber neurons (which respond to histamine and cowhage, respectively) are conducted through distinct lateral spinothalamic pathways, with projections to the thalamus. Processing of itch through either pathway activates several regions of the brain, which are similar to those involved in pain (see Table 5.4). Concomitant painful stimuli can reduce the sensation of itch, possibly by a descending inhibitory mechanism resulting from activation of the periaqueductal gray matter. In mice, gastrin-releasing peptide receptor-positive neurons transmit itch (but not pain) within the spinal cord; the role of such neurons in humans remains to be determined.
Adapted from Yosipovitch G. Pruritus: an update. Curr Probl Dermatol. 2003;15:137–64.

Pruritus Receptor Units

Removal of the epidermis abolishes the perception of itch, suggesting that pruritus receptor units (which have yet to be identified) are located predominantly within this layer. Light microscopic and ultrastructural studies of human skin have shown the existence of intraepidermal nerve fibers with "free" non-specialized nerve endings extending to the stratum granulosum[35]. Recent studies have identified a subclass of C nerve fibers in the epidermis that express MAS-related G protein-coupled receptors (MRGPRs) and are involved in chloroquine-induced pruritus[36]. The cell bodies of these neurons (located in the dorsal root ganglia) also express gastrin-related peptide (GRP), which binds the GRPRs that are known to relay itch-specific information in the spinal cords of mice[15] (see above).

Keratinocytes express a variety of neural mediators and receptors that appear to be involved in the sensation of itch (see Table 5.2). These

include opioids, proteases, substance P, NGF and neurotrophin 4 as well as their respective receptors, including μ- and κ-opioid receptors, PAR-2, neurotrophic tyrosine kinase receptor type 1 (NTRK1 [TRKA]), and transient receptor potential vanilloid ion channels (particularly TRPV1 and TRPV3). Keratinocytes also have ATP voltage-gated ion channels and adenosine receptor ligands similar to those observed in C nerve fibers involved in pain transmission. These structural similarities to nerve fibers suggest that keratinocytes may be involved in the transduction and generation of itch. PAR-2 receptors are thought to be involved in the itch of atopic dermatitis and mediate cowhage-induced itch (see above). Cathepsin S, an endogenous protease, also induces itch via PAR-2 and PAR-4 receptors[37].

MEDIATORS OF PRURITUS

Various mediators that act centrally and/or peripherally are involved in pruritus, including histamine, proteases, substance P, opiates, NGF and prostaglandins. In inflammatory skin diseases such as urticaria, pro-inflammatory mediators produce pruritus and also cause other signs of inflammation (e.g. erythema due to vasodilation, increased vascular permeability). The relative potencies of the major mediators with regard to these responses (including pruritus) are listed in Table 5.2. Some of these mediators cause pruritus indirectly by evoking release of histamine and other mediators (e.g. substance P and several opioid peptides) from mast cells or by potentiating the actions of other mediators (e.g. prostaglandins E_1 and E_2).

Histamine

Histamine is the archetypal mediator of signs and symptoms of inflammation, including pruritus. In the skin, histamine is contained primarily within the granules of dermal mast cells. Histamine can be released from mast cells upon activation of a range of receptors, including the high-affinity IgE receptor (FcεRI), the KIT receptor for stem cell factor, receptors for neuropeptides (e.g. substance P, NGF) and complement C5a. In IgE-mediated acute urticaria, histamine is released when a specific antigen cross-links adjacent FcεRIs via their α-chains. In autoimmune chronic urticaria, similar cross-linking occurs via functional circulating IgG or (less commonly) IgE autoantibodies that react with epitopes expressed on the α-chain of FcεRI[38] (see Fig. 18.3). Histologically, dermal mast cells and unmyelinated neurons are closely juxtaposed (Fig. 5.2), raising the possibility of a close ("synapsis-like") functional relationship between the immune and nervous systems.

Histamine's pruritic action can be potentiated by prostaglandin E_1 and E_2. Evidence for histamine as the main mediator of pruritus is limited to a few skin diseases, including acute and chronic urticaria and mastocytosis (e.g. urticaria pigmentosa). H_1 antihistamines are usually effective in these disorders.

Recognition of the histamine H_4 receptor has expanded our understanding of the physiologic actions of histamine. The H_4 receptor is expressed by neurons and bone marrow-derived cells (e.g. eosinophils, mast cells, dendritic cells, monocytes, $CD8^+$ T cells). It mediates chemotaxis in the latter group and is thought to have a role in the inflammation and pruritus of atopic dermatitis. H_4 antagonists are under development and have been shown to alleviate experimental pruritus. In animals models of itch, the effects of H_4 antagonists are synergistic with those of centrally acting H_1 antihistamines (e.g. diphenhydramine)[39,40].

Gastrin-Releasing Peptide

As noted above, itch-specific GRPR-positive neurons in the dorsal horn of the spinal cord have been identified in mice[15]. Although named for its role in regulating gastrointestinal functions, the GRP ligand of GRPRs is widely expressed in the CNS and peripheral sensory neurons, including MRGPR-expressing C-fiber neurons that terminate in the epidermis.

Proteinases

Human dermal mast cells produce two proteases: tryptase and chymase. The proximity of dermal mast cells to afferent C-neuron terminals within the skin suggests a functional relationship between these two cell types. Mast cell-derived tryptase contributes to the neurogenic inflammatory response[14]. The activated mast cell releases tryptase (along with other mediators, including histamine), which in turn activates PAR-2, a G protein-coupled receptor present on C- fiber terminals (see Fig. 5.2); specifically, "self-activation" of PAR-2 occurs after cleavage exposes a tethered ligand domain. Kallikrein and cathepsins in the skin have also been implicated in itch induction via activation of PAR-2. The activated C fibers transmit this information to the CNS, where it induces itch. In addition, activation leads to local release of neuropeptides, including substance P and calcitonin gene-related peptide, which induce neurogenic inflammation[41].

Studies using dermal microdialysis have shown that tryptase levels are elevated fourfold in non-lesional forearm skin of atopic dermatitis patients[14]. Expression of PAR-2, the receptor for tryptase, is significantly elevated in the epidermis and cutaneous nerve fibers of eczematous lesions, while non-lesional skin demonstrates a less pronounced increase in PAR-2. It is noteworthy that proteinase (e.g. cathepsin B) activity can also be found in common allergens (e.g. grass pollen, house dust mites)[42], and *Staphylococcus aureus* can induce secretion of proteases; both of these exogenous factors are known to aggravate atopic dermatitis and itch.

The role of epidermal serine proteases in eliciting itch is supported by a mouse model where overexpression of a serine protease led to severe itch and scratching (Table 5.3) as well as the serine protease inhibitor deficiency (leading to excess epidermal protease activity) that underlies Netherton syndrome, an autosomal recessive ichthyosiform disorder with prominent pruritus and atopic manifestations (see Ch. 57). These observations suggest that interactions between proteases and receptors on C fibers play important roles in itch and cutaneous inflammation.

Opioid Peptides

The concept of central pruritus (and the possible involvement of pruritic mediators located within the CNS) is becoming increasingly recognized in both cutaneous and systemic diseases, with implications for treatment. The perception of pruritus is modified by endogenous opiates via central and peripheral opioid receptors. It has been suggested that generalized pruritus is induced by an imbalance between the μ- and κ-opioid systems. Activation of μ-opioid receptors stimulates itch perception, whereas κ-opioid receptor stimulation inhibits μ-receptor effects, both centrally and peripherally[43,44].

Morphine and other endogenous and exogenous μ-opioid receptor agonists are known to cause generalized pruritus[1,2,44–46]. Morphine also causes pruritus and erythema when injected intradermally. This

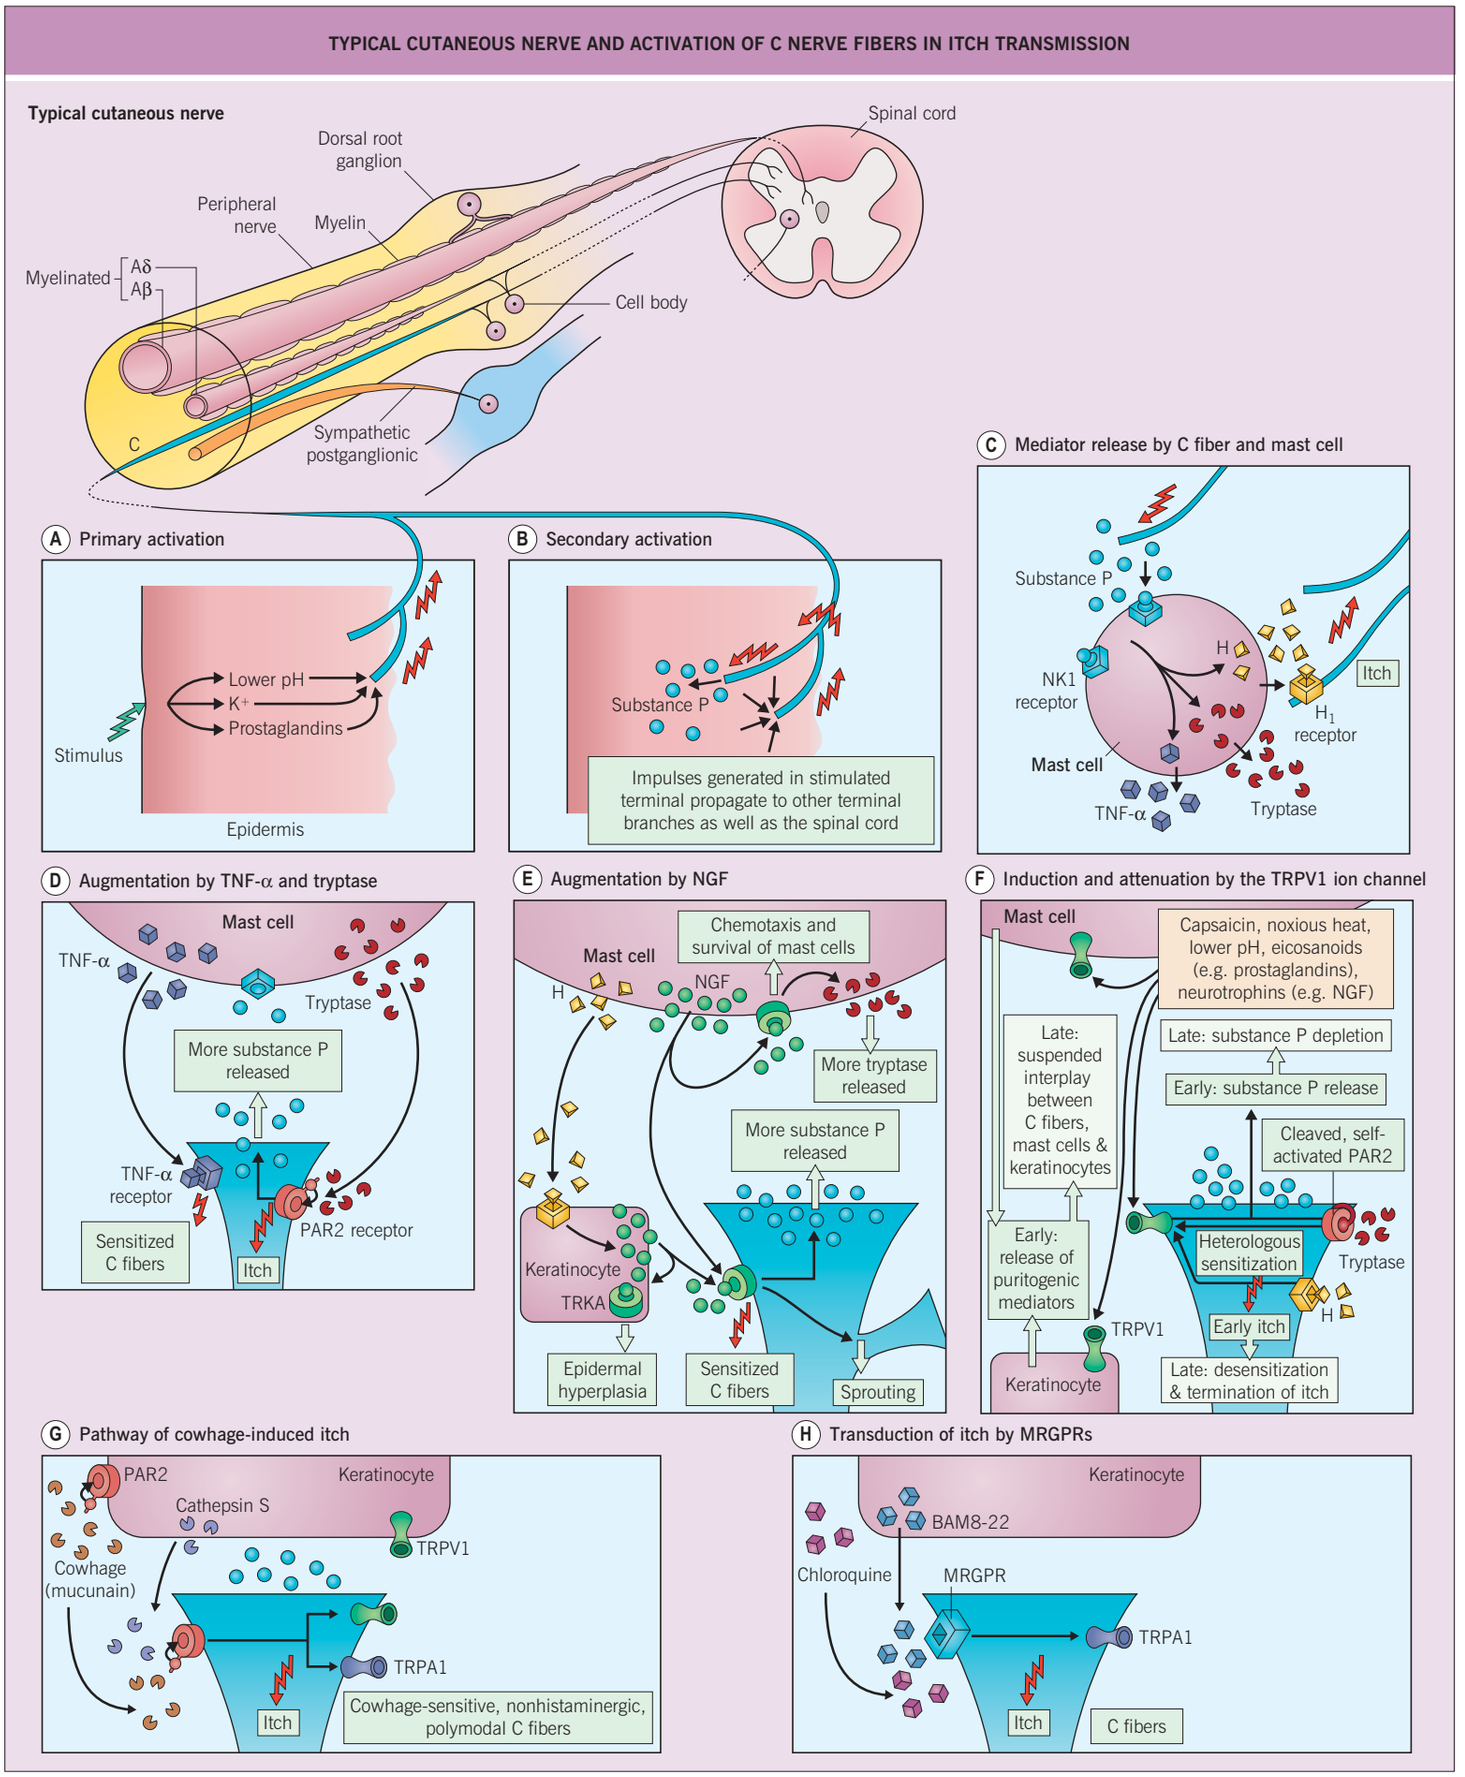

Fig. 5.2 See following page for legend.

Fig. 5.2 Typical cutaneous nerve and activation of C nerve fibers in itch transmission. There are two categories of axons in a typical cutaneous nerve: primary afferent Aβ, Aδ and C fibers (cell bodies in dorsal root ganglion) and sympathetic postganglionic fibers (cell bodies in sympathetic ganglion). Separate C fibers (~5% of total) are known to carry pruritogenic stimuli via two pathways: (1) histamine-induced itch that is transmitted by mechanically insensitive, capsaicin-sensitive (via *t*ransient *r*eceptor *p*otential *v*anilloid receptor 1 [TRPV1]) fibers; and (2) cowhage (mucunain)-induced itch accompanied by a burning sensation that is transmitted by polymodal fibers (sensitive to capsaicin, mechanical and other stimuli). **A** In primary (direct) activation of C fibers, the stimulus (e.g. impaired barrier function, environmental changes or inflammation) induces lower pH, potassium release, or synthesis of prostaglandins (the latter increasing sensitivity of C-fiber terminals to a number of substances). Environmental factors that increase (more likely to result in itch) or decrease (more likely to result in pain) stratum corneum pH can lead to C fiber activation. **B** In secondary activation, impulses generated in the stimulated terminal propagate not only to the spinal cord but also to other terminal branches (antidromic reflex arc), where they induce release of substance P. **C** Substance P primes mast cells via neurokinin-1 (NK1) receptors. Activated mast cells release histamine (H), which causes transmission of itch via H_1 receptors on histamine-sensitive C fibers. Mast cells also secrete tumor necrosis factor (TNF)-α and tryptase upon stimulation by substance P and nerve growth factor (NGF), respectively. **D** TNF-α sensitizes C fibers. Tryptase cleaves the extracellular portion of proteinase-activated receptor-2 (PAR2) on C-fiber terminals, exposing a tethered ligand domain that binds and "self-activates" PAR2. This results in transmission of itch by the C fibers as well as release of additional substance P. **E** NGF released by mast cells and keratinocytes (with increased production stimulated by histamine) activates tropomyosin-related kinase receptor A (TRKA) on C fibers, mast cells and keratinocytes. This induces C-fiber sprouting, sensitization and increased substance P release; mast cell chemotaxis, survival and increased tryptase release; and epidermal hyperplasia. Of note, TRKA is also referred to as neurotrophic tyrosine kinase receptor type 1 (NTRK1). **F** The TRPV1 ion channel on C fibers, keratinocytes and mast cells is activated by capsaicin, heat, low pH, eicosanoids and neurotrophins; although this initially stimulates transmission of itch and release of pruritogenic mediators, it may eventually lead to desensitization, neuropeptide depletion and attenuation of itch. The transmission of histamine-induced itch requires the presence of TRPV1. **G** Cowhage-induced itch occurs through the release of mucunain, a protease that activates PAR2 and PAR4 receptors (the latter not yet identified in the skin); these receptors can also be activated by endogenous proteases such as cathepsin S. Activation of PAR2/4 sensitizes TRPV1 and TRP ankyrin 1 (TRPA1) channels, resulting in cross-talk and itch transmission. **H** C nerve fibers (including those responsive to histamine) in the epidermis also express MAS-related G protein-coupled receptors (MRGPRs), which are stimulated by chloroquine or bovine adrenal medulla 8-22 peptide (BAM8-22; a proteolytically cleaved product of proenkephalin A). TRPA1 is required for transduction of itch by MRGPRs.

response is only partially inhibited by the μ-opioid receptor antagonist naloxone but is substantially inhibited by topical pretreatment of the injected skin with the potent H_1 antihistamine doxepin[47]. In contrast to morphine, the highly potent μ-opioid agonist fentanyl does not induce mast cell degranulation, even when applied in high doses. Therefore, opioids appear to induce itch via two possible mechanisms: (1) degranulation of cutaneous mast cells[48]; and (2) activation of μ-opioid receptors with a direct central and peripheral pruritogenic effect[48–51]. Morphine-induced itch was recently shown to result from activation of a heterodimeric receptor composed of the μ-opioid receptor and the gastrin-releasing peptide receptor; inhibition of the latter blocked opioid-related itch but not analgesia, an observation that may have therapeutic relevance[51a].

Nociceptin, the endogenous peptide ligand for the *o*pioid *r*eceptor-*l*ike 1 (ORL1) receptor, has also been implicated in cutaneous inflammation, pain and pruritus[52]. Investigations using a mouse model suggested that nociceptin interacts with ORL1 receptors expressed on keratinocytes, leading to the production of leukotriene B_4 that induces scratching[53]. Nociceptin-induced scratching was significantly inhibited by treatment with systemic naloxone.

Substance P

Substance P, a neuropeptide with a widespread distribution in peripheral nerves and the CNS, intensifies itch perception. Levels of substance P in the serum of patients with atopic dermatitis are elevated and correlate with disease severity[54]. Intradermal injection of substance P provokes itch as well as elements of neurogenic inflammation such as erythema and the wheal-and-flare reaction. Substance P is synthesized in the cell bodies of C neurons, transported towards the peripheral nerve terminals, and released by antidromic depolarization to cause vasodilation and increased vascular permeability (see Fig. 5.2).

Although endogenously released substance P does not degranulate mast cells in healthy human skin[55] or cause any sensation at physiologic concentrations[56], direct communication between nerve fibers and mast cells via substance P has been verified[57]. High concentrations of substance P can cause immediate mast cell degranulation, whereas low concentrations specifically activate neurokinin-1 (NK-1) receptors on mast cells, leading to sensitization of these cells and increased production of tumor necrosis factor (TNF)-α[58]. In turn, TNF-α sensitizes nociceptive nerve endings, producing a self-amplifying loop between neurons and mast cells.

Substance P co-localizes with other neurotransmitters such as serotonin, dopamine and calcitonin gene-related peptide, and it can act as

MURINE MODELS OF ITCH		
Model	**Clinical and laboratory features**	**Pathogenesis/comments**
Transgenic mice overexpressing PAR2	Epidermal hyperplasia and scaling as well as pruritus and scratching	
Transgenic mice overexpressing a serine protease	Pruritus and scratching	
TRPV1-deficient mice and Pirt-deficient mice	Lack of response to pruritogens	Pirt normally plays an important role in sensing itch (histaminergic and non-histaminergic; also pain) via TRPV1 channels (and also TRPV1-independent itch)
MRGPR-deficient mice and TRPA1-deficient mice	Lack of scratching response to chloroquine and BAM8-22, but preserved response to histamine	MGGPRs are normally activated by chloroquine and BAM8-22, so the lack of response in TRPA1-deficient mice implicates this receptor in downstream signaling
GRPR-deficient mice	Lacking of scratching response to pruritogens, but preserved response to painful stimuli	GRPR is expressed in the dorsal spinal cord
Bhlhb5-deficient mice	Enhanced scratching response to pruritogens	Selective loss of inhibitory interneurons in the dorsal horn that regulate pruritus
μ-Opioid receptor-deficient mice	Thinner epidermis, higher density of epidermal nerve endings, and less scratching	
Transgenic mice overexpressing interleukin-31	Pruritus, scratching, excoriations and alopecia	

Table 5.3 Murine models of itch. a neuromodulator. The relationship between substance P and keratinocytes expressing vanilloid receptors remains to be elucidated.

Neurotrophins

Neurotrophins are factors that regulate the growth and function of nerve cells. The prototypic neurotrophic factor is nerve growth factor (NGF). Other members of this family include neurotrophins 3, 4 and 5 and brain-derived neurotrophic factor (BDNF)[59]. Increased levels of epidermal NGF correlate with proliferation of terminal cutaneous nerves and upregulation of neuropeptides (e.g. substance P)[60]. NGF is known to induce sprouting of nerve fibers, sensitization of nerve endings, axonal transport in dorsal root ganglia cells, and increased expression of neuropeptides (e.g. substance P)[61].

Keratinocytes express high levels of NGF, and NGF not only is required for survival and regeneration of sensory neurons but also controls the responsiveness of such neurons to external stimuli[62,63]. Patients with atopic dermatitis have increased expression of NGF in cutaneous mast cells, keratinocytes and fibroblasts[64], and their plasma levels of NGF correlate with disease activity. There is growing evidence that NGF acts as a signaling molecule between mast cells and keratinocytes in allergic skin diseases. Mast cell-derived histamine induces keratinocytes to increase NGF production, and the latter may promote infiltration of mast cells into inflamed skin[65,66]. Upregulation of other neurotrophins, such as neurotrophin 4, has also been observed in keratinocytes from atopic dermatitis patients[67].

Prostanoids

In the skin, prostaglandins enhance histamine-induced itch[68,69]. Prostaglandins are the products of the transformation of the essential fatty acid arachidonic acid by cyclooxygenase-1 (COX-1) or cyclooxygenase-2 (COX-2). They are not by themselves pruritogenic when injected into skin. However, intradermal injection of prostaglandin E_1 (PGE_1) enhances pruritus due to histamine subsequently injected into the same site[70]. It appears that only itch-mediating neurons that display lasting activation following exposure to histamine are excited by PGE_2, and mechanosensitive fibers are unresponsive to both histamine and PGE_2.

PGE_2 has also been shown to have a direct, low-level pruritogenic effect both in healthy individuals and atopic dermatitis patients (without inducing protein extravasation). This suggests that prostanoids' peripheral action is not solely via histamine and that prostanoids may potentiate pruritus via other effects on nerve fibers.

Oral administration of aspirin, a cyclooxygenase inhibitor, does not ameliorate pruritus except in polycythemia vera[71]; however, topical application of aspirin may reduce pruritus in patients with chronic localized itch[72]. The role of other eicosanoids, including leukotrienes and 12-hydroxyeicosatetraenoic acid (12-HETE), in the pathogenesis of pruritus is unclear. In a mouse model, leukotriene B_4 provoked scratching[53].

Mediators that Activate Transient Receptor Potential Receptors

Neuromediators that activate ion channels belonging to the *t*ransient *r*eceptor *p*otential (TRP) family are also involved in the sensation of itch. TRP vanilloid 1 (TRPV1) is a vanilloid receptor located on C nerve fibers, dermal mast cells, dendritic cells and keratinocytes (see Fig. 5.2)[73]. This receptor is activated by capsaicin, endogenous substances such as cannabinoids (e.g. anandamide), prostaglandins and various neurotrophins, as well as by acidosis and temperatures above 43°C (109°F; mediates heat pain). Mechano-insensitive pruritoceptive C-nerve pathways can be activated by capsaicin, indicating that TRPV1 is expressed, and the experimental induction of histamine- and serotonin-mediated itch requires cooperation of TRPV1 receptors[74]. In addition, stimulation of TRPV1-positive nerve fibers releases multiple pruritoceptive mediators (e.g. interleukins [ILs], neuropeptides). Of note, cannabinoid receptors CB1 and CB2 are also found in the epidermis, and a cannabinoid agonist has been shown to inhibit histamine-induced itch[75].

TRPV3 is a thermosensor sensitive to temperatures >33°C (91°F; detects warmth) that is expressed in keratinocytes and dorsal root ganglion neurons in humans. In mice, a gain-of-function missense mutation in TRPV3 results in chronic itch, scratching and an atopic-like dermatitis[76]. In contrast, TRP melastatin 8 (TRPM8) on C nerve fibers functions as a thermosensor for cool (<28°C, 82°F) and is activated by menthol and icilin, which provide a "cooling" sensation that has been used to relieve itch.

TRP ankyrin 1 (TRPA1), a polymodal nociceptor, was recently found to be a downstream mediator of histamine-independent itch stimulated by MRGPRs (present in a subset of epidermal C fibers; see above) in mice[77]. Like TRPM8, TRPA1 can be activated by menthol.

Other Peripheral Mediators of Itch

Neurotransmitters

Neurotransmitters that play a role in itch include acetylcholine, an important neurotransmitter in the autonomic nervous system. Intradermal injection of acetylcholine typically induces pain; however, in patients with chronic itch, it induces itch. In murine models of itch, activation of the muscarinic receptor 3 triggers pruritus[78]. Currently there are no data regarding the role of norepinephrine, epinephrine or dopamine in itch transmission.

Peptidases

Mast cells that express neuropeptides also generate neuropeptide-degrading peptidases such as angiotensin-converting enzyme (ACE) and neural endopeptidases. The role they play in itch is unclear; however, medications such as ACE inhibitors, which can induce pruritus without a rash, may induce itch by inhibiting the activity of these degrading enzymes.

Other mediators with potential roles in itch

Serotonin has been implicated as an inducer of itch in murine models; however, in humans it is a very mild pruritogen. Nitric oxide is another factor that may induce itch via neurogenic inflammation[79]**.** The bovine adrenal medulla 8-22 (BAM8-22) peptide, a proteolytically cleaved product of proenkephalin A, is a potent activator of MRGPRs and can stimulate itch, usually accompanied by a stinging or burning sensation[80]. Chloroquine can also induce itch by activating MRGPRs, which are expressed by subset of C nerve fibers in the epidermis (see above).

Immune Cells as Itch Mediators and Modulators

Interactions between the nervous and immune systems in the skin have important roles in itch induction[81]. Neuropeptides released by cutaneous sensory nerves (e.g. substance P, calcitonin gene-related peptide, vasointestinal peptide) can activate transcription factors and regulate the expression of adhesion molecules and proinflammatory cytokines, thereby modulating immune and inflammatory responses[41]. These neuropeptides also influence cellular proliferation and differentiation, tissue repair, and antigen presentation involving a number of cell types, including keratinocytes, mast cells, dermal microvascular endothelial cells, and Langerhans cells. This interaction is bidirectional, as cytokines and chemokines are also able to regulate primary nerve afferents via receptor activation.

IL-2 is produced by activated T lymphocytes and causes pruritus when injected intradermally[82]. High-dose IL-2 administered intravenously to patients with cancer (including stage IV melanoma) causes intense generalized pruritus. Moreover, treatment with topical calcineurin inhibitors, which block the production of IL-2, can result in decreased itch. IL-2-induced pruritus is not reduced by antihistamines nor nonsteroidal anti-inflammatory drugs, and whether it represents a direct receptor-mediated effect or an indirect effect (e.g. via mast cells or endothelial cells) remains to be determined.

IL-31 is produced by T helper 2 (Th2) cells and induces pruritus by modulating the function of sensory neurons. IL-31 may exert its pruritogenic effect via activation of the IL-31 receptor (IL-31R, a heterodimer composed of the oncostatin M receptor [OSMR] β protein and the IL-31 receptor A) on keratinocytes, which could subsequently stimulate C fibers in the skin; the IL-31R is also found on cutaneous C fibers and in dorsal root ganglia. Signaling via the IL-31R and OSMR (a heterodimer composed of the OSMR β protein and a gp130 subunit) can result in keratinocyte proliferation, differentiation and apoptosis, as well as cutaneous inflammation[83]. In addition, mutations in the gene encoding the OSMR β protein underlie *familial primary localized*

cutaneous amyloidosis, an autosomal dominant disorder characterized by chronic localized itching and scratching that results in deposition of keratin-derived amyloid in the dermis[84]. Higher levels of IL-31 expression are found in the skin of patients with atopic dermatitis and prurigo nodularis[85,86], suggesting an important role for this cytokine in the intense itching that characterizes these conditions.

TNF-α is known to sensitize nociceptive nerve endings via its effect on TNF receptors (see Fig. 5.2); however, its role in itch is unclear. Although targeted TNF-α inhibitors (see Ch. 128) do not directly decrease pruritus, thalidomide (which has anti-TNF-α effects) can be effective in treating the itch associated with prurigo nodularis[87].

IL-6 is expressed by immune, nerve and Schwann cells[88], and levels of this cytokine are elevated in prurigo nodularis lesions[89].

Chronic Itch

Chronic itch may occur in the setting of pruritoceptive itch (originating from skin disease) or neuropathic itch (due to pathology in the nervous system) and can also have systemic or psychiatric causes[90]. It often has a significant effect on patients' quality of life. Chronic itch and chronic pain share a number of features, with both potentially involving peripheral and central sensitization[91] (Table 5.4).

Peripheral sensitization in chronic itch

An increased density of cutaneous nerve endings is observed in some forms of chronic itch[91]. Patients with chronic itch in the setting of atopic dermatitis have increased neurotrophin levels in involved skin, including NGF and neurotrophin 4[67]. Chronic localized pain is associated with elevated levels of the same neurotrophins, which are known to sensitize nociceptive neurons[59].

Central sensitization in chronic itch

Chronic itch leads to sensitization of second-order neurons within the dorsal horn (see Fig. 5.1), thereby leading to increased sensitivity to itch. There are two forms of increased sensitivity to itch: alloknesis and punctate hyperknesis. In alloknesis, stimuli that normally do not induce itch (e.g. touch, gentle warming) do so in the skin that surrounds a pruritic area[92]. This phenomenon is analogous to allodynia, in which gentle mechanical stimuli give rise to a perception of pain. Like allodynia, alloknesis requires ongoing activity in primary afferent C fibers and is mediated by low-threshold myelinated mechanoreceptor Aβ fibers (see Fig. 5.2). Alloknesis is common and represents a prominent feature of atopic dermatitis; it explains patients' complaints of severe pruritus associated with sweating, sudden changes in temperature, dressing and undressing. Punctate hyperknesis is characterized by more intense prick-induced itch sensations in the zone surrounding an area of inflammation (including that induced by histamine iontophoresis). It is similar to the phenomenon in chronic pain termed punctate hyperalgesia.

In patients with chronic itch, painful stimuli (e.g. electrical stimuli, heat pain) may be perceived as itch[93–95]. An analogous phenomenon can occur in patients with chronic pain, in whom histamine iontophoresis is perceived as painful[96]. These findings indicate that pain-induced inhibition of pruritus may be compromised in patients with chronic itch. This may also explain why scratching aggravates itch in patients with chronic itch and thereby induces a vicious itch–scratch cycle.

COMPARISON OF CHARACTERISTICS OF CHRONIC ITCH AND CHRONIC PAIN

	Chronic itch	Chronic pain
Peripheral sensitization	Peripheral sensitization of C nerve fibers	Peripheral sensitization of C nerve fibers
Central sensitization	Alloknesis Punctate hyperknesis	Allodynia Punctate hyperalgesia
Neuromediators	Nerve growth factor Neurotrophin 4	Nerve growth factor Neurotrophin 4
Chemical mediators	Histamine Cowhage (mucunain) Most opioids induce itch	Bradykinin Most opioids reduce pain
CNS areas activated	Anterior and posterior cingulate cortex Premotor area Precuneus Supramarginal gyrus Dorsolateral prefrontal cortex Insula-claustrum complex Somatosensory cortex I, II	Anterior cingulate cortex Premotor area Somatosensory cortex I, II Dorsolateral prefrontal cortex Insula-claustrum complex

Table 5.4 Comparison of characteristics of chronic itch and chronic pain.

Itch Related to Impaired Skin Barrier Function

Itch is a common symptom of xerotic skin and is aggravated during the winter in cold climates when the relative humidity falls indoors. Damage to the stratum corneum and the impaired barrier function that results can induce itch even without inflammation. Environmental changes (e.g. in pH, temperature and humidity) may serve as triggers that activate C nerve fibers to transmit the sensation of itch. Cross-talk between the stratum corneum and nerve fibers may explain the pruritus associated with impaired barrier function. Studies have demonstrated that keratinocytes release neuromediators upon damage to the stratum corneum barrier, and nerve fibers sprout in the epidermis in response to this damage. In a murine model of dry skin, enhanced c-*fos* expression in the CNS was observed, reflecting an activation of axons[97,98].

Additional evidence comes from a murine model of atopic dermatitis in which barrier damage was associated with significantly increased scratching, and scratching activity diminished when the barrier was repaired[99]. Serine proteases that activate PAR2 (thereby stimulating itch) are secreted in response to an increasing (alkaline) stratum corneum pH, which is commonly noted during barrier damage. This suggests that environmental factors that increase stratum corneum pH may increase itch perception (see Fig. 5.2). In contrast, a low-pH extracellular environment causes C nociceptors to induce pain.

Senescent Skin and Itch

Itch is a particularly frequent dermatologic symptom in individuals over 65 years of age[100,101]. Although dry skin is probably the most common trigger, elderly patients can have idiopathic itch without xerosis. Other possible explanations include age-related changes in nerve fibers and central disinhibition of itch due to loss of input from pain fibers. Additional cutaneous changes that may contribute to pruritus (as well as xerosis) in elderly patients include decreased skin surface lipids, decreased sweat and sebum production, and diminished barrier repair[102].

TREATMENT OF PRURITUS

Pruritus can significantly impair the quality of life in affected individuals. Acute itch may lead to agitation and difficulty concentrating, while chronic pruritus can have sequelae such as depression and decreased sexual desire or function[103].

Pharmacologic Treatments

Unlike pain, for which a host of effective medications are available, there are no general-purpose, consistently beneficial antipruritic drugs. However, recent discoveries of specific neural networks that are involved in itch transmission have led to advances in this relatively unexplored area of medicine. The mechanisms, uses and side effects of currently available antipruritic drug treatments are outlined in Table 5.5. Of note, although capable of relieving pruritus due to inflammatory skin disease, corticosteroids are not intrinsically antipruritic.

Non-Pharmacologic Treatments

Cutaneous field stimulation

Cutaneous field stimulation (CFS) is a technique that electrically stimulates afferent fibers, including nociceptive C fibers. CFS is similar to transcutaneous electrical nerve stimulation (TENS), but the latter activates large myelinated nerve fibers while CFS specifically targets unmyelinated C nerve fibers. In a study of patients with localized pruritus, CFS significantly reduced patient-reported itch and caused degeneration

Medication	**Mechanism(s) of action**	**Uses and efficacy**	**Major adverse effects**
TOPICAL AGENTS			
Capsaicin (active component in hot chili peppers)	• Activates and subsequently desensitizes TRPV1, a vanilloid TRP receptor[107] • Causes release from C neurons and (eventually) depleted stores of neuropeptides (e.g. substance P, CGRP, somatostatin) • Prolonged use leads to neuronal degeneration at sites of application, which can result in a reversible decrease in epidermal nerve fiber density[108]	• Used primarily for localized, chronic pruritic disorders, especially those of neuropathic origin[109] • Controlled studies support use for: – Notalgia paresthetica – Brachioradial pruritus – Hemodialysis-associated pruritus – Postherpetic neuralgia (transdermal patch FDA-approved for this indication)[110]	• Transient burning sensation, which usually resolves after several days of consistent use; application of topical lidocaine or EMLA may be helpful
Doxepin	• Tricyclic compound with potent antihistamine effects (H_1 and H_2); also anticholinergic properties	• Shown to relieve pruritus in patients with atopic dermatitis[111]	• Drowsiness in 25% of patients due to percutaneous absorption • Allergic contact dermatitis
Menthol	• Activates TRPM8 and TRPA1, producing a cool sensation[112]	• Inconsistent results in controlled studies[113,114] • May be especially beneficial for patients whose itch is relieved by cold showers	• Skin irritation
Pramoxine	• Anesthetic (blocks transmission of nerve impulses)	• Beneficial for histamine-induced itch and uremic pruritus in end-stage renal disease[115]	• Allergic contact dermatitis (uncommon)
Tacrolimus, pimecrolimus	• Calcineurin inhibitors that block production of multiple proinflammatory cytokines (see Ch. 128) • May initially activate and subsequently desensitize TRPV1[116]	• Can decrease itch related to the inflammation of atopic dermatitis	• Transient burning sensation
"Barrier repair" creams, other emollients and humectants	• Diminish transepidermal water loss and decrease flux between a distended and desiccated state • Minimize microfissures that expose C nerve fibers • Agents that acidify the stratum corneum may reduce itch, as alkaline agents (e.g. bar soaps) can activate proteases and increase lipid rigidity	• Decrease itch in patients with atopic dermatitis	None
SYSTEMIC AGENTS			
Antihistamines (especially doxepin)	• Doxepin is a tricyclic compound with potent antihistamine effects (H_1 and H_2) and anticholinergic properties; it represents a first-generation (classic), sedating antihistamine	• Decrease wheal formation as well as pruritus in patients with urticaria	• Sedation • Anticholinergic effects • Interaction with MAO inhibitors (for doxepin)
Naloxone, naltrexone	• μ-Opioid receptor antagonists*	• Controlled trials show efficacy for cholestatic and renal pruritus[117–121] • May be of benefit for severe pruritus of other etiologies[122]	• Hepatotoxicity • Nausea/vomiting • Insomnia • Reversal of analgesia
Nalfurafine (TRK-820)†	• κ-Opioid receptor agonist*	• Controlled trials show efficacy for renal pruritus[123]	• Insomnia
Butorphanol	• κ-Opioid receptor agonist and μ-opioid receptor antagonist*	• Relieves pruritus associated with morphine (with epidural administration of both agents)[124] • May reduce severe pruritus associated with systemic disease or inflammatory skin conditions[125‡]	• Nausea/vomiting • Dependence (rare)
Mirtazapine	• Serotonin and norepinephrine inverse agonist that reduces central itch perception	• May reduce nocturnal pruritus (at low doses, e.g. 15 mg nightly)[126]	• Sedation • Weight gain
Paroxetine	• Selective serotonin reuptake inhibitor (SSRI)	• A controlled study showed benefit for pruritus related to systemic disease[127]	• Sexual dysfunction • Sedation • Insomnia • Weight gain

*Inhibit itch transmission within the central nervous system.
†Currently not commercially available in the US.
‡An intranasal spray is currently available, and transdermal formulations are being developed.

Table 5.5 Drug treatment of pruritus. Topical naltrexone[104], aspirin and cannabinoids may also have antipruritic effects, and injections of botulinum toxin type A have been used to treat neuropathic itch[105]. In the future, topical drugs for the relief of itch may include prostaglandin DP1 receptor agonists[106], and agents that inhibit serine proteases (e.g. cathepsin S), nerve growth factor or neurotrophin 4. CGRP, calcitonin gene-related polypeptide; EMLA, eutectic mixture of local anesthetics (lidocaine + prilocaine); FDA, US Food and Drug Administration; MAO, monoamine oxidase; TRP, transient receptor potential ion channel family.

Continued

DRUG TREATMENT OF PRURITUS			
Medication	**Mechanism(s) of action**	**Uses and efficacy**	**Major adverse effects**
Thalidomide	• Blocks neuropathic afferent pathways (peripherally and centrally) • Inhibits TNF-α synthesis	• May be helpful for prurigo nodularis, actinic prurigo and pruritus of advanced age	• Teratogenicity • Peripheral neuropathy
Gabapentin, pregabalin	• Structural analogues of the neurotransmitter GABA • Thought to inhibit central itch pathways	• Beneficial for neuropathic itch (e.g. brachioradial pruritus), post-burn pruritus and postherpetic neuralgia[128–130a]	• Peripheral edema • Sedation • Abdominal pain
Aprepitant	• Antagonist of the neurokinin-1 receptor, which is activated by substance P	• Primarily used as an antiemetic in oncology patients, with anecdotal reports of reduced pruritus (e.g. in Sézary syndrome or erlotinib-induced pruritus)	• Fatigue • Hiccups

Table 5.5 Drug treatment of pruritus (cont'd). Topical naltrexone[104], aspirin and cannabinoids may also have antipruritic effects, and injections of botulinum toxin type A have been used to treat neuropathic itch[105]. In the future, topical drugs for the relief of itch may include prostaglandin DP1 receptor agonists[106], and agents that inhibit serine proteases (e.g. cathepsin S), nerve growth factor or neurotrophin 4. GABA, γ-aminobutyric acid; TNF, tumor necrosis factor.

of epidermal nerve fibers[131]. However, CFS is practical only for localized disease.

Behavioral therapy targeting the CNS

Stress and other psychogenic factors are important in itch[132]. Patients with pruritus experience higher levels of psychological stress than those without this symptom[133]. An impaired response of the autonomic nervous system to itch, scratching and emotional stress has also been identified in atopic dermatitis patients[134]. Several studies have shown that behavioral therapy reduces the intensity of itch that is perceived[135].

FUTURE DIRECTIONS

One of the most critical issues is to identify the specific mechanisms and mediators responsible for particular "itch states". Hopefully, our emerging understanding of the pathways of itch transmission will soon result in the development of effective targeted treatments.

Synonyms: ■ Aquagenic pruritus: bath pruritus ■ Prurigo nodularis: chronic circumscribed nodular lichenification (Pautrier) ■ Lichen simplex chronicus: neurodermatitis ■ Brachioradial pruritus: solar pruritus, solar pruritus of the elbow, brachioradial summer pruritus ■ Notalgia paresthetica: subscapular pruritus, posterior pigmented pruritic patch, hereditary localized pruritus

Key features

- Pruritus is the most common complaint of patients with dermatologic disease
- Pruritus can occur with or (e.g. in the setting of an underlying systemic disorder) without primary skin lesions
- Pruritus is a symptom with multiple complex pathogenic mechanisms that cannot be attributed to one specific cause or disease
- Pruritus should challenge the dermatologist to search for an underlying etiology
- Management of pruritus can often be achieved by implementing specific and nonspecific treatments

INTRODUCTION

Pruritus can be defined subjectively as a sensation (usually unpleasant) that elicits a desire to scratch. The biologic purpose of pruritus is to provoke scratching in order to remove a pruritogen, a response likely to have originated when most pruritogens were parasites.

Pruritus is the most common skin-related symptom. It often arises from a primary cutaneous disorder but represents a manifestation of an underlying systemic disease in approximately 10% to 25% of affected individuals[1]. Non-dermatologic conditions that can lead to generalized pruritus include hepatic, renal or thyroid dysfunction; lymphoma, myeloproliferative disorders (e.g. polycythemia vera, hypereosinophilic syndrome) and chronic lymphocytic leukemia; HIV or parasitic infections; and neuropsychiatric disorders (see Ch. 7). In some patients, pruritus occurs in the absence of visible skin signs. Although there is no definitive system for the categorization of pruritus[2,3], in 2007 a clinical classification scheme was proposed by the International Forum for the Study of Itch[4]. This system recognizes three major groups of pruritus: (1) affecting primarily diseased/inflamed skin; (2) with chronic secondary skin lesions due to scratching; and (3) affecting non-diseased/non-inflamed skin. Underlying etiologies are categorized as dermatologic, systemic, neurologic, psychogenic and mixed. Although the limited understanding of the pathogenesis of pruritus (see Ch. 5) has hampered the development of treatments, recent discoveries provide hope for more specific therapies in the future[5].

When a patient complains of pruritus, there is a rational way to assemble the myriad of etiologies into finite groups, to evaluate the patient in a systematic manner, and then to correct the underlying cause (if possible) and treat the pruritus with currently available therapies.

EPIDEMIOLOGY

It is reasonable to assume that all humans experience the sensation of pruritus at some point in their life, e.g. from insect bites (Fig. 6.1). However, relatively few studies have investigated the overall incidence and prevalence of pruritus. A recent population-based, cross-sectional study in Germany found that the self-reported point, 12-month and lifetime prevalences of chronic pruritus (lasting at least 6 weeks) were 13.5%, 16% and 22%, respectively[5a]. In a previous Norwegian population-based, cross-sectional study on self-reported skin morbidity, pruritus was the dominant symptom among adults, more so in women than in men (experienced within the past week by 9.2% and 7.5%, respectively)[6]. Table 6.1 summarizes the reported prevalences of pruritus in a number of medical conditions.

EVALUATION OF THE PATIENT

Patients with pruritus due to either a specific dermatologic condition or an underlying systemic disease can present with nonspecific cutaneous findings such as secondary lesions (e.g. erosions, excoriations and crusts), or with no detectable cutaneous changes at all. Pruritus associated with a systemic disease may also result from a specific related dermatologic disease (e.g. eosinophilic folliculitis in a patient with AIDS). Multiple underlying factors can be identified in approximately one-third of patients with chronic pruritus[16a]. Lastly, a pruritic cutaneous condition with nonspecific clinical findings upon initial evaluation may have diagnostic features at a later date. Therefore, re-examination over time is a critical aspect of the approach to the patient with pruritus[1].

Fig. 6.1 **Insect bites – "breakfast, lunch and dinner sign" – linear pruritic papules.**

History

A precise history may provide insight into the patient's disease processes. Important characteristics of pruritus are listed in Table 6.2. The onset, duration and nature of the pruritus can help to determine its cause. If several general clues are considered, the clinician will be able to narrow the differential diagnosis:

- Localized or generalized pruritus may be a consequence of a systemic disease, and no particular clinical characteristics reliably predict the likelihood of an underlying systemic disease[17].
- An acute onset of pruritus without primary skin lesions over a few days is less suggestive of an underlying systemic disease than chronic, progressive generalized pruritus.
- Lesions on the mid upper back suggest a primary skin disease, since this difficult-to-reach region is typically spared (referred to as the "butterfly sign") in patients with skin lesions entirely due to scratching (e.g. those with pruritus of systemic or psychogenic etiology). However, although this area is generally inaccessible to the patient's hand, it can be reached with instruments (e.g. "back-scratching" devices).

PREVALENCE OF PRURITUS IN SELECTED DISEASE STATES	
Disorder	**Reported prevalence of pruritus**
Psoriasis	≤85%
Cutaneous T-cell lymphoma	70–80%
End-stage renal disease on hemodialysis	previously 60–80%, now 20–50%
Primary biliary cirrhosis	80% (presenting symptom in 25–70%)
Hepatitis C virus-infected patients	15%
Hodgkin disease	10–30%
Non-Hodgkin lymphoma	2%
Leukemias	<5%
Polycythemia vera	30–50%
Herpes zoster	≤60%
Postherpetic neuralgia	≤30%
Pregnancy	20%

Table 6.1 Prevalence of pruritus in selected disease states[1,7–16].

DESCRIPTIVE AND HISTORICAL FEATURES OF PRURITUS
DESCRIPTIVE FEATURES OF PRURITUS
• Onset: abrupt, gradual, prior history of pruritic episodes • Time course: continuous, intermittent, cyclical, nocturnal • Nature: prickling, crawling, burning, dysesthetic • Duration: days, weeks, months, years • Severity: interference with normal activities or sleep • Location: generalized or localized, unilateral or bilateral • Relationship to activities: occupational, hobbies • Provoking factors: water, skin cooling, air, exercise • Patient's personal theory as to etiology of the pruritus
OTHER HISTORICAL FEATURES
• Medications, including topical agents: prescribed, over-the-counter, illicit; duration of use and relationship to onset of pruritus • Allergies: systemic, contact • Atopic history: atopic dermatitis, allergic rhinitis, asthma • Past medical history: thyroid, liver or renal dysfunction; other systemic diseases • Family history of atopy, skin disease or similar pruritic conditions • Occupation • Hobbies • Social history: household and personal contacts, food habits, stress • Drugs: nicotine, alcohol, intravenous drugs • Bathing habits and exposure to irritants • Pets and their care • Sexual history • Travel history • Prior diagnoses made by physician or patient

Table 6.2 Descriptive and historical features of pruritus.

- Patients with pruritus that is not related to a primary dermatologic disease typically have excoriations and other secondary changes, but no primary lesions.
- Medications (prescription, over-the-counter and illicit) and supplements that the patient is taking should be reviewed and drug-induced pruritus considered.
- Some severely pruritic dermatoses such as urticaria and mastocytosis uncommonly lead to excoriations from scratching but instead result in pressing and rubbing behaviors.
- Scabies and other infestations should be considered, especially when multiple family members are affected.
- Pruritus after emergence from a bath (possibly provoked by cooling or drying of the skin) may be a sign of polycythemia vera or idiopathic aquagenic pruritus.
- Nocturnal generalized pruritus in association with chills, sweating and fever represents a classic presentation of Hodgkin disease. Pruritus may precede the onset of the lymphoma by as much as 5 years[18].
- Whereas psychogenic pruritus rarely interferes with sleep, other pruritic diseases (with or without primary skin lesions) often cause nocturnal wakening.

Examination

Careful and complete examination of the skin, nails, scalp, hair, mucous membranes and anogenital area is recommended. An assessment should be made of primary lesions and secondary changes (including their morphology and distribution), with particular attention to lichenification (Fig. 6.2), xerosis (Fig. 6.3), the presence of dermographism and

Fig. 6.2 Lichen simplex chronicus on the posterior neck. Note the increased skin markings. *Courtesy, Ronald P Rapini, MD.*

Fig. 6.3 Extreme xerosis associated with pruritus in an HIV-infected patient.

POSSIBLE LABORATORY STUDIES IN THE EVALUATION OF PATIENTS WITH GENERALIZED PRURITUS OF UNKNOWN ETIOLOGY
• Erythrocyte sedimentation rate (ESR)
• Complete blood cell count (CBC) with differential and platelet count
• Blood urea nitrogen, creatinine
• Liver transaminases, alkaline phosphatase, bilirubin
• Lactate dehydrogenase (LDH)
• Thyroid function tests (thyroid-stimulating hormone [TSH] and thyroxine levels)
• Fasting glucose, hemoglobin A1c
• Serum iron, ferritin
• Stool for ova, parasites and occult blood
• Parathyroid function (calcium, phosphate and parathyroid hormone levels)
• Chest X-ray
• Skin biopsy for routine histology
• Direct immunofluorescence studies of skin, anti-tissue transglutaminase antibodies
• Viral hepatitis screen
• HIV testing
• Anti-mitochondrial and anti-smooth muscle antibodies
• Serum IgE level; allergen-specific IgE antibody tests
• Prick tests of major atopy allergens, relevant occupational allergens; patch tests
• Serum tryptase, histamine and/or chromogranin-A levels
• Urine for sediment; 24-hour urine collection for 5-hydroxyindoleacetic acid (5-HIAA; a serotonin metabolite) and methylimidazoleacetic acid (MIAA; a histamine metabolite)
• Additional radiographic and sonographic studies, e.g. abdominal CT scan
• Serum protein electrophoresis, serum immunofixation electrophoresis

Table 6.3 Possible laboratory studies in the evaluation of patients with generalized pruritus of unknown etiology. Performance of particular tests is based upon the patient's history and physical examination. Studies with a darker background color are commonly employed as an initial screen, and the results can help to direct further evaluation.

skin signs of systemic diseases (see Ch. 53). A general physical examination (including the lymph nodes, liver and spleen) may disclose an undiagnosed extracutaneous disease (e.g. lymphoma) and should be performed in conjunction with a primary care physician in patients with pruritus of unknown etiology.

Laboratory Investigation

In the setting of generalized pruritus of unknown etiology, laboratory investigation is recommended (Table 6.3). Biopsies of skin lesions (even if nonspecific clinically) are occasionally informative, and direct immunofluorescence studies of perilesional or normal-appearing (adjacent to lesions if present) skin may point to a specific dermatologic disease such as bullous pemphigoid or dermatitis herpetiformis.

PRURITUS IN DERMATOLOGIC DISEASE

This section focuses on the sensation of pruritus in selected skin diseases where this symptom is a prominent feature. A more comprehensive discussion of the diseases mentioned and the many additional dermatoses in which pruritus is a characteristic feature (Table 6.4) may be found in other chapters.

Infestations

Scabies

In patients with scabies, pruritus can be localized or generalized and it may have a burning component. The pruritus usually begins 3 to 6 weeks after a first-time infestation (see Ch. 84), and within a few days in subsequent infestations. The itch reflects various components of the immune response against mites, eggs and scybala[1].

Pediculosis (lice)

It is rare to make the diagnosis of pediculosis without pruritus as a symptom (see Ch. 84). Pruritus of the primary sites of infestation (e.g. scalp, groin) is a clue to the diagnosis of pediculosis capitis and pediculosis pubis. Generalized pruritus is characteristic of body lice but can also occur with other types of lice[1].

DERMATOLOGIC DISEASES ASSOCIATED WITH PRURITUS	
Dermatologic disease	**Cause**
Infestation/bites & stings	• Scabies • Pediculosis • Arthropod bites
Inflammation	• Atopic dermatitis • Stasis dermatitis • Allergic or irritant contact dermatitis • Seborrheic dermatitis, especially of the scalp • Psoriasis, parapsoriasis • Pityriasis rubra pilaris • Lichen simplex chronicus • Prurigo nodularis • Prurigo pigmentosa • Bullous diseases, e.g. DH, BP • PUPPP • Eosinophilic folliculitis • Urticaria • Drug eruptions, e.g. morbilliform • Mastocytosis • Polymorphous light eruption • Papular urticaria, urticarial dermatitis
Infections	• Bacterial infections, e.g. folliculitis • Viral infections, e.g. varicella • Fungal infections, e.g. inflammatory tinea • Parasitic infections, e.g. schistosomal cercarial dermatitis
Neoplastic	• Cutaneous T-cell lymphoma, e.g. mycosis fungoides, Sézary syndrome
Genetic/Nevoid	• Darier disease • Hailey–Hailey disease • Inflammatory linear verrucous epidermal nevus (ILVEN)
Other	• Xerosis, eczema craqelé • Anogenital pruritus • Notalgia paresthetica • Primary cutaneous amyloidosis (macular, lichenoid) • Postburn and post-stroke pruritus • Scar-associated pruritus • Fiberglass dermatitis • Aquagenic pruritus

Table 6.4 Dermatologic diseases associated with pruritus. BP, bullous pemphigoid; DH, dermatitis herpetiformis; PUPPP, pruritic urticarial papules and plaques of pregnancy.

Inflammatory Dermatoses

Atopic dermatitis

Pruritus is such an important aspect of atopic dermatitis that "the diagnosis of active atopic dermatitis cannot be made if there is no history of pruritus"[19] (see Ch. 12). The itch sensation typically comes in "attacks", which may be severe and are a central component of this condition's impact on quality of life[20]. Often, pruritus is the first indication of a disease flare. A number of immunologic (e.g. exposure to aeroallergens or ingestion of foods to which the patient is sensitized) and non-immunologic (e.g. emotional stress, overheating, perspiration or contact with wool, other rough fabrics or even air [atmoknesis]) stimuli can provoke pruritus in patients with atopic dermatitis[21] (Figs 6.4 & 6.5). There is also evidence for different seasonal patterns of symptom severity (including pruritus), with most children experiencing aggravation of symptoms during the winter and others having exacerbations primarily during the summer[22].

Despite intensive research efforts, the mediators of itch in atopic dermatitis have not been clearly elucidated and the neural mechanisms of pruritus are not well understood (see Ch. 5). For example, due to inconsistent findings regarding plasma histamine levels, there is controversy with regard to the role of histamine in the pathogenesis of

Fig. 6.4 Atopic dermatitis with multiple lesions of prurigo nodularis.

Fig. 6.5 Atopic dermatitis. Multiple linear excoriations are seen on the leg.

pruritus in atopic dermatitis[23]. The minimal effectiveness of antihistamines in alleviating the itch of atopic dermatitis indicates that histamine cannot be the only pruritogen and is most likely not the predominant mediator responsible for the pruritic sensation. In general, the benefits of antihistamines in these patients are thought to result from their sedative effects[24].

Some studies indicate that antihistamines are more likely to be effective in type 2 helper T cell (Th2)-driven atopic dermatitis (i.e. early, acute flares) than in Th1-driven disease (i.e. chronic lesions)[23]. Other studies have shown that the sensations evoked by acetylcholine (ACh) and vasoactive intestinal polypeptide (VIP) are different in atopic and non-atopic individuals and depend upon the inflammatory state of atopic skin[25]. For example, ACh tends to induce burning pain in those who do not have atopic dermatitis, pruritus in patients with acute atopic dermatitis, and a mixture of pain and pruritus in atopic dermatitis patients without active eczema. These data provide evidence that pruritus can be elicited by a histamine-independent cholinergic mechanism.

Other studies suggest a possible role for neuropeptides such as substance P, calcitonin gene-related peptide (CGRP) and neurotrophins (e.g. nerve growth factor), which have been detected in the skin and peripheral blood of atopic dermatitis patients[26,27]. Down-regulation of epidermal opioid receptors may also contribute to pruritus in chronic atopic dermatitis[28]. Lesional atopic dermatitis skin contains several proinflammatory cytokines that may play a role in pruritus. Interleukin (IL)-2 has moderate pruritogenic potential[26]. IL-31 is also pruritogenic, and both this cytokine and its heterodimeric receptor are overexpressed in atopic dermatitis lesions[29,30]. In addition, mast cell tryptase (via activation of proteinase-activated receptors [PAR-2]) may be involved in the sensation of itch in atopic patients[31] (see Ch. 5). Lastly, a chronic barrage of pruritoceptive input may elicit central sensitization for itch, so that nociceptive input no longer inhibits itch but is perceived as itch. This may explain why painful stimuli can evoke itch in atopic patients with chronic pruritus[32].

Urticaria

This entity is often intensely pruritic and can also produce stinging or prickling sensations. Early lesions and small superficial wheals are particularly symptomatic[1]. Histamine plays a primary role in the pruritus of urticaria (see Ch. 18), and H_1-receptor antagonists reliably decrease or eliminate this sensation as well as the wheals themselves[33].

Psoriasis

Although it is not typically regarded as a pruritic disease, studies have shown that up to 85% of psoriasis patients suffer from pruritus[7,34]. For example, in a large American survey, 79% of patients with psoriasis reported pruritus[35]. Exacerbating factors include heat, xerosis, sweating and stress[7,34]. The back, extremities, buttocks and abdomen have been reported as the sites that are most commonly pruritic, but in one study of hospitalized patients the scalp was most often pruritic[7]. Patients frequently describe the pruritus as having tickling, crawling and burning components[7], and antihistamines rarely provide relief[1,7]. A variety of mediators of itch (e.g. substance P, nerve growth factor, IL-2) may be present in psoriatic skin, suggesting a complex, multifactorial pathophysiology for the associated pruritus[36].

Cutaneous T-Cell Lymphoma

Cutaneous T-cell lymphoma (CTCL) may be intensely pruritic, especially in patients with folliculotropic mycosis fungoides or Sézary syndrome[33] (see Ch. 120). In one study, the presence of pruritus was associated with a twofold increased risk of death[1]. Treatment strategies for severe pruritus in CTCL patients include naltrexone (50–150 mg/day), gabapentin (900–2400 mg/day in divided doses) and mirtazapine (7.5–15 mg at bedtime)[37,38].

DERMATOSES THAT RESULT FROM PRURITUS AND ASSOCIATED BEHAVIORS

Prurigo Nodularis

The lesions of prurigo nodularis are produced by chronic, repetitive scratching or picking of the skin. An underlying disorder associated with pruritus is usually present (e.g. an atopic diathesis [Fig. 6.4], psychological condition or systemic disease). The nodules themselves are also pruritic, possibly due to hypertrophy and increased density of substance P-positive nerves within affected skin, leading to perpetuation of the itch–scratch cycle. Prurigo nodularis is primarily a disease of adults, especially middle-aged women. It occasionally occurs in children and adolescents, especially those with an atopic diathesis.

Multiple lesions are characteristically distributed symmetrically on the extensor aspects of the extremities; the upper back, lumbosacral area and buttocks may also be involved, but the difficult-to-reach mid upper back is classically spared ("butterfly sign") (Fig. 6.6). Involvement of flexural areas, the face and the groin is unusual. The basic lesion is a firm, dome-shaped papulonodule with varying degrees of central scale-crust, erosion or ulceration. The color ranges from skin-toned to erythematous to brown, and hyperpigmentation is particularly common in dark-skinned individuals. Lesions can develop a verrucous or fissured surface, and lichenification of adjacent skin may be observed.

Many affected individuals have pruritus due to another dermatologic condition such as atopic dermatitis, xerosis or a systemic disease (e.g. hyperthyroidism, hepatic or renal dysfunction, lymphoma). The

Fig. 6.6 Prurigo nodularis. A Firm, hyperpigmented papulonodules on the extensor forearm. **B** Numerous lesions on the trunk, with sparing of the mid upper back ("butterfly sign"). *A, Courtesy, Ronald P Rapini, MD.*

Fig. 6.7 Lichen simplex chronicus of the scrotum. Secondary pigmentary changes are more common in patients with darkly pigmented skin. *Courtesy, Louis A Fragola, Jr, MD.*

underlying process may also be psychological, with emotional distress, obsessive–compulsive disorder, depression or other psychiatric conditions leading to repetitive scratching. The clinical differential diagnosis of prurigo nodularis may include perforating disorders (e.g. acquired perforating dermatosis), pemphigoid nodularis, hypertrophic lichen planus, hypertrophic lupus erythematosus, scabetic nodules, persistent insect bite reactions, the pruriginous type of dominant dystrophic epidermolysis bullosa, and neoplasms such as multiple keratoacanthomas or granular cell tumors.

Histologically, prurigo nodularis features massive epidermal hyperplasia and thick, compact hyperkeratosis[39]. Keratinocyte atypia is minimal or absent, and erosion may be seen. Fibrosis of the papillary dermis with vertically arranged collagen fibers, increased numbers of fibroblasts and capillaries, and a perivascular or interstitial mixed inflammatory infiltrate represent additional findings. Although hypertrophic cutaneous nerves are characteristic of this condition, they are only occasionally evident.

When a patient presents with prurigo nodularis, it is important to exclude underlying systemic causes of pruritus (see above and Table 6.3). Treatment of prurigo nodularis is usually difficult and typically requires a multifaceted approach, which should be individualized depending on etiologic factors and the extent of disease. The skin hypertrophy itself may respond to superpotent topical corticosteroids under occlusion, intralesional corticosteroids or phototherapy (e.g. broadband or narrowband UVB, psoralen plus UVA [PUVA]); benefit from excimer laser therapy has also been described. Topical (e.g. menthol, pramoxine) and systemic (e.g. antihistamines) antipruritic agents may be useful.

Treatment directed toward any underlying compulsive behavior is important. Selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants have both been employed successfully, especially when a component of depression is present. Doxepin can be particularly helpful because of its antihistaminic as well as antidepressant properties. Thalidomide (50–200 mg daily) has been reported to be highly effective for patients with recalcitrant prurigo nodularis[40]. Additional treatments with reported benefit include topical capsaicin (0.025–0.3% four to six times daily), topical calcipotriene (calcipotriol), cryotherapy (which can lead to depigmentation and scarring) and (especially for patients with an atopic diathesis) oral cyclosporine.

Lichen Simplex Chronicus

Lichen simplex chronicus (LSC) represents epidermal hypertrophy that results from chronic, habitual rubbing or scratching of the skin. This leads to lesions that are broader and thinner than prurigo nodularis, which is caused by more focused picking or scratching (see above). Like prurigo nodularis, lesions of LSC itch spontaneously, leading to an "itch–rub–itch" cycle. LSC is most frequently observed in older adults and (outside the setting of lichenified lesions in atopic dermatitis) is relatively uncommon in children.

LSC is characterized by well-defined plaques exhibiting exaggerated skin lines (lichenification) with a "leathery" appearance, hyperpigmentation and varying degrees of erythema. Lesions may be solitary or multiple, with a predilection for the posterior neck (see Fig. 6.2), occipital scalp, anogenital region (e.g. scrotum, vulva) (Fig. 6.7), shins, ankles, and dorsal aspects of the hands, feet and forearms. Predisposing factors include xerosis, atopy, stasis dermatitis, anxiety, obsessive–compulsive disorder, and pruritus related to systemic disease.

The clinical differential diagnosis may include lichen amyloidosis and hypertrophic lichen planus, both of which present with chronic pruritic plaques that favor the shins. Histologic examination of LSC shows hyperkeratosis, acanthosis with irregular elongation of the rete ridges, and hypergranulosis. There may be vertically oriented collagen bundles in the papillary dermis and a sparse superficial perivascular infiltrate.

As the name implies, LSC is a chronic disorder that is often resistant to treatment. Management strategies are similar to those described above for prurigo nodularis. Underlying pruritic disorders should be identified and treated if possible. Topical corticosteroids, with or without occlusion, and intralesional corticosteroids are the mainstays of therapy. Topical calcineurin inhibitors may also be of benefit[40a]. Pruritus can be

managed with antihistamines and topical antipruritics such as menthol and pramoxine. Compulsive rubbing may improve with informal insight-oriented psychotherapy or with the use of SSRIs.

Lichen Ruber Moniliformis

First described in 1886 by Kaposi, this is a rare condition with only a handful of case reports in the literature (the most recent published almost three decades ago). Lichen ruber moniliformis manifests as erythematous, firm, cord-like linear lesions that can be composed of smaller papules. They may be both pruritic and painful. Histologic features include an atrophic epidermis, cystic dilation of eccrine sweat ducts, milia, and fibrosis of the dermis. This finding led Mehregan et al.[41] to speculate that there was an underlying abnormality in skin reactivity resulting in the formation of linear fibrotic bands, which may explain their persistence. Lesions are limited to areas of trauma, including rubbing. No effective treatments have been reported.

PRURITUS VARIANTS

Aquagenic Pruritus

Aquagenic pruritus often develops secondary to a systemic disease (e.g. polycythemia vera) or another skin disorder (Table 6.5). Criteria for the diagnosis of idiopathic aquagenic pruritus (which is uncommon) are the following: (1) severe pruritus occurring after water contact, irrespective of water temperature or salinity; (2) pruritus developing within minutes of water contact without visible skin changes, i.e. in the absence of urticaria or symptomatic dermographism; and (3) exclusion of chronic skin diseases, drug-related pruritus and systemic disorders (e.g. polycythemia vera)[42].

In aquagenic pruritus, prickling, tingling, burning or stinging sensations occur within 30 minutes of water contact and last for as long as 2 hours[1]. This is irrespective of water temperature or salinity. Typically, symptoms begin on the lower extremities and then generalize, with sparing of the head, palms, soles and mucosae[43]. Multiple etiologies for "secondary" aquagenic pruritus have been reported (see Table 6.5). The pathologic mechanism of aquagenic pruritus is unknown, although elevated dermal and epidermal levels of acetylcholine, histamine, serotonin and prostaglandin E_2 have been described[1].

Traditional therapies utilize alkalinization of bath water to a pH of 8 with baking soda. Systemic treatments including oral cyproheptadine, cimetidine and cholestyramine have shown minimal effectiveness[43]. Treatment with broadband or narrowband UVB and PUVA have been reported as efficacious, with PUVA appearing to be superior to broadband UVB[44]. Capsaicin cream (0.025%, 0.5% or 1.0%) applied three times daily for a minimum of 4 weeks can decrease symptoms, but long-term therapy may not be practical[45].

DIFFERENTIAL DIAGNOSIS OF PRURITUS OR PRICKLING SENSATIONS PROVOKED BY WATER CONTACT
DISEASE-ASSOCIATED SKIN FINDINGS TYPICALLY EVIDENT AT TIME OF VISIT
• Mastocytosis (cutaneous lesions, positive Darier's sign) • Hypereosinophilic syndrome (cutaneous lesions in >50% of patients) • Hemochromatosis (diffuse hyperpigmentation) • Polycythemia vera* (ruddy complexion)
URTICARIA BY HISTORY AND/OR CHALLENGE
• Cold urticaria • Cholinergic urticaria (secondary to hot water exposure) • Aquagenic urticaria
SKIN FINDINGS (BEYOND EVIDENCE OF SCRATCHING) TYPICALLY ABSENT
• Hodgkin disease • Myelodysplastic syndrome • Essential thrombocythemia • Itching during hot shower in sarcoidosis† • Aquagenic pruritus of the elderly (xerosis may be subtle) • Aquagenic pruritus (primary, idiopathic)
*Aspirin 300 mg once to three times daily may provide partial relief. †Single case report of a patient without cutaneous sarcoidosis.

Table 6.5 Differential diagnosis of pruritus or prickling sensations provoked by water contact.

Pruritus Ani

Pruritus ani is defined as pruritus localized to the anus and perianal skin. This condition occurs in 1–5% of the general population, with men more commonly affected than women in a ratio of 4:1[46]. The onset is insidious and symptoms may be present for weeks or years before patients seek medical attention.

Pruritus ani can be primary (idiopathic) or secondary in nature. Primary pruritus ani is defined as pruritus in the absence of any apparent cutaneous, anorectal or colonic disorder; it accounts for 25–95% of reported cases, depending upon the series[46]. Possible causes include dietary factors such as excessive coffee intake, poor personal hygiene and psychogenic disorders. Secondary pruritus ani represents perianal pruritus attributable to an identifiable etiology such as chronic diarrhea, fecal incontinence/anal seepage, hemorrhoids, anal fissures or fistulas, rectal prolapse, primary cutaneous disorders (e.g. psoriasis, lichen sclerosus, seborrheic dermatitis, allergic contact dermatitis), sexually transmitted diseases, other infections, infestations (e.g. pinworms), previous radiation therapy, and neoplasms (e.g. anal cancer)[47]. Findings on physical examination vary from normal-appearing skin to mild erythema of the perianal area to severe irritation with erythema, crusting, lichenification and erosions or ulcerations. Histologically, a nonspecific, chronic dermatitis is usually seen, but specific dermatologic diseases (e.g. lichen sclerosus) or a neoplastic disorder (e.g. extramammary Paget's disease) can be excluded.

Evaluation includes a complete history as well as a general physical and cutaneous examination, along with appropriate psychiatric screening. The latter is of importance considering that anxiety and depression have been described as aggravating factors for pruritus ani[46]. Patch testing should be considered, as one study demonstrated that 34 of 40 patients presenting with pruritus ani had an underlying dermatosis that accounted for their symptoms, including allergic contact dermatitis[48].

Rectosigmoidoscopy and/or colonoscopy may be necessary, particularly in patients with pruritus ani refractory to conventional treatment. In 109 patients with pruritus ani as their presenting complaint (mean age, 52 years), 83 (75%) had colonic or anorectal pathology ranging from hemorrhoids to cancer (26 patients had the latter diagnosis)[46]. The possibility of pinworm infection should be considered in patients with pruritus ani, especially children (see Ch. 83). If patients are receiving chronic antibiotic therapy and have liquid stools, pH testing can be performed. A pH of 8–10 has been associated with a deficiency of *Lactobacillus* spp., requiring replacement therapy.

Mild primary pruritus ani often responds to sitz baths, cool compresses, and meticulous hygiene using water-moistened, fragrance-free toilet paper or a bidet. The area is then blotted dry, with avoidance of rubbing and alkaline soaps (see Ch. 153). A mild corticosteroid cream or ointment (class 6 or 7) is often effective in controlling symptoms. However, with increasing disease severity, increasingly potent topical corticosteroids may be required, and with longstanding disease and lichenification, patients may need prolonged treatment, raising the risk of cutaneous atrophy. Topical calcineurin inhibitors (including use on a rotational basis with topical corticosteroids) may be helpful when longer courses of therapy are necessary.

Secondary pruritus ani improves with treatment of the underlying disorder, e.g. removal of a malignancy, antihelminthic therapy or hemorrhoidectomy.

Pruritus Vulvae and Scroti

These common disorders may be as incapacitating and emotionally disturbing as anal pruritus. Originally thought to be psychogenic illnesses, case series indicate that these conditions are psychogenic in only 1% to 7% of patients[1]. Like pruritus ani, patients with pruritus of the vulva or scrotum typically complain of symptoms that are worse at night, and, via repeated rubbing and scratching, lichenification often develops. The evaluation, differential diagnosis, and treatment options are similar to those for pruritus ani.

Acute pruritus of the vulva or scrotum is often related to infections, but allergic or irritant contact dermatitis should also be considered. *Chronic* pruritus in these sites may be caused by dermatoses

(e.g. psoriasis, atopic dermatitis, lichen sclerosus, lichen planus), malignancy (e.g. extramammary Paget's disease, squamous cell carcinoma) or atrophic vulvovaginitis[8,49]. Scrotal pruritus secondary to lumbosacral radiculopathy has also been described[50]. In general, irritation related to cleansing and toilet habits needs to be addressed.

Specific treatment of the underlying cause is necessary. For example, class 1 corticosteroid ointment twice daily for up to 2 months often produces a dramatic response in vulvar lichen sclerosus (see Ch. 73).

Scalp Pruritus

Skin disorders involving the scalp (e.g. seborrheic dermatitis, psoriasis, folliculitis, dermatomyositis) may present with pruritus localized to this area. However, pruritus of the scalp can also occur in the absence of any objective changes, most commonly in middle-aged individuals during periods of stress and fatigue. In such instances, various treatments such as emollients and topical corticosteroids have been employed with inconsistent efficacy[1].

Pruritus in Scars

Scar remodeling can last from 6 months to 2 years. Pruritus associated with normal wound healing is common and usually resolves over time[1]. Occasionally, pruritus and discomfort may be prolonged, sometimes in association with hypertrophic or keloidal scarring. Most likely, the pruritic sensation in immature or abnormal scars is a consequence of physical and chemical stimuli as well as nerve regeneration. Physical stimuli include direct mechanical stimulation of nerve endings during scar remodeling. Histamine, vasoactive peptides such as kinins, and prostaglandins of the E series (PGE) act as chemical mediators and may account for a "chemogenic" pruritus. The role of histamine in the early inflammatory phase of wound healing is well documented, and an increase in histamine content within keloids and hypertrophic scars appears to parallel the rate of collagen synthesis. Nerve regeneration occurs in all healing wounds, and the disproportionate number of thinly myelinated and unmyelinated C fibers present in immature or abnormal scars contributes to an increased perception of pruritus. The observation of abnormalities in small nerve fiber function within keloids has raised the possibility of a small nerve fiber neuropathy[51].

Therapy includes emollients, anti-inflammatory agents such as topical and intralesional corticosteroids, and silicone gel sheets. Oral antihistamines do not have a significant benefit. Relief of pain and pruritus associated with giant keloids was observed with oral pentoxifylline (400 mg two to three times daily)[52].

Postburn Pruritus

Approximately 85% of patients with burns experience pruritus during healing, particularly when the burns involve the limbs[53]. A gradual decrease in pruritus usually occurs, but it may be present for years. Histamine release during the inflammatory stage of the healing process correlates with collagen production. As morphine is the analgesic of choice in the treatment of burns, it may contribute to postburn pruritus as well.

Burn survivors often face psychological distress, which has been linked to an increase in pruritic sensations[54]. Reported predictors of pruritus include a deep dermal burn injury, female gender, and high psychological impact of the accident[55]. Topical emollients and antihistamines are frequently utilized but rarely provide adequate relief[54]. In a recent randomized controlled trial, oral gabapentin was found to be more effective than cetirizine for postburn pruritus[55a]. Topical anesthetics (e.g. lidocaine/prilocaine), massage therapy, and bathing in oiled water or with colloidal oatmeal may also be of benefit[56].

Miscellaneous

Fiberglass dermatitis

Fiberglass exposure is common in individuals with occupations in industry or construction, and it may provoke severe pruritus with or without visible skin lesions. Involvement of the hands and other noncovered body parts such as the upper extremities, face and upper trunk is typical. Clinically, fiberglass dermatitis may resemble scabies, eczematous dermatitis, folliculitis or urticaria (see Ch. 16)[33].

PRURITUS IN SYSTEMIC DISEASE

Renal Pruritus

Renal pruritus is a localized or generalized, paroxysmal symptom occurring in patients with chronic (not acute) renal failure. Unfortunately, the term "uremic pruritus" is often used synonymously. "Uremic pruritus" implies that the symptom is secondary to elevated serum urea levels, which is untrue.

The occurrence of renal pruritus is not associated with gender, age, race, duration of dialysis or etiology of the renal failure[1]. Patients on continuous ambulatory peritoneal dialysis (CAPD) are less affected than those on hemodialysis[1], and utilization of high-permeability rather than conventional hemodialysis may help to relieve renal pruritus[56a]. Pruritus peaks at night after 2 days without dialysis (in those on a standard hemodialysis treatment protocol), is relatively high during treatment and is lowest during the day following dialysis[9,57]. Renal pruritus has been shown to be an independent marker of mortality for patients on hemodialysis.

The etiology of renal pruritus is poorly understood, and the role of mast cells is controversial. Whereas some researchers have detected increased total numbers of mast cells (often degranulated) as well as proliferation of mast cells in the skin and various other organs (spleen, bone marrow, bowel wall), other investigators could not confirm these findings[58]. Increased plasma histamine levels in uremic patients have been detected in some but not all studies, and no relationship has been found between the plasma histamine level and severity of pruritus[58]. This is in accordance with the failure of antihistamine therapy to provide relief to affected individuals. Another possible explanation for renal pruritus is an accumulation of poorly dialyzed compounds that cross the dialysis membranes slowly[1].

Parathyroid gland activity is commonly increased in chronic renal failure, and a dramatic relief of pruritus after subtotal parathyroidectomy has been reported in some patients[1]. Serum calcium, phosphate and parathyroid hormone (PTH) levels have been shown to be significantly higher in dialysis patients with pruritus than in those without pruritus, but no correlation between the degree of symptoms and the PTH level has been observed[9,58a]. Immunohistochemical studies have failed to demonstrate PTH within the skin, nor does PTH produce pruritus when injected intradermally[9]. Additionally, pruritus is not always present in uremic patients with hyperparathyroidism[9]. In summary, the role of circulating PTH in renal pruritus is controversial.

Although xerosis is common in patients with chronic renal failure (Fig. 6.8), the presence of pruritus does not correlate with xerosis,

Fig. 6.8 Xerosis and pruritus in a patient with chronic renal failure who is receiving hemodialysis. There are a few papules of acquired perforating dermatosis admixed with the scratch marks. *Courtesy, Jean L Bolognia, MD*

THERAPEUTIC LADDER FOR RENAL PRURITUS
MEDICAL
• Topical capsaicin (0.025% three to five times daily) (2)
• Topical γ-linolenic acid (2.2% four times daily) (1)
• Topical pramoxine (1)
• Activated charcoal (6 g po daily) (1)
• Gabapentin (200–300 mg after each hemodialysis session) (1)
• Pregabalin (25 mg po daily) (2)
• UVB phototherapy (1)
• Cholestyramine (4–16 g po daily in divided doses) (2)
• Naltrexone (50 mg po daily) (2)
• Ondansetron (8 mg po or iv daily) (2)
• Nalfurafine* (TRK-820) (5 microg iv three times a week†) (1)
• Ketotifen (1–2 mg po daily) (3)
• Cromolyn sodium (135 mg po three times daily) (1)
• Montelukast (10 mg po daily) (1)
• Thalidomide (100 mg po daily) (1)
• Lidocaine (200 mg iv daily) (3)
• Erythropoietin (36 U/kg sc three times a week) (3)
SURGICAL
• Subtotal parathyroidectomy
• Renal transplant
*Kappa-opioid receptor agonist. †Post hemodialysis.

Table 6.6 Therapeutic ladder for renal pruritus. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

stratum corneum hydration or sweat secretion[59]. The role of elevated blood serotonin levels in hemodialysis patients also remains unclear[58]. Peripheral neuropathy affects up to 65% of patients who receive dialysis, raising the possibility that pruritus may be a manifestation of a neuropathy (see treatment below). The presence of specialized receptors for pruritus in chronic dialysis patients has also been proposed, but this theory does not explain the abruptness of symptom improvement after transplantation.

Opioids could potentially play a role, as they accumulate with renal failure. However, this accumulation is unrelated to the duration of disease and levels are unaltered by hemodialysis[1]. In addition, one study of hemodialysis patients found that renal pruritus was not related to serum levels of β-endorphin. Finally, it has been suggested that an immunologic alteration characterized by a proinflammatory pattern is involved in the pathogenesis of renal pruritus. In three patients, a 7-day course of topical tacrolimus ointment 0.03% led to a dramatic relief of pruritus[60]; however, these results could not be confirmed in a controlled study[61].

A brief overview of published therapeutic options for renal pruritus is provided in Table 6.6. Antihistamine use for this indication has shown only marginal efficacy[1]. Oral activated charcoal has produced good results in controlled studies, whereas cholestyramine has had variable success[1]. Ondansetron was reported as effective in patients receiving both continuous ambulatory peritoneal dialysis and hemodialysis, but these results could not be verified by more recent studies in hemodialysis patients[62]. Results of controlled trials of naltrexone have been mixed[63,64]. However, nalfurafine; a novel κ-opioid receptor agonist that is administered intravenously, was found to be effective in multicenter controlled studies[65]. In one controlled trial, thalidomide relieved pruritus in a significant number of patients[66]. There is evidence that gabapentin can also be a safe and effective therapy[67]. However, renal transplantation remains the most effective treatment, as pruritus ceases soon after this intervention.

Cholestatic Pruritus

Nearly any liver disease can present with pruritus, but the most commonly associated entities are primary biliary cirrhosis, primary sclerosing cholangitis, obstructive choledocholithiasis, carcinoma of the bile duct, cholestasis (also see drug-induced pruritus), chronic hepatitis C viral infection and other forms of viral hepatitis[1]. Pruritus in these settings tends to be generalized, migratory and not relieved by scratching. It is typically worse on the hands, feet and body regions constricted by clothing, and it tends to be most pronounced at night. In patients with chronic cholestasis, pruritus can be an early symptom that develops years before any other manifestation of the liver disease[1].

The etiology of cholestatic pruritus is unknown[10]. There are several major theories regarding mediators and mechanisms. For decades, a role for bile acids was postulated. Although intracutaneous injection of bile acids has been reported to induce pruritus, elevated serum levels of bile acids are not always associated with pruritus. Additionally, in patients with severe cholestasis, the development of hepatocellular failure tends to result in spontaneous cessation of pruritus[10]. Another hypothesis proposes that increased opioidergic neurotransmission or neuromodulation in the CNS contributes to the pruritus of cholestasis[10]. This is based upon the observation that opiate agonists induce opioid receptor-mediated scratching activity of central origin. Furthermore, cholestasis-related changes in the opioid system may lead to changes in other neurotransmitter systems such as altered serotoninergic neurotransmission. Recent studies have provided evidence that lysophosphatidic acid, a neuronal activator, may have a role in cholestatic pruritus[67a]. In summary, it is inferred that as yet unknown pruritogen(s) are produced in the liver and excreted in the bile, and they then accumulate in the plasma as a result of cholestasis[10,68].

Treatment of cholestatic pruritus depends on the underlying cause and includes gallstone removal, drug withdrawal, and interferon plus ribavirin therapy for chronic hepatitis C viral infection. Ultimately, liver transplantation for end-stage liver failure will improve symptoms. A number of systemic antipruritic therapies have been reported (Table 6.7). As there is no compelling evidence that histamine is involved in the pathogenesis of cholestatic pruritus, antihistamines have limited therapeutic benefit except for their sedating properties. Of note, gabapentin did not have a therapeutic advantage over placebo in a controlled study[68].

Hematologic Pruritus

Many hematologic diseases, especially myelodysplastic disorders, are associated with significant pruritus.

Iron deficiency

Patients with iron deficiency plus generalized or localized pruritus (especially of the perianal or vulvar region) that improved with iron supplementation have been described[1]. However, controlled trials have not been performed. Of note, iron deficiency can be a sign of polycythemia vera, other malignancies or systemic diseases that themselves cause pruritus. Excluding a gastrointestinal source of blood loss is an important consideration[11].

Polycythemia vera

Aquagenic pruritus (see above) may precede the development of polycythemia vera by several years, and approximately 30–50% of polycythemia vera patients have pruritus. Thus, this diagnosis must be suspected in all patients with aquagenic pruritus[33]. Platelet aggregation has been suggested as a possible mechanism leading to release of serotonin and other pruritogenic factors, including histamine. A mutation in the Janus kinase 2 gene (*JAK2*) that results in constitutive activation and agonist hypersensitivity in basophils has been shown to be associated with aquagenic pruritus in polycythemia vera patients. Treatment options include oral aspirin (300 mg once daily to three times a day), which is first-line therapy given the rapid relief it provides for 12–24 hours; UVB or PUVA phototherapy (reports of success); intramuscular interferon-α (good efficacy); and oral H_1- or H_2-receptor antagonists (variable results)[1,11,33].

Pruritus and Malignancy

Virtually any malignancy can induce pruritus as a paraneoplastic phenomenon, but the true relationship between cancer and this symptom is unclear. No reliable epidemiologic study has demonstrated whether malignant diseases are increased in patients suffering from unexplained pruritus. Persistent, unexplained pruritus or failure of generalized pruritus to respond to conventional therapy should warrant evaluation for an underlying malignancy[11,33]. Pruritus may be seen in advanced disease

TREATMENT OPTIONS FOR HEPATIC OR CHOLESTATIC PRURITUS	
BENEFIT CONFIRMED IN CONTROLLED CLINICAL TRIALS	
Cholestyramine*	4–16 g po daily
Ursodeoxycholic acid (ursodiol)	13–15 mg/kg po daily
Rifampin†	300–600 mg po daily (depending upon serum bilirubin level)
Naltrexone‡	25 mg po twice daily [day 1], then 50 mg po daily
Naloxone‡	0.2 microg/kg/min iv infusion preceded by 0.4 mg iv bolus
Nalmefene‡	2 mg po twice daily [day 1], 5 mg po twice daily [day 2], 10 mg po twice daily [day 3], then 20 mg po twice daily; increase as needed to maximum of 120 mg po twice daily
Propofol	10–15 mg iv (bolus), 1 mg/kg/h (infusion)
Thalidomide	100 mg po daily
EQUIVOCAL EFFECT IN CONTROLLED STUDIES	
Ondansetron§	4–8 mg iv or 8 mg po daily
BENEFIT OBSERVED IN CASE SERIES OR CASE REPORTS	
Dronabinol‖	5 mg po nightly
Sertraline¶	75 mg po daily
Paroxetine¶	10 mg po daily
Butorphanol spray**	–
Plasma perfusion (ion resin BR-350)	–
Phenobarbital	2–5 mg/kg po daily
Phototherapy: UVA, UVB	–
Stanozolol	5 mg po daily
Bright light therapy	10 000 lux reflected toward the eyes up to 60 min twice daily

*Improvement may be temporary.
†Increases hepatic metabolism of bile salts.
‡Mu-opioid receptor antagonists.
§Antagonist of 5-HT_3 receptors.
‖Cannabinoid B1 receptor agonist.
¶Selective serotonin reuptake inhibitor.
**Kappa-opioid receptor agonist and μ-opioid receptor antagonist.

Table 6.7 Treatment options for hepatic or cholestatic pruritus[33,65,68–78].

or it can be an early sign that is present for several years before the diagnosis is made[11]. However, the intensity and extent of pruritus do not correlate with the extent of tumor involvement[1].

Suggested mechanisms of tumor-associated pruritus include toxic products from necrotic tumor cells entering the systemic circulation, production of chemical mediators of pruritus by the tumor, allergic reactions to tumor-specific antigens, increased proteolytic activity and histamine release. Pruritus may also complicate malignant disease that results in obstruction of the biliary tree (e.g. carcinoma of the head of the pancreas or bile duct), and "central" pruritus (e.g. due to brain tumors) or pruritus as a consequence of treatment (e.g. surgery, radiotherapy, cytotoxic chemotherapy) can occur[11]. Pruritus associated with obstruction of the biliary tree tends to be generalized, sometimes with especially intense involvement of the palms and soles. Localized pruritus of the nose has been associated with brain tumors[1]. Symptomatic pharmacologic interventions include SSRIs, mirtazapine and thalidomide[11].

Hodgkin disease

There is a strong association between pruritus and Hodgkin disease[1]. Severe, persistent generalized pruritus is predictive of a poor prognosis, and return of this symptom may portend tumor recurrence. It has been proposed that pruritus should be added to the list of B symptoms in this disease[1].

Factors contributing to pruritus in Hodgkin disease may include eosinophilia and release of histamine (from basophils), leukopeptidases or bradykinin. Hepatic involvement by the lymphoma may occasionally play a role. Production of IL-5 by Reed–Sternberg cells can lead to eosinophilia, but whether the eosinophil count correlates with the degree of pruritus is unclear. Therapy should focus on treatment of the lymphoma, but topical corticosteroids and oral mirtazapine (7.5–30 mg/day) may be of benefit[11].

Non-Hodgkin lymphoma

Pruritus is generally less prevalent in non-Hodgkin lymphoma than in Hodgkin disease. An estimated 10% of patients with non-Hodgkin lymphoma suffer from pruritus at some time during the course of their disease. Amelioration after systemic interferon-α has been reported[11].

Leukemia

Pruritus is not a common symptom in patients with leukemia, but when it occurs, it is usually generalized. Chronic lymphocytic leukemia (CLL) and hypereosinophilic syndrome (which includes patients with eosinophilic leukemia and other hematologic malignancies; see Ch. 25) are often associated with pruritus. In addition, patients with CLL can develop exaggerated reactions to insect bites. Leukemia cutis may produce localized symptoms that include pruritus[11,33].

Endocrine Pruritus

Thyroid disease

Severe generalized pruritus may be a presenting symptom of hyperthyroidism. The cause is not known, but it is postulated to result from a direct effect of thyroid hormone on the skin[1]. Localized or generalized pruritus may also be seen in patients with hypothyroidism, but not as frequently. The skin in individuals with hypothyroidism is often dry, which can lead to asteatotic eczema accompanied by pruritus.

Diabetes mellitus

Generalized pruritus as a presenting symptom of diabetes mellitus may occur, but generalized pruritus is not significantly more common in diabetic than in non-diabetic patients[79]. Localized pruritus, especially in the genital and perianal areas (see pruritus ani), is significantly more common in diabetic women and is associated with poor glycemic control[79]. In some patients, a predisposition to candidiasis may play a role. Diabetic neuropathy is characteristically associated with pain, burning or prickling sensations, although pruritus has been described[1].

Pruritus in HIV Infection and AIDS

Occasionally, pruritus is the initial presenting symptom of AIDS. In as many as half of AIDS patients with pruritus, an additional diagnosis responsible for this symptom is not identified. However, HIV-infected individuals tend to develop a number of pruritic dermatoses such as pruritic papular eruption, eosinophilic folliculitis, severe seborrheic dermatitis, psoriasis, scabies, drug eruptions, xerosis (see Fig. 6.3) and acquired ichthyosis (see Ch. 78). Insect bites can be significantly more inflammatory and pruritic in the HIV-infected population; one hypothesis regarding the pruritic papular eruption of HIV infection is that it reflects an altered and exaggerated immune response to arthropod antigens[80]. Kaposi sarcoma lesions are occasionally pruritic, and patients with HIV infection may have causes of pruritus previously discussed (e.g. chronic renal failure, liver disease and non-Hodgkin lymphoma)[81].

Severe, treatment-resistant pruritus is relatively common in HIV-infected individuals. Immunologic analyses have shown that HIV patients with intractable pruritus have markedly elevated serum levels of IgE, peripheral hypereosinophilia and a Th2-type cytokine profile[82]. Augmented serum concentrations of IgE have been found to correlate with a faster decline in $CD4^+$ T-cell counts[1], and a possible correlation between intractable pruritus and increased HIV viral load has been observed.

Treatment should be directed at any underlying dermatoses that can be identified (see above). Topical corticosteroids, UVB phototherapy and antihistamines may be used symptomatically; antihistamines with anti-eosinophilic potential may be more effective (e.g. cetirizine). The safety of UV treatment in HIV-infected patients has been debated

COMMON PHARMACOLOGIC ETIOLOGIES OF PRURITUS	
Pathomechanism	**Medication**
Cholestasis	Chlorpromazine, erythromycin estolate, estrogens (including oral contraceptives), captopril, sulfonamides
Hepatotoxicity	Acetaminophen, anabolic steroids (including testosterone), isoniazid, minocycline, amoxicillin–clavulanic acid, halothane, phenytoin, sulfonamides
Sebostasis/xerosis	Beta-blockers, retinoids, tamoxifen, busulfan, clofibrate
Phototoxicity	8-Methoxypsoralen
Neurologic (or histamine release)	Tramadol, codeine, cocaine, morphine*, butorphanol, fentanyl, methamphetamine
Deposition	Hydroxyethyl starch
Idiopathic	Chloroquine, clonidine, gold salts, lithium
*Also non-immunologic release of histamine from mast cells.	

Table 6.8 Common pharmacologic etiologies of pruritus.

but such treatment is currently considered safe[44]. Although antiretroviral therapy (ART; formerly referred to as highly active antiretroviral therapy [HAART]) can lead to improvement in several pruritic dermatologic diseases, a variety of skin conditions (infectious, inflammatory and neoplastic) may flare when ART is started (immune reconstitution inflammatory syndrome; see Ch. 78)[81]. Another therapeutic option for pruritus and prurigo nodularis in patients with HIV infection and AIDS is thalidomide (100–300 mg/day), as it is not an immunosuppressant[33,83].

PRURITUS IN PREGNANCY

This symptom can have multiple etiologies in a pregnant patient[8] and is discussed in Chapter 27.

PHARMACOLOGIC PRURITUS

Essentially, any drug can cause a skin reaction that is associated with pruritus[1]. Pruritic drug reactions most often present as morbilliform or urticarial eruptions (see Ch. 21), but occasionally pruritus is the predominant manifestation (Table 6.8). Some medication effects (e.g. hepatotoxicity) that can lead to pruritus have a relatively long latency period. Treatment includes discontinuation of the offending agent.

PSYCHOGENIC PRURITUS

Psychogenic (somatoform) pruritus should be considered when other causes have been excluded. Psychogenic pruritus may have an intensity that parallels the emotional state and is often exaggerated[33]. No primary lesions are seen, and secondary lesions range from lichenification to excoriations. Although the patient's sleep pattern is usually uninterrupted, sedative antipruritics may be utilized as therapy, because topical agents alone are rarely effective. Generalized pruritus can be associated with anxiety disorders, depression and even psychosis (e.g. delusions of parasitosis; see Ch. 7). Consultation with a psychiatrist is recommended.

NEUROLOGIC ETIOLOGIES OF PRURITUS AND DYSESTHESIA

A dysesthesia is defined as an abnormal sensation such as tingling, burning, numbness or pruritus. It can result from abnormalities in the CNS (neurogenic) or peripheral nervous system (neuropathic). Dysesthesias, including pruritus, are usually localized (e.g. upper back, thigh; Fig. 6.9) when they are due to a neuropathy. Neurogenic causes of locoregional dysesthesia (e.g. chin, nose) include tumors of the CNS, stroke and multiple sclerosis.

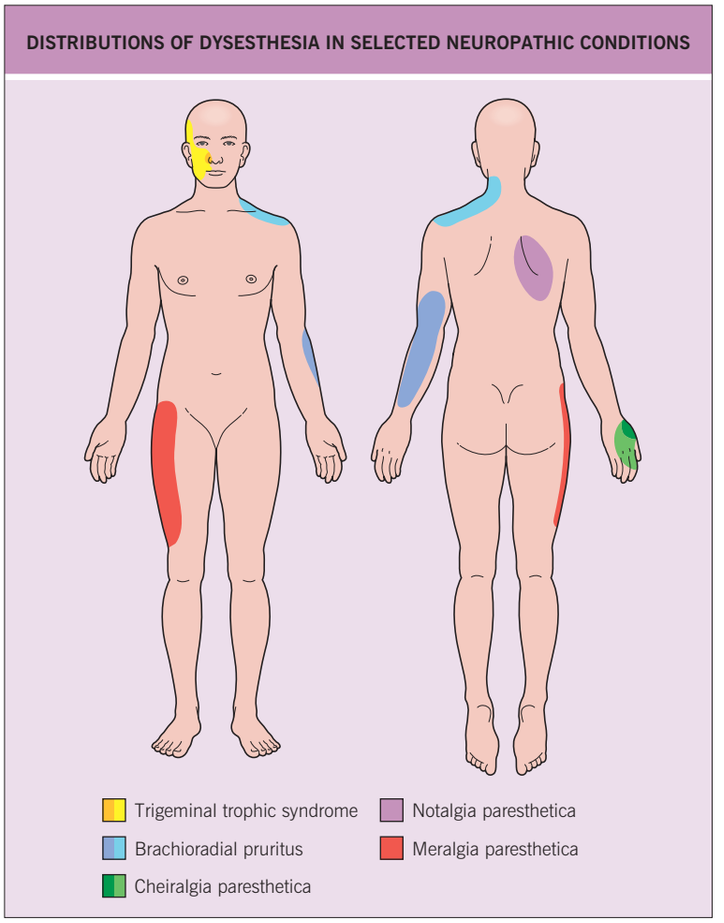

Fig. 6.9 Distributions of dysesthesia in selected neuropathic conditions. Cheiralgia paresthetica is caused by entrapment of the radial nerve. Darker shades indicate more common areas of involvement. *Courtesy, Kary Duncan, MD.*

Fig. 6.10 Brachioradial pruritus. The affected area is outlined by ink.

Brachioradial Pruritus

This chronic disorder is characterized by intermittent pruritus or burning pain on the dorsolateral aspects of the forearms and elbows (Fig. 6.10); there is sometimes more extensive involvement (e.g. of the shoulder area) (see Fig. 6.9). Cumulative solar damage and nerve root impingement due to degenerative cervical spine disease may be contributory factors[1,84]. Acute UV light exposure exacerbates the condition, and patients living in temperate climates report remissions in the fall and winter months. Sunlight is therefore an eliciting factor, and both photodamage and cervical spine disease are predisposing factors[84]. Patients may report that the application of ice provides some relief.

Examination often reveals excoriations localized to the vicinity of the brachioradialis muscle, but dermatitis of the affected area is rare. Evaluation should include a neurologic examination; if indicated, imaging of the cervical spine can be performed. In addition to sun protection, treatment options include topical capsaicin or pramoxine, gabapentin (600–1800 mg/day in divided doses), physical therapy and acupuncture[33].

Burning Mouth Syndrome

Orodynia, or burning mouth syndrome, is characterized by burning mucosal pain without clinically detectable oral lesions. The pain is typically bilateral, often involving the anterior two-thirds of the tongue, palate and lower lip[85]. The buccal mucosa and floor of the mouth are rarely involved. Histology of the affected areas in primary burning mouth syndrome is unremarkable. However, secondary causes, as listed below, may be identified.

The condition is thought to affect more than 1 million people in the US. It typically occurs in middle-aged or older adults, with a female : male ration of ~7 : 1[86]. Symptoms can last from a few months to several years. A classification system based on the pattern of disease over time has been described: *type 1* (35%) is characterized by the absence of symptoms upon awakening, with a gradual increase in severity over the course of the day; *type 2* (55%) features constant burning, both day and night; and *type 3* (10%) has days of remission that follow no identifiable pattern[86].

The evaluation of burning mouth syndrome should include a thorough physical examination to help exclude secondary causes, although the disorder is frequently idiopathic. Localized burning or itch may be the first indication of a malignant lesion (e.g. an oral squamous cell carcinoma), and a biopsy should be performed if a malignancy is suspected. Ill-fitting dentures, oral candidiasis, xerostomia (salivary flow studies in primary burning mouth syndrome have been inconclusive), and contact dermatitis to dental work have been reported as other secondary causes. All medications (prescription and over-the-counter) should be reviewed to identify any that have xerostomia as a side effect. Additional precipitating factors include iron, zinc, folate and vitamin B_{12} deficiencies, type 2 diabetes mellitus, hypothyroidism and the menopausal state[87]. Finally, depression and anxiety have been found more commonly in patients with burning mouth syndrome compared with pain-free controls[86].

When a secondary cause is identified, treatment of that disorder is indicated. Depending upon the initial evaluation, further consultations may be necessary (e.g. dentistry, psychiatry, otolaryngology, neurology). Direct questions concerning anxiety, fear of cancer and depression should be broached.

Reported successful treatments for primary burning mouth syndrome include oral tricyclic antidepressants (e.g. amitriptyline, doxepin), low-dose benzodiazepines and gabapentin, as well as topical clonazepam[88]. Initial doses of the antidepressants should be low and then increased slowly, given unwanted side effects such as xerostomia and sedation. In case reports and series, antifungal agents such as nystatin were shown to be effective (even when cultures were negative), as were topical capsaicin and anesthetics such as lidocaine or dyclonine; mouthwashes containing various combinations of anesthetics, nystatin, tetracycline, hydrocortisone, diphenhydramine and Maalox® have been utilized. There is some evidence that cognitive behavioral therapy and α-lipoic acid (600 mg daily) can improve symptoms[89].

Burning Scalp Syndrome

Burning scalp, also referred to as "scalp dysesthesia"[90], presents with diffuse burning pain, pruritus, numbness or tingling of the scalp without objective findings. Secondary causes such as seborrheic dermatitis, folliculitis, lichen planopilaris, allergic or irritant contact dermatitis and discoid lupus erythematosus should be excluded and (if present) treated. In a study examining the correlation between stressful life events and cutaneous symptoms, the most frequent body region affected was the scalp, and burning scalp syndrome is often associated with underlying depression and anxiety. Like other dysesthesias, burning scalp syndrome is often treated with gabapentin and tricyclic antidepressants[90] as well as topical capsaicin. An isolated case report noted resolution of chronic scalp pain in a patient with severe hyperlipidemia and eruptive xanthomas once the lipid abnormality was corrected[91].

Notalgia Paresthetica

Notalgia paresthetica is a common condition in adults that is characterized by focal, intense pruritus of the upper back, especially over the medial scapular borders (see Fig. 6.9); it is occasionally accompanied by pain, paresthesias or hyperesthesias[92]. A characteristic finding on physical examination is a hyperpigmented patch due to chronic rubbing of the affected area. Dermal melanophages are evident histologically, and there is considerable overlap with macular amyloidosis.

Various etiologies have been reported, including an association with Sipple syndrome (multiple endocrine neoplasia type 2A; especially if onset is during childhood or adolescence; see Ch. 63), increased dermal innervation, and viscerocutaneous reflex mechanisms. However, most evidence suggests that notalgia paresthetica represents a sensory neuropathy. In approximately 60% of affected patients, the symptoms correlate with spinal pathology, suggesting a pathogenic role for spinal nerve impingement[92].

Topical capsaicin cream applied five times daily for 1 week followed by three times daily for 3 to 6 weeks can improve symptoms[93]. Other options include topical corticosteroids, topical anesthetics (e.g. pramoxine, lidocaine), gabapentin and acupuncture. In one case report, a paravertebral block at spinal levels T3 through T6 with bupivacaine and methylprednisolone acetate produced a 12-month remission[94].

Meralgia Paresthetica

Meralgia paresthetica is a localized dysesthesia that presents with numbness, burning pain, tingling or itching of the anterolateral thigh (see Fig. 6.9). Allodynia (increased sensitivity to light touch) is another frequent manifestation, but cutaneous findings such as hyperpigmentation (Fig. 6.11) are less common than in notalgia paresthetica. Meralgia paresthetica occurs in the area of skin innervated by the lateral femoral cutaneous nerve, and it results from pressure on this nerve as it passes under the inguinal ligament. Predisposing factors include obesity, pregnancy, prolonged sitting, tight clothing and carrying heavy wallets in trouser pockets. Much less often, it results from a L1–L4 radiculopathy. Treatment is directed at relieving the pressure on the nerve. A focal nerve block at the inguinal ligament may be of benefit, and surgical decompression is sometimes required. Pharmacologic management as described for nostalgia paresthetica is occasionally helpful.

Dysesthetic Anogenital Pain Syndromes

The most common causes of anal pain are not dysesthesias, but rather hemorrhoids and fissures. Likewise, genital pain is often related to etiologies such as trauma, infection (e.g. chlamydia, herpes simplex, candidiasis) and (in men) testicular torsion. Since chronic pain may be a harbinger of malignancy, a thorough evaluation is indicated. However, patients with chronic or recurrent anogenital pain but no detectable abnormalities on physical examination may have a dysesthetic anogenital pain syndrome (Table 6.9). Vulvodynia (localized or generalized)

Fig. 6.11 Meralgia paresthetica. Hyperpigmentation and lichenification in a discrete area of dysesthesia on the anterior thigh.

DYSESTHETIC ANOGENITAL PAIN SYNDROMES	
Syndrome	**Clinical history**
Levator ani syndrome	Brief intermittent burning pain or tenesmus of the rectal or perineal area. Aggravated by sitting or elimination
Proctalgia fugax	Sudden stabbing pain in the perirectal area. Awakens patient from sleep
Coccydynia	Intermittent or persistent pain, usually burning type, localized to the coccyx
Male genital pain syndrome	Intermittent, continuous or episodic pain during penetration, ejaculation, micturition or exercise
Koro syndrome	Psychogenic disorder characterized by acute anxiety, fear of death and sensations that the genitalia are inwardly retracted and (variably) burning pain

Table 6.9 Dysesthetic anogenital pain syndromes. Vulvodynia is discussed in Chapter 73.

Fig. 6.12 Reflex sympathetic dystrophy with scaling and erosions of the fingertips. *Courtesy, Kalman Watsky, MD.*

THE STAGES OF REFLEX SYMPATHETIC DYSTROPHY
FIRST STAGE (WITHIN 1 TO 3 MONTHS)
• Hyperalgesia – pain experienced above that expected for a given stimulus • Allodynia – pain experienced from innocuous stimuli • Patients tend to categorize the pain as burning; clinical signs are rare
SECOND STAGE (WITHIN 3 TO 9 MONTHS)
• Hyperpathia – an increased pain threshold develops that, when exceeded, results in rapid maximal pain intensity that is not stimulus-dependent • Dystrophic nail changes – brittleness, thickening, and rigidity of the nail plate • Regional hypertrichosis and hyperhidrosis • Regional vasomotor dysfunction – livedo reticularis, cyanosis, edema, delayed capillary refill, and erythema may be seen • Motor dysfunction – inability to initiate movement, weakness, tremor, muscle spasms and dystonia. Upper extremity findings may include flexion-contractures of the fourth and fifth digits with adduction and flexion of the arm and wrist. When the lower extremity is involved, inversion of the foot with plantar flexion is common
THIRD STAGE (WITHIN 9 TO 18 MONTHS)
• Sudeck's atrophy – skeletal cystic and subchondral erosion with diffuse osteoporosis • Fibrous ankylosis of joints • Muscle, subcutaneous and pilar atrophy with fixed cutaneous mottling

Table 6.10 The stages of reflex sympathetic dystrophy.

TREATMENT OPTIONS FOR REFLEX SYMPATHETIC DYSTROPHY
NON-INVASIVE
Alpha-adrenergic antagonists: phenoxybenzamine, prazosin, terazosin Gabapentin Intranasal calcitonin Thalidomide
INVASIVE
Intrathecal
Baclofen, phenoxybenzamine, reserpine, corticosteroids, anesthetic agents
Surgical
Sympathectomy Acupuncture Transcutaneous nerve stimulation

Table 6.11 Treatment options for reflex sympathetic dystrophy.

is discussed in Chapter 73. Of note, anogenital pruritus (see above) can also represent a dysesthetic state.

Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy, also known as complex regional pain syndrome, is a debilitating disorder that develops in regions where damage to peripheral nerves has occurred. The most commonly affected areas are the upper limbs (especially the hands; Fig. 6.12), but the lower extremities may also be involved. Regional insult to nociceptive terminals results in a complicated signal cascade that ultimately amplifies the pain response of the CNS. The disease progresses through several stages (Table 6.10), which are thought to be due to autonomic nervous system dysfunction[95].

Many treatment modalities have been utilized and are summarized in Table 6.11. Most therapies are directed toward interruption of the autonomic nervous system and have had limited success[96].

Trigeminal Neuralgia

Trigeminal neuralgia, also known as tic douloureux, is characterized by recurrent paroxysms of sharp pain (lasting seconds to minutes) radiating into the territory of one or more of the trigeminal sensory divisions. The pain is generally unilateral (most often right-sided) and described as a stabbing, burning or shocking sensation. Attacks may occur as frequently as several times per day or as infrequently as a few times per month. Typically, the episodes increase in frequency and severity over time, occasionally culminating in a persistent pain flurry lasting for days to weeks, called acute trigeminal neuralgia crisis.

Various trigger stimuli have been reported, such as touching or washing the face, brushing the teeth, eating or talking. A thorough history is important because physical findings are nearly non-existent. Sensory and motor function should be intact, and abnormalities raise suspicion of structural neurologic abnormalities related to a tumor, stroke or multiple sclerosis. MRI is of value for detecting these entities but is low yield in primary trigeminal neuralgia[97].

The cause of trigeminal neuralgia remains unknown, although several hypotheses have been proposed. Early reports focused on trigeminal nerve demyelination. Of note, multiple sclerosis is a concurrent disease in 4–18% of patients with this condition. However, more recent theories include a component of vascular impingement on the trigeminal nerve. In one study, vascular compression of the trigeminal root was found in >90% of patients with trigeminal neuralgia, explaining high success rates (80–90%) with decompression therapy in subsequent reports[97].

Medical therapy is the first-line management of trigeminal neuralgia. Carbamazepine is the single most effective long-term oral medication (providing relief in 70–90% of patients), and phenytoin, baclofen and gabapentin can also be helpful. In an open-label study, injections of botulinum A toxin were reported as therapeutically successful[98].

Fig. 6.13 Trigeminal trophic syndrome. Erosions and ulcerations with hemorrhagic crusts favor the ala nasi (**A, B**). Obvious linear excoriations are seen in the second patient (**B**). *Courtesy, Kalman Watsky, MD.*

In cases refractory to medical therapy, surgical options such as the aforementioned microvascular decompression can be employed. Stereotactic radiosurgical techniques with gamma radiation have also been developed, providing high rates of relief with minimal invasiveness or risk for loss of neurologic function. Acute trigeminal neuralgia crisis has been controlled with intravenous phenytoin for upwards of 48 hours, thereby providing a window to modify oral therapeutic regimens.

Trigeminal Trophic Syndrome

Trigeminal trophic syndrome is a self-induced ulcerative condition of the central face that classically involves the nasal alae[99,100] (Fig. 6.13). Patients characteristically present with a small crust that develops into a crescentic ulcer that may gradually extend to involve the cheek and upper lip. The self-mutilation is triggered by paresthesias and dysesthesias that occur secondary to impingement of or damage to the sensory portion of the trigeminal nerve. The nasal tip, which is supplied by the external nasal branch of the anterior ethmoidal nerve (see Ch. 142), is typically spared. Most commonly, the underlying nerve damage is iatrogenic from ablation of the Gasserian ganglion in an attempt to treat trigeminal neuralgia. Other causes include infection (e.g. with varicella–zoster virus, herpes simplex virus or mycobacteria), stroke (with infarction of the posterior cerebellar artery), and CNS tumors or their treatment[100].

The differential diagnosis is that of a non-healing ulcer and includes cutaneous malignancies (most often basal cell or squamous cell carcinoma, but also nasal NK/T-cell lymphoma), infections (e.g. chronic herpes simplex, *Leishmania* spp., dimorphic fungi, yaws), inflammatory disorders (e.g. vasculitis including Wegener's granulomatosis, pyoderma gangrenosum) and factitial disease (see Table 45.3).

Treatment of trigeminal trophic syndrome is challenging and requires a multidisciplinary approach. Medications such as carbamazepine, diazepam, amitriptyline and pimozide have limited effectiveness. Protective barriers worn at night and patient education are important measures. Surgical repair of the defect(s) with innervated skin flaps provides the greatest chance for resolution[99,100].

TREATMENT

Thus far, no specific antipruritic drugs exist that equal aspirin's ability to relieve pain. Individualized management of each patient and disease process is necessary[33]. Patient education and elimination of provocative factors are important, including wearing soft breathable clothing (i.e. no wool or harsh synthetic fabrics, but rather cotton or silk), avoiding excessive bathing (lukewarm baths or showers with mild synthetic detergents [syndets]), using emollients on a daily basis (with application of a cream or ointment immediately after bathing) and managing dermographism if present. Elderly patients are especially prone to xerosis, and restricting bathing to once or twice weekly (with interim sponge bathing of odorous regions such as the groin and buttocks) may be helpful. Patients can be taught methods of interrupting the itch–scratch cycle, such as application of a cold washcloth or gentle pressure, and the nails should be kept short. Controlled physical exercise, relaxation therapy, and minimization of exposure to dust and heat as well as of stress and anxiety are beneficial.

Topical Treatment

A large variety of topical compounds that have antipruritic properties are available, including corticosteroids, coal tars (e.g. 5% liquor carbonis detergens) and anesthetics (e.g. pramoxine) as well as counterirritants (e.g. menthol).

Topical anesthetic agents decrease pain and pruritic sensations and may relieve tingling and dysesthesias. Lidocaine/prilocaine (EMLA®) cream has demonstrated antipruritic properties in experimentally induced pruritus and can be helpful in localized pruritic states such as notalgia paresthetica[101]. Effectiveness may be improved by combining the anesthetic with urea, also a potential antipruritic[101]. However, the therapeutic effect depends on the underlying disease; for example, in one study, no significant improvement was seen in atopic dermatitis[102].

The topical antihistamine dimethindene (not available in the US) may improve pruritus severity, depending on the underlying cause; again, no effect was seen in atopic dermatitis[101,102]. Topical doxepin has demonstrated antipruritic effects in atopic dermatitis and other eczematous dermatoses, including lichen simplex chronicus, nummular eczema and contact dermatitis[103]. Side effects such as drowsiness occur when large portions of the body are covered and young children are treated. If pruritus continues or dermatitis develops, the possibility of allergic contact dermatitis to topical doxepin should be considered; subsequent oral administration of doxepin could result in systemic contact dermatitis. Topical cromolyn sodium was recently shown to relieve allergen- and histamine-induced pruritus without blocking wheal formation, suggesting a mechanism involving inhibition of cutaneous sensory nerve fibers rather than preventing mast cell degranulation[103a].

Capsaicin is a naturally occurring alkaloid found in many botanical species of the nightshade family (Solanaceae). Capsaicin enhances the release and secondarily inhibits the reaccumulation of neuropeptides. One of these, substance P, is a powerful vasodilator that releases histamine from cutaneous mast cells by an indirect effect. In the literature, topical capsaicin therapy has reportedly been used successfully in several dermatologic disorders. However, no therapeutic benefit has been seen in atopic dermatitis[104]. Concentrations usually range from 0.025% to 0.3%, and it needs to be applied three to five times daily for maximal effect. Capsaicin has been shown to be a safe treatment even on large skin areas[105]. Side effects include stinging, burning, pain, erythema and irritation, all of which decrease with continued use.

Topical tacrolimus and pimecrolimus have both anti-inflammatory and antipruritic effects[106] (see Ch. 128). Burning and erythema at the application site are the most commonly reported adverse events.

Systemic Treatment

Most systemic drugs with antipruritic properties act centrally and have sedating effects. Placebo responses in pruritus patients are often substantial (e.g. 66% in one study)[33]. Many systemic drugs with antipruritic effects may work primarily by a placebo mechanism, demonstrating the powerful central nervous modulation of pruritus.

Physical Treatment Modalities

UV light (UVA, UVA1, broadband and narrowband UVB, UVA/UVB, PUVA) therapy has shown beneficial effects in pruritic inflammatory dermatoses, urticaria pigmentosa, renal pruritus, cholestatic pruritus due to primary biliary cirrhosis, pruritus of HIV infection, polycythemia vera-related pruritus, aquagenic pruritus and prurigo nodularis[44]. Transcutaneous electronic nerve stimulation has been reported as beneficial in different types of pruritus, such as that found in aged skin. This may be partially a placebo effect as it tends to decline with continued therapy[33]. Acupuncture has also been described as a successful treatment for pruritus vulvae, allergic contact dermatitis, and renal pruritus. Acupuncture was reported to decrease experimental histamine-induced pruritus but had no effect on maximal pruritus intensity or onset time[33].

Psychological Approaches

Pruritus may be precipitated, prolonged or enhanced by a number of stress-related mediators such as histamine and neuropeptides. There are also multiple secondary psychosomatic mechanisms through which pruritus may be generated or exacerbated, e.g. the sweat response, alterations in cutaneous blood flow and scratching[1]. Of note, psychological factors are thought to be able to diminish as well as augment pruritus.

Studies have shown that group psychotherapy, behavioral therapy, controlled physical exercise, support groups and biofeedback can help to stop scratching and improve quality of life[1,33].

Psychocutaneous Diseases

7

Chai Sue Lee and John YM Koo

INTRODUCTION

"Psychodermatology" refers to any aspect of dermatology in which psychological factors play a significant role. At least a third of patients seen in dermatology practices require consideration of associated emotional and psychosocial factors for effective management of their skin condition[1,2].

Many patients with psychodermatologic problems resist referral to a mental health professional, and some become upset or even furious if such a referral is suggested to them. While there are many reasons for their reluctance and refusal, ironically, the individuals who are the most psychologically "ill" are often the most adamant about refusing both to recognize the psychogenic nature of their condition and to be referred to a psychiatrist. For example, patients with psoriasis or eczema are usually willing to speak of how emotional stress adversely affects their condition. However, patients with delusions of parasitosis are typically resistant to any discussion of their situation in psychological terms because they have no insight into their disease.

Regardless of the reason for refusal of a referral to a psychiatrist, the dermatologist is thereby designated by the patient to handle the chief complaint, even though the main disorder is psychogenic. Given this, the dermatologist is faced with two choices. The first is to try to address the psychological/psychiatric condition. If a dermatologist decides to take this route, it is necessary to be familiar with the approach to diagnosis, therapeutic options (both pharmacologic and non-pharmacologic, including potential side effects of medications), and limitations of what can be accomplished in a dermatology practice. The other option is to "ignore" the psychological problem and allow this component of the patient's disorder to remain untreated, which is not optimal. For example, patients with delusions of parasitosis may remain delusional for decades if they do not receive an antipsychotic medication, switching from dermatologist to dermatologist in search of treatment, only to be continually disregarded by physicians. Dermatologists can learn to effectively handle psychodermatologic issues within the limits of their training and practice setting. Although less comprehensive than the treatment delivered by a psychiatrist, in the authors' opinion, management of these issues by a dermatologist is better than no treatment at all.

In this chapter, a clinically useful method of classifying psychodermatologic diseases is presented and selected psychodermatologic conditions that are commonly encountered in a dermatologic practice are discussed. These include delusions of parasitosis, body dysmorphic disorder, dermatitis artefacta, neurotic (psychogenic) excoriations, acne excoriée and trichotillomania. Strategies for the evaluation and management of patients with these disorders are presented, including pharmacologic and non-pharmacologic treatments. Prurigo nodularis and lichen simplex chronicus are covered in Chapter 6.

OVERVIEW

Psychodermatologic disorders can be classified in two ways: (1) by the type of psychodermatologic condition; or (2) by the nature of the underlying psychopathology. The second method is useful because knowledge of the psychopathology enables the clinician to choose the most appropriate first-line psychopharmacologic agent. For example, in obsessive–compulsive disorder (OCD), a selective serotonin reuptake inhibitor (SSRI; e.g. fluoxetine) is typically the first line of pharmacologic therapy. The psychodermatologic patients with the greatest need for psychopharmacologic treatment usually have "blatantly" psychiatric problems, and most of these individuals have psychiatric manifestations in one of the following categories: anxiety, depression, psychosis and OCD[3] (Fig. 7.1).

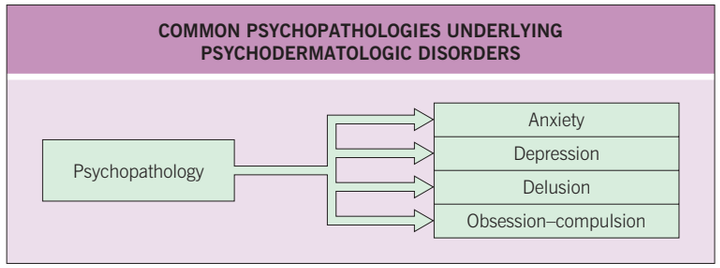

Fig. 7.1 Common psychopathologies underlying psychodermatologic disorders. *Reprinted with permission from Wolverton: Comprehensive Dermatologic Drug Therapy, W.B. Saunders, 2007.*

In the classification method based on psychodermatologic conditions, most patients can be grouped into one of five categories[3] (Fig. 7.2):

- *psychophysiologic disorders*, in which a genuine skin disorder, such as psoriasis, is exacerbated by emotional factors
- *primary psychiatric disorders*, in which the patient has no primary skin disease and all of the cutaneous findings are self-induced, such as in delusions of parasitosis
- *secondary psychiatric disorders*, in which the patient develops psychological problems as a result of a skin disease that causes physical disfigurement, as in vitiligo or alopecia areata
- *cutaneous sensory disorders*, in which the patient presents with a purely sensory complaint, such as pruritus, burning or stinging, without visible evidence of primary skin disease or a diagnosable underlying medical condition
- the use of *psychotropic medications for purely or primarily dermatologic conditions*, such as administration of doxepin to treat chronic urticaria or amitriptyline for postherpetic neuralgia.

COMMON PSYCHODERMATOLOGIC CONDITIONS

Delusions of Parasitosis

Synonyms: ■ Delusional parasitosis ■ Delusional infestation ■ Ekbom syndrome ■ Delusional disorder, somatic type ■ Monosymptomatic hypochondriacal psychosis

Key features

- False and fixed belief that an individual is infested with parasites
- May experience sensations of biting, crawling or stinging
- Need to distinguish from substance-induced formication

Introduction

Delusions of parasitosis falls under the classification of a primary psychiatric disorder. Affected individuals have the false and fixed belief that they are infested by parasites, in the absence of any objective evidence of infestation[4].

Clinical features

Patients with delusions of parasitosis are not schizophrenic but rather have the *somatic type of delusional disorder* (previously referred to as *monosymptomatic hypochondriacal psychosis*)[5] (Table 7.1). Their

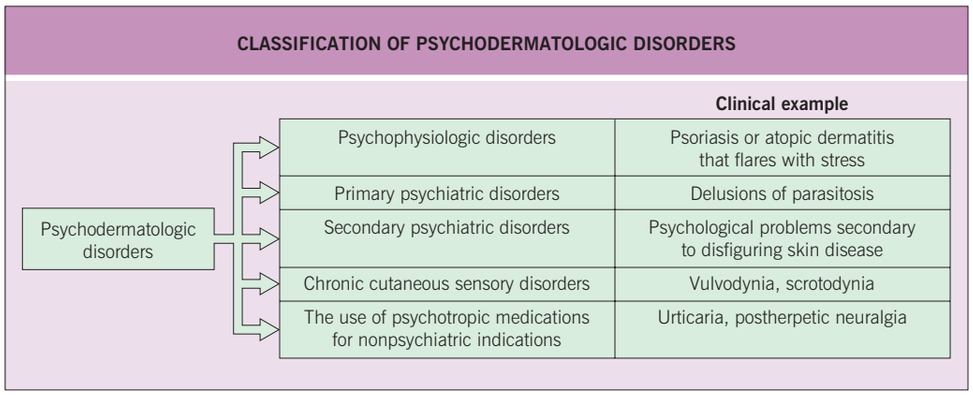

Fig. 7.2 Classification of psychodermatologic disorders. *Adapted with permission from Wolverton: Comprehensive Dermatologic Drug Therapy, W.B. Saunders, 2007*

SIGNS AND SYMPTOMS OF DELUSIONAL DISORDER, SOMATIC TYPE (MONOSYMPTOMATIC HYPOCHONDRIACAL PSYCHOSIS)
A DELUSION IS DEFINED AS:
• A false belief that the patient is absolutely convinced is true, despite a lack of objective evidence
THE DELUSION IN THIS CONDITION IS CHARACTERIZED AS:
• '*Encapsulated*' – i.e. has a narrow and specific focus, such as concerns about a particular parasite • *Somatic* (physical) and '*hypochondriac*' (health-related) in nature • Differing from the delusions of schizophrenia in that psychologic capacity outside of the specific delusion remains largely intact (e.g. proper affect, sociability, manners when discussing other aspects of life) • Not resulting directly from the effects of a drug of abuse, medication or general medical condition

Table 7.1 Signs and symptoms of delusional disorder, somatic type (monosymptomatic hypochondriacal psychosis). *Adapted with permission from Wolverton: Comprehensive Dermatologic Drug Therapy, W.B. Saunders, 2007.*

Fig. 7.3 Delusions of parasitosis. Samples of alleged "parasites" brought in by a patient ("matchbox sign").

delusional belief revolves around one particular medical concern and is "encapsulated", usually not compromising other aspects of their mental or psychosocial functioning.

Individuals with delusions of parasitosis typically present with a history of symptoms for months or even years. They have often already been evaluated by many physicians and tried to eradicate their alleged "parasites" by methods such as using pesticides, hiring exterminators or even changing their residence. The patients frequently bring in bits of skin, lint and other samples that they believe represent "parasites" (Fig. 7.3), which is referred to as the "matchbox sign". They often report cutaneous sensations of crawling, biting and/or stinging.

Skin findings in delusions of parasitosis range from none at all to excoriations, lichenification, prurigo nodularis and/or frank ulcerations. All of these are self-induced, often resulting from the patient's efforts to dig out "parasites".

One intriguing aspect of this disorder is the occurrence of a shared delusional system whereby the patient's close contacts come to believe in the delusion as well. *Folie à deux* ("craziness for two") is the term used to describe two people who share the same delusion. Interestingly, any number of people can be involved in the delusion.

Morgellons disease is a controversial condition with symptoms very similar, if not identical, to those of delusions of parasitosis[6]. A hallmark of this disorder is that patients claim to observe "fibers" exuding from their skin. Widespread coverage of Morgellons disease in the media and on the Internet has led to an increasing number of patients presenting to dermatologists. Multiple articles in the medical literature and a recent investigation by the Centers for Disease Control and Prevention have supported the categorization of Morgellons disease as a form of delusions of parasitosis[6a].

Epidemiology

The average age of onset is in the mid-50s to 60s. Among individuals over 50 years of age, women experience the disorder twice as often as men; however, prior to age 50, men and women are equally affected. Younger patients with this disorder are usually of a lower socio-economic status and may have a history of substance abuse, while older patients are usually of a higher socio-economic status.

Differential diagnosis

Additional diagnostic considerations for patients suspected to have delusions of parasitosis include:

- *formication*, in which patients experience the sensations of biting and crawling within their skin but have no firm convictions that these sensations are due to an infestation (and thus are not delusional)
- *delusionoid ideation*, in which a patient is mentally fixated on a particular perspective but, unlike a truly delusional patient, is not completely inflexible
- *formication and/or delusion as a result of substance abuse*, whereby, under the influence of substances (especially amphetamines and cocaine), patients manifest with a disorder clinically identical to idiopathic delusions of parasitosis.

One additional item in the differential diagnosis that is occasionally missed by dermatologists is a true primary skin disorder.

Management

After the diagnosis of delusions of parasitosis has been established, one of the most challenging aspects of managing these patients is getting them to agree to take an antipsychotic medication. The first step is to establish rapport with the patient and to address the chief complaint seriously, making sure to do a thorough dermatologic examination. While discussing the diagnosis with the patient, communicate it in a matter-of-fact manner and refrain from making any statements that may be misinterpreted by the patient as supporting his or her delusional ideation. Often, it is more feasible to introduce the antipsychotic medication as one that may work empirically for formication and agitation rather than to confront the individual about psychiatric issues. If the medication is presented in an objective and pragmatic manner, the patient may have less difficulty accepting it as a therapy.

The treatment of choice for delusions of parasitosis has traditionally been pimozide. As part of the discussion on therapy, the dermatologist should explain to the patient that he or she does not have Tourette syndrome or schizophrenia, the former being the condition that has

US Food and Drug Administration (FDA) approval for treatment with pimozide. Pimozide can be associated with a number of side effects, including extrapyramidal (pseudo-parkinsonian) symptoms and prolongation of the Q–T interval, as well as drug–drug interactions. There have been several reports of successful treatment of delusions of parasitosis with risperidone and olanzapine, newer antipsychotic medications (Table 7.2) that have more favorable side-effect profiles (see Treatment section below)[4].

Body Dysmorphic Disorder

Synonym: ■ Dysmorphophobia

Key features

- May affect as many as 10–14% of dermatology patients
- Often begins in early adulthood
- Preoccupation with a non-existent or slight defect in appearance
- Frequent body sites of concern are the nose, mouth, hair, breasts and genitalia
- Typically associated with compulsive or ritualistic behaviors

Introduction

Dermatologists, particularly those performing cosmetic procedures, and plastic surgeons appear to be the physicians most often seen by patients with body dysmorphic disorder, a distressing or socially impairing preoccupation with a non-existent or slight defect in appearance[7].

Clinical features

Patients with body dysmorphic disorder have a fundamental disturbance in the perception of their own body image. They are often socially isolated and preoccupy themselves with a concern about their face (especially the nose and mouth), hair, breasts or genitalia. In addition, these patients often adopt compulsive or ritualistic behaviors such as spending an excessive amount of time in front of a mirror or repeatedly checking for perceived imperfections.

A subtype of body dysmorphic disorder is *olfactory reference syndrome*, in which affected individuals are extremely preoccupied with the notion that they emit an unpleasant odor, which nobody else can perceive[8]. These patients often engage in compulsive behaviors in an attempt to eradicate the perceived odor, such as repetitive showering or excessive use of deodorants, perfumes or mouthwash.

Epidemiology

While the exact incidence of body dysmorphic disorder is unknown, it is estimated to affect up to 1% of the US population[7]. In one study, 10–14% of patients who visited a dermatologist screened positive for body dysmorphic disorder[7]; the mean age of onset was 34 years, with a male-to-female ratio of 1 : 1. This condition has been reported to last from 5 to 30 years.

Management

The spectrum of body dysmorphic disorder includes: (1) *obsessions* (preoccupation with perceived inadequacies), which fall within the *OCD spectrum* (Table 7.3); and *delusions* (fixed false beliefs about their appearance), which fall within the *psychotic spectrum* and can represent a variant of the somatic type of delusional disorder (see Table 7.1). For the purpose of treatment, it is useful to classify patients into one of these two categories, although the distinction is not always clear and individual patients sometimes fluctuate between delusional and non-delusional thinking. Those with the OCD variant of this disease will usually demonstrate behaviors such as repeatedly checking mirrors, excessive grooming and numerous visits to the physician for reassurance. In contrast, patients with the delusional variant have no insight into their disease and often go to extraordinary lengths, such as multiple surgeries, to correct their perceived deformity. It is important for cosmetic surgeons to recognize this disorder and avoid performing multiple unnecessary procedures. In addition, patients with body dysmorphic disorder are often dissatisfied with the results of any procedure that is performed[9].

SIDE EFFECTS OF PIMOZIDE AND ATYPICAL ANTIPSYCHOTIC DRUGS							
	Anticholinergic effects	**Sedation/ somnolence**	**QT prolongation**	**Increased prolactin**	**Weight gain**	**Metabolic effects***	**Extrapyramidal effects†**
Pimozide (Orap®)	++	+	++	++	++	–	++
ATYPICAL ANTIPSYCHOTIC DRUGS							
Aripiprazole (Abilify®)	–	±	±	–	–	–	+
Asenapine (Saphris®)	–	+	±	–	–	–	±
Clozapine‡ (Clozaril®)	++	++	±	–	++	++	+
Iloperidone (Fanapt®)	–	±	+	–	+	–	–

Ziprasidone (Geodon®)	–	±	+	+	–	–	+

*E.g. insulin resistance/type 2 diabetes mellitus, hyperlipidemia (especially hypertriglyceridemia).
†Parkinsonian symptoms.
‡Use is limited by a 1% incidence of potentially life-threatening agranulocytosis as well as increased risks of seizures (dose-dependent) and myocarditis.
§Another atypical antipsychotic drug, paliperidone (Invega®), represents the primary active metabolite of risperidone.

Table 7.2 Side effects of pimozide and atypical antipsychotic drugs. The use of antipsychotic drugs in elderly patients with dementia has been associated with an increased risk of mortality. A dose-dependent increased risk of sudden cardiac death has also been documented in patients receiving antipsychotic drugs.

SIGNS AND SYMPTOMS OF OBSESSIVE–COMPULSIVE DISORDER
• Presence of *obsession* – a recurrent, intrusive, ego-dystonic (i.e. feeling foreign to oneself) idea • Presence of *compulsion* – a behavioral response to an obsession. If suppressed, compulsive urges may build up • Obsession and compulsion need *not* both be present: the presence of one or the other is sufficient to make the diagnosis • Presence of varying degrees of insight (in contrast to psychosis, where, by definition, there is essentially no insight)

Table 7.3 Signs and symptoms of obsessive–compulsive disorder (OCD). *AReprinted with permission from Wolverton: Comprehensive Dermatologic Drug Therapy, W.B. Saunders, 2007.*

The first-line therapy for patients with the OCD variant of this disease is an SSRI, whereas antipsychotics are the treatment of choice for patients who are truly delusional (see Treatment section below).

Dermatitis Artefacta

Synonym: ■ Factitial dermatitis

Key features

- More common in women than men
- Motive is usually subconscious
- Self-inflicted cutaneous lesions that are often induced by foreign objects
- Typically located in areas that are easily reached by the hands

Introduction

Dermatitis artefacta is a psychocutaneous disorder in which patients inflict cutaneous lesions upon themselves to satisfy a psychological need of which they are usually not consciously aware. If asked, the patients deny having any role in creating the skin lesions. While some of these individuals create skin lesions as a maladaptive response to an acute psychosocial stress, the vast majority suffer from borderline personality disorder[10]. Given the frequent lack of honest disclosure and cooperation from the patient, this disorder is often difficult to diagnose and treat.

Clinical features

Dermatitis artefacta can mimic a wide variety of dermatoses. The lesions may be single or multiple and unilateral or bilateral. Although usually within easy reach of the hands, the lesions can be caused by methods such as carving with sharp instruments, applying chemicals and injecting foreign substances[11]. The morphology ranges from vesicles to purpura to subcutaneous emphysema. A clue to diagnosis is unusual shapes, particularly angulated edges, that suggest an external method of induction (Figs 7.4 & 7.5).

Pathology

Histologic changes seen with dermatitis artefacta vary considerably, depending upon the manner in which the lesions were produced. The findings are generally not diagnostic and can include erosion, ulceration, hyperkeratosis, irregular acanthosis, vascular proliferation, hypertrophied nerves (as observed in prurigo nodularis) and fibroplasia. Polarizing exogenous material with a variable foreign body response is occasionally evident[12].

Epidemiology

Dermatitis artefacta is uncommon and is reported to have a female-to-male ratio of 8 : 1. Although the onset is most frequently in adolescence and young adulthood, it can occur at any age. Many patients either work in or have a close family member who works in the healthcare field[13].

Differential diagnosis

In terms of the differential diagnosis (other than primary skin disorders), dermatitis artefacta must be distinguished from delusions of parasitosis, neurotic excoriations and malingering; the latter is characterized by skin lesions that are self-inflicted for a *conscious* gain. *Nonsuicidal self-injury* (e.g. "cutting"), which has received increased attention by the media and medical community in recent years, is fairly common in adolescents and young adults as a response to psychological distress; in contrast to dermatitis artefacta, the patients acknowledge that they inflicted the lesions on themselves. An additional consideration is *Münchhausen syndrome by proxy*, in which an individual

Fig. 7.4 Dermatitis artefacta. A Erosion with a "bizarre" shape and angulated borders, possibly created with a sharp instrument. **B** Erosions and ulcers with angulated borders in various stages of healing on the leg of a teenage girl. The patient denied knowing how the lesions had developed or having any role in the process.

Fig. 7.5 Scars from cigarette burns. *Courtesy, Ronald P Rapini, MD.*

produces lesions on another person in order to satisfy a psychological need that is not consciously recognized.

Management

Initially, wound care to help with healing is often indicated and the possibility of a primary dermatologic disorder needs to be excluded. There is controversy as to whether or not the patient should be confronted upon recognition of dermatitis artefacta. Given the nature of the disorder, it may be more fruitful to provide a supportive environment early in the doctor–patient relationship and then work up to the psychological aspects of the disease at subsequent visits. Antidepressant, antianxiety or antipsychotic medications (see Treatment section below) may be indicated when affected individuals have an underlying psychiatric disorder (Tables 7.4 & 7.5). Children or adults in whom the lesions represent a response to a transient stress have the most favorable prognosis. Dermatitis artefacta usually has a chronic course, with waxing and waning, depending upon circumstances in the affected individual's life[14].

Neurotic Excoriations

Synonym: ■ Psychogenic excoriation

Key features

- Most commonly seen in middle-aged women
- Repetitive, uncontrollable desire to pick, rub or scratch the skin
- Usually on the scalp, face, upper back, extensor surfaces of the forearms, shins or buttocks, but can occur on any easily reachable area of the body

Introduction

Some people have a tendency to inattentively but habitually pick incidental skin lesions, such as an arthropod bite, keratin plug, or lesion of acne or folliculitis. This action may be episodic or occur on a regular basis and, when controllable and non-destructive, can be regarded as a simple habit. In contrast, patients with neurotic excoriations have a conscious, repetitive and uncontrollable desire to pick, scratch or rub their skin, which results in characteristic lesions (Fig. 7.6). Picking activity may begin inadvertently as the hand comes across an irregularity on the skin, or it may take place in a ritualistic fashion.

Clinical features

The lesions may evolve from a pre-existing urticarial papule or acneiform lesion, or they may be created *de novo*. Repeated picking or rubbing results in excoriations with a variety of shapes (e.g. linear/angular, circular, oval). The distribution is characteristically on the extensor surfaces of the arms and forearms as well as the scalp, face, upper back and buttocks[10]. Lesions may range in size from a few millimeters to several centimeters, and several stages of evolution are often evident, from small superficial erosions to deep ulcerations with hypertrophic borders to hypo- or hyperpigmented scars. On the scalp, there may be broken hairs as well as areas of scarring alopecia.

According to more psychodynamically (i.e. Freudian) oriented investigations, individuals with neurotic excoriations often have an obsessive–compulsive personality: rigid, perfectionist, judgmental, controlling, and indecisive due to fear of making a mistake. They may have difficulty handling subconscious aggression, which may stem from unresolved feelings toward their parents. Patients may describe difficult childhoods with rejecting and punitive parents[15]. In some patients, the behaviors are thought to be a manifestation of the anxiety that results when aggressive feelings threaten to surface.

In mild cases, especially during childhood, neurotic excoriations can be a transient response to stress in someone with obsessive–compulsive personality traits. However, in severe and prolonged cases, psychiatric evaluation may reveal OCD (see Table 7.3).

Neurotic excoriations may also be an expression of generalized anxiety disorder or depression. The worries harbored by patients with generalized anxiety disorder are based in reality but are out of proportion to any actual risk. When tension mounts in these patients, there may be anxious and restless picking at any irregularity on the skin, resulting in characteristic lesions.

Epidemiology

Accurate statistics regarding the incidence of this disorder are not available, but there is a preponderance of women. Although the condition may occur at any age, the most severe and recalcitrant cases typically start in the third to fifth decades of life.

Management

Once causes of primary pruritus are excluded (see Ch. 6) and treatment of underlying cutaneous disorders (e.g. folliculitis) has been instituted,

SIGNS AND SYMPTOMS OF GENERALIZED ANXIETY DISORDER
• Excessive anxiety and worry
• Restlessness or feeling "keyed up" or "on edge"
• Difficulty concentrating or mind going blank
• Irritability
• Muscle tension
• Stress
• Sleep disturbance (difficulty falling or staying asleep; or restless, unsatisfying sleep)
• Dizziness
• Sweating
• Palpitations
• Abdominal complaints
• Frequent urination

Table 7.4 Signs and symptoms of generalized anxiety disorder. *Reprinted with permission from Wolverton: Comprehensive Dermatologic Drug Therapy, W.B. Saunders, 2007.*

SIGNS AND SYMPTOMS OF MAJOR DEPRESSION
• Depressed mood
• Anhedonia (i.e. markedly diminished interest or pleasure in activities)
• Significant weight loss when not dieting, weight gain, or change in appetite
• Insomnia or hypersomnia
• Psychomotor agitation or retardation
• Fatigue, lack of energy
• Feelings of helplessness, hopelessness or worthlessness
• Excessive guilt
• Difficulty with concentration, memory loss
• Suicidal ideation/plan
• Crying spells (i.e. finding oneself tearful for no reason or with minimal provocation)
• Somatization (i.e. preoccupation with vague, nonspecific, or exaggerated physical concerns but not of delusional intensity)

Table 7.5 Signs and symptoms of major depression. *Reprinted with permission from Wolverton: Comprehensive Dermatologic Drug Therapy, W.B. Saunders, 2007.*

Fig. 7.6 Neurotic excoriations. This patient picked vigorously at any blemish that he found on his face.

therapy can focus on associated pruritus (if present) and the psychological aspects of the condition. Treatment is based on symptom severity. When pruritus is present, topical antipruritics such as lotions containing pramoxine or menthol may be helpful. Cool compresses are soothing, hydrate the skin, and facilitate debridement of crusts. Antihistamines such as hydroxyzine can have beneficial sedative and antipruritic effects. Intralesional corticosteroids and flurandrenolide tape address the inflammatory component of existing lesions but not the formation of new lesions.

Doxepin may be particularly useful in patients with neurotic excoriations associated with depression and anxiety. If major depression is present, an antidepressant dose (usually 100 mg/day or higher) should be the goal. However, even if a patient can tolerate only 50–75 mg/day of doxepin (or 10–20 mg/day in the elderly), antidepressant efficacy may become evident.

Since obsessive–compulsive symptoms are associated with serotonin-mediated neural pathways, antidepressant drugs that selectively block serotonin reuptake (SSRIs) can be helpful in patients with neurotic excoriations. SSRIs represent the first-line treatment for OCD (see Table 7.3). Behavior modification, cognitive and psychodynamic therapy have been reported to be beneficial in case series[16,17]. The average duration of disease activity is 5–8 years without pharmacologic therapy, with the severity fluctuating in parallel with stressful situations.

Acne Excoriée

Synonym: ■ Acne excoriée des jeunes filles

Key features

- Frequently seen in young women
- Subset of neurotic excoriations
- Ritualistic picking of acne lesions

Introduction

Acne excoriée can be thought of as a subset of neurotic excoriations in which the scratching and picking is directed at acne lesions (Fig. 7.7). The underlying acne is often mild but accompanied by extensive excoriations. Lesions can become so deep that scarring may occur. Acne excoriée is most frequently seen in young women, thus the description *des jeunes filles*.

Management

Because acne excoriée is part of the broader spectrum of neurotic excoriations and is often associated with OCD, the treatment is the same as that described above. The use of doxepin and SSRIs may be beneficial, as has been described anecdotally. In addition to these agents, aggressive treatment of the underlying acne should be considered (see Ch. 36). Medications such as isotretinoin may be administered so that the substrate for the excoriations is eliminated. However, recurrence of even mild acne may be accompanied by resumption of picking unless the associated psychological disorder is addressed.

Trichotillomania

Synonym: ■ Habitual hair pulling

Key features

- More common in young girls
- Hair-pulling disorder involving scalp, eyebrows, eyelashes or pubic hair
- Varying lengths of hair distributed within areas of alopecia, with normal uninvolved areas
- Behavior modification therapy is the mainstay of treatment

Fig. 7.7 Acne excoriée. This patient compulsively picked at his acne lesions. *Courtesy, Richard Odom, MD.*

Fig. 7.8 Trichotillomania. Note the hairs of varying lengths and small areas of sparing.

Introduction

The American Psychiatric Association's *Diagnostics and Statistics Manual for Mental Health Disorders*, Fourth Edition (DSM-IV) classifies trichotillomania as an impulse disorder, but some authors have argued that it should be categorized as an obsessive–compulsive disorder[18] or stereotypic movement disorder[19]. To meet DSM-IV diagnostic criteria, a patient must feel rising tension just prior to hair pulling or during attempts to resist pulling and must experience a sense of pleasure or relief during or after the behavior. The authors favor the more simplified and straightforward definition used by dermatologists: anyone with a hair-pulling disorder.

Clinical features

Patients most commonly pull scalp hair, but eyebrows, eyelashes and pubic hair can also be targeted. The classic physical finding is hair of varying lengths distributed within the area of alopecia, with uninvolved areas of the scalp appearing completely normal (Fig. 7.8); the hairs are sometimes referred to as "irregularly irregular." This pattern likely reflects a favored hair-pulling technique of twisting multiple strands around the fingers and pulling them simultaneously. Lesions are usually single and can be large. Plucking may be confined to a specific time of the day and place, with ritualized manipulation of the pulled hairs prior to discarding. Some patients practice *trichophagy*, the chewing and swallowing of the hair that has been pulled out, possibly leading to intestinal obstruction from trichobezoars.

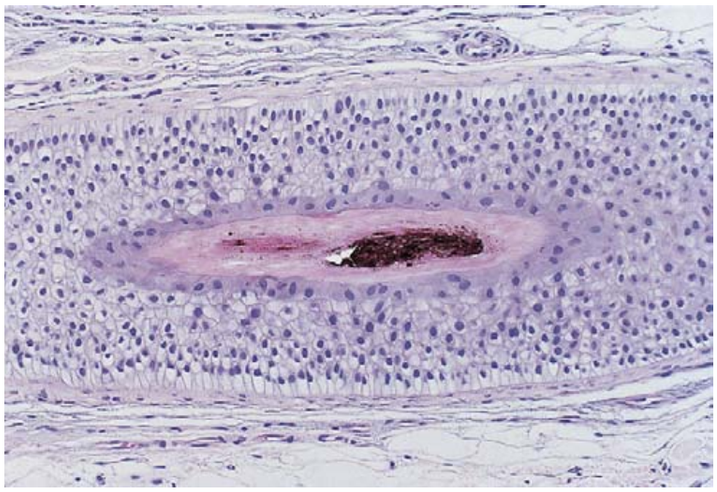

Fig. 7.9 Trichotillomania. Pigmented follicular cast. *Courtesy, Ronald P Rapini, MD.*

From a psychodynamic (i.e. Freudian) perspective, patients with trichotillomania are thought to have dysfunctional families and a lack of optimal conflict-free separation from their mother. Because adaptive mechanisms for tension release are not adequately developed, poor impulse control and unresolved subconscious anger ensue. Hair pulling is one way in which these patients manage their tension. In persistent cases, a spectrum of behavioral disorders is frequently encountered, including thumb sucking, nail biting, poor school performance, and dysfunctional peer as well as family relationships.

Epidemiology

Although encountered across the spectrum of psychiatric illnesses, in dermatologic practice trichotillomania is usually seen in relatively psychologically intact individuals. Peak onset is in childhood, with a mean age at onset of 8 years for boys and 12 years for girls[20]. There is a female preponderance, with a female-to-male ratio of 5:1[21]. The prevalence has been estimated to be approximately 0.6% of the general population using the strict DSM-IV criteria for "hair pullers". Of note, hair pulling in toddlers and preschool-aged children is more common in boys than girls and (unlike trichotillomania in older children) tends to resolve spontaneously.

Pathology

One helpful finding is the presence of pigmented hair casts (Fig. 7.9), which may also be seen with traction alopecia and other conditions that cause follicular trauma. Deformed hair shafts (trichomalacia) and empty follicles (hair shafts pulled out) are often encountered. Perifollicular lymphocytes, plasma cells and neutrophils are usually sparse or absent. Perifollicular hemorrhage is sometimes found in early lesions, and perifollicular fibrosis represents a late change. If the follicle is destroyed, a vertical fibrous tract often remains at the site.

Differential diagnosis

The differential diagnosis includes other causes of circumscribed nonscarring alopecia such as alopecia areata (see Ch. 69; occasionally coexists with trichotillomania) or tinea capitis. However, in trichotillomania there are no exclamation point hairs, scaling is absent, and fungal cultures are negative. If the hairs within a portion of the involved region are clipped close to the surface of the scalp or shaved, normal hair growth will be observed within this area over time. In difficult-to-diagnose patients, a biopsy specimen can be obtained.

Management

Management of trichotillomania is difficult and requires a flexible approach. Behavior modification therapy is the mainstay of treatment. This includes self-monitoring, teaching the patients to do something else whenever they are feeling the urge to pull their hair, relaxation techniques and positive reinforcement. In addition, a family and peer support network may be helpful. Antidepressants (especially SSRIs) have been reported to be effective in some studies[22]. However, two randomized controlled trials failed to show benefit of antidepressants compared to placebo, and several others found that behavioral therapy was more effective than antidepressants. In recent randomized controlled studies, treatment with olanzapine or *N*-acetylcysteine (a glutamatergic agent) led to more improvement in adults with trichotillomania than did placebo[23,24].

TREATMENT

As discussed earlier, the treatment of psychodermatologic disorders can be directed by classifying patients into four major psychopathologic categories: anxiety, depression, psychosis and OCD. In this section, the major psychopharmacologic agents used to treat the psychocutaneous disorders discussed previously will be presented, and non-pharmacologic therapies for these conditions will be outlined.

Pharmacologic Treatment

Anxiety disorder

In general, there are two broad categories of antianxiety medications:

- quick-acting benzodiazepines
- slow-acting non-benzodiazepines that are neither sedating nor dependency-provoking.

The prototypical fast-acting benzodiazepine is lorazepam. Usually, 0.5–2 mg every 6–8 hours on an "as needed" basis can be used to control acute anxiety. As with all benzodiazepines, addiction can develop with long-term use. Thus, the duration of treatment should be limited to no more than 4 weeks. This amount of time is usually adequate for treatment of anxiety related to acute situational stressors. Sedation is usually the only adverse effect encountered when lorazepam is used for such a short period of time, and this usually subsides after several days of treatment or can be controlled by dosage adjustment.

If a patient has chronic anxiety, the use of a non-benzodiazepine such as buspirone is preferable. This medication can be used for long-term maintenance because it is non-sedating and does not produce dependency. In this respect, it is much safer to use than benzodiazepines. Because the onset of action may be delayed for 2–4 weeks after initiating therapy, buspirone is not useful in acute anxiety. The recommended initial dose is 15 mg daily (usually divided into three doses). To achieve an optimal therapeutic response, the dosage may be increased by 5 mg a day every 2 to 3 days, up to a maximum of 60 mg a day if needed.

Antidepressants (see below) such as paroxetine (Paxil®; 20–50 mg/day), sertraline (Zoloft® 25–200 mg/day), fluoxetine (Prozac® 10–60 mg/day), escitalopram (Lexapro® 10–20 mg/day), low-dose doxepin (≤50 mg/day), and venlafaxine extended release (Effexor XR®; 75–150 mg/day) have also been shown to be useful for the treatment of chronic anxiety[25].

Depression

The numerous available antidepressants have similar efficacy rates of approximately 60–80%. The initial response to antidepressants usually begins 2–3 weeks after the therapeutic dose is reached, and at least 6 weeks of full-dose treatment is generally required before full therapeutic effectiveness is achieved. The US FDA requires that antidepressants have a black box warning noting an increased risk of suicidal thoughts and behavior (particularly during the first 1–2 months of therapy) in patients <25 years of age.

The tricyclic antidepressant that is most often used by dermatologists is doxepin. Doxepin is well suited for depressed patients with neurotic excoriations because, in addition to its antidepressant effects, it is a very powerful H_1 receptor antagonist that can help to break the itch–scratch cycle. For control of pruritus, a dosage of 10–25 mg at bedtime would be appropriate. To treat depression, this starting dose is increased by 10–25 mg every 1–2 weeks as tolerated, up to a therapeutic range of 100-300 mg daily (lower for elderly or small individuals). The most common adverse effect is sedation. Other side effects of doxepin are similar to those of other tricyclic antidepressants, including cardiac conduction abnormalities, weight gain, orthostatic hypotension, and anticholinergic effects (e.g. dry mouth, blurry vision, constipation, urinary retention).

SSRIs represent the most widely prescribed class of antidepressants and the first-line treatment for depression. They include fluoxetine (Prozac®), paroxetine (Paxil®), sertraline (Zoloft®), escitalopram (Lexapro®) and citalopram (Celexa®). These drugs are as effective as the tricyclic antidepressants but have a more favorable side-effect profile because they do not affect the cholinergic and histaminic receptors. The most common adverse effects are gastrointestinal symptoms such as nausea and diarrhea. As with all antidepressants, the clinical response is gradual. Patients showing no improvement in 6–8 weeks should be switched to another SSRI or to an agent from another class of antidepressants, such as venlafaxine or bupropion (Wellbutrin®).

Psychosis

The psychodermatologic conditions that typically require treatment with an antipsychotic medication are forms of somatic-type delusional disorder (see Table 7.1), most often delusions of parasitosis. Traditionally, the treatment of choice for delusions of parasitosis has been pimozide (Orap®). Careful titration of this medication is needed to ensure its safe use. Pimozide is usually started at a dose of 1 mg daily, which is increased by 1 mg every 1–2 weeks until the optimal clinical response is achieved, usually at 4–6 mg daily.

Although there have been reports of sudden death (presumably of cardiac cause) in patients with chronic schizophrenia who were treated with high-dose pimozide (>10 mg/day), there is less evidence for clinically significant cardiac effects at the lower doses used for psychodermatologic conditions. Since pimozide can potentially cause arrhythmias by prolonging the Q–T interval, an electrocardiogram should be performed before and after initiating treatment in patients with a history of cardiac conduction abnormalities. It has been debated whether an electrocardiogram is warranted for lower-dose pimozide therapy in young, healthy patients with no history of cardiac problems[25]. The patient's medications should be reviewed in order to identify any potential drug–drug interactions (see Ch. 131). For example, agents that inhibit the P450 CYP3A4 enzyme system (e.g. macrolide antibiotics, azole antifungals, HIV protease inhibitors; also grapefruit juice) can increase serum levels of pimozide, and some other medications (e.g. certain quinolones) also prolong the Q–T interval.

Most patients with delusions of parasitosis can be successfully tapered off pimozide after 2–6 months of therapy. Because this drug differs from haloperidol only by one methyl group, extrapyramidal side effects such as stiffness or a feeling of inner restlessness called akathisia (manifested outwardly by difficulty remaining still and fidgeting or pacing) are possible. Benztropine (Cogentin®; 1–2 mg up to four times daily) or diphenhydramine (Benadryl®; 25 mg up to four times daily) can be used to treat extrapyramidal side effects.

"Atypical" antipsychotic medications with more favorable side-effect profiles (e.g. fewer extrapyramidal symptoms, lack of Q–T prolongation; see Table 7.2) are now the most frequently prescribed medications for the treatment of psychosis. These drugs include risperidone (Risperdal®), olanzapine (Zyrexa®), quetiapine (Seroquel®), aripiprazole (Abilify®), ziprasidone (Geodon®) and lurasidone (Latuda®). This group of medications appears to be as effective as the older antipsychotics for various psychotic disorders and may prove useful and safe for somatic-type delusional disorder, although the optimal dosage range for the latter condition has not been established. Additional side effects of pimozide and (to a lesser degree) some atypical antipsychotic agents include anticholinergic symptoms (see above), increased prolactin, and weight gain.

Obsessive–compulsive disorder

Several psychodermatologic disorders have OCD-like features, including trichotillomania, onychotillomania, neurotic excoriations and acne excoriée. The SSRIs (see above) are the first-line treatment for OCD.

OCDs often require a higher dose of SSRIs and take longer to respond to therapy than depression. The initial response may appear at 4–8 weeks and a maximal response may take as long as 20 weeks. A 10–12-week trial with an SSRI at a therapeutic dosage for OCD is necessary to confirm a failure to respond. Once a therapeutic response is achieved, treatment should be continued for 6 months to a year.

Non-pharmacologic Treatments

A number of non-pharmacologic treatments exist for patients with psychodermatologic disorders. However, most dermatologists have neither the time nor the expertise to provide these treatments. Nevertheless, it is beneficial to be aware of these options, especially for patients who are willing and able to accept a referral to a mental health professional. Individual psychotherapy can be beneficial if there is a definable psychological/interpersonal issue to be discussed. Cognitive or group therapy may also provide benefit. For patients with anxiety-driven disorders, stress management courses, relaxation exercises and hypnosis may help to relieve "bottled-up" feelings. Patients with OCD-type conditions can be referred for behavior modification therapy. In an ideal situation, a comprehensive therapeutic plan involving both pharmacologic and non-pharmacologic approaches would be optimal for treating most psychiatric conditions.

SUMMARY

Psychodermatologic problems are prominent in any dermatology practice. By using a systematic approach to diagnosis and management, dermatologists can successfully treat these challenging patients.

Psoriasis 8

Peter CM van de Kerkhof and Frank O Nestlé

Key features

- Psoriasis is a chronic, immune-mediated disorder that results from a polygenic predisposition combined with environmental triggers, e.g. trauma, infections or medications
- The underlying pathophysiology involves T cells and their interactions with dendritic cells and cells involved in innate immunity, including keratinocytes
- Identification of susceptibility genes has pointed to a major role for both the innate and the adaptive immune systems
- Sharply demarcated, scaly, erythematous plaques characterize the most common form of psoriasis; occasionally, sterile pustules are seen
- The most common sites of involvement are the scalp, elbows and knees, followed by the nails, hands, feet and trunk (including the intergluteal fold)
- Typical histologic findings include acanthosis with elongated rete ridges, hypogranulosis, hyper- and parakeratosis, dilated blood vessels and a perivascular infiltrate of lymphocytes with neutrophils singly or within aggregates in the epidermis
- Psoriatic arthritis is the major associated systemic manifestation and the most common presentation is asymmetric oligoarthritis of the small joints of the hands and feet; other comorbidities include cardiovascular disease in patients with moderate to severe disease
- Phototherapy, methotrexate, cyclosporine and "biologic" therapies that target key immune effector cells and cytokines lead to significant clinical improvement

INTRODUCTION

Psoriasis is an immune-mediated polygenic skin disorder. Various environmental triggering factors, e.g. trauma, infections or medications, may elicit disease in predisposed individuals[1]. The characteristic lesion is a sharply demarcated erythematous plaque with micaceous scale, and the plaques may be localized or widespread in distribution. Histologically, hyperkeratosis, parakeratosis, acanthosis of the epidermis, tortuous and dilated vessels, and an inflammatory infiltrate composed primarily of lymphocytes are observed.

Psoriasis is a systemic disease process in which up to 20–30% of the patients have or will develop psoriatic arthritis. In addition, in patients with moderate to severe psoriasis, there is an increased relative risk for metabolic syndrome and atherosclerotic cardiovascular disease. Psoriasis also has a significant impact on patients' quality of life[2], and in surveys, patients feel that the current treatments, although often effective, do not provide a satisfactory long-term solution.

HISTORY

Hippocrates and his school (460–377 BC) provided meticulous descriptions of many skin disorders. In their classification, dry scaly eruptions were grouped together under the heading "lopoi". This group probably included psoriasis and leprosy.

Between 129 and 99 BC, the word "psora" (meaning a desquamative condition) was first used by Galen to describe a skin disorder characterized by a scaliness of the eyelids, corners of the eyes, and scrotum. The condition was pruritic and excoriations were present. Although called psoriasis, this affliction was probably a type of eczema.

It was not until the nineteenth century that psoriasis was recognized as an entity distinct from leprosy. Although Robert Willan (1809) was the first to give an accurate description of psoriasis, it would be another 30 years before Hebra (in 1841) definitively separated the clinical features of psoriasis from those of leprosy. In 1879, Heinrich Koebner described the development of psoriatic plaques at sites of skin injury. He designated this phenomenon as "artificial production of the psoriatic lesion".

EPIDEMIOLOGY AND GENETICS

In most reviews, the prevalence of psoriasis is said to be 2% of the world's population. However, in the US and Canada, prevalences as high as 4.6% and 4.7% have been reported, respectively. This contrasts with frequencies in Africans, African-Americans, Norwegian Lapps, and Asians of between 0.4% and 0.7%[2]. Brandrup and Green[3] reported that two-thirds of affected individuals were suffering from mild psoriasis, while one-third had more severe involvement. In one large group of patients with psoriasis (n = 1728), 79% had nail changes[4]. Psoriatic arthritis has been found to affect 5–30% of patients with cutaneous psoriasis in different series[2].

Psoriasis can first appear at any age, from infancy to the eighth decade of life. Two peaks in age of onset have been reported: one at 20–30 years of age and a second peak at 50–60 years. In approximately 75% of patients, the onset is before the age of 40 years[5–7], and in 35–50%, it is before the age of 20 years. Although the age of onset is earlier in women than in men, the natural history is similar – chronic with intermittent remissions. In one epidemiologic study, 39% of the patients stated they had experienced remissions of 1–54 years[7].

In Europe, the overall prevalence rate for juvenile psoriasis was found to be ~0.7%[8,9], with an increase from 0.37–0.55% in those 0 to 9 years of age to 1.01–1.37% in those 10-19 years of age[8–10]. Plaque psoriasis is the most frequent form of the disease in children, followed by guttate psoriasis[11].

Genetic Factors

Depending upon the series, a positive family history has been reported by 35% to 90% of patients with psoriasis. Based on a large survey-based study in Germany, if both parents had psoriasis, the risk of their child developing psoriasis was 41%, whereas if only one parent were affected, the risk was 14%; the risk was 6% if just one sibling had psoriasis[12].

Analysis of concordance rates among monozygotic and dizygotic twins is another method for examining the influence of genetic factors on a disease. Farber and Nall[13] reviewed the published data from twin pair studies in psoriasis. Of 141 monozygotic twin pairs, 82 were concordant for psoriasis and 59 were discordant; of 155 dizygotic twin pairs, only 31 were concordant and 124 were discordant for psoriasis. Thus, there is a two- to threefold increased risk of psoriasis in monozygotic twins as compared to dizygotic twins[7], implying that genetic factors are important. The distribution of the lesions, the severity, and the age of onset were similar in the monozygotic twin pairs, whereas these features differed in the dizygotic twin pairs. This observation suggested that genetic factors also play a role in the clinical course of psoriasis.

HLA studies

Histocompatibility antigens (HLA) are surface antigens on human cells, and the corresponding chromosomal region is called the major histocompatibility complex (MHC). It is situated on the short arm (p) of chromosome 6. Psoriasis is associated with HLA-Cw6, with the

presence of HLA-Cw6 conferring a relative risk of 13 for developing psoriasis in the Caucasian population and 25 in the Japanese.

HLA-Cw6 is strongly linked to the age of onset of psoriasis. In one series, HLA-Cw6 was expressed in 90% of the patients with early-onset psoriasis, in 50% of those with late-onset psoriasis, and only in 7% of a control population. A specific MHC class II antigen (DRB1*0701/2) also appeared to be associated with early-onset psoriasis, and the psoriasis-associated HLA alleles were often in an extended haplotype: Cw6-B57-DRB1*0701-DQA1*0201-DQB1*0303[14]. Individuals carrying this haplotype were found to have a 26-fold increased risk of developing early-onset psoriasis. As a result, some clinicians have designated patients with early-onset psoriasis, a positive family history of psoriasis, and expression of HLA-Cw6 as having *type I psoriasis* and those with late-onset disease, no family history, and a lack of expression of HLA-Cw6 as having *type II psoriasis*[15]. Other HLA alleles may be associated with different psoriasis variants and related conditions. For example, the HLA-B27 allele is a marker for sacroiliitis-associated psoriasis and reactive arthritis (see below).

Genome-wide association studies

Classic genome-wide linkage analysis has identified at least nine psoriasis susceptibility regions *(PSORS1–9)* in different chromosomal locations[16]. By far the most important genetic region is *PSORS1* (on chromosome 6p), which is estimated to account for up to 50% of psoriasis risk. *PSORS1* contains genes such as *HLA-C* (with the *HLA-Cw6* risk allele; see above) and corneodesmosin (*CDSN*). Due to high linkage disequilibrium in *PSORS1* (i.e. genes within this region are inherited as a block), it has been challenging to determine which gene(s) within *PSORS1* contribute to psoriasis pathogenesis. Use of genome-wide association studies (GWAS) has recently provided new insights into the genetic basis of psoriasis. In GWAS, hundreds of thousands of *s*ingle *n*ucleotide *p*olymorphisms (SNPs) across the entire human genome are examined in thousands of patients[17] (see Ch. 54). Genes that have been associated with psoriasis through utilization of this and other methods are summarized in Table 8.1.

Several conclusions regarding the genetic factors in psoriasis can be drawn from recent GWAS[18,19]. First, most of the genes that have been implicated have immune-related functions, underscoring the importance of the innate and adaptive immune systems in the pathogenesis of psoriasis; in contrast, relatively few genes that encode skin-specific proteins have been associated with psoriasis. Second, thus far surprisingly few interactions among the genetic variants have been identified (with the exception of HLA-Cw6 and ERAP-1; see below). Third, associated genes encode proteins with roles in particular immunologic and signaling pathways, especially those involving tumor necrosis factor (TNF), NF-κB, interferons (IFN) and interleukin (IL)-23/Th17 cells (see Immunopathogenesis)[19,20]. Lastly, the *ERAP1* gene encoding an aminopeptidase involved in MHC class I antigen processing is only associated with psoriasis risk in individuals carrying the *HLA-Cw6* risk allele, providing evidence for the role of an MHC-restricted antigen and its presentation through HLA-C in the pathogenesis of psoriasis.

Functional genomic studies

Microarray technology has been utilized to obtain a comprehensive picture of the genes expressed in psoriatic skin[21]. More than 1300 genes were found to be differentially expressed when compared to normal human skin. This group of genes included known markers of psoriasis in the skin, but it also contained numerous genes not known to be expressed in the skin. These analyses confirmed the known involvement, on a genomic scale, of T cells and dendritic cells (DCs), providing evidence for sustained chronic T-cell activation and persistence in psoriatic epidermis.

Microarray-based comparison between the transcriptome of lesional skin from patients with psoriasis versus atopic dermatitis have revealed not only differences in expression of genes with immune function, but also differences in genes expressed by keratinocytes. For example, skin-derived antimicrobial proteins were expressed at high levels in psoriatic skin but at low levels in skin affected by atopic dermatitis[22].

GENETIC LOCI LINKED TO PSORIASIS

Gene/Locus	Chromosomal location	Odds ratio for psoriasis	Comments	Other disease associations
PSORS1	6p	6.4	Contains *HLA-Cw6* (putative immune function; major candidate gene) and *CDSN*	None
PSORS2	17q	–	Putative role in immune synapse formation	None
IL12B	5q	1.4	T-cell differentiation	Crohn's disease
IL23R	1p	2.0	T-cell differentiation	Crohn's disease, ankylosing spondylitis, psoriatic arthritis
ZNF313 (*RNF114*)	20q	1.25	Ubiquitin pathway	None
CDKAL1	6p	1.26	Unknown	Crohn's disease, type 2 diabetes mellitus
PTPN22	18p	1.3	T-cell signalling	Juvenile idiopathic arthritis, systemic lupus erythematosus, rheumatoid arthritis, type 1 diabetes mellitus, autoimmune thyroid disease
IL4/IL13 cytokine gene cluster	5q	1.27	T-cell differentiation	Crohn's disease (distinct variant)
LCE3B/3C/3D	1q	1.31	Epidermal differentiation	
IL23A	12q	1.68	IL-23/Th17 axis	
ERAP1	5q	1.27	MHC class I antigen processing	Ankylosing spondylitis
TNFAIP3	6q	1.28	NF-κB pathway	Rheumatoid arthritis
TNIP1	5q	1.72	NF-κB pathway	
TRAF3IP2	6q	1.36	NF-κB pathway/ IL-23/Th17 axis	Psoriatic arthritis
NFKBIA	14q	1.19	NF-κB pathway	

Table 8.1 Genetic loci linked to psoriasis[18–20]. In addition, polymorphisms in other genes, e.g. interferon induced with helicase C domain 1 (*IFIH1*), have been associated with a decreased risk of developing psoriasis. *CDKAL1,* cyclin-dependent kinase 5 regulatory protein subunit 1-like 1; CDSN, corneodesmosin; *ERAP1,* endoplasmic reticulum aminopeptidase 1; IL, interleukin; *LCE,* late cornified envelope; MHC, major histocompatibility complex; *NFKBIA,* nuclear factor of κ light chain gene enhancer in B cells inhibitor α ; *PTPN22,* protein tyrosine phosphatase non-receptor type 22; *TNFAIP3,* tumor necrosis factor-α-induced protein 3; *TNIP1,* TNFAIP-interacting protein 1; TRAF3IP2, TNF receptor-associated protein 3 interacting protein 2; *ZNF313,* zinc finger protein 313. PATHOGENESIS

Because it primarily affects the interfollicular epidermis, psoriasis was long regarded as an epidermal disease in which the biochemical or cellular defect resided within the keratinocyte. Accordingly, prior to the early 1980s[23], a number of biochemical mediators, enzymes and pathways involved in epidermal function were incriminated as being abnormal in psoriasis, including cyclic AMP, eicosanoids, protein kinase C, phospholipase C, polyamines and transforming growth factor (TGF)-α. Although associated immunologic abnormalities were reported in the late 1970s[24], a major paradigm shift occurred when T-cell suppressive agents such as cyclosporine were found to result in significant improvement of psoriasis[25]. For the past two decades, psoriasis has been regarded as a T-cell-driven disease[25]. The role of lymphocyte subsets as well as cytokines involved in chemotaxis, homing and activation of inflammatory cells has been extensively investigated, culminating in the development of novel therapeutic approaches[25]. Although some regard psoriasis as an autoimmune disease, to date no true autoantigen has been definitively identified.

Immunopathogenesis

Role of T cells and dendritic cells

The association of psoriasis with particular MHC alleles, such as *HLA-Cw6*, and (in individuals carrying such alleles) variants in the *ERAP1* gene encoding an aminopeptidase involved in antigen processing strongly suggests a pathogenetic role for antigen-presenting cells and T cells (Fig. 8.1). The presence of specific T-cell subsets within the epidermis and dermis of lesional skin is well documented (see below). In addition, a number of compounds that affect T-cell function (e.g. by targeting the IL-2 receptor, CD2, CD11a and CD4) were found to result in clinical improvement of psoriasis[25]. Another argument supporting involvement of the adaptive immune system is the disappearance or development of psoriasis following hematopoietic stem cell transplantation[26,27]. In addition, analysis of lesional T cells has shown oligoclonality, indicating potential antigen-specific expansion of T-cell subpopulations, possibly triggered by exogenous microbial or viral antigens or cross-reacting autoantigens, e.g. keratins[28].

Animal models for psoriasis have also demonstrated the importance of T cells. In xenograft models in which uninvolved psoriatic skin was transplanted onto immunodeficient mice, donor immune cells (in particular resident T cells) were capable of expanding and inducing the complete lesional phenotype[29]. Induction of psoriatic lesions in these models was also shown to be dependent on TNF-α and on IFN-α derived from plasmacytoid DCs (pDCs)[29,30]. These experiments demonstrated that T cells can trigger psoriasis in a suitable patient-derived environment.

In humans, several cell types have been implicated in the initiation and maintenance of psoriatic lesions. Most of the epidermal T cells are $CD8^+$, whereas the dermal infiltrate is a mixture of $CD4^+$ and $CD8^+$ cells. The majority of the cells in both locations are memory T cells that express cutaneous lymphocyte antigen (CLA; the skin homing receptor) and chemokine receptors such as CCR4. Expression of $\alpha_1\beta_1$ integrin (VLA-1) on psoriatic T cells, which allows their interaction with basement membrane collagen IV, is key for the entrance of these cells into psoriatic epidermis and establishment of the psoriatic epithelial phenotype (see Fig. 8.1)[31]. Natural killer (NK) T cells represent another subset of T cells that are part of the innate immune system and are found in psoriatic skin lesions; they interact with CD1d on keratinocytes. The resulting production of IFN-γ could contribute to additional immune stimulation[32].

DCs are present in both uninvolved and lesional psoriatic skin, and because of their potent immunostimulatory capacity, they are likely to be involved in its pathogenesis. There is an increased number of dermal DCs in psoriatic skin, and they have an enhanced ability to activate T cells when compared to DCs from normal skin[33]. DC phenotype and function are quite plastic, with the ability to differentiate into potent proinflammatory DCs that produce inducible nitric oxide synthase (iNOS) and TNF-α (referred to as TIP [*T*NF/*i*NOS-*p*roducing] DCs)[34]. The role of DCs in psoriasis has been validated by the presence of a prominent genomic DC signature and the decrease of DCs during effective targeted therapy[35].

Based upon studies in humans and a xenograft model, another type of DC, the pDC, was shown to initiate psoriasis via the production of IFN-α[30]. Complexes of self DNA or RNA (from keratinocytes) plus antimicrobial peptide LL37 trigger IFN-α release by pDCs via a Toll-like receptor 9 (TLR9)-dependent mechanism (see Fig. 8.1). This leads to a breaking of tolerance to self nucleic acids and potentially explains the start of the inflammatory cascade in psoriasis[36,37].

The presence of neutrophils in the epidermis, either in spongiform pustules of Kogoj or in microabscesses of Munro, is a typical histopathologic feature of psoriasis, especially acute or pustular forms. Neutrophils are typically prominent in active lesions and in the marginal zone of expanding plaques, but, in contrast to T cells, they are not a consistent feature of lesional skin. Although activated neutrophils could contribute to its pathogenesis, they are not considered to be the primary cause of psoriasis.

Prominent angiogenesis is observed in plaques of psoriasis. There is increased expression of vascular endothelial growth factor (VEGF)[38], and anti-VEGF therapy leads to improvement in mouse models of psoriatic inflammation[39].

Cytokines and chemokines

Psoriasis is considered to be a disease with prominent involvement of helper T-cell subsets and their secreted cytokines[40]. Increased amounts of Th1 cytokines (IFN-γ and IL-2) are observed, whereas levels of the anti-inflammatory cytokine IL-10 are reduced. Based on animal studies and measurements in lesional skin, IL-12, IL-23 and IL-15 are likely to contribute to the disease. The striking response of psoriasis to ustekinumab, a human monoclonal antibody against the p40 subunit of IL-12 and IL-23, provides additional evidence for the role of cytokines. It is thought that IL-23 (produced by DCs) stimulates Th17 cells to release IL-17 and IL-22; the concerted action of these cytokines leads to proliferation of keratinocytes and dermal inflammation (see Fig. 8.1)[41]. Of note, circulating levels of IL-22 correlate with disease severity. It has also been proposed that there is a distinct subset of IL-22-producing helper T cells (Th22 cells) that contribute to the pathogenesis of psoriasis[42,43]. The IL-17-producing T cells in psoriatic epidermis might have a cytotoxic phenotype, qualifying them as Tc17 cells[44].

IFN-γ is released by activated T cells and NK T cells in the epidermis, and it activates members of the STAT transcription factor family, which drive the expression of a large number of immune-related genes that have roles in psoriasis pathogenesis. The IFN-γ-activated pathway is a key feature of psoriasis and explains several phenotypic alterations such as vasodilation (by the induction of iNOS) and accumulation of T cells (via the expression of various chemokines).

The innate immune cytokines IL-1, IL-6 and TNF-α are upregulated in psoriatic skin. TNF-α is a particularly relevant cytokine and its importance is underscored by the therapeutic efficacy of TNF-α inhibitors (see Treatment).

Chemokines are important mediators in the trafficking of leukocytes, and the increased presence of several chemokines and their cognate receptors in psoriatic lesions has been extensively documented. CXCL8 is thought to mediate the often-prominent infiltration by neutrophils. CCL17, CCL20, CCL27 and CXCL9-11 are implicated in attracting T cells to the psoriatic plaque. A pDC-attracting chemokine, chemerin, is increased in psoriatic skin and might contribute to the early recruitment of pDCs into psoriatic lesions[45].

Innate immunity and role of keratinocytes

In the skin, various cell types are involved in innate (non-adaptive) immune response pathways. These include DCs (myeloid DCs and pDCs), NK T cells and neutrophils (see above), as well as epidermal keratinocytes. For example, keratinocytes constitutively express antimicrobial proteins such as β-defensin-1 (hBD1) and secretory leukocyte protease inhibitor (SLPI), which have direct antimicrobial activity against a broad spectrum of pathogens. In addition, keratinocytes can be stimulated to express a wide variety of other inducible antimicrobials such as hBD2, the cathelicidin LL37, and SKALP/elafin[46]. In addition to these effector molecules, keratinocytes express TLRs and secrete signaling molecules such as IL-1, IL-6, IL-8 and TNF-α. Interestingly, the antimicrobial effector protein hBD2 was also shown to have chemotactic activity via CCR6 and to bind to TLR-4. Since most of these proteins are highly expressed in lesional psoriatic skin, it is likely that

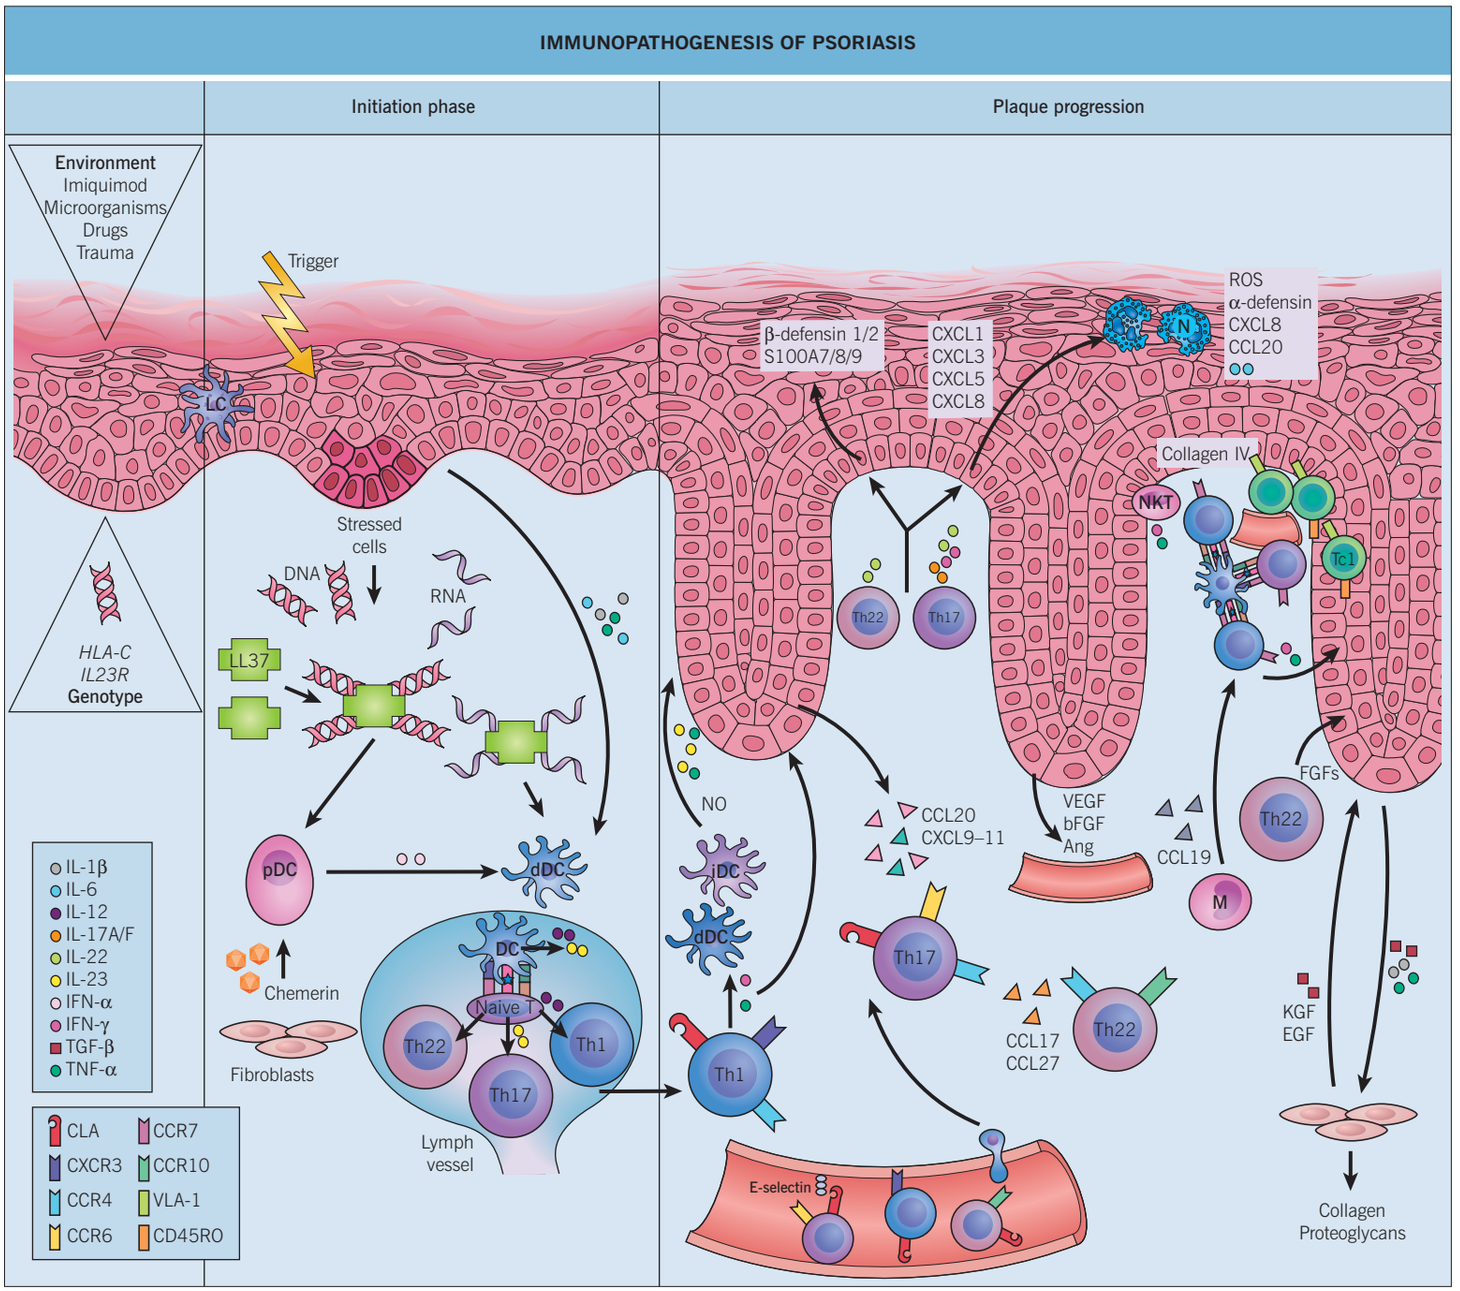

Fig. 8.1 Immunopathogenesis of psoriasis. The occurrence of triggering environmental factors in genetically predisposed individuals, carrying susceptibility alleles of psoriasis-associated genes, results in disease development. During the initiation phase, stressed keratinocytes can release self DNA and RNA, which form complexes with the cathelicidin LL37 that then induce interferon-α (IFN-α) production by plasmacytoid dendritic cells (pDCs; recruited into the skin via fibroblast-released chemerin), thereby activating dermal DCs (dDCs). Keratinocyte-derived interleukin-1β (IL-1β), IL-6 and tumor necrosis factor-α (TNF-α) also contribute to the activation of dDCs. Activated dDCs then migrate to the skin-draining lymph nodes to present an as-yet-unknown antigen (either of self or of microbial origin) to naive T cells and (via secretion of different types of cytokines by DCs) promote their differentiation into T helper 1 (Th1), Th17 and Th22 cells. Th1 cells (expressing cutaneous lymphocyte antigen [CLA], CXC-chemokine receptor 3 [CXCR3] and CC-chemokine receptor 4 [CCR4]), Th17 cells (expressing CLA, CCR4 and CCR6) and Th22 cells (expressing CCR4 and CCR10) migrate via lymphatic and blood vessels into psoriatic dermis, attracted by the keratinocyte-derived chemokines CCL20, CXCL9–11 and CCL17; this ultimately leads to the formation of a psoriatic plaque. Th1 cells release IFN-γ and TNF-α, which amplify the inflammatory cascade, acting on keratinocytes and dDCs. Th17 cells secrete IL-17A and IL-17F (and also IFN-γ and IL-22), which stimulate keratinocyte proliferation and the release of β-defensin 1/2, S100A7/8/9 and the neutrophil-recruiting chemokines CXCL1, CXCL3, CXCL5 and CXCL8. Neutrophils (N) infiltrate the stratum corneum and produce reactive oxygen species (ROS) and α-defensin with antimicrobial activity, as well as CXCL8, IL-6 and CCL20. Th22 cells secrete IL-22, which induces further release of keratinocyte-derived T cell-recruiting chemokines. Moreover, inflammatory DCs (iDCs) produce IL-23, nitric oxide (NO) radicals and TNF-α, while natural killer T (NKT) cells release TNF-α and IFN-γ. Keratinocytes also release vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and angiopoietin (Ang), thereby promoting neoangiogenesis. Macrophage (M)-derived chemokine CCL19 promotes clustering of Th cells expressing chemokine receptor CCR7 with DC in the proximity of blood vessels, with further T-cell activation. At the dermal–epidermal junction, memory $CD8^+$ cytotoxic T cells (Tc1) expressing very-late antigen-1 (VLA-1) bind to collagen IV, allowing entry into the epidermis and contributing to disease pathogenesis by releasing both Th1 and Th17 cytokines. Cross-talk between keratinocytes, producing TNF-α, IL-1β and transforming growth factor-β (TGF-β), and fibroblasts, which in turn release keratinocyte growth factor (KGF), epidermal growth factor (EGF) and TGF-β, and possibly Th22 cells releasing FGFs, contribute to tissue reorganization and deposition of extracellular matrix (e.g. collagen, proteoglycans). LC, Langerhans cell. *Courtesy, Dr Paola DiMeglio.*

they are involved in the initiation or control of the inflammatory process; however, their precise roles remain to be determined.

Any model of the pathogenesis of psoriasis also has to account for the dramatically increased proliferation rate of keratinocytes. The cytokines and chemokines found in lesional skin are generally not mitogenic for keratinocytes. For example, IFN-γ, a prominent Th1 cytokine, is itself antiproliferative, but it was found to be a crucial factor in supernatants of lesion-derived T-cell clones that could drive keratinocyte stem cell proliferation[47].

Keratinocytes within psoriatic plaques express STAT-3, suggesting that this transcription factor might be of pathogenetic importance. In a transgenic animal model, epidermal expression of STAT-3 (in cooperation with T cells) was found to induce psoriasis-like lesions in mice[48]. STAT-3 induced the upregulation of a number of genes relevant for psoriasis, such as those encoding ICAM-1 and TGF-α; the latter has been shown to stimulate proliferation of keratinocytes in psoriasis via an autocrine loop. As STAT-3 is activated by a variety of cytokines including IL-22 as well as IL-6, IL-20 and IFN-γ, this could represent a link between keratinocyte activation and immune cells in the development of the psoriatic lesion.

Triggering Factors

Triggering factors, both external (directly interacting with the skin) and systemic, can elicit psoriasis in genetically predisposed individuals.

External triggering factors

The Koebner phenomenon, i.e. the elicitation of psoriatic lesions by injury to the skin, is observed in approximately 25% of patients with psoriasis. A particular patient may be "Koebner-negative" at one point in time and later become "Koebner-positive". The Koebner phenomenon suggests that psoriasis is a systemic disease that can be triggered locally in the skin. Psoriatic lesions can also be induced by other forms of cutaneous injury, e.g. sunburn, morbilliform drug eruption, viral exanthem. The lag time between the trauma and the appearance of skin lesions is usually 2–6 weeks.

Systemic triggering factors

Infections

Infections, particularly bacterial infections, may induce or aggravate psoriasis. Provoking infections have been observed in up to 45% of psoriatic patients. Streptococcal infections, especially pharyngitis, are the most common offenders[49]. Streptococci can also be isolated from other sites, e.g. dental abscesses, perianal cellulitis, impetigo.

HIV

HIV infection has also been shown to aggravate psoriasis (see Ch. 78).

Endocrine factors

Hypocalcemia has been reported to be a triggering factor for generalized pustular psoriasis. Although active vitamin D_3 analogues improve psoriasis, abnormal vitamin D_3 levels have not been shown to induce psoriasis. Pregnancy may alter disease activity, e.g. 50% of the patients in one series reported improvement. However, pregnant women may develop pustular psoriasis, also referred to as impetigo herpetiformis (see below), sometimes in association with hypocalcemia.

Psychogenic stress

Psychogenic stress is a well-established systemic triggering factor in psoriasis[50]. It has been associated with initial presentations of the disease as well as flares of pre-existing psoriasis. In a prospective study, cognitive and behavioral patterns of worrying and scratching were both independently related to an increase in disease severity and pruritus 4 weeks later[51].

Drugs

Several drugs have been incriminated as inducers of psoriasis, in particular lithium, IFNs, β-blockers and antimalarials. Rapid taper of systemic corticosteroids can induce pustular psoriasis as well as flares of plaque psoriasis

Alcohol consumption, smoking and obesity

Obesity, increased alcohol consumption, and smoking have all been associated with psoriasis. In one analysis, smoking appeared to have a role in the onset of psoriasis, while obesity appeared to be a consequence of psoriasis[52], whereas other studies have suggested that weight gain often proceeds the development of psoriasis. Some studies have found that the prevalence of psoriasis in a population of individuals who stop smoking or who lose weight eventually reverts to background levels.

CLINICAL FEATURES

Chronic plaque psoriasis, the most common variant of psoriasis vulgaris, is characterized by sharply demarcated and erythematous papulosquamous lesions. Less often, nearly all of the body surface is involved ("*erythrodermic psoriasis*") or numerous, small, widely disseminated papules and plaques are seen ("*guttate psoriasis*"). Occasionally, there are obvious macroscopic pustules, as in generalized pustular psoriasis or pustulosis of the palms and soles.

From a clinical perspective, psoriasis can present with a spectrum of cutaneous manifestations. At any one point in time, different variants may coexist in a particular individual, but the skin lesions all share the same important hallmarks: erythema, thickening and scale. As noted in the section on Epidemiology and Genetics, there is also significant interindividual variability. For example, in patients with chronic plaque psoriasis, those with type I disease (HLA-$Cw6^+$) have an earlier onset, more widespread disease and frequent recurrences, compared to those with type II psoriasis.

Although the size of a lesion may vary from a pinpoint papule to over 20 cm in diameter, the outline of the lesion is usually circular, oval or polycyclic (the latter indicating that the lesion is derived from several smaller units). The configuration of psoriatic lesions due to the Koebner phenomenon reflects the etiology of the trauma. In addition to their highly characteristic sharp demarcation, psoriatic lesions are sometimes surrounded by a pale blanching ring, which is referred to as Woronoff's ring.

The classic findings of erythema, thickening and scale are reflections of the histologic findings of elongated dilated capillaries that are close to the skin surface, epidermal acanthosis plus cellular infiltrates, and abnormal keratinization, respectively. If the superficial silvery white scales are removed via curettage (grattage method), a characteristic coherence is observed, as if one has scratched on a wax candle ("signe de la tache de bougie"). Subsequently, a surface membrane is seen, which will also come off as a whole. If the latter is removed, then a wet surface is seen with characteristic pinpoint bleeding. This finding, called Auspitz sign, is the clinical reflection of elongated vessels in the dermal papillae together with thinning of the suprapapillary epidermis.

During exacerbations, psoriatic lesions often itch. Pinpoint papules surrounding existing psoriatic plaques indicate that the patient is in an unstable phase of the disease. In addition, expanding psoriatic lesions are characterized by an active edge with a more intense erythema. Inflamed lesions may be slightly tender. The involution of a lesion usually starts in its center, resulting in annular psoriatic lesions.

Chronic Plaque Psoriasis

In chronic plaque psoriasis, there is a relatively symmetric distribution of sharply defined, erythematous, scaly plaques (Figs 8.2 & 8.3). The degree of body surface area involvement can vary, from limited to extensive. The scalp, elbows, knees and presacrum are sites of predilection, as are the hands and feet (Figs 8.4 & 8.5). The genitalia are involved in up to 45% of patients (Fig. 8.6; see Ch. 73). Plaques may persist for months to years at the same locations. Although the course of this disease is chronic, periods of complete remission do occur and remissions of 5 years have been reported in approximately 15% of patients.

Because the percentage of body surface area involved does not reflect the severity of the individual lesions with respect to erythema, induration and scaling, the Psoriasis Area and Severity Index (PASI) was formulated (Table 8.2). This is a single score calculated from the body surface area involved (utilizing a seven-point score for involvement in each of four anatomic areas – head, upper extremities, trunk and lower extremities) and from the scores for erythema, induration and scaling (each scored using a five-point score from 0 to 4). The PASI is a cumbersome calculation and is more commonly utilized for clinical trials than for the routine management of patients with psoriasis. A score for

Fig. 8.2 Psoriatic plaques. A, B Note the sharp demarcation and silvery scale. *B, Courtesy Julie V Schaffer, MD.*

Fig. 8.3 Symmetric distribution of psoriatic plaques. A, B Both small and large plaques have a symmetric distribution pattern. Note the active border at the proximal edge of the plaques on the calves.

nail involvement has also been proposed, known as the Nail Psoriasis Severity Index (NAPSI), but it has not been widely utilized.

Guttate Psoriasis

Guttate psoriasis is more commonly seen in children and adolescents and is frequently preceded by an upper respiratory tract infection (Fig. 8.7). In over half of the patients, an elevated antistreptolysin O, anti-DNase B or streptozyme titer is found, indicating a recent streptococcal infection (see previous section).

Erythrodermic Psoriasis

This variant of psoriasis is characterized by generalized erythema and scaling, and its onset can be gradual or acute. Although there are many causes of erythroderma (see Ch. 10), clues to the diagnosis of psoriatic erythroderma include previous plaques in classic locations, characteristic nail changes, and facial sparing.

Pustular Variants

Generalized pustular psoriasis

In generalized pustular psoriasis, the infiltration of neutrophils dominates the histologic picture, while erythema and the appearance of sterile pustules dominate the clinical picture (Fig. 8.8). It is an unusual manifestation of psoriasis, and triggering factors include pregnancy, rapid tapering of corticosteroids (or other systemic therapies), hypocalcemia, infections, and, in the case of the localized pattern, topical irritants. Recently, biallelic mutations in the gene encoding the IL-36 receptor antagonist (leading to increased production of IL-8 and enhanced responses to IL-1β) have been identified in a subset of patients with generalized pustular psoriasis[53]. Generalized pustular psoriasis during pregnancy is also referred to as impetigo herpetiformis. Four distinct patterns of generalized pustular psoriasis can be seen:

- **von Zumbusch pattern**. This is a generalized eruption starting abruptly with erythema and pustulation (see Fig. 8.8). The skin is painful during this phase, and the patient has a fever and feels ill. After several days, the pustules usually resolve and extensive scaling is observed. Sometimes, chronic plaques of psoriasis, if

Fig. 8.4 Childhood psoriasis. A The scalp is a common site of involvement and psoriasis is distinguished by its sharp demarcation. **B** Annular and guttate lesions. *A, B, Courtesy, Julie V Schaffer, MD.*

present, can resolve. In the original case report by von Zumbusch (1910), nine episodes of pustulation occurred over a period of 10 years.

- **Annular pattern**. The eruption is characterized by annular lesions, consisting of erythema and scaling with pustulation at the advancing edge (Fig. 8.9). The lesions enlarge by centrifugal expansion over a period of hours to days, while healing occurs centrally.
- **Exanthematic type**. This is an acute eruption of small pustules, abruptly appearing and disappearing over a few days. It usually follows an infection or may occur as a result of administration of specific medications, e.g. lithium. Systemic symptoms usually do not occur. There is overlap between this form of pustular psoriasis and pustular drug eruptions, also referred to as acute generalized exanthematous pustulosis (AGEP; see Ch. 21).
- **"Localized" pattern**. Sometimes pustules appear within (Fig. 8.10) or at the edge of existing psoriatic plaques. This can be seen during the unstable phase of chronic plaque psoriasis and following the application of irritants, e.g. tars.

Pustulosis of the palms and soles

Pustulosis of the palms and soles is characterized by "sterile" pustules of the palmoplantar surfaces admixed with yellow–brown macules (Fig. 8.11); scaly erythematous plaques may also be seen. A minority of patients have chronic plaque psoriasis elsewhere. In contrast to the natural history of generalized pustular psoriasis, the pustules remain localized to the palmoplantar surfaces and the course of this disease is

Fig. 8.8 Generalized pustular psoriasis. Large areas of erythema with numerous pustules and the formation of lakes of pus.

chronic. Focal infections and stress have been reported as triggering factors and smoking may aggravate the condition. Pustulosis of the palms and soles is one of the entities most commonly associated with sterile inflammatory bone lesions, for which there are several names: chronic recurrent multifocal osteomyelitis, pustulotic arthro-osteitis, and SAPHO syndrome, which consists of *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis. Several neutrophilic dermatoses are associated with SAPHO (see Ch. 26).

Acrodermatitis continua of Hallopeau

This is a rare manifestation of psoriasis. Clinically, pustules are seen on the distal portions of the fingers (Fig. 8.12) and sometimes the toes. Pustulation is often followed by scaling and crust formation. Pustules may also form in the nail bed (beneath the nail plate), and there may be shedding of nail plates. Transition into other forms of psoriasis can occur and acrodermatitis continua may be accompanied by annulus migrans of the tongue.

Special Locations

Scalp psoriasis

The scalp is one of the most common sites for psoriasis. Unless there is complete confluence, the individual lesions are discrete, in contrast to the less well-defined areas of involvement in seborrheic dermatitis. At times, however, it is not possible to distinguish seborrheic dermatitis from psoriasis, and the two disorders may coexist. The lesions of

Fig. 8.10 "Localized" pattern of pustular psoriasis. The pustules are limited to pre-existing plaques of psoriasis.

Fig. 8.11 Pustulosis of the palms and soles. Multiple sterile papules are admixed with yellow–brown macules on the palm.

Fig. 8.12 Acrodermatitis continua of Hallopeau. Erythema and scale of the distal digit, pustules within the nail bed, and partial shedding of the nail plate.

psoriasis often advance onto the periphery of the face, the retroauricular areas and the upper neck. The scales sometimes have an asbestos-like appearance and can be attached for some distance to the scalp hairs (pityriasis amiantacea). Although pityriasis amiantacea can also be seen in patients with seborrheic dermatitis, secondarily infected atopic dermatitis and tinea capitis, psoriasis is the most common cause. Alopecia occasionally develops within involved areas (see Ch. 69). In addition, patients with dermatomyositis involving the scalp may have lesions that resemble psoriasis.

Flexural psoriasis

Flexural lesions are characterized by shiny, pink to red, sharply demarcated thin plaques (Fig. 8.13). There is much less scale than in untreated chronic plaque psoriasis. Often a central fissure is seen. The most common sites of involvement are the axillae, inguinal crease, intergluteal cleft, inframammary region and retroauricular folds. When flexural areas are the only sites of involvement, the term "inverse" psoriasis is sometimes used. Localized dermatophyte, candidal or bacterial infections can be a trigger for flexural psoriasis.

Oral mucosa

Migratory annular erythematous lesions with hydrated white scale (annulus migrans) have been observed in patients with acrodermatitis continua of Hallopeau and generalized pustular psoriasis. The most common location is the tongue, and the clinical (and histologic) appearance is similar to geographic tongue.

Fig. 8.13 Inverse psoriasis. Shiny erythematous plaques of the inframammary folds that lack scale.

Fig. 8.14 Nail psoriasis. Changes include thickening and yellow discoloration of the nail plate, distal onycholysis, pitting, red spotted lunula and subungual hyperkeratosis.

Nail psoriasis

Nail involvement (Fig. 8.14) has been reported in 10–80% of psoriatic patients, depending upon the series. The fingernails are more often affected than the toenails. In a survey from the Netherlands, 79% of patients reported involvement of their nails, with 52% experiencing associated pain and 14% major restrictions in daily life due to the nail changes. Patients with nail involvement appear to have an increased incidence of psoriatic arthritis (see below).

Psoriasis affects the nail matrix, nail bed and hyponychium. Small parakeratotic foci in the proximal portion of the nail matrix lead to pits in the nails (see Ch. 71). Leukonychia and loss of transparency (less common findings) are due to involvement of the mid portion of the matrix. If the whole nail matrix is involved, a whitish, crumbly, poorly adherent "nail" is seen. Psoriatic changes of the nail bed result in the "oil spot" or "oil drop" phenomenon, which reflects exocytosis of leukocytes beneath the nail plate. Splinter hemorrhages are the result of increased capillary fragility, and subungual hyperkeratosis and distal onycholysis are due to parakeratosis of the distal nail bed. Vigorous removal of distal subungual debris may be an exacerbating factor.

Psoriatic Arthritis

Psoriatic arthritis occurs in 5–30% of patients with cutaneous psoriasis[1], with some clinical investigators suggesting that classic studies of psoriatic arthritis may have underestimated its prevalence. In a minority of patients (10–15%), the symptoms of psoriatic arthritis appear before involvement of the skin. Currently, there are no specific serologic tests for establishing the diagnosis of psoriatic arthritis, but an important hallmark is erosive change radiographically, which may occur years after the presenting peri-articular inflammation. Psoriatic arthritis is more prevalent among patients with relatively severe psoriasis. Risk factors for a more severe course of the arthritis include: initial presentation at an early age, female gender, polyarticular involvement, genetic predisposition, and radiographic signs of the disease early on[54].The following classification has been outlined by Moll[55].

- **Mono- and asymmetric oligoarthritis**. Inflammation of the interphalangeal joints – both distal (DIP) and proximal (PIP) – of the hands and feet is the most common presentation of psoriatic arthritis (Fig. 8.15). Involvement of the PIP or both the DIP and PIP joints of a single digit can result in the classic "sausage" digit (Fig. 8.16). In contrast to rheumatoid arthritis, the metacarpophalangeal (MCP) joint is an unusual site for psoriatic arthritis. This form may be accompanied by inflammation of larger joints.
- **Arthritis of the distal interphalangeal joints**. Exclusive involvement of the DIP joints is a classic but uncommon presentation of psoriatic arthritis. This variant may occur in conjunction with contiguous nail involvement. In some patients, these joints will become fixed in a flexed position.
- **Rheumatoid arthritis-like presentation**. The clinical manifestations consist of a symmetric polyarthritis that involves small and medium-sized joints, in particular the PIP, MCP, wrist, ankle and elbow. Patients are usually seronegative, but some have a positive rheumatoid factor. Clinically, this variant is difficult to distinguish from rheumatoid arthritis. Whether seropositive patients have an overlap of the two disorders is debated.
- **Arthritis mutilans**. Fortunately, this is the least common variant of psoriatic arthritis. Patients have severe, rapidly progressive joint inflammation that results in destruction of the joints and permanent deformity. The digits become shorter, wider and softer to palpation because of osteolysis and a telescoping phenomenon. This variant can usually be distinguished from the arthritis mutilans that may accompany multicentric reticulohistiocytosis.
- **Spondylitis and sacroiliitis**. The spondylitis resembles that seen in ankylosing spondylitis, with axial arthritis as well as involvement of the knees and sacroiliac joints; many patients also have peripheral joint involvement. Individuals are often HLA-B27-positive and may have associated inflammatory bowel disease and/or uveitis.

In a recent study from Germany involving 1511 patients with chronic plaque psoriasis, 20.6% of the affected individuals had psoriatic arthritis[56]. DIP involvement was observed in ~40% of the patients with arthritis, and 5% suffered from arthritis mutilans[56]. Patients with psoriatic arthritis can have involvement of juxta-articular tendons and the sites where they insert into bone (entheses) as well as swelling of the fingers (dactylitis). Enthesitis and dactylitis have been reported in ~20% and 15–30%, respectively, of patients with "probable" or definite psoriatic arthritis[54].

Early diagnosis of psoriatic arthritis is important, as disease progression often results in loss of function.

Disorders Related to Psoriasis

A few disorders share important clinical and histologic features with psoriasis, but are distinct disease entities based upon genetic, epidemiologic or clinical features.

Inflammatory linear verrucous epidermal nevus (ILVEN)

ILVEN is characterized by linear psoriasiform lesions (i.e. scaling and erythematous plaques) that follow the lines of Blaschko (see Ch. 62). Based upon its chronicity and resistance to therapy, ILVEN is thought to be an entity separate from linear psoriasis.

Reactive arthritis (formerly Reiter's disease)

This syndrome features urethritis, arthritis, ocular findings and oral ulcers, in addition to psoriasiform skin lesions. The disorder is uncommon in children and occurs more frequently in men as compared to women. The urethritis may be mild or severe with complications such as cervicitis, salpingitis and cystitis. *Chlamydia trachomatis* is a major cause of urethritis and may trigger the entire syndrome, as may other infections such as shigellosis. Conjunctivitis is a common eye finding in affected patients, although iritis, uveitis with glaucoma, and keratitis may also occur. Polyarthritis and sacroiliitis are the most frequent joint manifestations. Cutaneous lesions occur in approximately 5% of reactive arthritis patients, with a predilection for the

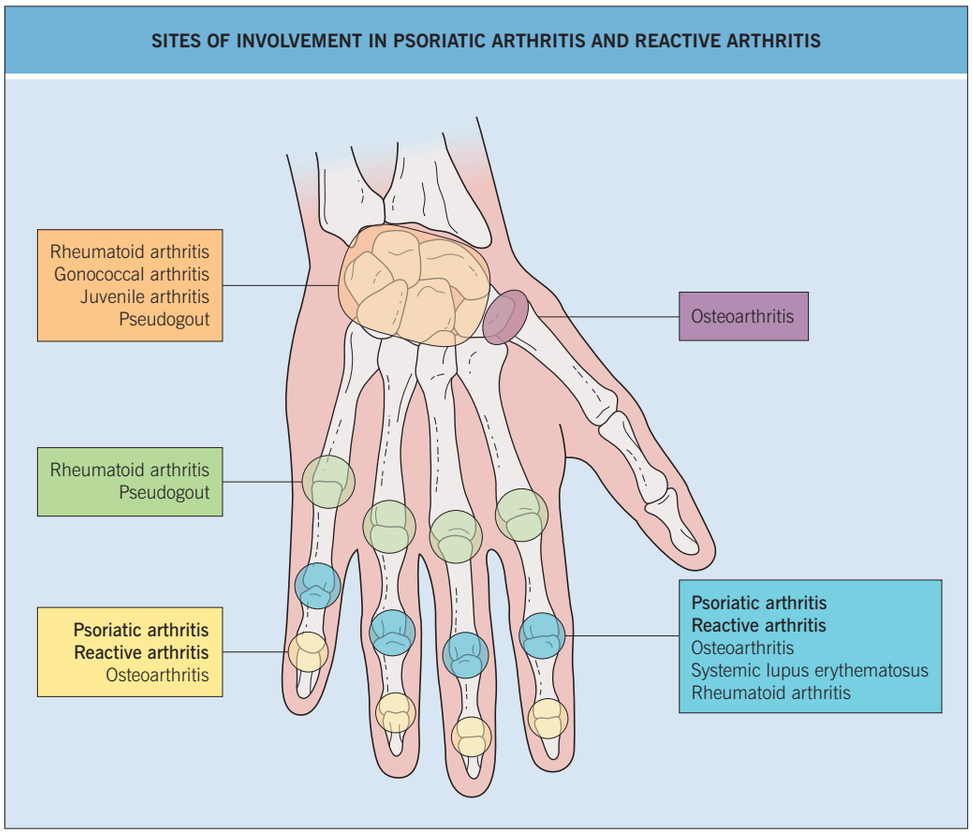

Fig. 8.15 Sites of psoriatic arthritis and reactive arthritis (formerly Reiter's disease). *Adapted from Longo DL, Fauci AS, Kasper D, et al. Harrison's Principles of Internal Medicine, 18th edn. New York: McGraw Hill, 2011.*

Fig. 8.16 Psoriatic arthritis. Asymmetric involvement of the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints. A "sausage" digit (third digit bilaterally) results from involvement of both the DIP and PIP joints.

soles, extensor surfaces of the legs, penis, dorsal aspects of the hands, fingers, nails and scalp (Fig. 8.17). The lesions on the plantar surface usually have thick yellow scale and are often pustular (keratoderma blennorrhagicum). Psoriatic plaques on the penis are referred to as balanitis circinata.

Reactive arthritis has a strong association with HLA-B27. Although the course is often self-limited, lasting weeks to months, some patients have disease that is chronic and disabling. Of note, HIV-infected patients can also develop this disorder and it may be severe.

Sneddon–Wilkinson disease (subcorneal pustular dermatosis)

This disorder is characterized by annular or polycyclic lesions, usually commencing in the flexures (Fig. 8.18A). Very superficial (subcorneal) sterile pustules (Fig. 8.18B,C) are the hallmark of Sneddon–Wilkinson disease, hence its second name. There may be a gravity-induced demarcation in some vesicopustules, with clear fluid superiorly and pus inferiorly. This disease has a cyclic course, i.e. as the pustules resolve they are replaced by superficial scaling and then new pustules form again. Some patients with Sneddon–Wilkinson disease have an associated IgA paraproteinemia. Its response to dapsone, combined with subcorneal pustules (in the absence of spongiform pustules), provide support for this condition being a disease entity distinct from pustular psoriasis, although some authors have questioned the existence of Sneddon–Wilkinson disease as a distinct entity. Of note, immunofluorescence studies are required to distinguish the subcorneal pustular dermatosis type of IgA pemphigus from Sneddon-Wilkinson disease.

Associations between Psoriasis and Other Diseases

Associations with skin diseases

There is a pronounced under-representation of allergic skin diseases in psoriatic patients as compared to age-matched controls without psoriasis. The frequencies of atopic dermatitis, asthma, urticaria and allergic contact dermatitis have been found to be lower in psoriatic patients. For example, in one study atopic dermatitis was seen approximately 50 times less often in psoriatic compared with non-psoriatic patients[1]. An obvious explanation is the immunologic difference between these two conditions, with a predominantly Th1 response in psoriasis and a predominantly Th2 response in atopic dermatitis. However, in patients with psoriasis in atypical locations and/or treatment-resistant lesions, the possibility of allergic contact dermatitis as a triggering factor needs to be considered. In the authors' experience, longstanding psoriatic lesions of the hands and external auditory canal are indications for patch testing.

A bi-directional relationship exists between lichen simplex chronicus (LSC) and psoriasis. If a psoriatic lesion is pruritic, superimposed LSC may develop and the surface becomes shiny with increased skin markings. Because the LSC itself is pruritic, the resultant rubbing may worsen the psoriasis (Koebner phenomenon). The patient then enters a vicious cycle. The combined picture is sometimes referred to as lichenified psoriasis or psoriasis neurodermiformis. Therapeutic regimens must address both disorders.

Fig. 8.18 Sneddon–Wilkinson disease. A Annular and polycyclic plaques in the axilla. **B** Subcorneal pustules with scale and crusts as well as background erythema. **C** Discrete subcorneal pustule with an erythematous rim. *C, Courtesy, Joyce Rico, MD.*

Seborrheic dermatitis is characterized by pink to red patches with yellowish, sometimes greasy, scales (see Ch. 13). The sites of predilection are the scalp, central face, ears, presternal area and intertriginous zones. As the clinical features of psoriasis and seborrheic dermatitis can be seen in the same patient, some authors use the term "sebopsoriasis", especially when diagnostic lesions of psoriasis are not present elsewhere.

Infections

In contrast to atopic dermatitis, psoriatic lesions are seldomly secondarily infected by bacteria (i.e. impetiginized). One explanation for this resistance to secondary bacterial infections is increased production of skin-derived antimicrobial peptides (e.g. defensins, SKALP/Elafin; see Pathogenesis).

The relationship between psoriasis and mycotic infections is more complex. In flexural psoriasis, concomitant *Candida* infections are frequently observed and have been incriminated as local triggering factors. *Candida* species, but not dermatophytes, are more commonly found in psoriatic nails than in normal nails.

Cancer

Patients with psoriasis may have an increased overall risk of cancer, including lymphoma, and treatment with immunosuppressive agents may increase this risk[57]. Psoriatic patients who have had specific therapies, e.g. >200 PUVA treatments, are at increased risk for the development of skin cancers, especially squamous cell carcinomas (SCCs). Of note, the use of cyclosporine in patients previously treated with PUVA significantly increases the number and rate of appearance of SCCs. Lastly, there is controversy regarding whether PUVA-treated patients have an increased risk of cutaneous melanoma.

Association with internal diseases (including comorbidities)

Cardiovascular diseases, e.g. myocardial infarctions, pulmonary emboli, peripheral arterial disease and cerebrovascular accidents, are more common in patients with severe psoriasis. Severe psoriasis is associated with a threefold increased risk for myocardial infarction and a 3.5–4.4-year reduction in life expectancy. This is largely due to an increased risk of obesity, hypertension and diabetes mellitus (components of the metabolic syndrome; see Ch. 53)[58–60]. In patients with psoriasis, serum levels of C-reactive protein (CRP) have been reported to be elevated (as compared to healthy controls), and elevated CRP levels represent a risk factor for the development of cardiovascular disease. It has also been shown that TNF-α and IL-6 can target adipocytes and induce dyslipidemia. Recently, evidence has been accumulating that treatment with methotrexate and/or TNF-α inhibitors may reduce the risk of atherosclerotic cardiovascular disease[61].

Non-alcoholic steatohepatitis, characterized by fatty infiltration, periportal inflammation and focal necrosis, is more commonly observed in patients with psoriasis. In a study of 142 adults with psoriasis, non-alcoholic fatty liver disease was detected in 59%, and it correlated with the presence of obesity, hyperlipidemia, the metabolic syndrome, an AST:ALT ratio >1 and psoriatic arthritis[62]. Chronic administration of methotrexate is associated with a significant risk for hepatic damage in patients with psoriasis, whereas similar methotrexate dosages in patients with rheumatoid arthritis do not pose such hepatotoxic potential. Although the reason for this difference is not known, several possible explanations have been put forward, including a genetic predisposition, increased alcohol consumption by psoriasis patients, and a higher incidence of non-alcoholic fatty liver disease.

Crohn's disease, ulcerative colitis and psoriasis share an association with sacroiliitis and HLA-B27 positivity[63]. Additional disorders that share susceptibility genes with psoriasis are listed in Table 8.1.

DIFFERENTIAL DIAGNOSIS

Although both seborrheic dermatitis (see above) and LSC are in the differential diagnosis of psoriasis, it is important to remember that either can coexist with psoriasis. When there is a single or limited number of erythematous plaques, especially if they are treatment-resistant, the possibility of SCC *in situ* (e.g. Bowen's disease, erythroplasia of Queyrat) needs to be excluded via histologic examination. Occasionally, a biopsy is necessary to distinguish chronic plaque psoriasis from the mycosis fungoides variant of cutaneous T-cell lymphoma (CTCL). Clinical features suggestive of the latter include wrinkling due to epidermal atrophy and progression to infiltrated plaques. Dermatomyositis can involve the scalp, elbows and knees, as well as the hands, and initially may be diagnosed as psoriasis.

When plaques of psoriasis involve the shins, they may be misdiagnosed as hypertrophic lichen planus, but characteristic violaceous lesions elsewhere and mucosal involvement usually point to the correct diagnosis. Palmoplantar plaque psoriasis can be confused with keratotic eczema of the palms and soles, as both may have scaling and fissures. Sharp margination of the lesions favors psoriasis and examination of the remainder of the skin surface can provide clues to the diagnosis, e.g. involvement of the scalp or intergluteal fold with psoriasis. Elsewhere, chronic lesions of dermatitis may develop an appearance that is similar (clinically and histologically) to partially treated psoriasis and vice versa. However, over time, characteristic lesions often become apparent. When plaques of psoriasis develop pronounced hyperkeratosis, the possibility of concomitant hypothyroidism should be considered.

There are other causes of erythroderma (see Ch. 10), in addition to psoriasis, including Sézary syndrome (see Ch. 120), pityriasis rubra pilaris (see Ch. 9) and drug reactions (see Ch. 21). In the case of guttate psoriasis, the differential diagnosis may include small plaque parapsoriasis (Ch. 9), pityriasis lichenoides chronica (Ch. 9), secondary syphilis (Ch. 82) and pityriasis rosea (Ch. 9). The lesions of guttate psoriasis rarely involve the palms or soles and are often more erythematous than those of parapsoriasis. When lesions are limited in number or have an annular configuration, the possibility of tinea corporis is raised, and when the upper trunk is the predominant site of involvement, pemphigus foliaceus may be considered.

Psoriasis of the flexures is one cause of intertrigo. Other etiologies include seborrheic dermatitis, cutaneous candidiasis, tinea incognito, necrolytic migratory erythema, extramammary Paget's disease, Bowenoid papulosis and contact dermatitis. Although KOH examination of associated scale allows a narrowing of the differential diagnosis, psoriasis and candidiasis can coexist (see above). In infants (more so than adults), the possibility of Langerhans cell histiocytosis (Ch. 91) needs to be considered. In these patients, there may also be scalp involvement with scaling and crusts. Occasionally, tinea capitis is in the differential diagnosis of scalp psoriasis.

When there are widespread pustules on a background of erythema, the possibility of a pustular drug eruption, also referred to as AGEP, needs to be considered in addition to generalized pustular psoriasis (see Ch. 21). The histologic findings of these conditions can be similar, including spongiform pustules of Kogoj and microabscesses in the stratum corneum. If eosinophils are also present, a pustular drug eruption is favored. In patients with pustulosis of the palms and soles and acrodermatitis continua, the initial evaluation includes the exclusion of a dermatophyte infection or secondarily infected dermatitis. The differential diagnosis of the annular form of pustular psoriasis includes Sneddon–Wilkinson disease and other causes of subcorneal pustules (Table 8.3). Reactive arthritis needs to be considered in any patient with the diagnosis of arthritis in the setting of psoriasiform skin lesions.

DIFFERENTIAL DIAGNOSIS OF SUBCORNEAL/INTRAEPIDERMAL NEUTROPHILIC PUSTULES

Disorder	Histologic clues
Impetigo	Gram-positive cocci in bulla cavity
Superficial candidiasis	Yeast and pseudohyphae in stratum corneum
Dermatophyte infection	Branching hyphae in stratum corneum
Superficial folliculitis	Pustule at follicular orifice and infundibulum
Pemphigus foliaceus	Acantholytic cells; DIF, IIF – intercellular IgG deposits; anti-desmoglein 1 antibody
IgA pemphigus, subcorneal pustular dermatosis type	DIF>IIF – intercellular IgA deposits; anti-desmocollin 1 antibody
Sneddon–Wilkinson disease (subcorneal pustular dermatosis)	No spongiform pustules
Pustular psoriasis	Spongiform pustules*
Acute generalized exanthematous pustulosis	Spongiform pustules, eosinophils*
Amicrobial pustulosis of the folds	Spongiform pustules*
Transient neonatal pustular melanosis	Subcorneal and intracorneal pustules
Acropustulosis of infancy	Subcorneal and intracorneal pustules

*Not all cases.

Table 8.3 Differential diagnosis of subcorneal/intraepidermal neutrophilic pustules. DIF, direct immunofluorescence; IIF, indirect immunofluorescence.

PATHOLOGY

Papulosquamous Lesions

Initial lesion

In the initial lesion, i.e. a pinhead-sized papule, the histopathologic features are not yet diagnostic. A superficial perivascular infiltrate of lymphocytes and macrophages is seen in the dermis along with papillary edema and a dilation of capillaries. In acute eruptive guttate lesions, mast cell degranulation is a constant feature.

There is mild epidermal acanthosis without parakeratosis and the keratinocytes have a swollen appearance. Macrophages (detected by CD68 staining) and lymphocytes appear in the epidermis focally and some spongiosis of the epidermis is seen at these sites. Per a large body of evidence, neutrophils are not yet detected in this early phase.

Active lesion

A fully developed guttate lesion or the marginal zone of an enlarging psoriatic plaque is designated as an "active lesion". The histopathologic findings in an active lesion are diagnostic for psoriasis.

In the dermis, the capillaries are increased in number and length and they have a tortuous appearance. Marked edema is seen, especially at the tops of the papillae. There is a mixed perivascular infiltrate of lymphocytes, macrophages and neutrophils, and lymphocytes and neutrophils have migrated into the epidermis.

The epidermis is acanthotic with focal accumulations of neutrophils and lymphocytes. At these sites, the epidermis is variably spongiotic. Above these foci, the granular layer is absent and the stratum corneum

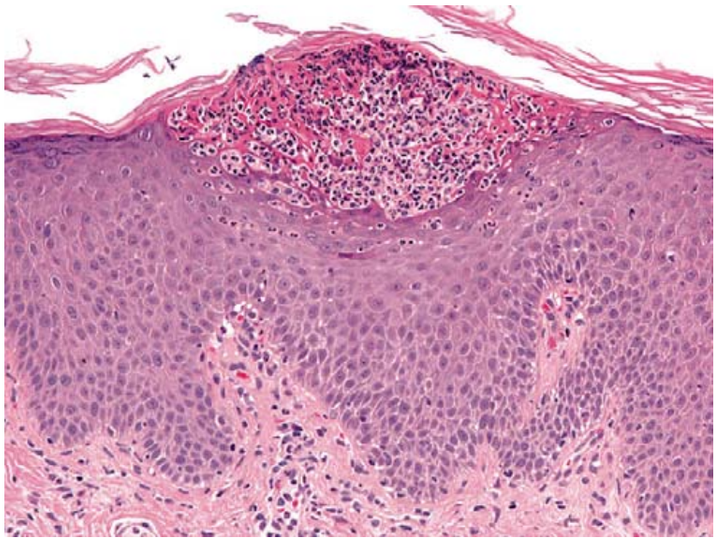

Fig. 8.19 Spongiform pustule of Kogoj. A collection of neutrophils is seen within the upper stratum spinosum. *Courtesy, Lorenzo Cerroni, MD.*

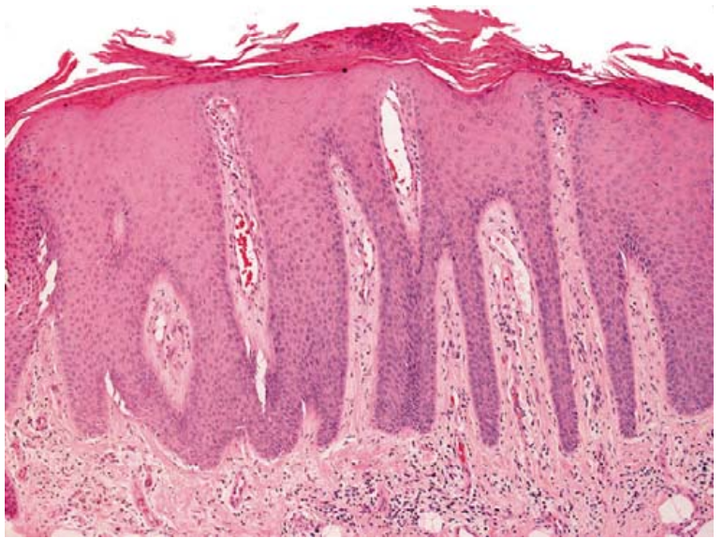

Fig. 8.20 Stable plaque psoriasis. Hyperplasia of the epidermis with "squared-off" rete ridges, elongation of the dermal papillae, dilated superficial blood vessels, hypogranulosis, and parakeratosis plus remnants of neutrophils (microabscess of Munro). *Courtesy, Lorenzo Cerroni, MD.*

still contains flattened nuclei (parakeratosis). The accumulation of neutrophils within a spongiotic pustule is referred to as a "spongiform pustule of Kogoj" (Fig. 8.19) and the accumulation of neutrophil remnants in the stratum corneum, surrounded by parakeratosis, as a "microabscess of Munro". These two findings are pathognomonic for psoriasis and AGEP.

Stable lesion

In the dermis, the capillaries are elongated and tortuous, extending upward into elongated club-shaped dermal papillae; only a small suprapapillary plate of epidermal cells covers the tip of these dermal papillae. This micromorphology explains the "Auspitz" phenomenon (see earlier). A modest perivascular infiltrate is seen that consists primarily of lymphocytes and macrophages. The psoriatic lesion is heterogeneous, consisting of active areas (hot spots) and chronic nonspecific areas (cold spots).

The hyperproliferation of the epidermis now has reached its characteristic pattern (Fig. 8.20). The rete ridges are elongated and have a squared-off appearance. Some rete ridges coalesce at the base. The horny layer has parakeratotic foci with an absence of the stratum granulosum. In some lesions, micropustules of Kogoj and microabscesses of Munro may be seen.

Pustular Psoriasis

In pustular psoriasis, accumulation of neutrophils is the predominant feature. Numerous neutrophils accumulate between eosinophilic strands of keratinocytes. In the stratum corneum, large accumulations of neutrophils are observed, surrounded by parakeratosis. As a result, exaggerated spongiform pustules of Kogoj and microabscesses of Munro, the histologic hallmarks of "active" psoriasis, are seen in pustular psoriasis (see Fig. 8.19).

Other

In reactive arthritis (formerly Reiter's disease), the cutaneous histologic findings are similar to those described for psoriasis. Spongiform pustules can be seen in palmoplantar lesions. In Sneddon–Wilkinson disease, subcorneal pustules are the characteristic finding.

TREATMENT

Care of the psoriatic patient needs to focus not only on the skin, but also on the comorbidities that exist or might develop. An appropriate treatment regimen for a particular patient is selected from available topical and systemic medications as well as phototherapies. In clinical trials, single agents are usually evaluated, but in practice most patients receive combination therapy. To date, no treatment has been shown to cure this disease, so counseling of the patient and family members regarding its natural history and management strategies is recommended.

A brief description of each available treatment for psoriasis is provided below. The management of psoriasis requires individualization of therapy, with consideration of the extent of the disease and its effects on the patient's quality of life as well as the likely benefits and potential side effects of specific treatments. The chronic nature of psoriasis necessitates adoption of a long-term approach with avoidance of dramatic short-term "fixes" that may actually produce a more reactive disease state (see below).

Topical Treatments

Guidelines of care for the treatment of psoriasis with topical therapies have been developed by the American Academy of Dermatology[64].

Vitamin D_3 analogues

In the early 1990s, vitamin D_3 analogues became commercially available as a topical treatment for psoriasis. When the epidermis is hyperproliferative, vitamin D_3 inhibits epidermal proliferation, and it induces normal differentiation by enhancing cornified envelope formation and activating transglutaminase; it also inhibits several neutrophil functions. Due to their therapeutic efficacy and limited toxicity, calcipotriene (calcipotriol) and other vitamin D_3 analogues have become a first-line therapy for psoriasis[65].

For a detailed description of topical vitamin D_3 analogues, the reader is referred to Chapter 129. Table 8.4 summarizes the major characteristics of commercially available vitamin D_3 analogues and Table 8.5 describes their indications and contraindications. Calcipotriene monotherapy has been shown to result in a ~60% reduction of PASI after 8 weeks of treatment, but practical use in psoriasis patients usually involves combination therapy with topical corticosteroids. When calcipotriene and betamethasone dipropionate are combined, an ~70% reduction in PASI has been observed (ointment formulation)[66] as has clearing/minimal disease in ~70% of patients with scalp psoriasis (gel formulation)[67].

Corticosteroids

Since their introduction in the early 1950s, topical corticosteroids have become a mainstay in the treatment of psoriasis. They are often first-line therapy in mild to moderate psoriasis and in sites such as the flexures and genitalia, where other topical treatments can induce

VITAMIN D ANALOGUES			
	Calcipotriene/Calcipotriol	**Calcitriol**	**Tacalcitol**
Concentration	50 mcg/g	3 mcg/g	2 mcg/g; 4 mcg/g
Formulations	Ointment, cream, lotion, solution	Ointment	Ointment, lotion
Frequency	BID	BID	BID; daily
Maximum weekly amount*	100 g	200 g	70 g; 70 g†
Chemical structure	26,27-cyclo-vitamin D_3 22,23 double bond Transposition of the 25-OH to the 24 position	1α,25-dihydroxy vitamin D (active natural vitamin D_3)	1α,24-dihydroxy vitamin D_3
Inactivating enzymes	22,23-reductase; 24-oxido-reductase	24-hydroxylase	25-hydroxylase

*To avoid hypercalcemia.
†Maximum weekly amount for 8 weeks of treatment.

Table 8.4 Vitamin D analogues. BID, twice daily. Calcipotriene is the US Adopted Name (USAN) and calcipotriol is the International Nonproprietary Name (INN).

INDICATIONS AND CONTRAINDICATIONS FOR VITAMIN D_3 ANALOGUES
INDICATIONS
• Mild to moderate psoriasis: first-line treatment as monotherapy or in combination • Severe psoriasis: combination treatment
CONTRAINDICATIONS
• Involvement requiring more than the maximally recommended quantity, e.g. 100 g/week of calcipotriene/calcipotriol (see Table 8.4) • Abnormality in bone or calcium metabolism* • Renal insufficiency • Allergy to the vitamin D_3 analogue or constituents of the preparation • Pregnancy or lactation
*For example, sarcoidosis, bone metastases.

Table 8.5 Indications and contraindications for vitamin D_3 analogues. If used in conjunction with phototherapy, vitamin D_3 preparations need to be applied after UV irradiation or at least several hours prior, because they may reduce UV penetration into the skin.

INDICATIONS AND CONTRAINDICATIONS FOR TOPICAL CORTICOSTEROIDS
INDICATIONS
• Mild to moderate psoriasis: first-line treatment as monotherapy or in combination • Severe psoriasis: often in combination with a vitamin D_3 analogue, a topical retinoid, anthralin or tar • Monotherapy for flexural and facial psoriasis (usually mild strength) • Recalcitrant plaques often require occlusion (plastic, hydrocolloid)
CONTRAINDICATIONS
• Bacterial, viral and mycotic infections • Atrophy of the skin • Allergic contact dermatitis due to corticosteroids or constituents of the formulation • Pregnancy or lactation*
*Can consider limited use of mild- to moderate-strength corticosteroids.

Table 8.6 Indications and contraindications for topical corticosteroids. Maximal quantities: 50 g/week of a superpotent corticosteroid; 100 g/week of a potent corticosteroid.

irritation. Chapter 125 provides detailed information on mechanisms of action, pharmacologic aspects and side effects of corticosteroid therapy.

Corticosteroids are manufactured in various vehicles, from ointments, creams and lotions to gels, foams and shampoos[68]; ointment formulations, in general, have the highest efficacy (see Ch. 125). Over the years, the anti-inflammatory properties of topical corticosteroids have been improved by increasing their lipophilicity by masking the hydrophilic 16- or 17-hydroxy groups or by introducing acetonides, valerates or propionates. Application under plastic or hydrocolloid occlusion also significantly enhances the penetration. Once-daily application has been shown to be as effective as twice-daily application, and long-term remissions may be maintained by applications on alternate days[69]. The indications and contraindications regarding the use of topical corticosteroids in the treatment of psoriasis are summarized in Table 8.6.

At least 80% of patients treated with high-potency topical corticosteroids experience clearance. In fact, the maximum improvement is usually achieved within 2 weeks. With maintenance therapy consisting of 12 weeks of intermittent applications of betamethasone dipropionate ointment (restricted to weekends), 74% of patients remained in remission, compared with 21% of the patients receiving a placebo ointment[69]. Unfortunately, no efficacy data are available on prolonged treatment for more than 3 months. As tachyphylaxis and/or rebound can occur fairly rapidly, i.e. within a few days to weeks, intermittent treatment schedules (e.g. once every 2 or 3 days or on weekends) are advised for more prolonged treatment courses. Combination topical therapy can take advantage of the rapid effect of topical corticosteroids as well as the prolonged benefits of topical vitamin D_3 analogues, anthralin or retinoids.

INDICATIONS AND CONTRAINDICATIONS FOR ANTHRALIN
INDICATIONS
• Mild to moderate or severe* psoriasis: second-line treatment as monotherapy or in combination
CONTRAINDICATIONS
• Unstable plaque psoriasis in a phase of progression • Pustular psoriasis • Erythrodermic psoriasis
*Severe psoriasis usually treated in day-care center or inpatient setting.

Table 8.7 Indications and contraindications for anthralin. To minimize irritation, concentration and application time are gradually escalated; neither should be increased more often than once every 3 days, given that peak erythema is seen 3–4 days following application.

Anthralin

Anthralin (dithranol, cignolin, 1,8-dihydroxy-9-anthrone) has been available since 1916; it is still used as a treatment for psoriasis, although it was more commonly utilized in the past (see Ch. 129). It has marked epidermal effects, including an anti-hyperproliferative effect. Anthralin also inhibits mitogen-induced T-lymphocyte proliferation and neutrophil chemotaxis. In Europe and other regions outside the US, it is used most often in day-care centers and the inpatient setting[70].

The indications and contraindications for the use of anthralin in the treatment of psoriasis are summarized in Table 8.7. In the authors'

INDICATIONS AND CONTRAINDICATIONS FOR TOPICAL TAZAROTENE
INDICATIONS
• Mild to moderate psoriasis: second-line treatment as monotherapy or in combination
CONTRAINDICATIONS
• Unstable plaque psoriasis in a phase of progression • Erythrodermic psoriasis • Allergic contact dermatitis to tazarotene or constituents of the formulation • Pregnancy or lactation

Table 8.8 Indications and contraindications for topical tazarotene.

experience, total clearing of psoriasis in at least 80% of patients occurs with 3–5 weeks of treatment in an inpatient setting or day-care center. If the anthralin treatment is performed at home, the efficacy is substantially less.

Topical retinoids

All-*trans*-retinoic acid and 13-*cis*-retinoic acid, although effective in the treatment of acne, are not effective for psoriasis. However, topical tazarotene, an acetylene retinoid that selectively binds retinoic acid receptor (RAR)-β and RAR-γ, can be used to treat psoriasis. Tazarotene has been shown to decrease epidermal proliferation and it inhibits psoriasis-associated differentiation (e.g. transglutaminase expression and keratin 16 expression). It is manufactured in cream and gel formulations and is applied once or twice daily.

Indications and contraindications of tazarotene for the treatment of psoriasis are summarized in Table 8.8. In view of its modest efficacy as monotherapy, it is usually prescribed as a second-line therapy. Irritation of the skin can limit the use of tazarotene; pruritus, burning, irritation and erythema have been observed in up to 23%, 18%, 9% and 8% of patients, respectively. For this reason, combination therapy with topical corticosteroids is useful. The maximal area that can be treated with tazarotene is 10–20% of the body surface, and safety data are available for up to 1 year of treatment.

The efficacy and safety of tazarotene as monotherapy have been investigated in several studies. After 6 weeks of treatment, at least 50% improvement (compared with baseline) was noted by 45% of the patients using twice-daily 0.05% tazarotene gel, compared to 13% of the patients using a placebo gel[71].

Additional topical treatments

If the psoriatic plaques have thick scale, this needs to be reduced to enhance penetration of topical medications and ultraviolet (UV) light. Options include salt-water baths, topical salicylic acid and oral retinoids. Salicylic acid 5–10% has a substantial keratolytic effect and, in the case of scalp psoriasis, salicylic acid can be formulated in an oil or ointment base. Application of salicylic acid to localized areas can be done daily, but, for more widespread areas, two to three times per week is preferred. This is to prevent systemic intoxication (see Ch. 129), especially in infants or those with reduced renal function.

Coal tar has a range of anti-inflammatory actions and is effective as an antipruritic. Although crude coal tar (see Ch. 129) may be the most effective tar available for the treatment of psoriasis, a distilled product, liquor carbonis detergens (LCD), is also used. In view of its mutagenic potential, tar is contraindicated in pregnant or lactating women. However, guidelines on the use of tar products may differ between countries.

Calcineurin inhibitors are used to treat facial and flexural psoriasis. Randomized, placebo-controlled studies have demonstrated efficacy and safety for this indication[71,72].

Photo(chemo)therapy and Systemic Medications

Evidence-based guidelines for the treatment of psoriasis with photo (chemo) therapy and classic systemic medications have been developed by various dermatologic organizations[73–74a], and the tables in this chapter are adapted from these recommendations.

INDICATIONS AND CONTRAINDICATIONS FOR PHOTO(CHEMO)THERAPY
INDICATIONS
• Moderate to severe psoriasis: first-line treatment as monotherapy or in combination
CONTRAINDICATIONS (ABSOLUTE OR RELATIVE)
• Genetic disorders characterized by increased photosensitivity or an increased risk of skin cancer (UVB and PUVA)* • Skin type I (UVB and PUVA)† • Photosensitive dermatoses (UVB and PUVA)† • Unavoidable phototoxic systemic or topical medications (UVB and PUVA)† • Vitiligo (UVB and PUVA)† • Previous history of arsenic exposure, ionizing irradiation or excessive photo(chemo)therapy (UVB and PUVA) • High cumulative number of PUVA treatments, i.e. >150–200 individual treatments (PUVA)* • Treatment with cyclosporine (UVB and PUVA)* • Immunosuppressive medication (UVB and PUVA) • Previous history of skin cancer (UVB and PUVA; * if current skin cancer, especially SCC or melanoma) • Atypical melanocytic nevi (UVB and PUVA) • Seizure disorder (risk of fall/injury; UVB and PUVA) • Poor compliance (UVB and PUVA) • Men and women in reproductive years without contraception (PUVA) • Pregnancy or lactation (PUVA)* • Impaired liver function or hepatotoxic medication (PUVA) • Cataracts (PUVA)
*Absolute contraindication †Need to adjust the dose and monitor closely.

Table 8.9 Indications and contraindications for photo(chemo)therapy. PUVA, psoralen + ultraviolet A; SCC, squamous cell carcinoma; UVB, ultraviolet B.

Photo(chemo)therapy

Photo(chemo)therapy represents a mainstay in the treatment of moderate to severe psoriasis. Phototherapy with broadband or narrowband ultraviolet B (UVB) and photochemotherapy with ultraviolet A (UVA) following ingestion of or topical application of a psoralen are classic treatment options. In the late 1970s, monotherapy with erythematogenic doses of broadband UVB proved to be an effective approach; later on, narrowband UVB (311–313 nm) was developed and is the optimal irradiation currently available. The 308 nm excimer laser can be used to treat a limited number of plaques in patients with localized disease.

Photo(chemo)therapy is discussed in detail in Chapter 134, and its indications and contraindications in psoriasis are summarized in Table 8.9.

Methotrexate

In 1971, amethopterin (methotrexate; MTX) was approved by the US Food and Drug Administration (FDA) as a treatment for psoriasis. The effect of MTX on lymphocytes, circulating and cutaneous, is a likely explanation for its antipsoriatic activity.

MTX is a first-line systemic therapy for psoriasis as it is highly efficacious for severe disease and all clinical variants of psoriasis. In chronic plaque psoriasis, initial improvement is observed between 1 and 7 weeks and maximum improvement can be expected after 8–12 weeks of treatment. MTX is administered weekly, usually as a single oral dose (but occasionally intramuscularly or subcutaneously) and less often every 12 hours for three doses per week; the maximum weekly dosage is usually 25 mg. Potential side effects restrict its use to moderate to severe disease resistant to topical treatments and photo(chemo)therapy and/or situations in which these are contraindicated. The use of folic acid supplementation during MTX administration is controversial due to the concern that folic acid may decrease the efficacy of MTX. Guidelines for MTX usage vary depending on the country and disease state.

Chapter 130 describes the mechanism of action, pharmacology and safety issues of MTX. Tables 8.10 and 8.11 summarize indications and contraindications as well as side effects of MTX.

INDICATIONS AND CONTRAINDICATIONS FOR METHOTREXATE
INDICATIONS
• Severe psoriasis – Chronic plaque psoriasis (>10–15% BSA or interference with employment or social functioning) – Pustular psoriasis (generalized or localized) – Erythrodermic psoriasis – Psoriatic arthritis (moderate to severe) – Severe nail psoriasis • Psoriasis not responding to topical treatments, photo(chemo)therapy and/or systemic retinoids
CONTRAINDICATIONS (ABSOLUTE OR RELATIVE)
• Impaired kidney function (creatinine clearance <60 ml/min)† • Severe anemia, leukopenia and/or thrombocytopenia* • Significant liver function abnormalities, hepatitis (active and/or recent), severe fibrosis, cirrhosis, excessive alcohol intake* • Concomitant hepatotoxic medications • Concomitant medications that increase MTX levels, e.g. trimethoprim–sulfamethoxazole* • Significantly reduced pulmonary function* • Pregnancy or lactation* • Currently planning to have children (male and female patients)‡ • Immunodeficiency syndromes • Severe infections* • Active infections • Peptic ulcer (active)* • Gastritis • Concomitant radiation therapy • Pleural effusion or ascites† • Hypersensitivity to MTX* • Unreliable patient*
*Absolute contraindication. †Requires significant reduction in dosage. ‡Because of possible mutagenic risk and teratogenicity, discontinue MTX 3 months prior to attempts to conceive; continue contraception during these 3 months.

Table 8.10 Indications and contraindications for methotrexate (MTX). BSA, body surface area.

SIDE EFFECTS OF METHOTREXATE		
Subjective symptoms	**Hematopoietic†**	**Mucocutaneous**
*Most frequent**,† Nausea Vomiting Abdominal pain Fatigue Headache *Occasional* Loss of libido Impaired memory	Leukopenia‡ Thrombocytopenia Anemia	Oral erosions† Alopecia Delayed phototoxicity Tenderness and/or necrosis of plaques due to overdose Rarely, urticaria, angioedema, vasculitis
Hepatic	**Pulmonary**	**Fetal development**
Hepatitis† Cirrhosis§	Interstitial pneumonitis (acute-onset cough, dyspnea)	Birth defects: cranial and absence of digits
Carcinogenesis‖		**Idiosyncratic reaction**
In rheumatoid arthritis patients, increased risk of lymphoma Risk factor for cutaneous SCC in PUVA-treated patients		Early in course with full dosage Severe pneumonia Gastrointestinal hemorrhage Pancytopenia
Opportunistic infections		**Additional/unusual**
Pneumocystis jiroveci pneumonia Cryptococcosis Disseminated histoplasmosis Disseminated herpes zoster		Osteopathy (pain, osteoporosis, compression fractures) Ventricular cardiac arrhythmias Lowered seizure threshold
*Same day or 2–3 days following MTX administration; may respond to folic acid, dose reduction or antiemetic drug. †May be reduced by folic acid (1–5 mg/day except on day MTX administered). ‡Up to 11% of patients on oral regimens. §Up to 25% of patients receiving long-term therapy. ‖No increased risk of malignancy was observed in large series of psoriasis patients[75,76].		

Table 8.11 Side effects of methotrexate (MTX). PUVA, psoralens + ultraviolet A; SCC, squamous cell carcinoma.

Cyclosporine

Cyclosporine is a cyclic undecapeptide that was isolated from the fungus *Tolypocladium inflatum* by Gams in 1970. Based on large controlled studies, cyclosporine is a highly effective treatment for the severe manifestations of psoriasis. As a calcineurin inhibitor, it prevents T-lymphocyte activation from being translated into the release of effector cytokines such as IL-2. Cyclosporine can be used safely, provided that the guidelines are strictly followed. In view of its nephrotoxic effects (e.g. reduced glomerular filtration rate, tubular atrophy), cyclosporine should be given for several-month courses (i.e. maximally 1 year, although duration is still a matter of debate) and alternated with other therapies. An alternative is an intermittent schedule using multiple short courses of a few weeks' duration.

The indications and contraindications of cyclosporine are summarized in Table 8.12. Cyclosporine can produce dramatic rapid improvement of psoriasis, but this must be balanced by the requirement for an appropriate replacement therapy, given the need to ultimately stop cyclosporine therapy.

Guidelines for pre-cyclosporine screening and long-term evaluation during cyclosporine administration are outlined in Chapter 130. An important aspect is assessment of renal function, and creatinine clearance should be estimated using the Cockrof-Gault formula:

$$\frac{(140 - \text{age in years}) \times (\text{weight in kg})}{\text{serum creatinine (mg/100 ml)} \times 72}$$

In elderly patients and patients with a history of hypertension, the risks of renal impairment and hypertension are increased.

Cyclosporine treatment in psoriatic patients has been reported to increase the frequency of SCCs, especially in those previously treated with PUVA. The underlying mechanism is not mutagenesis but a decrease in immunosurveillance of the skin. In particular, psoriatic patients who have been exposed to high cumulative doses of UV radiation are at risk for development of cutaneous malignancies. Although cyclosporine is an immunosuppressive agent, no increase in serious infections has been reported in patients treated with cyclosporine alone. Other side effects include: gastrointestinal discomfort, hypertrichosis, paresthesias, gingival hyperplasia, headache, vertigo, muscle cramps and tremor[77]. Metabolic side effects include hyperkalemia, hypomagnesemia, hyperuricemia (due to decreased clearance of uric acid), and elevated cholesterol and triglycerides.

The efficacy of cyclosporine for psoriasis has been clearly shown in multiple controlled and uncontrolled studies. For example, the European multicenter dose-finding studies have shown that doses of 1.25, 2.5–3 and 5 mg/kg/day of cyclosporine resulted in reductions of the PASI of 35%, 57% and 86%, respectively. An improvement in the PASI of 75% was achieved in 24%, 52% and 88% of the patients. Of note, because the criteria for these studies were different from those used for FDA approval of targeted immune modulators ("biologic" therapies), the PASI numbers are not directly comparable. Efficacy of cyclosporine has been demonstrated in all variants of psoriasis (including nail psoriasis), but less so for psoriatic arthropathy[78]. The improvement is observed within a few weeks. In general, a reduction of the PASI of 60–70% can be reached within 4 weeks of treatment[79]. During long-term treatment, there are no signs of tachyphylaxis.

Systemic retinoids

By the 1930s, vitamin A deficiency was known to cause hyperkeratosis of the skin (phrynoderma). Thirty years later, modifications of the vitamin A molecule resulted in the discovery of the so-called first generation of retinoids, including all-*trans*-retinoic acid (tretinoin) and 13-*cis*-retinoic acid (isotretinoin). Further research resulted in the

INDICATIONS AND CONTRAINDICATIONS FOR CYCLOSPORINE
INDICATIONS
• Severe psoriasis • Conventional therapies (topical treatments, photo(chemo)therapy, acitretin, methotrexate) ineffective or inappropriate
CONTRAINDICATIONS
• Impaired renal function* • Uncontrolled hypertension* • Primary or secondary immunodeficiency • Concomitant immunosuppressive therapy • Past or present* malignancy • Concomitant drugs affecting cyclosporine pharmacokinetics† • History of arsenic exposure • History of excessive photo(chemo)therapy (>200 PUVA treatments), radiotherapy* • Concurrent photo(chemo)therapy* • Severe infections* • Active infections • Pregnancy or lactation • Concurrent methotrexate administration • Significant hepatic disease • Hyperuricemia, hyperkalemia • Hypersensitivity to cyclosporine* • Vaccination with live vaccines • Seizure disorder • Poorly controlled diabetes mellitus • Severe chronic organ dysfunction • Alcohol and drug abuse • Malabsorption • Unreliable patient*
*Absolute contraindications. †Requires dose adjustment and careful monitoring; cyclosporine is inactivated by the cytochrome P450 3A isoform.

Table 8.12 Indications and contraindications for cyclosporine. The recommended starting dose is 3 mg/kg/day in two divided doses; at 2-week intervals, dosage can be increased to a maximum of 5 mg/kg/day. PUVA, psoralens + ultraviolet A.

INDICATIONS AND CONTRAINDICATIONS FOR ACITRETIN
INDICATIONS
• Severe psoriasis that cannot be managed by topical treatments or photo(chemo)therapy • Monotherapy is indicated for erythrodermic or pustular psoriasis • Combination therapy is indicated for chronic plaque psoriasis
CONTRAINDICATIONS
• Severe liver dysfunction* • Severe kidney dysfunction (elimination reduced)* • Pregnancy or lactation* • Women of childbearing potential who cannot guarantee adequate contraception during and up to 3 years following discontinuation of acitretin* • Hyperlipidemia, especially hypertriglyceridemia, that cannot be controlled* • Concomitant medications that interfere with retinoid bioavailability or whose metabolism is altered† • Concomitant hepatotoxic drugs, e.g. methotrexate‡ • Poorly controlled diabetes mellitus • History of pancreatitis • Excessive alcohol intake* • Use of contact lenses • Unreliable patient* • Atherosclerosis
*Absolute contraindications. †Requires dose adjustment and careful monitoring, e.g. phenytoin competes for plasma protein binding. ‡Reserved for treatment-resistant patients.

Table 8.13 Indications and contraindications for acitretin. Blood donation is contraindicated in patients receiving acitretin.

PRE-ACITRETIN SCREENING
• History to exclude contraindications • Complete blood count • Liver function tests (AST, ALT, γGT, alkaline phosphatase, bilirubin) • Serum triglycerides, cholesterol, HDL • Glucose • Serum creatinine • Pregnancy test • Consider spinal X-ray (often initially performed during the first 3 months of therapy if long-term treatment is anticipated)

Table 8.14 Pre-acitretin screening. ALT, alanine aminotransferase; AST, aspartate aminotransferase; γGT, gamma glutamyl transpeptidase; HDL, high-density lipoproteins

EVALUATION DURING ACITRETIN TREATMENT
• Monitor mucocutaneous side effects • Serum cholesterol/triglycerides/HDL and liver enzymes (every month for the first 2 months then every 2–3 months) • Serum creatinine (elderly patients or patients with mild to moderate renal dysfunction) • Monitor for development of hyperostosis by history (twice yearly) and by X-ray of spine (e.g. once yearly in patients receiving long-term treatment) • Pregnancy test (throughout treatment)

Table 8.15 Evaluation during acitretin treatment. HDL, high-density lipoproteins.

development of the second generation of retinoids, the mono-aromatic retinoids, etretinate and its free metabolite acitretin[79]. Acitretin is an effective treatment for psoriasis as well as disorders of keratinization and cutaneous lupus. A major problem with systemic retinoids is their teratogenicity, making contraception mandatory in women of childbearing age during treatment and (depending on the drug half-life) for a period of 2 months to 3 years after discontinuing therapy. Chapter 126 provides a description of the modes of action, pharmacologic aspects and side effects of these medications.

The indications and contraindications for the use of acitretin in the treatment of psoriasis are summarized in Table 8.13, and the recommended initial and ongoing evaluations are outlined in Tables 8.14 and 8.15, respectively.

In patients with chronic plaque psoriasis, 0.5 mg/kg/day is the initial dosage, which can be increased depending upon the clinical response and side effects. For erythrodermic psoriasis, the initial dosage is 0.25 mg/kg/day, and in pustular psoriasis, the dose should be maximized, i.e. doses up to 1 mg/kg/day. In patients with chronic plaque psoriasis, mild cheilitis (just perceived by the patient) is the goal, whereas in patients with pustular psoriasis, a dose that causes a clinically apparent but tolerable cheilitis is an endpoint.

The efficacy of acitretin monotherapy in chronic plaque psoriasis is limited, with approximately 70% of patients achieving a moderate or better response. In one study, 23% of patients treated with 50 mg of acitretin daily for 8 weeks achieved ≥75% improvement in their PASI[79]. Combination treatment with photo(chemo)-therapy and/or vitamin D_3 analogues results in a substantial improvement in clinical response. Maximal therapeutic efficacy is reached after 2–3 months. Acitretin has been shown to be an effective maintenance therapy. As monotherapy, acitretin is highly effective in erythrodermic and pustular psoriasis. Its efficacy in nail psoriasis and psoriatic arthritis is only modest.

Targeted immune modulators ("biologic" therapies)

Beginning in 2000, biologic therapies were introduced for the treatment of psoriatic arthritis and moderate to severe psoriasis. Their two major targets are T cells and cytokines, including TNF-α and IL-12/23. Table 8.16 lists the biologic agents that are currently commercially available. Although briakinumab (a human monoclonal antibody against the p40 subunit of IL-12 and IL-23) was found to have greater efficacy than methotrexate in patients with moderate to severe plaque psoriasis[79a],

COMMERCIALLY AVAILABLE BIOLOGIC AGENTS USED FOR THE TREATMENT OF PSORIASIS			
Biologic agent	**Target**	**Molecule**	**Approved***
Alefacept**	CD2	Human fusion protein	FDA
Etanercept	TNF-α†	Human fusion protein	FDA + EMA
Infliximab	TNF-α‡	Chimeric antibody	FDA + EMA
Adalimumab	TNF-α‡	Human antibody	FDA + EMA (psoriatic arthritis)
Ustekinumab	p40 subunit of IL-12/23	Human antibody	FDA + EMA

*By registration authorities for the treatment of psoriasis.
**Production of alefacept in the US was discontinued in 2011.
†Soluble form.
‡Soluble form and transmembrane TNF receptor.

Table 8.16 Commercially available biologic agents used for the treatment of psoriasis. EMA, European Medicines Agency; FDA, Food and Drug Administration; IL, interleukin; TNF, tumor necrosis factor

applications for approval by the FDA and European Medicines Agency (EMEA) were withdrawn due to safety concerns (including a possible increased risk of cardiovascular adverse events). Chapter 128 provides a description of the modes of action, dosages, side effects and monitoring recommendations for biologic agents. Of note, guidelines, including European S3-Guidelines, have been developed for the treatment of psoriasis patients with TNF-α inhibitors (adalimumab, etanercept and infliximab) and ustekinumab[74,80–82].

Biologic therapies are indicated for patients with moderate to severe psoriasis and/or psoriatic arthritis. Several guidelines restrict their use to "high-need patients" in whom all other existing treatments are contraindicated or have led to insufficient improvement, whereas some investigators have voiced the opinion that biologic therapies should be an option for patients who have failed to respond adequately to one classic systemic treatment[83]; the latter recommendation has to be balanced against the high cost of these medications. Both indications and contraindications for currently commercially available therapies are outlined in Table 8.17.

The relative efficacies of the various biologic agents are reviewed in Chapter 128. With regard to the percentage of patients achieving PASI 75 improvement, there is significant overlap between the efficacies of biologic agents (as assessed after 3 months of therapy) and those of photo(chemo)therapy and classic systemic medications such as MTX and cyclosporine, although only a few studies directly comparing biologic agents with classic systemic medications are available. In general, TNF-α inhibitors and anti-IL-12/23 antibodies have substantial efficacy and enable long-term control of psoriasis[84].

Other systemic therapies

Additional systemic therapies have been reported as beneficial in the management of psoriasis (Table 8.18). In general, they are used less often than the medications previously described in this chapter, and there are regional differences in their use.

INDICATIONS AND CONTRAINDICATIONS FOR COMMERCIALLY AVAILABLE TARGETED IMMUNE MODULATORS ("BIOLOGIC" AGENTS)
INDICATIONS
General indications
• Patients with moderate to severe psoriasis, eligible for a systemic treatment
• Patients with psoriatic arthritis, particularly those who have failed other disease-modifying antirheumatic drugs (DMARDs)
Restricted indication
• Patients with moderate to severe psoriasis who are not candidates for topical treatments, photo(chemo)therapy or classic systemic treatments because of insufficient efficacy or contraindications
CONTRAINDICATIONS
(The exact contraindications vary by agent [see Ch. 128]; some listed below are relative, while others are absolute [*])
• Guttate, pustular, or erythrodermic psoriasis
• Significant viral, bacterial or fungal infections*
• Increased risk for developing sepsis*
• Active tuberculosis*
• Immunosuppressed patient
• Past history of hepatitis B
• Pregnancy (TNF-α inhibitors, alefacept† and ustekinumab are category B)
• Breastfeeding
• Malignancy within the past 5 years (does not include adequately treated single cutaneous squamous or basal cell carcinoma)
• Excessive chronic sun exposure or photo(chemo)therapy
• Allergic reaction to the biologic agent*
• Selective for alefacept†: CD4 counts <250 cells/mcl*; HIV infection*
• Selective for TNF-α inhibitors: ANA+ (especially if high titer) or autoimmune connective tissue disease, blood dyscrasias, congestive heart failure (NYHA grade III or IV) or demyelinization disorders (the latter also in first-degree relatives)*
• Selective for ustekinumab: BCG vaccination within the past 12 months (mode of action expected to increase susceptibility to mycobacterial infections)
†Production of alefacept in the US was discontinued in 2011.

Table 8.17 Indications and contraindications for commercially available targeted immune modulators ("biologic" agents). Administration of live vaccines (see Table 128.9) is contraindicated in patients receiving biologic agents for psoriasis. BCG, Bacillus Calmette-Guérin; NYHA, New York Heart Association.

ADDITIONAL SYSTEMIC THERAPIES FOR PSORIASIS	
Medication	**Side effects**
Fumarates[85]	Renal impairment, flushing, gastrointestinal disturbances, headache, fatigue
Mycophenolate mofetil[86]	See Ch. 130
Oral calcitriol[87] (0.5–3 mcg/day)	Hypercalcemia, hypercalciuria
6-thioguanine (40–160 mg/day)	Myelosuppression, hepatotoxicity, gastrointestinal disturbances
Hydroxyurea	See Ch. 130

Table 8.18 Additional systemic therapies for psoriasis.

Therapeutic Management

General considerations

Before considering a specific treatment in an individual psoriatic patient, it is important to exclude triggering factors. Aggravating factors such as focal infections, medications and psychological stress have been described above. Furthermore, it is also crucial to assess the various aspects of disease severity, in particular[88]:

- The area of involvement and the degree of erythema, induration and desquamation of the cutaneous lesions. For research purposes, these aspects can be summarized as the PASI (see Table 8.2).
- The impairment of quality of life. The visibility of the lesions and symptoms such as pruritus are relevant factors, and psycho-emotional stress and the response of family and friends to the psoriasis should also be considered. Impact of psoriasis on quality of life can be measured by questionnaires (e.g. Dermatology Life Quality Index [DLQI], Skindex29).
- The responsiveness to previous treatments. Individual patients report a wide variation with respect to their clinical response to various treatments. For example, some patients, even those with widespread disease, may experience excellent improvement with a mild topical therapy, whereas patients with localized disease may prove recalcitrant to even high-dose systemic treatments.

Relative and absolute contraindications to the various treatment options have to be recognized, especially in the case of photo(chemo)

therapy and systemic medications. Because psoriasis is a chronic condition, patients have to cope not only with their disease, but also with their treatments, for prolonged periods of time. For example, individual circumstances may restrict the time available for intensive daily treatments. Lastly, some patients cannot accept a few coin-sized lesions in visible sites, while for others this is less of a problem. Therefore, treatment selection is a multivariable decision-making process and not a simple stepwise therapeutic ladder.

Management with topical agents

It is important before instituting topical therapy that the patient understands that due to the Koebner phenomenon, trauma (e.g. from scratching or debriding lesions) can negate therapeutic interventions. Although it may seem obvious, patients should also be told that topical agents do not prevent new lesions from appearing at additional sites. For patients with mild to moderate involvement, topical treatments are the first choice. Patients with more widespread involvement may also be treated with a topical agent; however, a high degree of compliance is required and this can be difficult to achieve.

Evidence for the efficacy of various topical treatments was reassessed in a recent meta-analysis[89]. From this analysis, it was concluded that only very potent topical corticosteroids tended to be more effective than monotherapy with the vitamin D_3 analogue calcipotriene. In ambulatory patients, calcipotriene was more effective than anthralin, coal tar, the other vitamin D_3 analogues (tacalcitol and calcitriol) and the retinoid tazarotene[89]. The efficacy of coal tar and anthralin are difficult to assess, as the success of these topicals is highly dependent on the treatment setting. A day-care or inpatient setting is optimal, as it allows the patient to more easily cope with the side effects of staining, stinging and irritation.

Combination treatment is advised for the vast majority of patients, thereby increasing efficacy and reducing side effects. For example, a fixed combination of calcipotriene and betamethasone dipropionate applied once daily proved to be superior to twice-daily calcipotriene or twice-daily betamethasone dipropionate monotherapy[90].

Based on the above discussion, the authors recommend the following: start with calcipotriene cream or ointment twice daily for a period of 8 weeks (except for sensitive skin areas and the scalp). If this regimen is not successful or if rapid clearing is required, the combination of calcipotriene and a potent topical corticosteroid is applied for 4 weeks. In the case of an insufficient response or irritation, another vitamin D_3 analogue or tazarotene may be tried as monotherapy or in combination with a topical corticosteroid. In addition, a topical corticosteroid under hydrocolloid occlusion can be used for a few recalcitrant plaques.

A trial of tar or anthralin may be tried, especially in patients with longstanding disease and incomplete responses or fast relapses. These treatments often require a day-care or inpatient facility as their use in the ambulatory setting is disappointing. With regard to maintenance therapy, some patients prefer only intermittent clearing courses with no intervening therapy, while other patients want continuous treatment. Daily use of a topical vitamin D_3 analogue (below the maximum allowed weekly dosage) provides a safe long-term form of maintenance therapy. If the therapeutic response is insufficient, intermittent application of a topical corticosteroid (once or twice weekly) is helpful.

Psoriasis in sensitive areas and on the scalp should be managed differently. Psoriasis of the face and flexures can be treated with a calcineurin inhibitor, resulting in a rapid improvement[91]. In these sensitive areas, tacalcitol and calcitriol tend to result in less irritation as compared to calcipotriene; the use of ultrapotent corticosteroids should be avoided. For scalp psoriasis, removal of scale with a formulation containing 10–20% salicylic acid is the initial step. Intermittent use of potent and ultrapotent topical corticosteroids (or corticosteroid-containing shampoos) in combination with calcipotriene lotion is our preferred regimen for scalp psoriasis.

If topical therapies do not provide adequate improvement, treatment with photo(chemo)therapy or a systemic agent is indicated.

Management with photo(chemo)therapy and classic systemic medications

For patients with moderate to severe involvement, topical therapies may be ineffective or impractical. On a chronic basis, patients with widespread disease often cannot manage their psoriasis with topical treatments and become frustrated and non-compliant. Evidence for the efficacy of photo(chemo)therapy and classic systemic treatments has been reassessed in a meta-analysis[92]. PUVA had the highest percentage of patients with clearance (70%), followed by UVB (67.9%) and cyclosporine (64%). The investigators also developed practice guidelines and recommended the following sequence of therapies: UVB, PUVA, methotrexate, acitretin and then cyclosporine[92].

However, in the selection of a systemic treatment for an individual patient, the existence of relative and absolute contraindications has to be considered. Therefore, it is not always practical to define a therapeutic ladder. For example, photo(chemo)therapy would not be chosen for patients with a history of excessive exposure to UV radiation, but these same patients could be excellent candidates for retinoid therapy (considering its anticancer effects). Methotrexate is contraindicated in patients with excessive alcohol intake or active hepatitis, while cyclosporine is contraindicated in those with renal insufficiency or hypertension.

Despite these considerations, some general recommendations can be offered. If the response to topical therapies is unsatisfactory, the first treatment to be considered is typically narrowband UVB phototherapy. If a few months of UVB therapy do not result in adequate improvement or a sufficient long-term remission is not achieved, one of the other treatment modalities previously discussed should be selected (with a consideration of individualized risk factors). An important issue is whether a maintenance treatment is needed or desired. Cyclosporine should not be used as a maintenance treatment, whereas methotrexate, acitretin and fumarates can be employed for long-term control of psoriasis; fumarates are only available in some European countries. However, long-term use of these systemic treatments is restricted by their cumulative toxicity potential. The concept of rotational therapies is valuable but complex. If neither photo(chemo)therapy nor classic systemic medications provide adequate improvement, treatment with a biologic agent is indicated.

Targeted immune modulators ("biologic" therapies)

Several biologic therapies are currently available worldwide for the treatment of psoriasis and/or psoriatic arthritis: adalimumab, etanercept, infliximab and ustekinumab. Despite the availability of effective topical and classic systemic medications as well as phototherapy, safety concerns, lack of efficacy, and inconveniences are important restrictions, in particular for long-term use[93]. For such patients, biologic agents can provide benefit for their skin disease as well as psoriatic arthritis (especially TNF-α inhibitors), with prevention of permanent destructive changes. Reduction of inflammation resulting from active psoriasis may also impact the development of metabolic syndrome and the cardiovascular diseases.

The side-effect profiles are very different from those of photo(chemo)-therapy and classic systemic medications, with no indication to date of cumulative toxicity. As a 1-year course of biologic therapy costs approximately $20 000 (~€15 000), national health authorities and managed care insurance companies have adopted a restrictive approach. Therefore, in many countries, biologic agents are available exclusively for those patients with severe psoriasis who cannot be treated adequately with the classic treatments. However, a possible impact on comorbidities (see above) may influence decisions in the future.

How to combine treatments

Enhanced clinical response and a possible reduction in side effects are the goals of combination therapy. However, for safety reasons, some combinations are contraindicated.

Beneficial combinations

The combination of calcipotriene with superpotent topical corticosteroids has been shown to be more effective than either treatment as monotherapy, whereas the combination of calcipotriene plus medium-strength corticosteroids did not have a substantial additive effect compared with each as monotherapy. However, the irritation caused by calcipotriene can be reduced by the addition of medium-strength corticosteroids. Improved efficacy has also been observed with the combination of calcipotriene–cyclosporine and calcipotriene–acitretin, compared with each as monotherapy[94,95]. For example, with low-dose cyclosporine (2 mg/kg/day) plus topical calcipotriene, marked

improvement or clearing was seen in 90% of patients. In a dose-escalating study of acitretin, the combination of acitretin and calcipotriene was more effective and permitted a lower dose of both acitretin and calcipotriene as compared to each as monotherapy. The combination of calcipotriene and PUVA is characterized by a marked reduction in the cumulative dose of UVA required and enhanced efficacy, compared with the respective monotherapies. However, evidence for a beneficial effect of the combination of UVB and calcipotriene is less convincing. Combining etanercept (25 mg subcutaneously once weekly) and acitretin has been shown to be as effective as etanercept 25 mg subcutaneously twice weekly[96].

Topical corticosteroids are frequently combined with other antipsoriatic treatments. Although increases in the duration of subsequent remission periods have been noted, controlled studies are required to substantiate these claims. The combination of phototherapy with application of anthralin or tar is a time-honored therapy. However, if phototherapy is optimized by using near-erythematogenic doses, the additive benefit of anthralin or tar above that of phototherapy alone has not been substantiated, although remission periods following the combination of anthralin and optimized phototherapy are prolonged.

Contraindicated combinations and combinations with restricted use

The combination of acitretin and cyclosporine carries the risk of accumulation of cyclosporine, because cyclosporine is inactivated by the cytochrome P450 system, which is inhibited by acitretin. An increased occurrence of SCCs has been observed in patients treated with the combination of cyclosporine and PUVA, either simultaneously or sequentially (PUVA followed by cyclosporine)[97]. As a result, the combination of cyclosporine and photo(chemo)therapy is contraindicated. Although a combination of methotrexate and PUVA has been reported to be safe[98], additional long-term studies are needed.

The combination of coal tar with PUVA is contraindicated as it may induce significant phototoxic responses. The combination of cyclosporine and methotrexate has been viewed as high risk because both are immunosuppressants. However, this combination has been used with success by rheumatologists, and, in recalcitrant psoriasis, the combination has proved to be very effective without major side effects. The combination of methotrexate and acitretin has been used in those patients in whom all treatments have failed[99]. Although this combination can be very effective, severe hepatotoxicity has been reported; therefore, careful monitoring is mandatory.

How to manage childhood psoriasis

In a recent review, the efficacy and safety of treatment modalities in children were described[100]. Only two randomized controlled trials were identified; one examined topical calcipotriene and the other etanercept. The authors recommended topical calcipotriene as first-line therapy for mild to moderate juvenile psoriasis, combined with mild- to moderate-strength topical corticosteroids (if necessary). For treatment-resistant flexural and/or facial psoriasis, tacrolimus 0.1% ointment can be added to the treatment regimen. Anthralin is then considered if this treatment regimen is not effective or the psoriasis is moderate to severe. The next step is to recommend treatment with narrowband UVB, especially in adolescents, with attention to the number of treatments. Although controversial, the use of antibiotics can be considered in patients with guttate psoriasis where there is suspicion of a streptococcal infection. Of the systemic medications, methotrexate is regarded as the treatment of choice, with retinoids considered in pustular and erythrodermic psoriasis. Cyclosporine is occasionally utilized for exceptional cases, and etanercept should be considered as a third-line drug for therapy-resistant psoriasis[100].

Future Treatments

Future treatments for psoriasis will include additional targeted biologic therapies, which focus on one key aspect of psoriasis pathogenesis. For example, antagonism of IL-17, IL-20 or IL-22 may prove to be as beneficial as targeting IL-12/IL-23. A number of small molecules are also under investigation, including oral inhibitors of kinases such as Janus kinase (JAK), protein kinase C or p38 kinase, as well as inhibitors of STAT-3 (see Pathogenesis) such as topical STA-21/ochromycinone.

SMALL PLAQUE PARAPSORIASIS AND LARGE PLAQUE PARAPSORIASIS

Synonyms: ■ Parapsoriasis en plaques (small and large plaque parapsoriasis) ■ Digitate dermatosis (small plaque parapsoriasis) ■ Xanthoerythrodermia perstans (small plaque parapsoriasis) ■ Chronic superficial dermatitis (small plaque parapsoriasis) ■ Retiform parapsoriasis (variant of large plaque parapsoriasis) ■ Parakeratosis variegata (variant of large plaque parapsoriasis) ■ Patch stage of mycosis fungoides (some cases of large plaque parapsoriasis)

Key features

- Chronic, asymptomatic, erythematous scaly patches characterize both major forms of parapsoriasis
- In small plaque parapsoriasis, the lesions are generally less than 5 cm in diameter or digitate
- In large plaque parapsoriasis, the lesions are generally greater than 5 cm in diameter
- Histologically, superficial perivascular, interface or lichenoid lymphocytic infiltrates are seen
- There is a predominance of $CD4^+$ T cells in the infiltrate
- A dominant T-cell clonality is demonstrable in many cases

Introduction

Small plaque parapsoriasis and large plaque parapsoriasis are idiopathic, chronic dermatoses classified within the parapsoriasis group of skin diseases. Related disorders include acute and chronic variants of pityriasis lichenoides and lymphomatoid papulosis (see Ch. 120). This group is significant for the tendency of its disorders to coexist or overlap with one another and for its association with lymphomas[1].

History

Small plaque parapsoriasis and large plaque parapsoriasis were included in the parapsoriasis group as defined by Brocq in 1902[2] and refined subsequently by several authors whose work was summarized by Lambert and Everett in 1981[1]. In the mid to late twentieth century, it became widely accepted that small plaque parapsoriasis and large plaque parapsoriasis were distinct entities[3], and that large plaque parapsoriasis and its variants were closely related to the patch stage of mycosis fungoides[4].

Epidemiology

Small plaque parapsoriasis and large plaque parapsoriasis are more common in middle-aged and elderly individuals, but they may also occur in children. They peak during the fifth decade of life and occur in all racial groups and geographic regions. There is a male predominance that is greater for small plaque parapsoriasis, where it approximates 3 : 1.

Pathogenesis

The etiologies of small plaque and large plaque parapsoriasis are unknown. Both disorders are characterized by superficial cutaneous lymphoid infiltrates composed primarily of $CD4^+$ T cells[5,6]. Dominant T-cell clonality has been demonstrated in many cases of large plaque parapsoriasis and in fewer cases of small plaque parapsoriasis[6–8]. The difference may be an artifact of a lower T-cell density in small plaque parapsoriasis. Alternatively, it may be that some cases are truly polyclonal and represent a distinct biologic subset of disease. Of note, more recent studies have failed to confirm earlier reports of human herpesvirus-8 within lesions of large plaque parapsoriasis[9].

It is now well established that at least some cases of large plaque parapsoriasis and its variants are manifestations of the patch stage of mycosis fungoides (see Ch. 120). This helps to explain the progression of large plaque parapsoriasis to more overt forms of lymphoma at a rate of 10% to 35% over a period of 6–10 years[1,10,11]. The concept of "clonal dermatitis" has been put forth to describe T-cell lymphoproliferative disorders that may constitute an intermediate or transitional step between chronic dermatitis and overt cutaneous T-cell lymphomas[7] (Fig. 9.1). A mycosis fungoides pyramid can be envisioned, in which a relatively small number of cases evolve from a much larger pool of chronic dermatitis through the intermediary of clonal dermatitis. Small retrospective studies suggest that clonal dermatitis has an approximately 20% risk of progression to cutaneous T-cell lymphoma over 5 years[12].

Although both small plaque and large plaque parapsoriasis can be viewed as forms of clonal dermatitis, large plaque parapsoriasis appears to have a significantly greater risk of progression to overt lymphoma. However, in contrast to those cases of parapsoriasis in which dominant clonality precedes the evolution of histologically overt mycosis fungoides, it appears that some cases of early mycosis fungoides may still contain oligoclonal T cells from which a dominant clone has yet to evolve[13]. Other examples of clonal dermatitis can be found among cases of primary idiopathic erythroderma and chronic dermatitis.

Clinical Features

Despite inclusion of the word "plaque" in their terminology, both small plaque and large plaque parapsoriasis are diseases composed of patches rather than plaques. In both entities, skin lesions are chronic and generally asymptomatic or mildly pruritic. They may wax and wane early in their clinical course, but they typically become persistent and can slowly progress to become more extensive. Some cases regress fully, either spontaneously or after therapy, but this may require a period of several years. Lesions can be widespread on the trunk and extremities or more limited in their distribution. In the latter instance, they often favor more sun-protected sites.

Small plaque parapsoriasis typically presents as round–oval patches that are generally less than 5 cm in diameter (Fig. 9.2A). They are variably erythematous (but often less intense than psoriasis) and

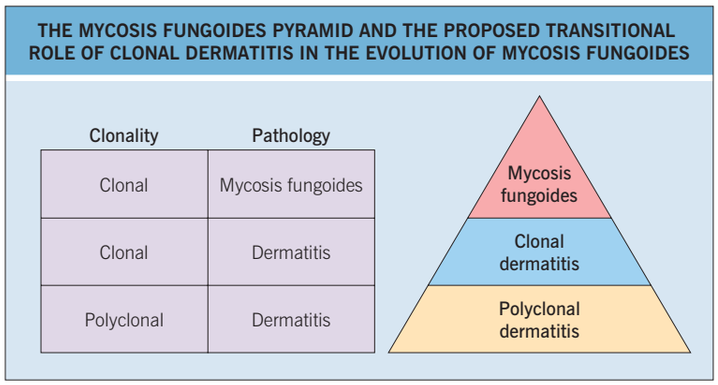

Fig. 9.1 The mycosis fungoides pyramid and the proposed transitional role of clonal dermatitis in the evolution of mycosis fungoides.

Fig. 9.2 Small plaque parapsoriasis. A Small (<5 cm), erythematous, slightly scaly patches. **B** Digitate dermatosis with elongated finger-like lesions on the flank.

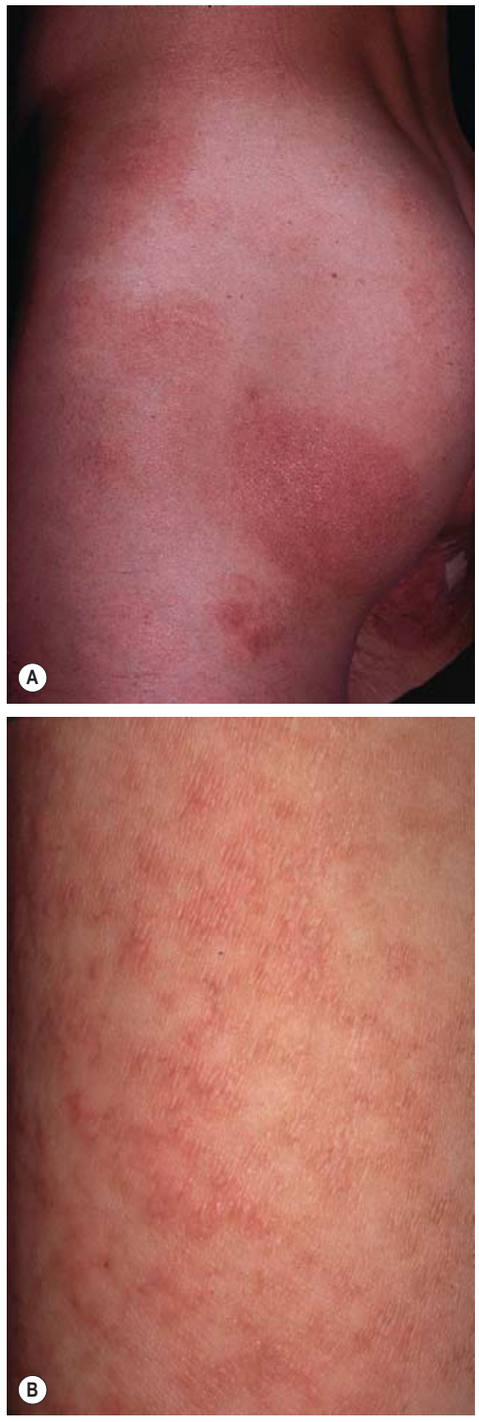

Fig. 9.3 Large plaque parapsoriasis. A Large, variably erythematous patches in the bathing trunk region is a classic presentation. **B** Retiform parapsoriasis with atrophic, red–brown papules in a net-like pattern.

covered with a fine scale. Those with a yellow hue have been termed "xanthoerythrodermia perstans"[1]. An important variant of small plaque parapsoriasis is "digitate dermatosis", which presents as elongated, finger-like patches symmetrically distributed on the flanks[3] (Fig. 9.2B). These lesions are an exception to the 5-cm rule in that they may measure 10 cm or more along their long axis. The reported risk of progression to mycosis fungoides varies from zero[14] to low[11].

Large plaque parapsoriasis presents as variably erythematous, round or irregularly shaped scaly patches that are larger than 5 cm (Fig. 9.3A). They may or may not exhibit the clinical triad of atrophy, telangiectasia and hyper/hypopigmentation that warrants the descriptive designation "poikiloderma vasculare atrophicans". Rather than being a specific entity, poikiloderma can be seen in several disorders, including certain autoimmune connective tissue diseases (e.g. dermatomyositis) and genodermatoses, in addition to large plaque parapsoriasis and mycosis fungoides. "Retiform parapsoriasis", also known as "parapsoriasis variegata", "parakeratosis variegata" or "parapsoriasis lichenoides", is a variant of large plaque parapsoriasis in which there are widespread, ill-defined patches in a net-like or zebra-stripe pattern[1] (Fig. 9.3B). Long-term follow-up has shown that virtually all of these rare retiform cases progress to overt mycosis fungoides. As noted earlier, patients with other forms of large plaque parapsoriasis develop clinically unequivocal lymphomas (mostly mycosis fungoides) at a rate of 10% to 35% per decade.

PRINCIPAL DIFFERENTIAL DIAGNOSIS OF SMALL PLAQUE PARAPSORIASIS AND LARGE PLAQUE PARAPSORIASIS	
Small plaque parapsoriasis	**Large plaque parapsoriasis**
Pityriasis rosea	Mycosis fungoides
Drug eruption, in particular pityriasis rosea-like	Drug eruption, in particular mycosis fungoides-like
Pityriasis lichenoides chronica	Psoriasis
Psoriasis, including guttate	Poikilodermatous autoimmune connective tissue disease (e.g. dermatomyositis)
Mycosis fungoides	Poikilodermatous genodermatoses (see Table 63.8)
Secondary syphilis	Chronic radiodermatitis
Nummular dermatitis

THERAPEUTIC LADDER FOR SMALL PLAQUE PARAPSORIASIS AND LARGE PLAQUE PARAPSORIASIS
Topical corticosteroids (2)
Topical calcineurin inhibitors (3)
Topical coal tar products (3)
Sunlight (2)
Ultraviolet B (UVB) phototherapy – broadband or narrowband (2)
PUVA (psoralen plus UVA) phototherapy (2)
Topical bexarotene (2)
Topical imiquimod (3)
Topical mechlorethamine (nitrogen mustard)* (2)
Topical carmustine (BCNU)* (2)
Antihistamines† (3)
*More appropriate for patch-stage mycosis fungoides.
†If there is pruritus.

Table 9.2 Therapeutic ladder for small plaque parapsoriasis and large plaque parapsoriasis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

Pathology

Patches of small plaque parapsoriasis exhibit a mild, nonspecific spongiotic dermatitis and parakeratosis. Lesions of large plaque parapsoriasis may have similar histologic findings or an interface lymphocytic infiltrate with a variable degree of lichenoid features. Some cases of large plaque parapsoriasis are indistinguishable from the patch stage of mycosis fungoides and may contain atypical lymphoid cells (see Ch. 120). These cases should be diagnosed as mycosis fungoides; however, their proportion is difficult to establish because experts disagree on the minimum criteria required to histopathologically diagnose mycosis fungoides. The term "large plaque parapsoriasis" should be used for those remaining patients who fail to show the histopathologic features of mycosis fungoides. Poikilodermatous variants of large plaque parapsoriasis demonstrate the histopathologic triad of epidermal atrophy, telangiectasias and pigment incontinence.

Differential Diagnosis

The diagnosis of small plaque parapsoriasis and large plaque parapsoriasis is based on a correlation between clinical and histopathologic findings; other tests are of minimal value. They are distinguished from each other by their clinical features. The principal differential diagnostic considerations are listed in Table 9.1. Both small plaque and large plaque parapsoriasis are differentiated from mycosis fungoides based on failing to meet the minimum histopathologic criteria for that disorder. While some patients with lesions clinically consistent with large plaque parapsoriasis will meet microscopic criteria for mycosis fungoides, others will not. Therefore, large plaque parapsoriasis remains a useful designation for such patients. Poikilodermatous variants of large plaque parapsoriasis must be distinguished from poikilodermatous patches associated with dermatomyositis, lupus erythematosus, Rothmund–Thomson syndrome, Kindler syndrome, dyskeratosis congenita and chronic radiodermatitis.

Small plaque parapsoriasis is distinguished from pityriasis rosea by the presence of a herald patch and resolution of the latter disorder within a few months. Psoriasis and secondary syphilis are excluded on the basis of clinicopathologic and serologic features. Patients with pityriasis lichenoides, acute and chronic, generally have lesions that are smaller and more widely distributed than do patients with small plaque parapsoriasis. Drug eruptions resembling pityriasis rosea or mycosis fungoides must also be excluded by clinicopathologic correlation.

Treatment

All therapeutic approaches are based primarily on uncontrolled case series, case reports or anecdotal evidence (Table 9.2). In this author's opinion (GSW), patients with small plaque parapsoriasis should be reassured that their risk of developing mycosis fungoides is practically not an issue. Ackerman and co-workers disagree and have expressed the opinion that even small plaque parapsoriasis is mycosis fungoides. Patients with small plaque parapsoriasis may be followed without treatment if they prefer. Standard therapy includes topical corticosteroids, topical coal tar products, and various forms of phototherapy. The role of newer topical agents, such as bexarotene, calcineurin inhibitors and imiquimod, remains to be established. There is some concern that calcineurin inhibitors might be implicated if lymphoma were to develop. Until this issue is clarified, due caution should be exercised in the treatment of small plaque parapsoriasis.

Patients with large plaque parapsoriasis should be treated regardless of whether one believes that their lesions already represent or may evolve into mycosis fungoides. Initial therapy may be similar to that described for small plaque parapsoriasis. Those cases of large plaque parapsoriasis that meet the histopathologic criteria for mycosis fungoides can be treated with all the agents commonly used in the early stages of that disease. In addition to topical corticosteroids and phototherapy, these include topical mechlorethamine (nitrogen mustard), topical carmustine (BCNU), topical bexarotene, and subcutaneous interferon-α. Experimental therapies include interleukin-12[15] and the excimer laser (308 nm).

PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA AND PITYRIASIS LICHENOIDES CHRONICA

Synonyms: ■ Mucha–Habermann disease (PLEVA) ■ Guttate parapsoriasis (PLC)

Key features

- Pityriasis lichenoides et varioliformis acuta (PLEVA) and pityriasis lichenoides chronica (PLC) are two ends of a disease spectrum
- Both entities are characterized by recurrent crops of spontaneously regressing erythematous papules
- Lesions of PLEVA are crusted, vesicular or pustular, whereas in PLC they are scaly
- Individual patients may show intermediate or mixed lesions
- Histologically, an interface dermatitis with necrotic keratinocytes is seen
- The infiltrate is predominantly T cells that are often monoclonal

Introduction

The acute and chronic forms of pityriasis lichenoides exist on a disease spectrum with variable presentations that can pose diagnostic and therapeutic challenges[16,17]. These are papular, clonal T-cell disorders that may rarely be associated with mycosis fungoides.

Fig. 9.4 Clinical spectrum of pityriasis lichenoides. In the acute form (PLEVA), widespread erythematous papules and papulovesicles are admixed with crusted lesions (**A**, **B**); sometimes, there can be an ulcerative component (**C**). Individuals with the chronic form (PLC) develop multiple red–brown papules, some of which have scale (**D**). A number of patients will have lesions characteristic of both PLEVA and PLC, i.e. an overlap (**E**). *A, Courtesy, Julie V Schaffer, MD. B, Courtsey, Thomas Schwarz, MD. E, Courtesy, Kalman Watsky, MD.*

History

Pityriasis lichenoides, including its two main variants PLEVA and PLC, was first described between 1894 and 1925. Mucha and Habermann are credited with recognition of PLEVA[18,19], while Juliusberg is associated with PLC[20]. Pityriasis lichenoides was included in Brocq's 1902 treatise on a group of chronic, idiopathic dermatoses that he termed "parapsoriasis".

Epidemiology

Pityriasis lichenoides is more prevalent in the pediatric population, but it affects patients in all age groups, races and geographic regions. There is a male predominance.

Pathogenesis

The etiology of pityriasis lichenoides is unknown. It has been postulated to be a response to foreign antigens such as infectious agents and drugs. A few reports describe its association with specific infections (e.g. HIV), medications (e.g. estrogen–progesterone, TNF-α inhibitors [infliximab, adalimumab]), and radiocontrast dye. Of note, increased numbers of maternally derived keratinocytes have been detected within the epidermis of young male patients with pityriasis lichenoides (as compared to normal skin) and perhaps they triggered a host-(child) versus-graft (mother) disease.

Both PLEVA and PLC contain lesional T-cell infiltrates, with a general predominance of $CD8^+$ cells in PLEVA and $CD4^+$ cells in PLC[21,22]. Both types of lesions can exhibit dominant T-cell clonality, although it is more easily demonstrated in PLEVA, where the infiltrate is denser[23–25]. This clonality indicates that pityriasis lichenoides is a T-cell lymphoproliferative disorder like lymphomatoid papulosis and some forms of T-cell cutaneous lymphoid hyperplasia. Indeed, some patients with lymphomatoid papulosis develop individual lesions indistinguishable from pityriasis lichenoides, suggesting that these two conditions may be related[21,26]. The concept of pityriasis lichenoides as a T-cell lymphoproliferative disorder may help to explain its occasional association with other lymphoproliferative disorders such as cutaneous T-cell lymphoma, Hodgkin disease and other lymphomas[27–30].

Clinical Features

Pityriasis lichenoides presents as recurrent crops of spontaneously regressing erythematous to purpuric papules. The acute form (PLEVA) and the chronic form (PLC) exist on a disease continuum. Many patients have intermediate or mixed manifestations, either serially or concurrently. In patients with PLEVA, individual lesions develop crusts, ulcers, vesicles or pustules, which may heal with varioliform scars if dermal damage is extensive (Fig. 9.4). Lesions are usually asymptomatic and typically resolve within weeks. Disease manifestations are confined to the skin, except rarely, when acute lesions are associated with malaise, fever, lymphadenopathy, arthritis and/or bacteremia. The term "febrile ulceronecrotic Mucha–Habermann disease (FUMHD)" has been used to refer to such severe variants in which mucosal, gastrointestinal and pulmonary involvement can be observed[31]. Transition from PLEVA to this febrile variant has been associated with increased serum levels of TNF-α.

In PLC, the papules are erythematous to red–brown and scaly (see Fig. 9.4). They pursue a more indolent course, regressing over weeks to months. When these lesions subside, there may be residual

hypopigmented macules; the latter are more obvious in darkly pigmented individuals and may be the presenting complaint (see Ch. 66). Pityriasis lichenoides can resolve spontaneously after weeks to months or it may pursue a chronic relapsing course, sometimes interspersed with long periods of remission. Some studies have suggested that the distribution of skin lesions is more important than their acute or chronic nature in predicting outcome[32]. Patients with a diffuse distribution of lesions had the shortest average course of disease (11 months), while those with a peripheral distribution had the longest average clinical course (33 months). The central distribution variant was intermediate.

Pathology

Pityriasis lichenoides exhibits a superficial perivascular interface dermatitis in all cases (Fig. 9.5). Those lesions at the acute end of the spectrum contain a denser infiltrate that may be top-heavy and wedge-shaped. Lymphocytes predominate in the infiltrate, although neutrophils may be admixed. The epidermis shows focal parakeratosis and evidence of damage ranging from edema to extensive epidermal necrosis in well-developed lesions. Extravasation of erythrocytes is usually present. The usual histopathologic alterations accompany the presence of crusts, vesicles, pustules and ulcers. Lymphocytic vasculitis is sometimes described, but most cases lack true fibrinoid necrosis of blood vessels (and use of this histologic term can be confusing to clinicians). All of these changes are blunted in the more chronic skin lesions, where the principal microscopic features include parakeratosis and a milder interface lymphocytic infiltrate accompanied by focal keratinocyte necrosis and mild erythrocyte extravasation. Lymphoid atypia is not a standard feature of pityriasis lichenoides. Although some pathologists allow occasional atypical lymphocytes, others regard this as a sign of lymphomatoid papulosis.

Differential Diagnosis

The diagnosis of pityriasis lichenoides is made by the correlation of clinical features with lesional histopathology. The principal differential diagnostic considerations for pityriasis lichenoides are listed in Table 9.3. For PLEVA, the main clinical and histopathologic differential diagnostic considerations include lymphomatoid papulosis, drug eruptions, arthropod reactions, cutaneous small vessel vasculitis, and varicella. For PLC, the principal differential diagnosis includes small plaque parapsoriasis, guttate psoriasis, lichen planus (exanthematous), pityriasis rosea, secondary syphilis, lymphomatoid papulosis, drug eruptions and papular dermatitis. All of these differential diagnostic possibilities can usually be excluded on the basis of key historical, clinical, pathologic and laboratory findings. More than one biopsy specimen may be required to achieve clinicopathologic correlation.

Aside from immunopathology, most other laboratory tests offer little diagnostic value. A preponderance of $CD8^+$ T cells supports the diagnosis of PLEVA because there are few skin disorders that share this feature. Conversely, the demonstration of $CD30^+$ cells generally excludes pityriasis lichenoides and helps establish the alternative diagnosis of lymphomatoid papulosis. Direct fluorescent antibody (DFA) and serologic testing as well as immunohistochemical staining are helpful in excluding varicella and syphilis.

Treatment

All treatments for pityriasis lichenoides are based primarily on uncontrolled case series, case reports or anecdotes (Table 9.4). If a drug association is suspected, trial discontinuance of the suspected agent is warranted. First-line therapy includes topical corticosteroids, topical coal tar preparations, tetracycline, erythromycin and various types of phototherapy. Oral tetracycline and erythromycin are used for their anti-inflammatory rather than antibiotic effects, with erythromycin favored in children. A several-month course is often required, followed by a gradual taper. Other antibiotics may be employed if there is secondary infection, usually with *Staphylococcus aureus*.

More fulminant cases may require low-dose weekly methotrexate. Those rare cases associated with fever and arthritis may benefit from systemic corticosteroids, IVIg or cyclosporine, once infection has been excluded. Antihistamines may be helpful in those instances where significant pruritus is present. There are recent reports of the efficacy of etanercept, oral bromelain (bromelin) and photodynamic therapy.

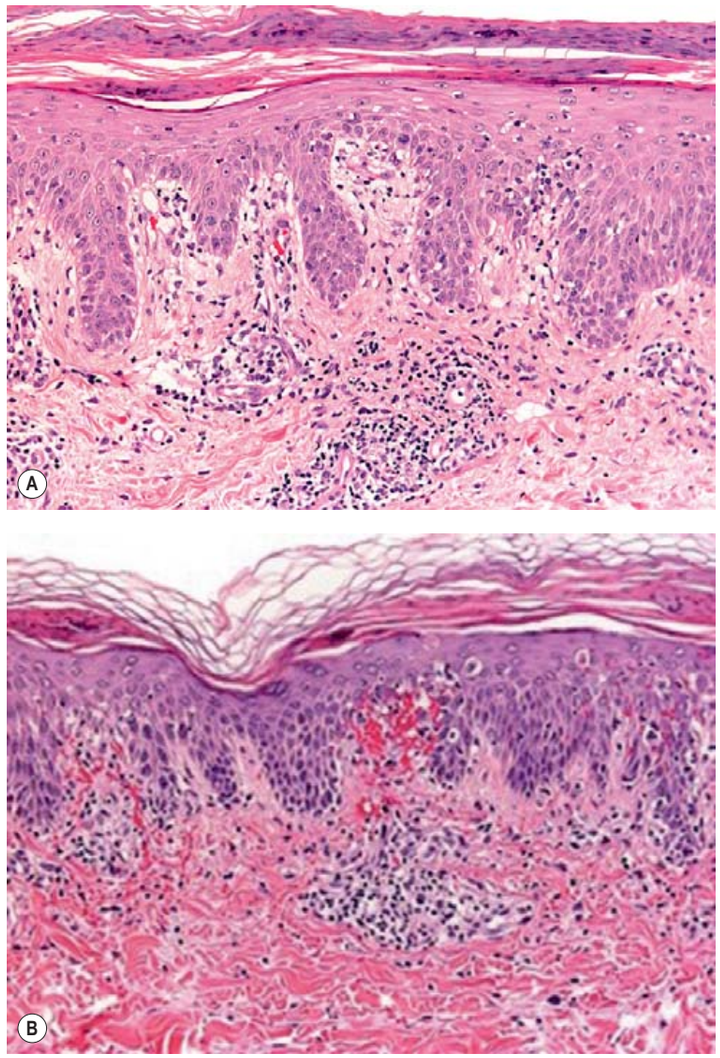

Fig. 9.5 Pityriasis lichenoides – histopathologic features. A In the chronic form (PLC), parakeratosis may be more prominent, but the epidermal destruction is less intense. **B** In the acute form (PLEVA), extravasated erythrocytes as well as apoptotic keratinocytes are seen. Uniformly present is a superficial perivascular interface dermatitis. As with the clinical presentations, there is a continuous histologic spectrum. *Courtesy, Lorenzo Cerroni, MD.*

PRINCIPAL DIFFERENTIAL DIAGNOSIS OF PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA (PLEVA) AND PITYRIASIS LICHENOIDES CHRONICA (PLC)

PLEVA	PLC
Lymphomatoid papulosis	Small plaque parapsoriasis
Cutaneous small vessel vasculitis	Guttate psoriasis
Lichenoid drug eruption	Lichen planus
Arthropod reactions	Pityriasis rosea
Varicella, enteroviral exanthems	Secondary syphilis
Folliculitis	Lymphomatoid papulosis
Erythema multiforme	Papular dermatitis
Dermatitis herpetiformis	Lichenoid drug eruption

PITYRIASIS RUBRA PILARIS

Synonyms: ■ Lichen ruber pilaris ■ Devergie's disease ■ Lichen ruber acuminatus

Key features

- Follicular papules with an erythematous base are a characteristic finding, including on the proximal dorsal fingers
- There is a coalescence of orange–red plaques, but with obvious islands of sparing
- An orange–red waxy keratoderma of the palms and soles is often seen
- Of the five types described, the classic adult form is the most common
- The classic types (adult and juvenile) typically resolve within 3–5 years
- Histologically, there is alternating vertical and horizontal ortho- and parakeratosis

History

Pityriasis rubra pilaris (PRP) was first described in 1835 by Claudius Tarral as a variant of psoriasis. Devergie[33] later recognized it as a separate entity in 1857 and named it "pityriasis pilaris". In 1889, Besnier[34] recommended the name "pityriasis rubra pilaris", and it has persisted.

Epidemiology

Although PRP shows no gender bias, affecting both men and women equally, ethnic variations may exist. For example, in one report, the incidence in Great Britain was 1 in 5000 new patient visits whereas in India it was 1 in 50 000 visits. The incidence has either two or three peaks. The first is during the first and second decades and the second is during the sixth decade. The third peak, if real, results from splitting the first and second decades into two separate peaks.

Nearly all cases are acquired, with occasional reports of a familial form. An autosomal dominant inheritance pattern with variable penetrance is more commonly observed, although an autosomal recessive pattern has also been described. Of patients with PRP, from zero to 6.5% are reported to have a family history of PRP[35]. Except for the non-classic forms of PRP, it appears to be a self-limited disease process, resolving within 3 to 5 years in almost all cases.

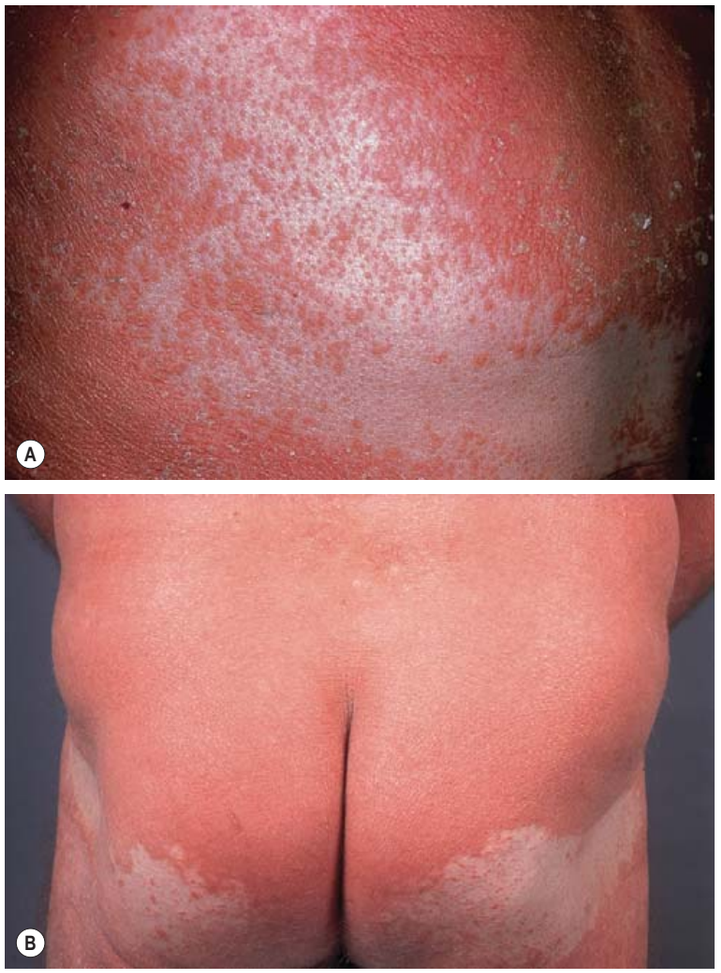

Fig. 9.6 Pityriasis rubra pilaris. A Follicular papules and confluent orange–red scaly plaques with islands of sparing. **B** The islands of sparing may be sharply demarcated; note the salmon color of the plaques.

Pathogenesis

No clear etiology has been established. Early on, a vitamin A deficiency was proposed, but this has not been substantiated. The therapeutic success of systemic retinoids suggests a possible dysfunction in keratinization or vitamin A metabolism. Infections, UV exposure and various minor traumas to the skin have been reported to precede the onset of PRP, implicating a physical trigger or superantigen in selected patients.

The possibility of an autoimmune pathogenesis has also been raised. For example, there are reports of PRP in association with myasthenia gravis, celiac disease, myositis, inflammatory arthritis, and hypothyroidism. An abnormal immunologic response to particular antigens has been suggested by the coexistence of PRP with HIV infection[36], as well as with internal malignancies (e.g. renal cell, bronchogenic and hepatocellular carcinomas)[37].

Clinical Features

The multiple, well-described clinical features of classic PRP are helpful in making the diagnosis. Follicular hyperkeratosis on an erythematous base is a key finding. This results in rough papules, especially on the dorsal aspect of the proximal fingers, which have been described as reminiscent of a nutmeg grater. These papules are also seen on the trunk and extremities, and they can coalesce to form large salmon-colored to orange–red plaques with distinctive "islands of sparing" (Fig. 9.6). The plaques can then progress to an erythrodermic appearance

Fig. 9.7 Pityriasis rubra pilaris. In areas of diffuse erythroderma, follicular hyperkeratosis (knee) may not be as apparent as within relatively spared islands (compare to Fig. 9.6A).

Fig. 9.8 Pityriasis rubra pilaris. The orange–red color of the skin, including that of the palms, aids in the clinical diagnosis; note the waxy appearance of the keratoderma. *Courtesy, Irwin Braverman, MD.*

with varying degrees of exfoliation (Fig. 9.7). The palms and soles are commonly involved with a distinctive orange–red waxy keratoderma (Fig. 9.8). Erythema with a fine diffuse scale is often seen on the scalp[35,38]. Scalp disease that mimics seborrheic dermatitis is a common initial clinical manifestation of adult PRP, and rapid progression to erythroderma can occur over several weeks.

Nail involvement is characterized by a thickened plate with a yellow–brown discoloration and subungual debris. The mucous membranes are rarely involved, but they may show features similar to oral lichen planus.

The most common form of PRP (see below) usually begins in the head and neck region and then progressively advances caudally. Pruritus and burning have been reported in 20% of patients with PRP. Although less common than in atopic dermatitis or Darier disease, Kaposi's varicelliform eruption can occur in patients with PRP. As with other forms of erythroderma (see Ch. 10), eruptive seborrheic keratoses may appear. Both photoaggravated and phototriggered forms of PRP can also occur. Resolving PRP may have a clinical appearance that resembles erythema gyratum repens (see Ch. 19).

To distinguish the different clinical presentations of PRP, Griffiths[39] proposed a classification schema based upon age, duration, and type of cutaneous involvement (Fig. 9.9). A generalized eruption is seen in all of the forms except for the circumscribed juvenile type. Type I (classic adult) PRP is the most common form, accounting for a little over half of cases. It is typically self-limited, clearing within 3 years in 80% of patients. Its features are those described above. Type II is also seen in adults and differs from type I by a palmoplantar keratoderma with a coarse and lamellated scale, a more ichthyosiform scaling on the lower extremities, and occasional alopecia. Only 20% of type II patients experience clinical resolution within 3 years.

PRP types III–V are seen in children and adolescents. Type III, the classic juvenile form, represents 10% of cases; it most closely resembles the classic adult form and also typically clears within 3 years. Type IV (circumscribed) is the most common of the juvenile forms, and its focal nature sets it apart from the other clinical presentations. Type V, the atypical juvenile form, has features similar to adult type II disease with more ichthyosiform scaling and a chronic course. In addition, scleroderma-like changes of the fingers have been described. The rare patients with familial forms of PRP present with the atypical adult (type II) and atypical juvenile (type V) forms of the disease.

A type VI has been proposed for those with HIV infection who develop PRP[36]. This type is often recalcitrant to conventional therapy for PRP, but it may respond to antiretroviral therapy. Patients can also have nodulocystic lesions of acne conglobata and hidradenitis suppurativa as well as elongated follicular spines.

Pathology

Psoriasiform dermatitis with irregular hyperkeratosis and alternating vertical and horizontal ortho- and parakeratosis ("checkerboard pattern") is distinctive (Fig. 9.10A). The hair follicles are dilated and filled with a keratinous plug, while the "shoulder" of stratum corneum surrounding the follicular opening frequently shows parakeratosis (Fig. 9.10B). The interfollicular epidermis often exhibits hypergranulosis as well as thick, shortened rete pegs. A sparse lymphohistiocytic perivascular infiltrate is seen in the underlying dermis. Acantholysis and focal acantholytic dyskeratosis within the epidermis have been described. These latter features are claimed to be helpful when distinguishing PRP from psoriasis.

Differential Diagnosis

The major entity in the differential diagnosis is psoriasis. The distinctive orange–red palmoplantar keratoderma plus the keratotic follicular papules with a nutmeg grater appearance, the classic islands of sparing of the trunk, and no family history of psoriasis help differentiate PRP from psoriasis. The presence of oil-drop changes, small pits, and marginal onycholysis of the nails favor psoriasis. Microscopically, acantholysis and focal acantholytic dyskeratosis, if present, are especially useful in diagnosing PRP. A thickened granular cell layer, short thicker rete pegs, limited vascular dilation in the dermal papillae, and the absence of both neutrophilic migration towards the epidermis and Munro microabscesses further help distinguish PRP from psoriasis.

Early PRP of the scalp can mimic seborrheic dermatitis. As additional clinical features of PRP develop, these two entities can be distinguished. Furthermore, scalp dermatitis is much more responsive to conventional therapy. The relative recalcitrant nature of scalp PRP may serve as a clue to the diagnosis. A PRP-like eruption can be seen in patients with dermatomyositis (Wong type) and cutaneous T-cell lymphoma, as can erythema and scaling of the scalp. Children with acute-onset PRP may be misdiagnosed as having Kawasaki disease, and, occasionally, PRP is confused with progressive symmetric erythrokeratoderma. The various disorders that can present as an erythroderma are discussed in Chapter 10.

Treatment

Therapy for PRP is primarily empiric because a unifying etiology remains elusive and the number of patients required for large-scale, randomized trials is generally not available. Furthermore, it is difficult to assess treatment outcomes when the natural course of the disease

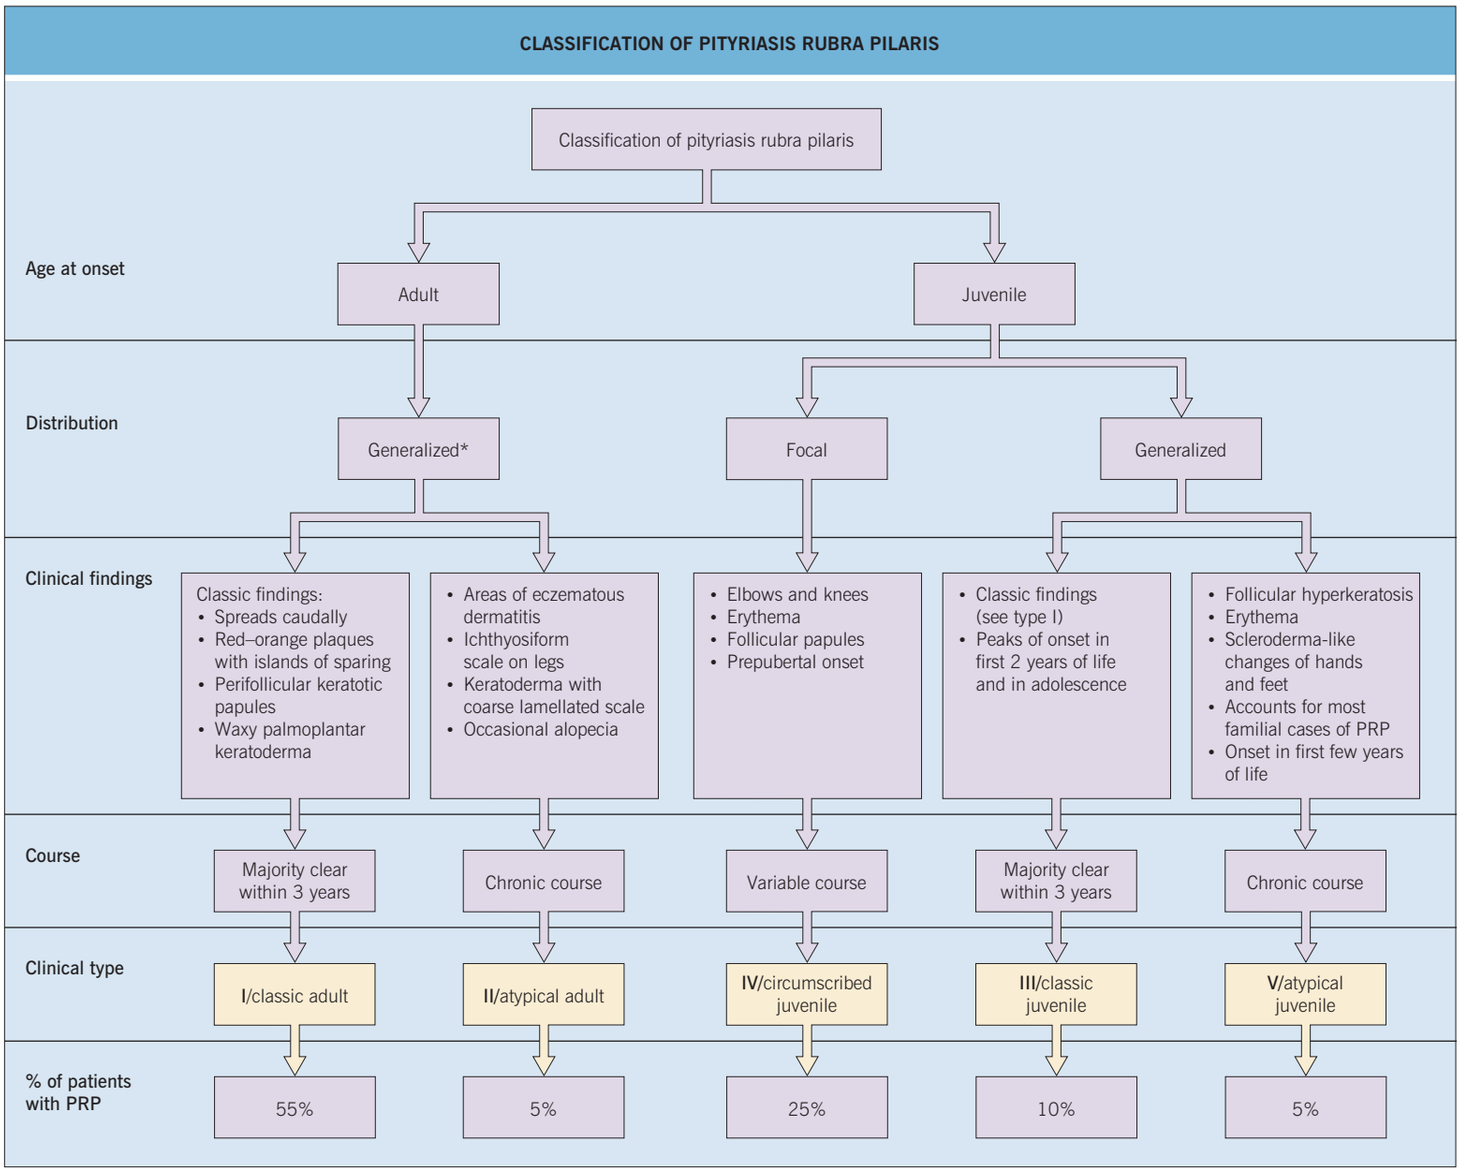

Fig. 9.9 Classification of pityriasis rubra pilaris (PRP). *A generalized distribution of PRP, often with findings similar to type I, may be seen in association with elongated follicular spines, acne conglobata and hidradenitis suppurativa in HIV-infected individuals; this is referred to as type VI PRP or the HIV-associated follicular syndrome.

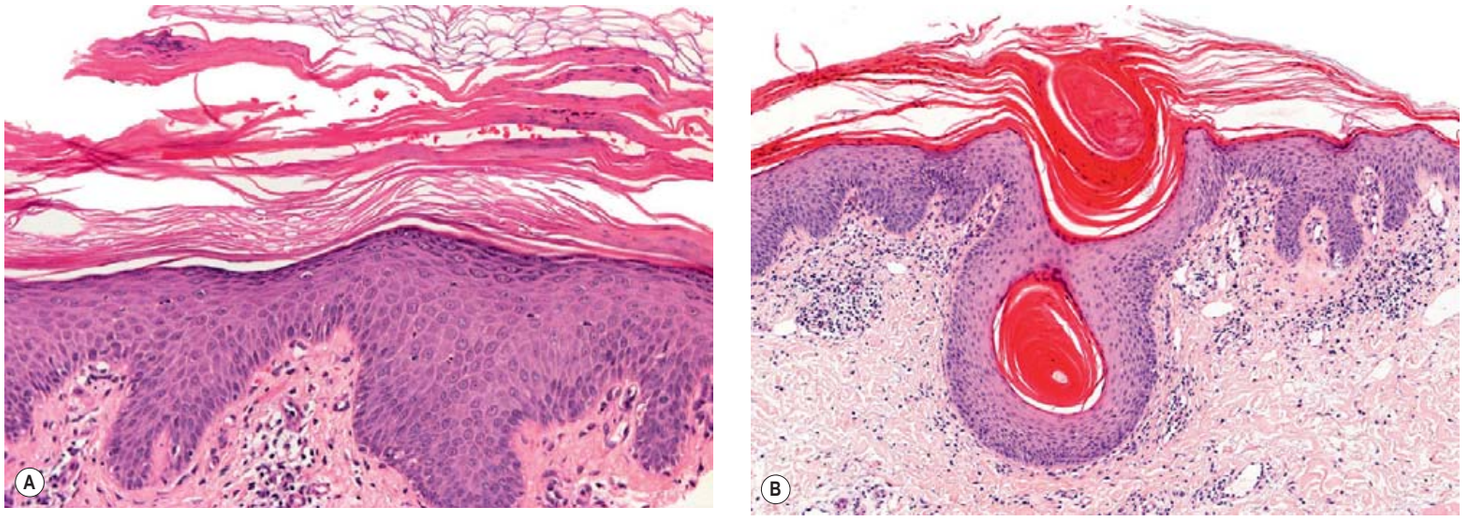

Fig. 9.10 Pityriasis rubra pilaris – histopathologic features. Psoriasiform dermatitis with alternating vertical and horizontal ortho- and parakeratosis ("checkerboard pattern") (**A**), as well as follicular hyperkeratosis with parakeratosis in the shoulders of the follicular plug (**B**). *Courtesy, Lorenzo Cerroni, MD.*

in many patients is spontaneous resolution. Regardless, PRP has been recognized as an acute cutaneous disorder for over 150 years, allowing for the collection of considerable therapeutic experience[40].

Initial reports of successful treatments for PRP involved oral vitamin A, sometimes in combination with vitamins B and D. However, toxic doses of vitamin A were often required and liver toxicity was a potential problem. Systemic retinoids have received considerable attention as a useful therapy. Isotretinoin, in doses of 1–1.5 mg/kg per day, can induce significant clearing within 3–6 months of instituting therapy. In a retrospective report of 30 PRP patients (19 years of age or younger) who were treated with oral isotretinoin, the greatest improvement was noted within 6 months, with a recurrence rate of 17% post discontinuation of the medication[41]. Higher doses (up to 2 mg/kg per day) are occasionally required. Acitretin is also beneficial in the treatment of PRP and there have been recent case reports of the successful use of alitretinoin[41a]. The effect of retinoids on familial PRP appears less certain.

Methotrexate has also been reported to lead to significant clinical improvement of PRP. Weekly oral doses of 10–25 mg are usually administered, and responses are seen within 3–6 months. Hepatotoxicity and myelosuppression are well-known potential side effects (see Ch. 130). When more toxic, but not yet proven to be more effective, regimens are used (e.g. methotrexate 5 days per week), severe myelosuppression, increased hepatotoxicity, and opportunistic infections such as *Pneumocystis jiroveci* pneumonia can be seen.

In severe cases of PRP, a combination of methotrexate (5–30 mg/week) plus a systemic retinoid (previously etretinate and now acitretin) has been utilized. Both agents can be given at the onset of therapy, or the second medication can be added if the response to the first is inadequate. In this situation, an increased risk for hepatotoxicity must be kept in mind.

There are reports and small case series in which TNF-α inhibitors and ustekinumab have led to improvement of PRP[42,42a]. Other potential therapies include topical retinoids, calcineurin inhibitors and vitamin D analogues as well as systemic immunosuppressives – azathioprine, corticosteroids, cyclosporine – and, in response to reports of decreased serum levels of retinol-binding proteins in patients with PRP, anabolic steroids. These medications have met with variable results. Although UV light therapy runs the risk of exacerbating the disease, there are some reports of success with narrowband UVB, UVA1 or PUVA in combination with an oral retinoid[43]; even one patient with UVB-provoked PRP reportedly responded to bath PUVA.

Less toxic regimens are recommended for the classic juvenile form of PRP, given the high likelihood of spontaneous remission and the potential long-term effects of aggressive systemic therapies.

PITYRIASIS ROSEA

Synonym: ■ Pityriasis rosea Gibert

Key features

- A self-limited papulosquamous eruption that is occasionally pruritic
- Seen primarily in adolescents and young adults, favoring the trunk and proximal extremities
- Individual lesions are usually oval in shape and their long axis is oriented along Langer's lines of cleavage
- Less common variants include inverse, vesicular, purpuric and pustular

Introduction

Pityriasis rosea is a common, "acute", self-limited papulosquamous eruption that favors otherwise healthy adolescents and young adults. Its striking appearance often prompts a request for medical evaluation. There is an absence of significant systemic manifestations, and its spontaneous resolution provides great consolation to the patient. Although the classic presentation is readily recognized, atypical forms may present a greater challenge. A viral etiology has been postulated, but this remains unproven.

History

Robert Willan described "roseola annulata" in 1798 as a self-limited eruption in otherwise healthy children. In 1860, the French physician Camille Melchior Gibert first named the condition pityriasis (scaly) rosea (pink)[44]. This aptly conveyed the clinical features and remains the name that is still used today.

Epidemiology

Most cases of pityriasis rosea occur in young healthy persons, the majority of whom are between the ages of 10 and 35 years[45]. Its peak incidence is during adolescence, and it is rarely diagnosed before the age of 2 years. There is no racial predilection and it is found worldwide. There is a slight female predominance, and some studies have even suggested a female : male ratio of 2 : 1. The typical eruption lasts 6 to 8 weeks, though exceptionally it can persist for 5 months or longer. Some authors report a modest seasonal variation with peaks in the spring and fall.

Pathogenesis

The precise cause of pityriasis rosea remains elusive, and a viral etiology is frequently proposed. Most recently, attention has focused on human herpesvirus-7 (HHV-7) and, less so, on HHV-6. However, some studies have shown no difference in the prevalence of DNA from HHV-6 or HHV-7 in peripheral blood mononuclear cells of patients with pityriasis rosea; attempts to identify HHV-7 DNA within cutaneous lesions have been unsuccessful[46]. Proponents of a viral etiology[47] point to the prodromal symptoms experienced by some patients, the clustering of cases, and the almost complete absence of recurrent episodes, suggesting an immunologic defense against an infectious agent.

Clinical Features

Although classic pityriasis rosea is usually easily recognized, the more unusual variants can be more challenging to diagnose. In the classic situation, a solitary lesion appears on the trunk and enlarges over several days. Less often, this initial lesion is seen on the neck or proximal extremities. It predates the remainder of the eruption by hours to days and is referred to as the "herald patch" because it heralds the onset of the disease. Its incidence varies from 12% to 94%, depending on the study, but in most series it has been seen in over 50% of cases. Multiple herald patches have also been reported.

The herald patch is a skin- to pink- to salmon-colored patch or plaque with a slightly raised advancing margin (Fig. 9.11). The size commonly varies from 2 to 4 cm, but it can be as small as 1 cm or as large as 10 cm. The center shows the characteristic small fine scales of pityriasis rosea, and the margin has a larger, more obvious trailing collarette of scale with the free edge pointing inwards. Approximately 5% of patients may experience a mild prodrome with headache, fever, arthralgias or general malaise. On occasion, the herald patch appears simultaneously with the more widespread eruption.

Fig. 9.13 Pityriasis rosea. A, B Both oval and round plaques can be seen as well as central fine scale or a collarette of scale. *B, Courtesy, Julie V Schaffer, MD.*

Fig. 9.14 Inverse pityriasis rosea. Oval annular plaques in the groin.

Typically, within the next few days, there is a blossoming of lesions on the trunk and proximal extremities. These numerous smaller thin papules and plaques are reminiscent of the larger herald patch that predated them; in darkly pigmented skin, the lesions tend to be more papular and hyperpigmented (Fig. 9.12). Again, there is a subtle advancing border, central fine scaling, and the characteristic collarette of scale (Fig. 9.13). The lesions are usually round to oval in shape, with their long axis following Langer's lines of cleavage (Fig. 9.14). On the posterior trunk, such an orientation leads to what is often referred to as a "fir tree" or "Christmas tree" pattern. Minute pustules can also be seen during this initial phase of pityriasis rosea. The face, palms and soles are usually (but not always) spared. When all these features are present, the diagnosis is easiest to establish. This is also the time when patients are most alarmed by their clinical appearance and are likely to seek medical attention.

The eruption of pityriasis rosea usually persists for 6–8 weeks and then spontaneously resolves; however, occasional patients have lesions that may last 5 months or longer. In the latter situation, the possibility of pityriasis lichenoides chronica arises. Most patients with pityriasis rosea experience few, if any, symptoms. In approximately 25% of patients, pruritus is noted that is mild to severe[48,49].

Atypical forms of pityriasis rosea require a more astute observer. Inverse pityriasis rosea involves the axillae and inguinal areas (see Fig. 9.14) and sometimes the face. It is more common in younger children and in those with darkly pigmented skin. Oral lesions are also uncommon, but they may be underreported. Urticarial, erythema multiforme-like, vesicular[50], pustular and purpuric variants have also been described.

Pathology

The microscopic features of pityriasis rosea are nonspecific. Small mounds of parakeratosis, spongiosis, and a mild lymphohistiocytic perivascular and interstitial papillary dermal infiltrate can be seen. There may be mild erythrocyte extravasation. In severe cases, these features are more pronounced, including the rare formation of epidermal pustules.

Most patients with pityriasis rosea do not have biopsies performed, because the clinical picture is quite characteristic and the histopathology relatively nonspecific.

Differential Diagnosis

Pityriasis rosea can sometimes be difficult to distinguish from secondary syphilis. The presence of cutaneous signs such as split papules and condyloma lata points to syphilis, as does the history or presence of a primary chancre. Patients with secondary syphilis usually have more systemic complaints, and they often have peripheral lymphadenopathy. Histologically, the absence of plasma cells favors pityriasis rosea and nowadays immunohistochemical staining for spirochetal antigens can be done (see Ch. 0). Serologic testing – e.g. Venereal Disease Research Laboratory (VDRL), fluorescent treponemal antibody absorbance (FTA-ABS) – allows the diagnosis of secondary syphilis to be confirmed.

There are drug eruptions that can mimic pityriasis rosea; they have been reported in patients receiving angiotensin-converting enzyme (ACE) inhibitors, metronidazole, isotretinoin, gold, arsenic, bismuth, imatinib and clonidine, as well as omeprazole, etanercept, tripelennamine, ketotifen, salvarsan and BCG vaccine. A drug-induced

pityriasis rosea-like eruption is often slower to resolve than the idiopathic form.

The herald patch or generalized eruption can resemble tinea corporis or nummular dermatitis. The presence of the collarette of scale, the orientation of the lesions, and the history can help distinguish pityriasis rosea from nummular dermatitis, but it can be difficult in the case of vesicular pityriasis rosea. Guttate psoriasis usually has a thicker scale, smaller size, and lacks the fir-tree distribution. Other papulosquamous disorders such as pityriasis lichenoides should also be considered, especially when lesions last longer than 4 months. Patients with the atypical variants of pityriasis rosea may overlap with a wider spectrum of diseases.

Treatment

Because pityriasis rosea is often asymptomatic and self-limited, patient education and reassurance represent a satisfactory treatment plan. In patients with pruritus, counterirritant antipruritic lotions or low- to medium-strength topical corticosteroids may be needed for symptomatic relief. In more severe cases, UVB phototherapy (broadband or narrowband) or natural sunlight exposure and oral antihistamines can be used. Rarely, a brief course of systemic corticosteroids may be required[51].

In a double-blind, placebo-controlled trial, 73% of patients had complete resolution after receiving 14 days of erythromycin in divided doses[52]. The placebo group showed no resolution over the same time period. In a bilateral comparison trial of UVB, a reduction in severity, but not pruritus or duration, was observed[53].

PITYRIASIS ROTUNDA

Synonyms: ■ Tinea circinata ■ Pityriasis circinata

Key features

- Asymptomatic dermatosis seen primarily in the Far East and Mediterranean basin and in individuals of African descent
- There are large circular and polycyclic scaly patches with sharp margins and no evidence of inflammation clinically
- In most patients, lesions are hyperpigmented and localized to the trunk and extremities
- Histologic features are similar to those of ichthyosis vulgaris, raising the possibility of an unusual form of ichthyosis
- In some patients it may be associated with malnutrition, mycobacterial infections and/or underlying malignancies, while in others it is familial

Introduction

Pityriasis rotunda has been associated with a number of unrelated conditions and in many patients is suspected to be due in part to malnutrition[54,55]. It is possible that malnutrition is a final common pathway for patients with underlying infectious diseases or malignancies. One proposal is that pityriasis rotunda represents a minor acquired ichthyosis that can be familial[56]. Nonetheless, it remains an unusual dermatosis, the pathogenesis of which has yet to be determined[57].

History

Pityriasis rotunda was first described by Toyama in 1906 as "tinea circinata" and was later named pityriasis rotunda by Matsura.

Epidemiology

Pityriasis rotunda is most commonly observed in adults between the ages of 25 and 45 years and has a slight female predominance[54–56,58]. It has been described in the Far East (Japan and China), the Mediterranean basin (Morocco, Italy and Israel), and in Africans, African-Americans, and Caribbean blacks in the UK.

Pathogenesis

No clear unifying cause has been identified. A pre-existing chronic disorder is often, but not invariably, found. Associations with malnutrition, mycobacterial diseases (tuberculosis and leprosy), malignancies (hepatocellular carcinoma, gastric carcinoma and multiple myeloma) and hepatic cirrhosis have been reported[54,55]. Although Caucasian patients with pityriasis rotunda are occasionally reported, they are generally in good health[55]. Some authors have suggested that pityriasis rotunda is a reflection of malnutrition in genetically susceptible patients with a possible underlying disorder. This hypothesis is supported by the observation that the lesions improve when the patient's nutritional status improves. In southern Italy, an association with glucose-6-phosphate dehydrogenase (G6PD) deficiency and favism has been reported[58].

Clinical Features

Pityriasis rotunda is typically asymptomatic, and it may be overlooked by the patient. It is characterized by large circular and polycyclic lesions that are often 10 cm (and may be up to 30 cm) in diameter. They have associated fine scale and are moderately hyperpigmented with a sharp margin and no inflammation. The trunk and extremities are favored. A hypopigmented halo has been described in some patients, and sometimes the entire lesion can be hypopigmented.

Grimalt proposed categorizing pityriasis rotunda into two groups[56]. Type I is said to occur primarily in blacks and Asians as hyperpigmented lesions, possibly in association with an internal malignancy but with no family history. Type II pityriasis rotunda is thought to occur more commonly in Caucasians and be characterized by numerous (>30) lesions; patients may have a family history of the disorder but no associated internal malignancy.

Pathology

Pityriasis rotunda has microscopic features of ichthyosis vulgaris. There is an absent or diminished granular cell layer with moderate hyperkeratosis without parakeratosis. There may be increased pigmentation of the basal cell layer, and epidermal atrophy can be seen along with areas of pigment incontinence, a minimal perivascular lymphohistiocytic infiltrate, and occasional follicular plugging[54]. Special stains for fungi are negative.

Differential Diagnosis

The differential diagnosis includes tinea corporis, tinea versicolor, leprosy and large plaque parapsoriasis. It lacks the pruritus and inflammation of dermatitis, and there is no associated anesthesia or peripheral nerve thickening. The combination of a potassium hydroxide examination, fungal culture and routine histology excludes major entities in the differential diagnosis. Of note, mycobacteria have never been isolated. Because of the large size of the lesions, the hypopigmented variant of pityriasis rotunda can resemble one form of progressive macular hypomelanosis; however, the latter has no associated scale and it lacks the histologic features of ichthyosis vulgaris.

Treatment

Pityriasis rotunda is relatively difficult to treat. Trials with topical lactic acid, urea, tars, emollients and corticosteroids have provided little benefit. Topical tretinoin cream 0.1% can result in modest improvement and systemic retinoids warrant consideration for patients with more extensive disease. However, reversal of any underlying disorder – in particular, malnutrition, infection or malignancy – should be addressed first.

GRANULAR PARAKERATOSIS

Synonyms: ■ Axillary granular parakeratosis ■ Intertriginous granular parakeratosis

Key features

- The primary lesions are brownish-red keratotic papules that can coalesce into plaques
- The adult form occurs almost exclusively in women
- In most adult cases, lesions are localized to the axillae, but other intertriginous sites can be affected
- The infantile form is associated with diaper wearing and presents as bilateral plaques in the inguinal folds or erythematous geometric plaques underlying pressure points from the diaper
- Histopathologically, there is distinct retention of basophilic keratohyaline granules within areas of parakeratosis in the stratum corneum
- A defect in processing profilaggrin to filaggrin is a proposed mechanism

Introduction

Granular parakeratosis is typically a pruritic disorder, initially reported to occur only in the axillae. It is now recognized that other intertriginous sites (i.e. the groin, inframammary and abdominal folds) can also be involved[59–61]. An underlying disorder in keratinization has been suggested that may explain its distinct histopathologic findings[62].

History

Northcutt and colleagues[59] first described granular parakeratosis in 1991. Mehregan et al. proposed renaming this condition "intertriginous granular parakeratosis" to reflect its localization to these areas.

Epidemiology

Granular parakeratosis is observed most commonly in adult women[59–61]. It affects middle-aged or older adults, and it has been reported in both darkly pigmented and lightly pigmented individuals. Although it is an unusual condition in young adults[62], there is an infantile form in which diaper-wearing plays a role[63].

Pathogenesis

Granular parakeratosis is thought to be an acquired keratotic dermatosis that was initially linked to the use of personal hygiene products. These included deodorants and antiperspirants in roll-on or stick form, as well as creams and soaps used in excess and/or in a susceptible individual[59–62]. However, patients without a known irritant have also been reported[62]. The mechanism that underlies the role of diapers is also unknown.

A disorder of keratinization characterized by a basic defect in the processing of profilaggrin to filaggrin has been proposed. Based on ultrastructural and immunohistochemical studies, Metze and Rutten[62] came to the same conclusion as Northcutt et al.[59] that the retention of keratohyalin granules within the stratum corneum could be due to a defect in filaggrin metabolism. In this model, there is a failure to degrade keratohyalin granules and to aggregate keratin filaments during cornification.

Clinical Features

The primary lesions are keratotic brownish-red papules that can have a conical shape. They can coalesce into larger well-demarcated plaques with various degrees of maceration secondary to local occlusion (Fig. 9.15). Lesions can persist for months or longer and recur. Pruritus is the most common complaint, but irritation is also a problem if there are erosions or fissures. Some patients experience a flare with an increase in ambient temperature and sweating. The axillae are the most common sites of involvement, with both unilateral and bilateral lesions having been described. Additional intertriginous areas such as the groin and inframammary fold may be affected.

In the infantile form, there may be bilateral plaques in the inguinal folds or erythematous geometric plaques underlying pressure points from the diaper.

Pathology

The characteristic feature is an unusual form of parakeratosis. The stratum corneum is thickened and compacted with increased eosinophilic staining (Fig. 9.16). Retained nuclei are present throughout this keratin layer, creating the parakeratosis. The most unusual feature is the visible retention of basophilic keratohyalin granules within these areas of parakeratosis[64].

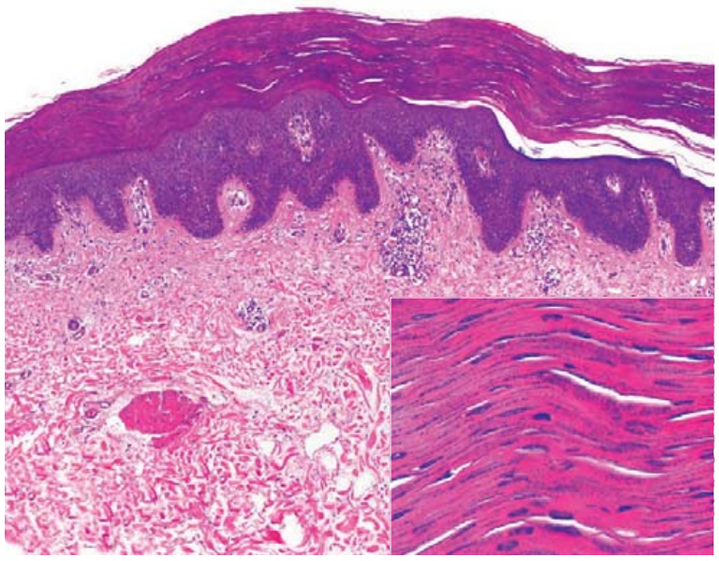

Fig. 9.16 Axillary granular parakeratosis. Marked, compact parakeratosis with small bluish granules within the stratum corneum representing keratohyaline granules (insert). *Courtesy, Luis Requena, MD.*

Differential Diagnosis

The differential diagnosis includes the most common causes of intertrigo (e.g. seborrheic dermatitis, candidiasis, inverse psoriasis, erythrasma) and Hailey–Hailey disease, Darier disease and pemphigus vegetans[59–62]. Sometimes the papules may be confused with seborrheic keratoses and the plaques with acanthosis nigricans. Irritant or allergic contact dermatitis also needs to be considered in some patients. A biopsy will confirm the diagnosis of granular parakeratosis.

Treatment

Based upon case reports and small series, therapeutic success has been reported with topical corticosteroids, vitamin D analogues, retinoids, ammonium lactate and antifungals[59–62]. In addition, cryotherapy as well as oral isotretinoin and oral antifungals have been used. Spontaneous resolution has also been observed (including in infants), as have relapses.

Pityriasis rubra pilaris. Diffuse erythroderma with desquamation and follicular hyperkeratosis on the knee.

Pityriasis rosea in darkly pigmented skin. It tends to be more papular than that in lightly pigmented skin. Note the associated hyperpigmentation.

Erythroderma 10

Wolfram Sterry and Matthias Steinhoff

Synonyms: ■ Exfoliative dermatitis ■ Exfoliative erythroderma ■ Red man syndrome

Key features

- Erythroderma is defined clinically as generalized redness and scaling of the skin
- Systemic manifestations include peripheral edema, tachycardia, loss of fluid and proteins, and disturbances in thermoregulation
- Erythroderma has multiple etiologies; the most common causes are psoriasis, drug reactions, atopic dermatitis and cutaneous T-cell lymphoma (CTCL)
- Establishing the correct diagnosis requires consideration of initial sites of involvement, additional clinical findings, histologic and molecular features, and associated systemic abnormalities, as well as a complete medical history
- Despite an intensive evaluation, the cause remains unknown (idiopathic) in 25–30% of patients; some of these patients eventually develop CTCL
- Treatment strategies should address the dermatologic disease as well as the underlying etiology and the systemic complications of the erythroderma

INTRODUCTION

Erythroderma is defined as a generalized redness and scaling of the skin. However, it does not represent a defined entity, as it is the clinical presentation of a variety of diseases. Most commonly, erythroderma is due to generalization of pre-existing dermatoses (such as psoriasis or atopic dermatitis), drug reactions or cutaneous T-cell lymphoma (CTCL). Although up to 50% of the patients have a history of more localized skin lesions prior to the onset of the erythroderma, identification of the underlying disease process represents one of the most complex challenges in dermatology. Sustained efforts during longitudinal evaluation may lead to the precise identification of the etiology. In approximately one-quarter of the patients, no specific etiology is found, and these cases are called "idiopathic erythroderma".

Attention should also be focused on the potential systemic complications of erythroderma. Hypothermia, peripheral edema, and loss of fluid, electrolytes and albumin with subsequent tachycardia and cardiac failure are a serious threat to the erythrodermic patient. In addition, long-lasting erythrodermas may be accompanied by cachexia, diffuse alopecia, palmoplantar keratoderma, nail dystrophy and ectropion.

HISTORY

The term "erythroderma" was introduced in 1868 by Hebra to describe an exfoliative dermatitis involving more than 90% of the skin surface. Based upon the clinical course, erythroderma was classified into chronically relapsing (Wilson–Brocq), chronically persisting (Hebra), and self-limiting epidemic (Savill) variants. However, these subdivisions are no longer employed.

EPIDEMIOLOGY

No precise data exist regarding the prevalence or incidence of erythroderma as most reports are retrospective and do not address the issue of overall incidence. Large series of patients have focused on male-to-female ratios, average age, and underlying diseases[1–6]. Men are more commonly affected (male-to-female ratio from approximately 2:1 to 4:1). An even higher ratio can be found in the subset of idiopathic erythroderma, also referred to as "red man syndrome" (not to be confused with the cutaneous reaction to rapid infusion of vancomycin). The average age at onset of erythroderma was 52 years, with an average of 48 years in series including children, and 60 years in those excluding them[1,3,4,6].

Of a total of 746 patients, dermatitis (24%), psoriasis (20%), drug reactions (19%) and CTCL (8%) represented the most common underlying causes of erythroderma[1,3,4,6]. When categories within the dermatitis group were examined, atopic dermatitis (9%) was the most common type, followed by contact dermatitis (6%), seborrheic dermatitis (4%) and chronic actinic dermatitis (3%).

For adults, unusual causes include ichthyoses, bullous dermatoses (usually pemphigus foliaceus), pityriasis rubra pilaris, Ofuji's papuloerythroderma, and systemic lupus erythematosus (Table 10.1). Despite multiple skin biopsies, an in-depth clinical investigation and a detailed medical history, the underlying cause of erythroderma is not found in at least 25% of patients.

With regard to infants and neonates, ichthyoses, immunodeficiencies, dermatitides, psoriasis, and consequences of infection (e.g. staphylococcal scalded skin syndrome) represent the major causes of erythroderma (Table 10.2)[7]. In addition, the possibility of drug-induced erythroderma needs to be considered.

PATHOGENESIS

The pathogenetic mechanisms of the underlying diseases will be discussed in the respective chapters. The pathways involved in the *de novo* genesis of erythroderma or the generalization of pre-existing skin lesions are not well understood. The number of germinative cells as well as their mitotic rate is increased in erythrodermic skin, and the transit time of cells through the epidermis is shortened. Consequently, scales consist of material normally retained by the skin (nucleic acids, amino acids, soluble protein), and the daily loss of scales increases from 500–1000 mg to 20–30 g[8]. In acute erythroderma, the lost material usually has marginal metabolic significance.

CLINICAL FEATURES

Cutaneous Manifestations

Erythroderma is defined clinically by the presence of erythema and scaling involving more than 90% of the skin surface. Based upon its natural history, erythroderma can be classified into primary or secondary types. In the primary form, the erythema (often initially on the trunk) extends within a few days or weeks to involve the entire skin surface, and this is followed by scaling (Fig. 10.1). The secondary form of erythroderma is defined as a generalization of a preceding localized skin disease – for example, psoriasis or atopic dermatitis.

With the exception of very slowly progressing secondary erythroderma, erythema precedes the development of exfoliation by 2–6 days. The associated scaling varies extensively in size and color depending upon the stage of the erythroderma and nature of the underlying disease. In more acute phases, scales are usually large and crusted,

CAUSES OF ERYTHRODERMA IN ADULTS			
Underlying disease	**Clinical clues**	**Histologic clues**	**Additional hints**
		COMMON	
Psoriasis (Ch. 8)	• Pre-existing psoriatic plaques • Often spares the face • Nail changes (oil-drop, pits, onycholysis) • Subcorneal pustules • Inflammatory arthritis	• Confluent parakeratosis • Bottleneck-like rete ridges • Tortuous vessels in papillary dermis • Neutrophils within epidermis • Often reduced granular layer	• Personal or family history of psoriasis • Withdrawal of corticosteroids, methotrexate or cyclosporine (also efalizumab prior to its removal from the market)
Atopic dermatitis (Ch. 12)	• Pre-existing lesions (flexures) • Severe pruritus • Lichenification, including eyelids • Prurigo nodularis	• Mild to moderate acanthosis • Variable spongiosis • Dermal eosinophils • Parakeratosis	• Elevated serum IgE, eosinophilia • Personal or family history of atopy (e.g. asthma, allergic rhinitis) • Cataracts
Drug reactions (Ch. 21)	• Preceded by morbilliform or scarlatiniform exanthem • Facial edema • In dependent areas, may become purpuric	• Perivascular infiltrate with eosinophils • Lichenoid infiltrate • Necrotic keratinocytes at all levels of epidermis • Vacuolar degeneration of basal layer	• No history of skin diseases • Usually resolves within 2–6 weeks after withdrawal of responsible drug; possible exception is DIHS/DRESS
Idiopathic erythroderma	• Elderly men • Chronic, relapsing • Severe pruritus • Palmoplantar keratoderma • Dermatopathic lymphadenopathy	• Nonspecific	• Consider less commonly associated drugs (see Table 10.3) • Continue to re-evaluate for cutaneous T-cell lymphoma
		LESS COMMON	
Cutaneous T-cell lymphoma (Ch. 120)	• Sézary syndrome more common than erythrodermic mycosis fungoides • Intense pruritus • Deep purple–red hue • Painful, fissured keratoderma • Alopecia • Leonine facies	• Nuclear atypia in lymphocytes • Clustering of atypical cells within epidermis • Often lichenoid infiltrate	• Elevated $CD4^+$:$CD8^+$ ratio (blood), with ≥10:1 ratio seen in Sézary syndrome • Detection of clonal T-cell population in skin (and blood) • In Sézary syndrome: ≥1000 Sézary cells/mm^3; ≥40% $CD4^+/CD7^-$; or ≥30% $CD4^+/CD26^-$ (blood)
Pityriasis rubra pilaris (Ch. 9)	• Salmon-colored erythema • Islands of sparing (nappes claires) • Waxy keratoderma • Perifollicular keratotic papules	• Psoriasiform epidermal hyperplasia • Alternating parakeratosis and orthokeratosis, both vertically and horizontally • Follicular plugs with "shoulder parakeratosis"	• Flare after sun exposure • Cephalocaudal progression • Appearance of erythema gyratum-like lesions as erythroderma improves
Dermatitis (non-atopic), including contact (Chs 14 & 15) and stasis with autosensitization (Ch. 13)	• Pre-existing localized disease • Distribution of initial lesions	• Variable spongiosis	• Occupation and hobbies • Patch testing • Review oral medications (systemic contact dermatitis)
Paraneoplastic erythroderma	• Fine scaling • Melanoerythroderma • Cachexia	• Nonspecific changes	• Lymphoproliferative disorders, including other types of T-cell lymphoma • In the case of solid-organ malignancies, usually late stage
		BULLOUS DERMATOSES (CHS 29 & 30)	
Pemphigus foliaceus	• Pre-existing lesions, often on upper trunk • Impetigo-like erosions and vesicles • Moist scale-crust; cornflake scale	• Acantholysis, superficial epidermis • DIF, intercellular IgG	• IIF, intercellular
Bullous pemphigoid	• Urticarial plaques • Tense bulla • Elderly patients	• Subepidermal blister • Eosinophils • DIF, BMZ C3 and IgG	• IIF, BMZ
Paraneoplastic pemphigus	• Mucosal erosions and hemorrhagic crusts • Erythema multiforme-like lesions • Mucocutaneous lichenoid lesions	• Interface dermatitis with necrotic keratinocytes • Focal acantholysis • DIF, intercellular and BMZ IgG	• IIF, intercellular and BMZ (+ IIF rat bladder)
Congenital ichthyoses (Ch. 57)	• Present from birth or early infancy (see Table 10.2)	• See Table 10.2	• See Table 10.2
		RARE	
Papuloerythroderma of Ofuji	• Widespread, pruritic, flat-topped red–brown papules that can become confluent • Sparing of skin folds ("deck-chair" sign) • Favors elderly men	• Dense perivascular infiltrate of lymphocytes and eosinophils in the upper to mid dermis	• Multiple etiologies, including atopy, lymphomas (esp. CTCL), drugs (e.g. DDI, aspirin), infections (e.g. HIV, hepatitis C) • May have peripheral eosinophilia, lymphopenia

Table 10.1 Causes of erythroderma in adults. BMZ, basement membrane zone; DDI, dideoxyinosine; DIF, direct immunofluorescence; DIHS, drug-induced hypersensitivity syndrome; DRESS, drug reaction with eosinophilia and systemic symptoms; IIF, indirect immunofluorescence.

CAUSES OF ERYTHRODERMA IN ADULTS			
Underlying disease	**Clinical clues**	**Histologic clues**	**Additional hints**
Chronic actinic dermatitis (Ch. 87)	• Initial lesions in photodistribution	• Lichenoid infiltrate of lymphocytes and exocytosis • Possible lymphocyte nuclear pleomorphism	• Drug history • UVA, UVB and visible light phototesting • Photopatch testing
OTHER RARE CAUSES			
• Hypereosinophilic syndrome (Ch. 25) • Crusted (Norwegian) scabies (Ch. 84) • Lichen planus • GVHD (Ch. 52) • Autoimmune connective tissue disease (e.g. acute or subacute cutaneous lupus erythematosus, juvenile dermatomyositis [adolescents])		• Dermatophyte infection • Primary immunodeficiencies (Ch. 60) • Sarcoidosis • Mastocytosis • Hemophagocytic lymphohistiocytosis • T-cell leukemia	

Table 10.1 Causes of erythroderma in adults (cont'd).

CAUSES OF ERYTHRODERMA IN NEONATES AND INFANTS			
Underlying disease	**Clinical clues**	**Histologic clues**	**Additional findings**
INHERITED ICHTHYOSES (CH. 57)¶			
Epidermolytic ichthyosis (previously referred to as bullous congenital ichthyosiform erythroderma)	• Formation of superficial blisters and erosions during the first days of life • Later, corrugated hyperkeratosis in flexural areas	• Classic epidermolytic hyperkeratosis	• Mutations in *KRT1* and *KRT10*, which encode keratins 1 and 10
Congenital ichthyosiform erythroderma (previously referred to as non-bullous congenital ichthyosiform erythroderma)	• Collodion baby • Generalized scaling involving flexures • Cicatricial alopecia, nail dystrophy (subungual hyperkeratosis, ridging), rapid nail growth • Ectropion	• Non-diagnostic	• Mutations in *TGM1* (encodes transglutaminase 1), *ALOXE3* (lipoxygenase 3), *ALOX12B* (12[R] lipoxygenase), *NIPAL4* (ichthyin), *ABCA12**, and *CYP4F22**
Netherton syndrome	• Atopic-like dermatitis • Food allergies • Immune deficiency • Erythroderma in neonates • Erythroderma may persist or ichthyosis linearis circumflexa develops • Examine eyebrows and eyelashes as well as scalp hairs for trichorrhexis invaginata ("bamboo hair") • Failure to thrive	• Routine histology – non-diagnostic • LEKT1 antibody	• By electron microscopy: premature secretion and abnormal lamellar bodies • Elevated serum IgE levels • Mutations in *SPINK5* (encodes serine peptidase inhibitor, Kazal type 5)
Conradi–Hünermann–Happle syndrome (X-linked dominant chondrodysplasia punctata)	• Linear and swirled pattern • Skeletal (chondrodysplasia punctata) and ocular anomalies (cataracts)	• Hyperkeratosis, reduced granular layer, follicular plugging	• Mutations in *EBP* at Xp11 (encodes emopamil binding protein [sterol isomerase])
IMMUNODEFICIENCIES (CH. 60)			
Omenn syndrome	• Onset in neonatal period • Exfoliative erythroderma with diffuse alopecia • Lymphadenopathy and hepatosplenomegaly • Recurrent infections • Diarrhea	• Necrosis of keratinocytes • Dense dermal infiltrate (predominantly T cells) • Acanthosis, parakeratosis	• Leukocytosis, eosinophilia • Hypogammaglobulinemia • Elevated serum IgE levels • Lymph nodes: disruption of germinal centers and abundant $S100^+$ interdigitating reticulum cells • Mutations in *RAG1* and *RAG2* (see Ch. 60)
Other forms of SCID†, agammaglobulinemia, complement deficiencies (e.g. C3, C5)	• "Leiner phenotype" of exfoliative dermatitis, chronic diarrhea and recurrent infections	• Non-diagnostic	• See Ch. 60
Wiskott–Aldrich syndrome	• Primarily affects boys • Petechiae, ecchymoses • Atopic-like dermatitis • Recurrent sinopulmonary infections	• Non-diagnostic	• Microthrombocytopenia • Lymphopenia, eosinophilia • Elevated serum IgE levels • Mutations in *WAS*

**ABCA12* and *CYP4F22* encode ATP-binding cassette (ABC), sub-family A, member 12 and cytochrome P450, family 4, subfamily F, polypeptide 22, respectively.
†Erythroderma can also occur secondary to GVHD (see Fig. 10.10).
¶Present from birth or early infancy.

Table 10.2 Causes of erythroderma in neonates and infants. SCID, severe combined immunodeficiency.

CAUSES OF ERYTHRODERMA IN NEONATES AND INFANTS			
Underlying disease	**Clinical clues**	**Histologic clues**	**Additional findings**
PRIMARY DERMATOSES			
Atopic dermatitis	• Crusted eczematous lesions on extensor surfaces, face, scalp • Spares diaper area • Pruritus • Onset week 6–16	• See Table 10.1	• See Table 10.1
Seborrheic dermatitis	• Greasy, scaling plaques and satellite papules on scalp and in skin folds • Diaper area involvement • Non-pruritic • Early onset (week 2–12)		
Psoriasis	• Silvery white scaling and sharply demarcated plaques on face, elbows and knees • Diaper area involvement • Nail pits • Usually later onset	• See Table 10.1	• Family history of psoriasis
DRUG REACTIONS (Table 10.1)			
INFECTIONS			
Staphylococcal scalded skin syndrome	• Temperature instability/low-grade fever • Irritability • Skin-fold accentuation • Large areas of tender erythema • Superficial bulla formation followed by desquamation • Radiating perioral scale-crusts • Extracutaneous staphylococcal infections often responsible	• Blister roof consists of the cornified layer and parts of the granular layer • Subcorneal blisters contain a few neutrophils and lymphocytes	• Positive culture for *Staphylococcus aureus* (conjunctivae, nares, throat, rectum) • Identification of exfoliative toxins (ET-A & ET-B) via slide latex agglutination, double immunodiffusion, or ELISA (see Ch. 74) • ET-A produced by *S. aureus* specifically cleaves desmoglein 1
Neonatal toxic shock-like exanthematous disease	• Generalized diffuse macular erythema or morbilliform eruption with confluence • Minimal scaling • Fever • Occurs during first week of life		• Colonization of umbilical stump, nasopharynx or skin with TSST-1-producing MRSA • Thrombocytopenia
Congenital cutaneous candidiasis	• Maternal vaginal *Candida* infection with intrauterine spread • Pustules, collarettes of scale • Oral cavity spared • May have paronychia and nail dystrophy	• Yeast and pseudohyphae in the stratum corneum (PAS) • Subcorneal and spongiform pustules within the epidermis	• KOH examination, fungal culture
OTHERS			
• Pityriasis rubra pilaris (Ch. 9) • GVHD (e.g. maternal–fetal or transfusion-related in the setting of SCID) (Ch. 52) • Diffuse cutaneous mastocytosis (Ch. 118) • Rare ichthyoses – trichothiodystrophy, keratitis–ichthyosis–deafness (KID) syndrome, Sjögren–Larsson syndrome, neutral lipid storage disease with ichthyosis (Ch. 57) • Ankyloblepharon–ectodermal dysplasia–clefting (AEC) syndrome (Ch. 63) • "Nutritional dermatitis", including kwashiorkor (Ch. 51)			

Table 10.2 Causes of erythroderma in neonates and infants (cont'd). ELISA, enzyme-linked immunosorbent assay; MRSA, methicillin-resistant *Staphylococcus aureus*; SCID, severe combined immunodeficiency; TSST-1, toxic shock syndrome toxin 1.

whereas in chronic states they tend to be smaller and drier. Occasionally, the cause of the erythroderma is suggested by the character of the scale – for example, fine in atopic dermatitis or dermatophytosis, bran-like in seborrheic dermatitis, crusted in pemphigus foliaceus, and exfoliative in drug reactions.

Despite the varied causes, erythrodermas have several common clinical features. Pruritus, the most frequent complaint, is observed in up to 90% of patients. This symptom varies according to the underlying cause, and it is most severe in patients with dermatitis or Sézary syndrome[9]. Given the itch–scratch cycle, the skin may become thickened, and areas of lichenification are seen in one-third of cases. Especially in the case of chronic erythrodermas, patients develop dyspigmentation, with hyperpigmentation (40/90 patients, 45%) observed more frequently than hypo- or depigmentation (18/90 patients, 20%)[4]. Palmoplantar keratoderma appears in approximately 30% of erythrodermic patients, and it is often an early sign in pityriasis rubra pilaris[9]. A keratoderma with scale-crust can point to crusted scabies, whereas a painful and fissured keratoderma can occur in Sézary syndrome.

In cases of pre-existing dermatoses, nail changes may precede the erythroderma (e.g. pits in psoriasis or horizontal ridging in atopic dermatitis), whereas others develop subsequently. Nail changes are said to be present in approximately 40% of patients. Most often "shiny" nails are observed, but discoloration, brittleness, dullness, subungual hyperkeratosis, Beau's lines, paronychia and splinter hemorrhages can be seen. The nails may even be totally shed. Due to their slower development, nail changes are of potential value in differentiating the underlying cause. Diffuse non-scarring alopecia appears in 20% of patients with chronic erythroderma, including that due to CTCL; the latter is also associated with cicatricial alopecia.

Patients with erythroderma due to a variety of causes can begin to develop multiple seborrheic keratoses, and these papules may be pale in color compared with the background erythema (Fig. 10.2). Colonization of the skin with *Staphylococcus aureus* is common in the setting

Fig. 10.1 Erythroderma with desquamation. Obvious exfoliation of scale with underlying erythema.

Fig. 10.2 Eruptive seborrheic keratoses in a patient with idiopathic erythroderma. *Courtesy, Jean L Bolognia, MD.*

of erythroderma, and this can lead to secondary cutaneous infections. Independent of the cause of the erythroderma, bilateral ectropion and purulent conjunctivitis can develop as ocular complications. Lastly, an exacerbation of the erythroderma can follow UV irradiation or drug ingestions, and this is not restricted to patients with photosensitive eczema and drug-induced erythroderma, respectively[4].

Systemic Manifestations

An awareness of potential systemic complications of erythroderma is essential for proper patient management. Pedal or pretibial edema is observed in approximately 50% of patients (182/380)[1,3–5], and probably results from a shift of fluid into extracellular spaces. In patients with drug-induced erythroderma, facial edema may also develop. Because of the markedly increased blood flow through the skin and an increased fluid loss by transpiration, tachycardia affects 40% of patients, and there is a risk of high-output cardiac failure, particularly in elderly persons. Furthermore, increased skin perfusion leads to thermoregulatory disturbances. Although hyperthermia (37%, 146/391 patients) is more frequent than hypothermia (4%, 14/391), most patients describe chilly sensations[1,2,4,6]. The chronic and excessive loss of heat leads to a compensatory hypermetabolism with subsequent development of cachexia. Anemia, characterized by features of both iron deficiency and anemia of chronic disease, is also observed in patients with chronic erythroderma.

The most common extracutaneous manifestation of erythroderma is generalized peripheral lymphadenopathy, which is found in approximately half of the patients. Even in the absence of an underlying lymphoproliferative disorder, the lymphadenopathy may be prominent and, if so, histologic and molecular examination of a lymph node is recommended (in particular, flow cytometry and T-cell receptor gene analysis)[10]. The major differential diagnosis is between lymphomatous involvement and reactive dermatopathic lymphadenopathy. Hepatomegaly occurs in 20% of the cases (113/578), with a slight predominance in erythroderma due to drug-induced hypersensitivity. Splenomegaly is rarely seen and occurs most often in association with lymphoma[1–4,6].

Fig. 10.3 Psoriatic erythroderma. The disease flare correlated with the administration of lithium. *Courtesy, Jean L Bolognia, MD.*

Specific Findings of the Underlying Disease

In addition to the aforementioned general features, the clinical presentations can have additional, sometimes specific, features suggesting the underlying etiology (see Tables 10.1 & 10.2).

Psoriasis

Psoriasis is the most common underlying disorder in adults, whereas in children it represents the second most common cause of erythroderma, after drug eruptions. As a rule, psoriatic erythroderma is preceded by typical psoriatic plaques (see Ch. 8). Its onset is most often a result of the withdrawal of potent topical or oral corticosteroids, cyclosporine or methotrexate; occasionally, widespread flares follow irritant contact dermatitis (e.g. tar), phototoxicity or systemic infection. After generalization of the erythema, the typical features of psoriatic plaques are lost (Fig. 10.3), and disseminated sterile subcorneal pustules may develop. Due to a slower turnover rate, nail changes, such as oil-drop changes, onycholysis or nail pits (Fig. 10.4), may still be visible and provide valuable clues to the diagnosis of psoriatic erythroderma. Treatment of the erythroderma may result in the reappearance of more characteristic plaques of psoriasis.

Fig. 10.4 Psoriatic erythroderma. Nail findings (pitting and onycholysis with a proximal rim of inflammation) point to the diagnosis of psoriasis.

Atopic dermatitis

Although occurring at any age, atopic erythroderma develops most frequently in patients with a history of moderate to severe atopic dermatitis. As a result, well-established pre-existing lesions can be found, especially when the erythroderma is of recent onset. The pruritus is intense, and secondary excoriations or prurigo-like lesions are frequently observed. Lichenification is often prominent and atrophy of the skin due to topical corticosteroids may be seen. Increased serum IgE and eosinophilia may accompany other signs and symptoms of atopy.

Drug reactions

The number of drugs that can cause erythroderma is staggering (Table 10.3; see also Ch. 21). Whereas erythroderma resulting from topical medications usually begins as dermatitis, eruptions due to systemic drugs begin as a morbilliform or scarlatiniform exanthem. In areas of greatest hydrostatic pressure (ankles and feet), the lesions may become secondarily purpuric. Of the group of erythrodermas, those that are drug-induced have the shortest duration, usually resolving 2–6 weeks after withdrawal of the responsible drug. However, it is imperative to exclude a drug reaction with eosinophilia and systemic symptoms (DRESS), nowadays often referred to as drug-induced hypersensitivity syndrome (DIHS).

Idiopathic erythroderma

In approximately one-third of erythrodermic patients, no underlying disease is detectable. This group consists primarily of elderly men with a chronic course of relapsing pruritic erythroderma in association with dermatopathic lymphadenopathy and extensive palmoplantar keratoderma (Fig. 10.5); this constellation is referred to as "red man syndrome" or "l'homme rouge" (not to be confused with the red man syndrome that accompanies rapid intravenous infusions of vancomycin). When this group was compared with the entire group of erythrodermic patients, lymphadenopathy (68% vs 44%) and peripheral edema (54% vs 40%) were found to be more common than in other types of erythroderma, and hypothermia exceeded hyperthermia[12]. In one series, atopic dermatitis, drug-induced and CTCL were the most common etiologies not initially identified in patients with idiopathic erythroderma[2]. In a second series, CTCL was the most common underlying disease, using the detection of a cutaneous clonal T-cell population as a diagnostic criterion[13]. However, it is important to note that the presence of a T-cell clone in the peripheral blood of elderly individuals may reflect a diminished T-cell receptor repertoire rather than CTCL.

DRUGS ASSOCIATED WITH ERYTHRODERMA	
COMMON	
• Allopurinol	• Phenytoins
• Beta-lactam antibiotics	• Sulfasalazine
• Carbamazepine/oxcarbazepine	• Sulfonamides*
• Gold	• Zalcitabine
• Phenobarbital	
LESS COMMON	
• Captopril/lisinopril	• Lithium
• Carboplatin/cisplatin	• Mercury compounds
• Cytarabine	• Minocycline
• Cytokines (IL-2/GM-CSF)	• Omeprazole/lansoprazole
• Dapsone	• Ribavirin
• Diflunisal	• Telaprevir
• Fluindione	• Thalidomide
• Hydroxychloroquine/chloroquine	• Tocilizumab
• Isoniazid	• Vancomycin†
• Isotretinoin/acitretin	
RARE‡	
• Abacavir	• Mitomycin C
• Amiodarone	• Nifedipine/diltiazem
• Aspirin (ASA)	• Other NSAIDs
• Aztreonam	• Penicillamine
• Beta-blockers	• Pentostatin
• Chlorpromazine	• Pseudoephedrine
• Cimetidine	• Rifampin
• Ciprofloxacin	• St. John's wort
• Clofazimine	• Sulfonylureas
• Codeine	• Tear gas (CS gas)
• Erythropoietin	• Terbinafine
• Fluorouracil	• Tobramycin
• Imatinib	• Tramadol
• Indinavir	• Vinca alkaloids
• Lamotrigine	• Zidovudine
• Methotrexate	

* Includes furosemide.
† Not to be confused with red man syndrome due to rapid infusion of drug.
‡ For additional drugs, see ref. 11.

Table 10.3 Drugs associated with erythroderma.

Fig. 10.5 Idiopathic erythroderma. This is the type of patient that requires longitudinal evaluation to exclude the development of cutaneous T-cell lymphoma.

Fig. 10.6 Erythroderma secondary to pityriasis rubra pilaris. A few islands of sparing are noted on the upper back (**A**), but are more noticeable on the flank and breast (**B**). Note the salmon color.

Fig. 10.7 Erythroderma due to pityriasis rubra pilaris. Large thin scales are seen as well as the characteristic orange–red color.

Cutaneous T-cell lymphoma

Erythroderma due to CTCL is subdivided into Sézary syndrome and erythrodermic mycosis fungoides (see Ch. 120). Sézary syndrome is defined by the triad of erythroderma, circulating malignant T lymphocytes, and generalized lymphadenopathy. Additional clinical features include a painful and fissured keratoderma, diffuse alopecia, and leonine facies. The skin may be quite infiltrated or hyperpigmented (melanoerythroderma), and severe pruritus is common. To aid in distinguishing between Sézary syndrome and erythrodermic mycosis fungoides, revised criteria were recently proposed by the International Society of Cutaneous Lymphomas and the Cutaneous Lymphoma Task Force of the EORTC for the diagnosis of Sézary syndrome – erythroderma and evidence of a T-cell clone in the blood plus one of the following: (1) ≥1000 Sézary cells/mm^3; (2) a CD4:CD8 ratio of ≥10:1; or (3) an increased percentage of CD4$^+$ cells with an abnormal phenotype (≥40% CD4$^+$/CD7$^-$ or ≥30% CD4$^+$/CD26$^-$)[14].

Pityriasis rubra pilaris

Erythrodermic pityriasis rubra pilaris (PRP) can be observed in children and adults (see Ch. 9). Usually, the lesions have a salmon to orange–red color (Fig. 10.6A). The degree of scaling varies, but it can be marked with large scales (Fig. 10.7). The combination of follicular keratotic papules on the knees, elbows and dorsal aspects of the fingers plus nappes claires (islands of uninvolved skin within the erythroderma) favors the diagnosis of PRP (Fig. 10.6B). When the classic histologic features are present (see below), this is also helpful in distinguishing PRP from psoriasis. Occasionally, CTCL can have an appearance similar to PRP.

Paraneoplastic erythroderma

Paraneoplastic erythroderma is most commonly associated with lymphoproliferative malignancies, including types of T-cell lymphoma other than Sézary syndrome. In the case of solid-organ malignancies, the erythroderma usually appears late in the course of the disease. Fine scales and erythema can be accompanied by a brownish hue (i.e. melanoerythroderma). Additional signs of malignancy, such as cachexia or fatigue, may be seen.

Bullous dermatoses

Among the bullous dermatoses, pemphigus foliaceus most commonly presents as erythroderma; erythrodermic forms of paraneoplastic pemphigus and bullous pemphigoid are rare (see Table 10.1; see also Chs 29 & 30). In pemphigus foliaceus, impetigo-like blisters and erosions are followed by collarettes of scale and scale-like crusts (Fig. 10.8). Usually, the erythroderma is preceded by localized lesions on the face and upper trunk.

Ichthyoses

Erythroderma due to one of the inherited ichthyoses is usually present from birth or infancy. In neonates, one must consider congenital ichthyosiform erythroderma (CIE; previously referred to as non-bullous CIE), epidermolytic ichthyosis (previously referred to as bullous CIE), and Netherton syndrome (see Table 10.2; see also Ch. 57). As a rule, CIE presents as a collodion baby (90% of the cases)[15]. Within a few days after birth, an erythroderma with fine white scaling appears. Epidermolytic ichthyosis initially presents as generalized erythema with superimposed superficial blisters and erosions. This disorder may be mistakenly diagnosed as staphylococcal scalded skin syndrome or as a form of epidermolysis bullosa. Later, children develop spiny, corrugated hyperkeratoses, particularly in flexural areas, and blisters and erosions become less prevalent. Netherton syndrome manifests as an ichthyosiform erythroderma in neonates. It is associated with trichorrhexis invaginata ("bamboo hair"), elevated serum levels of IgE, and an immune defect that can result in life-threatening infections, particularly within the first years of life. Later, either the ichthyosiform erythroderma persists or ichthyosis linearis circumflexa develops, which is characterized by garland-like scaly eruptions.

Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome (SSSS; see Ch. 74) is seen primarily in children (<5 years of age), and it is due to a circulating

Fig. 10.8 Erythroderma due to pemphigus foliaceus. Generalized erythema with widespread scale-crusts and large areas of erosion.

exfoliative toxin produced by *Staphylococcus aureus*. Since desmoglein 1 is cleaved by exfoliative toxin A, pemphigus foliaceus and SSSS exhibit clinical similarities, with the latter often becoming erythrodermic. Common foci for the initial infection include the nares, nasopharynx, conjunctivae and umbilicus. After a period of 1–2 days of a low-grade fever, large areas of tender erythema develop. The skin appears tense and subcorneal blisters appear, which subsequently desquamate. A very similar syndrome, the toxic shock syndrome, can be caused by staphylococcal or streptococcal exotoxins. It favors adults, but acral exfoliation has a delayed appearance, usually 2 weeks later.

Omenn syndrome

Omenn syndrome represents an autosomal recessive form of severe combined immunodeficiency (see Ch. 60), and it is characterized by failure to thrive, leukocytosis with prominent eosinophilia, hypogammaglobulinemia, and elevated serum IgE levels. Cutaneous findings, which appear in neonates, are generally the first sign of the syndrome and include an erythroderma with diffuse alopecia. Systemic manifestations include prominent lymphadenopathy, hepatosplenomegaly and recurrent diarrhea. In the absence of hematopoietic stem cell or bone marrow transplantation, the disease is rapidly fatal with recurrent infections.

PATHOLOGY

Although sometimes subtle, histopathologic features of the underlying disease are present in about two-thirds of patients. Diagnostic findings were frequently found in psoriasis (81% of 16 patients in one series)[16], but less often in PRP or CTCL (50% of 6 and 8 patients, respectively). Erythroderma due to drug hypersensitivity and dermatitis had typical pathologic findings in 67% (4 of 6) and 64% (9 of 16) of patients, respectively[16]. Specific histopathologic clues to the underlying disease are discussed below.

Psoriasis

In 60% of erythroderma patients diagnosed as having psoriasis, changes associated with "early" psoriasis are found[17]. These findings include slight epidermal hyperplasia, a reduced or absent granular layer, focal parakeratosis, an edematous papillary dermis, and a perivascular and interstitial lymphohistiocytic infiltrate. Sometimes, extravasated erythrocytes can be observed. Epidermal hyperplasia with bottleneck-like rete ridges, confluent parakeratosis, absence of the granular layer, elongated dermal papillae, and a sparse lymphohistiocytic infiltrate define the fully developed plaque form of psoriasis, and appear in 30% of patients with psoriatic erythroderma. Ten percent of patients with psoriatic erythroderma exhibit findings of regressing psoriasis (i.e. slight epidermal hyperplasia, a normal or even thickened granular layer, and a fibrotic papillary dermis)[17].

Atopic dermatitis

A constant finding in atopic erythroderma is mild to moderate spongiosis, which is sometimes located in the follicular infundibulum. However, spongiosis is found in other forms of dermatitis, including contact dermatitis. Almost always, acanthosis and parakeratosis are additional histologic features. A perivascular, rarely epidermotropic infiltrate is observed in the upper dermis; it is accompanied by dermal edema and prominent dermal vessels. In one series, numerous eosinophils were found within the infiltrate in 77% of patients[12].

Drug reactions

Histologically, changes vary considerably (see Ch. 21). Eosinophils may or may not be present.

Idiopathic erythroderma

The findings in idiopathic erythroderma are generally nonspecific. Subacute forms may have parakeratosis, acanthosis, spongiosis, papillary edema and a superficial perivascular lymphohistiocytic infiltrate, whereas chronic forms exhibit hyperkeratosis, psoriasiform acanthosis, little (if any) spongiosis and a thickened papillary dermis[9]. In order to identify the underlying disease in patients with idiopathic erythroderma, the submission of multiple biopsies from untreated affected skin (taken either simultaneously or sequentially) is advocated. Clinicopathologic correlation is important as sometimes there is evidence of two disorders, e.g. dermatitis superimposed upon psoriasis.

Cutaneous T-cell lymphoma

The histologic features of typical erythrodermic CTCL consist of a band-like infiltrate in the papillary dermis containing small to medium-sized (and occasionally large) mononuclear cells with hyperchromatic, cerebriform nuclei as well as a variable number of admixed inflammatory cells. Neoplastic cells, or sometimes groups of neoplastic cells, colonize the basal layer of the epidermis, and the cells are either evenly distributed or form Pautrier's microabscesses; the latter are pathognomonic but occur in a minority of cases. In contrast to circumscribed forms of mycosis fungoides, there is often less epidermotropism and the morphology of the neoplastic cells is sometimes more monotonous in erythrodermic mycosis fungoides and Sézary syndrome[18].

Pityriasis rubra pilaris

The characteristic histologic finding in PRP is foci of orthokeratosis alternating with parakeratosis in both vertical and horizontal directions. These features are also found in the follicular infundibula. A slight psoriasiform hyperplasia may be present, but the granular layer is normal and the rete ridges do not become thinned. In addition, a superficial and sparse interstitial infiltrate of lymphocytes is observed, and neutrophils are absent[17].

Ichthyoses

With the exception of epidermolytic hyperkeratosis in epidermolytic ichthyosis (bullous CIE), the histopathologic findings in ichthyosiform erythrodermas are generally non-diagnostic. In the non-bullous inflammatory type, psoriasiform hyperplasia, focal spongiosis and focal parakeratosis are found to a variable extent; a sparse perivascular lymphocytic infiltrate may be present.

Bullous dermatoses

The major histologic features of the bullous dermatoses are outlined in Table 10.1, as are the immunofluorescence microscopy findings. The latter are required for precise diagnosis (see Chs 29 & 30).

Staphylococcal scalded skin syndrome

Subcorneal blisters typically contain sparse acantholytic keratinocytes and few inflammatory cells.

Omenn syndrome

The histologic features of Omenn syndrome can resemble GVHD, with vacuolar degeneration of the basal layer and keratinocyte necrosis, but the former disorder is characterized by a denser dermal infiltrate of lymphocytes (as well as macrophages and eosinophils), acanthosis and parakeratosis. Degeneration of subcutaneous fat lobules may be observed. Examination of the enlarged lymph nodes shows an absence of lymph node architecture with massive infiltration of histiocytes and eosinophils.

DIFFERENTIAL DIAGNOSIS

Erythroderma is a clinical presentation for a variety of diseases, and identification of the underlying etiology represents one of the most complex challenges in dermatology (Figs 10.9 & 10.10; see Tables 10.1 & 10.2). The evaluation starts with a complete medical history: up to 45% of the patients will have a prior history of a more localized skin disease, and approximately 20% of cases represent drug reactions[1–6].

A comprehensive clinical examination may reveal additional clues to the underlying disease. Once the number of possible underlying diseases is reduced, further laboratory investigation can aid in establishing the final diagnosis.

TREATMENT

Erythroderma can represent a serious medical threat to the patient, therefore hospitalization may be required. Regardless of the underlying disease, the initial management consists of nutritional assessment, correction of fluid and electrolyte imbalances, prevention of hypothermia, and treatment of secondary infections. Sedating oral antihistamines may ease the often severe pruritus[9]. Systemic corticosteroids may be necessary in idiopathic erythroderma and drug reactions. With an initial dose of 1–2 mg/kg/day of prednisone, and a maintenance dose of 0.5 mg/kg/day or less, rapid and often continued clearing of the erythroderma can be achieved. Caution must be exercised upon tapering, as rebound may occur. Topical therapy includes open wet dressings and bland emollients or low-potency corticosteroid ointments. High-potency topical corticosteroids should be reserved for lichenified areas, and chronic, extensive application should be avoided. Coal tar ointments may aggravate the condition.

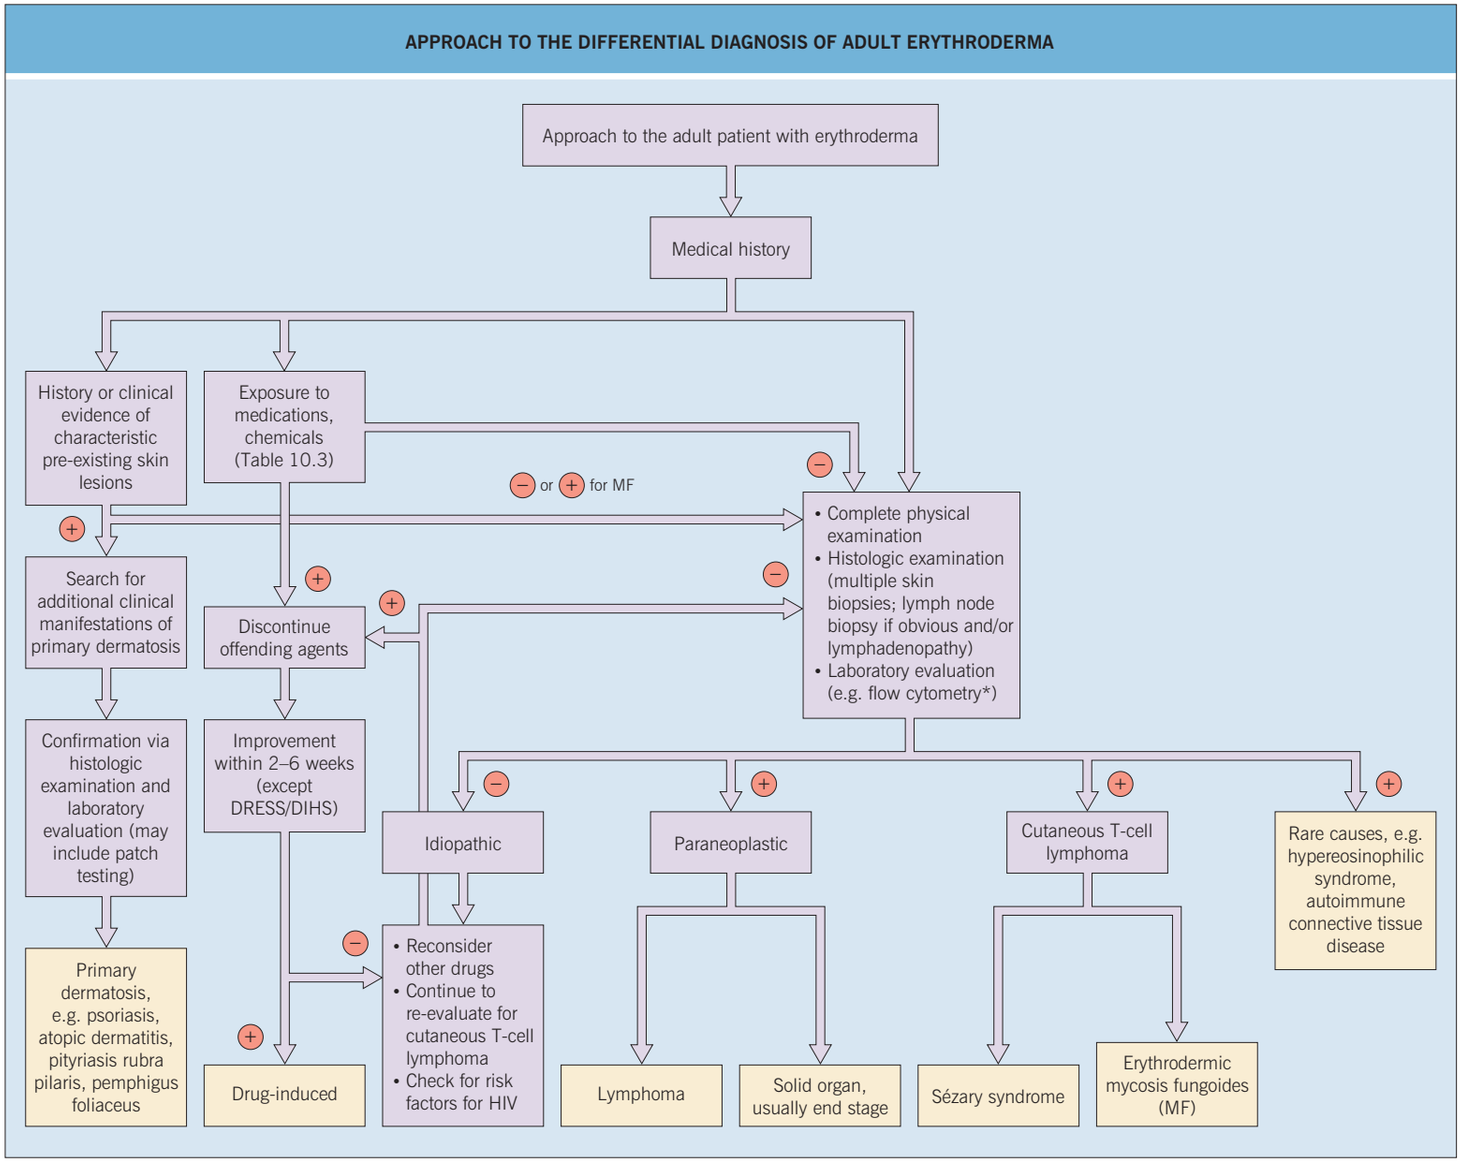

Fig. 10.9 Approach to the differential diagnosis of adult erythroderma. *Of peripheral blood and/or tissue. DRESS/DIHS, drug reaction with eosinophilia and systemic symptoms/drug-induced hypersensitivity syndrome.

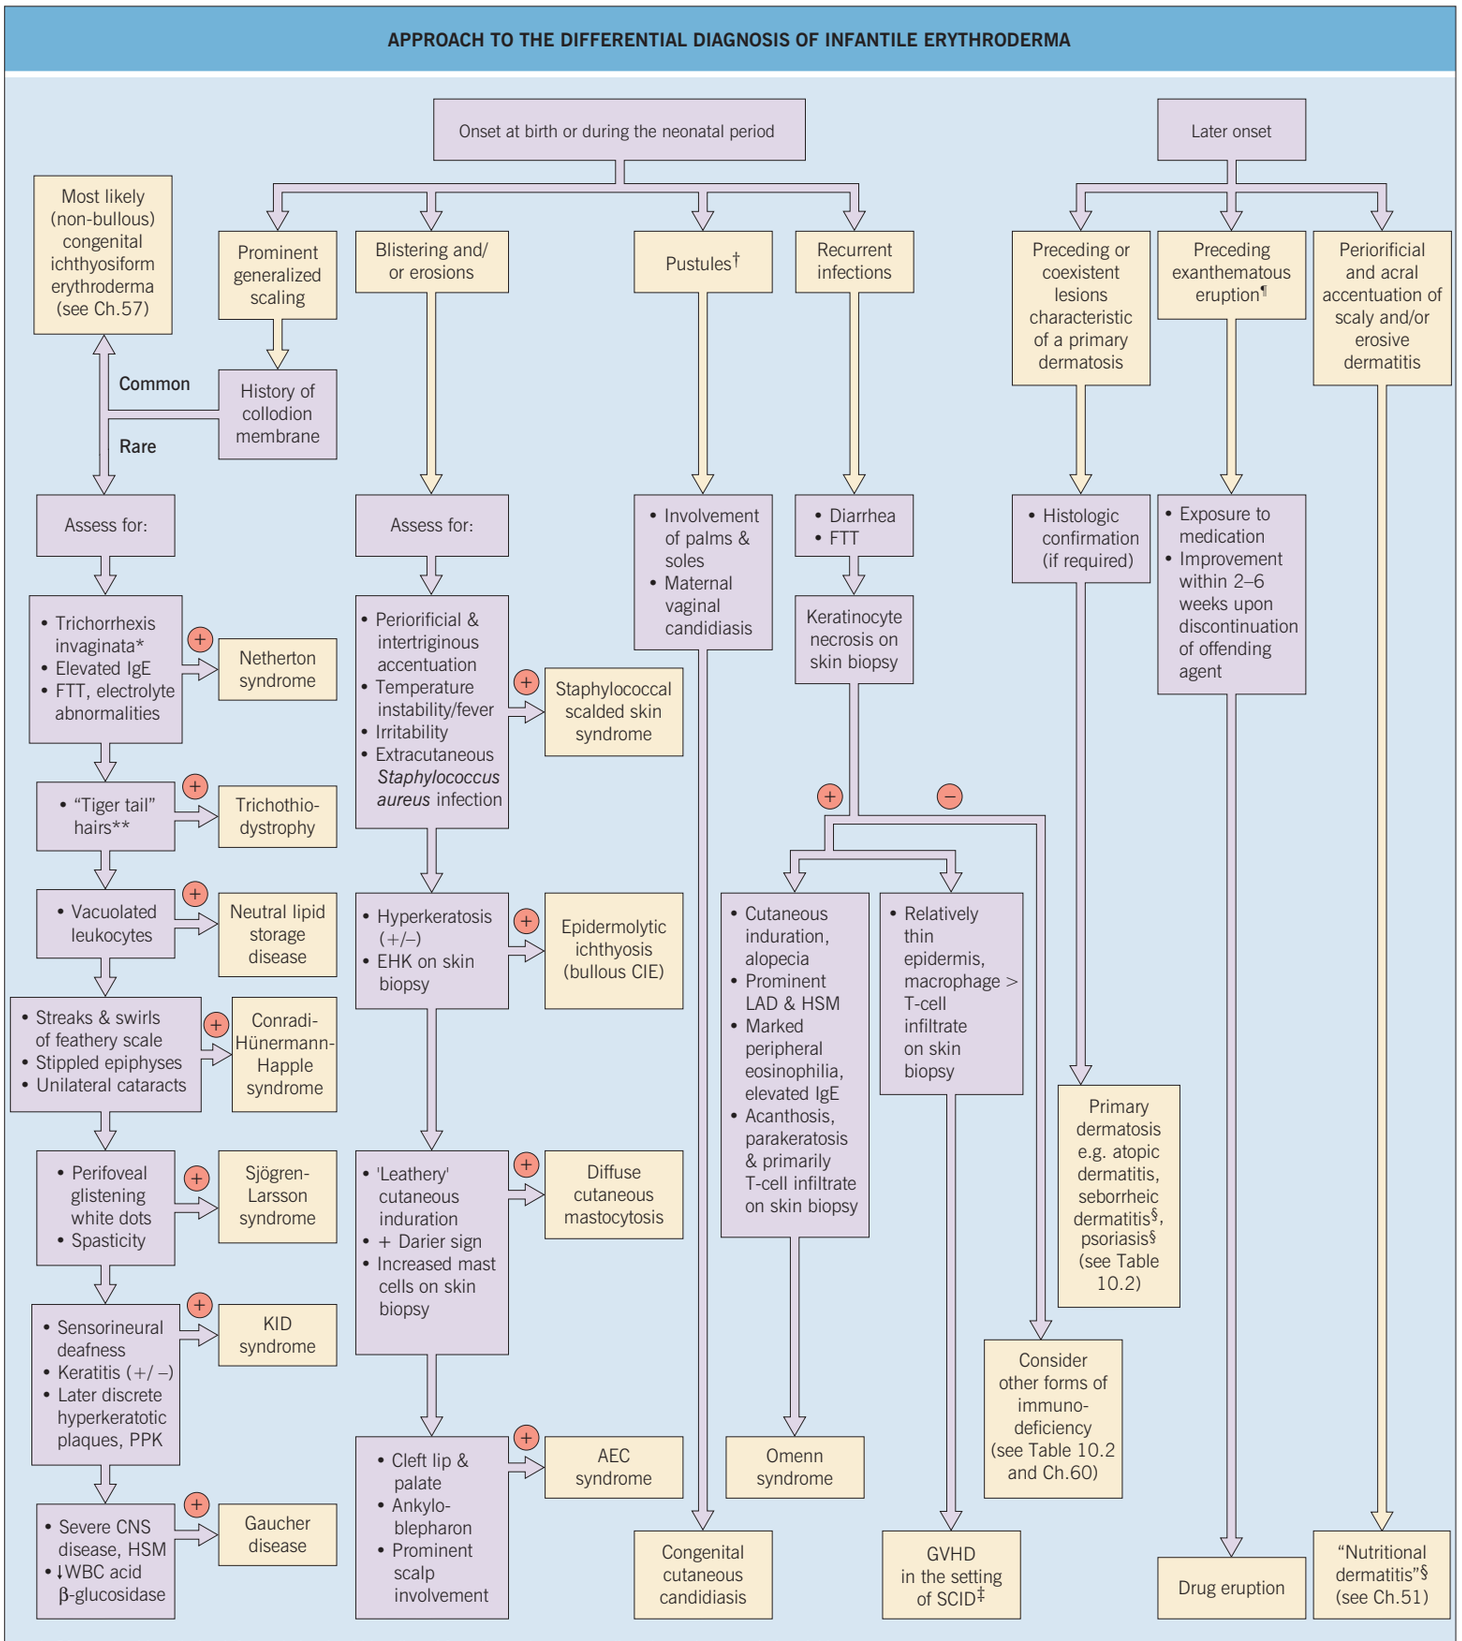

* Often not evident during infancy; hairs should be clipped from the eyebrows as well as the scalp to maximize yield.
** Detected in virtually all hairs in patients with trichothiodystrophy.
† The differential diagnosis includes pustular psoriasis.
‡ Maternal-fetal or transfusion-related GVHD can also occur outside the setting of SCID.
¶ Progression of a morbilliform eruption to erythroderma can also characterize neonatal toxic shock-like exanthematous disease and GVHD.
§ Earlier onset is occasionally observed.

AEC, ankyloblepharon-ectodermal dysplasia-clefting; CIE, congenital ichthyosiform erythroderma; CNS, central nervous system; EHK, epidermolytic hyperkeratosis; EHK, epidermolytic hyperkeratosis; FTT, failure to thrive; GVHD, graft-versus-host disease; HSM, hepatosplenomegaly; KID, keratitis-ichthyosis-deafness; LAD, lymphadenopathy; PPK, palmoplantar keratoderma; SCID, severe combined immunodeficiency

Fig. 10.10 Approach to the differential diagnosis of infantile erythroderma.

In neonates and children with erythroderma, management of fluid and electrolyte balance is critical in order to prevent hypernatremic dehydration. Emollients, topical antibiotics and, depending upon the extent and severity of the secondary infections, systemic antibiotics are administered. Due to increased transcutaneous absorption, topical salicylic and lactic acid should be avoided[19].

Treatment of specific underlying diseases is outlined in the respective chapters (see Tables 10.1 & 10.2). In the case of psoriatic erythroderma, administration of methotrexate, acitretin, cyclosporine or targeted immunomodulators (biologic agents) is preferred over systemic corticosteroids, given the risk of a pustular flare when corticosteroids are tapered[20]. For drug reactions, following the discontinuation of all non-essential drugs and all suspected drugs, erythroderma usually improves within 2–6 weeks (with the exception of some patients with DRESS/DIHS). However, systemic prednisone (1–2 mg/kg/day) or even the administration of IVIg may be useful in severe cases. After careful exclusion of any underlying cause, idiopathic erythroderma may be treated with low-potency topical corticosteroids and oral antihistamines. In refractory cases, cyclosporine has been used successfully, with an initial dosage of 5 mg/kg/day, and subsequent reduction to 1–3 mg/kg/day. Additional steroid-sparing agents include methotrexate, azathioprine and mycophenolate mofetil, all of which have been used anecdotally, with dosages similar to those for recalcitrant atopic dermatitis. There are a few case reports of the use of etanercept.

LICHEN PLANUS

Synonym: ■ Lichen ruber planus

Key features

- Idiopathic inflammatory disease of the skin, hair, nails and mucous membranes, seen most commonly in middle-aged adults
- Flat-topped violaceous papules and plaques favoring the wrists, forearms, genitalia, distal lower extremities and presacral area
- Clinical variants include annular, bullous, hypertrophic, inverse, linear, ulcerative, vulvovaginal–gingival, drug-induced and lichen planopilaris
- Some lichenoid drug eruptions have a photodistribution, while others are clinically and histologically indistinguishable from idiopathic lichen planus
- The most commonly incriminated drugs include angiotensin-converting enzyme (ACE) inhibitors, thiazide diuretics, antimalarials, quinidine and gold
- Histologically, there is a dense, band-like lymphocytic infiltrate and keratinocyte apoptosis with destruction of the epidermal basal cell layer
- In this T-cell-mediated autoimmune disorder, basal keratinocytes express altered self-antigens on their surface

Introduction

Lichen planus (LP), the prototype of lichenoid dermatoses, is an idiopathic inflammatory disease of the skin and mucous membranes. Classic LP is characterized by pruritic, violaceous papules that favor the extremities[1]. Histologically, a dense, band-like lymphocytic infiltrate is seen underlying an acanthotic epidermis with hypergranulosis, apoptosis, and destruction of the basal cell layer. The etiology and pathogenesis of LP are not fully understood, but the disorder has been associated with multiple environmental exposures, including viral infections, medications, vaccinations and dental restorative materials. LP-like lesions that resemble idiopathic LP may also develop in chronic GVHD, where alloreactive T cells that recognize foreign major histocompatibility complex (MHC) molecules are central effectors (see Ch. 52). This lends support to the hypothesis that an autoimmune reaction against epitopes on lesional keratinocytes that have been modified by viral or drug antigens may be responsible for this disorder.

Lichenoid eruptions represent a heterogeneous group of conditions that resemble idiopathic LP in terms of their clinical appearance and histologically demonstrate a lichenoid tissue reaction. The latter is a pattern characterized by vacuolar alteration of epidermal basal cells intimately associated with a band-like infiltrate of primarily lymphocytes in the papillary dermis. Many clinically distinct inflammatory dermatoses have in common varying elements of these lichenoid histologic features, and they are referred to as lichenoid dermatoses (Table 11.1).

History

The term lichen planus was initially introduced by Erasmus Wilson in 1869 to describe the condition that had been previously named leichen ruber by Hebra[1].

Epidemiology

Although its incidence varies depending upon geographic locale, cutaneous LP has been reported to affect from 0.2% to 1% of the adult population[1], whereas oral lesions have been observed in up to 1–4% of the population. There is no overt racial predisposition. The onset of LP occurs most commonly during the fifth or sixth decade, with two-thirds of patients developing the disease between the ages of 30 and 60 years. LP is rare in both infants and the elderly and, in general, only 1–4% of patients are children. However, more recent studies have suggested that LP may actually be more common in children, especially in Arab populations. Oral LP is also quite uncommon in young people and it usually affects middle-aged to elderly individuals (mean age at diagnosis being 52 years). Although LP is frequently thought to have no gender predilection, some studies have found that women were affected approximately twice as often as men.

Mucosal involvement, particularly oral lesions, may be observed in up to 75% of patients with cutaneous LP, but the former can be the only manifestation of the disease. Only 10–20% of patients whose initial presentation is oral LP will eventually develop cutaneous LP. Although reports of familial LP are rare, it may occur more frequently than previously thought; for example, LP occurs in up to 10% of first-degree relatives of affected patients. Cases of familial LP have been noted to have an earlier age of onset, a higher relapse rate, and more frequent oral mucosal involvement. Nonetheless, reports of concurrent LP in monozygotic twins who were living together suggest an environmental trigger.

Pathogenesis

There is a growing body of evidence that LP represents T-cell-mediated autoimmune damage to basal keratinocytes that express altered self-antigens on their surface.

Target antigens

Clinical observations and anecdotal evidence have long suggested a relationship between exposure to a number of exogenous agents (e.g. viruses, medications, contact allergens) and the development of LP (see Table 11.1). A critical component for the generation of effector T cells with cytotoxic potential is the presentation of these exogenous antigens in the context of antigen-presenting cells.

Hepatitis C virus

Of the many potential exogenous antigens, greater attention has been focused on the possible role of viruses, particularly hepatitis C virus

MAJOR LICHENOID DERMATOSES AND POSSIBLE ASSOCIATED TARGET ANTIGENS	
Lichenoid dermatoses	**Possible target antigens**

Table 11.1 Major lichenoid dermatoses and possible associated target antigens. The variation in clinical presentations may reflect the differences in the effector mechanisms by which epidermal cells are damaged and/or target antigens. The shaded entities are discussed in this chapter. Allo, alloantigens; Auto, autoantigens; C, contact allergens; D, drug antigens; T, tumor antigens; V, viral antigens.

(HCV). In several case–control studies, the prevalence of HCV (3.4–38%) was 2- to 13.5-fold higher in patients with LP than in controls. This association seems to be strongest in Japanese and Mediterranean populations, probably due to the high prevalence of HCV infection in these countries. In the US, one case–control study found that 12 (55%) of 22 patients with LP had anti-HCV antibodies, and this was significantly higher than the 25% of 40 psoriatic patients or the 0.17% of blood donors who tested positive[2]. While it may still be premature to conclude that HCV infection and LP are causally related, a recent systematic review and meta-analysis of existing epidemiologic studies demonstrated that an association between LP and HCV infection did exist in certain geographic regions (e.g. East and Southeast Asia, South America, the Middle East, Europe), but not in others (e.g. North America, South Asia, and Africa)[3]. It remains to be determined whether HCV infection precedes the development of LP and is directly involved in its pathogenesis.

Of the various types of LP, it is the oral form that is most commonly viewed as a manifestation of HCV infection. The PCR technique (see Fig. 3.3) detected HCV RNA in 93% of oral LP lesions[4], suggesting HCV replication within LP lesions; however, this result was not confirmed by a less sensitive immunoperoxidase staining procedure or by other PCR studies. In addition, the effects of anti-HCV therapy (e.g. a combination of interferon and ribavirin) are highly variable; some LP lesions actually appeared or flared during therapy. Possible explanations for these conflicting results include detection of HCV RNA simply reflecting the absorption of antibody-coated viral particles onto the cell surface membrane (supported by the inability to consistently detect HCV genomic sequences), HCV merely acting as a triggering factor in predisposed individuals, and technical difficulties due to the genomic diversity of HCV.

Of note, an increased frequency of the HLA-DR6 allele has been reported in Italian patients with HCV-associated oral LP[5], raising the possibility that $CD4^+$ T cells activated upon recognition of HCV-encoded peptides bound to HLA-DR6 molecules could be directly involved in the pathogenesis of LP. In support of this possibility, HCV tetramer analysis has shown that HCV-specific $CD4^+$ and/or $CD8^+$ T cells are present with higher frequency in oral LP lesions compared with the circulating compartment, suggesting that they play a role in the pathogenesis of LP[6].

Other viruses

With regard to the role of other viruses in LP, human herpesvirus *(HHV)-6* was detected in 67–100% of oral LP lesions by *in situ* hybridization and immunohistochemical techniques when it was absent from normal oral tissues. In addition, a retrospective survey of 18 lesional LP tissue samples (as well as 11 non-lesional LP and 11 lesional psoriasis samples) found that 11 of the 18 lesional LP samples contained *HHV-7* DNA as compared to 1 of 11 and 2 of 11 non-lesional LP and lesional psoriasis samples, respectively[7]. Remission of LP was associated with decreased HHV-7 protein expression, in particular within infiltrating plasmacytoid dendritic cells[8]. There are also sporadic case reports of LP lesions developing in areas recently affected by herpes simplex virus (*HSV*) or varicella zoster virus (*VZV*) infections[9], although the presence of these viruses in the lesions was not confirmed by PCR and a Koebner phenomenon represents a possible alternative explanation. Even when viral DNA is detected within LP lesions, it may simply represent a previous (unrelated) local infection, or a systemic or even distant site infection, rather than proof of causation.

While measurements (via PCR) of viral genomes within lesional skin or blood have been inconclusive, virus-specific T cells are present within lesions. This suggests that the pathology is a direct consequence of immune responses (perhaps to virally induced alterations in the antigenicity of epidermal cells; see below) rather than the viruses themselves. It is also possible that virus-specific T cells are nonspecifically trapped within sites of inflammation, having been activated systemically or locally at distant sites, and then they expand and mediate tissue damage "accidently" due to cross-reactivity with other antigens (e.g. drugs)[10].

Vaccines

A number of reports have described the appearance of LP after administration of different types of HBV vaccines[11]. The time interval between the initial dose and the development of cutaneous or mucosal lesions has varied from a few days to 5 months. Interestingly, a bullous variant was reportedly observed in five of 18 pediatric patients, in whom LP is generally rare. It is possible that HBV-reactive T cells cross-react with epitopes expressed on keratinocytes. One recommendation is that patients who develop LP before completing their vaccination series should avoid further injections because of an increased risk of developing severe LP lesions.

Bacteria

Studies investigating a possible bacterial connection in LP have been limited. Specifically, studies have not supported a definitive etiologic role for *Helicobacter pylori* in LP.

Contact allergens

The role of contact allergy to a variety of metals in the exacerbation or induction of oral LP has been well described, based on exposure to metallic dental restorations or constructions, positive patch test results, and then regression or complete clearing after removal of the sensitizing metal and replacement with other materials. Because involved allergens are dissolved and spread via saliva, mucosal reactions may extend beyond the contact areas. The metals that aggravate oral LP include amalgam (mercury), copper and gold. Although approximately 95% of patients had improvement after removal of the sensitizing metal, 75% of patients with negative patch test results also reported clearing of oral LP after removal of the metal and replacement with other materials. Such results indicate that spontaneous remissions may occur and draw into question the importance of contact allergy to metals in the pathogenesis of LP. Nevertheless, some authors have argued that even in patients who improved after the removal but had negative patch test results, mercury may have acted as an irritant factor in the pathogenesis of LP (via the Koebner phenomenon).

The development of contact allergy to metals within dental restorations in patients with LP could be explained by easy penetration of the metal via damaged mucosa. Thus, contact allergy to dental amalgam restorations should be suspected and patch tests should be performed in patients with oral LP, especially if the lesions are in close contact with amalgam fillings.

DRUGS IMPLICATED IN LICHENOID DRUG ERUPTIONS

ANTIMICROBIALS
- Ethambutol
- Griseofulvin
- Isoniazid
- Ketoconazole
- Pyrimethamine
- Streptomycin
- Sulfamethoxazole
- Tetracyclines

ANTIHYPERTENSIVES
- **Captopril**
- **Enalapril**
- **Labetalol**
- **Methyldopa**
- **Propranolol**
- Diazoxide*
- Doxazosin
- Prazosin

ANTIMALARIALS
- **Chloroquine**
- **Hydroxychloroquine**
- **Quinacrine**

ANTIDEPRESSANTS, ANTIANXIETY DRUGS, ANTIPSYCHOTICS AND ANTICONVULSANTS
- Amitriptyline
- Carbamazepine
- Chlorpromazine
- Imipramine
- Levomepromazine
- Lorazepam
- Methopromazine
- Phenytoin

TNF-α INHIBITORS
- Adalimumab
- **Etanercept**
- **Infliximab**
- Lenercept

DIURETICS
- **Chlorothiazide**
- **Hydrochlorothiazide**
- Furosemide
- Spironolactone

HYPOGLYCEMIC AGENTS
- Chlorpropamide
- Glyburide
- Tolazamide
- Tolbutamide

METALS
- **Gold salts**‡
- Arsenic
- Bismuth
- Mercury
- Palladium

NSAIDS
- Acetylsalicylic acid
- Benoxaprofen
- Diflunisal
- Fenclofenac
- Flurbiprofen
- Ibuprofen
- Indomethacin

Table 11.2 Drugs implicated in lichenoid drug eruptions. More commonly associated drugs are in **bold**. NSAIDs, nonsteroidal anti-inflammatory drugs.

Drugs

Cutaneous eruptions similar or even identical to LP (both clinically and histologically) have been linked to a variety of drugs. The terms "lichen planus-like" and "lichenoid" are often used to describe this phenomenon[12]. A wide variety of drugs have been associated with lichenoid drug eruptions and the list of such drugs steadily increases (Table 11.2). However, recurrence of the lesions subsequent to drug rechallenge has not been documented for the majority of these drugs. The mechanism by which certain drugs can induce a lichenoid tissue reaction in susceptible hosts is unknown, but appears to be similar to LP.

Autoantigens

In occasional patients, LP has been reported as a possible autoimmune reaction triggered by an underlying neoplasm. Also, a lichenoid tissue reaction is seen in patients with paraneoplastic pemphigus. The temporal relationship between LP and the underlying neoplasm in the reported patients suggests that the neoplasms may have stimulated a cell-mediated immune response against tumor antigens that led to the generation of autoreactive T cells that cross-reacted against antigens expressed on epidermal cells.

Although numerous case reports describe patients with both LP and autoimmune diseases, studies with larger numbers of patients with LP have shown no increased incidence of autoimmune diseases. Many investigators have described a significant association between specific HLA antigens and LP; for example, an increased frequency of HLA-B27, HLA-B51, HLA-Bw57 (oral LP in English patients), HLA-DR1 (cutaneous and oral LP), HLA-DR9 (oral LP in Japanese and Chinese patients) and HLA-DR6 (HCV-associated oral; see above). However, a true association with a particular HLA allele has been difficult to establish because of significant geographic heterogeneity and clinical patient selection.

A murine model of LP has been established by employing autoreactive T cells capable of producing interferon- γ (IFN-γ) and tumor necrosis factor-α (TNF-α) (Fig. 11.1)[13]. Intradermal inoculation of $CD4^+$ autoreactive T-cell clones into the footpads of syngeneic mice can induce local histologic changes similar to LP or lichenoid skin diseases. In this model, the autoreactive T cells can respond to self MHC class II antigens constitutively expressed on macrophages and Langerhans cells, and they migrate into the epidermis, resulting in epidermal injury. These T cells, therefore, can induce LP-like lesions without any alteration in the antigenicity of the epidermis. However, in the natural disease process, exogenous agents (e.g. viral infections, drugs) could induce alterations in the antigenicity of epidermal cells and trigger the activation of T cells. Of note, such autoaggressive reactions could function to eliminate abnormal keratinocytes altered by these exogenous agents. However, in the situation where T cells initially responding to self-antigens modified by exogenous agents subsequently become cross-reactive with some self-epitopes, these T cells would then chronically respond to the previously ignored self-epitopes, leading to perpetuation of an autoimmune attack by such T cells[13] rather than elimination of the abnormal keratinocytes.

Effector cells

There are conflicting data regarding the phenotype of the inflammatory infiltrate in LP lesions. Although initial immunohistochemical studies showed that the cellular infiltrate contained an increased ratio of $CD4^+$ to $CD8^+$ T cells[14], other investigators found a predominance of $CD8^+$ T cells, particularly in older lesions. Evidence to support the crucial role of $CD8^+$ T cells in autoimmune damage to basal keratinocytes has been provided by $CD8^+$ T cells isolated from lesional skin; these T cells exhibited specific cytotoxic activity against autologous lesional and normal keratinocytes[15]. One caution is that these $CD8^+$ T-cell lines and clones could represent an *in vitro* selection and/or expansion of autoreactive T cells during their culture with autologous antigen-presenting cells.

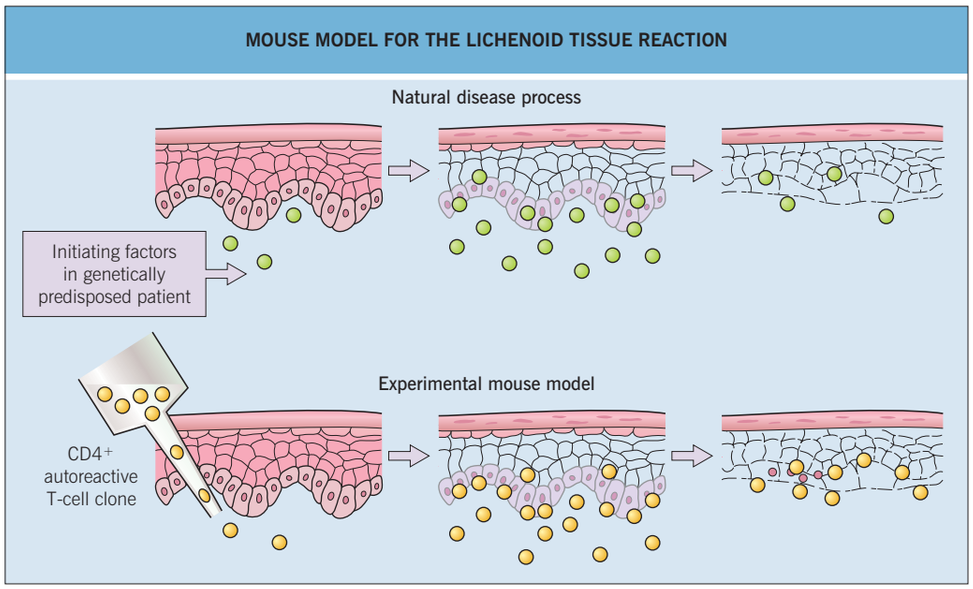

Fig. 11.1 Mouse model for the lichenoid tissue reaction. Because in humans all the analyses are performed on existing skin lesions (after the inflammatory response is underway), it is difficult to provide insight into initiating events and to establish whether the T cells present are indeed relevant to the pathogenesis. This experimentally induced animal model has the advantage that the orchestrated series of events resulting in epidermal injury can be examined from the onset and over time.

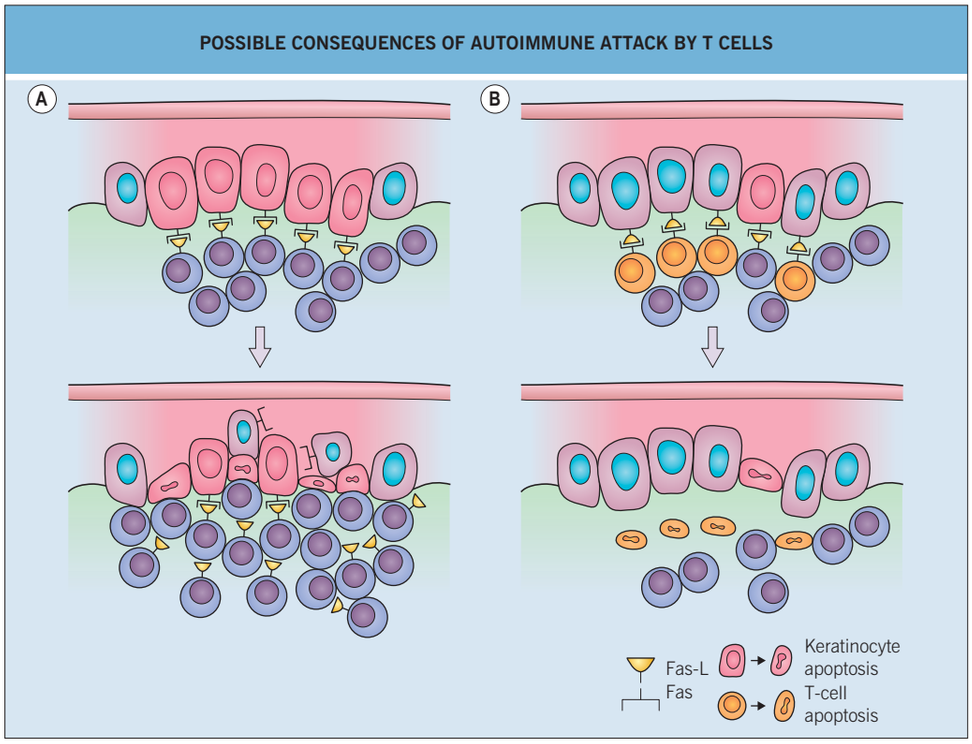

Fig. 11.2 Possible consequences of autoimmune attack by T-cells. A Activated memory T cells express Fas ligand (Fas L), which binds to Fas expressed on epidermal keratinocytes, resulting in apoptosis. Apoptosis can also be induced via the release of cytotoxic granules which contain perforin and granzyme B (see Ch. 20). Fas/Fas L and perforin/granzyme can independently trigger the cell death program, but the process leading to apoptosis is similar in both pathways. $CD8^+$ cytotoxic T cells and NK cells use both pathways.
B Because keratinocytes are not only targets but also produce granzyme B, perforin and Fas L to protect themselves from immune-mediated damage, Fas L-bearing keratinocytes can induce Fas/Fas L-mediated death in neighboring Fas-bearing T cells, contributing to the resolution of the lichenoid tissue reaction. This pathway serves to eliminate potentially harmful autoaggressive T cells. Thus, keratinocytes should not be viewed just as victims of the immune-mediated damage. Recovery from the inflammation is associated with the migration of regulatory T (Treg) cells into the site.

Basal cell damage as evidenced by apoptotic DNA fragments is greatest in the epidermis. A possible mechanism is illustrated in Figure 11.2 in which IFN-γ produced by $CD8^+$ T cells upregulates Fas expression by keratinocytes, rendering them susceptible to T-cell-mediated, Fas ligand-driven apoptosis. This interaction triggers a cascade of intracellular enzymatic reactions resulting in DNA fragmentation (see Ch. 107). In addition to Fas, death receptor-induced apoptosis involves signaling processes via TNF-R1, TRAIL-R1 and 2, and DR3 or DR6. Because type 1 helper T cells (Th1), like the autoreactive $CD4^+$ T cells in the murine model (see Fig. 11.1), can produce large amounts of IFN-γ and TNF-β upon activation and thereby induce or enhance the expression of apoptosis-associated proteins such as Fas and TRAIL, they may also play a role in extensive epidermal damage by promoting apoptotic death of keratinocytes. It is also likely that when epidermal damage is severe, perforin and granzyme are involved as well (see Ch. 20).

Additionally, IFN-γ and TNF-α, released by both $CD4^+$ T cells and $CD8^+$ T cells, can induce keratinocyte expression of ICAM-1, thereby rendering these T cells more adhesive to the keratinocytes and thus facilitating exocytosis of granules containing perforin and granzymes. Of note, these cytokines have been shown to be present at high concentrations in LP lesions. More recent studies have shown that granule exocytosis, rather than the Fas/Fas-ligand system, is the main pathway of cytotoxicity mediated by $CD4^+$ and $CD8^+$ T cells in humans[16]. However, a combination of the two mechanisms is most likely, with predominance depending upon the particular stage in the disease process.

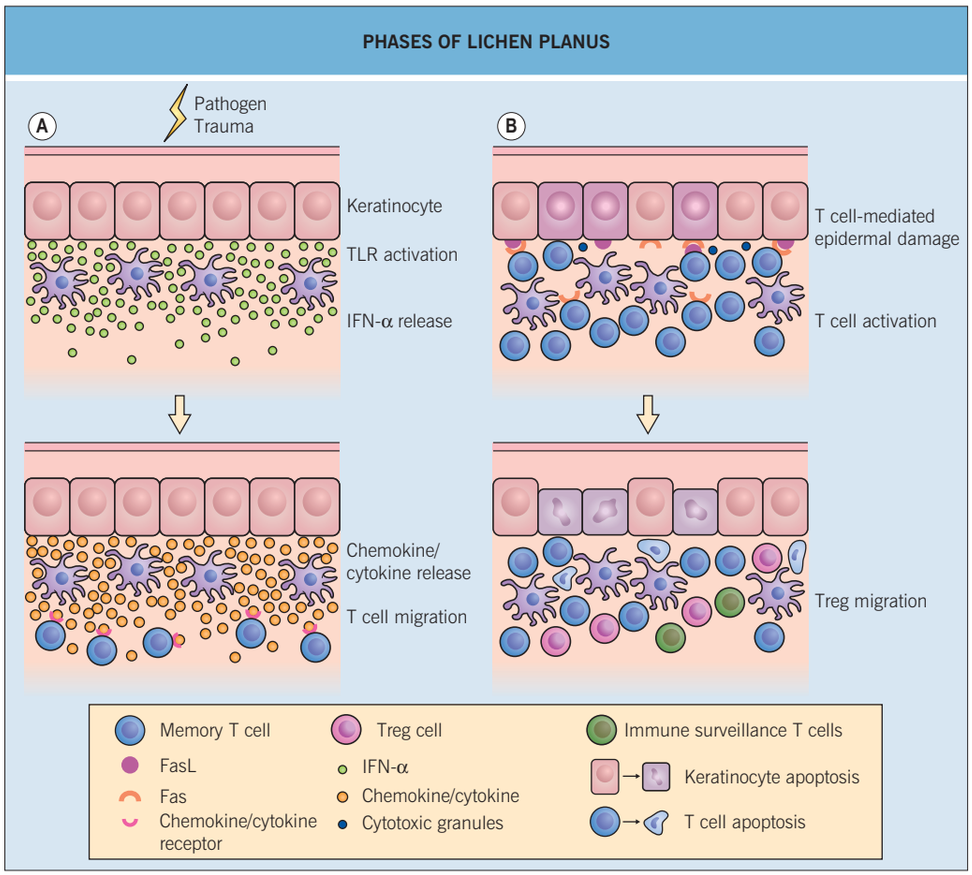

Fig. 11.3 Phases of lichen planus. A In the induction phase, keratinocytes and plasmacytoid dendritic cells (pDCs), upon stimulation of their Toll-like receptors (TLRs) by pathogens or endogenous ligands, can release type 1 IFNs (e.g. IFN-α); this represents an early event in the cascade leading to T-cell-mediated epidermal damage. Activated keratinocytes, via production of IL-1β and TNF-α, can induce activation and migration of DCs. Chemokines, such as IP10/CXCL10, released locally by pDCs, serve to attract CXCR3-expressing $CD8^+$ or $CD4^+$ effector memory T cells (which have differentiated from naive T cells within lymph nodes following presentation by DCs of self-peptides modified by exogenous antigens [viruses, medications and contact allergens]). Additional chemokine and chemokine receptor pairs have also been implicated in this process (see Table 11.3), and the precise mix of chemokines and cytokines released into the tissue plays an important role in determining the composition of the inflammatory infiltrates. **B** In the evolution phase, effector T cells (Te) that come to express skin-homing receptors (E-selectin ligands) migrate into the inflammatory site and upon recognition of antigens, are activated and release proinflammatory cytokines and cytotoxic granules, which in turn cause epidermal injury. In addition, Fas/FasL can trigger cell death (see Fig. 11.2). "Inflammatory" and "'homeostatic" chemokines produced by keratinocytes direct the traffic of not only "pathogenic" T cells (Te) but also "immune surveillance" T cells (Ts) or regulatory T cells (Treg) into the sites; the relative balance of chemokines produced may determine the outcome of the T-cell-mediated immune responses.

Effector T cells' access to the epidermis

A critical event in the initiation of immune responses in LP lesions is for memory T cells to migrate from the circulation into a particular skin site. Release of type 1 IFNs, such as IFN-α, from activated plasmacytoid dendritic cells (pDCs) and keratinocytes may be critical in inducing skin-directed migration of effector memory T cells (Fig. 11.3A). Stimulation of Toll-like receptors (TLRs) expressed on pDCs and keratinocytes by pathogens or endogenous ligands (released via skin damage) represents one of the earliest events and it is sufficient to induce type 1 IFN production. Type 1 IFN signaling and type 1 IFN-inducible chemokines (e.g. IP10/CXCL10) then serve to recruit chemokine receptor CXCR3-expressing effector memory T cells (Th1 cells) into the skin via CXCR3/IP10 interactions (Table 11.3). A number of other molecular interactions, such as CCR4/TARC, CCR10/CTACK and LFA-1/ICAM-1 expressed on T cells and keratinocytes, respectively, have also been implicated in the recruitment of memory T cells and pDCs to the dermal–epidermal junction[17–19]. Because IFN-α from pDCs induces IFN-γ production by T cells and IFN-γ also sustains IFN-α production, a positive feedback loop may be operational within LP lesions. This ordered sequence of events provides a possible explanation for why LP lesions develop within traumatized sites and virally induced lesions.

Although chemokines produced at inflammatory skin sites are thought to regulate the composition of the Th1- or Th2-driven cellular infiltrates, memory T cells with a "surveillance" function can also migrate to skin sites under non-inflamed conditions. "Homeostatic" chemokines constitutively produced under non-inflamed conditions can mediate the skin-directed migration of these "immune surveillance" T cells (Table 11.3), leading to clearance of invading pathogens such as viruses. In addition, $CD4^+$ regulatory T (Treg) cells that have the capacity to suppress activated T cells are also able to enter inflamed skin sites (Fig. 11.3B). Lastly, it should be noted that there is no definitive means of distinguishing "immune surveillance" T cells or protective regulatory T cells from "pathogenic" T cells in LP lesions.

While the epidermotropic migration of effector T cells leading to epidermal damage is clearly a complicated, multistep process, the latter can be bypassed (at least in part) in the case of fixed drug eruptions. This is because effector T cells responsible for the epidermal damage persist as a stable population in previously affected, but normal-appearing, skin. As a result, fixed drug eruption represents a simplified disease model for studying the pathogenesis of lichenoid tissue reactions, and the orchestrated series of events can be analyzed from prior to drug challenge to resolution of lesions (Fig. 11.4)[20].

Clinical Features

The characteristic primary lesion of LP is a small, polygonal-shaped, violaceous, flat-topped papule; some papules are umbilicated. The surface is slightly shiny or transparent, and a network of fine white lines called "Wickham's striae" (Fig. 11.5) or small gray–white puncta are also seen. The latter correspond histologically to focal thickening of the granular layer. The papules may be widely dispersed or they may cluster or coalesce into larger plaques (Fig. 11.6). LP is usually pruritic. Although the Koebner phenomenon (i.e. isomorphic response) is commonly seen in LP (Fig. 11.7), excoriations and impetiginization are unusual. Linear papules may be the initial presentation of the disease, presumably reflecting koebnerization into sites of previous trauma or scratching. However, such lesions need to be distinguished from the linear variant of LP which follows the lines of Blaschko (see below).

The most frequently involved sites are the flexor surfaces of the wrists and forearms; the dorsal surface of the hands, anterior aspect of the lower legs, neck and presacral area are also common sites. The mucous membranes, especially the oral mucosa (see below), are affected in more than half of patients, and this is often the only site of involvement. Lesions are also commonly seen on the glans penis, where they can have an annular or figurate configuration (Fig. 11.8A) and may become erosive. Several of the distinctive variants of LP are discussed separately.

The duration of the disease is dependent upon the LP variant. While the lesions of exanthematous LP typically resolve within a year,

CHEMOKINES AND CHEMOKINE RECEPTORS INVOLVED IN T-CELL MIGRATION INTO THE SKIN

Chemokines*	Chemokine receptors	Functional type of chemokines/T cells attracted†
RANTES (CCL5) MCP-2 (CCL8) Eotaxin-1, -2, -3 (CCL11,24,26)	CCR3	Inflammatory/Th2 cells
TARC (CCL17) MDC (CCL22)	CCR4	Inflammatory/Th2 cells
MIP-1α,β (CCL3,4) RANTES (CCL5) MCP-2 (CCL8)	CCR5	Inflammatory/Th2 cells
CCL1	CCR8	Homeostatic/memory T cells
CTACK (CCL27) MEC (CCL28)	CCR10	Homeostatic/memory T cells
MIG (CXCL9) IP-10 (CXCL10) I-TAC (CXCL11)	CXCR3	Inflammatory/Th1 cells
CXCL16	CXCR6	Inflammatory/Th1 cells

*Cytokines that have chemoattractant activity; two major groups are differentiated based on the position of two cysteine (C) residues compared with the other amino acid residues (X): CXC- or α-chemokines and CC- or β-chemokines.

†"Inflammatory" chemokines are produced at sites of cutaneous inflammation and mediate skin-directed migration of memory T cells (Th1, Th2); "homeostatic" chemokines are constitutively produced within non-inflamed skin and mediate skin-directed migration of memory T cells with an "immune surveillance" function.

Table 11.3 Chemokines and chemokine receptors involved in T-cell migration into the skin. Binding of MCP-1 (CCL2) to CCR2 on monocytes plays an important role in their recruitment to sites of cutaneous inflammation. CCR, receptor for CC chemokines; CTACK, cutaneous T-cell-attracting chemokine; CXCR, receptor for CXC chemokines; IP-10, interferon-inducible protein 10; I-TAC, interferon-inducible T cell α-chemoattractant; MCP-2, monocyte chemoattractant protein 2; MDC, macrophage-derived chemokine; MEC, mucosal-associated epithelial chemokine; MIG, monokine induced by interferon-γ; MIP-1α, macrophage inflammatory protein 1α; RANTES, regulated on activation normal T cell expressed and secreted; TARC, thymus- and activation-regulated chemokine.

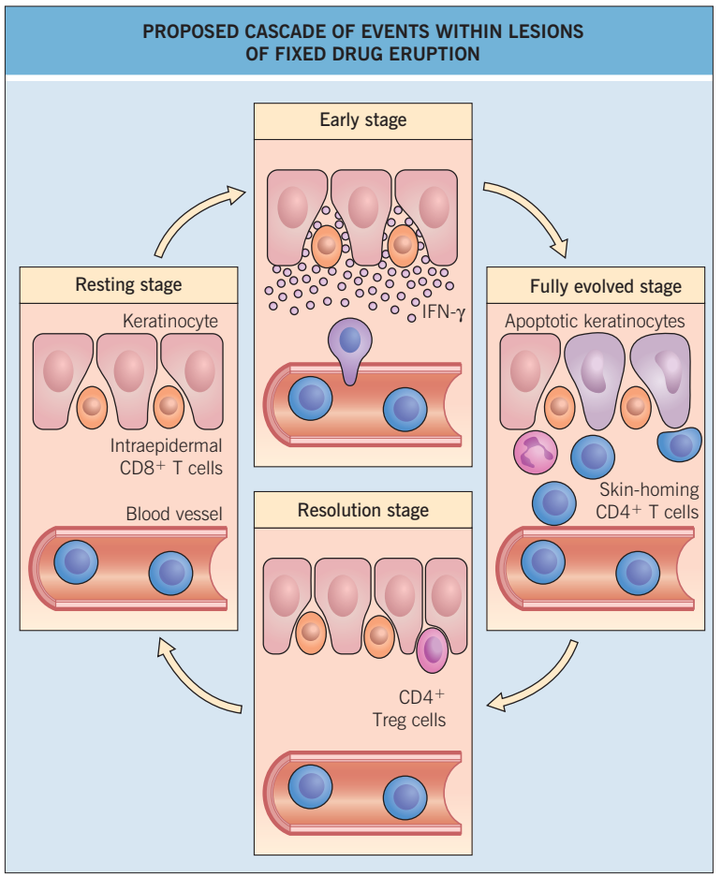

Fig. 11.4 Proposed cascade of events within lesions of fixed drug eruption (FDE). In resting lesions (previous sites of FDE but prior to drug challenge), intraepidermal CLA^+ $CD8^+$ T cells remain quiescent, but in a primed state as evidenced by CD69 expression. They also express TCR αβ, CD3, CD8, CD45RA and CD11β, but not CD27 and CD56, and therefore most closely resemble effector memory T cells. Upon administration of the causative drug, these T cells are activated to release IFN-γ and cytotoxic granules into the local environment. Nearby mast cells contribute to activation of the intraepidermal $CD8^+$ T cells by releasing TNF-α and inducing adhesion molecules on surrounding keratinocytes. In fully evolved lesions, keratinocytes are killed by the direct action of cytotoxic granules released from the $CD8^+$ T cells in concert with both $CD4^+$ effector T cells and neutrophils recruited from the circulating bloodstream. At the end of the immune response, Treg cells are recruited into the lesions and serve to ameliorate severity. Although the majority of activated cell populations are removed by apoptosis, a proportion of intraepidermal $CD8^+$ T cells is prevented from undergoing apoptosis by IL-15 (produced by surrounding keratinocytes) and persists as a stable population with a memory function. Treg, regulatory T cell.

hypertrophic, oral and nail LP tend to be more persistent. In particular, ulcerative oral LP may be a lifelong affliction.

Actinic LP

This variant is reported under a variety of names, including LP actinicus, LP subtropicus, LP tropicus and lichenoid melanodermatitis. Although the majority of reported patients have been from Middle Eastern countries, it has been observed worldwide. Most patients are young adults or children. There is no predilection for either sex. The onset of this variant is during the spring and summer, and the lesions primarily involve sun-exposed skin of the forehead and face, followed by the dorsal surfaces of the arms and hands and the neck. The lesions usually consist of red–brown plaques with an annular configuration, but melasma-like hyperpigmented patches have been observed. Summertime actinic lichenoid eruption (see below) has sometimes been regarded as a variant of or synonymous with actinic LP, but in the authors' opinion they are two separate entities with different histologic features.

Acute (exanthematous) LP

Because lesions are usually widely distributed and disseminate rapidly, this form is also known as exanthematous or eruptive LP. The commonly affected areas include the trunk (Fig. 11.9), the inner aspects of the wrists and the dorsal aspect of the feet. Reports in the literature of this form probably include lichenoid drug eruptions. The clinical course is usually self-limited and, in general, lesions resolve with hyperpigmentation within 3 to 9 months.

Annular LP

This form is thought to occur when papules spread peripherally and the central area resolves (see Fig. 11.8). The annular edge is slightly raised and typically purple to white in color, while the central portion is hyperpigmented or skin-colored; lesions can resemble granuloma annulare (except for the associated scale in annular LP). Annular lesions occur in about 10% of patients with LP and are usually scattered among more typical lesions, but the former may represent the predominant finding. The most common site of involvement is the axilla, followed by the penis (see Fig. 11.8A), extremities and groin. Most patients are asymptomatic, while some have pruritus.

Atrophic LP

Atrophic LP may represent a resolving phase of LP, given the history of the lesions: papules coalesce to form larger plaques that often, over time, become centrally depressed and atrophic with residual hyperpigmentation. The clinical appearance of atrophic LP is likely a result of thinning of the epidermis rather than degeneration of elastic fibers, and the epidermal atrophy may be accentuated by the use of potent topical corticosteroids. The most common site of involvement is the lower

extremity. This form closely resembles lichen sclerosus clinically (Fig. 11.10A); it may even mimic the early phase of morphea. Occasionally, morphea of the trunk has been reported in association with oral LP, as has the simultaneous occurrence of LP and lichen sclerosus, as well as the combination of LP, morphea and lichen sclerosus, the latter reflecting the well-known relationship between morphea and lichen sclerosus.

Recent reports have suggested the existence of another variant, referred to as "annular atrophic LP", in which there is complete loss of elastic fibers in the center (± the active borders) of the annular lesions.

Bullous LP and LP pemphigoides

Bullous or vesiculobullous lesions can develop solely within pre-existing LP lesions or more randomly, including within previously uninvolved skin. The former is called bullous LP (Fig. 11.10B), while the latter is referred to as LP pemphigoides (Fig. 11.10C).

A consensus has emerged that LP pemphigoides can be differentiated from bullous LP. In the latter, blisters occur in longstanding lesions of LP as a result of an intense lichenoid infiltration of lymphocytes and extensive epidermal damage, i.e. exaggerated Max-Joseph spaces. In contrast, in LP pemphigoides there are circulating IgG autoantibodies directed against the 180 kDa BP antigen (BPAG2, type XVII collagen), as in idiopathic BP. These findings suggest that damage to the basal layer by a lichenoid infiltrate may expose hidden antigens to the autoreactive T cells, leading to the formation of autoantibodies and subepidermal bullae. Indeed, LP pemphigoides evolving into pemphigoid nodularis has been described. To date, no reactivity against the 230 kDa BP antigen, type VII collagen or the laminin-5 subunits has been detected.

Hypertrophic LP

This variant is also referred to as LP verrucosus (Fig. 11.11). Extremely pruritic, thick hyperkeratotic plaques are seen primarily on the shins or dorsal aspect of the foot and may be covered by a fine adherent scale. The lesions are usually symmetric and tend to be chronic because of repetitive scratching. The average duration of hypertrophic LP in patients whose lesions had cleared was reported to be 6 years. Chronic venous stasis frequently contributes to the development of this condition. Squamous cell carcinoma may develop within a background of longstanding hypertrophic LP. It should be noted that there are patients who develop hypertrophic LP-like reactions with infundibulocystic follicular hyperplasia that may progress to multiple keratoacanthomas or follicularly based squamous cell carcinomas[21].

Inverse LP

In this unusual variant, an inverse distribution pattern is observed. Pink to violaceous papules and plaques appear in intertriginous zones (axillae > inguinal and inframammary folds; Fig. 11.12) and less often in the popliteal and antecubital fossae. Occasionally, LP lesions occur elsewhere on the body. Hyperpigmentation is usually present as well and it may be the sole manifestation, leading to overlap with LP pigmentosus.

LP pigmentosus

LP pigmentosus typically presents in individuals with skin types III and IV as brown to gray–brown macules in sun-exposed areas of the face and neck, usually with no preceding erythema and often evolving into diffuse or reticulated pigmentation (see Ch. 67). Involvement of intertriginous sites is occasionally observed, and a linear distribution following Blaschko's lines has also been described. Although the clinical and histologic (e.g. marked pigment incontinence and epidermal atrophy) features as well as the skin-type predilection of LP pigmentosus are similar to those of erythema dyschromicum perstans (see below), the former condition can be distinguished by its photo- and flexural distribution as well as an older mean age at onset (fourth to fifth versus first to third decades), a tendency for irregularly shaped or confluent rather than discrete oval lesions, and the coexistence of classic LP lesions in approximately 20% of patients.

Lichen planopilaris

In lichen planopilaris, involvement of the hair follicle is observed, both clinically and histologically. This variant is also called follicular LP and

Fig. 11.10 Unusual variants of lichen planus. A Atrophic lichen planus of the lower extremities. **B** Bullous lichen planus on the shin. **C** Lichen planus pemphigoides in a patient with anti-basement membrane zone autoantibodies.

Fig. 11.13 Lichen planopilaris. A Keratotic spines surrounded by a violaceous rim in a linear variant and **B** scattered on the trunk. **C** Cicatricial alopecia with "end-stage" changes centrally, but perifollicular inflammation at the margins.

LP acuminatus. Multiple, keratotic plugs surrounded by a narrow violaceous rim are observed primarily on the scalp, although other hair-bearing areas can also be affected (Fig. 11.13). The inflammatory process may result in scarring and loss of follicular structure, i.e. a permanent alopecia. Over time, the areas of involvement often "burn out" centrally and are indistinguishable from other causes of "end-stage" cicatricial alopecia (see Ch. 69). However, examination of the periphery may reveal the primary lesions (see Fig. 11.13C). Women are more frequently affected than men, and this form may occur alone or with typical LP lesions elsewhere.

A variant of lichen planopilaris known as Graham Little–Piccardi–Lassueur syndrome is characterized by the triad of: (1) non-cicatricial loss of pubic and axillary hairs and disseminated spinous or acuminated follicular papules (see Fig. 11.13B); (2) typical cutaneous or mucosal LP; and (3) scarring alopecia of the scalp with or without atrophy (see Fig. 11.13C). These features need not be present simultaneously. Another more recently recognized variant of LP of the scalp is frontal fibrosing alopecia which occurs primarily in elderly women.

Linear LP

Although linear lesions frequently occur in sites of scratching or trauma in patients with LP (as a result of the Koebner phenomenon), the term

linear LP (Fig. 11.14) is usually reserved for lesions that appear spontaneously within the lines of Blaschko (see Fig. 11.13A). Some authors consider linear LP an intermediate entity between LP and lichen striatus. This form has also been referred as zosteriform but the distribution pattern of LP is generally not dermatomal (with the exception of the koebnerization of LP into the site of a previous herpes zoster infection). The possibility exists that when LP has a strictly dermatomal pattern, this represents an isotopic phenomenon following "zoster sine herpete".

Although linear LP is usually seen in patients in their late 20s or early 30s, the initial presentation can be in the first to eighth decades. Presumably this pattern reflects somatic mosaicism (see Ch. 62), but how the involved and uninvolved skin differ is not known.

LP–lupus erythematosus overlap syndrome

Patients whose lesions have overlapping features of both LP and lupus erythematosus (LE) have been reported. These lesions are preferentially located in acral sites. Histologic and direct immunofluorescence (DIF) microscopic findings show features of both LP and LE. Whether systemic immunologic abnormalities such as high titers of ANA are present in these patients is controversial, but case reports suggest that some patients have disease at the chronic cutaneous LE end of the clinical spectrum while others meet the criteria for systemic LE.

Nail LP

The nails are affected in approximately 10% of patients with LP; usually, several nails are affected (see Ch. 71). The characteristic nail abnormalities include lateral thinning (Fig. 11.15A), longitudinal ridging, and fissuring (11.15B). These changes are manifestations of matrix damage, which can lead to scarring and dorsal pterygium formation (Fig. 11.15C) if left untreated. Nonspecific changes in the nail bed include yellow discoloration, onycholysis and subungual hyperkeratosis. In some patients, twenty-nail dystrophy may represent a variant of LP. Nail LP presenting as twenty-nail dystrophy is much more common in children than in adults, although other forms of nail involvement are extremely rare in children.

Fig. 11.14 Linear lichen planus. Coalescence of violaceous lesions with Wickham's striae along the lines of Blaschko on an extremity. Note the postinflammatory hyperpigmentation proximally. *Courtesy, Joyce Rico, MD.*

Oral LP

Oral LP can appear in at least seven forms, which occur separately or simultaneously: atrophic, bullous, erosive, papular, pigmented, plaque-like and reticular. The most common and characteristic form of oral LP is the reticular pattern (Fig. 11.16A). It is characterized by slightly raised whitish linear lines in a lace-like pattern or in rings with short radiating spines. This form is usually asymptomatic and the most common site of involvement is the buccal mucosa; lesions are often bilateral and symmetric. Gingival involvement is common, and oral LP affecting the gingivae exclusively is seen in approximately 10% of cases. It typically presents as chronic desquamative gingivitis. Gingivitis also occurs as a component of the "vulvovaginal–gingival syndrome" (see below).

Atrophic, erosive (Fig. 11.16B) and bullous lesions are associated with symptoms ranging from mild discomfort to severe pain. There is a higher incidence of plaque-like lesions among tobacco smokers. For unknown reasons, oral LP is very uncommon in young patients, and in some studies, women have been affected about twice as often as men.

Patients with oral LP should be questioned about symptoms related to esophageal involvement[21a] and examined for other mucosal lesions, particularly genital lesions, and vice versa, because ~70% of patients with mucosal vulvovaginal LP have clinical signs of oral LP. It has been reported that the erosive or ulcerative type of oral LP is less frequently associated with cutaneous LP than are all other types of oral LP. Such mucous membrane lesions are more therapy-resistant and less likely to spontaneously remit than cutaneous lesions. Malignant transformation of longstanding, non-healing oral LP has been reported, but it must be distinguished from pseudoepitheliomatous hyperplasia.

Several studies have reported a relationship between oral LP and chronic liver disease, particularly that due to HCV infection (see Pathogenesis)[4,5]. Some authors found that in patients with the reticular and plaque forms, there were statistically significant differences between those with and those without HCV infection, whereas other authors reported an association of HCV with the erosive type. In the HCV-positive oral LP group, oral lesions were more frequently located on the tongue, labial mucosa and gingivae[22].

Ulcerative LP

Ulcerations can occur within palmoplantar lesions of LP, particularly those on the soles. Palmoplantar LP is not as rare as was once thought

Fig. 11.15 Nail lichen planus. A Thinning of the nail plate with lateral loss. **B** Longitudinal fissuring of shortened nail plates. **C** Violaceous discoloration of the periungual area with pterygium formation.

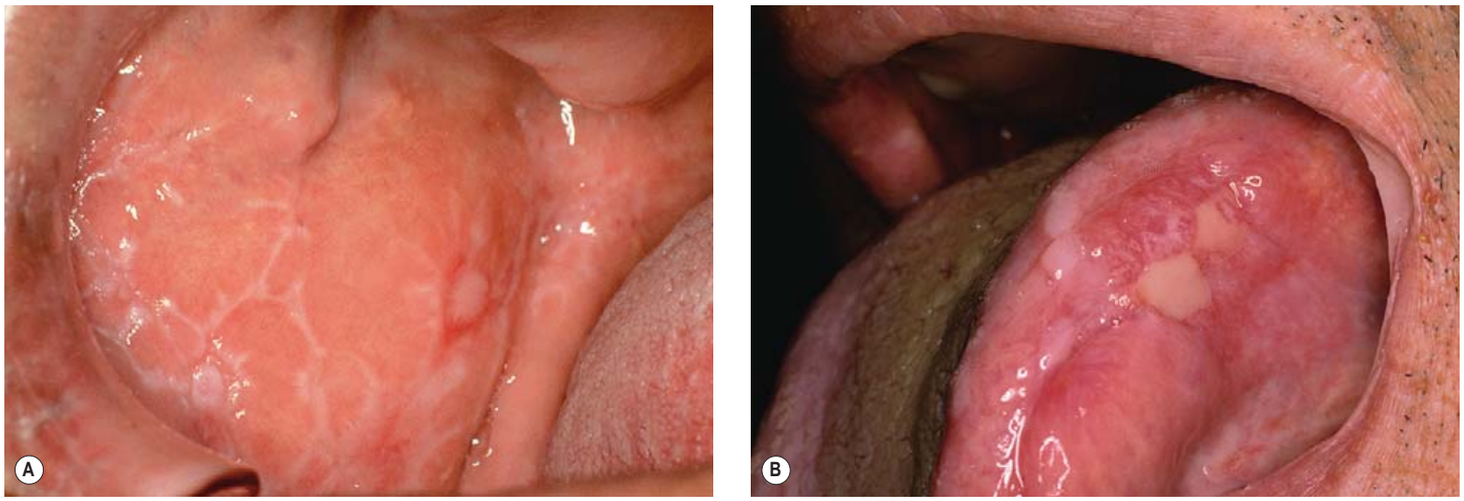

Fig. 11.16 Oral lichen planus. A White lacy pattern and an erosion on the buccal mucosa, the most common location for the reticular form. Note the ring configuration with short radiating spines. **B** Erosions on the lateral aspect of the tongue in addition to lacy white plaques and scarring. *B, Courtesy, Louis A Fragola, Jr, MD.*

and usually appears between the third and fifth decade of life. Although palmoplantar LP is more common in men than in women, ulcerative LP prevails in female patients. Typical LP lesions may be present in additional sites of the body. The ulcers are intensely painful and often recalcitrant to conventional therapy. Chronic ulcerative lesions are at risk of developing squamous cell carcinoma.

Vulvovaginal LP

LP of the vulva can present with several clinical variants, but the most common appears to be erosive disease[23]. Vaginal involvement occurs in up to 70% of women with erosive vulvar LP, and because there is often oral mucosal involvement as well, the term "vulvovaginal–gingival syndrome" has been introduced. The differential diagnosis of vulvovaginal LP includes lichen sclerosus and blistering diseases (see Ch. 73). Since scarring may be a sequela of vulvovaginal LP, patients should be carefully monitored for the development of malignancy, including after the resolution of active disease.

Lichenoid drug eruption (drug-induced LP)

Despite the significant overlap between LP and lichenoid drug eruption (Fig. 11.17), there are both clinical and histologic clues that favor one diagnosis over the other (Table 11.4)[24]. Both sexes are equally affected, but lichenoid drug eruptions tend to occur in adults approximately 10 years older than those with idiopathic LP.

There is usually a latent period of several months from drug introduction to the appearance of the cutaneous eruption. Halevy and Shai[12] reported 17 patients with lichenoid eruptions induced by a variety of drugs and found that the mean latent period was 12 months. The latent period varies depending not only on the offending drug, but also on other factors such as the frequency of drug administration, the dosage, and the intensity of the patient's individual reaction to the offending drug. For example, the latent period has been reported to be between 2 months and 3 years for penicillamine, approximately 1 year for β-blockers, and 4–6 weeks for quinacrine. In contrast to morbilliform eruptions, the time course between drug cessation and lesional resolution can be several weeks to months.

A wide range of cutaneous eruptions have been observed in patients receiving TNF-α inhibitors; they include new onset or paradoxical worsening of psoriasis (including palmoplantar pustulosis), eczematous eruptions, interstitial granulomatous dermatitis, granuloma annulare, cutaneous small vessel vasculitis, cutaneous lupus erythematosus, and lichenoid eruptions. The latter are not limited to any particular TNF-α inhibitor, and while some patients have clinical features similar to idiopathic LP, others have less specific skin lesions clinically, but on histologic examination lichenoid interface changes are seen. The time interval between initiation of TNF-α blockade and appearance of the lichenoid eruption varies from 3 weeks to 16 months. In some patients, complete resolution or significant improvement followed discontinuation of the TNF-α inhibitor, whereas in others, clearance occurred despite continued administration of the drug. In that TNF-α inhibitors are used to treat severe LP, a possible explanation for the paradoxical induction of lichenoid eruptions is a tipping of the balance between Th1 and Th2 immune responses, Treg and Th17 cellular responses, or IFN-α and IFN-γ production. Perhaps inhibition of TNF-α allows for upregulation of other cytokines such as IFN-α.

Fig. 11.17 Lichenoid drug eruption. Photodistributed lichenoid eruption due to hydrochlorothiazide (note sparing under watchband).

"Giant cell lichenoid dermatitis" is a relatively novel, usually drug-associated entity, characterized by a lichenoid dermatitis with a granulomatous infiltrate composed of histiocytes and multinucleated giant cells. Patients present with red–purple papules and plaques, and diagnosis of the disease, also called granulomatous lichenoid dermatitis, is based solely on histologic criteria. Additional histologic features include infiltration of hair follicles and eccrine structures. When this reaction pattern represents a hypersensitivity drug reaction, it may develop during the active or resolving phase of a viral infection[25]. The implicated drugs include antibiotics, ACE inhibitors, β-blockers,

FEATURES FOR DISTINGUISHING LICHENOID DRUG ERUPTION FROM LICHEN PLANUS		
	Lichenoid drug eruption	**Idiopathic lichen planus**
Mean age	66 years	50 years
Location	More generalized; often spares the "classic" sites of LP	Wrists, flexor forearms, presacral, lower legs, genitalia
Morphology	More eczematous, psoriasiform or pityriasis rosea-like	Shiny, flat-topped, polygonal, violaceous papules
Wickham's striae	Uncommon	Present
Hyperpigmentation	Very common, sometimes persistent	Common
Photodistribution	Frequent*	Unusual
Mucous membranes	Usually spared	Often involved
Histology	Varying degree of eosinophilic and/or plasma cell infiltrates	Eosinophils and plasma cells uncommon
	Deep infiltrate may be present	Dense band-like infiltrate of lymphocytes
	Parakeratosis	No parakeratosis

*Especially with medications such as hydrochlorothiazide.

Table 11.4 Features for distinguishing lichenoid drug eruption from lichen planus.

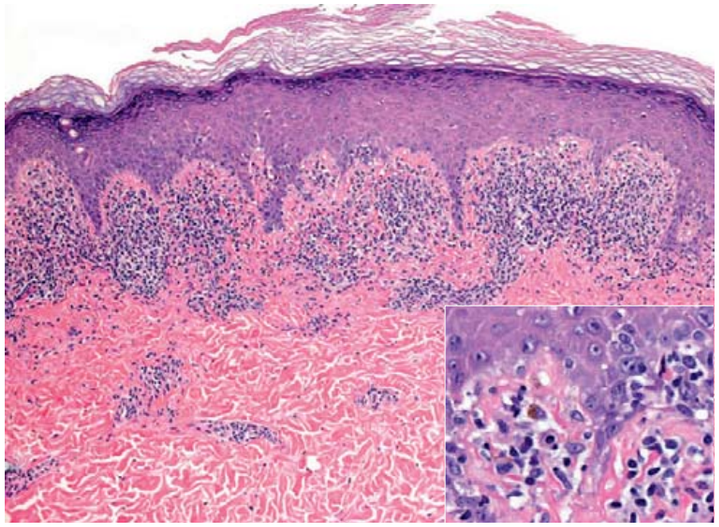

Fig. 11.18 Histopathologic features of lichen planus. Hyperkeratosis, focal increase in the granular layer, sawtoothing of the epidermis with keratinization of the basal layer, and a lichenoid infiltrate. Apoptosis of keratinocytes and melanophages are also present (insert). *Courtesy, Lorenzo Cerroni, MD.*

lipid-lowering agents, phenolphthalein, and nonsteroidal anti-inflammatory drugs (NSAIDs).

Pathology

Despite its different clinical manifestations, the histopathology of LP is fairly uniform. The primary features are hyperkeratosis without parakeratosis, focal increases in the granular cell layer, irregular acanthosis with a "sawtooth" appearance, liquefactive degeneration of the basal cell layer, and a band-like lymphocytic infiltrate at the dermal–epidermal junction (Fig. 11.18). Colloid bodies representing apoptotic or dyskeratotic keratinocytes (also referred to as Civatte, hyaline or cytoid bodies) are usually present in the lower levels of the epidermis and the superficial dermis. Vacuolar changes within the basal cell layer may become confluent and result in small separations between the epidermis and the dermis (called "Max-Joseph spaces"). There is often incontinence of pigment with multiple dermal melanophages.

The number of epidermal Langerhans cells is usually increased in active lesions. The majority of cells in the inflammatory infiltrate are lymphocytes, mainly $CD3^+$ T cells (see Pathogenesis, above). However, exocytosis of lymphocytes into the epidermis is usually not abundant in LP. Plasma cells, macrophages or eosinophils may be seen within the dermis, but not frequently and the latter more commonly in drug-induced LP. Neutrophils are not commonly seen in LP.

Oral LP lesions often show parakeratosis rather than hyperkeratosis, and the epidermis frequently becomes atrophic. Lesions of lichen planopilaris are characterized by an inflammatory cell infiltrate around the hair follicles even at an early stage. Most of the inflammation involves the upper half of the follicle, with the isthmus affected in one-third of patients. Destruction of the follicles represents a later stage. In LP pemphigoides, a primary histologic feature of the bullous lesions is a subepidermal separation with an abundance of eosinophils (occasionally neutrophil-rich infiltrates), whereas the papular lesions have the usual features of LP. DIF microscopy of peribullous skin shows linear deposition of IgG and C3 along the dermal–epidermal junction, similar to BP.

Apoptotic cells, as evidenced by Civatte bodies, tend to remain in the lower levels of the epidermis in idiopathic LP; in contrast, they are found in the spinous or granular layer in lichenoid drug eruptions. In a nonspecific "sponge-like" manner, colloid bodies often stain with IgM, IgA, IgG or C3, and this is the characteristic finding by DIF microscopy. In lichen planopilaris lesions, IgM, IgG and IgA are found in varying combinations along the follicle–dermal interface. Although the band-like inflammatory infiltrate is usually restricted to the papillary dermis in LP and involvement of the deep vascular plexus suggests a lichenoid drug eruption (though observed in <50% of cases), inflammation and destruction of the distal and proximal ends of the sweat ducts is also seen in some cases of LP; however, the secretory glands are unaffected.

The histologic changes in lichenoid drug eruption are very similar to those in idiopathic LP (see Table 11.4). Van den Haute et al.[24] conducted a retrospective study in which they compared histologic sections from 15 patients with idiopathic LP and 15 with a lichenoid drug eruption. They noted that no single feature was significantly more likely to occur in the latter than in the former. Nonetheless, they assigned some histologic signs to a list of "lichenoid drug eruption-related criteria" because they were present in more than 50% of the drug eruption cases and were not seen in idiopathic LP (in their study); these included focal parakeratosis, focal interruption of the granular layer, and cytoid bodies in the cornified and granular layers. Although eosinophils were observed exclusively in the lichenoid drug eruptions, they were found in only 2 of the 15 cases. Thus, these results indicate that the absence of eosinophils cannot be interpreted as a sign of idiopathic LP. Also, there were no significant differences in DIF findings between lichenoid drug eruptions and idiopathic LP. In sum, it would be ill advised to make the diagnosis of lichenoid drug eruption solely on the basis of histologic criteria.

Differential Diagnosis

LP can be viewed as one of the major reaction patterns in response to various exogenous agents such as drugs, viruses and contact allergens. Before labeling patients as having "idiopathic LP", an in-depth search should be undertaken to identify any such inducing factors, because there are no definite criteria (either clinical or histologic) for differentiating drug-induced LP from idiopathic LP. Patients with oral LP lesions in apposition to metallic dental restorations should undergo patch testing with relevant metals (see Ch. 14). These metals include amalgam (mercury), copper and gold. A lichenoid "id" reaction can be seen in children with contact dermatitis to nickel (e.g. in metal snaps in pants).

Other inflammatory conditions that are in the clinical differential diagnosis include lupus erythematosus (LE), lichen nitidus, lichen striatus, lichen sclerosus, pityriasis rosea, erythema dyschromicum perstans (ashy dermatosis), psoriasis, annular lichenoid eruption, lichenoid GVHD, and secondary syphilis. Patients with paraneoplastic pemphigus can have clinical features of a mucocutaneous lichenoid eruption (see Ch. 29).

The disease that is most difficult to differentiate from LP is LE, particularly in patients with oral or scalp lesions alone. In these patients, the diagnosis of LE may only be made after additional biopsies are performed or other signs of LE appear. DIF studies are helpful; granular or homogeneous bands of immunoglobulin in the basement membrane zone have been demonstrated in lesional and non-lesional mucosa in systemic LE (100% and 71%, respectively) and in lesional mucosa in chronic cutaneous (discoid) LE (73%), but only rarely in LP (4%)[26]. The situation becomes even more complicated when there is a flare of disease in a patient with cutaneous LE who is receiving an antimalarial drug, one of the more common causes of a lichenoid drug eruption (see Table 11.2).

When LP affects the mucosal surface of the vulva, the lesions may be difficult to differentiate clinically or histologically from other inflammatory diseases, especially lichen sclerosus. While LP typically involves the inner aspects of the labia minora and consists of a glazed erythema that may easily bleed on touching, lichen sclerosus is typically observed on the outer aspects of the labia minora, and the vagina and oral mucosa are usually not involved. This mucosal vulvar variant of LP affects adult women and has not been reported before puberty, while lichen sclerosus is frequently seen in children.

Treatment

It is difficult to evaluate the efficacy of different forms of therapy in LP, because the majority of reports regarding its treatment consist of small series of patients or anecdotes (Table 11.5). In addition, spontaneous remission of cutaneous and oral LP can occur after varying amounts of time. For example, spontaneous remission of cutaneous LP has been observed in up to two-thirds of patients after 1 year, whereas the reported mean duration of oral LP is about 5 years and the erosive form rarely spontaneously resolves[22].

In all instances, the possibility that LP is drug-induced should be considered before embarking on therapy. The diagnosis of lichenoid drug eruption is confirmed by withdrawal of the suspected drug followed by disappearance of the lesions and their recurrence upon re-exposure to the drug. However, rechallenge is often not performed. There are reports of patch testing and *in vitro* tests that involve incubation with the offending drug (e.g. lymphocyte stimulation and macrophage migration inhibition tests[12]) being used to identify the causative drugs, but they remain of limited value in confirming the diagnosis.

The next step is to determine which drug – or drugs, if multiple drugs are prescribed – should be withdrawn. The degree of difficulty depends upon the ability to substitute an unrelated but equally effective drug. Lastly, both the patient and the physician who prescribed the medication must be advised that withdrawal of the causative drug may not lead to quick resolution of the skin eruption and that therapies utilized for idiopathic LP may be required (see below).

Well-described therapies for LP include topical, intralesional and systemic corticosteroids, systemic retinoids, narrowband UVB, PUVA, topical calcineurin inhibitors, antimalarials and, for severe or treatment-resistant cases, oral immunosuppressive agents. In mild cases, symptomatic treatment includes topical corticosteroids and oral antihistamines for reducing pruritus. Topical corticosteroids are particularly popular for children. Hypertrophic LP lesions may benefit from intralesional corticosteroids or topical corticosteroids under occlusion. Vulvovaginal LP is best treated with topical superpotent (class I) corticosteroids and calcineurin inhibitors (see Table 11.5)[27], but if they fail, oral immunosuppressive drugs (e.g. methotrexate, mycophenolate mofetil) and/or low-dose oral prednisone may be required. Of note, despite their worldwide use as a mainstay of therapy, the efficacy of topical corticosteroids in cutaneous LP has not been systematically evaluated. Inhaled forms of corticosteroids are sometimes used for oral LP.

In several studies, tacrolimus 0.1% ointment was found to be effective in reducing the symptoms of oral LP unresponsive to more conventional therapies, including erosive disease. Most patients experienced symptomatic improvement in less than 1 month following twice-daily application. However, in one study, the median relapse time was 5 weeks (range, 2 to 20 weeks), and patients often require intermittent therapy to prevent subsequent flares[28]. Symptoms of burning did resolve with continued use of the ointment. To date, serious adverse effects from long-term use (>1 year) have not been reported. However, given the FDA warning regarding topical calcineurin inhibitors and a possible increased risk of cutaneous carcinomas plus the increased risk of developing squamous cell carcinoma in the setting of erosive oral and vulvar LP, continued safety monitoring is recommended.

In a recent small case series, topical rapamycin (sirolimus) resulted in a complete (4/6 patients) or partial (2/6 patients) remission by 3 months in individuals with refractory erosive oral LP. The proposed mechanism of action of rapamycin is an increase in the number of Treg cells, leading to decreased activation of T cells and B cells.

Systemic therapies

In severe, acute cases, systemic *corticosteroids* remain a commonly employed intervention. Although different dosage regimens have been proposed, the minimal effective daily dose of prednisone for treating LP is usually 15 to 20 mg[1]; treatment is continued for 2–6 weeks and then gradually tapered over several weeks. Rebound and relapses may occur, but long-term maintenance therapy with systemic corticosteroids should be avoided. One study demonstrated that the median time to clearing was 18 weeks in the corticosteroid-treated group and 29 weeks in the placebo group[29].

Acitretin is the only systemic retinoid that has a relatively good level of evidence regarding its efficacy in the treatment of cutaneous LP. A therapeutic regimen consisting of acitretin 30 mg/day for 8 weeks resulted in significant improvement or remission in 64% of those in the treatment group, compared with 13% in the placebo group. Retinoids tend to be used for recalcitrant cases, and, therefore, relapses may occur after discontinuation of the drug; as a result, long-term maintenance therapy may be required. The authors have successfully used etretinate (50 mg/day) to treat patients with the acute, exanthematous form of LP.

Long-term (3 to 6 months) administration of *griseofulvin* was shown to result in complete improvement in 86% of patients with LP[1]; however, the methods used in this study were not described in complete detail, so definitive conclusions cannot be made. In particular, oral erosive lesions have been reported to respond favorably to this drug. As a result, griseofulvin is often tried in such patients. A complete response or significant improvement (79%) of generalized LP (mean duration of disease, 3.5 months) was observed with *metronidazole*, 500 mg twice daily for 20 to 60 days[30]. More recently, in a

†Often a first-line therapy for severe, acute cutaneous LP.

Table 11.5 Therapeutic ladder for lichen planus. Systemic treatments are usually reserved for more severe disease. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

retrospective study, *hydroxychloroquine* (200 mg twice daily) was shown to improve both lichen planopilaris and frontal fibrosing alopecia[31]. Oral *sulfasalazine* administered in increasing doses from 1.5 to 3 g/day for at least 4 weeks was reported to be effective for cutaneous LP but not for mucosal LP. Recently, a randomized, double-blind, placebo-controlled trial utilizing a maximum of 2.5 gm/day of sulfasalazine found cutaneous improvement (>50%) in 82.6% vs 9.6% of patients at six weeks[31a].

Based upon a case series, weekly low-dose *methotrexate* was noted to improve oral LP[32]. Efficacy of methotrexate for generalized LP has also been described. A complete response was achieved in 10 of 11 patients within 1 month and the medication was well tolerated without adverse effects.

Based on a small case series, oral *cyclosporine* was reported as useful in inducing a remission in severe cases of LP resistant to retinoids and systemic corticosteroid therapy[33]. Complete responses have been observed with doses of cyclosporine ranging from 1 to 6 mg/kg/day. The majority of patients have not experienced a relapse during follow-up periods of several months, but a rebound in disease activity can occur upon discontinuation of cyclosporine. Similar successful results were described in lichen planopilaris; alleviation of symptoms, resolution of clinical activity, and halting the progression of hair loss was achieved within 3 to 5 months[34]. However, long-term use of cyclosporine can be associated with renal toxicity, hypertension and an increased risk of developing cutaneous squamous cell carcinomas (see Ch. 130).

Mycophenolate mofetil, an immunosuppressive agent which specifically and reversibly inhibits the proliferation of activated T cells, was reported to be effective in the management of disseminated, erosive, hypertrophic and bullous variants of LP as well as lichen planopilaris[35]. It may be preferable to other immunosuppressive drugs such as cyclosporine because of its safer side-effect profile. *Thalidomide* has also been reported to be an effective therapy.

Newer *TNF-α inhibitors* (see Ch. 128) as well as T-cell-modulating biologic therapies (e.g. *alefacept)* have been used in scattered patients with severe recalcitrant LP. For example, *basiliximab*, a chimeric antibody directed against the IL-2 receptor, reportedly improved severe erosive oral LP. Another observation was a more rapid response to alefacept in two patients with LP as compared to those with psoriasis, perhaps suggesting a more direct role for $CD4^+$ T cells. Specific recommendations await larger clinical trials.

Phototherapy

In patients with resistant longstanding LP, significant improvement has been observed after bath or systemic PUVA. However, the risk of promoting carcinogenesis, especially in patients with skin types I and II, has to be balanced against the benefits. The usefulness of PUVA has prompted evaluation of extracorporeal photopheresis (ECP) for recalcitrant LP. One case series demonstrated that erosive oral LP cleared in all seven patients after an average of 24 sessions of ECP (two consecutive days per month) and follow-up at 24 months revealed no recurrences[36].

UVA1 has been shown to be effective in the treatment of therapy-resistant LP, including disease exacerbated during PUVA therapy. The use of narrowband UVB (peak emission 311 nm) for recalcitrant LP has also been reported. In an open prospective trial in 10 patients with recalcitrant LP, complete clearance occurred after 30 exposures (mean cumulative dose, 17.7 J/cm^2) in five patients, while partial responses were observed (without any recurrences for 6 months) in the remainder. The excimer laser (308 nm) was used to treat oral LP unresponsive to conventional therapies and was reported to produce excellent results[37]. Remission times ranged from 2 to 17 months. Of note, the only poor responder in the study had chronic active HCV infection.

LICHEN STRIATUS

Synonyms: ■ Linear lichenoid dermatosis ■ *B*laschko *l*inear *a*cquired *i*nflammatory *s*kin *e*ruption (BLAISE)

Key features

- An asymptomatic, linear dermatosis that primarily affects children
- The primary lesion is a small, flat-topped papule that ranges in color from pink to skin-colored to tan (hypopigmented)
- Multiple lesions appear over the course of days to weeks along the lines of Blaschko and usually on an extremity
- Spontaneously resolves over months to a few years
- Digital involvement may result in nail dystrophy

Introduction

Lichen striatus is an asymptomatic, uncommon, self-limited, linear dermatosis of unknown etiology that generally affects children. The diagnosis is usually made clinically based upon the appearance of the primary lesions and the distinctive developmental pattern. Its distribution along Blaschko's lines plus the age of the patient usually narrows the differential diagnosis rather quickly. Occasionally, there is overlap with linear LP and "blaschkitis" (see Ch. 62).

History

In 1898, Balzer and Mercier first described a peculiar linear papular eruption that they termed "lichenoid trophoneurosis". Forty years later, Senear and Caro proposed the name "lichen striatus". Ever since the condition was first described, the pathogenesis of its linearity has been the subject of debate. Brocq proposed that it represented a locus minoris resistentiae, but we now know that it is a manifestation of mosaicism (see Ch. 62).

Epidemiology

Lichen striatus is seen primarily in children between the ages of 4 months and 15 years, although the disorder occasionally occurs in adults; the median age of onset is 2 to 3 years and the vast majority of cases occur in preschool-age children[38]. The reported female : male ratio has varied from 1.6 : 1[39] to 2 : 1[38].

Pathogenesis

Although the distribution of lichen striatus along Blaschko's lines points to somatic mosaicism (see Ch. 62), neither the gene(s) involved nor the triggering factors are known. Environmental agents, particularly viruses, have been implicated, given the predominance of the disorder in young children and its seasonal variation (it appears more commonly during spring and summer). However, to date, a viral association has not been proven via serologic testing or cultures.

In theory, during early fetal development, aberrant clone(s) of epidermal cells produced by somatic mutation migrate out along the lines of Blaschko. Exposure to an infectious agent (e.g. virus, BCG vaccine) or other precipitant could then break previous tolerance to the aberrant clone by inducing a novel membrane antigen. The presence of $CD8^+$ T cells scattered or in clusters around necrotic keratinocytes supports a cell-mediated immunologic reaction by which cytotoxic T cells would attack and eliminate the mutated or virally modified keratinocyte clones. A similar mechanism has been proposed for linear LP, and a post-transplant loss of tolerance could explain linear GVHD.

Lichen striatus may represent a manifestation of an atopic diathesis with the abnormal immune responses usually associated with atopy being a predisposing factor. The timing and relative infrequency of lichen striatus suggests that an infectious agent acts as a trigger in genetically predisposed individuals. Lastly, there are scattered reports of lichen striatus occurring at sites of injury (e.g. the periphery of a burn scar[39]) rather than along Blaschko's lines, but this could also be explained by a break in tolerance.

Clinical Features

Lichen striatus is typically asymptomatic, but intense pruritus can occasionally occur. The eruption consists of a continuous or interrupted band composed of discrete or clustered pink, skin-colored or tan

Fig. 11.19 Lichen striatus. A Linear array of pink flat-topped papules on the hand in association with dystrophy (splitting, fraying) of R2 (lateral) and R3 (medial) nails. **B** Single streak on the lower extremity composed of multiple pink flat-topped papules. The primary differential diagnosis would be blaschkitis and linear LP.

(hypopigmented) papules that are flat-topped, smooth or scaly, and range in diameter from 2 to 4 mm. Infrequently, vesicles may be present. Typically, there is a single, unilateral streak on an extremity along Blaschko's lines (Fig. 11.19); occasionally, there is a bilateral distribution pattern and/or multiple parallel bands. It is uncommon for lichen striatus to involve the trunk or head and neck region. There are reports of the eruption speading distally from the trunk down an extremity, as well as observations of proximal extension along an extremity[40]. Although lichen striatus does not usually recur, relapses may occasionally occur, either in the same site or on the same side of the body[38].

The eruption usually appears suddenly, develops fully over days to weeks, and after several months to a year or more, undergoes spontaneous resolution, leaving postinflammatory hypopigmentation, particularly in those with more darkly pigmented skin. In the latter individuals, the eruption is often first noticed as linear hypopigmentation. When lesions involve the nail apparatus, onycholysis, splitting, fraying and total nail loss may result (see Fig. 11.19A).

Pathology

The histologic features of lichen striatus are variable and depend upon the age of the lesion at the time the biopsy is performed. In addition, different areas within the same streak can have different findings. In general, there is a lichenoid tissue reaction in addition to varying degrees of involvement of the hair follicles and sweat glands and ducts. Even though the lichenoid inflammation that may be present around hair follicles is indistinguishable from that seen in lichen planopilaris, sweat gland and hair follicle involvement can still be a helpful diagnostic feature of lichen striatus[39].

The alterations within the epidermis are secondary and include intercellular and intracellular edema, exocytosis, parakeratosis, dyskeratosis, and focal or diffuse lysis of the basal layer in areas where the lichenoid infiltrate invades the epidermis. Dyskeratotic keratinocytes may be found in the granular and horny layers (similar to the corps ronds in Darier disease) and at the dermal–epidermal junction in up to half of the cases. Older lesions may have features similar to those seen in LP or lichen nitidus. By immunohistochemistry, $CD3^+$ T-cell infiltrates were noted in which $CD8^+$ T cells surrounded necrotic keratinocytes and infiltrated vesicles filled with Langerhans cells. Depending upon the age of the lesions, Langerhans cells were either decreased (earlier lesions due to the attack by $CD8^+$ T cells) or increased (later phase due to an influx of precursor cells).

Differential Diagnosis

Although the differential diagnosis includes other inflammatory diseases that can assume a linear pattern, such as linear porokeratosis, linear psoriasis, inflammatory linear verrucous epidermal nevus, and linear Darier disease, the primary differential diagnosis is linear LP, blaschkitis and linear GVHD. The latter occurs in a specific clinical setting, while blaschkitis favors the trunk, is usually seen in adults, often consists of multiple streaks, and can have features of dermatitis. Although linear LP and lichen striatus can occasionally be indistinguishable histologically, the primary lesions usually differ in size and color, and hypopigmentation is a frequent sequela of lichen striatus, while, in general, hyperpigmentation appears in the wake of LP. Lichen striatus is also characterized by minimal, if any, pruritus, as well as spontaneous resolution within a short period of time. In lichen nitidus, linear lesions reflect previous traumatic injury to the skin.

Treatment

Treatment of lichen striatus is usually not needed, except for the unusual case in which there is significant pruritus. Topical corticosteroids under occlusion have successfully been used to hasten spontaneous resolution. In scattered case reports, topical calcineurin inhibitors have also been reported to be effective, including for the nail dystrophy. Obviously, with any purported therapy, the natural history of lichen striatus must be kept in mind.

LICHEN NITIDUS

Key features

- The eruption consists of multiple, tiny, discrete, shiny papules, often in clusters
- Favored sites of involvement include the flexor aspects of the upper extremities, the genitalia and the anterior trunk
- Linear arrays of papules occur secondary to the Koebner phenomenon
- The histologic correlate of the papule is a well-circumscribed infiltrate composed of lymphocytes and epithelioid cells confined to the width of two to three dermal papillae

Introduction

Lichen nitidus is an uncommon chronic eruption consisting of multiple, tiny, discrete, skin-colored papules that are often arranged in larger clusters. The papules have a distinctive histology with a dense, well-circumscribed, lymphohistiocytic infiltrate closely apposed to the epidermis. There has been considerable debate, however, as to whether lichen nitidus represents a distinct and separate entity or should be regarded as an unusual variant of LP; their coexistence has certainly been reported and progression from lichen nitidus to LP has also been observed. It is generally accepted that lichen nitidus has no relationship to any systemic illness; only a few authors believe that it may be a cutaneous manifestation of Crohn's disease[41].

History

In 1901, Pinkus first described a peculiar papular eruption he termed "lichen nitidus" and suggested that it was a distinct entity histologically. Based upon the presence of epithelioid cells within the well-circumscribed inflammatory infiltrate, early authors believed that lichen nitidus was of tuberculous origin.

Epidemiology

Reliable epidemiologic data are difficult to accumulate because of the relative rarity of lichen nitidus. In a US study of 43 patients, primarily Caucasians and African-Americans, the disorder was not found to be restricted to any specific population group based on race, sex or age[42]. Other authors have reported that lichen nitidus is more prevalent among children or young adults, and a female predominance has been described in the generalized variant. It has also been reported in patients with Down syndrome.

Pathogenesis

Although much attention has been focused on the relationship of lichen nitidus to LP, there has been limited recent study of its pathogenesis. Lichen nitidus was initially thought to represent a tuberculous lesion or tuberculid because of its histologic features. However, no causative (infectious) agents have ever been demonstrated, even by repeated inoculations of tissue into animals.

Even though LP and lichen nitidus can coexist in the same patient and they share some similar clinical features (Table 11.6), most authors believe that lichen nitidus is a separate entity because of its distinctive clinical and histologic features. The possibility exists that the two conditions represent different responses to a similar triggering factor (e.g. hepatitis B vaccine). For example, Kano et al.[41] described a patient who had Crohn's disease in whom LP and lichen nitidus developed over different time frames. However, in view of the distinct differences in the composition of the respective cellular infiltrates, immunologic mechanisms responsible for the development of lichen nitidus are likely different from those in LP.

Clinical Features

Lichen nitidus is characterized by numerous tiny, discrete, skin-colored, uniform, pinhead-sized papules (Fig. 11.20A) that occasionally exhibit a central depression. Individual papules are usually flat with a shiny surface (Fig. 11.20B). Pruritus can occur, but it is an uncommon feature. Although most often skin-colored, the papules may exhibit a variety of hues, from pink or yellow to red–blue or brown. In darkly pigmented individuals, the papules tend to be hypopigmented, but sometimes they are hyperpigmented; marked hyperpigmentation has rarely been reported.

The lesions are usually distributed on the flexor aspects of the upper extremities as well as the genitalia, chest, abdomen and dorsal aspects of the hands. Less commonly, the face, neck, lower extremities, palms, soles and mucous membranes are involved. Oral lesions are thought to be rare but are probably underestimated; they appear as minute, flat, gray–white papules on the soft mucosa or white plaques on the tongue and hard palate. Nail involvement is observed up to 10% of patients (primarily adults) and the changes include pitting, rippling, longitudinal ridging, terminal splitting, and increased longitudinal linear striations. Occasionally, the typical papules of lichen nitidus are seen in the perungual region.

COMPARISON OF CLINICAL AND HISTOLOGIC FEATURES OF LICHEN NITIDUS VERSUS LICHEN PLANUS

	Lichen nitidus	Lichen planus
CLINICAL		
Size	Pinhead	Pinhead to larger plaques
Color	Skin-colored	Violaceous
Number	Multiple to numerous	Multiple
Distribution	Upper extremities (flexor aspects), genitalia, chest, abdomen	Wrists, flexor forearms, presacral, dorsal aspect of hands, anterior lower legs, genitalia
Oral involvement	Rare*	Common (>50%)
Nail involvement	<5–10%	~10%
Wickham's striae	Absent	Common
Hyperpigmentation	Uncommon	Common
Hypopigmentation	Common†	Unusual
Koebner phenomenon	Common	Common
Pruritus	Sometimes	Common
HISTOLOGIC		
Parakeratotic cap	Common	Rare
Granular layer	Thin to absent	Focally increased
Dermal infiltrate	Lymphocytes, epithelioid cells and occasional Langhans giant cells; usually confined to width of 2–3 dermal papillae; "ball and claw" configuration due to hyperplastic rete ridges	Band-like infiltrate of lymphocytes
Transepidermal elimination	Unusual	Rare
Deposits of immunoreactants	Absent	Globular deposits of IgG, IgA, IgM and/or C3 in lower levels of the epidermis

*May be underestimated.
†Especially in darkly pigmented individuals.

Table 11.6 Comparison of clinical and histologic features of lichen nitidus versus lichen planus.

Lichen nitidus is one of several diseases that exhibit the Koebner phenomenon. The latter is especially prevalent in patients with generalized disease. Vesicular and hemorrhagic lesions are found in some patients, and they are often admixed with the more typical papules. Several other variants have been described, including palmoplantar, linear and follicular spines. A perforating variant has also been reported, usually in association with LP. While grouped papules tend to remain distinct, they may coalesce into plaques (especially in the generalized type), and when this occurs on the elbows and knees, it can have a psoriasiform appearance. According to one study, the duration in two-thirds of the patients was 1 year or less and the longest duration was 8 years[42]. It is generally accepted that lichen nitidus is not associated with any systemic diseases or abnormal laboratory findings.

Pathology

The constellation of histologic features in lichen nitidus is very distinctive. As a result, the clinical diagnosis can be confirmed histologically. A well-circumscribed infiltrate composed of lymphocytes, epithelioid cells and occasional Langhans giant cells is typically "clutched" by the surrounding hyperplastic rete ridges in a "ball and claw" configuration (Fig. 11.21). In most lesions, the infiltrate is confined to the width of two to three dermal papillae.

The overlying epidermis is usually atrophic and frequently exhibits a parakeratotic "cap" centrally. Absence or thinning of the overlying

Fig. 11.20 Lichen nitidus. A Numerous tiny flat-topped papules on the hand. **B** A close-up view shows the shiny surface.

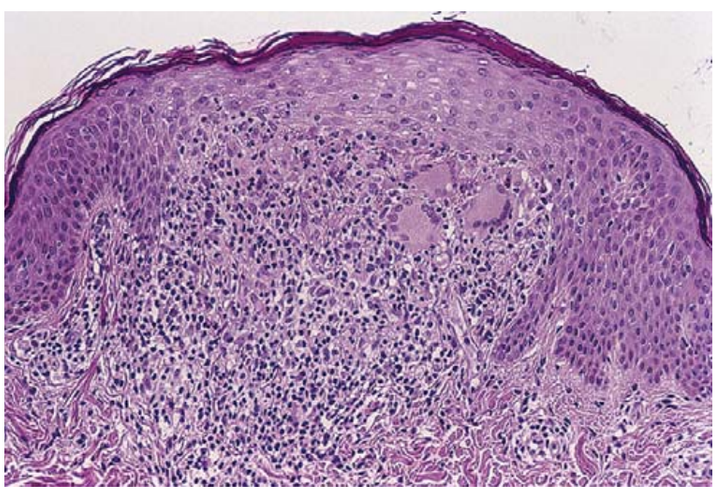

Fig. 11.21 Histopathologic features of lichen nitidus. Note the typical "ball and claw" configuration for the infiltrate and epidermis, respectively. Several Langhans giant cells are within the infiltrate.

granular layer is seen and liquefactive degeneration of the basal layer is consistently observed, often accompanied by incontinence of melanin pigment. Civatte bodies are occasionally seen. A Max-Joseph-like space, i.e. focal separation of the epidermis and dermis secondary to liquefactive degeneration, is sometimes observed. The lichenoid infiltrate closely apposes the epidermis and is thought to play a role in inducing reactive epidermal proliferation of the surrounding rete ridges and atrophy of the overlying epidermis. In perforating lichen nitidus, transepidermal elimination is observed (see Ch. 96).

The predominant cell types in the dermal infiltrate are lymphocytes and epithelioid cells, and in some cases, epithelioid cells predominate. Immunohistochemical studies have shown a marked predominance of $CD4^+$ T cells over $CD8^+$ T cells[43], as well as the presence of large numbers of $CD1^+$ Langerhans cells in the dermal infiltrates. Of note, the pattern in lichen nitidus lesions of a mixed cellular infiltrate characterized by macrophages and a helper T-cell response with few *c*utaneous *l*ymphocyte *a*ntigen-positive (CLA^+) cells is different from that seen in LP[44].

Differential Diagnosis

The differential diagnosis includes LP, lichen striatus, guttate lichen sclerosus, lichen spinulosus, lichen scrofulosorum, verruca plana, papular sarcoidosis, the lichenoid variant of secondary syphilis, frictional lichenoid dermatitis (elbows and knees), and papular eczema (especially in skin types V and VI). All of these diagnoses (except LP and perhaps lichen scrofulosorum) can usually be excluded relatively easily on the basis of clinical plus histologic findings. It is not always possible to differentiate early tiny papules of LP because they may be clinically and histologically indistinguishable from lichen nitidus (see Table 11.6). Furthermore, lesions identical to lichen nitidus can be found in 25% to 30% of patients with LP. In such cases, the lack of variation in size, the absence of a violaceous color or Wickham's striae, and no deposits of immunoglobulin in dermal papillae would suggest the diagnosis of lichen nitidus.

Periappendageal inflammation is more typical of lichen striatus, but patients with the latter have been described where both periappendageal inflammation and superficial features of lichen nitidus were present, suggesting a morphologic spectrum. Lichen spinulosus is characterized by follicular keratotic papules, 1–3 mm in size with a central horny spine, that are grouped into patches on the neck, buttocks, abdomen and upper limbs. The possibility of the spinous follicular variant of lichen nitidus should be kept in mind when a patient presents with spiny keratotic papules plus typical histologic features of lichen nitidus. Lastly, lichen nitidus-like lesions can be seen in a photodistribution in summertime actinic lichenoid eruption, also referred to as actinic lichen nitidus (see below).

Treatment

Since the majority of patients experience spontaneous clearing within one or several years, treatment is primarily symptomatic. When significant pruritus is present, topical corticosteroids and oral antihistamines may be helpful. Anecdotally, topical calcineurin inhibitors have been reported as an effective therapy in children with lichen nitidus. Generalized lichen nitidus that had failed to respond to topical corticosteroids has been successfully treated with either narrowband UVB or photochemotherapy (PUVA)[45]. In case reports, resolution of lichen nitidus has also been described with oral etretinate and oral itraconazole. Nevertheless, the anecdotal nature of these reports makes it difficult to evaluate their true effectiveness and the risk-to-benefit ratio must always be kept in mind. One patient with peripheral $CD4^+$ T-cell lymphocytopenia and lichen nitidus who was treated with topical dinitrochlorobenzene (DNCB) developed a pruritic erythematous eruption followed by resolution of the lesions of lichen nitidus[46].

ERYTHEMA DYSCHROMICUM PERSTANS

Synonyms: ■ Ashy dermatosis ■ Ashy dermatitis

Key features

- Slowly progressive appearance of gray, gray–blue or gray–brown, oval-shaped macules and patches
- Occasionally, there is a peripheral rim of erythema
- As in pityriasis rosea, the long axis of oval lesions can follow skin cleavage lines
- Seen most commonly in Latin American patients with skin types III and IV
- Histologic examination demonstrates multiple dermal melanophages

Introduction

This entity was first described in 1957 by Ramírez as an asymptomatic, slowly progressive, ashy-colored, macular hyperpigmentation and was referred to as "dermatitis cenicienta". The disorder was subsequently renamed erythema dyschromicum perstans (EDP) or ashy dermatosis. Some authors consider EDP to be a variant of LP because of the overlapping clinical and histologic features (see LP pigmentosus). However, flat-topped violaceous papules and plaques are not seen in patients with EDP, and in this textbook, they are viewed as separate entities.

History

In 1957, Ramírez referred to these patients as *los cenicientos* (the ash-colored ones) and named the condition "dermatitis cenicienta". Subsequently, five patients from Venezuela were reported who were believed to be similar to those described by Ramírez. These authors suggested calling the disorder "erythema chronicum figuratum melanodermicum" because they considered it to be a new variant of erythema perstans. Sulzberger then proposed a less cumbersome and more descriptive term, "erythema dyschromicum perstans".

Epidemiology

Although it has been observed that EDP occurs most often in more darkly pigmented Latin Americans, there have been occasional reports in Asians and Caucasians. The disorder clearly favors individuals with skin types III and IV. In general, no gender predilection exists, although a few authors reported that women were more commonly affected than men. While the age of onset is variable, EDP frequently appears during the first to third decade of life.

Pathogenesis

In 1973, Pinkus[47] speculated that an as-yet-unidentified set of pollutants in our environment, either contactants or inhaled or ingested substances, may be the cause of EDP in certain predisposed individuals. Indeed, there have been sporadic case reports of temporal associations with the ingestion of ammonium nitrate, whipworm infestation, and HIV seroconversions; in one patient, characteristic lesions occurred suddenly after a radiographic study using orally administered contrast medium (barium sulfate). However, to date, a rigorous epidemiologic study examining potential triggers has not been performed. Lastly, the possibility has been raised that some patients with multiple fixed drug eruptions or lichenoid drug eruptions are misdiagnosed as having EDP[48], emphasizing the need to carefully review all medications, including over-the-counter drugs and herbal remedies.

Clinical Features

Most patients present with a slow progression of gray, gray–brown or gray–blue macules and patches (Fig. 11.22). The presence of an erythematous, peripheral margin measuring 1–2 mm in width is actually uncommon. When present, these borders eventually disappear after several months. Most lesions measure between 0.5 and 2.5 cm but can be larger. Although the lesions may vary in shape, many are oval with their long axes following skin cleavage lines, thus assuming a pattern similar to that of pityriasis rosea.

The macules may slowly enlarge or multiply to involve large areas of the body. The most common sites of involvement are the neck, trunk and proximal arms, and the distribution is usually symmetric. Occasionally, asymmetric lesions, usually located on the face and neck, have been observed, as well as lesions along the lines of Blaschko. Characteristically, there is sparing of the palms, soles, scalp, nails and mucous membranes. Although spontaneous clearing can occur, especially in prepubertal children (~70% within 2–3 years), the lesions usually persist for years in adults.

Fig. 11.22 Erythema dyschromicum perstans. Numerous, oval to polygonal, gray–brown macules on the extremities. *Courtesy, Wake Forest University.*

Pathology

The histologic findings vary depending on the phase in the life of the lesion. In the border of active lesions, vacuolization of the basal layer, occasional colloid bodies and a lichenoid lymphocytic infiltrate of a varying degree are typically seen. These histologic findings may be seen even in the perilesional normal-appearing skin, suggesting that the pathologic processes have already begun in these areas. In inactive ashy-colored lesions, a considerable amount of pigment incontinence with variable epidermal change, including atrophy and effacement of the normal pattern of rete ridges, is seen. Again, these findings in the active and late inactive lesions are quite similar to those of the different stages of fixed drug eruptions.

DIF microscopy studies of the active border have demonstrated IgM, IgG, fibrinogen and C3 staining of colloid bodies, as in LP. However, positive staining for fibrinogen at the dermal–epidermal junction is often the only finding in immunofluorescence studies of EDP. Immunopathologic studies have shown the dermal infiltrate (when present) to be composed of $CD4^+$ and $CD8^+$ T cells, a common pattern in LP.

Differential Diagnosis

The clinical differential diagnosis includes primarily generalized fixed drug eruption and postinflammatory hyperpigmentation secondary to a lichenoid drug eruption, pityriasis rosea, small plaque parapsoriasis, LP or erythema multiforme. Although the lesions of pityriasis rosea are often oval, the resultant hyperpigmentation is predominantly epidermal, not dermal. Histologically, in fixed drug eruptions, there is incontinence of pigment, but clinically the shape of the lesions is usually more circular and the color more brown. Less common entities in the differential diagnosis are macular urticaria pigmentosa, pinta and leprosy. There is a lack of consensus as to whether idiopathic eruptive macular pigmentation is a variant of EDP seen more commonly in children or a distinct entity. Distinguishing EDP from a lichenoid drug eruption can prove quite difficult and a search for incriminating drugs is essential.

Treatment

In general, proposed treatments for EDP are unsuccessful; they include sun protection, topical corticosteroids, retinoids and vitamin C, chemical peels, oral antibiotics, vitamin A, dapsone, antimalarials, griseofulvin and corticosteroids. On the basis of a case series, clofazimine was

reported as a successful treatment. Spontaneous remission can occur, but unfortunately many patients have the disease for years.

KERATOSIS LICHENOIDES CHRONICA

This entity was first described in 1895 by Kaposi. He used the term "lichen ruber acuminatus verrucosus et reticularis" to describe a patient with a linear, warty lichenoid eruption. Since his original description, patients with similar lesions have been reported, but with a confusing nomenclature which includes lichen verrucosus et reticularis, porokeratosis striata lichenoides, keratosis lichenoides chronica, lichenoid trikeratosis and Nékam's disease[49]. Over time, keratosis lichenoides chronica has become the most consistently used name for this disorder.

Keratosis lichenoides chronica is characterized by violaceous, keratotic lichenoid papules that are arranged in a characteristic linear and reticulated pattern (Fig. 11.23A). Lesions are usually symmetrically distributed on the limbs (Fig. 11.23B) and the trunk[49]. Another prominent feature is a greasy and scaly eruption involving the upper portion of the face which has been described as a seborrheic dermatitis-like mediofacial eruption or psoriasiform scaling plaques (Fig. 11.23C). Keratotic papules are sometimes present on the palms and soles, and the nails and scalp may also be affected. Although the clinical course of keratosis lichenoides chronica is usually chronic and progressive, occasionally, regression of individual lesions during the summer or with aging has been reported.

The histologic features of keratosis lichenoides chronica are very similar to those seen in LP. Furthermore, there are no significant differences in immunofluorescence or immunopathologic findings between keratosis lichenoides chronica and idiopathic LP, suggesting that it may be an unusual variant of LP or an unusual isomorphic response. Treatment should be symptomatic and it is usually unsatisfactory; topical and systemic corticosteroids, methotrexate, cyclosporine, etretinate, oral vitamin A and PUVA have all been tried but with little success, although a beneficial effect from UVB or etretinate plus PUVA has been reported.

ACTINIC LICHEN NITIDUS (SUMMERTIME ACTINIC LICHENOID ERUPTION)

Summertime actinic lichenoid eruption was first described by Bedi[50] in 1978. Since its initial description, the disorder has been reported under a variety of names, including LP subtropicus, LP tropicus, lichenoid melanodermatitis, LP atrophicus annularis and LP actinicus. Of note, the last-mentioned is synonymous with actinic LP and the first three terms have also been used to describe actinic LP, so although many authors have regarded summertime actinic lichenoid eruption as synonymous with actinic LP, Bedi considered it to be a separate entity. The former typically occurs in young adults with skin types IV or V following prolonged exposure to the summer sun and presents with pinhead-sized lichenoid papules that are almost exclusively confined to sun-exposed areas.

Isaacson et al.[51] broadened the clinical spectrum of summertime actinic lichenoid eruption to include several types of lichenoid eruptions: annular hyperpigmented plaques, melasma-like patches, grayish-white pinhead-sized papules, and typical LP-like papules/plaques. As a result, their description of the histologic findings varied according to the morphology of the different types of clinical lesions. Hussain[52] then proposed that the designation "summertime actinic lichenoid eruption" should be limited to papular eruptions exclusively in sun-exposed areas with lichen nitidus-like histologic features, while the term actinic LP should be used to describe annular lesions with classic histopathologic features of LP. In addition, he suggested abolishing the term summertime actinic lichenoid eruption and replacing it with actinic lichen nitidus or lichen nitidus actinicus. This view has been supported by other authors.

ANNULAR LICHENOID DERMATITIS (OF YOUTH)

Annular lichenoid dermatitis of youth was first described in 2003 by Annessi and colleagues[53]. They observed, in a series of young patients, peculiar annular lesions whose clinical features appeared to overlap with those of inflammatory morphea, mycosis fungoides, inflammatory vitiligo, and figurate erythemas. In the initial reports, the annular lichenoid dermatitis occurred primarily in children and young adults (age range, 5–22 years), with no sexual predilection. However, in a more recently reported series of six patients, four were adult men, ranging in age from 33 to 45 years[54].

Patients present with erythematous macules that enlarge into annular patches with a reddish-brown, non-scaling border and central hypopigmentation. The lesions are usually 5 to 15 cm in diameter, involve

Fig. 11.23 Keratosis lichenoides chronica. **A** Linear and stellate keratotic plaques. **B** Symmetrical distribution of linear and reticulated keratotic plaques admixed with small, violaceous lichenoid papules. **C** Crusted psoriasiform scaling plaques on the face. *B, Courtesy, Kathyrn Schwarzenberger, MD; C, Courtesy, Jiro Arata, MD.*

primarily the groin and flanks, and are either solitary or multiple (range, 2–12 lesions; mean, 3).

Histologically, there is a band-like lymphocytic infiltrate within the papillary dermis, along with vacuolar changes of the epidermal basal layer and epidermotropism of lymphocytes. Although variable in number, apoptotic keratinocytes are localized to the tips of the rete ridges (a notable finding that distinguishes this entity from mycosis fungoides). Neither spongiosis nor changes in the horny and granular layers are observed. The infiltrate is composed primarily of $CD4^+$ T cells or $CD8^+$ T cells, with few B cells and macrophages. A normal number of melanocytes is present in the hypopigmented areas, a finding that is helpful in differentiating annular lichenoid dermatitis from inflammatory vitiligo. The absence of T-cell receptor rearrangements aids in excluding indolent mycosis fungoides[54].

The disease follows a chronic course, with some lesions spontaneously resolving while others are quite persistent. Although the pathogenesis remains unknown, it is thought to represent a reaction pattern to antigenic triggers (including hepatitis B vaccine), as is suspected in other lichenoid dermatoses. Topical or systemic corticosteroids and phototherapy have led to marked improvement or complete regression of the lesions.

Atopic Dermatitis 12

Thomas Bieber and Caroline Bussmann

Synonym: ■ Atopic eczema

Key features

- Common inflammatory skin condition that typically begins during infancy or early childhood and is often associated with other "atopic" disorders such as asthma and allergic rhinoconjunctivitis
- Complex genetic disease with environmental influences
- Characterized by intense pruritus and a chronic or chronically relapsing course
- Acute inflammation and involvement of the cheeks, scalp and extensor aspects of the extremities predominates in infants, shifting to chronic inflammation with lichenification and a predilection for flexural sites in children and adults
- A proactive approach to management is recommended, including avoidance of trigger factors, daily use of emollients, and anti-inflammatory therapy to control subclinical inflammation as well as overt flares

INTRODUCTION

Atopic dermatitis (AD) is the most common chronic inflammatory skin disease, and its increasing prevalence presents a major public health problem worldwide[1]. Characteristic features of AD include pruritus and a chronic or chronically relapsing course, usually beginning during infancy (early onset) but occasionally first developing in adulthood (late onset)[2]. AD is a paradigmatic complex genetic disease and is often accompanied by other atopic disorders such as allergic rhinoconjunctivitis and asthma. These conditions may appear simultaneously or develop in succession. AD has a predilection for infants and young children, while asthma favors older children and pollen allergy predominates in adolescents. This characteristic age-dependent sequence is referred to as the "atopic march"[3,4] (Fig. 12.1). Considering that the atopic disease progression starts with AD, management should not be concentrated solely on the treatment of acute flares, but also be directed towards improving the underlying genetically determined epidermal barrier dysfunction and preventing active dermatitis (e.g. via maintenance therapy). Such an approach could potentially block the sensitizations and ongoing inflammation that drive the atopic march forward[5].

HISTORY AND DEFINITIONS

Since its description during the nineteenth century, the clinical phenotype of AD has been given multiple different names, including "Besnier's prurigo" and "disseminated neurodermatitis". The association of AD with allergic rhinitis and asthma was recognized by Besnier in 1892. The term "atopy" (originating from the Greek word *atopos*, meaning strange or unusual) was first applied to this triad in the 1920s, including the use of "atopic eczema". A decade later, Hill and Sulzberger proposed the name "atopic dermatitis". The list of characteristic features proposed by Hanifin and Rajka[6] in 1980 (Table 12.1) helped to establish unity in the clinical concept of AD. In 1994, Williams and co-workers[7] simplified Hanifin and Rajka's criteria to establish the UK Working Party's Diagnostic Criteria for AD, which were validated for the purpose of clinical studies; these criteria were modified slightly by Williams in 2005 (Table 12.2)[2].

According to the current consensus nomenclature by the World Allergy Organization (WAO)[8], the term "atopy" is tightly linked to the presence of allergen-specific IgE antibodies in the serum, as documented by positive fluorescence enzyme immunoassays (previously radioallergosorbent [RAST] tests) or skin prick tests. Thus, an *IgE-associated* or *allergic* form of dermatitis corresponds to AD in the strict sense (formerly known as *extrinsic AD*). The remaining 20–30% of patients with the clinical phenotype of AD who have no evidence of IgE-sensitization are categorized as having a *non-IgE-associated* or *non-allergic* form of dermatitis (formerly known as *intrinsic AD*). However, IgE-associated/allergic "true" AD and non-IgE-associated/non-allergic dermatitis have substantial overlap and cannot be considered as two separate diseases; for example, the latter often represents an early transitional form of IgE-associated AD.

EPIDEMIOLOGY

The current prevalence of AD in most high-income and some low-income countries is approximately 10–30% in children and 2–10% in adults, representing a two- to threefold increase over the past several decades[1]. In general, the prevalence of AD in rural areas and low-income countries is significantly lower than in their urban and high-income counterparts, illustrating the importance of lifestyle and environment in the pathogenesis of atopic disease. This observation supports the controversial hygiene hypothesis, which postulates that decreased exposure to infectious agents in early childhood increases susceptibility to allergic diseases.

Three subsets of AD based on age of onset have emerged from epidemiologic studies:

- *early-onset type*: defined as AD beginning in the first 2 years of life. This is the most common type of AD, which develops during the first 6 months of life in 45% of affected individuals, during the first year of life in 60%, and before 5 years of age in 85%. Approximately half of children with disease onset during the first 2 years of life develop allergen-specific IgE antibodies by 2 years of

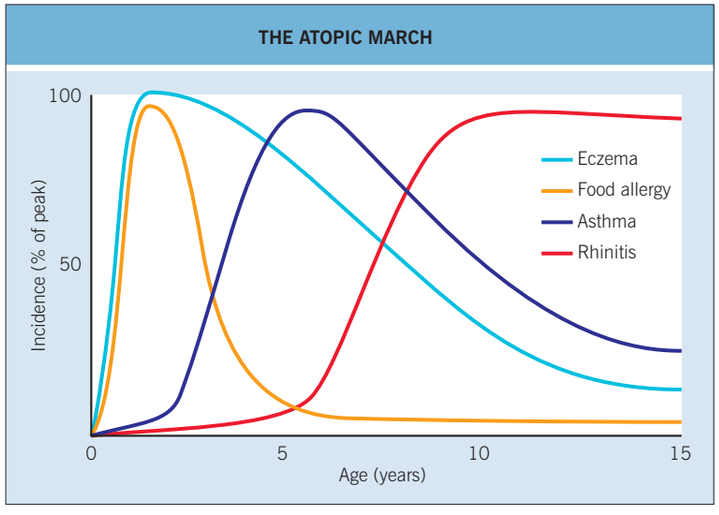

Fig. 12.1 The atopic march.

DIAGNOSTIC FEATURES OF ATOPIC DERMATITIS
MAJOR FEATURES (3 OF 4 PRESENT)
• Pruritus • Typical morphology and distribution of skin lesions • Chronic or chronically relapsing dermatitis • Personal or family history of atopy
MINOR FEATURES (3 OF 23 PRESENT)
• Xerosis • Ichthyosis/palmar hyperlinearity/keratosis pilaris • Immediate (type I) skin test reactivity • Elevated serum IgE • Early age of onset • Tendency toward cutaneous infections/impaired cell-mediated immunity • Tendency toward nonspecific hand or foot dermatitis • Nipple eczema • Cheilitis • Recurrent conjunctivitis • Dennie–Morgan infraorbital fold • Keratoconus • Anterior subcapsular cataract • Orbital darkening • Facial pallor/erythema • Pityriasis alba • Anterior neck folds • Pruritus when sweating • Intolerance to wool and lipid solvents • Perifollicular accentuation • Food intolerance • Course influenced by environmental/emotional factors • White dermographism/delayed blanch

Table 12.1 Diagnostic features of atopic dermatitis[6].

DIAGNOSTIC GUIDELINES FOR ATOPIC DERMATITIS
Must have: • An itchy skin condition (or parental report of scratching or rubbing in a child)
Plus three or more of the following: • History of involvement of the skin creases such as folds of elbows, behind the knees, fronts of ankles, the neck and around the eyes* • A personal history of asthma or hayfever (or history of atopic disease in a first-degree relative in children under 4 years of age) • A history of generally dry skin in the last year • Visible flexural eczema (or eczema involving the cheeks/forehead and extensor limbs in children under 4 years of age) • Onset under 2 years of age (not used if child is under 4 years of age)
*Original 1994 guidelines also included the cheeks in young children.

Table 12.2 Diagnostic guidelines for atopic dermatitis[2,7].

age. About 60% of infants and young children with AD go into remission by 12 years of age, but in others disease activity persists into adolescence and adulthood

- *late-onset type*: defined as AD that starts after puberty. There are few recent epidemiological studies on AD with onset in adulthood. Approximately 30% of AD patients overall are in the non-IgE-associated category, and among adults, the vast majority of such patients are women
- *senile-onset type*: an unusual subset of AD that begins after 60 years of age has been identified more recently[9].

PATHOGENESIS

Genetics

The concordance rate for AD is higher among monozygotic twins (77%) compared to dizygotic twins (15%), supporting the importance of genetic factors in its pathogenesis. Although the entities in the atopic triad cluster together in families, a parental history of AD is a stronger risk factor for the development of AD than either asthma or allergic rhinitis, suggesting the existence of genes specific to AD[10]. AD is a complex genetic disease, and both gene–gene and gene–environment interactions have pathogenic roles (Fig. 12.2). Two major sets of genes have been implicated in AD: (1) genes encoding epidermal proteins; and (2) genes encoding proteins with immunologic functions that are not specific to the skin. Selected chromosomal loci and candidate genes in these two groups that have been identified to date are listed in Table 12.3. In addition to classic genetic changes, epigenetic alterations may have a role in the development of AD.

Mutations in the filaggrin gene (*FLG*), which encodes a protein that aggregates keratin filaments during terminal differentiation of the epidermis, are responsible for ichthyosis vulgaris (see Table 12.5 and Ch. 57) and represent a major predisposing factor for AD[13]. A number of studies have shown that the same loss-of-function filaggrin variants that cause ichthyosis vulgaris have a prevalence of 20–50% in European children and adults with AD (compared to ≤10% of the general population)[14], and different loss-of-function filaggrin variants have been identified in similar proportions of Asian patients with AD (± ichthyosis vulgaris). With an overall odds ratio of ≥4, these filaggrin variants represent one of the strongest known genetic factors for a complex disease, with penetrances of ~60% for one variant allele and ~90% for two variant alleles. The presence of the filaggrin variants is correlated with early-onset, relatively severe, "extrinsic" (specific IgE-associated) AD that tends to persist into adulthood; affected individuals have an increased risk of eczema herpeticum and peanut allergies as well as a

SELECTED SUSCEPTIBILITY LOCI AND CANDIDATE GENES FOR ATOPIC DERMATITIS		
Chromosomal location	**Candidate gene(s)**	**Defective protein(s)**
GENES ENCODING EPIDERMAL PROTEINS		
1q21 (epidermal differentiation complex)	*FLG*	Filaggrin (loss-of-function variants; see text)
5q31–q32	*SPINK5*	Serine protease inhibitor LETKI
11q13.5	(rs7927894 SNP)	? (synergistic interaction with *FLG* null mutations)
19q13	*KLK7/SCCE*	Kallikrein-related peptidase 7/stratum corneum chymotryptic enzyme
GENES ENCODING IMMUNOLOGIC PROTEINS		
1q23	*FCER1A*	High-affinity IgE receptor, α chain
4q32	*TLR2*	Toll-like receptor-2
4q34	*IRF2*	Interferon regulatory factor 2
5q31	*IL4* *IL5* *IL12B* *IL13* *GM-CSF* *CD14*	Interleukin-4 Interleukin-5 Interleukin-12B Interleukin-13 Granulocyte–macrophage colony-stimulating factor Monocyte differentiation antigen CD14
8p23	*DEFB1*	β-defensin 1
11q13	*GSTP1*	Glutathione S-transferase P1
11q22	*IL18*	Interleukin-18
14q11	*CMA1*	Mast cell chymase
16p12	*IL4R*	Interleukin-4 receptor, α subunit (gain-of-function polymorphisms)
17q11	*CCL5/RANTES*	Chemokine (C-C motif) ligand 5/RANTES (gain-of-function polymorphisms in the promoter region)

Table 12.3 Selected susceptibility loci and candidate genes for atopic dermatitis[10–18]. Genome-wide association studies have identified other susceptibility loci, including 3q21, 3p26, 16q, 17q25 and 20p. FCER1A, Fc fragment of IgE high-affinity receptor I alpha polypeptide; LETKI, lymphoepithelial Kazal-type-related inhibitor; RANTES, regulated on activation, normally T-cell expressed and secreted; SNP, single nucleotide polymorphism; *SPINK5*, serine peptidase inhibitor Kazal type 5.

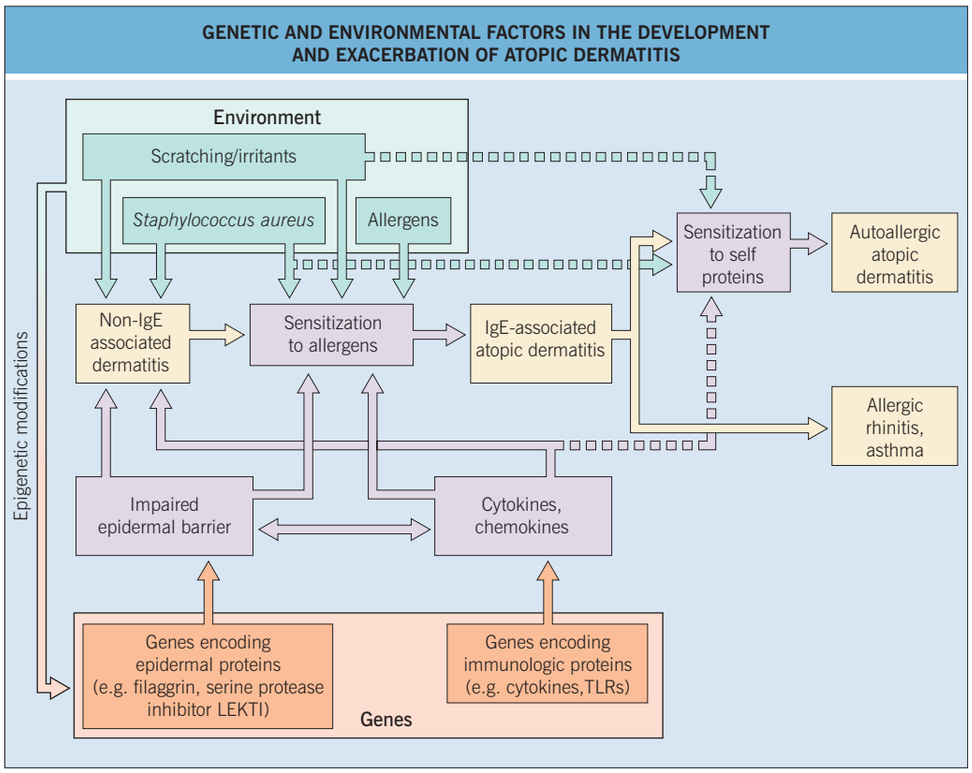

Fig. 12.2 Genetic and environmental factors in the development and exacerbation of atopic dermatitis TLR, Toll-like receptor. Adapted with permission from ref. 5.

propensity to later develop asthma[14,14a]. However, in general, there is no correlation between the filaggrin variants and asthma without prior AD, supporting a role for epicutaneous sensitization and inflammation in the skin (related to the disrupted epidermal barrier) in the subsequent development of asthma.

Epidermal Barrier Dysfunction

AD is characterized by dry, scaly skin (xerosis) in lesional and nonlesional areas, which is the consequence of epidermal barrier dysfunction and an altered stratum corneum leading to increased transepidermal water loss[19]. Factors that contribute to the impaired cutaneous barrier of AD are summarized in Table 12.4.

Immunopathology

Immunologic mechanisms involved in the pathogenesis of AD are presented in Table 12.4.

Pruritus

AD is characterized by persistent, severe pruritus, which significantly impacts the quality of life in affected individuals. The mechanisms of pruritus have just started to be understood. Since classic antihistamines are ineffective in AD, it is assumed that this mediator does not have a crucial role in AD-related pruritus. In contrast, neuropeptides, proteases, kinins, and cytokines such as interleukin (IL)-31 are known to induce itch. IL-31 is strongly pruritogenic and exerts its biologic activity through a heterodimeric receptor composed of the IL-31 receptor A and oncostatin M receptor β protein, both of which are overexpressed in lesional skin of AD[41–43]. These findings imply that IL-31 has an important role in the pruritus of AD.

CLINICAL FEATURES

Disease Course

AD is characterized by a broad clinical spectrum that varies depending upon the age of the patient, and it is divided into infantile, childhood and adolescent/adult stages. In each stage, patients may develop acute, subacute and chronic eczematous lesions, all of which are intensely pruritic and often excoriated. Acute lesions predominate in infantile AD and are characterized by edematous, erythematous papules and plaques that may exhibit vesiculation, oozing and serous crusting. Subacute eczematous lesions display erythema, scaling and variable crusting. Chronic lesions, which typify adolescent/adult AD, present as thickened plaques with lichenification as well as scale; prurigo nodule-like lesions can also develop (see below). Perifollicular accentuation and small, flat-topped papules (papular eczema) are particularly common in individuals with darkly pigmented skin. In any stage of AD, the most severely affected individuals may evolve to a generalized exfoliative erythroderma (see Ch. 10). All types of AD lesions can leave postinflammatory hyper-, hypo- or (in more severe cases) depigmentation upon resolution (Fig. 12.3).

Infantile AD (age <2 years) typically develops after the second month of life, often initially appearing as edematous papules and papulovesicles on the cheeks (often sparing the central face), which may evolve to form large plaques with oozing and crusting (Fig. 12.4). Involvement of the scalp, neck, extensor aspects of the extremities, and trunk (Fig. 12.5) can also occur, usually with sparing of the diaper area. In the first 6 months of life, the face and the neck are affected in over 90% of patients with AD[44]. Young infants may attempt to relieve itch through rubbing movements against their bedding, whereas older infants are better able to directly scratch affected areas.

In ***childhood AD (age 2 to 12 years)***, the lesions are less exudative and tend to become lichenified. The classic sites of predilection are the antecubital and popliteal fossae (flexural eczema) (Fig. 12.6). In addition, the head (especially periorificial regions), neck, wrists, hands, ankles and feet are often affected (Fig. 12.7). Xerosis typically becomes pronounced and widespread.

Adult/adolescent AD (age >12 years) also features subacute to chronic, lichenified lesions, and involvement of the flexural folds typically continues. However, the clinical picture may also change. Adults with AD frequently present with chronic hand dermatitis that has both endogenous and exogenous components (Fig. 12.8), while others have primarily facial dermatitis (Fig. 12.9), often with severe eyelid involvement (see below). Additional sites of predilection include the retroauricular region, neck and chest. Patients who have suffered from continuous AD since childhood are more likely to have extensive or even erythrodermic disease that is resistant to treatment. Such individuals may also have severe excoriations and chronic papular skin lesions (Fig. 12.10) as a result of habitual scratching and rubbing.

EPIDERMAL DEFECTS AND IMMUNOLOGIC MECHANISMS INVOLVED IN THE PATHOGENESIS OF ATOPIC DERMATITIS
IMPAIRMENT OF THE EPIDERMAL BARRIER
• Changes in the balance between proteolytic enzymes (e.g. kallikrein-related peptidase 7/stratum corneum chymotryptic enzyme) and their antiprotease counterparts (e.g. the serine protease inhibitor LETKI) lead to a net increase in protease activity that accelerates degradation of corneodesmosomes and lipid-processing enzymes; one result is a failure to generate ceramides[15,20] • Deficiency of filaggrin, which normally contributes to the assembly of the cornified envelope and (via its breakdown products) increases the water-binding capacity of the stratum corneum; of note, Th2-type inflammation can decrease the expression of filaggrin[21] • Disturbed maturation of lamellar bodies, potentially due to variations in the pH of the stratum corneum as well as alterations in epidermal lipid metabolism • Other alterations in epidermal differentiation, including changes in cornified envelope proteins (e.g. involucrin, loricrin) and lipid composition • As a result of the defective epidermal barrier, there is increased penetration of environmental irritants and allergens into the skin, triggering inflammation and sensitization[22]
MECHANISMS OF INFLAMMATION IN THE ABSENCE OF IgE-MEDIATED SENSITIZATION*
• Increased epidermal protease activity may initiate an inflammatory cascade[16] • Neuropeptides, irritants and scratching can stimulate the release of proinflammatory cytokines by keratinocytes • T-cell-mediated (but IgE-independent) reactions to epicutaneous (through the disrupted epidermal barrier) allergen exposure, as demonstrated by atopy patch testing[23]
EPICUTANEOUS SENSITIZATION
• Animal models have shown that epicutaneous sensitization can induce both a localized AD-like dermatitis and bronchial hyperreactivity to aerosolized allergens[24] • Allergens have increased cutaneous penetration due to the impaired epidermal barrier • Keratinocytes in AD patients produce high levels of thymic stromal lymphopoietin (TSLP), an IL-7-like cytokine that drives dendritic cells to induce Th2 polarization[25] • Pollen-associated prostaglandin-like bioactive lipids and water-soluble mediators also modulate dendritic cell function and promote Th2 polarization[26] • Proinflammatory mechanisms may be amplified by increased epidermal protease activity[16] • Chronic cutaneous inflammation in AD patients has systemic consequences (e.g. functional changes in circulating monocytes[27]); the skin may therefore represent the "point of entry" for atopic sensitization and deliver systemic signals promoting sensitization upon allergen exposure in the lungs or gut
ROLE OF DENDRITIC CELLS (DCS)
• Key roles that link innate and adaptive immunity[28] • *Plasmacytoid DCs* (responsible for antiviral defense) are almost absent in AD lesional skin[29] • Two distinct populations of *myeloid DCs* are present: *Langerhans cells* (*LCs*) and *inflammatory dendritic epidermal cells* (*IDECs*; only found in inflamed skin)[30] – Both express the high-affinity receptor for IgE (FcεRI) only in IgE-associated (extrinsic) AD; inflammatory signals can lead to upregulation of FcεRI expression[31] – Participate in the sensitization phase (see above) – Central roles in the uptake and presentation of allergens to Th1/Th2 cells and possibly Tregs[32] • LCs promote Th2 polarization and have a limited capacity to produce proinflammatory cytokines • IDECs promote Th1 polarization and produce proinflammatory cytokines; in acute AD, IDECs are actively recruited and large numbers invade the epidermis after 48–72 hours[33]
T-CELL RESPONSES, CYTOKINES AND CHEMOKINES
• Th2 cytokines (e.g. IL-4, IL-5, IL-13) predominate in acute AD lesions and in the systemic immunologic background of IgE-associated (extrinsic) AD • Th1 cytokines (e.g. IFN-γ, IL-12) predominate in chronic AD lesions • IDECs and eosinophils produce IL-12 and may be instrumental in the Th2 to Th1/Th0 switch • An orchestra of cytokines and chemokines produced by keratinocytes and endothelial cells contributes to inflammatory cell recruitment and evolution of the inflammatory reaction over time[34] – TSLP (see above) stimulates DCs to: (1) release CCL17 and CCL22; and (2) expand T cells that produce IFN-γ as well as those that produce IL-5 and IL-13 – CCL1, CCL27 (CTACK) and CCL18 attract $CCR4^+$ Th2 cells • IL-22-producing $CD4^+$ or $CD8^+$ T cells that do not produce IL-17 have been described in AD patients • The role of $CD25^+/Foxp3^+$ Tregs in AD is not yet fully understood – Circulating CLA^+, $CCR6^+$ Tregs are increased in AD patients – Lesional AD skin is devoid of functional Tregs[35]
ROLE OF MICROBIAL COLONIZATION
• Epidermal keratinocytes express a variety of pattern recognition receptors (e.g. Toll-like receptors [TLRs]) that bind to specific microbial structures, which induces an inflammatory response and the release of antimicrobial peptides such as defensins and cathelicidins (see Ch. 4); however, production of the latter peptides is down-regulated in the skin of patients with AD • *S. aureus* colonization of the skin occurs in >90% of AD patients due to factors such as decreased levels of antimicrobial peptides and increased bacterial adherence to eczematous/excoriated skin • *S. aureus* contributes to sensitization and inflammation in AD via several mechanisms – TLR-2 recognition of *S. aureus* cell wall components (e.g. lipoteichoic acid, peptidoglycan) stimulates an inflammatory response – Staphylococcal superantigens amplify inflammatory reactions via multiple pathways[36] and may contribute to corticosteroid resistance by inducing the competing β isoform of the glucocorticoid receptor – Staphylococcal enterotoxins A–D (SEA-D) can provoke IgE-mediated sensitization, which correlates with disease severity[37] – Staphylococcal toxins also augment inflammation by subverting the function of Tregs
ROLE OF AUTOIMMUNITY
• Some patients with AD have circulating IgE antibodies directed against self-proteins expressed by keratinocytes and endothelial cells[38] – The presence of these antibodies correlates with disease severity – Prevalence of ~25% in adult patients; have also been detected in infants[39] – Predisposing factors include early-onset AD, severe pruritus, recurrent bacterial skin infections and high serum IgE levels • Structural similarities between exogenous allergens and human proteins are thought to have a role in the development of IgE autoantibodies; this likely occurs in the context of cutaneous inflammation and scratching/cellular damage that leads to exposure of the autoantigens (see Fig. 12.2) • Some autoallergens induce Th1 responses[40] • These observations suggest that AD exists at the frontier between allergy and autoimmunity
*Commonly occurs in early-onset as well as intrinsic forms of AD.

Table 12.4 Epidermal defects and immunologic mechanisms involved in the pathogenesis of atopic dermatitis (AD). CCL or CXCL, chemokine (C-C or C-X-C motif) ligand; CCR or CXCR, chemokine (C-C or C-X-C motif) receptor; CLA, cutaneous lymphocyte antigen; CTACK, cutaneous T-cell-attracting chemokine; IL, interleukin; Tregs, regulatory T cells.

Fig. 12.5 Atopic dermatitis on the extensor surface of an infant's arm. Involvement of the extensor aspects of the extremities is common in this age group. Note the follicular prominence on the trunk.

Senile AD (age >60 years) is characterized by marked xerosis. Most of these patients do not have the lichenified flexural lesions typical of AD in children and younger adults.

AD has a profound adverse impact on the quality of life of affected children and adults, with intense pruritus and stigmatization often resulting in sleep disturbances, psychological distress, social isolation, disrupted family dynamics and impaired functioning at school or work.

Regional Variants of Atopic Dermatitis

Several regional variants of AD can occur in isolation or together with the classic age-related patterns of involvement described above. The face is a frequent location for site-specific manifestations. Eczema of the lips, referred to as ***cheilitis sicca***, is common in AD patients, especially during the winter. It is characterized by dryness ("chapping") of the vermilion lips, sometimes with peeling and fissuring, and may be associated with angular cheilitis. Patients try to moisten their lips by licking, which in turn may irritate the skin around the mouth, resulting in so-called ***lip-licker's eczema.*** Another common feature of childhood AD is ***ear eczema***, presenting as erythema, scaling and fissures under the earlobe and in the retroauricular area, sometimes in association with bacterial superinfection. ***Eyelid eczema*** can represent the only manifestation of AD, especially in adults. In contrast to eyelid eczema due to other causes, it is characterized by lichenification of the periorbital skin.

"Head and neck dermatitis" represents a variant of AD that typically occurs after puberty and primarily involves the face, scalp and neck. When older children and teenagers present with this form of AD, it usually persists into adulthood. It is postulated that lipophilic *Malassezia* yeasts, members of the normal skin flora that colonize the head and neck area, represent an aggravating factor for this condition. Serum levels of *M. furfur*-specific IgE have been shown to correlate with the severity of head and neck dermatitis[45], and improvement with systemic antifungal treatment has been observed in some patients. Sweating, heat, dryness, sun exposure and emotional stress can also aggravate this form of AD.

Fig. 12.6 Atopic dermatitis extending from the antecubital fossae to the wrists and hands. Note the excoriations and lichenification.

Fig. 12.11 Nipple eczema in an adolescent with atopic dermatitis. *Courtesy, Julie V Schaffer, MD.*

Eczema variants also occur in acral sites. ***Juvenile plantar dermatosis*** presents with "glazed" erythema, scale and fissuring on the balls of the feet and plantar aspect of the toes in children with AD, especially during the winter (see Ch. 13). ***Atopic hand eczema*** (see Fig. 12.8) affects approximately 60% of adult patients with AD and may be the only manifestation of the condition. It often occurs in atopic individuals whose hands are frequently exposed to water and other irritants in household or occupational settings. Atopic hand eczema typically involves the volar wrists and dorsum of the hands. The palms and sides of the fingers may develop the deep-seated vesicles of ***dyshidrotic eczema*** (see Ch. 13).

The ***prurigo form of AD*** favors the extensor aspects of the extremities and is characterized by firm, dome-shaped papules and nodules with central scale-crust, similar to prurigo nodularis lesions in non-atopic patients. ***Nummular lesions*** also tend to develop on the extremities in children and adults with AD, appearing as coin-shaped eczematous plaques, usually 1 to 3 cm in diameter and often with prominent oozing and crusting (similar in appearance to the lesions that characterize nummular dermatitis occurring outside the setting of atopy; see Ch. 13). Colonization with *Staphylococcus aureus* is thought to represent a trigger for this type of eczema. Intense pruritus is a feature of both prurigo and nummular lesions. ***Frictional lichenoid eruption*** has a predilection for atopic children (especially boys) and presents as multiple small, flat-topped, pink to skin-colored papules on the elbows and (less often) knees and dorsal hands. It classically occurs in the spring or summer, pruritus is variable, and the histologic findings are nonspecific. Lastly, chronic ***nipple eczema*** can develop in children and adults with AD (Fig. 12.11).

Associated Features

Pruritus

Intense pruritus is a hallmark of AD. The itch is often worse in the evening and may be exacerbated by exogenous factors such as sweating or wool clothing. Rubbing and scratching in response to pruritus can initiate flares or exacerbate existing dermatitis, explaining why AD

ASSOCIATED FEATURES OF ATOPIC DERMATITIS ("ATOPIC STIGMATA")	
Xerosis	• Important feature that is present in most patients with AD • Often most prominent on the lower legs; may be generalized • Dry skin with fine scale in areas without clinically apparent inflammation • Typically worse during the winter • Impaired epidermal barrier function from decreased water content in the stratum corneum leads to easier entry of irritants, which can promote pruritus and initiate an inflammatory response
Ichthyosis vulgaris	• Autosomal semidominant disorder with incomplete penetrance caused by mutations in the filaggrin gene (*FLG*; see text and Ch. 57) • ~15% of patients with AD have moderate to severe ichthyosis vulgaris; conversely, >50% of patients with ichthyosis vulgaris have AD • Excessive fine, whitish to brown scaling that favors the lower legs (especially the shins) and spares the flexures
Keratosis pilaris	• Common condition that affects >40% of patients with AD and ~75% of those with ichthyosis vulgaris • Onset typically in childhood; may improve after puberty (especially facial involvement) • Affects the lateral aspect of the upper arms, thighs and (especially in children) lateral cheeks > trunk and extensor aspects of the distal extremities • Keratotic follicular papules, often with a rim of erythema (see Fig. 12.12A) or (especially on the cheeks) a background of patchy erythema • The *keratosis pilaris rubra (KPR)* variant features numerous tiny, "grain-like" follicular papules superimposed on prominent confluent erythema (see Fig. 12.12B&C); often widespread (face & ears > trunk & proximal extremities) and tends to persist after puberty; presence of erythema rather than hyperpigmentation differentiates KPR from erythromelanosis follicularis faciei et colli, and a lack of atrophy in KPR differentiates it from keratosis pilaris atrophicans (see Ch. 38) • Keratolytic agents and topical retinoids are sometimes used to decrease the hyperkeratotic component, but the benefit is limited and these agents can be irritating, especially in AD patients; treatment with vascular lasers (e.g. the pulsed dye laser) can improve associated erythema
Palmar and plantar hyperlinearity	• Increased prominence of the palmar and, less often, plantar creases (see Fig. 12.13) • Associated with ichthyosis vulgaris and *FLG* mutations
Dennie–Morgan lines	• Symmetric, prominent horizontal fold(s) (single or double) just beneath the margin of the lower lid, originating at or near the inner canthus and extending one-half to two-thirds the width of the lid (see Fig. 12.14)
Periorbital darkening ("allergic shiners")	• Skin around the eyes appears gray to violet–brown, while the rest of the facial skin is rather pale • Periorbital edema and lichenification may also be seen
Anterior neck folds	• Horizontal folds across the middle of the anterior neck
Hertoghe sign	• Absence or thinning of the lateral eyebrows
White dermographism	• Stroking the skin leads to a white streak that reflects excessive vasoconstriction • Most apparent on the forehead • Mid-facial pallor (see Fig. 12.14) and a delayed blanch response represent additional manifestations of aberrant vascular reactivity in patients with atopic dermatitis
Follicular prominence	• "Goose bump-like" appearance of the skin, most often on the trunk (see Fig. 12.5) • More commonly observed in children with darkly pigmented skin

Table 12.5 Associated features of atopic dermatitis ("atopic stigmata"). AD, atopic dermatitis.

is known as the "itch that rashes". Excoriations (linear or punctate) are frequently present, providing evidence of scratching (see Figs 12.6 & 12.7A). With repeated rubbing and scratching, the skin becomes thickened and leathery with exaggerated skin markings (see Figs 12.6 & 12.7).

Atopic stigmata

Physical findings other than dermatitis that are frequently observed in patients with AD are presented in Table 12.5 (see Figs 12.12–12.15).

Pityriasis alba

Pityriasis alba frequently affects children and adolescents with AD. It is characterized by multiple ill-defined hypopigmented macules and patches (usually 0.5 to 2 cm in diameter) with fine scaling, which are typically located on the face (especially the cheeks; Fig. 12.15) but occasionally appear on the shoulders and arms. These lesions are most obvious in individuals with darkly pigmented skin and/or following sun exposure. Pityriasis alba is thought to result from a low-grade eczematous dermatitis that disrupts the transfer of melanosomes from melanocytes to keratinocytes. Similar hypopigmented lesions can appear upon resolution of more overtly inflamed, erythematous lesions of AD (see Fig. 12.3A). The differential diagnosis of pityriasis alba also

Fig. 12.16 Infected hand dermatitis in a patient with atopic dermatitis. There is impetigo-like crusting as well as pustules. *Courtesy, Louis A Fragola, Jr, MD.*

includes postinflammatory hypopigmentation secondary to other dermatoses (e.g. psoriasis or pityriasis lichenoides chronica; usually also extrafacial involvement), pityriasis versicolor (typically more sharply demarcated, small lesions that may coalesce centrally), vitiligo (sharply demarcated and depigmented rather than hypopigmented) and (occasionally if extrafacial involvement) hypopigmented mycosis fungoides. Regular use of sunscreens and other forms of photoprotection may minimize the appearance of pityriasis alba.

Complications

Infections

Patients with AD are predisposed to the development of skin infections because of factors including an impaired skin barrier and modified immune milieu (see Table 12.4). Bacterial and viral infections represent the most common complications of AD. Considering that *S. aureus* colonizes the skin of the vast majority of patients with AD, it is not surprising that ***impetiginization*** (which can also occur due to *Streptococcus pyogenes*) occurs quite frequently (Fig. 12.16). Bacterial infections may also exacerbate AD by stimulating the inflammatory cascade, e.g. via *S. aureus* exotoxins that act as superantigens (see Table 12.4).

Eczema herpeticum represents rapid dissemination of a herpes simplex viral infection over the eczematous skin of AD patients[46]. It initially develops as an eruption of vesicles, but affected individuals more often present with numerous monomorphic, punched-out erosions with hemorrhagic crusting (Fig. 12.17). Eczema herpeticum is frequently widespread and may occur at any site, with a predilection for the head, neck and trunk. It is often associated with fever, malaise and lymphadenopathy, and complications may include superinfection with *S. aureus* or *S. pyogenes* as well as herpetic keratoconjunctivitis and meningoencephalitis[46]. Patients with mutations in t he filaggrin gene and those who have both severe AD and asthma have an increased risk for eczema herpeticum, and decreased production of antimicrobial peptides may have a pathogenic role. Patients with AD are also predisposed to the development of widespread ***molluscum contagiosum***, sometimes with several hundred lesions (see Ch. 81).

Ocular complications

Besides development of acute conjunctivitis as a component of allergic rhinoconjunctivitis, the spectrum of atopic eye disease also includes chronic manifestations such as atopic keratoconjunctivitis (typically in adults) and vernal keratoconjunctivitis (favors children living in warm climates)[47]. Symptoms include ocular itching, burning, tearing and mucus discharge, often in association with conjunctival injection and (especially in atopic keratoconjunctivitis) blepharitis that manifests as swelling and scaling of the eyelids. Vernal keratoconjunctivitis features large, cobblestone-like papillae on the upper palpebral conjunctiva, and atopic keratoconjunctivitis is more prone to scarring. Additional infrequent ocular complications of AD include subcapsular cataracts (anterior more specific to AD, posterior more common)[48], keratoconus and retinal detachment.

DIAGNOSTIC CRITERIA

Several authors and groups have suggested guidelines to assist in establishing the clinical diagnosis of AD. Major features in these sets of criteria include pruritus, eczematous skin lesions in typical age-specific distribution patterns, a chronic or chronically relapsing course, early age at onset, and a personal and/or family history of atopy. Atopic stigmata (see Table 12.5), especially xerosis, are also recognized as supporting features. The Diepgen score represents another validated set of diagnostic criteria, which is separated into objective, subjective and laboratory features[49]. Validated scores to assess the severity of AD include the EASI (Eczema Area Scoring Index), SCORAD (SCORing Atopic Dermatitis) and POEM (Patient-Oriented Eczema Measure)[50]. IgE-associated and non-IgE-associated AD are distinguished based on the evaluation of total serum IgE levels (elevated in the former; normal <150 IU/ml) and the presence or absence of specific IgE. Although recognition of the latter can support the diagnosis of an atopic state, exposures to the allergens identified are not necessarily relevant to aggravation of AD (see below).

PATHOLOGY

The histologic features of AD depend upon the stage of the lesion sampled. *Acute*, exudative eczema is characterized by marked spongiosis, with intraepidermal fluid collection leading to the formation of vesicles (micro and macro) or even bullae. Some dermal edema may also be present, together with perivascular lymphocytes that extend into the epidermis and a variable number of eosinophils (Fig.12.18A). In *subacute* lesions, vesiculation is absent whereas acanthosis, hyperkeratosis and parakeratosis become evident (Fig. 12.18B). In *chronic*, lichenified eczema, epidermal thickening is more pronounced in a pattern that may be either irregular or regular (psoriasiform). Changes in the granular layer vary from thickening secondary to rubbing (as in lichen simplex chronicus) to thinning when there is a psoriasiform pattern (seen in some nummular lesions). Spongiosis and inflammation are less conspicuous, but there may be an increased number of mast cells and dermal fibrosis.

These features are not specific, as similar findings are observed in other eczematous dermatoses such as allergic contact dermatitis. There are occasionally histologic clues to the etiology, such as individually necrotic keratinocytes that suggest an irritant contact dermatitis. However, a skin biopsy is usually more helpful in excluding other entities that can mimic AD clinically, such as mycosis fungoides.

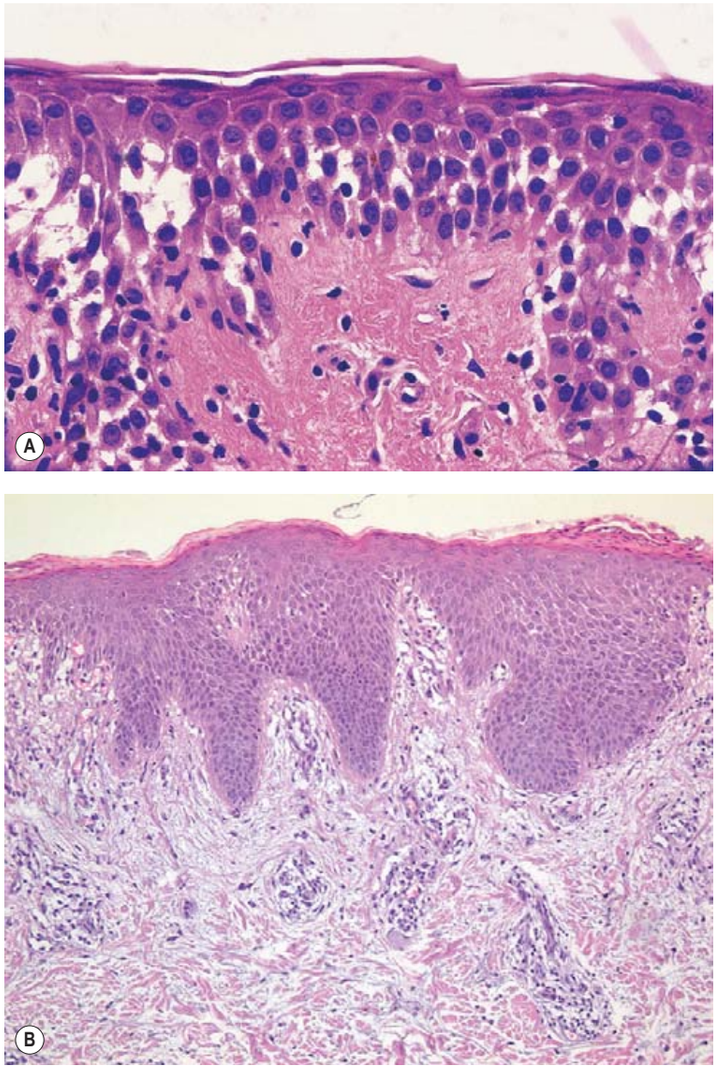

Fig. 12.18 Histologic features of acute and subacute atopic dermatitis. **A** Acute lesion showing spongiosis, intraepidermal vesicles and exocytosis of lymphocytes. **B** Subacute lesion with parakeratosis and less spongiosis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of AD is broad and includes other chronic dermatoses, infections, infestations and malignancies as well as metabolic, genetic (e.g. primary immunodeficiencies) and autoimmune disorders (Table 12.6). Depending upon the age of the patient and the clinical presentation, such entities may be considered prior to diagnosing AD, especially when the history, morphology and/or distribution of the skin lesions are atypical.

In infants, AD is often preceded and/or accompanied by seborrheic dermatitis, which commonly presents during the first month of life as yellowish-white, adherent scale-crusts on the scalp. Infantile seborrheic dermatitis also has a predilection for skin folds (where lesions may be oozing and lack scale) and the forehead, in contrast to the typical distribution of infantile AD on the extensor surfaces of the extremities and cheeks as well as the scalp. Scabies in infants often has generalized involvement and can mimic AD; in addition to the presence of burrows or identification of the mite or eggs (e.g. via dermoscopy or skin scrapings), scabies can usually be distinguished by the predominance of discrete small crusted papules, involvement of the axillae and diaper area, and the presence of acral vesiculopustules. Other less common conditions that occasionally represent a diagnostic consideration in infants, such as primary immunodeficiencies, are listed in Table 12.6.

Adolescents and adults without a personal or family history of atopy who present with an eczematous eruption should have a thorough history and (when indicated) patch testing to assess for the possibility of allergic contact dermatitis. This diagnosis should also be considered

DIFFERENTIAL DIAGNOSIS OF ATOPIC DERMATITIS		
CHRONIC DERMATOSES		
C>A	Seborrheic dermatitis	Common
B	Contact dermatitis (allergic* or irritant)	Common
B	Psoriasis (especially palmoplantar)	Common
A>C	Nummular dermatitis	Uncommon (although nummular lesions can be seen in AD, nummular eczema outside this setting is uncommon)
A	Asteatotic eczema	Common
A>C	Lichen simplex chronicus (secondary to pruritus of variable etiology)	Common
INFECTIONS AND INFESTATIONS		
B	Scabies	Common
B	Dermatophytosis*	Common
B	HIV-associated dermatoses	Variable
C	HTLV-1-associated "infective dermatitis"	Variable
C	Chronic mucocutaneous candidiasis	Rare
C	Neonatal mucocutaneous candidiasis	Variable
B	Impetigo	Variable (nummular lesions of AD most commonly mimic impetigo)
C	Congenital syphilis	Variable
PRIMARY IMMUNODEFICIENCIES		
C	Wiskott–Aldrich syndrome	Rare
C	Hyperimmunoglobulin E syndrome	Rare
C	Severe combined immunodeficiency	Rare
C	DiGeorge syndrome (congenital thymic aplasia)	Rare
C	Immunoglobulin deficiencies: X-linked hypogammaglobulinemia, common variable immunodeficiency, IgA deficiency	Variable
C	Ataxia telangiectasia	Rare
MALIGNANCIES		
A>C	Mycosis fungoides and Sézary syndrome	Uncommon
C	Langerhans cell histiocytosis	Rare
METABOLIC AND GENETIC DISORDERS		
C	Netherton syndrome	Rare
C	Ectodermal dysplasias	Rare
B	Keratosis pilaris	Common
C	Hartnup disease	Rare
C	Phenylketonuria	Rare
B	Acrodermatitis enteropathica, glucagonoma syndrome, pellagra, riboflavin deficiency	Rare
C>A	Other causes of "nutritional dermatitis", e.g. biotin deficiency, essential fatty acid deficiency, organic acidurias, cystic fibrosis	Rare
AUTOIMMUNE DISORDERS		
A>C	Dermatitis herpetiformis	Uncommon
A>C	Pemphigus foliaceus	Uncommon
B	Dermatomyositis	Uncommon (but often misdiagnosed as AD in children)
A>C	Lupus erythematosus	Uncommon
OTHER		
B	Drug eruptions	Uncommon (although drug eruptions are common, those resembling atopic dermatitis are uncommon)
A>C	Photoallergic contact dermatitis	Uncommon
A	Chronic actinic dermatitis	Uncommon
B	Graft-versus-host disease	Uncommon

*More common causes of disseminated eczema ("id reaction"), which is especially frequent in the setting of stasis dermatitis + allergic contact dermatitis.

Table 12.6 Differential diagnosis of atopic dermatitis. A, adults; B, both; C, children/infants.

in children and adults with established AD who fail to respond as expected to treatment or develop lesions in an atypical distribution pattern. Components of emollients or topical corticosteroid preparations represent potential allergens in these individuals. Protein contact dermatitis can also present as a chronic eczematous dermatitis and is more common in atopic individuals. Common causes include a variety of foods and animal products (Table 12.7; see Ch. 16), and it is diagnosed by prick testing or observation of an urticarial reaction within 30 minutes of patch testing on previously affected skin.

Mycosis fungoides (MF) should be considered in adolescents and adults with chronic dermatitis poorly responsive to topical corticosteroid treatment. Because the histologic findings of early MF may be difficult to distinguish from those of AD, multiple biopsies are recommended, preferably from untreated areas of skin since corticosteroids can eliminate epidermotropic T cells that point to the diagnosis of MF. Longitudinal evaluation of such individuals is required, especially when the clinical and/or histologic features are not classic for AD, with additional biopsies as indicated.

TREATMENT

Because AD is a chronic relapsing disease, the classic approach to therapy is targeting acute flares with short-term treatment regimens, i.e. reactive management. Based on recent insights into the underlying skin barrier defect and its relationship to inflammatory processes in the skin and other organs, a proactive approach that includes long-term maintenance therapy is now recommended[51]. Currently, management of AD includes the following components:

- avoidance of trigger factors, including irritants, relevant allergens and microbial agents
- skin care that aims to compensate for the genetically determined impaired epidermal barrier function
- anti-inflammatory therapy to control subclinical inflammation as well as overt flares
- in selected cases, adjunctive or complementary modalities.

As a rule, management should be adapted to the severity of the disease. While mild cases can typically be controlled by continuous use of emollients and intermittent use of a low-potency topical corticosteroid for flares, moderate AD may also require proactive maintenance with anti-inflammatory agents. In more severe and refractory cases, the use of phototherapy and systemic drugs may be necessary to control the disease (Table 12.8). An appropriate educational program for patients and parents is another essential component of the management of AD.

Avoidance of Trigger Factors

Multiple environmental and psychological factors can trigger AD, including allergens (e.g. pollen, dust mites, animal dander), sweating, harsh soaps, wool or other rough fabrics, cigarette smoke and emotional stress. These vary depending upon the patient and may be identified (and subsequently avoided) by a careful history and (when indicated) allergy testing. Fluorescence enzyme immunoassays (which have largely replaced RAST tests) can be performed on serum samples to quantify specific IgE antibodies against suspected allergens; skin prick testing represents another option to assess for immediate hypersensitivity. The atopy patch test can provoke an eczematous reaction through the epicutaneous application of aeroallergens (for which the test has been standardized) or food allergens, with readings at 48 and 72 hours to detect delayed hypersensitivity[52]. It holds promise as a relatively specific tool to evaluate children with AD for clinically significant allergies.

Allergen-specific immunotherapy, which can abrogate allergic sensitizations, represents a strategy to block trigger factors in selected patients with AD. For example, in some randomized controlled studies, sublingual or subcutaneous immunotherapy led to improvement of skin disease in AD patients with specific sensitizations against house dust mites[53]. Modest improvement in this subset of AD patients has also been observed after reducing dust mites in the home (especially the bedroom) through methods such as utilization of mattress and pillow covers, high-filtration vacuum cleaning and miticide sprays.

Food hypersensitivity affects about 10–30% of infants and children with AD, and ~90% of reactions in this patient population are caused by five allergens: eggs (most often linked to AD exacerbations), milk, peanuts, soy and wheat. Reactivity to peanuts (as well as tree nuts, fish and shellfish) tends to persist, but children usually "outgrow" sensitivities to other foods[54]. The clinical history and (in selected instances) provocation tests should be used to determine the *relevance* of positive laboratory and skin prick tests, since results of the latter tests do not necessarily identify allergies that are exacerbating the patient's AD. For example, double-blind food challenges may be useful in young children with a history of food-induced paroxysms of pruritus. Although avoidance of food allergen triggers can help to prevent flares in a subset of patients with the IgE-associated form of AD (especially infants with severe, refractory disease), this must be balanced with the potential for

CAUSES OF PROTEIN CONTACT DERMATITIS
• Fruits (banana, fig, kiwi, lemon, pineapple) • Grains (barley, rye and wheat flours) • Latex • "Meats" (fish, seafood, beef, pork, poultry) • Mites and insects (rice flour beetle, dust mite, storage mite) • Nuts (almond, hazelnut, peanut) • Spices (caraway, curry, dill, garlic, paprika, parsley) • Vegetables (carrot, cauliflower, celery, cucumber, lettuce, mushroom, onion, parsnip, potato) • Animal dander, hair, saliva or urine (cow, deer, goat, dog, cat, rodents, hedgehog, rabbit, giraffe)

Table 12.7 Causes of protein contact dermatitis.

THERAPEUTIC LADDER FOR ATOPIC DERMATITIS	Evidence
Emollients (basic therapy)	1
Topical corticosteroids	1
Topical calcineurin inhibitors	1
UVB (narrowband>broadband), UVA-UVB, UVA1 or oral PUVA	1
Systemic corticosteroids (short term for severe acute flares; "rebound" exacerbations often occur upon discontinuation)	2
Cyclosporine (short/intermediate term)	1
Azathioprine	1
Mycophenolate mofetil/enteric-coated mycophenolate sodium	1*/2
Methotrexate	1*/2
Interferon-γ	**
IVIg	2†
Omalizumab	2†
Rituximab	2
Other (crude coal tar, hydroxychloroquine, extracorporeal photochemotherapy)	2–3
ADJUNCTIVE THERAPIES	
Wet wraps, open wet dressings or soaks (combined with topical corticosteroids for acute flares)	
Dilute sodium hypochlorite (bleach) baths	
Treatment of associated bacterial, viral or fungal infections	
Oral antihistamines for antipruritic‡ and sedative effects	
Leukotriene antagonists‡	
Sodium cromoglycate (topical or oral)‡	
Probiotics‡ (may have efficacy in primary prevention)	

*In recent randomized controlled trials in adults with severe AD, enteric-coated mycophenolate sodium was found to have similar efficacy to cyclosporine as maintenance therapy, and methotrexate was found to have similar efficacy to azathioprine (see text).
**Although found to be effective in one randomized controlled trial, results of other studies have been inconsistent (see Ch. 128).
†No significant benefit was found in a small controlled trial.
‡Inconsistent demonstration of efficacy in controlled trials.

Table 12.8 Therapeutic ladder for atopic dermatitis (AD). Key to evidence-based support: (1) prospective controlled trial; (2) retrospective trial or large case series; (3) small series or individual case reports.

adverse sequelae from unnecessarily restrictive diets (e.g. kwashiorkor due to "rice milk" diets). Modified diets should be supervised by a pediatric dietician to ensure that they are nutritionally adequate.

Because *S. aureus*, which densely colonizes the skin in most AD patients, is known to amplify the cutaneous inflammation that underlies AD (see Table 12.4), reduction of bacterial load can play a role in the management of AD. In a recent randomized controlled study, 0.005% sodium hypochlorite baths (0.5 cup of household bleach [6% sodium hypochlorite] added to a full 40-gallon bathtub) twice weekly together with intermittent use of intranasal mupirocin ointment over a 1- to 3-month period led to greater improvement of moderate to severe, superinfected AD than did placebo (with both groups initially receiving a 2-week course of oral cephalexin)[55]. Cleansers and emollients containing antiseptics such as triclosan or clioquinol represent additional options. In general, the use of topical and systemic antibiotics should be restricted to short-term treatment of superinfections in order to prevent the development of bacterial resistance. There is some evidence that the *S. aureus* strains that colonize and superinfect patients with AD are more likely to be susceptible to first-generation cephalosporins (e.g. cephalexin) than are those that cause other *S. aureus* skin infections in the same communities[55,56].

Basic Therapy (Skin Care)

Recent findings highlighting the critical role of an impaired skin barrier in the pathogenesis of AD underscore the importance of a continuous basic therapy with emollients, even in periods and sites in which the AD is not active. The formulation of the emollient should be chosen based upon the degree of dryness of the skin, the sites of application, acceptance by the patient and the season. Ointments (e.g. petrolatum) and water-in-oil creams are more occlusive and tend to cause less burning and stinging than oil-in-water creams and lotions. However, the greasiness of an ointment is not acceptable to all patients. Potentially allergy-provoking ingredients such as perfumes, lanolin and herbal extracts should be avoided. The addition of moisturizing factors that are able to bind water (e.g. glycerol, urea) leads to increased hydration of the epidermis[57]. However, emollient products with higher concentrations of urea or α- and β-hydroxy acids, which can decrease scaling as well as dryness, tend to sting when used in children and on acutely inflamed or excoriated skin. Emollients containing particular combinations of lipids that are normally present in the stratum corneum (e.g. cholesterol, fatty acids, ceramides) may optimize barrier repair[58]. Emollients should be applied twice daily to the entire cutaneous surface.

AD patients should use mild, non-alkaline cleansers (e.g. syndet bars; see Ch. 153) as needed (e.g. focusing on soiled and apocrine-containing areas). Bubble baths and scented salts or oils should be avoided. Although allowing moisture to fully evaporate from the skin following bathing can worsen xerosis, application of an emollient to the skin within 3 minutes of exiting a daily lukewarm bath or shower increases skin hydration and barrier function. If treatment with a topical corticosteroid is indicated, it should be applied immediately after bathing, prior to the emollient. For acute flares of AD, 10- to 20-minute soaks in lukewarm bathwater or tap water compresses followed directly with corticosteroid application ("soak and smear") or placement of wet wraps after topical corticosteroid application can soothe oozing or crusted lesions and result in rapid improvement. Scalp care should include a bland shampoo. Shampoos, lotions and creams containing tar (5–10% liquor carbonis detergens) are helpful in some patients but may be irritating in children and when used on acutely inflamed skin.

Topical Anti-inflammatory Therapy

Topical corticosteroids are the mainstay of pharmacologic therapy for AD, and topical calcineurin inhibitors (TCIs) also play an important role. For the treatment of acute flares of AD, *topical corticosteroids* represent the first-line therapy because of their potent anti-inflammatory effects. These agents suppress production of several transcription factors, which leads not only to reduced expression of proinflammatory cytokines, but also to inhibition of cell growth and decreased synthesis of collagen and other structural proteins (explaining side effects such as skin atrophy; see Ch. 125). Topical corticosteroids designed to have decreased systemic bioavailability and a favorable therapeutic index (e.g. prednicarbate, hydrocortisone butyrate, fluticasone propionate, mometasone furoate) may be preferable, especially for infants and young children with widespread involvement.

Considerations in selecting the potency and vehicle of the topical corticosteroid include the location, type (e.g. acute versus chronic), thickness and extent of the AD lesions as well as the age of the patient. The corticosteroid should have an appropriate potency to quickly gain control of the flare, and continuation of daily therapy until the active dermatitis is completely clear minimizes the likelihood of a rebound. Long-term daily use of an inadequately potent topical corticosteroid can result in a greater risk of side effects (as well as less control of the eczema) than relatively brief use of a more potent agent. After clinical resolution of longstanding or severe lesions, tapering to every-other-day treatment may be considered prior to decreasing to maintenance therapy. For children and adults with moderate to severe AD, randomized controlled trials have demonstrated that the risk of relapse can be significantly reduced by proactive maintenance with twice-weekly application of a mid-potency topical corticosteroid to the usual areas of involvement (in conjunction with emollient use), with no evidence of cutaneous atrophy after up to a year of treatment[59–61].

For the face and body folds, high-potency corticosteroids (particularly long-term use) should be avoided if possible due to risk of cutaneous atrophy. Potent corticosteroids (e.g. class 1–2) are often needed for thick or lichenified plaques, nummular or prurigo-like lesions, and eczema on the palms and soles. Flurandrenolide tape represents another option for prurigo-like lesions, since it physically blocks scratching and rubbing of the affected area. Corticosteroid ointments (which minimize burning/stinging) and creams are generally preferred considering the dryness of the skin in AD patients and the emollient effects of these vehicles. Application immediately after bathing improves cutaneous penetration and also decreases burning. Corticosteroid solutions, foams or (especially for children and individuals of African descent) oils represent choices for AD on the scalp.

Two *topical calcineurin inhibitors (TCIs)* have been approved by the US Food and Drug Administration (FDA) for the treatment of AD: tacrolimus 0.03% and 0.1% ointment (for "moderate to severe" disease) and pimecrolimus 1% cream (for "mild to moderate" disease) (see Ch. 128). These agents suppress T-cell activation and modulate the secretion of cytokines and other proinflammatory mediators. Their efficacy in the treatment of AD has been proven in clinical trials in adults and children at least 2 years of age (and, for pimecrolimus, infants ages 3–23 months, although it is not approved for this group)[62,63]. The major side effect of both medications is burning at the site of application; they are not associated with cutaneous atrophy.

There has been no short-term or intermediate-term (>10 years) evidence of systemic immunosuppression or an increased risk for malignancy in clinical studies or post-marketing surveillance of topical tacrolimus and pimecrolimus, and long-term data collection is ongoing[64,65]. However, in 2006 the FDA introduced black box warnings for both drugs concerning a theoretical cancer risk; this was based on the occurrence of lymphomas in mice exposed to systemic levels 30–50-fold greater than the highest recorded blood levels in human patients. Pharmacokinetic studies in children and adults with AD have demonstrated minimal systemic absorption of TCIs, with transient detectable (but low) blood levels occasionally observed in patients with severe AD involving a large portion of the body surface area.

TCIs are particularly suitable for AD affecting the face and intertriginous areas, sites where corticosteroid-induced skin atrophy is of increased concern and TCI therapy is especially effective. TCIs are also beneficial in patients with frequently flaring or persistent AD that would otherwise require almost continual use of topical corticosteroids. Recent randomized controlled studies have shown that the proactive application of tacrolimus ointment (e.g. twice weekly as maintenance) can prevent flares of AD without increasing the overall amount of medication used[66,67].

Phototherapy

AD patients can benefit from treatment with ultraviolet (UV) light. *UVA1*, *UVA combined with UVB*, and *narrowband UVB* have each been shown to improve both the eczema and associated pruritus. The immunomodulatory effects of phototherapy occur via induction of T-cell

apoptosis, reduction of dendritic cells, and modified cytokine expression (e.g. decreased IL-5, IL-13 and IL-31 after treatment of AD with UVA1)[68] (see Ch. 134). In addition, treatment with UVB has been shown to reduce *S. aureus* colonization of the skin in AD patients[69]. Narrowband UVB and high-dose UVA1 can both be helpful for chronic AD, and UVA1 may also be useful in the treatment of acute flares. Phototherapy can be combined with topical corticosteroids, particularly in the initial phase of treatment. The side-effect profile of phototherapy is favorable compared to systemic immunosuppressive agents, with potential risks of "sunburn" and, with long-term treatment, photoaging and possibly induction of cutaneous malignancies. The time and effort required to travel several times a week to a phototherapy center may be problematic for some patients (e.g. disrupting school and work), and a home UV unit may be an option for those receiving chronic treatment. In younger children, phototherapy may be difficult for practical reasons (e.g. lack of cooperation), and some centers limit its routine use to patients ≥12 years of age.

Systemic Anti-inflammatory Therapy

Systemic anti-inflammatory treatment should be restricted to severe, refractory cases of AD that do not respond adequately to intensive topical therapy. The risk–benefit profile should be carefully considered before starting an immunosuppressive agent, and patients receiving these medications require close monitoring for side effects. Of note, no systemic medications besides corticosteroids have been FDA-approved for treatment of AD. However, in general, treatment of AD with *systemic corticosteroids* should be avoided due to a propensity for significant rebound flares upon their discontinuation[69a] and the unacceptable side effects of long-term use (see Ch. 125). In the occasional exception of a severe, generalized acute flare (e.g. with a specific trigger) resistant to aggressive topical management, treatment with a systemic corticosteroid should be limited to a short course, with transition to a topical regimen, phototherapy and/or an alternative systemic agent.

Administration of *oral cyclosporine* typically leads to rapid improvement of skin disease and associated pruritus in patients with AD, and its efficacy has been established in randomized controlled trials. However, the use of oral cyclosporine to treat AD is limited by potential side effects such as nephrotoxicity (which can develop after as little as 3–6 months of therapy) and increased blood pressure, which seem to be dose-dependent. Treatment is frequently started with a dose of 5 mg/kg/day, which should be gradually reduced to the minimal effective maintenance dose (usually ~2 mg/kg/day). Of note, cyclosporine is often not sufficient as monotherapy, requiring combination with topical corticosteroids to reach an almost complete remission.

Azathioprine can be an effective treatment for moderate to severe AD in children and adults[70], with modest benefit documented in a randomized controlled trial. Because individuals with genetically determined low activity of the enzyme thiopurine methyltransferase (TPMT) have increased susceptibility to azathioprine-induced myelotoxicity, the risk of this complication can be decreased by determining TPMT activity and/or genotyping for *TPMT* polymorphisms prior to initiating therapy and adjusting the dose accordingly (2–3.5 mg/kg/day if normal, 0.5–1 mg/kg/day if low)[71]. The results of several uncontrolled studies suggest that *mycophenolate mofetil* (1–2.5 g/day; 25–50 mg/kg/day in children) is also an effective and safe treatment for moderate to severe AD[72]. A recent randomized controlled trial found that enteric-coated mycophenolate sodium and cyclosporine (3 mg/kg daily) overall had similar effectiveness for long-term maintenance treatment (following 6 weeks of cyclosporine 5 mg/kg daily) of severe AD in adults, although patients receiving mycophenolate had more flares early in maintenance and those receiving cyclosporine had shorter remissions following discontinuation of therapy[72a]. In AD patients treated with either azathioprine or mycophenolate mofetil, initial responses are often delayed a month or more, and full benefit typically occurs after 2–3 months of therapy. *Methotrexate* (7.5–25 mg/week) has shown promising results in small series of adults with AD and had similar efficacy to azathioprine in a recent randomized controlled trial[73].

Adjunctive Pharmacologic Therapy

Sedating antihistamines (e.g. hydroxyzine, diphenhydramine, doxepin) can be useful in breaking the "itch–scratch cycle" in AD when given at bedtime, especially in patients with pruritus that disrupts sleep or who scratch excessively during the night. Non-sedating antihistamines are occasionally helpful, but the most benefit is usually obtained at higher doses, that are sedating. In controlled trials, adjunctive therapy with antihistamines and other medications, including leukotriene inhibitors and antimicrobial agents aimed at reducing colonization (see above), has not consistently demonstrated efficacy (see Table 12.8).

Alternative/Complementary Therapy

Dietary lipid supplements (e.g. evening primrose and borage oils) have been studied as a treatment for AD but showed no advantage over placebo. Chinese herbal therapy for AD has been evaluated in controlled trials; although benefit was reported in some of these studies, other investigators have not been able to replicate the results. In one report, analysis of "herbal creams" noted by parents in the UK to improve their children's AD revealed that 80% contained a corticosteroid, more than half of which represented clobetasol propionate[74].

Patients with AD and parents of affected children often seek and tend to be receptive to alternative treatment methods such as biofeedback and hypnotherapy. Although beneficial effects of such modalities have been reported, efficacy has not been established in controlled studies, and placebo groups in controlled trials of AD treatments often have high response rates.

Targeted Molecular Therapy ("Biologics")

The anti-IgE monoclonal antibody *omalizumab*, which inhibits the binding of IgE to its high-affinity receptor (FcεRI), is FDA-approved for the treatment of asthma in patients ≥12 years of age with sensitization to aeroallergens and a total IgE level up to 700 IU/ml (with dosing based on the IgE level). It is administered every 2–4 weeks via subcutaneous injection, which must be performed in-office due to the risk of anaphylaxis. Improvement of AD upon treatment with omalizumab has been described in several uncontrolled series. However, in a small randomized controlled trial in adults with AD, a clinical response was not noted despite depletion of IgE and decreased responses to allergens in immediate- and delayed-type skin tests[75]. Whether a subgroup of AD patients (e.g. with acute disease) may respond better than others remains to be determined.

The anti-CD20 monoclonal antibody *rituximab* (administered via two intravenous infusions separated by 2 weeks), which inhibits mature B cells but does not affect plasma cells or IgE levels, has been shown in an open-label trial to substantially improve severe AD in adults[76]. The monoclonal antibody *mepolizumab* inhibits IL-5, a crucial factor for growth and differentiation of eosinophils. Although mepolizumab can decrease the eosinophil count in patients with AD, it failed to lead to a significant clinical improvement in a controlled trial[77].

Emerging Therapies

Additional targeted molecular therapies are currently under development for the treatment of asthma and AD, with goals of blocking factors such as cytokines involved in the regulation of IgE synthesis (e.g. IL-4) or chemoattractant receptor-homologous molecule expressed on Th2 cells (CRTH2). Other potential targets are involved in the migration of inflammatory cells, such as the chemokine receptor CCR3 and phosphodiesterase 4. Since AD patients are deficient in antimicrobial peptides, the development of similar synthetic antimicrobial agents could improve control of microbial, fungal and viral infections. Designing better agents to repair the skin barrier represents another area of investigation.

Educational Programs

Education of patients and their parents about skin care and the natural history, triggers and rationale for proactive management of AD is very important. Parents often seek an eradicable cause for their child's AD and have difficulty accepting "control" rather than a "cure" of the condition[78]. The majority of patients and parents are particularly anxious about corticosteroid use, which often leads to delayed and inadequate treatment[79]. Addressing their specific concerns and acknowledging the stresses associated with this chronic disease (also noting the improvement in pruritus and sleep disturbances likely to result from

treatment) make it easier for families to deal with AD and facilitate doctor–patient/parent communication. Interdisciplinary educational programs involving psychologists and dieticians as well as dermatologists have been shown to improve both the severity of the eczema and quality of life[80]. Patients and families can also receive information and support from groups such as the National Eczema Association (www.nationaleczema.org).

Primary Prevention

Although the therapeutic armamentarium available for AD can successfully control the disease in most patients, primary prevention of AD represents a highly desirable goal. For infants with a family history of atopy, there is evidence that exclusive breastfeeding during the first 4–6 months of life or feeding with formulas based on hydrolyzed milk products rather than intact cow's milk protein can protect against the development of AD (no benefit from soy milk)[81,82]. In these high-risk infants, some studies have also shown a modest benefit with a low-allergen maternal diet during breastfeeding, but manipulated maternal diets during pregnancy have been associated with preterm labor and lower birthweights. In several randomized placebo-controlled studies, administration of probiotics (e.g. lactobacilli) or prebiotics (non-digestible oligosaccharides that promote the growth of desirable bacteria) to pregnant mothers and infants has been associated with significantly decreased frequencies of AD at 1 to 4 years of age (approximately half of the frequencies in placebo groups)[83,84]. There is no substantial evidence for effects of dietary interventions beyond 4–6 months of age (including delayed introduction of allergenic foods such as eggs) on the development of AD[81].

In addition to contact and atopic dermatitis, there exists a heterogeneous group of inflammatory skin diseases that obviously share the hallmarks of eczemas but display characteristic additional features. Their pathogenesis is generally less well understood than that of contact or atopic dermatitis, but most display distinctive etiologic features. There is some overlap within the entire group.

SEBORRHEIC DERMATITIS

Key features

- Infantile and adult forms
- Lesions favor the scalp, ears, face, central chest, and intertriginous areas
- Etiologic links with active sebaceous glands, abnormal sebum composition, and *Malassezia furfur* (*Pityrosporum ovale*)
- Can be a cutaneous sign of HIV infection

Introduction

Seborrheic dermatitis is a common mild chronic eczema typically confined to skin regions with high sebum production and the large body folds. Although its pathogenesis is not fully elucidated, there is a link to sebum overproduction (seborrhea) and the commensal yeast *Malassezia*.

History

Seborrheic dermatitis was first described by Unna[1], who also suspected *Malassezia furfur* (*Pityrosporum ovale*) as a causative factor. The nosologic position of seborrheic dermatitis was widely discussed for decades, the focus resting on dysfunction of the sebaceous glands and the high amounts of *M. furfur* present in scales of seborrheic dermatitis. In 1984 it was shown by Shuster[2] that seborrheic dermatitis could be suppressed by systemic ketoconazole. This finding was corroborated by later studies[3], and it became clear that seborrheic dermatitis was strongly linked to *Pityrosporum* yeasts. Today, a direct role of *M. furfur* in seborrheic dermatitis is accepted.

Epidemiology

An infantile and an adult form are distinguished, the former being self-limited and confined to the first 3 months of life, while the latter is chronic with a peak in the fourth to sixth decades. Adult seborrheic dermatitis is probably the most common type of eczema. Its prevalence is estimated at 5%, but its lifetime incidence is much higher. There are no reliable incidence data because seborrheic dermatitis of the scalp (its most common presentation) cannot be completely separated from the common problem of dandruff in population-based studies. Men are afflicted more often than women. There is neither a genetic predisposition nor horizontal transmission. Extensive and therapy-resistant seborrheic dermatitis is an important cutaneous sign of HIV infection[4], Parkinson's disease, and mood disorders[5].

Pathogenesis

Malassezia

The genus *Malassezia* is part of the normal resident skin flora (see Table 77.3)[6,7]. Studies on the predominance of certain *Malassezia* spp. have revealed conflicting results[8,9]. *M. furfur* may behave as an opportunistic pathogen (e.g. fungemia in neonates receiving intravenous lipid emulsions) or cause or aggravate a spectrum of skin (and even systemic) diseases: pityriasis versicolor, *Pityrosporum* folliculitis, seborrheic dermatitis and possibly atopic dermatitis.

Malassezia *and seborrheic dermatitis*

M. furfur can be regularly isolated from lesions of seborrheic dermatitis, including infantile seborrheic dermatitis (whereas healthy prepubertal children are not colonized to a significant degree). This coincides with the presence of enlarged sebaceous glands in the neonatal period. There is no simple stoichiometric relationship between yeast number and severity of seborrheic dermatitis, and unaffected skin may carry a load of organisms similar to seborrheic dermatitis lesions. Even in the scalp (in which *M. furfur* is the predominant organism of the resident flora), only twice as many yeasts may be recovered from areas of seborrheic dermatitis as from normal controls[6]. Similarly, severely immunodeficient HIV-infected patients with seborrheic dermatitis do not harbor more organisms than HIV-infected patients without seborrheic dermatitis[10]. However, the number of yeasts drops in parallel with the therapeutic benefit of antimycotic agents and rises again when seborrheic dermatitis relapses.

Active sebaceous glands and seborrheic dermatitis

Seborrheic dermatitis occurs predominantly in areas of the skin with active sebaceous glands and is often associated with sebum overproduction. In infants, sebum is produced for a few weeks after birth, and the adult form of seborrheic dermatitis does not develop before puberty. This argues for a role of sebaceous gland activation by androgens. However, patients with seborrheic dermatitis may have normal sebum production and those with excessive sebum production are often free of seborrheic dermatitis. Thus, the amount of sebum produced alone does not appear to be the decisive risk factor.

It has been proposed that the composition of the skin surface lipids is the relevant factor[11]. In patients with seborrheic dermatitis, triglycerides and cholesterol are elevated but squalene and free fatty acids are significantly decreased. Free fatty acids (which have a known antimicrobial effect) are formed from triglycerides by bacterial lipases, produced by the lipolytic *Propionibacterium* (*Corynebacterium*) *acnes*. A major constituent of the resident microbial skin flora, *P. acnes* has been found to be greatly reduced in seborrheic dermatitis[12]. Seborrheic dermatitis may thus be linked to an imbalance of the microbial flora.

Immune responses to M. furfur *in seborrheic dermatitis*

An etiologic role for immune mechanisms against *M. furfur* – particularly in view of the prominence of seborrheic dermatitis in HIV-infected individuals – has been suspected but never convincingly proven[13]. However, studies on cellular immunity have yielded contradictory results[6,7]. The inflammation seen in seborrheic dermatitis may be irritant, caused by toxic metabolites, lipase and reactive oxygen species[6,13,14].

Clinical Features

Seborrheic dermatitis is defined by clinical parameters, including:

- sharply demarcated patches or thin plaques that vary from pink–yellow to dull red to red–brown with bran-like to flaky "greasy" scales; vesiculation and crusting may occur but are rare and mostly due to irritation
- a predilection for areas rich in sebaceous glands – scalp, face, ears, presternal region – and, less often, the intertriginous areas
- a mild course with little or moderate discomfort.

Seborrheic dermatitis is most often limited in extent, but generalized and even erythrodermic forms can occur, albeit rarely.

Infantile seborrheic dermatitis

This form usually begins about one week after birth and may persist for several months. Initially, mild greasy scales adherent to the vertex and anterior fontanelle regions arise which may later extend over the entire scalp. Inflammation and oozing may finally result in a coherent scaly and crusty mass covering most of the scalp ("cradle cap"). Disseminated lesions, usually of lesser intensity, may appear on the face, retroauricular folds, neck, trunk and proximal extremities, often displaying a psoriasiform appearance. Lesions of the axillae and inguinal folds are acutely inflamed (Fig. 13.1), oozing, sharply demarcated and surrounded by satellite lesions. Superimposed infection with *Candida* spp. may occur.

Adult seborrheic dermatitis

In adults, seborrheic dermatitis is generally found on the scalp and, usually of milder intensity, on the face; less often, lesions occur on the central upper chest and the intertriginous areas. Erythrodermic seborrheic dermatitis has been described as a rarity.

Pityriasis simplex capillitii (dandruff) is defined as a diffuse, slight to moderate, fine white or greasy scaling of the scalp and terminal hair-bearing areas of the face (beard area), but without significant erythema or irritation. Scales accumulate visibly on dark clothing. This common condition may be the mildest form of seborrheic dermatitis of the scalp.

In seborrheic dermatitis of the scalp, there is inflammation and pruritus in addition to dandruff. The vertex and parietal regions are predominantly affected, but in a more diffuse pattern than the discrete plaques of psoriasis. Towards the forehead, the erythema and scaling are usually sharply demarcated from uninvolved skin, with the border either at the hairline or slightly transgressing beyond it. Pruritus is usually moderate but may be intense, particularly in patients with male pattern alopecia; folliculitis, furuncles and meibomitis are not uncommon complications, elicited by scratching and rubbing.

Seborrheic dermatitis of the facial skin is often strikingly symmetric, affecting the forehead, medial portions of the eyebrows, upper eyelids, nasolabial folds and lateral aspects of the nose, retroauricular areas (Fig. 13.2), and occasionally the occiput and neck. Lesions are yellowish-red, with a typical bran-like scale. Non-purulent otitis externa is often observed. If present, lesions of the trunk are preferentially found in the presternal and intertriginous areas; those in the central chest can have a petaloid appearance. Seborrheic dermatitis, like inverse psoriasis, is a cause of intertrigo.

Fig. 13.1 Infantile seborrheic dermatitis. Glistening red plaques of the neck, axillary and inguinal folds as well as the penis and umbilicus. Note disseminated lesions on the trunk and extremities. *Courtesy, Robert Hartman, MD.*

Fig. 13.2 Adult seborrheic dermatitis of the face, ear and scalp. **A** Sharply demarcated pink plaque with flaky white and greasy scale. Note the fissure in the retroauricular sulcus. **B** Sharply demarcated pink–orange thin plaques with yellow, greasy scale, especially in the melolabial fold. When this degree of severity is seen, the possibility of underlying HIV infection needs to be considered. **C** Symmetric red–brown to violet plaques of the central forehead, nasal bridge and medial cheeks with an associated hypopigmented figurate rim. *C, Courtesy, Jeffrey P Callen, MD.*

In patients with seborrheic dermatitis, the skin is sensitive to irritation, and exposure to sun or heat, febrile illnesses and overly aggressive topical therapy may precipitate flares and dissemination. Irritated seborrheic dermatitis lesions can become bright red and erosive. *Pityrosporum* folliculitis is another complication characterized by pruritic erythematous follicular papules, sometimes pustules, typically in sites rich in sebaceous glands.

Adult seborrheic dermatitis has a chronic relapsing course. Patients feel well and systemic signs are absent. Extensive and severe seborrheic dermatitis, however, should raise the suspicion of underlying HIV infection. In patients with Parkinson's disease, seborrheic dermatitis is a common finding, along with seborrhea. Its severity, however, is not correlated with that of the Parkinson's disease[15]. The facial immobility of patients with Parkinson's disease might result in a greater accumulation of sebum on the skin, resulting in a permissive effect on the growth of *Malassezia*[15,16]. Rebound flares of seborrheic dermatitis can follow tapers of systemic corticosteroids.

Pathology

Acute seborrheic dermatitis displays spongiosis with a superficial perivascular and perifollicular lymphocytic infiltrate composed mainly of lymphocytes. Older lesions show irregular acanthosis and focal parakeratosis. The latter may appear similar to psoriasis, but exocytosis of neutrophils, Munro's microabscesses and confluent parakeratotic horny layers are absent.

Differential Diagnosis

Infantile seborrheic dermatitis is distinguished from *atopic dermatitis* by its earlier onset, different distribution pattern, less intense inflammation, and, most importantly, by the absence of pruritus, irritability and sleeplessness. In contrast to atopic dermatitis, infants with seborrheic dermatitis generally feed well and are content. *Irritant diaper dermatitis* is confined to the diaper area and tends to spare the skin folds (see below). *Candidiasis* of the diaper area may result from colonization with fecal yeast. *Infantile psoriasis* may be difficult to distinguish from psoriasiform seborrheic dermatitis. It has been suggested that psoriasiform diaper dermatitis is a primary manifestation of psoriasis, but most affected infants do not subsequently develop psoriasis.

Rare conditions to be considered are Langerhans cell histiocytosis (see Ch. 91), Wiskott–Aldrich syndrome (see Ch. 60) and Leiner's disease. The last-mentioned is a questionable entity, once thought to be the maximal variant of infantile seborrheic dermatitis, but nowadays viewed as erythroderma in the setting of underlying immunosuppression (see Chs 10 & 60).

When there is scalp scaling in prepubertal, especially black, children, the possibility of *tinea capitis* due to *Trichophyton tonsurans* should be considered. In *pityriasis amiantacea*, thick asbestos-like scales adhere to tufts of scalp hairs; up to a third of the affected children and adolescents eventually develop psoriasis.

A number of entities are included in the differential diagnosis of adult seborrheic dermatitis. Distinction of seborrheic dermatitis *of the scalp* from psoriasis can be difficult, and there may be overlap (due to the Koebner phenomenon). However, the plaques of psoriasis tend to be thicker, with silvery white scale, more discrete, less pruritic and unassociated with seborrhea. In addition, features of psoriasis may be found elsewhere. Dry scaling of the scalp, along with dry brittle hair (as opposed to greasy hair), is a symptom of dispositionally dry skin (e.g. in atopic dermatitis), frequently mistaken for (and mistreated as) seborrheic dermatitis. Mild erythema and scale of the posterior scalp, often with demonstrable hair loss, can be seen in dermatomyositis (Fig. 13.3)[17].

Seborrheic dermatitis *of the face* may closely resemble both early rosacea and the butterfly lesions of systemic lupus erythematosus. Lupus erythematosus rarely affects the nasolabial folds and often has a clearly demonstrable photodistribution. Notably, seborrheic dermatitis and rosacea frequently coexist. The differential diagnosis of seborrheic dermatitis *of the trunk* includes pityriasis rosea (but, in this entity, the lesions are ellipsoid in shape, have collarette-like scaling, and there is no predilection for the central chest) as well as superficial eruptive psoriasis and subacute cutaneous lupus erythematosus.

Seborrheic dermatitis *of the intertriginous areas* must be distinguished from inverse psoriasis, erythrasma, intertriginous dermatitis, candidiasis, and, rarely, Langerhans cell histiocytosis.

Fig. 13.3 Seborrheic-like dermatitis due to dermatomyositis. This patient presented with severe pruritus of the scalp. In addition to the scalp involvement, she had Gottron's papules and a photodistributed poikiloderma. *Courtesy, Jeffrey P Callen, MD.*

Treatment

Infantile seborrheic dermatitis

Infantile seborrheic dermatitis usually responds satisfactorily to skin care measures such as bathing and application of emollients. Ketoconazole cream (2%) is indicated in more extensive or persistent cases[18]. Short courses of low-potency topical corticosteroids may be used initially to suppress inflammation. Mild shampoos are recommended for the removal of scalp scales and crusts. Avoidance of irritation (e.g. the use of strong keratolytic shampoos or mechanical measures to remove the scales from the scalp) is important.

Adult seborrheic dermatitis

The mainstay of therapy is the use of topical azoles (e.g. ketoconazole), either as shampoos (scalp) or as creams (body). The high response rate (75–90%) of this treatment has been documented in double-blind trials[3]. Ciclopirox olamine has antifungal and anti-inflammatory activities and has also been shown to be effective as a shampoo or cream in double-blind, randomized trials. Because seborrheic dermatitis is a predispositional disorder, it tends to relapse if treatments are not carried out repetitively. As *M. furfur* has a slow proliferation rate, an interval of two to several weeks will pass until relapses appear. The intervals of topical therapy should follow this rhythm.

Additional measures, particularly in the initial stages of treatment, include low-potency topical corticosteroids and emollients. Second-line treatment options include zinc pyrithione and tar shampoos as well as topical calcineurin inhibitors. Recently, a nonsteroidal cream that contains shea butter and several plant extracts has reported to be efficacious[19].

ASTEATOTIC ECZEMA

Synonyms: ■ Eczema craquelé ■ Winter eczema ■ Winter itch ■ Dessication dermatitis

Key features

- Dry, rough, scaly and inflamed skin with superficial cracking that resembles a "dried riverbed"
- Sites of predilection are the shins, lower flanks, and posterior axillary line
- Associated with aging, xerosis, low relative humidity, and frequent bathing

Introduction

Dry skin (xerosis, exsiccosis, asteatosis) may result from both exogenous and endogenous causes: a dry climate or low indoor humidity; excessive exposure to water, soaps and surfactants; marasmus and malnutrition; renal insufficiency and hemodialysis; and hereditary conditions such as ichthyosis vulgaris and atopic dermatitis. The most common cause of xerosis is aging. Rarely, but especially when widespread and refractory to therapy, eczema craquelé may be related to an underlying systemic lymphoma[20].

History

Asteatosis as the cause of "nummular eczema" was first mentioned by Gross[21] in the late 1940s.

Epidemiology

Dry skin probably occurs in everyone over the age of 60 years, but its severity is strongly linked to the exogenous factors mentioned above.

Pathogenesis

Xerosis of aging skin is not caused by deficient sebum production, but by a complex dysfunction of the stratum corneum (see Ch. 124)[22]. There is a decrease of intercellular lipids with a deficiency of all key stratum corneum lipids[23] and an altered ratio of fatty acids esterified to ceramide 1[24], persistence of corneodesmosomes[25], and premature expression of involucrin and formation of the cornified envelope[26], resulting in corneocyte retention and marked impairment of barrier recovery[23]. The water-binding capacity of the stratum corneum layer is reduced owing to decreased synthesis of "natural moisturizing factor" (NMF) which contains urea and degradation products of filaggrin[27]. Consequently, the stratum corneum desiccates, loses its pliability and forms small cracks, which render the skin surface dull, rough and scaly.

Mild xerosis is asymptomatic, but if more pronounced, the skin conveys unpleasant sensations such as itching and stinging. Inflammation is enhanced by the release of proinflammatory cytokines secondary to barrier perturbation, mechanical factors (scratching, rubbing), and the application of irritative or sensitizing substances in topical preparations and skin care products.

Clinical Features

Xerosis first arises on the shins. Later it may spread to the thighs, proximal extremities and trunk, but spares the face and neck as well as the palms and soles. It develops insidiously over many years, whereas asteatotic eczema often has a more subacute to acute onset.

Xerotic skin is dry, dull, with fine bran-like scales which may be released as powdery clouds when patients take off their stockings. If more advanced, the skin exhibits a criss-cross pattern of superficial cracks and fissures of the horny layer ("crazy-paving", eczema craquelé, "dried riverbed") and appears pink to light red in color (Fig. 13.4). The skin becomes rough, and may develop an appearance similar to ichthyosis vulgaris ("pseudo-ichthyosis"). In more advanced stages of asteatotic eczema, there is a dull erythema as well as oozing, crusting and abundant excoriations; disseminated nummular lesions are frequently seen. Vesiculation and lichenification are not regular features except when irritant or allergic contact dermatitis is superimposed.

Pathology

Histologically, xerotic skin appears rather normal except for a compact and slightly irregular stratum corneum. Asteatotic eczema in addition exhibits mild focal spongiosis, parakeratosis and a lymphocytic infiltrate with neutrophils in the superficial dermis.

Differential Diagnosis

Conditions that need to be distinguished from asteatotic eczema include stasis dermatitis, adult atopic dermatitis (which may overlap with asteatotic eczema), allergic contact dermatitis, nummular dermatitis and scabies.

Treatment

Asteatotic eczema usually clears within a few days of the application of topical corticosteroid ointment. Proper attention must be given to the care of xerosis in order to avoid relapses: regular use of emollients, including petrolatum-, urea-, ceramide- or lactic acid-containing preparations, use of bath oils, and the elimination of factors that aggravate dry skin (see above). Topical calcineurin inhibitors have also been used. Coexisting stasis dermatitis should be treated as well (see below).

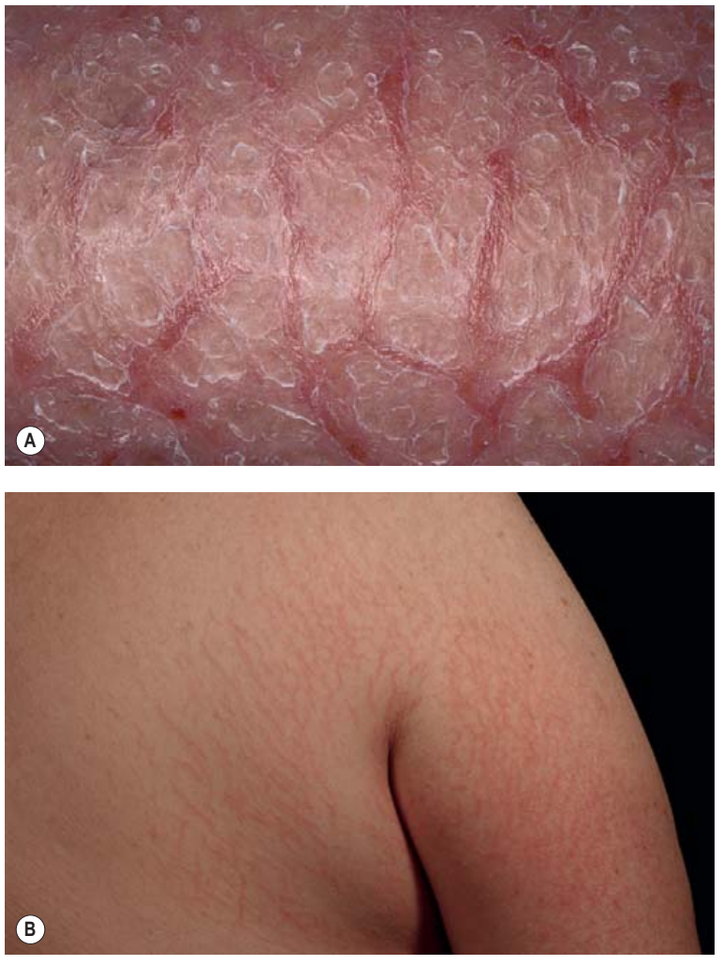

Fig. 13.4 Asteatotic eczema (eczema craquelé). A The distal lower extremity has obvious inflammation and xerosis with adherent white scales (pseudo-ichthyosis) as well as a criss-cross pattern of superficial cracks and fissures said to resemble a dried riverbed. **B** When widespread, there can be involvement of the trunk and proximal extremities. Along with the distal lower extremity, the posterior axillary line is a common site for asteatotic eczema. *A, Courtesy, Louis A Fragola, Jr, MD; B, Courtesy, Thomas Schwarz, MD.*

STASIS DERMATITIS

Synonyms: ■ Gravitational dermatitis ■ Varicose eczema ■ Congestion eczema

Key features

- Often associated with other signs of venous hypertension
- Can be complicated by allergic contact dermatitis
- One of the most common causes of disseminated eczema (autosensitization dermatitis)

Introduction

Stasis dermatitis is a common component of the clinical spectrum of chronic venous insufficiency of the lower extremities (see Ch. 105). It may arise as an early sign of chronic venous insufficiency, but can persist or recur throughout all stages and is often most prominent when ulcers are present. There is little doubt that chronic venous hypertension *per se* is the initial trigger for stasis dermatitis. Over time,

additional etiological factors may act in concert, most importantly contact sensitization to ingredients of topical therapies. Stasis dermatitis is one of the most common causes of secondary dissemination of dermatitis, and is therefore a complex and multifactorial condition.

History

The term "stasis dermatitis" was introduced by Pillsbury[28], and the term "gravitation dermatitis" by Belisario[29].

Epidemiology

The prevalence of chronic venous insufficiency is variable among different ethnic groups and societies. In Central Europe, approximately 15% of the adult population has symptoms of chronic venous insufficiency and about 1% suffers from venous ulcers. Prevalence rates clearly rise with age.

Pathogenesis

Chronic venous insufficiency and the microvasculature

Venous hypertension of the lower limbs is linked to the upright position and is caused by multiple factors, most importantly valvular incompetence of the deep leg veins. Venous hypertension slows the blood flow in the microvasculature, distends the capillaries and damages the capillary permeability barrier, allowing the passage of fluid and plasma proteins into the tissue (edema) and extravasation of erythrocytes (stasis "purpura" and hemosiderin deposition). These processes lead to microangiopathy, with serious consequences[30].

- Proteins (particularly fibrin) are deposited around the vessels as hyaline cuffs; these may, together with interstitial edema, inhibit oxygen diffusion and metabolic exchange.
- Slow blood flow induces upregulation of ICAM-1 and VCAM-1 on endothelia[31], expression of L-selectin on neutrophils[32], and activation of neutrophils and macrophages[33]. Neutrophils are attracted into and trapped within affected areas (notably the medial supramalleolar region)[34].
- Release of inflammatory mediators, free radicals and proteases by neutrophils leads to pericapillary inflammation. Free iron ions released from hemosiderin deposits create a proinflammatory vicious cycle by increasing free radical production and lipid peroxidation and activating matrix metalloproteinases[35]. Platelets accumulate in the microvasculature and may trigger focal thrombosis.
- The subsequent imbalance in the capillary network can produce fibrosis and tissue remodeling, lipodermatosclerosis (i.e. dermal sclerosis and septal sclerosis that present as sclerosing panniculitis), dysfunction of the lymphatics, and stellate sclerotic areas depleted of capillaries with the formation of peripheral giant capillaries ("atrophie blanche"). These same processes may later result in the formation of venous ulcers.

Of note, patients with stasis dermatitis (with or without ulceration) have elevated plasma levels of homocysteine, when compared to a control population[36], and hyperhomocysteinemia is associated with an increased risk of thromboses.

Pathogenesis of stasis dermatitis

Chronic inflammation and microangiopathy are likely to be responsible for stasis dermatitis. Stasis dermatitis typically occurs in the same (i.e. the medial supramalleolar) regions where microangiopathy is most intense, and the patches of dermatitis arise preferentially over dilated varicose veins. Also, dermal inflammation is known to induce epidermal dysfunction (e.g. barrier impairment).

Sometimes, patients report intense pruritus that even becomes manifest before the eczema. Pruritus may be caused both by repeated congestion and decongestion, and by the release of inflammatory mediators within the dermis. Scratching or rubbing worsens and perpetuates the dermatitis.

Complicating pathogenetic factors

- Contact sensitization. Even before stasis dermatitis is manifest, pruritus and dryness of the skin invariably prompts the patient to apply various creams and ointments (including home remedies), and even more so after ulcers have formed. Sensitizations are therefore frequently found, most notably to topical antibiotics, lanolin derivatives, emulsifiers, antiseptics (iodine), preservatives (parabens), balsam of Peru, fragrances, chemicals of plant origin, topical corticosteroids, and modern wound dressings. Patients with chronic venous insufficiency more often than not exhibit multiple contact allergies[37,38].
- Irritant dermatitis due to wound secretions. Once venous ulcers are present, draining exudates macerate the surrounding skin and increase inflammation. They also favor colonization with resident and transient skin flora bacteria which play an additional proinflammatory role ("microbial eczema").

Clinical Features

The first sign of chronic venous insufficiency is usually a cushion-like pitting edema of the medial aspects of the shin and calf around and proximal to the ankle, corresponding to the location of the major communicating veins. Edema is more pronounced in the evening and resolves overnight. Bouts of stasis purpura lead to spotty hemosiderin deposits. At this stage, stasis dermatitis is mild or absent; the skin may be dry and itchy. Later, the edema extends to the distal third of the calf and subfascial edema arises, often accompanied by inflammation which may mimic cellulitis ("pseudoerysipelas"; acute lipodermatosclerosis). Over a period of years, the skin, subcutaneous adipose tissue and deep fascia become progressively indurated and mutually adherent (chronic "lipodermatosclerosis"; see Ch. 100). A firm circular cuff is formed which appears to strangle the distal calf, creating an inverted wine bottle appearance. The skin may show intense hemosiderin pigmentation and atrophie blanche. In this setting, venous ulcers develop spontaneously or are triggered by scratching or other trauma. They arise most often in the supramalleolar region, but may later expand.

At the latest stage, stasis dermatitis appears when lipodermatosclerosis develops. Erythema and scaling are most pronounced around the inner malleoli, but may extend to involve the entire distal lower extremity. It is severely pruritic, as evidenced by multiple scratch marks, which lead to oozing and crusting. Episodes of vesiculation occur infrequently, always raising the suspicion of superimposed contact sensitization. Chronic lesions of stasis dermatitis invariably exhibit considerable lichenification. Once ulcers are formed, stasis dermatitis often becomes highly irritated, oozing and erosive.

Contact sensitization often leads to secondary dissemination. Patches of eczema arise in a strikingly symmetric distribution pattern, particularly on the anterior aspect of the contralateral leg, the anterior thighs and the extensor surface of the upper extremities (Fig. 13.5); lesions may generalize to involve the trunk and face.

Fig. 13.5 Autosensitization dermatitis in a patient with venous ulceration. Note the involvement of the extensor surfaces of the upper extremities in this patient with an allergic contact dermatitis to neomycin, as well as stasis dermatitis and venous ulceration. *Courtesy, Jean L. Bolognia, MD.*

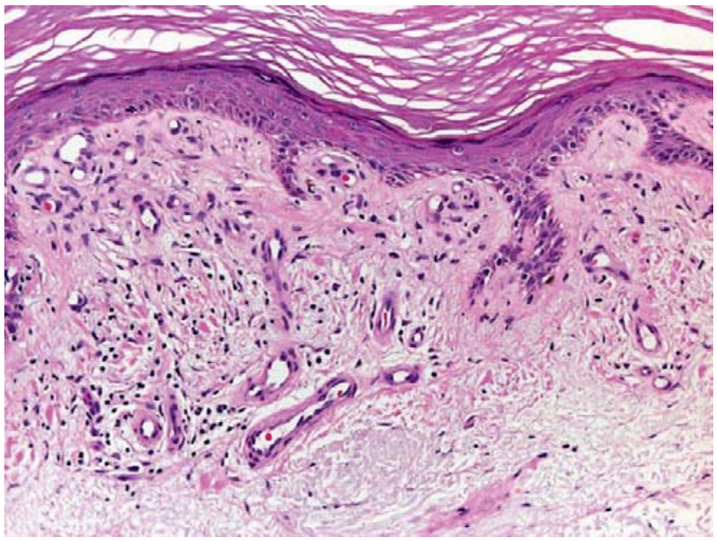

Fig. 13.6 Stasis dermatitis – histologic features. Increased number of blood vessels in a slightly fibrotic papillary dermis. Note also extravasation of erythrocytes and a mild lymphocytic infiltrate. *Courtesy, Lorenzo Cerroni, MD.*

Pathology

The histologic features of eczema, including stasis dermatitis, vary according to the stage of the lesion. In acute eczematous eruptions, intraepithelial edema predominates, with fluid accumulation as micro- or macrovesicles, accompanied by lymphocytes in a perivascular array in the superficial dermis and exocytosis of lymphocytes into the epidermis. In the subacute phase, spongiosis is still evident, but may be subtle; vesicle formation is absent. The epidermis thickens variably and parakeratosis may develop. Lymphocytes persist in the dermis and epidermis, but in fewer numbers.

In the chronic phase, thickening of the epidermis is more pronounced and it occurs in a regular, psoriasiform pattern or has a more irregular profile. Inflammation and spongiosis are mild to absent. Change in the granular layer is variable, from thickening, simulating lichen simplex chronicus, to thinning, when the pattern more closely approaches psoriasis; the latter changes are seen more often in nummular eczema (see below). Ascribing a specific cause of the dermatitis based upon this constellation of histologic findings is impossible, although individually necrotic keratinocytes suggest the diagnosis of an irritant dermatitis.

In stasis dermatitis, biopsy specimens display the histologic features just outlined, as well as signs of venous hypertension: dilated capillaries surrounded by cuffs of fibrin, hemosiderin deposits, and hyperplastic (and at times thrombotic) venules (Fig. 13.6). In later stages, there is fibrosis of the dermal connective tissue and sclerosis of the adipose tissue (see Ch. 100).

Differential Diagnosis

Stasis dermatitis is a straightforward diagnosis if the cutaneous signs of venous hypertension are present. Difficulties may arise in differentiating the individual etiologic components, such as asteatotic eczema and irritant or allergic contact dermatitis. Patch testing is required to exclude the latter. Plaques of stasis dermatitis may be mistaken for nummular eczema, psoriasis or even mycosis fungoides.

Treatment

The major aim of therapy is the management of venous hypertension – a complex goal which is reviewed in Chapter 105. Basic measures include the regular use of adequate compression bandages or stockings to improve venous return, lifestyle changes, and exercise of the calf muscles. If indicated, surgical strategies are undertaken (see Ch. 155). However, these surgical approaches do not replace the need for ongoing compression therapy. Topical treatment is the same as for other types of eczemas: judicious use of topical corticosteroids and emollients. Whether correction of hyperhomocysteinemia will have any therapeutic impact remains to be determined.

DISSEMINATED ECZEMA (AUTOSENSITIZATION)

Synonyms: ■ Autosensitization dermatitis ■ Generalized eczema ■ Id reaction

Key features

- Secondary lesions of eczema distant from the primary site of exposure or involvement
- Symmetric distribution pattern
- Most often associated with allergic contact dermatitis and stasis dermatitis

Introduction

Dermatitis caused by exogenous agents initially arises at the site of contact. Not infrequently, additional patches of eczema develop at distant sites. This phenomenon, termed secondary dissemination, has puzzled dermatologists for decades. It is most often observed in allergic contact dermatitis, particularly if associated with stasis dermatitis (see Fig. 13.5), but may occur with uncomplicated stasis dermatitis, other forms of eczema, and, occasionally, severe tinea pedis.

Disseminated eczema appears later than the primary lesions by a few days to weeks, tends to follow a strikingly symmetric distribution pattern, and shows a predilection for analogous body sites (e.g. extensor aspects of the lower and upper extremities, palms and soles). It may even arise in the absence of and without a preceding "primary" eczema, e.g. in nummular dermatitis (see below). Disseminated eczema must be distinguished from atopic dermatitis, which *a priori* arises in a disseminated fashion.

History and Pathogenesis

The phenomenon of secondary dissemination of eczemas was first described by Whitfield[39], but its pathogenesis is still not fully elucidated. The orderly and symmetric distribution pattern may reflect systemic (hematogenous) dissemination and argues against simple spread of contact irritants or allergens on the body surface. It is unclear, however, what exactly is disseminated via the bloodstream. It could be allergens; for example, the ingestion of allergens such as nickel has been shown to elicit disseminated eczema in sensitized individuals[40,41].

Hematogenous dissemination of microbial products leading to a variety of (non-infectious) manifestations distant from the site of infection, such as "tuberculids" and "bacterids", was an accepted pathogenic model in the first half of the twentieth century and was extrapolated to the phenomenon of disseminated eczema. Dyshidrotic eczema of the soles, for example, was interpreted as an "id" reaction associated with tinea pedis, and nummular eczema as an "id" reaction caused by "focal" infections of the tonsils. Because disseminated eczema could hardly be attributed to infections as a whole, attention shifted to an "autosensitization" to epidermal antigens mediated by cytotoxic autoantibodies. This hypothesis, however, was never verified.

Instead, it became clear both from animal experiments[42] and from routine patch testing ("excited skin syndrome", "angry back")[43,44] that inflammatory processes of the skin, both allergic and irritant or caused by infections, lower the irritancy threshold of distant skin and thus facilitate the development of an eczematous reaction. Obviously, circulating activated memory T cells may play an additional role in disseminated eczema associated with allergic contact dermatitis, including that seen with poison ivy dermatitis following a short, rapid taper of systemic corticosteroids. It remains to be determined which factors regulate the symmetric distribution of disseminated eczema.

Epidemiology

An estimated two-thirds or more of patients with contact dermatitis associated with stasis dermatitis develop episodes of disseminated eczema. The incidence is much lower in the other types of eczema or tinea pedis.

Clinical Features

Disseminated eczema in allergic contact dermatitis is characterized by moderately to poorly demarcated patches of eczema, most often on the extremities (Fig. 13.7A). Lesions are also found on the face, and less so on the trunk (Fig. 13.7B). The areas of involvement vary greatly in size and number and may consist of discrete papules which are often excoriated. Disseminated eczema in patients with seborrheic and asteatotic eczema differs slightly in predilection sites and morphology (see above).

Pathology

In biopsy specimens of disseminated eczema, the histologic findings are those of an acute or subacute dermatitis (see previous section).

Differential Diagnosis

Conditions to be distinguished are those eczemas that can arise in a widespread or disseminated fashion: atopic dermatitis, airborne contact dermatitis, contact dermatitis caused by constituents of textiles, and photoallergic dermatitis. Other conditions to be considered are mycosis fungoides and Sézary syndrome.

Treatment

Topical corticosteroids and systemic antihistamines are the mainstay of therapy. Short courses of systemic corticosteroids may be required, but aggressive topical treatment of the inciting dermatosis is necessary to help prevent recurrences or a rebound flare.

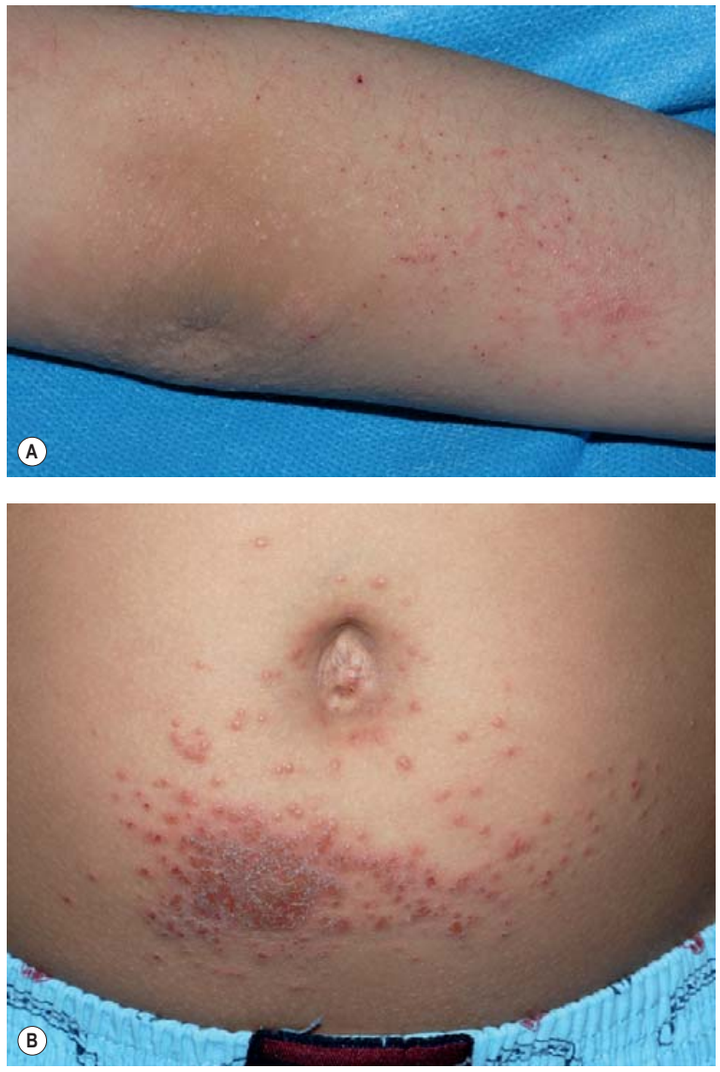

Fig. 13.7 Id reactions in children due to allergic contact dermatitis (ACD) to nickel. A Multiple flat-topped papules, several of which have been excoriated, in addition to patches of eczema. **B** Square-shaped area of ACD due to nickel in a buckle with an id reaction. The latter consists of edematous crusted papules.

NUMMULAR DERMATITIS

Synonyms: ■ Nummular eczema ■ Discoid eczema ■ Microbial eczema

Key features

- Coin-shaped, disseminated, eczematous lesions
- Usually very pruritic
- Chronic course

Introduction

Nummular dermatitis is an uncommon disseminated eczema characterized by its coin-shaped lesions. Because such lesions can occur as a feature of atopic dermatitis, asteatotic eczema and stasis dermatitis, the position of nummular dermatitis as an independent clinical entity has been questioned.

Epidemiology

Nummular lesions of eczema are not uncommon. However, in the literature there are widely discrepant data on the prevalence of nummular dermatitis, ranging from 0.1% to 9.1%[4]. Some of this variability may reflect the degree to which a distinction is made between nummular dermatitis and coin-shaped lesions observed in patients with other forms of eczema. Men are affected slightly more often and at a later age than women (>50 vs <30 years, respectively).

Pathogenesis

The pathogenesis has not been fully elucidated (see above). The traditional view of nummular dermatitis being "microbial" in origin, i.e. either secondary to bacterial colonization or due indirectly to hematogenous dissemination of bacterial toxins, has not been corroborated. However, the search for "focal" infections is still part of the routine evaluation in some institutions. Nummular lesions of dermatitis are not infrequently associated with contact sensitization as well as with xerosis and venous hypertension. Nummular dermatitis of the dorsa of the hands may be a manifestation of chronic irritant or allergic dermatitis. Clinical and laboratory signs of atopy are absent in "true" nummular dermatitis.

Clinical Features

Nummular dermatitis is defined as an eruption of round (discoid) eczematous patches almost exclusively of the extremities (Fig. 13.8), often the lower legs in men and the forearms and dorsal aspects of the hands in women. The lesions are well demarcated and measure 1–3 cm, only occasionally being larger. They may be acutely inflamed with vesicles and weeping, but are more often lichenified and hyperkeratotic. Pruritus may be intense and excoriations are often prominent. Nummular dermatitis usually takes a very chronic course. A particularly therapy-resistant variety has been termed "oid-oid disease" (Sulzberger–Garbe syndrome)[45].

Pathology

Histologically, the changes of subacute to chronic dermatitis are seen (see section "Stasis dermatitis").

Fig. 13.8 Nummular dermatitis. Coin-shaped lesions of acute and subacute dermatitis that are fairly well demarcated. There is often marked pruritus. *Courtesy, Kalman Watsky, MD.*

Fig. 13.9 Pityriasis alba. Hypopigmented macules and patches on the cheek of an African-American girl. *Courtesy, Anthony J Mancini, MD.*

Differential Diagnosis

Nummular dermatitis must be distinguished from nummular lesions of atopic dermatitis and dissemination secondary to contact dermatitis or stasis dermatitis. Other conditions to be considered are psoriasis, Bowen's disease, mycosis fungoides and tinea corporis.

Treatment

Options comprise medium- to high-potency topical corticosteroid ointments, topical tacrolimus or pimecrolimus, and emollients. Tar preparations have also been used successfully. However, a number of patients will require phototherapy to clear the lesions.

PITYRIASIS ALBA

Key features

- Minor feature of atopic dermatitis
- Ill-defined, hypopigmented patches, primarily on the face of children and adolescents
- More clinically evident in individuals with darkly pigmented skin
- Spontaneous remission

Pityriasis alba is a fairly common, low-grade, eczematous dermatosis characterized by ill-defined, patchy hypopigmentation (Fig. 13.9). It is regarded as a minor feature of atopic dermatitis (see Table 12.1). For details, see Chapter 12.

INFECTIVE DERMATITIS

Key features

- Rare dermatologic disorder of childhood and adolescence
- Association with human T-cell lymphotropic virus type I (HTLV-1)
- Eczema of the scalp, axillae and groin; watery discharge of the nose
- Prompt response to antibiotics

Introduction and Pathogenesis

Human T-cell lymphotropic virus type I (HTLV-1), also referred to as human T-cell leukemia virus type I and adult T-cell lymphoma virus type 1, was first detected in 1980[46], and it can infect T cells, B cells and monocytes. HTLV-1 is transmitted primarily via sexual intercourse, blood transfusions, needle sharing in intravenous drug users, and breastfeeding. It has been associated with adult T-cell leukemia/lymphoma (ATLL), tropical spastic paraparesis, and infective dermatitis. The activity of HTLV-1 in infected subjects appears to be low – more than 90% of carriers remain asymptomatic[47] and the majority of disease symptoms (other than infective dermatitis) emerge during adulthood. HTLV-1 induces spontaneous T-cell proliferation independent of exogenous stimuli, followed by interleukin (IL)-2 receptor expression (CD25), increased IL-2 secretion, and induction of interferon-γ, IL-5 and IL-10. In symptomatic patients, levels of tumor necrosis factor-α and IL-6 are elevated[48]. Infected individuals are more susceptible to a variety of infections and parasitoses such as scabies and strongyloidiasis[49].

Epidemiology

Major endemic areas of HTLV-1 infection include Africa, northeastern South America, the Caribbean basin, southern Japan, and Iran. Infective dermatitis was first described in 1966 by Sweet[50], preceding the detection of HTLV-1 by almost 15 years. Walshe[51], in 1967, was the first to suggest an underlying immune defect because relapses of the dermatitis frequently occurred, even after a prompt initial response to antibiotic treatment. The probability of developing infective dermatitis was estimated to be 2% amongst perinatally infected children[52].

Clinical Features

Infective dermatitis presents as an exudative and crusty eczematous dermatosis, affecting primarily the scalp, axillae and groin, ears, paranasal skin, eyelid margins and/or neck[47]. A generalized fine papular rash is occasionally observed. Complications include parasitic infestations, corneal opacities, and progression to more severe HTLV-1-associated disorders (e.g. ATLL). Infective dermatitis rarely persists until adulthood. However, according to Bittencourt[53], 44% of adult patients in Bahia with HTLV-1-associated ATLL had a history of infective dermatitis. Diagnosis is established by major and minor criteria (Table 13.1)

Differential Diagnosis

The major entity in the differential diagnosis is atopic dermatitis. Apart from serologic evidence of HTLV-1 infection, lesions of infective dermatitis are more exuberant and obviously infected, but pruritus is less intense. Crusting of the nasal vestibule and blepharoconjunctivitis are more prominent than in atopic dermatitis. Other disorders to consider include seborrheic dermatitis and impetigo.

CRITERIA FOR THE DIAGNOSIS OF INFECTIVE DERMATITIS
MAJOR
• Eczema of the scalp, axillae and groin, ears, paranasal skin, eyelid margins and/or neck
• Chronic watery nasal discharge and/or crusting of the anterior nares
• Chronic relapsing dermatitis which responds quickly to antibiotics but relapses promptly after withdrawal
• Onset during early childhood
• Seropositivity for HTLV-1
MINOR
• Positive cultures for *Staphylococcus aureus* and/or β-hemolytic streptococci from the skin or anterior nares
• Generalized fine papular rash
• Anemia, elevated erythrocyte sedimentation rate
• Hyperimmunoglobulinemia
• Elevated $CD4^+$ and $CD8^+$ T-cell counts; elevated CD4/CD8 ratio

Table 13.1 Criteria for the diagnosis of infective dermatitis. To establish the diagnosis, four major criteria are required, with mandatory inclusion of human T-cell lymphotropic/leukemia virus type I (HTLV-1) seropositivity. For the first two major criteria, the involvement of at least two body regions is required. Adapted from ref. 49.

Treatment

Oral antibiotics result in improvement of the skin lesions but do not prevent relapses. Topical treatments include antibiotics (including intranasal), corticosteroids, and bleach baths.

DYSHIDROTIC ECZEMA

Synonyms: ■ Pompholyx (larger bullae) ■ Acute and recurrent vesicular hand dermatitis

Key features

- Firm, pruritic vesicles of the palms, soles, and lateral and medial aspects of the fingers and toes
- Association with atopic dermatitis and contact dermatitis (allergic and irritant)
- No disturbance of sweat gland function

Introduction

Dyshidrotic eczema is a not-infrequent, chronic, relapsing palmoplantar eczematous dermatosis characterized by firm, pruritic vesicles and bullae. While the vesicles are due to spongiosis within the epidermis, their intact nature is explained by the thick tear-proof horny layer in these sites. Dyshidrotic eczema is not an independent disease entity because it is often a manifestation of other types of eczema, especially atopic dermatitis and irritant or allergic contact dermatitis.

Pathogenesis

Although the formation of vesicles is not linked to sweat gland dysfunction or trapping of sweat within the epidermis (as the term may suggest), hyperhidrosis can be an aggravating factor in some patients. Notably, treatment of hyperhidrosis with onabotulinumtoxinA may ameliorate dyshidrotic eczema[54].

Dyshidrotic eczema is frequently an expression of atopic dermatitis, particularly as a late-stage manifestation. In these patients, its intensity is usually low to moderate with a protracted and relapsing course, and it is accompanied by only a few other signs of atopic dermatitis. Less often, dyshidrotic eczema is a manifestation of acute or subacute allergic contact dermatitis. Flares can also result from exposure to known irritants (see Ch. 15).

Fig. 13.10 Dyshidrotic eczema. A Clinically, firm vesicles are seen along the side of the thumb and thenar eminence. Some of them are deep-seated. **B** Histopathologically, spongiosis within the epidermis is accompanied by macrovesicles; the thickened stratum corneum points to an acral location. *A, Courtesy, Louis A Fragola, Jr, MD; B, Courtesy, Lorenzo Cerroni, MD.*

Occasionally, administration of IVIg is followed by acute episodes of dyshidrotic eczema. The role of ingestants, in particular nickel and cobalt, has been debated, but improvement with a low-nickel diet (in nickel-sensitive patients with a positive oral provocation test) has been observed. Lastly, flares can also follow periods of emotional stress as well as exposure to hot climates and (rarely) sunlight.

Clinical Features

Dyshidrotic eczema is characterized by symmetric, firm, deep-seated vesicles of the palms, the lateral and medial aspects of the fingers, and less often the soles and toes (Fig. 13.10A). The size of the vesicles may vary from pinhead-sized to several centimeters ("pompholyx"). When smaller lesions are clustered, they have been likened to tapioca pudding. While the markedly pruritic vesicles initially contain clear fluid, they have a tendency for purulent superinfection. It resolves via desquamation of characteristically thick scales.

Dyshidrosis lamellosa sicca (also referred to as keratolysis exfoliativa) is a minimal variant which displays no blisters but only small annular collarettes of white scale.

Pathology

Histologically, a spongiotic dermatitis is seen with the formation of micro- and macrovesicles within the epidermis (Fig. 13.10B). There is no association with sweat glands.

Differential Diagnosis

Inflammatory tinea manuum and pedis, scabies and palmoplantar pustular psoriasis need to be considered as well as dyshidrosiform pemphigoid, dyshidrotic cutaneous T-cell lymphoma, erythema multiforme, fixed drug eruption, and, in children, infantile acropustulosis. Distinguishing between an id reaction involving the palms or soles and dyshidrotic eczema can sometimes be difficult and some clinicians view them as overlapping entities.

Treatment

Topical and systemic corticosteroids are the mainstay of treatment. Topical calcineurin inhibitors may be helpful. Bath PUVA has been shown to be more effective than oral PUVA or UVB[55]. An underlying allergic or irritant contact dermatitis needs to be considered and addressed.

JUVENILE PLANTAR DERMATOSIS

Synonyms: ■ Atopic winter feet ■ Forefoot dermatitis ■ Dermatitis plantaris sicca ■ Moon-boot foot syndrome ■ Sweaty sock dermatitis

Key features

- Dry, scaly, glazed and fissured plantar surface of the forefoot
- Prepubertal children are affected
- Association with atopy and exogenous factors

Introduction

The feet are a fairly common site for various eczematous dermatoses (Table 13.2). Juvenile plantar dermatosis is a characteristic condition that occurs primarily (but not exclusively) in children with an atopic diathesis.

History

Juvenile plantar dermatosis was first reported by Mackie and Husain[56].

Epidemiology

Juvenile plantar dermatosis occurs in prepubertal children, from the age of 3 years and upwards (when shoes are worn for longer periods of time), and is only rarely seen in adults. There is seasonal variation (worsening during the winter) and boys are affected slightly more often than girls.

Pathogenesis

An atopic disposition is clearly a risk factor, but exogenous factors play an equally important role. Juvenile plantar dermatosis has been observed more often since impermeable materials such as plastic and rubber have been used for sports shoes, which youngsters often wear all day long. The humid environment leads to hydration of the horny layer, which is then much less resistant to wear and tear. It is rubbed off by friction, leading to a characteristic glazed and thinned appearance of the skin. As involved areas become xerotic, cracks are formed. The inherently dry skin of atopic individuals may be a predisposing factor. Adults have a much thicker horny layer of their plantar skin and are thus less at risk of developing the condition.

Clinical Features

The balls of the feet and the toe pads exhibit strikingly symmetrical changes: fairly well demarcated shiny, reddish, tender, dry lesions with some scaling (Fig. 13.11), and often with painful cracks and fissures. The dorsa of the feet, the interdigital spaces and the instep are typically spared. Similar lesions may be found on the hands.

Pathology

Histologically, the features of a chronic dermatitis are seen.

DIFFERENTIAL DIAGNOSIS OF DERMATITIS OF THE FOOT
ALLERGIC CONTACT DERMATITIS (FOOTWEAR DERMATITIS)
• Dermatitis of the dorsal aspects of the feet and toes (allergen contained in the "top" of the shoes) • Dermatitis of the weightbearing areas of the soles (allergens contained in the sole of the shoes) – Most common allergens: dichromate, rubber accelerators, colophony, dyes, formaldehyde resins; also consider topical antibiotics, e.g. bacitracin – Association with atopy and hyperhidrosis – Distinguish from sock and stocking dermatitis where lesions extend more proximally (popliteal area, thighs) – most common allergen is azo dyes
TYLOSIS
• Mechanically induced hyperkeratosis, dryness and fissuring • Predilection sites: heels and weightbearing areas of the soles • In middle-aged to elderly individuals • Associated with obesity and hyperhidrosis
ACQUIRED PLANTAR KERATODERMA (KERATODERMA CLIMACTERICUM)
• Same as tylosis but more intense • Typically occurs in women over the age of 45 years, but may also be seen in men • Similar lesions may appear on palms
JUVENILE PLANTAR DERMATOSIS
See section in this chapter
TINEA PEDIS (ATHLETE'S FOOT)
• Dermatophyte infections of the plantar skin are usually accompanied by involvement of the interdigital spaces as well as lateral aspects of the foot • Often symmetric, accompanied by onychomycosis • Lesions on the lateral and dorsal aspects of the feet have well-demarcated circinate borders • Occasionally vesicular variant
PSORIASIS (SEE CH. 8)
• Diffuse erythema and thick adherent scales, dryness and fissuring • Psoriatic plaques found elsewhere on the body • Nail involvement, e.g. pitting and oil-drop changes
DYSHIDROTIC ECZEMA
See section in this chapter
RECURRENT FOCAL PALMAR AND PLANTAR PEELING
• Probably represents a mild form of dyshidrosis • Dry, circinate thin scales of palms and soles • Vesicles are absent
PUSTULOSIS OF THE PALMS AND SOLES (SEE CH. 8)
• A neutrophilic dermatosis, possibly related to pustular psoriasis • Chronic course with crops of non-pruritic, short-lived, superficial pustules, particularly of the instep • Yellow–brown macules admixed with pustules
SÉZARY SYNDROME (SEE CH. 120)
• Palms and soles are tender and exhibit scaling, which can be quite thick • Associated with hypertrophic onychodystrophy and erythroderma
OTHER
• Atopic dermatitis • Irritant contact dermatitis (e.g. due to occlusive footwear) • Pityriasis rubra pilaris • Acrokeratosis paraneoplastica • Keratoderma blennorrhagicum • Inherited palmoplantar keratodermas (see Ch. 58) • Palmoplantar keratoderma associated with hypothyroidism • Crusted scabies

Table 13.2 Differential diagnosis of dermatitis of the foot.

Differential Diagnosis

Juvenile plantar dermatosis needs to be distinguished from *allergic contact dermatitis* to chemicals contained in leather (e.g. chromates, dyes) or rubber. However, the latter is rare in children and, if present, often involves the dorsa of the feet as well. *Tinea pedis* is equally uncommon in children, and the interdigital spaces are usually

Fig. 13.11 Juvenile plantar dermatosis in a child. Erythema and scaling of the plantar surface of the great toes and fifth toes as well as the ball of the foot bilaterally. Note the glazed appearance of the skin of the left foot. *Courtesy, Kalman Watsky, MD.*

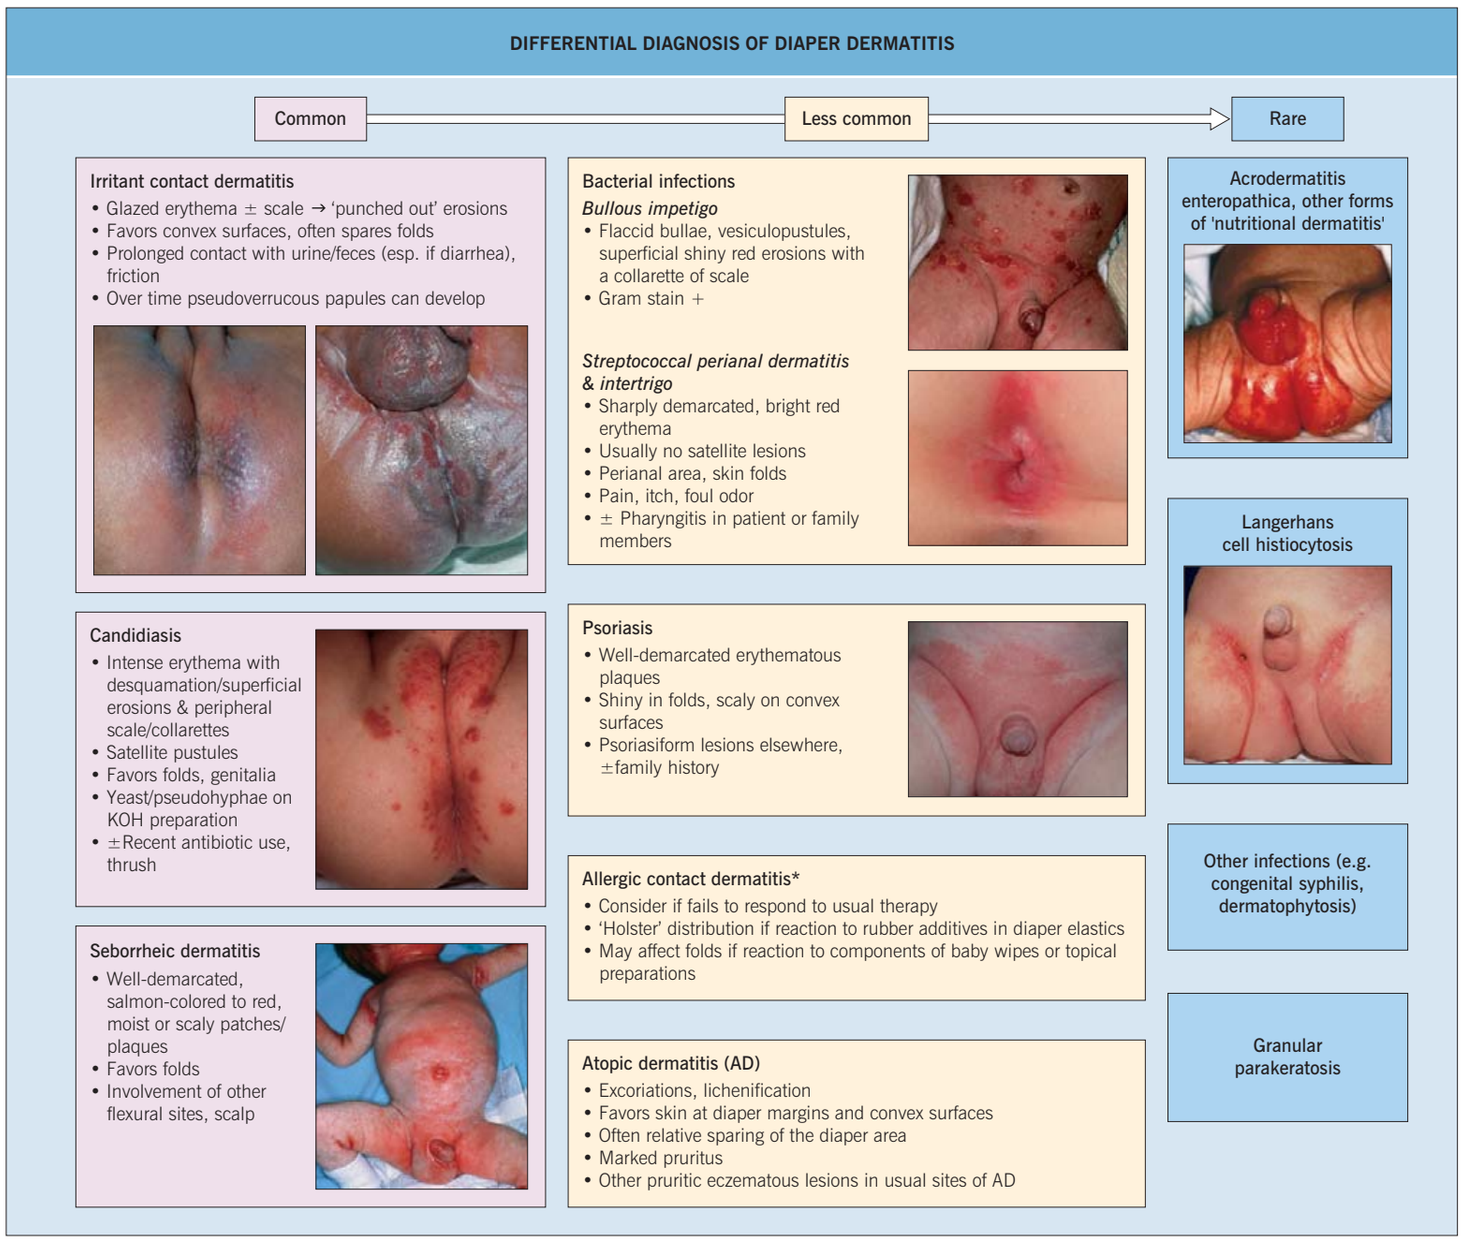

Fig. 13.12 Differential diagnosis of diaper dermatitis. While the most common etiologies are irritant contact dermatitis, cutaneous candidiasis and seborrheic dermatitis, patients often have a combination with one disorder superimposed on another. Discrete papules or nodules are seen in scabies, granuloma gluteale infantum and perianal pseudoverrucous papules, whereas congenital syphilis often presents with erosions and even ulcerations. *Potential allergens include sorbitan sesquioleate (an emulsifier in diaper balms), fragrances, disperse dyes, rubber additives (e.g. mercaptobenzothiazole), and preservatives in baby wipes (e.g. iodopropynyl butylcarbamate). *Inserts, Courtesy, Robert Hartman MD; Julie V Schaffer, MD.*

predominantly affected. Patch testing and KOH preparations may help in establishing the diagnosis.

Treatment

Juvenile plantar dermatosis is a chronic but self-limiting condition. Patients should be advised to avoid wearing impermeable socks and shoes, and the application of emollients, keratolytics and/or paraffin-type ointments is beneficial. When shoes are removed, socks, if damp, should also be removed and replaced by dry socks.

DIAPER DERMATITIS

Key features

- Frequently, an irritant dermatitis of the diaper area due to occlusion and prolonged exposure to urine and feces
- Secondary infection with *Candida albicans* often occurs
- May be associated with seborrheic dermatitis and psoriasis

Epidemiology

Diaper dermatitis develops in at least 50% of infants, and it is responsible for a considerable percentage of dermatologic consultations in infants and toddlers. Seborrheic dermatitis is a predisposing factor.

Pathogenesis

Diaper dermatitis is the cumulative result of several factors, in particular dampness and exposure to urine and feces. In the past, ammonia derived from the urea in urine was held as primarily responsible for diaper dermatitis. More recently, the blame has been placed on the (alkaline) pH of the urine and the role of fecal bacteria. Enzymes produced by fecal bacteria, as well as residual pancreatic proteases and lipase in the stool, act as irritants and these enzymes are also activated in the alkaline milieu[57,58]. In addition, ureases are produced by fecal bacteria, resulting in a further increase of the urinary pH. This explains why diaper dermatitis is more likely to appear in cow milk-fed than in breast-fed infants: cow milk formulas are colonized by a greater number of urease-producing bacteria[59].

Prolonged use of diapers, dampness, and the factors detailed above lead to the breakdown of the horny layer barrier function. An alkaline pH also facilitates the development of secondary C. *albicans* infection.

As diaper dermatitis tends to be most prominent on the inner parts of the thighs, genitalia and buttocks, friction between the skin and the diaper material likely acts as a physical factor that leads to further irritation. In addition, chemical constituents of the diaper and/or topical preparations and baby wipes may lead to contact sensitization.

Clinical Features

Diaper dermatitis is strictly confined to the diaper area, presenting with mild to pronounced erythema, erosions and scaling. In the common form due to irritant contact dermatitis, genitocrural folds are typically spared. Depending on whether there is a secondary infection or an underlying dermatosis (e.g. seborrheic dermatitis, psoriasis), the clinical picture can vary (Fig. 13.12).

Differential Diagnosis

The differential diagnosis is outlined in Figure 13.12.

Treatment

In the acute phase, mild corticosteroid preparations are helpful. Topical imidazole creams are added for secondary infection with *Candida* spp. The major goal of long-term management is avoidance of the causative factors. Frequent changing of highly absorbent disposable diapers is associated with a lower incidence and severity of diaper dermatitis, and it leads to a more physiologic pH.[60] Emollients containing white paraffin (Vaseline®) or soft zinc pastes provide both protective and soothing effects.

Allergic Contact Dermatitis 14

Christen M Mowad and James G Marks Jr

Synonyms: ■ Contact dermatitis ■ Contact eczema

Key features

- Allergic contact dermatitis (ACD) is a pruritic, eczematous reaction
- Acute ACD and many cases of chronic ACD are well demarcated and localized to the site of contact with the allergen
- ACD can also have a diffuse, patchy distribution, depending on the allergen and/or the development of disseminated eczema (autosensitization dermatitis)
- The prototypic reactions are ACD due to poison ivy and nickel
- Patch testing remains the gold standard for accurate and consistent diagnosis

INTRODUCTION

Many adverse events can occur when the skin comes in contact with external agents. These reactions are varied, and include hyperpigmentation, hypopigmentation, acne, urticaria, phototoxic reactions and eczema. The eczema that is seen can be either allergic or irritant in nature. Irritant contact dermatitis (ICD) accounts for approximately 80% of all contact dermatitis (see Ch. 15) and allergic contact dermatitis (ACD) accounts for the remaining 20%[1]. ICD is the result of a local toxic effect when the skin comes in contact with irritant chemicals such as soaps, solvents, acids or alkalis. ACD is a delayed-type hypersensitivity reaction that is elicited when the skin comes in contact with a chemical to which an individual has previously been sensitized.

The cutaneous responses of ACD and ICD are dependent on the particular chemical, the duration and nature of the contact, and individual host susceptibility. The chemicals that cause contact dermatitis are found in jewelry, personal care products, plants, topical medications (prescription, over-the-counter or herbal) and home remedies, as well as chemicals the individual comes in contact with at work, during avocations or via contact with another individual (e.g. consort contact dermatitis). The type of cutaneous reaction discussed in this chapter is ACD.

ICD and ACD, especially the chronic forms, can take on similar clinical appearances. The classic picture of contact dermatitis is a well-demarcated erythematous vesicular and/or scaly patch or plaque with well-defined margins corresponding to the area of contact (Fig. 14.1A). The distribution can be linear, when an object such as a leaf or branch is rubbed against the skin (Fig. 14.1B), or localized to the site where there has been contact with the offending chemical or product, e.g. hand dermatitis caused by ACD to gloves or foot dermatitis due to ACD to shoes (Figs 14.2–14.4). Because ICD and ACD are not always discernible clinically, patch testing is required to help identify an allergen or exclude an allergy to a suspected allergen. Patch testing remains the gold standard for diagnosing ACD.

Patients with the most common clinical presentations of ACD often do not seek medical attention. Those who have earring dermatitis or erythema and pruritus under a ring may simply diagnose themselves as having an allergy to jewelry. An individual who is gardening over the weekend may never present to a physician, because the "poison ivy rash" is so familiar. Nickel (worldwide) and poison ivy (US; see Ch. 17) are among the most common etiologies of ACD and are often not further investigated because the cause is obvious. However, the clinical picture and history are often not sufficiently specific to identify the causative allergen, and patch testing is then necessary. For example, the patient with chronic hand dermatitis or eyelid dermatitis who comes to the office for treatment is often unaware that a personal care product could be the cause of the problem. These are the patients who can be most helped by a thorough history and cutaneous examination, as well as the diagnostic procedure of patch testing.

ACD is an exciting field of interest within dermatology. It requires an understanding of the disease process, the ability to recognize the many ways in which ACD can present, a keen level of interest and an appropriate level of suspicion for the possibility of an allergen, as well as the ability to patch test, interpret, and educate patients on this disease process. Hopefully, this chapter will raise interest and awareness and help the reader come to a better understanding of these issues.

The patient had a positive patch test to potassium dichromate. *Courtesy, Louis A Fragola, Jr, MD.*

HISTORY OF PATCH TESTING

Jadassohn has been credited with describing the technique of patch testing over 100 years ago. In 1931, Sulzberger and Wise[2] formally brought the technique to the US and described its use as a diagnostic tool for identifying a causative allergen responsible for dermatitis. This technique has been further developed over the years on a worldwide basis, with standardized allergens, testing devices, and protocols.

Patch testing has remained the gold standard for diagnosing ACD. However, despite the value of this diagnostic tool, studies have shown that it is underutilized and not taught in many dermatology residency programs, including those in the US[3].

EPIDEMIOLOGY

ACD can affect individuals in all walks of life. It can affect the old, the young, individuals of all races, and of both sexes. Differences between genders may be seen but are generally based upon exposure patterns, such as nickel allergy occurring more frequently in women, presumably because of their greater exposure to jewelry[4]. Of course, occupations and avocations play an important role in the epidemiology of ACD (see

Fig. 14.5 Acute vesiculobullous allergic contact dermatitis (ACD). A ACD to poison ivy; this distribution pattern is seen in patients who wear gloves. **B** ACD to compound benzoin tincture; note the geometric shape.

A Periorbital edema, in addition to crusted and weeping plaques, due to poison ivy. **B** Obvious edema of the shaft of the penis plus subtle crusts of the glans due to application of tiger balm (contains extracts of several plants, including mint, clove, and Chinese cinnamon).
A, Courtesy, Jean L Bolognia, MD. B, Courtesy, Louis A Fragola, Jr, MD.

Ch. 16). Allergens, and therefore patch test results, also differ from region to region, e.g. preservatives used in personal care products can vary based on government legislation. While quaternium-15 is the most common cosmetic preservative in the US to cause ACD, some have argued that it is not even needed in the European Standard Series[5] (see Table 14.3). In addition, even in a particular locale, some allergens can increase in clinical importance over time while others decrease due to usage patterns, and new allergens are continually being introduced.

PATHOGENESIS

ACD is a delayed-type hypersensitivity response. It is an allergen-specific reaction that requires prior sensitization of the individual to the chemical in question. The pathogenesis of ACD involves an initial sensitization phase when the patient first comes in contact with the chemical, which penetrates the skin and then elicits a cascade of events that results in sensitization (see Ch. 4 for details). The subsequent re-exposure of the skin leads to the presentation of the responsible allergen to an already primed T-cell milieu, causing the release of multiple cytokines and chemotactic factors and resulting in the clinical picture of eczema. Once sensitized, all that is needed to elicit a reaction is contact with a low concentration of the causative chemical.

CLINICAL FEATURES

In order to diagnose ACD and treat it adequately, the clinician needs to be familiar with its clinical presentations. The typical appearance is often a well-demarcated pruritic eczematous eruption, which may be acute (blistering, weeping and/or edema, e.g. Figs 14.1, 14.5 & 14.6) or chronic (lichenified or scaly plaques, e.g. Figs 14.3, 14.4B, 14.7 & 14.8). This reaction is typically localized to the area of skin that comes in contact with the allergen. However, the clinician must also be aware that patchy or diffuse distributions can also be seen, depending on the nature of the causative allergen (e.g. Fig. 14.9). For example, body washes or shampoos that get rinsed over the body may cause a more patchy or diffuse clinical dermatitis. Other less common presentations of allergic contact dermatitis are listed in Table 14.1.

PATHOLOGY

Although the diagnosis of ACD is in large part a clinical one aided by the diagnostic procedure of patch testing, histology can sometimes be helpful. This is especially true when excluding other diagnoses, such as mycosis fungoides. The pathology of ACD is most helpful in acute lesions, as subacute or chronic lesions often produce confusing patterns that are not diagnostic. Histologically, ACD is the prototype of

Fig. 14.7 Allergic contact dermatitis due to aloe-containing cream. The degree of involvement on the upper and lower lips is similar, as opposed to actinic cheilitis.

Fig. 14.8 Chronic allergic contact dermatitis due to glutaraldehyde. The patient was an optometrist. *Courtesy, Kalman Watsky, MD.*

LESS COMMON PRESENTATIONS OF ALLERGIC CONTACT DERMATITIS	
Based primarily upon type of primary lesion	**Based primarily upon distribution and/or pathogenesis**
• Pigmented (e.g. fragrances, bactericides; often facial) • Lichenoid (e.g. color film developers) • Erythema multiforme (e.g. tropical woods, poison ivy*) • Purpuric (e.g. rubber diving suits) • Granulomatous (e.g. zirconium) • Pseudolymphomatous (e.g. Compositae)	• Photoinduced (photoallergic contact dermatitis; see Ch. 87) • Airborne contact dermatitis • Systemic contact dermatitis (see Table 14.12) • Baboon syndrome – symmetric erythema of the gluteal and inguinal area in addition to other flexural sites†
*The lesions of erythema multiforme may favor sites previously unaffected by poison ivy. †Overlap with systemic contact dermatitis and clinical overlap with *s*ymmetrical *d*rug-*r*elated *i*ntertriginous and *f*lexural *e*xanthema (SDRIFE).	

Table 14.1 Less common presentations of allergic contact dermatitis (ACD). Contact urticaria, both immunologic and non-immunologic, can also complicate the clinical picture.

Fig. 14.9 Allergic contact dermatitis due to cashew nut shell oil. This represented an occupational exposure.

spongiotic dermatitis. In the acute stage, there is a variable degree of spongiosis, with a mixed dermal inflammatory infiltrate containing lymphocytes, histiocytes and a variable number of eosinophils. In moderate to severe reactions, marked spongiosis results in intraepidermal vesiculation. In subacute to chronic stages, epidermal hyperplasia, often psoriasiform, develops (Fig. 14.10).

However, even when spongiotic dermatitis is present, clinicopathologic correlation is always required, as ACD is not the only cause of this reaction pattern. In addition, as with any dermatitis, the application of topical corticosteroids may alter the histologic findings. Occasionally, other histopathologic patterns are seen in ACD, as outlined in Table 14.1.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ACD includes many other forms of dermatitis, such as ICD, atopic dermatitis, stasis dermatitis and seborrheic dermatitis, as well as the erythematous form of rosacea. Hand and foot ACD also needs to be distinguished from psoriasis and tinea (see Table 13.1 & Fig. 15.6). In general, when evaluating regional dermatoses (e.g. eyelid, hand and foot), other disorders common to the area need to be considered as well as allergens specific to that area (Table 14.2). If there is widespread disease, either because of widespread contact with an allergen or autosensitization, additional causes of erythroderma (see Ch. 10), e.g. Sézary syndrome, enter the differential diagnosis.

Deciphering and differentiating these diseases can sometimes be a challenge. Distribution and history can be helpful (see Figs 14.3–14.6), as can simple tests such as a KOH preparation. In addition, dermatoses are sometimes multifactorial, and ACD may be superimposed on atopic dermatitis or stasis dermatitis. However, in order to diagnose ACD, the clinician must first consider the possibility, then ask the right questions, and, finally, use the appropriate allergens to diagnose this condition. What follows will hopefully provide the clinician with an outline to the appropriate questions to ask and procedures to use when investigating ACD.

Patch Testing

Patch testing is a deceptively simple office procedure upon which the diagnosis of ACD often rests. Although the procedure is straightforward, deciding when and what to patch test requires training and experience. Unfortunately, patch testing is still underutilized. Past surveys have shown that only 50% of all residency programs in the US have a patch test center, and 27% of the responders did no patch testing at all[3].

The TRUE Test®, which is approved by the US Food and Drug Administration (FDA), consists of panels with pre-impregnated

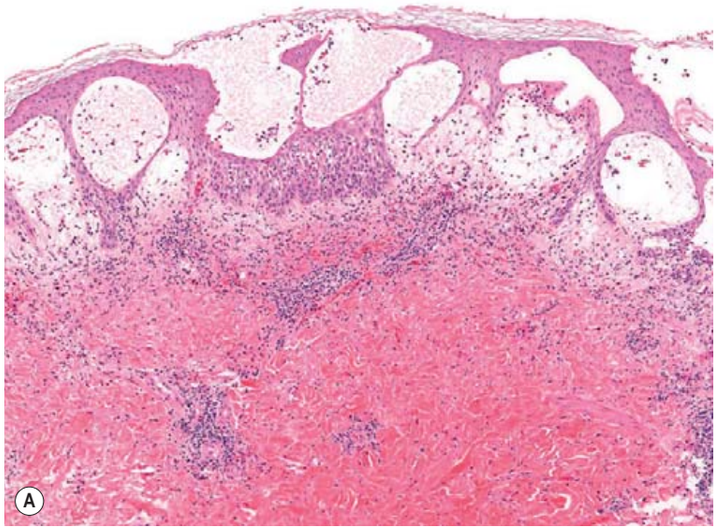

Fig. 14.10 Allergic contact dermatitis – histologic features. A Acute ACD with marked spongiosis leading to intraepidermal vesiculation. There is a perivascular infiltrate of lymphocytes and eosinophils as well as exocytosis of these cells into the epidermis. **B** Chronic ACD with irregular psoriasiform epidermal hyperplasia and significantly less spongiosis. There is also a primarily perivascular infiltrate of lymphocytes admixed with eosinophils. *Courtesy, Lorenzo Cerroni, MD.*

EYELID DERMATITIS – DIFFERENTIAL DIAGNOSIS AND MOST COMMONLY ASSOCIATED ALLERGENS	
Differential diagnosis	**Allergens most commonly associated with ACD of the eyelids***
• Atopic dermatitis • Seborrheic dermatitis • Rosacea (eyelid margin) • Allergic contact dermatitis • Irritant contact dermatitis • Dermatomyositis	• Fragrances, including *Myroxylon pereirae* (balsam of Peru) • Preservatives – quaternium-15, DMDM hydantoin, methylchloroisothiazolinone, methyldibromoglutaronitrile • Topical antibiotics – neomycin (see Fig. 14.17) • Metals – nickel, cobalt chloride, gold sodium thiosulfate • Surfactants – cocamidopropyl betaine, amidoamine
*Adapted from North American Contact Dermatitis Group (2003–2004); Dermatitis 2007;18:78–81.	

Table 14.2 Eyelid dermatitis – differential diagnosis and most commonly associated allergens. ACD, allergic contact dermatitis.

Fig. 14.11 Allergens contained within syringes being placed by nurse into Finn chambers.

allergens, allowing for increased ease of use and perhaps resulting in increased patch testing. However, it currently screens for only 28 allergens (there is one control, which accounts for the 29th spot), and, although this is helpful, extended testing beyond these allergens has been shown to be more beneficial[6–8]. For example, extended testing detected 37–76% more positive reactions, and 47% of the patients had positive reactions *only* to non-screening allergens[6–8]; these additional allergens come in multi-use syringes or tubes (Fig. 14.11). Of note, the manufacturers of TRUE Test® are continuing to work on expanding the number of allergens in their testing series in order to increase diagnostic sensitivity. If clinicians were to increase their use of patch testing and expand the number of allergens tested, they would hopefully enhance patient care through improved allergen identification and avoidance.

Prior to the application of the patch tests, the clinician should ask questions about exposures both at home and at work, and attempt to understand the mechanics of the work environment. The effect of vacations and time away from work or home should also be ascertained. In addition, all personal care products should be inventoried and hobbies explored. The information gained can help to direct allergen selection more appropriately.

Technique

Although the TRUE Test® has only 28 allergens (Table 14.3), referral centers with patch test clinics routinely patch test to an "expanded" series of 60+ allergens. Such panels include the North American Contact Dermatitis Group Screening Series and the European Standard Series, in addition to more specific allergen panels, e.g. the hairdressing tray, dental tray or florist tray, which contain allergens unique to a particular occupation. The companies from which these allergens and other supplies can be obtained are listed in the Appendix. Although these expanded series of allergens are not FDA-approved, they are often required to establish the precise etiology.

Chemicals brought by patients to the dermatologist should *not* be tested in a blinded fashion. The physician should be aware of the chemical ingredients of the product, or severe irritation such as a burn or ulceration could occur. Therefore, no unknown product or chemical should be applied as a patch test. Material safety data sheets (MSDS) can sometimes help in further evaluating the chemical. However, not all ingredients are listed on these forms: those chemicals that represent a small percentage and fall below a certain threshold do not need to be listed, even though they may be the causative allergens. Identification of the latter requires communication with the manufacturer, so that full disclosure of the chemical ingredients can be obtained.

When patients bring all their personal care products to the office for patch testing, special attention is required. The general rule regarding testing of these products is that products intended to be left on the skin

COMPONENTS OF THE NORTH AMERICAN CONTACT DERMATITIS GROUP (NACDG) SCREENING SERIES, THE EUROPEAN STANDARD (BASELINE) SERIES, AND THE TRUE TEST® SERIES	
Series/Compound	**Concentration (in NACDG series* except where compound not part of NACDG series)**
NACDG, EUROPEAN STANDARD AND TRUE TEST®	
2-Mercaptobenzothiazole	1% petrolatum
Colophony	20% petrolatum
4-Phenylenediamine base	1% petrolatum
Neomycin sulfate	20% petrolatum

Amerchol L 101	50% petrolatum
DMDM hydantoin	1% petrolatum
Bacitracin	20% petrolatum
Mixed dialkyl thioureas	1% petrolatum
Glutaraldehyde	0.5% petrolatum
2-Bromo-2-nitropropane-1,3-diol	0.5% petrolatum
Propylene glycol	30% aqueous
2-Hydroxy-4-methoxybenzophenone	10% petrolatum
4-Chloro-3,5-xylenol	1% petrolatum
Ethyleneurea/melamine-formaldehyde mix	5% petrolatum
Ethyl acrylate	0.1% petrolatum
Glyceryl monothioglycolate	1% petrolatum
Tosylamide/formaldehyde resin	10% petrolatum
Methyl methacrylate	2% petrolatum
Disperse 106/124 mix	1.0% petrolatum
Iodopropynyl butyl carbamate	0.2% petrolatum
Compositae mix II	5% petrolatum
Hydrocortisone-17-butyrate	1% petrolatum
Dimethylol dihydroxyethyleneurea	4.5% aqueous
Cocamidopropyl betaine	1% aqueous
Triamcinolone acetonide	1% petrolatum
EUROPEAN STANDARD ONLY	
Clioquinol	5% petrolatum
Lyral® (fragrance)	5% petrolatum
Primin	0.01% petrolatum
TRUE TEST® ONLY	
Caine mix (benzocaine, tetracaine, dibucaine)	0.63 mg/cm^2 in polyvidone
Black rubber mix (N-isopropyl-N′-phenyl PPD, N-cyclohexyl-N′-phenyl PPD, and N,N′-diphenyl PPD)	0.075 mg/cm^2 in polyvidone
Thimerosal	0.008 mg/cm^2 in hydroxypropyl cellulose
Quinoline mix	0.19 mg/cm^2 in polyvidone
*Concentrations in European Series can differ, e.g. higher for mercapto mix, nickel, paraben mix and lower for quaternium-15.	

Table 14.3 Components of the North American Contact Dermatitis Group (NACDG) Screening Series, the European Standard (Baseline) Series, and the TRUE Test® Series. NACDG allergens represent those that are commercially available as the "North American Screening (Baseline) Series (50)". PPD, paraphenylenediamine.

Table 14.3 Continued

(so-called "leave-on" products), such as moisturizers and make-up, may be tested "as is". Products that are intended to be diluted by water or rinsed off (so-called "rinse-off" products), such as soaps and shampoos, need to be diluted prior to patch testing. There are helpful guides for determining appropriate patch test concentrations for numerous chemicals[9]. When these non-standard allergens are tested, controls (including vehicles) must be tested to evaluate for the possibility of ICD.

After allergen selection has been finalized, appropriate technique is necessary to ensure adequate testing. The most common site is the upper back. The patient should not have a sunburn in this area and should not have applied topical corticosteroids to the sites of patch testing for 1 week[10,11]. Systemic and longer-lasting injectable corticosteroids should also be avoided for at least 1–2 weeks[12]. (If necessary for disease control, the daily oral AM dose of corticosteroids should not exceed the equivalent of 20 mg of prednisone during testing.) Any one of these factors may decrease the individual's ability to elicit a reaction when challenged by an allergen, resulting in a false-negative test[10–12].

A nurse or technician in the office can be trained to apply the patches, and this leads to improved efficiency. Either the pre-packaged allergens are placed on the back, as in the case of the TRUE Test®, or the allergens are poured into Finn chambers (see Fig. 14.11) (Epitest Ltd, Tuusula, Finland; available in the US from Allerderm Laboratories, Inc.) that are adhered to Scanpor® tape (Norgeplaster, Vennesia, Norway; available in the US from Allerderm Laboratories, Inc.) or IQ Chambers™ (Chemotechnique® Diagnostics; distributed by Dormer Laboratories, Inc.) and then applied to the back (Fig. 14.12). These patches are then reinforced with more Scanpor® tape and the patient is sent home with instructions to keep the back dry and the patches secured

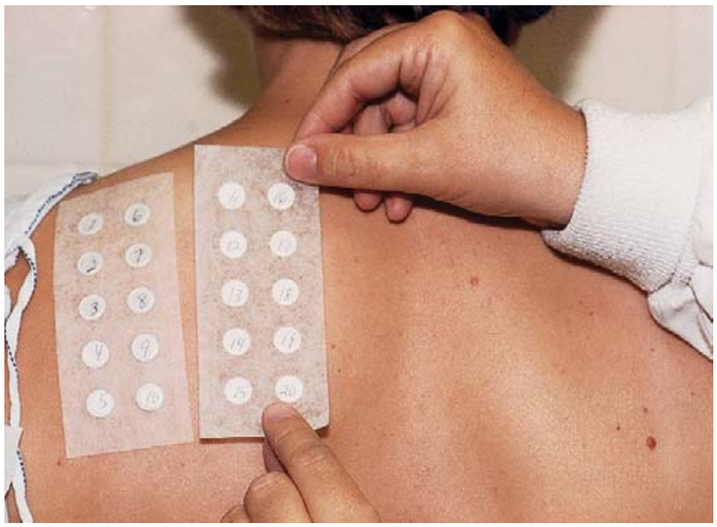

Fig. 14.12 Fixing allergens to patient's back using Scanpor® tape.

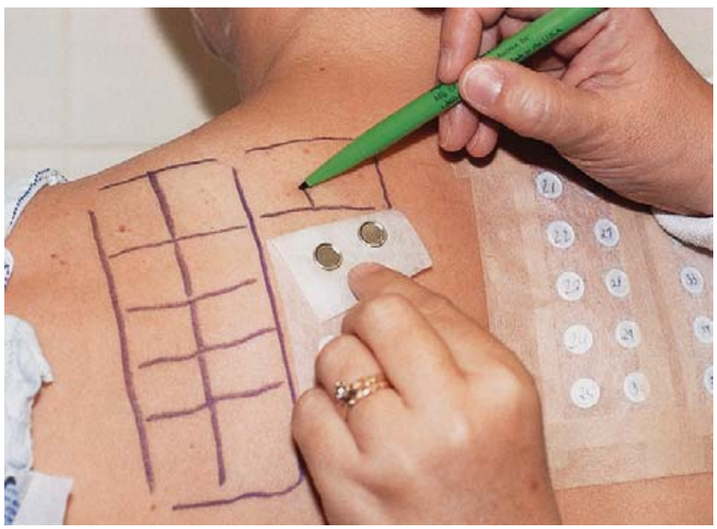

Fig. 14.13 Allergens being marked upon removal of Scanpor® tape.

until the second visit at 48 hours. Patients should also be told to avoid excessive sweating and to avoid heavy lifting, as the patches may come loose. Antihistamines can be prescribed, as they will not affect the outcome of the testing. A map of where the allergens were placed should be constructed for future reference.

When the patient returns at 48 hours, the patches need to be examined to ensure that the testing technique was adequate. Initial inspection can determine that the patches are still in place. Confirmation comes from observing whether the chambers have adhered adequately so as to leave an impression in the skin (see Fig. 14.14F). As the patches are removed, their sites of application should be marked in order to identify the location of the particular allergens (Fig. 14.13). Two types of marking pen are recommended for this procedure: either a permanent surgical marker or a fluorescent highlighter. Highlighters are less messy and do not rub off as easily as the permanent marker. Because of the latter property, permanent markers can soil clothing and make interpretations at the second reading more difficult. Any positive reactions are scored according to the International Grading System (Table 14.4; Fig. 14.14). The patient is again asked to keep the back dry until the second reading, which can be performed from 72 hours to 1 week after the initial application of patches.

When the patient returns for the second reading, the map is used to identify any positive reactions. If a fluorescent marker has been utilized, a Wood's lamp may be needed to identify the markings. Positive reactions are again graded according to the standard system (see Table 14.4).

INTERNATIONAL GRADING SYSTEM FOR PATCH TESTS	
+/–	Doubtful reaction, faint macular erythema
+	Weak, non-vesicular reaction with erythema, infiltration and papules
++	Strong, vesicular reaction with erythema, infiltration and papules
+++	Spreading bullous reaction
–	Negative reaction
IR	Irritant reaction

Table 14.4 International Grading System for patch tests. See Figure 14.14.

A delayed reading is necessary as patch test responses to some allergens such as gold and disperse blue dyes may be delayed. The actual products the patient uses in his or her work and/or home environment are examined and the ingredients compared with the positive reactions. In so doing, products can be divided into groups: those that are free of the suspected allergen(s) and are safe to use, and those that contain these chemical(s) and should be avoided. There will usually be some products with no ingredients listed, and these will have to be further investigated by the patient or physician by contacting companies and inquiring about ingredients.

Interpreting the test

Through the process of reviewing exposures and products, the clinical *relevance* of positive test results can be determined. Allergens may have past relevance. For example, the patient who presents with a known allergy to nickel and reactions to costume jewelry is found on patch testing to have a positive reaction to nickel. The nickel may have past relevance to the patient's problem with costume jewelry but no current relevance to the chronic hand dermatitis. Relevance may also be determined to be current. For example, a positive reaction to tuliposidase A (see Ch. 17) in a florist who has hand dermatitis and contact with *Alstroemeria* when arranging flowers would have present relevance. In some individuals, relevance may be unknown, as in a patient with an eyelid dermatitis and a positive reaction to thimerosal but no past history of an allergy to contact lens solutions and no identifiable contact with thimerosal.

TREATMENT AND PATIENT EDUCATION

Once allergens are positively identified, the patient should be given written information on all of these chemicals. The information sheets should contain data regarding the name of the chemical, possible synonyms, typical uses for the chemical, how to avoid exposure, and, when appropriate, substitutions. The sheets can be individually composed or obtained from books and copied for patient use[13] (Table 14.5). In addition, the American Contact Dermatitis Society website (www.contactderm.org) is an excellent resource for allergen and product information, including patient information sheets. The Contact Allergen Management Program (CAMP) is another feature of the website (available to members of the society): this allows the user to input the known allergens and the database assembles a list of products free of the allergens entered. With this CAMP-generated list, the patients can then purchase products that lack the ingredients to which they are allergic. In addition, this website contains a Contact Dermatitis Alternatives Database which assists both patients and physicians with regard to appropriate substitutions for known allergens.

The patient should also be instructed on how to read the labels of any new or old products not reviewed, in order to avoid future exposure. Each time the patient considers buying a product, he or she should utilize updated information sheets, because ingredients in a given product can change over time. In addition, ingredients in a particular product can change from location to location (e.g. between countries, or between the East and West Coast of the US) without a change in the packaging.

After identifying the substances to which the patient is allergic, the most important step a physician takes is to educate the patient regarding the names of the allergens and how to avoid them. This empowers

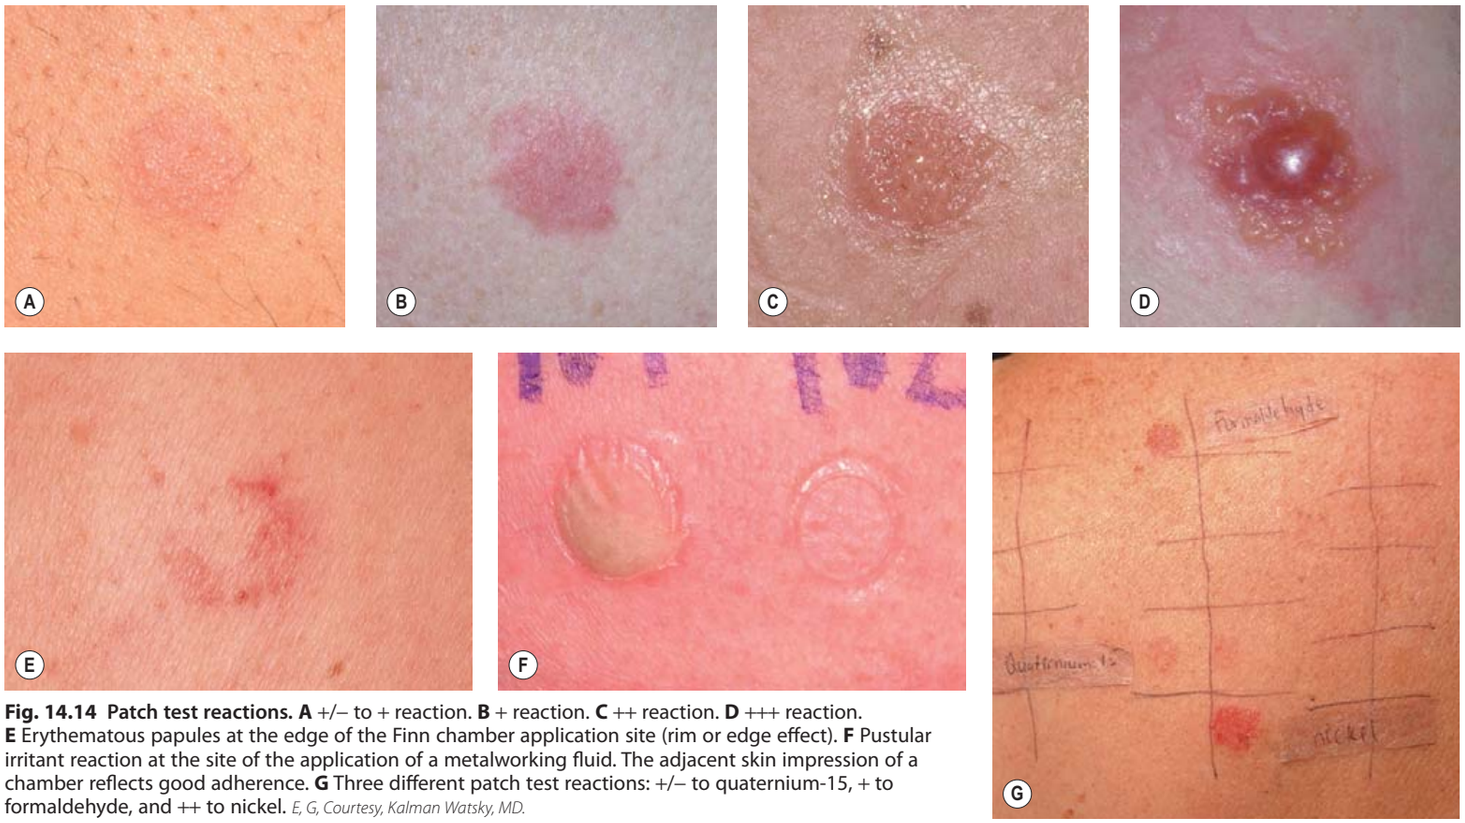

Fig. 14.14 Patch test reactions. A +/– to + reaction. **B** + reaction. **C** ++ reaction. **D** +++ reaction. **E** Erythematous papules at the edge of the Finn chamber application site (rim or edge effect). **F** Pustular irritant reaction at the site of the application of a metalworking fluid. The adjacent skin impression of a chamber reflects good adherence. **G** Three different patch test reactions: +/– to quaternium-15, + to formaldehyde, and ++ to nickel. *E, G, Courtesy, Kalman Watsky, MD.*

EXPOSURE INFORMATION SHEET: BALSAM OF PERU (*MYROXYLON PEREIRAE*)	
SYNONYMS AND OTHER NAMES	
Balsamum peruvianim	Indian balsam
Black balsam	Peruvian balsam
China oil	Surinam balsam
Honduras balsam	
USES	
Balsam of Peru is a natural mixture of resins and essential oils. A positive patch test response is an indication of allergy to fragrances and flavors used in the cosmetic, pharmaceutical, tobacco, and food industries and may indicate sensitivity to the following products: 1. Fragrances in cosmetics and household products 2. Baby products (diaper powders and ointments) 3. Flavors (pastries, cakes, soft drinks, tea, wines, liqueurs, and tobacco) 4. Spices (cinnamon, cloves, vanilla, and curry) 5. Medicated creams, ointments, suppositories, cough syrups and lozenges, and traditional Chinese medicaments 6. Sensitivity (cross-reactions) may also occur to colophony, balsam of Tolu, wood tars, turpentine, propolis, storax, and benzoin	
PREVENTION	
A positive patch test response to balsam of Peru strongly suggests a fragrance allergy. Thus the patient needs to use fragrance-free cosmetics and household products and avoid fragranced medicines. Diaper rash, stasis dermatitis, and hemorrhoids must be treated with topical medications not containing fragrances or balsam of Peru.	
Generalized rash or hand dermatitis has uncommonly occurred after the ingestion of spices by patients who are allergic to balsam of Peru. The wholesale avoidance of this flavor additive or spices in foods such as peel of citrus fruit, chocolate, baked goods, ice cream, soft drinks, candy, chewing gum, tea, and aperitifs should be a last resort in patients with generalized or hand eczema.	

Table 14.5 Exposure information sheet: Balsam of Peru (*Myroxylon pereirae*). With permission from Marks et al.[13]

the individual and allows the physician to transfer to the patient the responsibility for avoiding said chemicals. When trying to identify allergens in the patient's environment, one must also consider allergens transferred from other sources – so-called consort dermatitis (e.g. from spouse to spouse, such as the cologne on the husband causing a reaction on the face of his wife).

Treatment of ACD primarily involves identification of the causative allergens. Once the allergens have been identified, the physician should try to clear the dermatitis with appropriate treatments, such as topical or, if necessary, systemic corticosteroids. The educated patient then needs to be diligent in avoiding the identified allergens. It may take 6 weeks or more to see complete and prolonged clearing, even when allergens are being avoided (Fig. 14.15). If the ACD is superimposed upon another dermatosis (e.g. stasis dermatitis, atopic dermatitis), then the latter will also need to be addressed and will hopefully prove easier to manage.

If a patient is unable to undergo patch testing for some reason, or confirmation of patch test results is desired, a repeat open application test may be performed. This open use test, sometimes referred to as the "poor man's patch test", can prove useful. In an open use test, the patient applies the product in question to the same predetermined location (where there is no dermatitis) twice daily for 1–2 weeks; a common site is the antecubital fossa or flexor forearm. If dermatitis develops, it can be concluded that the patient is reacting to that product. Unfortunately, this type of testing does not allow the identification of individual ingredients. Avoidance of the product in question may result in clearing of the dermatitis. However, many products in the same class use similar ingredients, and therefore the information may not be as useful as first anticipated, i.e. switching to another product may not result in continued clearance of the dermatitis.

ALLERGENS

With an understanding of how to patch test, the next step is a review of some common allergens. The top 10 allergens, as identified by the North American Contact Dermatitis Group (NACDG) in 2006, are nickel sulfate, *Myroxylon pereirae* (balsam of Peru), fragrance mix I, quaternium-15, neomycin sulfate, bacitracin, formaldehyde, cobalt

Fig. 14.15 Allergic contact dermatitis to fragrance found in cologne. A Patient at the time of diagnosis. **B** Patient after avoidance of fragrances and his cologne.

TOP TEN ALLERGENS AS IDENTIFIED BY THE NORTH AMERICAN CONTACT DERMATITIS GROUP		
Test substance	**Allergic reactions (%)**	**Relevant reactions (%) (definite, probable, possible [combined])**
Nickel sulfate	19	57
Myroxylon pereirae (balsam of Peru)	12	87
Fragrance mix I	11.5	86
Quaternium-15	10	89
Neomycin sulfate	10	28
Bacitracin	9	39
Formaldehyde	9	91
Cobalt chloride	8.5	48
Methyldibromoglutaronitrile/ phenoxyethanol	6	75
p-Phenylenediamine	5	56

Table 14.6 Top 10 allergens as identified by the North American Contact Dermatitis Group. The two new members are methyldibromoglutaronitrile/ phenoxyethanol and p-phenylenediamine, which replaced thimerosal and sodium gold thiosulfate.
Adapted from Patch-test results of the North American Contact Dermatitis Group 2005–2006. Dermatitis. 2009;20:149–60.

chloride, methyldibromoglutaronitrile, and p-phenylenediamine[14] (Table 14.6). It should be noted that the list contains three preservatives, two metals, two topical antibiotics, two fragrance components and one dye. Table 14.7 provides a list of additional important allergens (and the frequently identified routes of exposure). Of note, ACD in children is becoming increasingly recognized, and the most common allergens, as identified by the NACDG, in this age group are outlined in Table 14.8. Lastly, the modern era has brought us new products (e.g. cellular phones), changes in manufacturing sites and a craving for "natural" products (Table 14.9).

The following section will briefly discuss pertinent information regarding several key allergens.

Nickel

Nickel ranks as the most common allergen tested by the NACDG, with 19% of patch test clinic patients reacting to it. In patch test clinics worldwide, nickel is the most common allergen. The relevance of these reactions has been estimated to be 50%, suggesting that although this is a common allergen it is not always relevant to the dermatitis in question[15]. However, upon questioning, past relevance may be discovered (e.g. previous mid-abdomen dermatitis). Nickel is a strong silver-colored metal that is commonly used in jewelry, buckles and snaps, as well as other metal-containing objects.

It has been proposed that the high rate of nickel sensitivity, which in some patch test clinics approaches 30–40%, can be attributed in large part to ear piercing. Studies have shown that the metal posts used in ear piercing release varying amounts of nickel, allowing for direct exposure to an injured cutaneous surface[16]. Traditionally, the prevalence of nickel sensitivity has been higher in women; however, with newer trends toward piercing multiple body sites by both men and women, a gender difference may become less apparent[4].

Clinically, nickel dermatitis can have many presentations. One of the most common is an earring dermatitis, or dermatitis under a necklace or a watch back that consists of a nickel-containing metal. Dermatitis of the mid-abdomen caused by a belt buckle or snap is common (Fig. 14.16A), and eyelid dermatitis from metal eyelash curlers can also be seen. In children, the former can be accompanied by a widespread lichenoid papular eruption (see Ch. 13). More recently, facial dermatitis due to ACD to nickel within cellular phones has been described (Fig. 14.16B).

ADDITIONAL IMPORTANT ALLERGENS	
Allergens	**Uses/found in**
PRESERVATIVES	
Methylchloroisothiazolinone/ methylisothiazolinone (Kathon CG®)	Preservative/cosmetics, personal care products
Iodopropynyl butylcarbamate	Preservative/cosmetics, personal care products
Thimerosal	Preservative/otic and ophthalmic drops (otherwise often lacks clinical relevance)
PRESERVATIVES – FORMALDEHYDE RELEASERS	
2-Bromo-2-nitropropane-1,3-diol (Bronopol®)	Preservative/cosmetics, personal care products
Diazolidinyl urea	Preservative/same as above
Imidazolidinyl urea	Preservative/same as above
DMDM hydantoin	Preservative/same as above
COMPONENTS OF RUBBER PRODUCTS	
Carba mix	Rubber accelerator/rubber, latex products
Mercaptobenzothiazole (MBT), mercapto mix	Rubber accelerator/rubber, latex products
Thiuram mix	Rubber accelerator/rubber, latex products
Mixed dialkyl thioureas	Rubber accelerator/rubber, latex products, photocopying, photography
HAIR AND NAIL ALLERGENS	
Glyceryl thioglycolate	Alters disulfide bonds/permanent wave solutions ("acid", "heat"); can persist for months
Tosylamide formaldehyde resin	Film former/nail polish
Acrylates	Artificial nails/nail glues
TEXTILE ALLERGENS	
Ethyleneurea/melamine formaldehyde resin	Thermosetting resin/permanent press clothing
Disperse blue 106 and 124	Textile dyes/darkly colored > lightly colored clothing
ADHESIVE ALLERGENS	
Colophony	Resin/adhesives, cosmetics, topical medications
Epoxy resin	Resin/adhesives
p-tert-Butylphenol formaldehyde resin	Resin/adhesives
OTHER	
Potassium dichromate	Metals, leather, cement
Sodium gold thiosulfate	Metal/jewelry, dental implants (clinical relevance can be difficult to determine)
Propylene glycol	Emulsifier/cosmetics, topical medicaments
Cinnamic aldehyde	Fragrance/flavoring
Budesonide	Corticosteroid/topical creams, ointments
Tixocortol-21-pivalate	Corticosteroid/topical creams, ointments
Ethylenediamine dihydrochloride	Antihistamine/topical creams
Lanolin (wool alcohol)	Emollient/topical creams, lotions
Benzocaine	Anesthetic/topical preparations
Cocamidopropyl betaine	Surfactant/shampoos, cosmetics
Amidoamine	Contaminant of cocamidopropyl betaine

Table 14.7 Additional important allergens. See Table 14.6 for 'Top 10' allergens identified by the North American Contact Dermatitis Group.

TOP 20 ALLERGENS IN CHILDREN AND ADOLESCENTS (<18 YEARS OF AGE) AS IDENTIFIED BY THE NORTH AMERICAN CONTACT DERMATITIS GROUP
Metals – nickel sulfate, cobalt chloride*, gold sodium thiosulfate, potassium dichromate†
Preservatives – thimerosal, quaternium-15, formaldehyde, diazolidinyl urea
Topical antibiotics – neomycin sulfate, bacitracin
Fragrances, including *Myroxylon pereirae* (balsam of Peru)
Components of rubber products – mercaptobenzothiazole, carba mix
Other – lanolin alcohol, colophony, propylene glycol, benzalkonium chloride, p-phenylenediamine, disperse blue dye
*Also contained in ceramics (see text). †Also contained in leather.

Table 14.8 Top 20 allergens in children and adolescents (<18 years of age) as identified by the North American Contact Dermatitis Group. *Adapted from Contact allergy in children referred for patch testing, North American Contact Dermatitis Group Data, 2001–2004. Arch Dermatol. 2008;144:1329–36.*

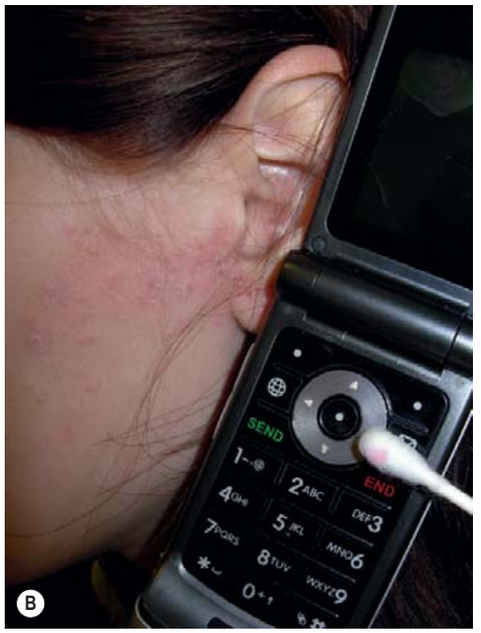

Fig. 14.16 Allergic contact dermatitis to nickel. A Excoriated pink plaques due to nickel within the belt buckle. **B** Facial dermatitis due nickel within a cellular phone. The latter is demonstrated by a positive dimethylglyoxime test (pink indicator). *A, Courtesy, Julie V Schaffer, MD.*

Concomitant reactions to nickel and cobalt have been reported and may be due to the frequency with which the two metals are used in combination[17]. Sweating can increase the amount of metal leached from a product. A useful test to determine whether a particular item contains nickel is the dimethylglyoxime test (see Appendix), which identifies objects that release nickel using a pink color indicator (see Fig. 14.16B). A color indicator test to detect the presence of cobalt is now available based on disodium-1-nitroso-2-naphthol-3, 6-disulfonate.

Individuals with nickel allergy should avoid costume jewelry. They can usually wear jewelry made of stainless steel, platinum or gold, but

ALLERGIC CONTACT DERMATITIS IN THE MODERN ERA		
Product	**Allergen**	**Clinical presentation**
Mobile (cellular) phones	Nickel	Facial dermatitis (see Fig. 14.16B)
Sanitary (baby or wet) wipes	Methylchloroisothiazolinone*	Direct contact – anogenital dermatitis (all ages) Indirect contact – posterior thighs (commode seat)
Anti-mold sachets inside leather products to prevent mold formation during shipping (e.g. couches, chairs, shoes)	Dimethylfumarate	When heated, fumes are created which penetrate through leather and clothing, leading to dermatitis of the back, buttocks and posterolateral thighs if in furniture
"Natural" botanical products resurgence plus grooming practices, e.g. beeswax-containing lip balm	Propolis	Cheilitis of both the upper and lower lip
Increase in temporary tattoos	Paraphenylenediamine	Allergic reaction at site of temporary tattoo
*Also cause of allergic contact dermatitis to moistened toilet paper.		

Table 14.9 Allergic contact dermatitis in the modern era.

not white gold. Some clinicians advocate coating nickel-containing surfaces such as snaps on jeans with clear nail polish to prevent leaching by sweat onto the skin. However, the nail polish can rub off and should be reapplied if it is effective. A new cream containing calcium carbonate nanoparticles has been shown in animals to protect against nickel-induced reactions in the setting of nickel allergy[17a].

Myroxylon Pereirae

Myroxylon pereirae (balsam of Peru) is a naturally occurring fragrance material that is the second most common allergen identified by the NACDG. The International Fragrance Association has recommended that balsam of Peru not be used as a fragrance ingredient[13,18]. Allergy to balsam of Peru is most commonly found in those with fragrance allergy (see below), but it is also seen in those with allergies to spices, particularly cloves, Jamaican pepper and cinnamon[18].

A positive reaction to balsam of Peru requires counseling of the patient to avoid fragrances. Occasionally, spices and other sources such as colas, tobacco, wines and vermouth can also be the cause of allergy to balsam of Peru[13,18].

Fragrance Mix

Fragrances are ubiquitous in our environment. They are used to provide a pleasant odor and have been used extensively for centuries. Fragrances were identified as the third most common allergen according to the NACDG, with a rate of 11.5%, and the most common cosmetic allergen to cause ACD[19].

The detection of a fragrance allergy was made easier with the introduction of a fragrance mix in the 1970s. Prior to that, fragrance allergy was identified primarily through testing with balsam of Peru, which detected only about 50% of those affected[20]. The current fragrance mix I contains eight different fragrance components (at 1% each; Table 14.10).

Of note, the first fragrance mix I had each of the components in Table 14.10 at a 2% concentration, but this was changed to try to reduce the number of false-positive reactions[21,22]. Fragrance mix I is the most useful tool for detecting fragrance allergy[20,23]. However, the composition of fragrance-containing products continually changes. Therefore, by including additional allergens such as those in fragrance mix II (see Table 14.10), the detection rate of fragrance allergy can be increased. It is estimated that 26% of patients allergic to fragrance would be missed if fragrance mix II were not used[23a].

In product formulations, fragrances can be used to provide a pleasant odor. However, they can also be used to mask an unpleasant odor – a so-called masking fragrance. This often occurs in products labeled "unscented". Patients who are identified as being allergic to fragrance must be instructed to read all labels and to avoid any product that lists a fragrance, is labeled "unscented", or has an obvious scent (see Fig. 14.15). They should be instructed to look instead for "fragrance-free" products. Unfortunately, there are several fragrance ingredients that have other purposes, i.e. they act as a preservative or emollient. These covert fragrances, e.g. balsam of Peru, benzylaldehyde, benzyl alcohol, bisbalol and others[24], can be used in a product and the product may still be labeled fragrance-free as long as the potentially allergenic ingredient has been identified as being used for a purpose other than fragrance. Obviously, this causes significant problems for the individual with fragrance allergy who is trying to avoid fragrances. Label reading may not always be enough unless the patient is educated about some of these practices. Complete disclosure on labels of all ingredients regardless of intended function would be helpful, but this is not yet part of industry practice. For the individual allergic to fragrances, repeat open application testing is very helpful in screening for an allergy to new or old products.

COMPONENTS IN FRAGRANCE MIX I AND FRAGRANCE MIX II	
FRAGRANCE MIX I	**FRAGRANCE MIX II**
• Cinnamic aldehyde • Cinnamyl alcohol • Hydroxycitronellal • Isoeugenol • Eugenol • Oak moss absolute • α-Amyl cinnamic aldehyde • Geraniol	• Lyral® • Citral • Farnesol • Citronellol • Hexyl cinnamic aldehyde • Coumarin

Table 14.10 Components in fragrance mix I and fragrance mix II.

Formaldehyde

Formaldehyde is ubiquitous. It is a colorless gas that can be found in the workplace as well as in cosmetics, medications, textiles, paints, cigarette smoke, paper and formaldehyde resins (e.g. plastic bottles)[25]. Formaldehyde can cause several different forms of reactions, ICD being the most common[26]. ACD, contact urticaria and mucous membrane irritation, especially of the conjunctiva and respiratory tract, can also be seen. Formaldehyde is in the air, as it is released in cigarette smoke and automobile exhaust.

Today, formaldehyde is rarely used in personal care products or cosmetics. However, allergy to formaldehyde is commonly seen in association with other formaldehyde-releasing preservatives, such as quaternium-15, imidazolidinyl urea, diazolidinyl urea, DMDM hydantoin, 2-bromo-2-nitropropane-1,3-diol and tris(hydroxymethyl) nitromethane, and therefore formaldehyde-sensitive individuals should generally avoid these substances[25].

Textile dermatitis can be caused by formaldehyde resins, because the latter are used as a finish on "wash-and-wear" or wrinkle-resistant clothes. Of the various textiles, 100% polyester is believed to have the least amount of formaldehyde[13,26]. A study of many fabrics showed that some free formaldehyde was present in all of those tested[13]. Washing clothes, especially those that are "permanent press" or "drip dry", several times prior to wearing will decrease the amount of formaldehyde present but will not eliminate it.

Another occult source of formaldehyde is "formaldehyde-free" products that are packaged in containers coated with a formaldehyde outer resin. Studies have demonstrated that formaldehyde can be released from these containers into the product[27].

As formaldehyde is so widespread, avoidance is often difficult. As a result, the positive patch test can be difficult to manage and clinical relevance should be determined.

Quaternium-15

Quaternium-15 is a quaternium compound that is used as a preservative. It is an effective biocide against *Pseudomonas aeruginosa* and *P. cepacia*, as well as other bacteria and fungi. Although quaternium-15 is used in several industries, the incidence of associated occupational contact dermatitis is very low[25,28]. Quaternium-15 more typically plays a role as an allergen in personal care products such as shampoos, moisturizers, conditioners and soaps. Quaternium-15 is the most common cosmetic preservative to cause ACD[13]. Its allergenicity could be due to its release of formaldehyde[28,29]. Studies have shown that up to 80% of those reacting to quaternium-15 are also formaldehyde-sensitive[30–32]. Allergy to quaternium-15 is often relevant to the patient's dermatitis[30,31].

In addition to coexisting with formaldehyde sensitivity, allergy to quaternium-15 can be seen in association with other formaldehyde-releasing preservatives, such as imidazolidinyl urea, diazolidinyl urea, 2-bromo-2-nitropropane-1,3-diol, DMDM hydantoin and tris(hydroxymethyl)nitromethane[13,25,28]. Avoidance of quaternium-15 is possible through careful label reading. If the individual allergic to quaternium-15 is not allergic to the other formaldehyde-releasing preservatives mentioned above, they need only avoid quaternium-15. Obviously, avoidance of the other formaldehyde-releasing preservatives may be necessary depending on the patch test results. Quaternium-15, formaldehyde, diazolidinyl urea and imidazolidinyl urea are in the TRUE Test® series. However, other formaldehyde-releasing preservatives may be missed if expanded patch testing beyond the TRUE Test® is not performed (see Table 14.3). As a group, the quaternium amino compounds are infrequent sensitizers and the other quaternium compounds can be safely used in those allergic to quaternium-15[25].

Neomycin Sulfate

Neomycin is an antibiotic that is used topically rather than orally because it has poor gastrointestinal absorption. It is the most commonly used topical antibiotic and is the most common sensitizer among the topical antibiotics[13].

Neomycin is found in many over-the-counter preparations, including antibacterial ointments, hemorrhoid creams, and otic and ophthalmic preparations (Fig. 14.17). It is frequently used in conjunction with other antibacterial agents, such as bacitracin and polymyxin, as well as with topical corticosteroids. Co-reactivity is commonly seen with neomycin and bacitracin. These antibiotics are not chemically related and therefore this reaction is believed to be co-sensitization, as the chemicals are so frequently used together (e.g. Neosporin®)[13].

Bacitracin

Bacitracin is a topical antibiotic with activity against Gram-positive bacteria and spirochetes. It is used in topical antibacterial creams as well as in otic and ophthalmic preparations. Bacitracin is commonly used in combination with other topical antibiotics and corticosteroids.

Fig. 14.17 Allergic contact dermatitis to neomycin. Note the erythema and edema of the upper eyelids.

It is frequently used in combination with neomycin, and although the two antibacterial agents are chemically unrelated, they often show co-reactivity. This is believed to be due to sensitization to both, as they are so frequently used in combination[33,34]. In addition to ACD, bacitracin rarely causes anaphylaxis and/or contact urticaria[35,36].

Cobalt

Cobalt is a metal that is often used in association with other metals to add hardness and strength. It is frequently combined with nickel, chromium, molybdenum and tungsten. This may be the cause of the frequent finding of sensitization to cobalt in combination with sensitization to either nickel or chromium. Approximately 80% of individuals with a cobalt sensitivity have a co-sensitivity to chromate (more common in men) or nickel (more common in women)[13].

Exposure to cobalt is typically through a metal, e.g. in jewelry, snaps, buttons and tools. However, it is also found in cosmetics, hair dyes, joint replacements, ceramics and enamel, as well as in cement, paints and resins[13]. Exposure can come from hobbies such as pottery making and occupations such as bricklaying.

When patch testing to cobalt, one may see a particular reaction, described as "poral", that appears as erythematous to violaceous dots. This is not an allergic reaction but is believed to result from the allergen residing in the acrosyringia[37].

Methyldibromoglutaronitrile/Phenoxyethanol

Methyldibromoglutaronitrile is a preservative that can be found alone or in combination with phenoxyethanol. It is used in both leave-on and rinse-off products. In Europe, this chemical has been banned due to reports of a significant risk of ACD. As the same level of allergic reactions has not been identified in the US and the number of positive reactions has remained relatively stable over the past several years, it is still present in personal care products in the US.

p-Phenylenediamine

Paraphenylenediamine (PPD) is the most commonly used permanent hair colorant and it is recognized as a common cause of ACD. Once fully oxidized, the disperse dye is no longer allergenic, but in reality the chemical is not always fully oxidized. More recently, PPD has been found in temporary tattoos in concentrations higher than those present in hair color products. As a result, PPD has resurfaced as an allergen in a new population.

Thimerosal

Thiosalicylic acid and ethylmercuric chloride are the two components that are combined to form thimerosal – sodium ethylmercurithiosalicylate – a preservative that is used in a few products. It is believed that the most likely cause of sensitization to thimerosal comes from its use as a preservative in vaccines[38,39]. Reports of sensitivity to ethylmercuric chloride and thiosalicylic acid have been published and both compounds have been found to be capable of inducing a delayed hypersensitivity reaction[38,40,41].

Many positive reactions to thimerosal are found on patch testing. Clinical relevance may be found in patients who use otic or ophthalmic drops. However, positive reactions often lack identifiable clinical relevance, and some argue that although positive reactions are common, clinical relevance is low and therefore routine testing to this allergen should be reconsidered[42]. Currently, thimerosal is in neither the NACDG Screening Series nor the European Standard Series (see Table 14.3), but is still an allergen in the TRUE Test®.

Gold

Worldwide rates of positive gold reactions vary, and with routine testing they range from 0.78% to 10%[43–45]. In one NACDG series, 90% of gold-allergic patients were women, and there appeared to be a higher rate of nickel (33.5%) and cobalt allergies (18%) in patients with gold allergy than in the general population (14% and 9%, respectively)[15]. Similar findings have been reported in other studies[45].

When relevant, the most common clinical presentation is that of a hand, facial or eyelid dermatitis[15,43]. One of the difficulties with gold patch testing is that the relevance of positive reactions is usually difficult to determine[15,43–45]. Gold sodium thiosulfate is not included

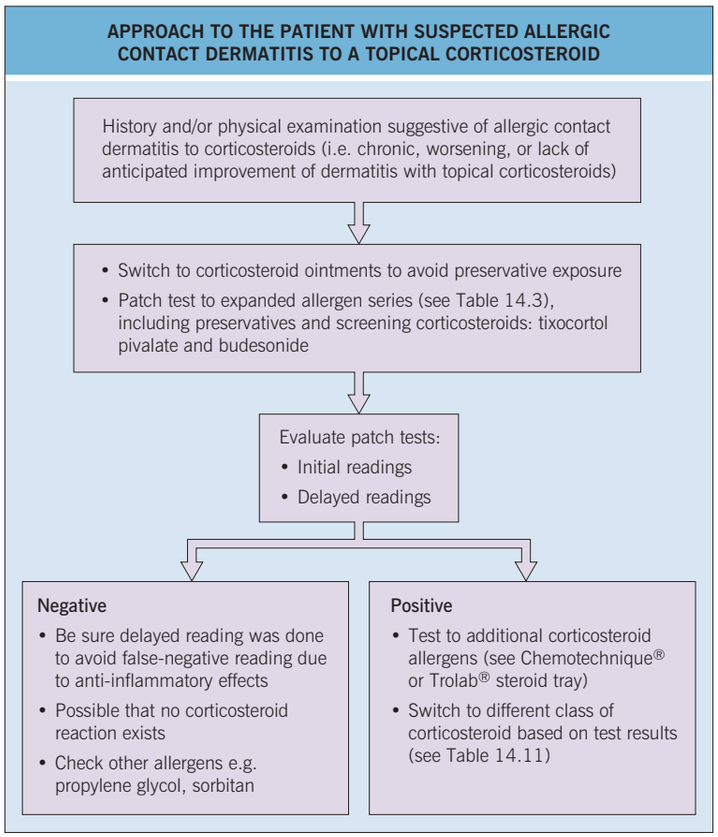

Fig. 14.18 Approach to the patient with suspected allergic contact dermatitis to a topical corticosteroid.

in the NACDG Screening Series, the European Standard Series or the TRUE Test®, with patch testing to gold done only in selected situations[14].

Corticosteroids

Corticosteroids are administered in many different forms: topical, oral, intravenous, intralesional, inhalational and intra-articular. They are anti-inflammatory agents and have been shown to cause ACD in 0.2–6% of patients[46,47]. Four classes of corticosteroids have been identified based primarily on chemical structure (Table 14.11). It is suspected that ACD to these agents may be underdiagnosed, either because of insufficient testing to the allergens or perhaps owing to incomplete testing, as a second reading is necessary given the anti-inflammatory nature of these compounds[46,48,49]. Clinical scenarios that should raise the question of a possible allergy to topical corticosteroids include chronic dermatitis, failure to clear with topical corticosteroids, and exacerbation of dermatitis after use of topical corticosteroids. This should lead to a consideration of patch testing.

Tixocortol-21-pivalate and budesonide are believed to be adequate screening agents for this problem (see Table 14.11), with 91.3% of corticosteroid allergic reactions detected with these allergens in one study[47]. Adding other corticosteroid allergens, such as hydrocortisone-17-butyrate, will increase the yield. It may be prudent to screen with tixocortol-21-pivalate and budesonide and then test to a broader corticosteroid tray if either of these two allergens is positive. Positive patch test reactions to corticosteroids are often unexpected results in routine testing, but are usually relevant. They are often seen with other positive reactions. Figure 14.18 may help direct the clinician in approaching the patient suspected of having an ACD to topical corticosteroids.

In addition to the anti-inflammatory nature of corticosteroids complicating patch test interpretation, an edge effect has also been observed. During the first reading, there may be erythema only at the rim of the test chamber, with a clear center that may later become involved. This is believed to be due to the anti-inflammatory effect of corticosteroids. In the center, the corticosteroid may be concentrated, inhibiting a reaction, but be less concentrated at the rim, where a reaction may occur more readily[50].

CORTICOSTEROID CLASSES AND PATCH TEST CONCENTRATIONS

Drug	Concentration (%)**
CLASS A: HYDROCORTISONE AND TIXOCORTOL TYPE	
Cortisone	
Cortisone acetate	25
Hydrocortisone[*†]	2.5 ethanol (1, 2, 5, 10, 25, ethanol or petrolatum)
Hydrocortisone acetate*	25
Methylprednisolone	
Methylprednisolone acetate	10
Prednisolone	5 (10)
Prednisolone acetate	5
Tixocortol pivalate[†]	0.1
CLASS B: TRIAMCINOLONE ACETONIDE TYPE	
Triamcinolone acetonide[†]	1
Triamcinolone alcohol	
Halcinonide	1
Flucinonide	1
Flucinolone acetonide[†]	0.5 (0.05, 1, 5, 10)
Desonide	0.05
Budesonide[†]	0.01
Amcinonide	0.5
CLASS C: BETAMETHASONE TYPE	
Betamethasone	
Betamethasone–disodium phosphate	1
Desoximetasone	1
Dexamethasone	
Dexamethasone–disodium phosphate	1
Fluocortolone	
CLASS D: HYDROCORTISONE-17-BUTYRATE AND CLOBETASONE-17-BUTYRATE TYPE	
D1	
Alclometasone dipropionate	1
Betamethasone dipropionate	5
Betamethasone-17-valerate	1
Clobetasone butyrate	0.5
Clobetasol propionate	1
Fluocortolone hexanoate	1
Fluocortolone pivalate	1
Mometasone furoate	1 alcohol
D2	
Hydrocortisone butyrate[†]	1 alcohol
Hydrocortisone valerate	1
Prednicarbate	

*Available without prescription in the US.
†Suggested screening agents (in italics); all but hydrocortisone are in the NACDG screening series.
**In petrolatum unless stated otherwise. Parentheses contain additional suggested concentrations or vehicles.

Table 14.11 Corticosteroid classes and patch test concentrations.

TEXTILE DERMATITIS

Textile dye dermatitis often goes undetected because of low suspicion and a lack of routine testing with screening allergens. The allergens most likely to cause textile dermatitis are not the synthetic or natural fibers from which the textiles are made, but rather the dyes used to color them and the resins (e.g. ethyleneurea/melamine formaldehyde

Fig. 14.19 Systemic contact dermatitis. This patient, who was previously sensitized to ethylenediamine, received intravenous aminophylline.

EXAMPLES OF TOPICAL ALLERGENS THAT MAY RESULT IN SYSTEMIC CONTACT DERMATITIS AFTER SYSTEMIC EXPOSURE	
Cutaneous allergen	**Systemic exposure**
Ethylenediamine hydrochloride	Aminophylline, hydroxyzine/cetirizine
Poison ivy	Cashews, mangoes
Fragrance (balsam of Peru)	Foods (tomatoes, citrus), sodas, mouthwashes, spices
Sorbic acid	Preservative in food
Nickel and other metal salts	Nickel (and other metal salts) in food, nickel from catheter hub
Quinolones	Oral antibiotics
Ampicillin	Surgical solution
Neomycin	Streptomycin, kanamycin
Thiuram	Disulfiram (Antabuse®)

Table 14.12 Examples of topical allergens that may result in systemic contact dermatitis after systemic exposure.

resin, dimethylol dihydroxyethyleneurea) used to make clothes less likely to wrinkle or shrink[51,52]. Textile dermatitis typically occurs in areas where clothing fits more tightly, and it is more common in women[51]. Dyes, particularly disperse blue dyes 106 and 124, have been found to be a common cause of textile dermatitis and can be used as screening agents[51]. They frequently cross-react and positive patch test reactions can be delayed up to 7–10 days[51]. Although p-phenylenediamine is a disperse dye, it is not a good screening allergen for textile dye dermatitis[51]. Screening with an individual's garment can also produce a relevant positive patch test reaction.

SYSTEMIC CONTACT DERMATITIS

Systemic exposure to a chemical may result in a diffuse dermatitis. This reaction generally involves a chemical to which the patient has had a prior contact allergy; the patient is then exposed to the same chemical (or one that cross-reacts) via a systemic route, such as an injection or oral, intravenous or intranasal administration. This reaction is believed to be due to a delayed T-cell-mediated immune response. Historically, one of the most common examples of systemic contact dermatitis was the patient with a history of ACD to ethylenediamine who then developed a diffuse dermatitis secondary to intravenous aminophylline, which contains ethylenediamine (Fig. 14.19).

Other causes of systemic contact dermatitis due to ingestion of allergens that have previously caused an ACD include antibiotics, plants/plant products, propylene glycol, sorbic acid and metals[53–59]. Marks et al.[53] reported the ingestion of cashews tainted with oil from the cashew nut shell resulting in a systemic contact dermatitis in patients with a prior history of poison ivy dermatitis. In addition, ingestion of a pesto sauce made with cashew nuts resulted in systemic contact dermatitis in the form of the "baboon syndrome" (symmetric, sharply demarcated erythema of the gluteal or inguinal area plus other intertriginous or flexural sites)[54]. Ingestion of both cashews and mangoes has been shown to cause reactions in patients sensitive to poison ivy and poison oak, as they are all members of the Anacardiaceae family (see Ch. 17).

In the proper clinical setting, patch tests demonstrating a sensitivity to balsam of Peru or fragrance mixture can support the diagnosis of a systemic contact dermatitis due to balsam-related foods or spices. A diet avoiding such foods or spices may result in an improvement of the dermatitis[60]. The ingestion of metals can also cause systemic contact dermatitis, and nickel is the metal most commonly implicated[61]. However, the use of low-nickel diets to treat dermatitis in patients with positive patch tests to nickel is controversial. Of note, Fowler[61] reported a patient with systemic contact dermatitis following ingestion of chromium picolinate, a nutritional supplement. Patch testing was positive to potassium dichromate, and upon discontinuation of the chromium picolinate, the dermatitis subsided.

Examples of other cutaneous allergens and their common sources of systemic exposure are listed in Table 14.12. An extensive chapter on this subject is in *Fisher's Contact Dermatitis* textbook[55] and the reader is referred there for additional information.

Fig. 14.20 Airborne contact dermatitis. Note the significant involvement of the eyelids. *Courtesy, Joyce Rico, MD.*

AIRBORNE CONTACT DERMATITIS

Allergens that are airborne can come in contact with the skin and result in several different reactions, including ACD and ICD. Photoallergic contact dermatitis, phototoxic contact dermatitis, and phototoxicity or photoallergy secondary to systemic medications are reactions that can clinically resemble airborne contact dermatitis (see Fig. 87.16). Ragweed dermatitis, a good example of an airborne contact dermatitis, is most noticeable on the face[62]. Prolonged and repetitive exposure to airborne allergens generally produces an ACD that is lichenified and dry and is predominantly located in the exposed portions of the skin: face, eyelids, V of the neck, arms and legs (Fig. 14.20)[63]. The most common causative agents are plants, especially Compositae allergen, natural resins, woods, plastics, rubbers, glues, metals, pharmaceutical chemicals, insecticides and pesticides[64].

Airborne ACD has been associated with a wide range of allergens, from common allergens such as plants (see above) to more obscure causes such as essential oils volatilized during aromatherapy, preservatives in paints, and thyme dust in farmers, to name but a few[64–67]. Occupationally induced reactions appear to be the most common cause of airborne contact dermatitis. Dermatoses in exposed areas should raise the possibility of a possible airborne contact allergy, leading to a series of questions regarding possible exposure sources and to appropriate patch testing when indicated.

Irritant Contact Dermatitis 15

David E Cohen and Aieska de Souza

Synonyms: ■ Irritant reaction ■ Irritant dermatitis ■ Irritant dermatitis syndrome ■ Irritant contact dermatitis syndrome ■ Toxic contact dermatitis ■ "Housewife's eczema" ■ "Chemical burn"

Key features

- Irritant contact dermatitis (ICD) is a localized, non-immunologically initiated, cutaneous inflammatory reaction. Its clinical characteristics are polymorphous, and they include erythema, scaling, edema, vesiculation and erosions in acute cases, and erythema, lichenification, hyperkeratosis and fissures in chronic cases
- ICD results from a direct cytotoxic effect due to single or repeated application of a chemical substance or physical insult to a cutaneous site
- ICD is a frequent disorder and represents an important spectrum of diseases in both general and occupational dermatology, occurring when the normal epidermal barrier is disrupted and secondary inflammation develops
- Despite different pathogeneses, allergic contact dermatitis and ICD have similar clinical appearances, especially their chronic variants
- ICD is a multifactorial syndrome determined by the properties of the irritating substance as well as host and environmental factors; a dose–response relationship is related to exposure parameters such as concentration, pH, temperature, occlusion, repetition and duration of contact
- Strong or absolute irritants such as strong acids and alkalis, as well as oxidants, produce erythema, edema, vesicles that may coalesce into bullae, oozing, and, in severe cases, necrosis and ulceration. The latter is vernacularly termed a "chemical burn"
- The clinical features of chronic ICD from repeated exposure to low-grade or marginal irritants (such as soaps, solvents, cleansers) include erythema, lichenification, excoriations, scaling and fissures

INTRODUCTION

There are two major forms of contact dermatitis: irritant and allergic. Irritant contact dermatitis (ICD) is a cutaneous inflammatory disorder resulting from activation of the innate immune system by direct cytotoxic effect of a chemical or physical agent, whereas allergic contact dermatitis is a delayed-type hypersensitivity immune reaction mediated by hapten-specific T cells[1].

Occupational contact dermatitis is a matter of public health importance[1], contributing to combined direct and indirect annual costs in the US of up to $1 billion when accounting for medical costs, workers' compensation, and lost time from work[2–4]. Overall, the impact of occupational skin diseases for both society and the individual is formidable in light of both prevalence and economic factors.

HISTORY

One of the earliest documented irritant skin reactions is in the writings of Celsus around 100 AD, when he described skin ulceration resulting from corrosive metals[5]. Little attention was then paid to the skin problems incurred by tradesmen for several centuries. The first accounts of occupational skin diseases focused on ill health among miners, and in 1556, Georg Agricola detailed the deep ulcers observed among metal workers. Eleven years later in 1567, Paracelsus discussed the etiology, pathogenesis and therapy of skin changes caused by salt compounds. In 1700, Bernardino Ramazzini of Modena published a clear and detailed historic treatise on the diseases of tradespeople, where he described skin disorders incurred by bath attendants, bakers, gilders, midwives, millers and miners[5]. Physicians began to more widely recognize occupational irritant dermatitis during the Industrial Revolution with the development of new materials and chemicals, both natural and synthetic, for both industrial and household use[6]. Germany and France were the first to enact laws compensating workers for industrial skin diseases. Early prospective studies of ICD in 1919 involved experimentation with the irritant mustard gas dichloroethylsulfide[7].

EPIDEMIOLOGY

ICD is the most common form of occupational skin disease, estimated to constitute between 70% and 80% of all occupational skin disorders. Data from the North American Contact Dermatitis Group indicate that in groups of patients with contact dermatitis, ICD (as a primary diagnosis) accounts for 9–10% of those screened for allergic contact dermatitis via patch testing, and when hands are affected, ICD predominates over all other causes of contact dermatitis[8,9].

The US Bureau of Labor Statistics data show that occupational skin diseases accounted for a consistent 30% to 45% of all patients with occupational illnesses from the 1970s through the mid-1980s. However, occupational skin disease rates have fallen dramatically (e.g. from an average rate of 16.2 events/10 000 full-time workers in 1972 to 3.7 events in 2007), and in 2007, skin disease accounted for only 17% of all recorded non-fatal occupational illnesses. In addition to a decline in the rates of disease, the raw reported cases of occupational skin disease decreased from 89 400 in 1974 to 35 300 in 2007, with work in the areas of natural resources (e.g. agriculture, forestry, fishing, mining), manufacturing, education/health services, leisure/hospitality and construction accounting for the highest rates of non-fatal occupational skin diseases[10]. Nonetheless, because of limitations in the Bureau of Labor Statistics annual survey of approximately 250 000 US employers, it has been estimated that the number of actual occupational skin disease cases may be of the order of 10–50 times higher than that reported by the Bureau. The incidence of occupational contact dermatitis in several other countries is similar to that in the US, with a range of 50 to 70 cases per 100 000 workers per year[11]. In 1996, the United Kingdom created a voluntary reporting system that combined information from the EPIDERM study with the occupational physicians' reporting activity (OPRA). The annual incidence of occupational contact dermatitis reported by dermatologists was 0.9 per 10 000 workers, and for occupational physicians, it was 3.1 per 10 000 workers[1,12]. Rubber chemicals, soaps and cleansers, wet work, resins, acrylics and nickel were the most common sources for contact dermatitis (Table 15.1), and high-risk occupations included workers in the petrochemical, rubber, plastic, metal and automotive industries[1,12].

Clinical manifestations of ICD are determined by the properties of the irritating substance as well as host and environmental factors. These include concentration, pH, mechanical pressure, temperature, humidity, and duration of contact. Low ambient humidity and cold are important factors in decreasing the water content of the stratum corneum and, consequently, increasing the permeability to irritants such as soaps, detergents and solvents. Cold alone may also reduce the

CAUSES OF OCCUPATIONAL CONTACT DERMATOSES IN THE UNITED KINGDOM (1996–2001)		
Exposure	**Contact dermatitis Number of cases (%)**	**Contact urticaria Number of cases (%)**
Rubber chemicals and materials	377 (12)	78 (51)

IRRITANTS AND MECHANISMS OF TOXICITY	
Irritant	**Mechanisms of toxicity**
Detergents	Barrier disruption Protein denaturation Membrane toxicity
Acids	Protein denaturation Cytotoxicity
Alkalis	Barrier lipid denaturation Cytotoxicity through cellular swelling
Oils	Disorganization of barrier lipids
Organic solvents	Solubilization of membrane lipids Membrane toxicity
Oxidants	Cytotoxicity
Reducing agents	Keratolysis
Water	If barrier is disrupted, cytotoxicity through swelling of viable epidermal cells

Table 15.2 Irritants and mechanisms of toxicity.

plasticity of the horny layer, with consequent cracking of the stratum corneum. However, in one study, the application of cold had a protective effect on the development of ICD if applied during the provocative exposure, in this case to sodium lauryl sulfate[13]. Occlusion, excessive humidity and maceration increase the water content of the stratum corneum, with consequent enhanced percutaneous absorption of water-soluble substances (Fig. 15.1). In addition, irritated skin may become more susceptible to superimposed allergic sensitization.

Important predisposing characteristics of the individual include age, sex, pre-existing skin disease, anatomic region exposed, and sebaceous activity. There are age-associated changes in the skin that can alter the skin's response to irritants. Both infants and the elderly are more often affected by ICD because of their less robust epidermal barrier, and they also develop more severe symptoms. While skin irritation may be seen more often on the upper extremities of women than men, this higher prevalence of ICD may be due to increased frequency of exposure rather than inherent gender differences. Genetic factors also play a role in the development of ICD, as shown in studies with monozygotic twins[14]. Patients with a history of atopic dermatitis have a 13.5 times greater risk of developing occupational dermatitis[15], and a reduction in epidermal filaggrin can reduce the inflammatory threshold for irritants[16]. Lastly, the most commonly affected sites are exposed areas such as the hands and the face, with hand involvement seen in approximately 80% of patients and facial involvement in 10%[11]. Excessive exposure to water, soaps and detergents, common causes of ICD, obviously play a role.

PATHOGENESIS

Although the cellular mechanisms of ICD remain unknown, increasing evidence suggests that activated keratinocytes act as signal transducers in controlling the host homeostatic responses to exogenous stimuli and serve as the key immunoregulators. While other mediators such as prostaglandins, leukotrienes and neuropeptides may possibly play a role, cytokines carry the most interest in ICD as they are the central mediators in T-cell inflammation.

Several mechanisms have been commonly associated with ICD, including denaturation of epidermal keratins, disruption of the permeability barrier (see Ch. 124), damage to cell membranes, and direct cytotoxic effects, with different mechanisms at work with different irritants (Table 15.2). The mechanisms involved in the acute and chronic phases of ICD are fundamentally different. Acute reactions involve direct cytotoxic damage to keratinocytes, while repeated exposures to solvents and surfactants cause slower damage to cell membranes by removal of surface lipids and water-retaining substances.

The pathogenic pathway in the acute phase of ICD, common to many chemically unrelated irritants, begins by penetration through the permeability barrier, mild damage to keratinocytes, and the release of mediators of inflammation with resultant T-cell activation. In this manner, once activation is initiated via epidermal cells, continuous T-cell activation independent of the exogenous antigen may be maintained. Tumor necrosis factor-α (TNF-α) and interleukin (IL)-1α are the major mediators, and they are capable of inducing production of other

cytokines, chemokines and adhesion molecules, leading to leukocyte recruitment to the site. Specifically, TNF-α, IL-6 and IL-1β upregulate expression of intercellular adhesion molecule-1 (ICAM-1)[17]. This is a predominant feature of ICD. In addition, IL-1 receptor antagonist (IL-1RA) and IL-8 increase substantially after exposure to the common irritant sodium lauryl sulfate.

In the chronic phase of ICD, the role of the stratum corneum as a barrier is disrupted. Damage to the stratum corneum lipids (which mediate barrier function) is associated with loss of cohesion of corneocytes, desquamation, and an increase in transepidermal water loss. Transepidermal water loss is one of the triggering stimuli that promote lipid synthesis, keratinocyte proliferation and transient hyperkeratosis during the restoration of the cutaneous barrier. However, damage with a solvent can disrupt this protective mechanism by occlusion and blockage of water evaporation, thus halting lipid synthesis and barrier recovery. After chronic exposure, the result is increased epidermal turnover manifested clinically by the chronic eczematoid irritant reaction[18].

CLINICAL FEATURES

Several different types of ICD have been described[19] (see below). Consequences of the myriad forms of ICD range from postinflammatory pigmentary changes to poorly healing ulcers (Table 15.3).

Acute Irritant Contact Dermatitis

Acute ICD, commonly seen with occupational accidents, develops when the skin is exposed to a potent irritant. The irritant reaction reaches its peak quickly, usually within minutes to hours after exposure, and then starts to heal. This is termed the decrescendo phenomenon. Symptoms of acute ICD include burning, stinging and soreness of the directly affected sites. Physical signs include erythema, edema, bullae and possibly necrosis. These lesions are restricted to the area where the irritant or toxicant damaged the tissue, with sharply demarcated borders and asymmetry pointing to an exogenous cause. If there is no dermal injury, there should be no permanent scarring[20]. The potent irritants that most frequently lead to ICD are acids and alkaline solutions, resulting in chemical burns.

Acute Delayed Irritant Contact Dermatitis

Acute delayed ICD is a retarded inflammatory response characteristic of certain irritants, such as anthralin (dithranol), benzalkonium chloride (preservative/disinfectant) and ethylene oxide. Adverse reactions to these chemicals are considered idiosyncratic, except when they are applied to previously injured skin (sites of xerosis or atopic dermatitis)[20]. Clinically, visible inflammation is not seen until 8 to 24 hours (or more) after exposure, and thus may mimic allergic contact dermatitis; however, the associated symptom is more frequently burning rather than pruritus. Sensitivity to touch and water is elicited. This form of ICD is commonly seen during diagnostic patch testing.

Irritant Reaction Irritant Contact Dermatitis

Irritant reaction ICD is a type of subclinical irritant dermatitis in individuals exposed to wet chemical environments, such as hairdressers, caterers or metal workers. It is characterized by one or more of the following signs: scaling, redness, vesicles, pustules and erosions, often beginning under occlusive jewelry (e.g. rings) and then spreading onto the fingers and then the hands and the forearms. It may simulate dyshidrotic dermatitis and ultimately result in cumulative ICD if exposure is prolonged; however, ICD tends to resolve if exposure is discontinued.

Cumulative Irritant Contact Dermatitis

Cumulative ICD is a consequence of multiple sub-threshold skin insults, without sufficient time between them for complete restoration of skin barrier function. It may be due to a variety of stimuli or frequent repetition of one factor (i.e. exposure to water both at the work place and at home). Clinical symptoms develop only after the cumulative damage exceeds an individually determined manifestation or elicitation threshold, which may decrease with progression of the disease. Weak irritants do not lead to clinical ICD if they are encountered far enough apart to allow for restoration of skin barrier function. However, if the same irritant exposures follow each other closely in time, or when the manifestation threshold is reduced (e.g. in a patient with active atopic dermatitis), cumulative ICD can develop. The properties of the irritating substance (e.g. pH, solubility, detergent action, physical state) are also important. In contrast to acute ICD, the lesions of chronic ICD are less sharply demarcated. Pruritus and pain due to fissures of hyperkeratotic skin are symptoms of chronic ICD. Signs may include xerosis, erythema and vesicles, but lichenification and hyperkeratosis predominate.

CLINICAL FEATURES SUGGESTING AN IRRITANT OR TOXIC ETIOLOGY

Clinical feature	Possible irritant or toxin
Ulcerations	Inorganic acids (chromic, hydrofluoric, nitric, hydrochloric, sulfuric) Strong alkalis (calcium oxide, sodium hydroxide, potassium hydroxide, ammonium hydroxide, calcium hydroxide, sodium metasilicate, sodium silicate, potassium cyanide, trisodium phosphate, sodium carbonate, potassium carbonate) Salts (arsenic trioxide, dichromates) Solvents (acrylonitrile, carbon bisulfide) Gases (ethylene oxide, acrylonitrile)
Folliculitis	Arsenic trioxide Glass fibers Oils and greases Tar Asphalt Chlorinated naphthalenes Polyhalogenated biphenyls
Miliaria	Occlusive clothing and overheating Adhesive tape Ultraviolet radiation Infrared radiation Aluminum chloride
Pigmentary changes	
• Hyperpigmentation	Any irritant or allergen, especially phototoxic agents such as psoralens, tar, asphalt, psoralen-containing plants Metals, such as inorganic arsenic (systemically), silver, gold, bismuth, mercury Radiation: ultraviolet, infrared, microwave, ionizing
• Hypopigmentation	*p*-Tert-amylphenol *p*-Tert-butylphenol Hydroquinone Monobenzyl ether of hydroquinone Monomethyl ether of hydroquinone *p*-Tert-catechol *p*-Cresol 3-Hydroxyanisole Butylated hydroxyanisole 1-Tert-butyl-3, 4-catechol 1-Isopropyl-3, 4-catechol 4-Hydroxypropriophenone
Alopecia	Borax Chloroprene dimers
Urticaria	Animals (arthropods, caterpillars, corals, jellyfish, moths, sea anemones) Balsam of Peru Cosmetics (e.g. sorbic acid) Drugs (alcohol [ethanol], benzocaine, camphor, capsaicin, chloroform, iodine, methyl salicylate, resorcinol, tar extracts) Foods (cayenne pepper, fish, mustard, thyme) Fragrances and flavoring agents (cinnamon oil, cinnamic acid and aldehyde, benzaldehyde) Metals (cobalt) Plants (seaweed, stinging nettles), woods Preservatives (benzoic acid) Textiles (e.g. blue dyes)

Table 15.3 Clinical features suggesting an irritant or toxic etiology.

Asteatotic Dermatitis

Asteatotic dermatitis, also referred to as asteatotic eczema or exsiccation eczematid ICD, is a special variant seen primarily during the dry winter months. Elderly individuals who frequently bathe without remoisturizing are at particular risk of developing asteatotic dermatitis. Intense pruritus is common, with the skin appearing dry with ichthyosiform scale and characteristic patches of superficially cracked skin termed "eczema craquelé" (see Ch. 13).

Traumatic Irritant Contact Dermatitis

Traumatic ICD may develop after acute skin trauma, such as from burns, lacerations or acute ICD. Patients should be asked whether they have cleansed the skin with strong soaps or detergents. It is characterized by eczematous lesions, most commonly on the hands, that last for weeks to months with persistent redness, infiltration, scale and fissuring in the affected areas.

Pustular and Acneiform Irritant Contact Dermatitis

Pustular and acneiform ICD results from exposure to certain irritants, such as metals, croton oil, mineral oils, tars, greases, cutting and metal working fluids, and naphthalenes (see Table 15.3 and Ch. 16). This syndrome should be considered in conditions in which folliculitis or acneiform lesions develop in settings outside of typical acne, particularly in patients with atopic dermatitis, seborrheic dermatitis or prior acne vulgaris. The pustules are sterile and transient. Miliarial reactions, which may become pustular, can develop in response to occlusive clothing, adhesive tape, or ultraviolet and infrared radiation.

Non-erythematous Irritant Contact Dermatitis

Non-erythematous ICD may be defined as a subclinical form of ICD with early stages of skin irritation seen as changes in the stratum corneum barrier function without a clinical correlate.

Subjective or Sensory Irritant Contact Dermatitis

Subjective or sensory ICD is characterized by reports of a stinging or burning in the absence of visible cutaneous signs of irritation. Irritants capable of eliciting this reaction include propylene glycol, hydroxy acids, ethanol, and topical medications such as lactic acid, azelaic acid, benzoic acid, benzoyl peroxide, mequinol and tretinoin. Sorbic acid, a preservative in concentrations of up to 0.2% in foods, cosmetics and drugs, may also produce sensory irritation in predisposed individuals. This reaction to irritants such as lactic or sorbic acid may be reliably reproduced with dose responsiveness in double-blinded exposure tests.

Airborne Irritant Contact Dermatitis

Airborne ICD develops in irritant-exposed sensitive skin of the face and periorbital regions. While this often simulates photoallergic reactions, involvement of the upper eyelids, philtrum and submental regions in patients with airborne ICD may aid in distinguishing between these two entities.

Frictional Irritant Contact Dermatitis

Frictional ICD is a distinct ICD subtype resulting from repeated low-grade frictional trauma. It is often acknowledged to also play an adjuvant role in allergic contact dermatitis and ICD. The frictional response involves hyperkeratosis, acanthosis and lichenification, often progressing to hardening, thickening and increased toughness.

Contact Urticaria

Contact urticaria is divided into non-immunologic and immunologic subtypes (see Ch. 16), with the former occurring more frequently and in the absence of previous exposure. Irritants that can produce *immunologic* contact urticaria include parabens (preservatives), henna, ammonium persulfate (oxidizing agent), and latex. *Non-immunologic* contact urticaria can be caused by a number of exposures, from caterpillars and jellyfish to stinging nettles and foods (see Table 15.3)[21]. Risk factors include atopy, hand dermatitis, previous mucosal exposure to latex (e.g. urinary catheterization), and allergies to fruits (e.g. kiwi, avocado, banana, melon; see Table 16.6).

PATHOLOGY

The histologic features of ICD vary, but often include mild spongiosis, necrosis of epidermal keratinocytes, and an inflammatory infiltrate. The combination of an upper dermal perivascular infiltrate of lymphocytes with minimal extension of inflammatory cells into the overlying epidermis and widely scattered necrotic keratinocytes is most typical. True features of interface dermatitis are absent, and spongiosis should be focal or absent. Over time, additional histologic findings include acanthosis with mild hypergranulosis and hyperkeratosis. In aggregate, these elements are not specific, and they cannot be confidently differentiated from either chronic allergic contact dermatitis or other types of chronic eczematous dermatoses.

Classification of Irritant Chemicals

Acids

A variety of both inorganic and organic acids can be corrosive to the skin. Acids cause epidermal damage via protein denaturation and cytotoxicity. Principally, all strong acids give the same symptoms and major features, including erythema, vesication and necrosis.

Inorganic acids are commonly used in industry, especially hydrofluoric, sulfuric, hydrochloric, chromic, nitric and phosphoric acids (Table 15.4). Hydrofluoric acid and sulfuric acid cause the most severe burns, even at low concentrations[24,25].

In general, the organic acids tend to be less irritating. Among the organic acids, acetic, acrylic, formic, glycolic, benzoic and salicylic acids are the most common irritants, particularly after prolonged exposure. The uses and properties of *acrylic acid* and *formic acid* are outlined in Table 15.4. *Acetic acid* is a constituent of vinegar, flavoring agents and astringent mouthwashes, whereas *glycolic*, *benzoic* and *salicylic acids* are mild irritants whose properties can be harnessed for therapeutic and cosmetic purposes, when used in low concentrations.

Alkalis

Alkalis or bases often cause more painful and severe damage than most acids, with the exception of hydrofluoric acid. There are generally no vesicles, but rather necrotic skin that first appears dark brown, then black, and ultimately becomes hard, dry and cracked. Alkalis disrupt barrier lipids and denature proteins with subsequent fatty acid saponification, thus subjecting the cell to edema and resultant cytotoxicity. The emulsifying effect of soaps formed in the process facilitates the further penetration of the alkali into the deeper layers of the skin. Strong alkalis include sodium, ammonium, calcium and potassium hydroxide; sodium and potassium carbonate; and calcium oxide, used primarily in the manufacture of bleaches, dyes, vitamins, pulp, paper, plastics, and soaps and detergents[26,27]. Calcium hydroxide is liberated from wet cement, which has an initial pH of 10–12 that rises to 12–14 as the cement sets (see Table 15.4).

Metal salts

A wide variety of metal salts can cause irritation, ranging from folliculitis and pigmentary changes to ulceration (see Table 15.4).

Solvents

A wide variety of solvents are used daily in processes such as chemical reactions, hydraulic systems, metal refining, dry cleaning and metal degreasing. Nearly all of them are primary irritants to varying degrees (see Table 15.4), with only a few, such as turpentine, also being able to elicit allergic sensitization. Solvents act mainly by dissolving the intercellular lipid barrier of the epidermis, thereby increasing percutaneous penetration. Prolonged skin contact can result in severe burns as well as systemic symptoms and even death, making early recognition of skin manifestations important in the prevention of systemic toxicity. After repeated exposure, the hands, and occasionally the hands and face, develop erythema, scaling and dryness, eventually evolving into eczema (Fig. 15.2). The irritating capacity of organic solvents, attributed mainly

IRRITANT CHEMICALS: USES, PROPERTIES AND SIDE EFFECTS		
Compound	**Uses/Exposures**	**Properties and side effects**
	INORGANIC ACIDS	
Chromic acid	• Metal treatments (chrome plating, copper stripping and aluminum anodizing)	• Ulcerations known as "chrome holes" • Nasal septal perforation
Hydrochloric acid	• Production of fertilizers, dyes, paints and soaps • Electroplating, oil refining and food processing	• Erythema, vesication and necrosis
Hydrofluoric acid	• Semiconductor industry (etching glass, metal and stone; can dissolve silicon) • Household and commercial rust, stain and lime-scale removers	• Extremely cytotoxic agent that can lead to severe tissue damage • Penetrates intact skin due to its limited dissociation constant • Painful penetration may continue for days after exposure • With low concentrations, the onset of symptoms may be delayed for up to a day • Intense pain is due to the capacity of fluoride ions to bind tissue calcium, thereby affecting nerve conduction • Hypomagnesemia and a fluoride-mediated increase in pulmonary vascular resistance may also play a role in toxicity
Nitric acid	• Production of fertilizers and explosives; metal etching and cleaning • Fuming nitric acid – a chemical intermediate used in rocket fuels and as a laboratory reagent	• Chemical burns • Irritant contact dermatitis • Distinctive yellow discoloration • Fuming nitric acid – highly corrosive
Phosphoric acid	• Phosphate fertilizer, pharmaceuticals, water treatment, animal feeds, soaps and detergents, and cotton dyeing	• Erythema, vesication and necrosis
Sulfuric acid	• Manufacture of fertilizers, inorganic pigments, textile fibers, explosives, pulp and paper • Occupational risk: jewelers, electroplaters, metal cleaners and storage battery makers	• Erythema, vesication and necrosis
	ORGANIC ACIDS	
Acrylic acid	• Monomer for acrylic plastics, synthetic resins, dentures, artificial nails, adhesives and paints	• Highly irritating and corrosive • Capable of penetrating rubber gloves • Also allergic contact dermatitis
Formic acid	• Neutralizer in leather manufacture, an antiseptic in brewing, and a coagulant in the production of natural latex	• Greatest corrosive potential of the organic acids
	ALKALIS	
Cement (mixed with water)	• Construction	• Acute ulcerative damage as a result of the high alkalinity of wet cement (due to liberation of calcium hydroxide) • Necrotic skin changes appear 8–12 hours after exposure • Chronic irritant cement dermatitis – develops over months to years from continued exposure; can accompany allergic contact dermatitis to chromium • Most common locations – lower limbs (kneeling, contaminated footwear), hands (glove contamination)
	METAL SALTS	
Arsenic compounds (including arsenic trioxide)	• Aerosolized during the smelting of copper, gold, lead and other metals • Manufacture of pesticides and herbicides • Semiconductor industry and smelting operations	• Persistent folliculitis • Potential for systemic toxicity (see Ch. 88)
Beryllium	• Production of hard, corrosion-resistant alloys	• Ulcerated granulomatous skin lesions (local reaction; see Ch. 94) • Sarcoidosis-like granulomas of the skin and lung (systemic reaction)
Calcium oxide (quicklime)	• Manufacture of pulp, steel and paper	• Releases heat on contact with water, causing painful cutaneous ulcerations
Cobalt salts	• Alloys, ceramics, electroplating, electronics, magnets, paints, varnishes and hair dyes	• Irritant and allergic contact dermatitis
Copper salts (e.g. sulfates, oxides and cyanides)	• Used as a biostatic surface and in wood preservatives and fungicides	• Impart a greenish-black color to hair, skin and teeth if persistent exposure to dust forms • Inhalation of copper oxides (as well as magnesium and zinc oxides) can cause metal fume fever, a brief influenza-like illness usually associated with welding operations

Table 15.4 Irritant chemicals: uses, properties and side effects. Glycols/alcohols and detergents/cleansers are discussed in the text.

Continued

IRRITANT CHEMICALS: USES, PROPERTIES AND SIDE EFFECTS		
Compound	**Uses/Exposures**	**Properties and side effects**
Mercury, inorganic	• Products containing inorganic mercury have been banned since 1990; limited exposure possible from old cans of latex paint	• Bluish linear pigmentation of the tongue and gums, which may serve as a marker for systemic mercury poisoning
Mercury, organic	• Phenyl mercury salts are used as preservatives in cosmetics and vaccines, as fungicides, herbicides and pesticides in agriculture, and in dental restorative materials	• Although once used as skin disinfectants, both irritant and allergic contact dermatitis have restricted use • Positive patch tests to mercury (as well as other metals such as gold) observed in patients with oral lichenoid reactions to dental materials (see Ch. 11) • Mercury within the amalgam may act as an irritant via a Koebner phenomenon
Selenium compounds (including sulfide)	• Therapeutic shampoo (selenium sulfide)	• Skin irritation, conjunctivitis
Thimerosal	• Topical medicaments, vaccines, cosmetics	• Common cause of both allergic and irritant patch-test reactions[22,23]
	SOLVENTS	
Benzene	• Manufacture of polymers, plastics, resins, adhesives, rubber, lubricants, dyes, detergents, drugs, explosives and pesticides	• Petechial eruption of the trunk, extremities and mucous membranes • Petechiae considered to be a marker for aplastic anemia
Chlorinated hydrocarbons (e.g. carbon tetrachloride, trichloroethylene, tetrachloroethane, methylene chloride, ethylene chloride)	• Production of vinyl chloride, which is then converted to polyvinyl chloride • Pesticides • Dry cleaning	• Cutaneous irritation • Systemic effects: liver and kidney damage, CNS depression, and carcinogenesis • Methylene chloride can hydrolyze to form hydrochloric acid, thus leading to significant cutaneous irritation (see above) • "Degreaser's flush" – sudden erythema in extensive areas of the face, neck and shoulders; caused by alcohol ingestion shortly before or during inhalation of trichloroethylene
Coal tar derivatives (e.g. toluene, xylene, ethyl benzene, cumene)	• Medications • Solvents	• Skin drying and defatting • Exposure solely to vapors can cause xerosis
Petrochemicals (e.g. gasoline, hexane, kerosene, Stoddard solvent)	• Fuels • Insecticides • Dry cleaning • Hexanes – gasoline, glues and for extraction of cooking oils from seeds	• Irritant contact dermatitis • Absorption of hexane via inhalation or percutaneously can also cause paresthesias, hypoesthesia and motor weakness
	DISINFECTANTS	
Aldehydes (e.g. formaldehyde, glutaraldehyde, hexa-methylenetetramine)	• Adhesives, resins • Disinfectants, biocides • Tissue fixative, embalming agent	• More irritating than alcohols • Formaldehyde – high chemical reactivity with proteins; both allergen and irritant, even at low concentrations
Ethylene oxide	• Sterilization of medical equipment	• Oxidizing agent • Severe chemical burns
Halogens – Chlorines	• Disinfectants, including wounds* • Bleach (sodium hypochlorite)	• Denature proteins via deaminating or chlorinating amino acids • Oxidizing agent (sodium hypochlorite) • Acute skin and mucosal irritant reactions, particularly at high temperatures
Halogens – Iodines	• Broad-spectrum antimicrobial and sporicidal agents • Surgical scrub, shampoo and skin cleanser (povidone-iodine in a surfactant base)	• Inhibit DNA, RNA and protein synthesis • Irritant contact dermatitis • Contact urticaria
Phenolic compounds (e.g. Lysol® [cresol and soap solution], pentachlorophenol, chloroxylenol)	• Disinfectants • Preservative in over-the-counter products (baby powders, shampoos), especially chloroxylenol	• Irritant contact dermatitis • Chemical leukoderma (amyl- and butyl-phenol compounds; see Table 15.3)
Quaternary ammonium salts (e.g. benzalkonium chloride)	• Cosmetics, medications (e.g. ophthalmic solutions) • Antiseptics (e.g. cleaning surgical instruments) • Detergent	• Cationic surfactants that can precipitate or denature proteins and destroy microorganisms • Local skin irritation depends on the solution concentration • Benzalkonium chloride – irritant reactions frequent during patch testing (concentration, 0.1%); can also be an allergen (e.g. healthcare workers, leg ulcer patients) so clinical correlation required
*Dakin's solution contains sodium hypochlorite and EUSOL (Edinburgh solution of lime) contains chlorinated lime and boric acid.		

Table 15.4 Irritant chemicals: uses, properties and side effects (cont'd). Glycols/alcohols and detergents/cleansers are discussed in the text.

Fig. 15.2 Bilateral irritant contact dermatitis of the palms secondary to repeated contact with paint solvents. Extensive patch testing excluded allergic contact dermatitis in this professional paint and crayon illustrator. *Courtesy, Kalman Watsky, MD.*

Fig. 15.3 Moderately severe irritant contact dermatitis of the hands due to chronic exposure to disinfecting solutions and antiseptics. The results of patch testing, latex challenge testing, and RAST testing were negative in this practicing dentist.

to their lipophilicity, follows the order: aromatic > aliphatic > chlorinated > turpentine > alcohols > esters > ketones[28].

Alcohols/Glycols

Alcohols are used widely as solvents, disinfectants, preservatives in cosmetics, and penetration enhancers in drug delivery systems. Most have only mild irritating effects, with irritancy decreasing (and bactericidal activity increasing) as the molecular weight and length of the carbon side chain increases[29]. Alcohols are the safest known topical antiseptic compounds, providing bactericidal activity against most Gram-positive and Gram-negative bacteria as well as many fungi and viruses. Most appropriate for this use are diluted solutions of ethyl alcohol, propyl alcohol and isopropyl alcohol, which act by means of protein denaturation. In cosmetics, alcohol is used as a preservative to prevent microbial contamination and to decrease viscosity. The principal mechanism by which alcohols enhance percutaneous absorption is hypothesized to be the extraction of intercellular lipids from the stratum corneum[30,31].

Glycols, or diols, such as ethylene glycol and propylene glycol, are aliphatic alcohols commonly used in cosmetic products as solvents, emulsifiers, humectants or keratolytics. Propylene glycol can produce both allergic and irritant contact dermatitis and sources of exposure include personal care products, topical corticosteroids and other topical medications[32]. Of note, propylene glycol is typically used in cosmetics in concentrations less than 50%[33].

Detergents and cleansers

A detergent includes almost any surface-active agent (surfactant) that concentrates at oil–water interfaces and holds both cleansing and emulsifying properties. Detergents most commonly cause chronic forms of ICD and are present in skin cleansers, cosmetics and household cleaning products. With normal use, ICD is rare from skin cleansers, the exception being in individuals with susceptible skin. Detergents' cleansing actions are derived from their ability to lower the surface tension between two non-mixable phases due to their hydrophilic (polar head) and lipophilic (apolar tail) components. Skin toxicity arises from their damaging influence on the stratum corneum, which impairs barrier function. Surfactants concomitantly bind to keratin and cause protein denaturation. When the stratum corneum is disrupted, detergents can damage viable epidermis and papillary dermal structures.

Irritancy from detergents is best evaluated by measuring transepidermal water loss since the latter represents the surrogate measurable change indicative of irritancy damage with this group of chemicals. As a group, anionic detergents such as alkyl sulfates and alkyl carboxylate salts (soap) are more irritating than are non-ionic and amphoteric groups. Greater length of the carbon chain also correlates with increased irritant potential. Sodium lauryl sulfate is often used as a reference irritant in studies because of its consistent, non-allergic, rapid toxic response. Amphoteric surfactants such as *cocamidopropyl betaine* – which are used in therapeutic formulations, personal care products and cosmetics – have the lowest irritation potential[34,35].

Cocamide DEA (diethanolamine) is a non-ionic, biodegradable surfactant that is used as a viscosity booster, stabilizer and foam booster. It is found in hand soaps, liquid shampoos, detergents and dishwashing liquids. Cocamide DEA is one of the more irritating surfactants[36], and it is commonly involved in occupation-related contact dermatitis in North American healthcare workers[37]. *Cocamide MEA* (monoethanolamine) is also a surfactant that is used as a foaming or emulsifying agent and is derived from fatty acids present in coconut oils that have been reacted with ethanolamine. Cocamide MEA at a concentration of 50% was found to be non-irritating to mildly irritating in animal tests, in contrast to cocamide DEA 30% which produced moderate irritation. Cocamide MEA can be used in a concentration of up to 10% in leave-on products[38]. Skin cleansers may be solid or liquid, based on soap and/or synthetic detergents, and may contain solvents or abrasives, depending on use requirements (see Ch. 153). Although the primary factor that determines skin irritancy is the detergent component, skin tolerance cannot be adequately predicted from the composition of products alone. Such an assessment is largely left to trial and error.

Disinfectants

Most disinfectants used to destroy pathogens in the environment act as weak toxic agents and cause chronic ICD as a result of cumulative doses of subclinical irritancy (Fig. 15.3). Various compounds may be used, such as alcohols (see above), aldehydes, phenolic compounds, halogenated compounds and quaternary ammonium salts (see Table 15.4), in addition to dyes, oxidizing agents and mercury compounds[39–42].

Dyes of the triphenylmethane family are also extensively used as topical antiseptics; they are capable of producing phototoxic dermatitis but uncommonly cause irritant reactions. Benzoyl peroxide is a common *oxidizing agent* used as an anti-acne antimicrobial topical medication that is capable of causing mild irritation. Most *mercury* compounds are skin irritants by way of precipitation of proteins, but have fallen into disuse as a result of hazards of systemic toxicity.

Plastics

Plastics are synthetic macromolecular end products consisting of large polymers formed by the linkage of small monomers into large chain-like units. A large number of plastic resins are commercially important and they can be divided into three categories:

- thermoplastics – polyacrylates, polyethylene, polystyrene, polyvinyl chloride and saturated polyesters

- thermosettings – epoxy resins, phenol–formaldehyde resins, and polyurethanes
- elastomers – synthetic rubbers.

Skin damage is almost exclusively attributable to the monomer ingredients, hardeners, and other additives such as stabilizers. The final hardened plastic product is generally considered inert and non-hazardous to the skin, but residual non-polymerized monomers may be the offending agents. Both irritant and allergic contact dermatitis are common, and they may only be differentiated by patch testing[43].

Food

Food and food additives often contain compounds that elicit contact sensitivity and irritation, particularly in those working in agriculture, fishing, catering, and food processing industries. Most of the work in these sectors is done without gloves under damp working conditions with frequent hand washing – factors further aggravating skin irritation. Mechanical, thermal and climatic factors also contribute. A large majority of exposed persons in food handling and fishing professions may be affected by chronic irritant hand dermatitis[44]. Slight irritant skin changes are often accepted as "normal" for the patient's occupation and medical advice is often not sought.

Examples of foods that can lead to ICD include pineapples, which contain the proteolytic enzyme bromelain (bromelin; see Ch. 17), and garlic, which contains allicin and diallyl disulfide. Mustard, horseradish, cabbage, broccoli, cauliflower, brussels sprouts and radish contain allyl isothiocyanate, and the latter can cause ICD after exposure to water.

Foods can also lead to contact urticaria (see Table 15.3) and protein contact dermatitis; both of these entities are discussed in detail in Chapter 16.

Water

Water, the universal solvent, is a particularly ubiquitous skin irritant. Wet workers such as hairdressers, hospital cleaners, cannery workers, and bartenders have an increased incidence of hand eczema. Several mechanisms such as osmolarity, pH, hardness and temperature might account for the irritancy of water. Stratum corneum hydration may facilitate penetration of polar and non-polar substances via connections in the lacunar network (see Ch. 124) as well as support the overgrowth of pathogenic organisms. The irritancy of water is often exacerbated by occlusion, as it changes the barrier properties of the stratum corneum and may activate Langerhans cells and trigger cytokine production[45].

Bodily fluids

Urine, feces (especially in the setting of diarrhea) and saliva can lead to ICD. In babies, irritant diaper dermatitis is a common problem and is often characterized by glazed erythema of convex surfaces and at the diaper margins, with sparing of the skin folds; edema, scaling and superficial erosions may be observed (see Fig. 13.12). Incontinence can lead to similar problems in the elderly[46].

Children, more so than adults, develop the habit of lip licking. In these patients, irritant dermatitis may involve the perioral skin as well as the lips (Fig. 15.4). In a series of 75 patients with cheilitis who were referred for patch testing, ICD was the most common cause of cheilitis (Table 15.5)[47,48]. Figure 15.5 outlines the clinical approach to a patient with cheilitis. Periurethral ICD may be seen in patients with bladder-drained pancreatic allografts and in those receiving foscarnet.

DIFFERENTIAL DIAGNOSIS

Despite their different pathogeneses, allergic and irritant contact dermatitis, especially of the chronic type, show a remarkable similarity with respect to clinical appearance, histology and immunohistology. Clinically, the reactions often look identical, with erythema, plaques, xerosis, scaling and lichenification locally distributed and sharp borders delineating the areas of contact. In the clinical setting, the substance in question is often unknown, as is the concentration and duration of exposure. As a result, the diagnosis of ICD has remained a diagnosis of exclusion – when the dermatitis cannot be explained by a positive patch test to a known allergen. Another helpful, but not conclusive, clinical feature is the more frequent complaint of burning and stinging with ICD, in contrast to pruritus in areas of allergic contact dermatitis (Fig. 15.6).

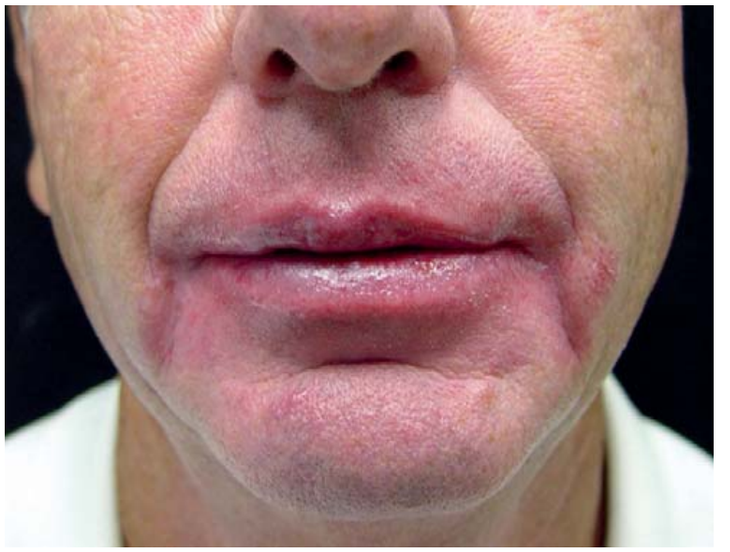

Fig. 15.4 Cheilitis due to irritant contact dermatitis. This patient had the habit of licking his lips and there is involvement of the vermilion and cutaneous lips as well as the perioral region. *Courtesy, Jeffrey P Callen, MD.*

CAUSES OF CHEILITIS IN PATIENTS REFERRED FOR PATCH TESTING	
Irritant contact dermatitis Most frequent cause: lip licking	36%
Allergic contact dermatitis Most common allergens [% of patients in a second series]*: fragrance mix, 30%; *Myroxilon pereirae* (balsam of Peru), 23%; nickel, 22%; gold, 13%; neomycin, 12%; cobalt, 10%; propylene glycol, 8%; lanolin, 7%; cinnamic aldehyde, 7%; bacitracin, 5%; benzophenone, 5%; methyldibromoglutaronitrile/ phenoxyethanol, 5%; tea tree oil, 5%; budesonide, 5%	25%
Atopic dermatitis	19%
Eczema (cause unknown)	9%
Non-eczematous causes (angioedema, photosensitivity, psoriasis, erosive candidal cheilitis, functional)	9%
Seborrheic dermatitis	1%
*See ref. 48.	

Table 15.5 Causes of cheilitis in patients who were referred for patch testing (n = 75). Adapted from ref. 47.

PROGNOSIS

In many individuals, ICD resolves spontaneously even with continuous exposure, a process referred to as "accommodation" or "hardening"[49]. The exact mechanisms are still unclear, but the following changes have been observed after repetitive cutaneous exposure to irritants:

- improvement of the physical barrier via formation of a thicker stratum corneum and a thicker stratum granulosum and increased production of ceramide 1
- increased skin permeability to irritants and changes in vascular reactivity that allow faster removal of irritants
- immunologic alterations that favor an anti-inflammatory response to irritants, e.g. increased ratio of IL-1RA (an anti-inflammatory cytokine) to IL-1α (a proinflammatory cytokine)
- a systemic hyporeactive state following repetitive exposure to low-dose irritants[49].

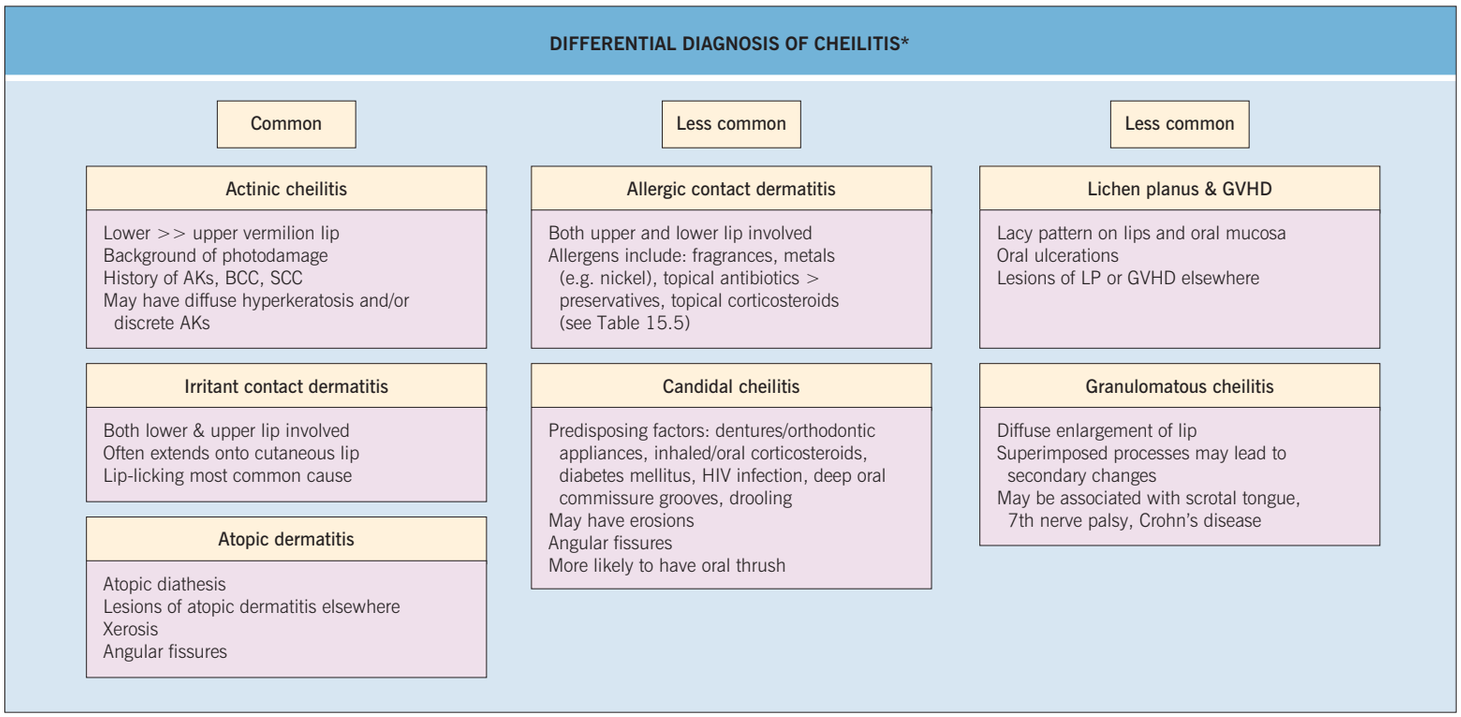

Fig. 15.5 Differential diagnosis of cheilitis. Uncommon causes include cheilitis glandularis, actinic prurigo, lichen sclerosus, and nutritional deficiencies. *Often a combination, e.g. atopic dermatitis plus irritant contact dermatitis. AKs, actinic keratoses; BCC, basal cell carcinoma; GVHD, graft-versus-host disease; LP, lichen planus; SCC, squamous cell carcinoma. *Courtesy, Jean L Bolognia, MD.*

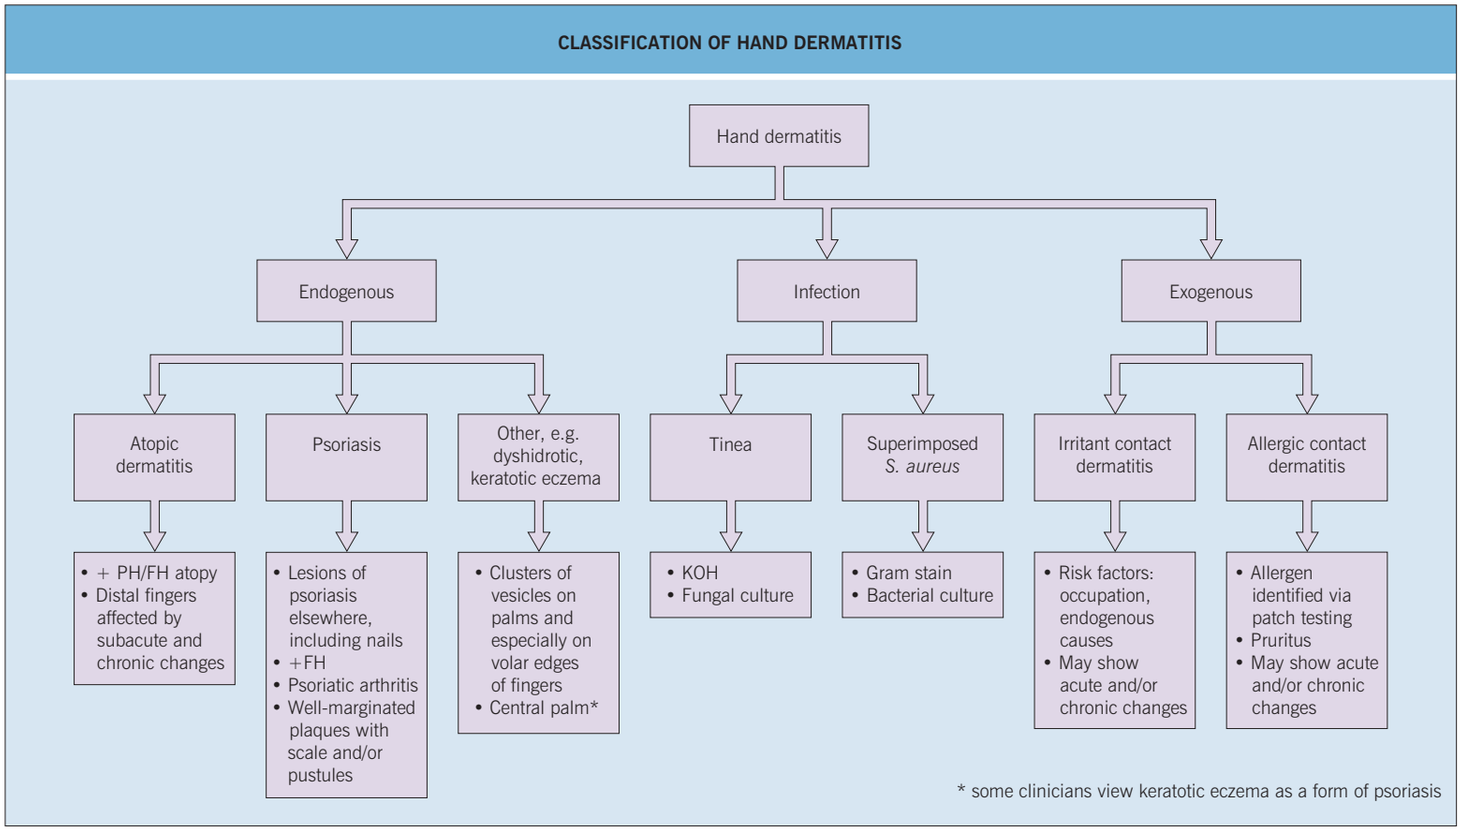

Fig. 15.6 Classification of hand dermatitis. More than one etiology may be present, e.g. atopic dermatitis plus irritant contact dermatitis. For further details, see reference 48a. FH, family history; PH, personal history.

The time required for "accommodating" to the aggravating stimulus varies amongst individuals, and for some individuals, ICD can be a chronic and devastating problem. Poor prognosis is related to a previous history of atopy, female gender, and the presence of allergic contact dermatitis (as well as ICD). Factors that can potentially improve prognosis are early diagnosis, treatment, and patient knowledge about the disease[50].

TREATMENT

Avoidance of causative irritants in the home or the workplace is the primary treatment for ICD. Strategies in the prevention of ICD include the identification of irritants with appropriate substitution, the establishment of engineering controls to reduce exposure, the utilization of personal protective equipment such as gloves and special clothing, and barriers such as ointments, emollients or creams. Other preventive strategies include emphasizing personal and occupational hygiene, establishing educational programs to increase awareness in the workplace, and providing health monitoring.

In the workplace, by far the most effective measure to reduce the incidence of contact dermatitis is technical avoidance. This can be accomplished via shielding and personal protection of the workers and limiting the use of potent irritants to closed or automated systems. Preventive skin care at the workplace incorporates pre-exposure protection by application of protective creams to intact skin, removal of irritants by mild cleaning agents, and enhancement of barrier function generation by emollients or moisturizers[51]. Non-irritating fatty substances such as petrolatum preclude hydrophilic chemical penetration and restore barrier function. The efficacy of barrier creams for skin protection (as compared to bland emollients) remains a topic of debate[52]. In a randomized controlled trial, both barrier creams and moisturizing vehicles were found to positively influence skin status and hydration without significant differences in efficacy[53]. Newer moisturizers containing ceramides can also improve barrier function, but further trials are necessary to ascertain their efficacy[54,55]. Lastly, while new bioengineering techniques have been proposed for the assessment of individual irritant sensitivity, their value in predicting occupational ICD, especially of the cumulative type, remains unclear.

The establishment of appropriate educational prevention programs is essential. A project in Finland showed a significantly better outcome for employees with occupational hand dermatitis attending an "eczema school"-like clinic run by a specialized nurse compared with an unschooled control group[56]. Another study found that most occupational skin diseases responded to effective secondary preventive measures, combining employee medical treatment and exposure analysis-based individual and group training in preventive measures[57]. Education was important in making the employees aware of initial skin changes, such as slight erythema and scaling in the interdigital folds, indicating the need to optimize skin protection and care measures in order to prevent exacerbation and chronicity.

The goal of treatment is to restore normal epidermal barrier function. Topical corticosteroids are frequently used, but their efficacy has been controversial, as experimental studies have provided conflicting results[58]. In one double-blind, vehicle-controlled study, statistically lower values of erythema and transepidermal water loss were observed in sites irritated by sodium lauryl sulfate after 7 days of treatment with betamethasone valerate[59]. Systemic corticosteroids, although potentially helpful in reducing acute inflammation, are not useful in the treatment of chronic ICD unless corrective measures are taken to avoid the offending contactants. Photochemotherapy (PUVA) or narrowband ultraviolet B irradiation may be considered for chronic dermatitis that does not respond to any other form of therapy. Hyperkeratotic palmoplantar dermatitis from frictional or chronic ICD or a combination of dermatitis and psoriasis may benefit from the adjunctive use of systemic retinoids such as acitretin and alitretinoin or systemic immunomodulators such as methotrexate, cyclosporine and possibly targeted (biologic) therapy[60].

Occupational Dermatoses 16

S Mark Wilkinson

INTRODUCTION

Occupational dermatoses[1] comprise any skin disease in which occupational exposure is a major causal or contributory factor. In all the diverse occupations that people pursue, there are thousands of chemicals and other potentially noxious insults which can impinge on the skin. These may harm the skin in many different ways and induce pathologic processes. When this occurs via occupational exposure, they are referred to as "occupational dermatoses". Traditionally, the types of hazardous exposure are categorized as:

- mechanical – friction, pressure, vibration, mechanical disruption
- chemical – elements and chemical compounds (organic, inorganic and proteins)
- physical – heat, cold, radiation (UV and ionizing)
- biological – organisms including viruses, bacteria, fungi and parasites.

The types of dermatoses induced by exposure to these noxious occupational hazards can be grouped as outlined in Table 16.1.

This chapter differs from many of the others in that it deals with diverse conditions, many of which are also covered in detail in specific chapters.

CLINICAL CLASSIFICATION OF OCCUPATIONAL DERMATOSES
CONTACT DERMATITIS
• Irritant chemically induced photoinduced mechanical • Allergic
CHEMICAL BURN
CONTACT URTICARIA
CANCER
• Sunlight/UV-induced • Ionizing radiation-induced • Chemically induced
FOLLICULAR DISEASE
• Acne • Folliculitis • Chloracne
AUTOIMMUNE CONNECTIVE TISSUE DISEASE
• Systemic sclerosis (silica; see Ch. 43) • Scleroderma-like (vinyl chloride, organic solvents; see Ch. 43) • Vibration-induced
PIGMENTARY DISORDERS
• Hypopigmentation (see Ch. 66) • Hyperpigmentation (see Ch. 67)
FOREIGN BODY REACTIONS (see Ch. 94)
INFECTION
• Viral • Bacterial • Fungal • Parasitic

Table 16.1 Clinical classification of occupational dermatoses.

In a UK household survey, a rate of occupational dermatosis of 15/10 000 population for those who had ever been employed demonstrates the high frequency of affected individuals and compares with 5.1/10 000 reported by physicians in Denmark and Finland, where occupational disease is notifiable. After musculoskeletal disorders (45%), skin diseases (23%) are the most common cause of medical illness. In the US in 1985 it was estimated that the annual cost of occupational skin disease due to lost productivity, medical care and disability payments was between $222 million and $1 billion[2]. In the 1990s, the average cost per claim for occupational dermatitis was US$3550 and the period of disability 24 days[3].

HISTORY

Occupational disease has existed for a long time. For example, on their long-distance voyages in the sixteenth century, Drake and Magellan experienced significant problems from scurvy due to the lack of vitamin C from fresh fruit and vegetables. However, one of the first written descriptions of occupational dermatoses was by the Italian Bernardino Ramazzii (1633–1714). He described diseases associated with a variety of occupations, including the different characteristics of ulceration in fresh- and salt-water fishermen. In 1747, James Lind performed the first controlled trial to show the protective effects of citrus fruits against scurvy. In 1795, the British Navy included lemon juice in ships' stores as one of the earliest forms of prevention for an occupational skin disease.

EPIDEMIOLOGY

The reported distribution of occupational skin disease varies with the specialty of the physician[4] (Fig. 16.1). The difference in the incidence of neoplasia as reported by dermatologists and occupational physicians reflects the delay between exposure and development of disease as well as the fact that the majority of workers have left employment when the cancer develops. Differences between occupations in terms of reporting disease also reflect the distribution of occupational health departments in industry: vehicle assembly, glass and ceramic workers, and scientific technicians were often seen by occupational physicians, whereas hairdressers, for example, were seen primarily by dermatologists.

THE OCCUPATIONAL DERMATOSES

Contact Dermatitis

Synonym: ■ Contact eczema

Key features

- Pruritus, vesicles, erythema and scale
- Develops within hours to days of exposure and persists for weeks, sometimes longer
- The most common causes of occupational *allergic* contact dermatitis are (in order of decreasing frequency): rubber, nickel, epoxy and other resins, and aromatic amines
- The most common causes of occupational *irritant* contact dermatitis are (in order of decreasing frequency): soaps, wet work, petroleum products, and cutting oils and coolants

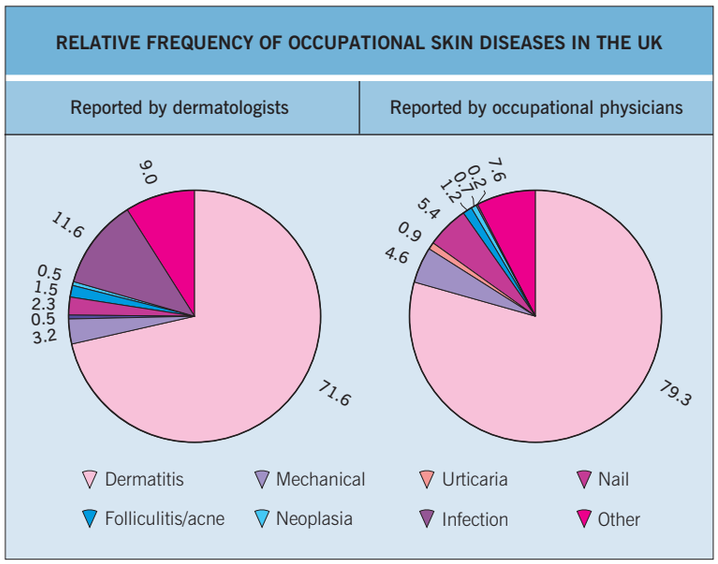

Fig. 16.1 Relative frequency of occupational skin diseases in the UK[1].

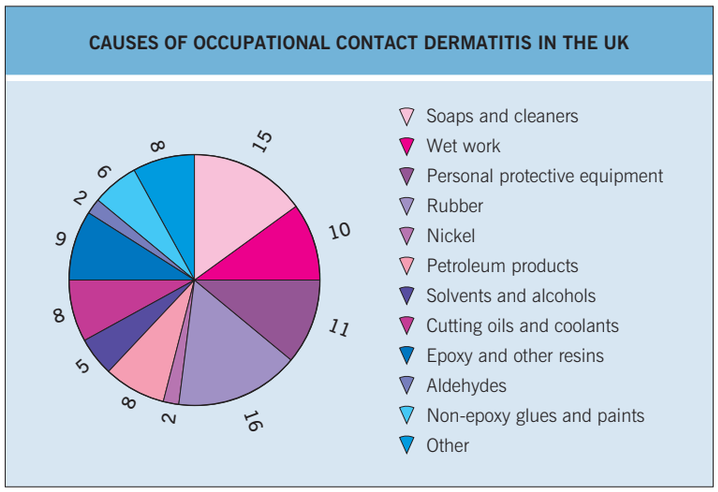

Fig. 16.2 Causes of occupational contact dermatitis in the UK. Materials identified by occupational physicians.

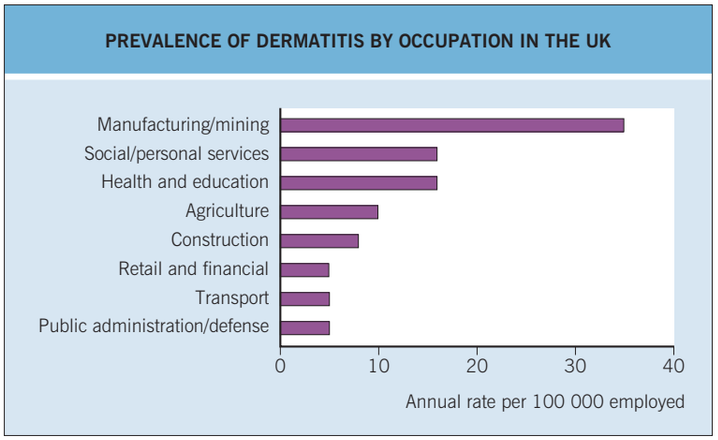

Fig. 16.3 Prevalence of dermatitis by occupation in the UK (annual rate per 100 000 employed)[2].

Introduction

Contact dermatitis accounts for the majority of occupational skin disease that predominantly affects the hands. The prevalence of hand dermatitis in the population has been estimated at approximately 0.5%, rising in some studies to 10% when an industrial workforce has been examined. While most individuals will remain at work, over half will change jobs and a large proportion will be absent from work for a month or more.

History

In the first century AD, Pliny the Younger recorded dermatitis in some individuals after they cut down pine trees.

Epidemiology

An age-related increase in rates of occupational dermatitis is seen in men, but in women the peak age of incidence is 16–29 years with a reduction in older age groups. However, a comparison of rates by age within specific occupational groups suggests that the sexes follow a similar pattern. Among chefs and cleaners of either sex, higher rates are seen in young workers, whereas rates among machine tool operators steeply increase with age, reflecting the type of occupational exposure. Materials reported in the UK as giving rise to contact dermatitis are shown in Figure 16.2, and UK occupations at greatest risk in Figure 16.3[5]. In contrast to the UK, in Finland and the US, the highest rate of skin disease is among agricultural workers. Over the past decade, there has been a consistent decline in the reported incidence of contact dermatitis in the UK[6].

Pathogenesis

The initial events of both irritant and allergic contact dermatitis (see Chs 14 & 15) are basically identical. The skin responds to chemical perturbation with a complex response designed to recruit immunologic surveillance mechanisms to assess the nature and "danger" level of the perturbing agent. This reaction exhibits dose-responsiveness: strong irritants and sensitizers both evoke a stronger response than weak irritants and sensitizers, and even supposedly bland agents such as white soft paraffin can evoke some degree of response in some individuals.

Whether this acute response becomes clinically apparent will be determined by the strength of the perturbing insult, but even if it does not, a tissue response still occurs. If the irritant insult is repeated before the tissue response has subsided, it will boost the response to a higher level. Following repeated exposures to the irritant insult, the tissue response is ultimately boosted to the point at which it becomes clinically apparent as cutaneous inflammation (Fig. 16.4). If the level of tissue perturbation is maintained via repeated insults, the changes of chronic irritant dermatitis ensue, while an early withdrawal of insults may result in healing.

Clinical features

Contact dermatitis, both allergic and irritant, is morphologically indistinguishable from an endogenous eczema (Fig. 16.5). Not all patients will have a clinical configuration and/or distribution of lesions that suggests an exogenous insult. To induce contact dermatitis, a chemical must first penetrate the stratum corneum and then interact either directly with keratinocytes to cause irritant contact dermatitis or with the cutaneous immune system to cause an allergic contact dermatitis.

Although most cases of dermatitis will result from direct exposure that leads to localized dermatitis, it should be remembered that other routes of absorption can lead to dermatitis. In the case of solvents, inhalation may result in widespread dermatitis, often with systemic involvement.

Diagnosis is dependent on a thorough dermatologic and occupational history (Table 16.2) combined with examination of the entire skin. The material safety data sheets (MSDS) provide a guide to the nature of materials handled at work. They usually list the main ingredients and the hazards associated with the product, i.e. irritant, corrosive or known to contain a sensitizer. Total reliance should not be placed on the MSDS, as they may not list all ingredients of relevance, and communication with the manufacturer may prove helpful. When occupational dermatitis is suspected but a cause cannot be established from the history, a workplace visit may prove invaluable and may also elucidate the source of an allergen previously detected via patch testing.

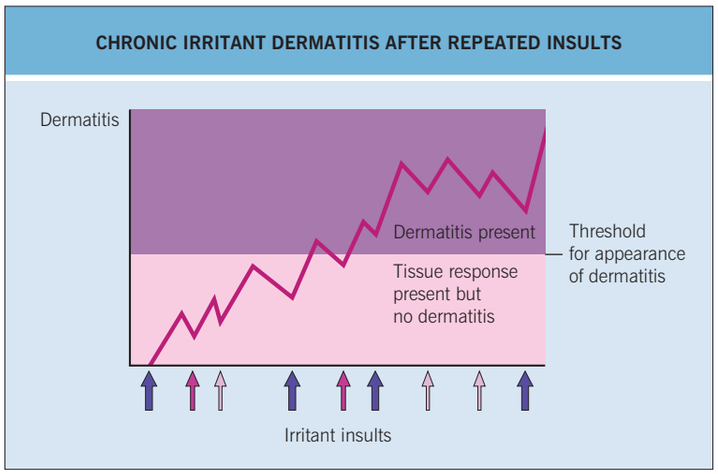

Fig. 16.4 Chronic irritant dermatitis after repeated insults. Initial subclinical response to tissue perturbation by an irritant becomes manifest as chronic irritant dermatitis after repeated insults. Each arrow represents an irritant insult of different intensity.

Fig. 16.5 Hand of a builder who presented with a dyshidrotic (pompholyx) pattern of eczema. Investigation demonstrated allergic contact dermatitis to chromate found in cement and contact urticaria to latex in the gloves he was using for hand protection.

POINTS TO CONSIDER WHEN TAKING AN OCCUPATIONAL HISTORY	
Primary (initial) site of disease	In 90%, it is the hands
• Time course	Is this consistent with work exposure as a cause?
	Does time off result in improvement?
Materials handled	
• Labels and material safety data sheets (MSDS)	Irritant, corrosive or sensitizing
• Other persons affected	Suggests an irritant contact dermatitis
• Protection provided	Is it appropriate?
	Is there an allergy to personal protective equipment?
Previous skin disease or history of atopy	Is this a recurrence of a previous problem?
Known allergies	Is there unrecognized exposure?
Treatment	May cause allergic contact dermatitis
Hobbies	May be a more likely cause than occupation

Table 16.2 Points to consider when taking an occupational history.

Although the primary site is usually the hands, spread to *adjacent* areas of skin (even without primary contact) is relatively common. Spread to *distant* sites, such as the face and feet, is more frequently seen in allergic contact dermatitis than in irritant contact dermatitis. Notably, airborne allergens, e.g. from paint sprayers, can lead to a pattern of dermatitis that suggests the exposure. Covered areas such as the trunk and feet are unusual sites of onset of disease. Improvement of the dermatitis during periods away from work is important in determining a primarily occupational cause, but it should be remembered that an endogenous eczema may also be exacerbated by workplace exposures. As the dermatitis becomes chronic, the relationship between work and exacerbations becomes less clearcut.

Allergic contact dermatitis

Allergic contact dermatitis (see Ch. 14) is not as common as irritant contact dermatitis. Once sensitization has occurred, very small amounts of allergen are required to perpetuate the dermatitis. As a consequence, avoidance may prove difficult, especially if the allergen is widely distributed within the home environment as well as at work. Patch testing is essential for establishing the diagnosis and should be performed in any individual with a dermatitis that may be work-related or for whom a change of job is being contemplated. Testing with work materials is essential (Table 16.3) if contact allergy is not to be missed, as not all allergens are commercially available and the MSDS may not disclose all relevant ingredients. A guide to testing 4350 chemicals has been published[7]. When a reaction occurs to an unknown substance, the use of a dilutional series and the testing of approximately 20 controls is essential to confirm that the reaction is allergic rather than irritant.

In an extensive surveillance report, the most common causes of an occupational allergic contact dermatitis were rubber (23.4% of cases), nickel (18.2%), epoxy and other resins (15.6%), aromatic amines (8.6%), chromate (8.1%), fragrances and cosmetics (8.0%), and preservatives (7.3%)[5]. Rarely, substances can cause an allergic contact dermatosis that mimics other conditions such as erythema multiforme (Table 16.4). Patch testing with the suspect material will confirm the correct diagnosis. Typically there is an eczematous patch test reaction, but features of these other dermatoses may appear.

Irritant contact dermatitis (see Ch. 15)

An irritant is a chemical capable of causing direct cell damage. Strong irritants are usually recognized and protection provided. Most occupational dermatitis results from repeated exposures to weak irritants which cause cumulative damage to the skin (see Fig. 16.4). Individual susceptibility varies widely and differs from one chemical to another. Employees with previous atopic dermatitis, especially with hand involvement, are particularly at risk. In a recent study, loss-of-function mutations in the filaggrin gene conferred susceptibility to hand dermatitis due to combined allergic and irritant contact dermatis[8].

Soaps (22.0% of cases), wet work (19.8%), petroleum products (8.7%), solvents (8.0%), and cutting oils and coolants (7.8%) are the most frequently cited causes of occupational irritant dermatitis[5].

Chemical burns

A chemical burn is an acute irritant reaction in which the injury to the skin is irreversible and cell death occurs. Depending on the nature of the chemical, it can occur following a single exposure. Initial symptoms consist of burning and smarting with progressive development of erythema, blisters, erosions and then ulceration. Symptoms usually develop in close association with the exposure, but some chemicals, such as phenols and weak hydrofluoric acid, can have a delayed onset. Common occupational causes[9] include:

- **strong acids:** e.g. sulfuric, nitric, hydrochloric, chromic. Most coagulate skin proteins and as a result form a barrier which impedes further penetration. Hydrofluoric acid differs in that it causes a liquefactive necrosis: penetration, even down to bone, can continue for several days after exposure. Pain, which can last several days, is typical of hydrofluoric acid and other fluorides. If more than 1% of the body surface area is affected, systemic toxicity can develop

SUGGESTED CONCENTRATIONS FOR PATCH TESTING SELECTED WORK MATERIALS		
Sample	**Dilution**	**Occupation(s)**
Personal care products		
• Leave on	As is	Hairdresser/beautician
• Wash off	1–5% aqueous or open[†]	Hairdresser/beautician
Plants[‡]		
Bulb, leaf, flower	As is	Gardener/florist Agriculture/vegetable processing
Woods – sawdust	As is/10% petrolatum	Joiner/woodworker
Dyes (clothing)	1% petrolatum	Textiles
• Cloth	As is – moistened	
Foods[§]	As is	Catering/chef
Glue	10% aqueous/ petrolatum	Various
• Methacrylate monomer	1% petrolatum	Dentist/orthopedic surgeon
• Acrylate monomer	0.1% petrolatum	
• Epoxy resin	1% petrolatum	Painter – 2 part paints
• Epoxy hardener	0.1% petrolatum	
Ink	As is	Printing
• UV cured	1% petrolatum	
Oil		
• Cutting (coolant) – water miscible	10% aqueous or open	Metal machining
• Lubricant – immiscible with water	As is	Various-use machinery
Paint	10% aqueous/ petrolatum	Painter/decorator
Photographic chemicals	10% aqueous	Photographer
Solvents/thinners	10% acetone	Various

[†]Open test: apply the substance to a 3 cm diameter area of skin and allow to dry. Read as normal but do not occlude.
[‡]Do not test unless the plant has been identified and is recognized not to be irritant. There may be a risk of sensitization.
[§]Prick testing is essential to exclude contact urticaria.

Table 16.3 Suggested concentrations for patch testing selected work materials. This is a guide only: the final decision must always be made in light of the information available in relation to the suspected material. Tests are usually performed on the upper back.

NON-ECZEMATOUS ALLERGIC CONTACT DERMATOSES		
Dermatosis	**Occupation**	**Exposure**
Erythema multiforme-like	Woodworker	Tropical woods – *Dalbergia nigra; Machaerium scleroxylon; Eucalyptus saligna*
	Laboratory worker	9-bromofluorene
	Textile worker	Para-phenylenediamine (PPD) Nickel
Pigmented purpura-like	Various	Black rubberized clothing: N-phenyl-N-isopropyl PPD
Lichen planus-like	Photography: color developer	CD2, CD3, CD4
	Motor vehicle manufacture	Methacrylic acid ester

Table 16.4 Non-eczematous allergic contact dermatoses. CD, color developer; CD2, 4-N,N-diethyl-2-methyl-1,4-phenylenediamine; CD3, 4-(ethyl-N-2-methan-sulfonamidoethyl)-2-methyl-1,4-phenylenediamine; CD4, 4-(ethyl-N-hydroxyethyl)-2-methyl-1,4-phenylenediamine.

Fig 16.6 Cement burns. Ulcerations on the fingertips of a construction worker exposed to wet cement. *Courtesy, PJ Coenraads, MD.*

- **strong alkalis:** e.g. sodium, calcium, potassium hydroxides; wet concrete (Fig. 16.6); sodium and potassium cyanides. Degradation of lipids and saponification of the resulting fatty acids form soaps which aid the penetration of alkalis deeper into the skin. As a consequence, damage is more severe than with most acids (apart from hydrofluoric acid) and pain is also a feature
- **organic and inorganic chemicals:** e.g. dichromates; arsenates; phenolic compounds. Phenols and unhardened phenolic resins easily penetrate the skin. Nerve damage may cause anesthesia, but rarely in the absence of visible skin damage. Vasoconstriction may contribute to the necrosis that develops and, following systemic absorption, shock and renal damage may ensue
- **solvents and gases:** e.g. acrylonitrile; ethylene oxide; carbon disulfide; mustine. Ethylene oxide gas is used to sterilize medical instruments, textiles and plastic materials, and it can remain on these items for several days if not allowed to evaporate off prior to use. The possibility of exposure may therefore not be obvious.

Fiberglass dermatitis

Glass fibers are subdivided into various types, depending on fiber diameter, and are used for their insulating (thermal, acoustic and electrical), strengthening and filtering abilities. They are chemically inert and the mechanism of skin injury is via direct penetration, which is directly proportional to the diameter (>3.5 microns) of the fiber and inversely proportional to its length. Histologically, eczematous changes including spongiosis are seen.

Pruritus and tingling are the usual initial symptoms. Subsequently, erythematous papules develop (often with follicular accentuation), either on exposed areas when there is airborne exposure or on the forearms when there is contamination of a work surface (Fig. 16.7)[10]. Contamination of clothing causes problems, especially in the flexural areas and where there is contact with the skin. Paronychia is common and airborne exposure may also cause burning eyes, sore throat and cough.

The diagnosis is often based on clinical findings, but it can be confirmed by detecting the fibers in tape strippings of affected skin or by examining skin scrapings in 20% potassium hydroxide. The dermatitis resolves rapidly after cessation of exposure. In most individuals, hardening occurs and symptoms resolve over a few weeks despite continued exposure; of note, the use of resins to bind glass fibers can result in an allergic contact dermatitis.

Phototoxic eruptions

Chemical photosensitivity occurs when a chemical becomes activated through interaction with light. The photoactivated chemical has altered properties which can be directly tissue damaging (phototoxic reaction) or may be immunogenic (photoallergic reaction). Most occupational photosensitivity is phototoxic in nature and commonly heals with hyperpigmentation. The most common scenario is exposure to

naturally derived psoralens from plants in outdoor workers. This may be from a food such as celery or parsnip, members of the Apiaceae (formerly Umbelliferae) family, or weeds as in "strimmer" dermatitis when plant sap splatters the body of a worker inadequately protected when cutting down plants such as cow parsley and wild chervil (see Ch. 17).

Coal tar and its products, including creosote, cause a reaction known as tar/pitch smarts. A burning or stinging sensation develops after as little as 15 minutes of sun exposure.

Mechanical

Occupational marks are usually areas of lichenification or calluses and corns that develop at sites of friction and are specific to a particular job (Fig. 16.8). Mechanical injury to the skin is also thought to cause dermatitis analogous to irritant chemical damage. It may result in a keratotic hand dermatitis or post-traumatic eczema (Koebner phenomenon).

Pathology

The histologic features of allergic contact dermatitis and irritant contact dermatitis are discussed in Chapters 14 and 15, respectively.

Differential diagnosis

The etiology of occupational dermatitis is frequently multifactorial and endogenous eczema (e.g. atopic, dyshidrotic, nummular) may contribute to the clinical appearance. Tinea manuum may resemble hand dermatitis, especially following treatment with topical corticosteroids, and scabies infestation of the interdigital spaces can simulate irritant dermatitis.

Psoriasis frequently affects the palms, resulting in keratotic plaques, sometimes with fissures. This can be difficult to distinguish from dermatitis when there are no lesions elsewhere. Furthermore, it may be work-related with repeated trauma leading to Koebner phenomena. Nail involvement and plaques over the interphalangeal joints are helpful clues.

Fig. 16.7 Fiberglass dermatitis. Multiple pruritic pink papules at the site of exposure.

Treatment

Prevention reduces the possibility of needing to treat dermatitis[11]. During pre-employment screening, a history of severe childhood atopic dermatitis, particularly with hand involvement, indicates an individual at risk of developing dermatitis from exposure to irritants. Employment in a "dry" job should be recommended. In the workplace, the use of protective equipment and skin care preparations should be encouraged (Table 16.5). As an interim measure, dermatitis requires palliation of symptoms with emollients and topical corticosteroids. In severe cases, short-term therapy with systemic drugs such as prednisone, azathioprine, methotrexate, mycophenolate mofetil or cyclosporine may be required.

The most important aspect of treatment, however, is avoidance of the cause. Ideally, a change in the production process may avoid the need for exposure, but this may be costly. A practical compromise is frequently the use of personal protective equipment and/or substitution of a particular chemical. It is often forgotten that natural rubber latex gloves are effective protection against water-miscible materials but may be inappropriate for other exposures, e.g. organic solvents. Advice on appropriate glove type may be found on the material safety data sheets or from manufacturers (e.g. www.ansellpro.com). A further issue is the passage of some allergens through latex gloves, e.g. acrylate glues (orthopedic surgeons and dentists), the hair dye para-phenylenediamine and acid perm solutions containing glycerol monothioglycolate (hairdressers).

Initial treatment of chemical burns requires irrigation with large volumes of water. When the chemical is insoluble in water, a soap solution may be used instead. High pressures should not be used, in order to avoid splashing other areas of the body or bystanders with the corrosive material. For some chemicals, specific antidotes can then be used, e.g. 2.5% calcium gluconate gel for hydrofluoric acid; disappearance of pain is a sign of successful treatment. When there is a risk of toxicity from systemic absorption, as with chromic acid, early debridement of necrotic areas reduces blood levels.

Ulcerated areas should be managed with antibacterial creams or ointments to prevent secondary infection while re-epithelialization occurs. If there is a surrounding inflammatory reaction, a moderately potent topical corticosteroid can be applied. Frequent evaluation is required

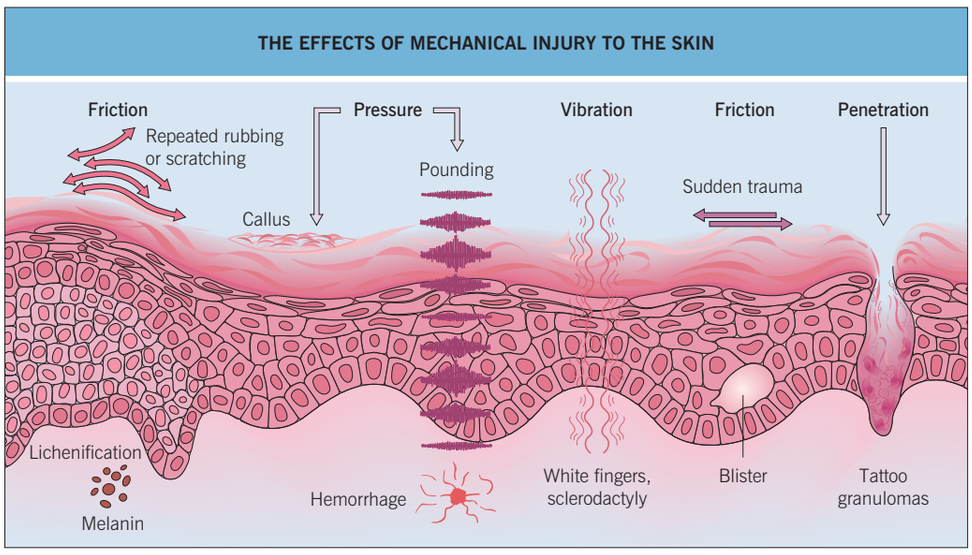

Fig. 16.8 The effects of mechanical injury to the skin. Both friction and pressure lead to callus formation. *Adapted from Adams RM. Occupational Skin Disease, 3rd edn. Philadelphia: WB Saunders, 1999:36.*

GUIDELINES AIMED AT PREVENTING CONTACT DERMATITIS		
Advice		**Explanation**
Do not wear rings		Chemicals/water accumulate underneath
Hand washing	• Use lukewarm water and dry thoroughly	• Skin damage from detergent is reduced at a low temperature • Dermatitis often begins at sites that are missed, e.g. fingerwebs
Wear gloves	• For wet work • For as short a time period as possible • With a cotton inner liner if prolonged exposure • That are dry, clean and intact	• Wet work is the major risk factor for contact dermatitis • Glove occlusion also damages the skin • Liners absorb moisture and reduce irritation • Occlusion of chemicals inside gloves increases irritancy
Use moisturizer	• Frequently throughout the day • To the whole hand • That is fragrance-free and preservative-free	• Encourages barrier repair • Need to include web spaces • Prevents sensitization and development of ACD to common allergens
For antisepsis	• Use alcohol gel	• Less irritating than soaps or antiseptic detergents
Follow the same advice at home		Domestic exposures are additive

Table 16.5 Guidelines aimed at preventing contact dermatitis. ACD, allergic contact dermatitis.

because the ulcers can progress over several days. Subsequent management with excision, debridement, semi-permeable membrane dressings and/or grafting may speed the healing process. When the ulcer extends into the dermis, healing frequently results in a scar and pigmentary change is common.

Several chemicals (e.g. hydrofluoric acid, phenolic compounds, chromic acid, gasoline) carry a significant risk of systemic toxicity even when the area of skin involved is small (approximately 1% of body surface area). In these instances, regular monitoring of blood, liver and kidney function plus appropriate supportive treatment (e.g. dialysis) is required. When the chemical is a sensitizer, allergic contact dermatitis may subsequently appear on re-exposure to non-irritant concentrations, as burns and irritant dermatitis appear to promote sensitization.

Once it has developed, the outlook for occupational contact dermatitis is poor[12]. In a follow-up study of 954 patients with occupational dermatitis seen over 8 years, in which at least 60% were assessed more than 2 years after diagnosis, 55% still had disease. Of those who were still in the same job or occupation, 68% were still symptomatic, compared with 37% of those who had moved to a different work environment. Notably, when changing jobs, 25% of individuals had inappropriately moved to a workplace with the same or similar chemical exposures. Of the total, 11.5% had persistent disease in the absence of any obvious cause, for which the term "persistent post-occupational dermatitis" was coined.

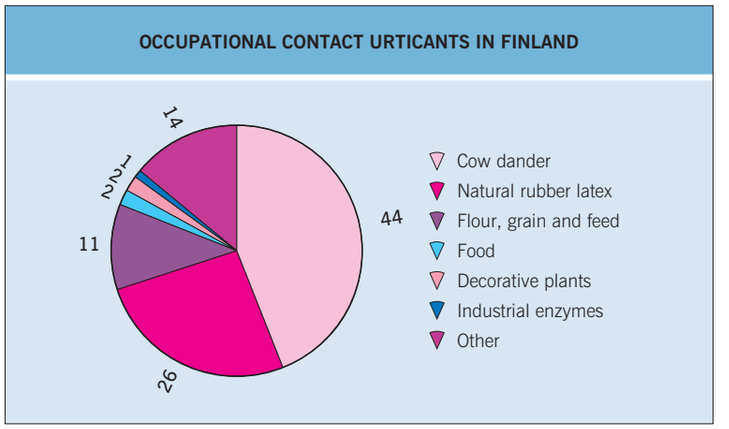

Fig. 16.9 Occupational contact urticants in Finland. Relative frequencies are represented[1].

Contact Urticaria

Synonyms: ■ Contact urticaria syndrome ■ Immediate contact reaction ■ Protein contact dermatitis

Key features

- Pruritus and wheal-and-flare reaction
- Develops within 60 minutes of exposure and resolves within 24 hours
- It is the protein content of latex rubber that is responsible for the associated contact urticaria
- In suspected cases of latex-induced contact urticaria, the specific IgE test may be negative, requiring prick testing with a commercial latex extract and a usage test

Introduction

Contact urticaria has been reported following exposure to a wide range of substances[13]. With regard to occupational skin disease, plant- and animal-derived proteins are recognized causes, especially among food handlers and agricultural, animal laboratory and veterinary workers. In extreme circumstances, systemic symptoms (i.e. rhinoconjunctivitis, bronchospasm and anaphylaxis) may be seen. With the introduction of universal precautions in the 1980s and increased use of natural rubber gloves, latex protein emerged as an important cause of contact urticaria, particularly in the healthcare setting.

History

Contact urticaria was first defined as a clinical entity during the 1970s but it had long been recognized.

Epidemiology

Based on official statistics, occupational causes of contact urticaria have been well classified in Finland[1]. The relative frequency of various urticants is shown in Figure 16.9 and reflects the high prevalence of reactions in the farming community. The reactions to cow dander are probably the result of high exposure, as cattle are kept indoors from September to May/June. The prevalence varied from 140/100 000 for bakers to 2.1/100 000 for shop assistants and was higher in women, irrespective of occupation. For the occupations most at risk, the relative risk by occupation is shown in Figure 16.10. The incidence of contact urticaria falls with age, and approximately 30% of individuals have coexistent contact dermatitis.

Pathogenesis

Contact urticaria is classified as either irritant/nonimmune-mediated or allergic/immune-mediated. An additional category includes those cases in which the mechanism is uncertain, the most common cause of which is ammonium persulfate in hairdressing.

The mechanism of nonimmune contact urticaria is not well defined but involves the release of vasoactive mediators. It is inhibited by non-steroidal anti-inflammatory drugs but not antihistamines, suggesting a

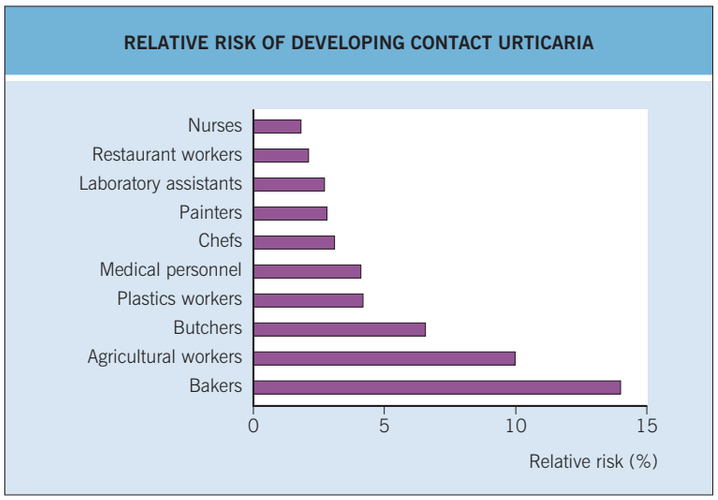

Fig. 16.10 Relative risk of developing contact urticaria by occupation.

POTENTIAL CROSS-REACTIONS BETWEEN CAUSES OF CONTACT URTICARIA

Food/natural product	Risk (%)	Cross-reactions
Fruit (kiwi, avocado, banana)	11	Latex
Latex	35	Fruits (e.g. kiwi, avocado, banana)
A shellfish (e.g. crab)	75	Other shellfish (e.g. prawn, lobster)
A fish (e.g. salmon)	50	Other fish (e.g. swordfish, sole)
A grain (e.g. barley)	20	Other grains (e.g. wheat, rye)
A legume (e.g. peanut)	5	Other legumes (e.g. peas, beans, lentils)
Peach	55	Other Rosaceae fruit (e.g. apple, pear, cherry, plum)
Melon	92	Other fruits (e.g. watermelon, banana, avocado)

Table 16.6 Potential cross-reactions between causes of contact urticaria. If allergic to item in column 1, risk of cross-reacting with item in column 3.

role for prostaglandins. Symptoms develop in the majority of those exposed and are most often due to simple chemicals, e.g. sorbic acid.

Immunologic contact urticaria is mediated by allergen-specific IgE (see Ch. 18). Binding of antigen, usually protein, to mast cells in a previously sensitized individual results in degranulation and release of mast cell mediators, including histamine. Atopic individuals are at greater risk of this type of reaction.

Clinical features

Signs and symptoms range from nonspecific, i.e. pruritus, tingling and burning, to more typical urticaria with a wheal and flare, usually developing within 30 minutes of exposure at the site of contact. Resolution occurs within hours. Individuals with immunologically mediated urticaria[14] may also experience systemic symptoms with generalized urticaria, rhinoconjunctivitis, orolaryngeal and gastrointestinal symptoms, asthma, and, at worst, anaphylaxis.

Foods

One of the more common causes of contact urticaria is foodstuffs, which can provoke either orolaryngeal symptoms when ingested or hand symptoms when handled (e.g. in fish processors, slaughterhouse workers or those in the catering industry). There is a diverse range of responsible foods, including meats, fish, eggs, fruits, vegetables and flour, as well as associated enzymes such as α-amylase (found as an additive in flour). In Scandinavia, a strong association is seen between the incidence of birch pollen allergy and contact urticaria to fruits and vegetables, due to the presence of similar peptides. Birch pollen is a common aeroallergen in Scandinavia, whereas in the UK the most common aeroallergens are the house dust mite and grass pollen; this may explain why there are fewer reports of contact urticaria in food handlers in the UK. If contact urticaria is confirmed, there are recognized cross-reactions between the various foodstuffs (Table 16.6)[15].

Latex

Contact urticaria to latex was first described in 1979. The term "latex" defines an aqueous dispersion of a rubber. The rubber obtained from latex by drying or coagulation is termed "latex rubber". Natural latex is derived from the sap of the tree *Hevea brasiliensis*. Natural latex contains polyisoprene (30–40%) together with a variety of other plant chemicals, including proteins (2.3%).

After 1985, the demand for latex gloves for medical and dental use to prevent the transmission of infectious agents[16] more than doubled. Paralleling this rise in usage were reports of type I allergy to latex gloves. Occupational latex contact urticaria occurs more frequently in women, atopic patients (particularly those with hand eczema), and workers frequently exposed to latex gloves (e.g. hairdressers). Rates ranging from 3% to 16% have been reported in groups of healthcare workers.

Most problems arise from items made by coating a mold with concentrated liquid latex, e.g. gloves, balloons, condoms. Nowadays, however, many gloves are manufactured by methods designed to leave lower levels of protein allergen in the final product. Latex which is allowed to dry before processing by compression molding or extrusion (e.g. syringe plungers, vial stoppers) causes fewer problems, as a result of degradation of the protein allergen during the manufacturing process. When latex protein is absorbed onto starch particles in gloves, it can become airborne and cause conjunctivitis, rhinitis and asthma. Ideally, powder-free gloves should be used to avoid this risk.

In latex there is more than one protein against which an immunologic reaction may develop, and in a subgroup of patients, hypersensitivity reactions to bananas, avocados, chestnuts, kiwis and other fruits also occur (see Table 16.6). Radioallergosorbent inhibition studies have shown that they contain a similar antigen. In some individuals, the primary sensitization is to the fruit, with latex sensitivity being a secondary phenomenon.

Common household sources of exposure to latex are gloves, balloons, latex contraceptives, latex mattresses and pillows, rubber bands, swimming caps and baby pacifiers. The term "hypoallergenic glove" refers to latex gloves with reduced levels of accelerators and antioxidants (causes of allergic contact dermatitis); these gloves are not suitable for individuals allergic to latex (with immediate-type hypersensitivity).

Non-latex alternatives should be sought. Vinyl (PVC) gloves are suitable for home use. For those in the medical and dental professions, alternative gloves, typically nitrile (both sterile and non-sterile), are available from the major glove suppliers. Affected individuals should warn any doctor or dentist that they visit of their sensitivity so that measures can be taken to prevent a reaction. The most severe reactions have followed mucosal and parenteral exposures. Death has occurred following the use of a natural rubber latex cuff on a barium enema device and anaphylaxis after intraoperative, oral or vaginal exposure to latex gloves. Wearing a bracelet or necklace to alert the medical profession in the event of an emergency has been advocated.

Low-molecular-weight chemicals

Although rare, these chemicals can be important causes of occupational contact urticaria in the industrial setting. Some are also potential causes of occupational asthma. The diagnosis may prove difficult to establish because skin testing may require conjugation of the low-molecular-weight chemical with protein to form the allergen. Chemicals (and industries) associated with contact urticaria include: antibiotics (pharmaceutical industry); ammonium persulfate and paraphenylenediamine (hairdressing); phthalic anhydrides, epoxy resin systems and poly-functional aziridines (plastics and glue industry); and reactive dyes (textile workers).

Protein contact dermatitis

The term "protein contact dermatitis" was originally used to describe an eczematous reaction to protein-containing material in food handlers. The reactions were both allergic and non-allergic, although many had a positive prick test or the presence of specific IgE antibodies, implying an IgE-mediated mechanism. In some, positive patch tests pointed to the coexistence of delayed-type hypersensitivity. The clinical picture is

usually that of a chronic eczema with episodic exacerbations following contact with the allergen[17].

Pathology

The histologic findings of contact urticaria are described in Chapter 18.

Differential diagnosis

After a detailed history and clinical examination, skin testing may be undertaken to confirm the diagnosis of contact urticaria. When the patient has experienced anaphylactic symptoms and a specific IgE test is available, the blood test may confirm the diagnosis, avoiding the risk of anaphylaxis as a result of skin tests. Skin testing should be performed with appropriate positive and negative controls. With an unknown allergen, exposure should be graded; an initial application test (open and subsequently occluded) is followed by a prick test and, if necessary, an intradermal test. If the patient has a positive test, control individuals should be tested; a positive response in the latter group points to the presence of a nonimmune contact urticant. While commercial allergen extracts are available, it should be remembered that, unless adequately standardized, they may not contain the relevant protein allergens, resulting in a false-negative test result. The gold standard for testing is a sample of fresh material. Skin tests should only be performed where resuscitation facilities are available.

In the case of latex, the specific IgE blood test is not sensitive and a negative test does not exclude the diagnosis (Fig. 16.11). While skin tests with glove extracts have been recommended, many gloves now contain low levels of latex protein and prick testing with these home-made extracts frequently leads to false-negative results. Prick test solutions of latex are commercially available, some of which claim >98% sensitivity and 100% specificity (Fig. 16.12). If a particular glove type appears to elicit symptoms, a so-called "prick to prick" test can be used: the suspected item itself is pricked with the lancet, after which the patient's skin is pricked with the antigen-"contaminated" lancet. The final arbiter is a usage test in which a patient wears the suspect glove on a moistened hand and is observed for any reaction.

Although reactions to gloves are common, a proportion of individuals have symptoms caused by irritation. In the absence of a latex allergy, localized symptomatic dermographism is a common cause of urticaria to gloves (see Fig. 16.11).

Treatment

Management consists of avoidance, as desensitization for the majority of involved allergens is not available. Avoidance may be achieved by improved occupational hygiene and the use of personal protective equipment, but in extreme circumstances may necessitate a change of occupation. Treatment of the acute episode includes the use of systemic antihistamines and epinephrine (adrenaline), depending on the severity of the attack. In the case of latex, the use of powder-free gloves containing low levels of protein has been shown to prevent the development of latex hypersensitivity by reducing the level of exposure in the at-risk population[18]. There has also been a movement in healthcare facilities to use only non-latex gloves. The development of a commercial method for latex desensitization without significant risk of systemic adverse reactions also offers the potential for better symptom control in those who are unable to completely avoid exposure[19].

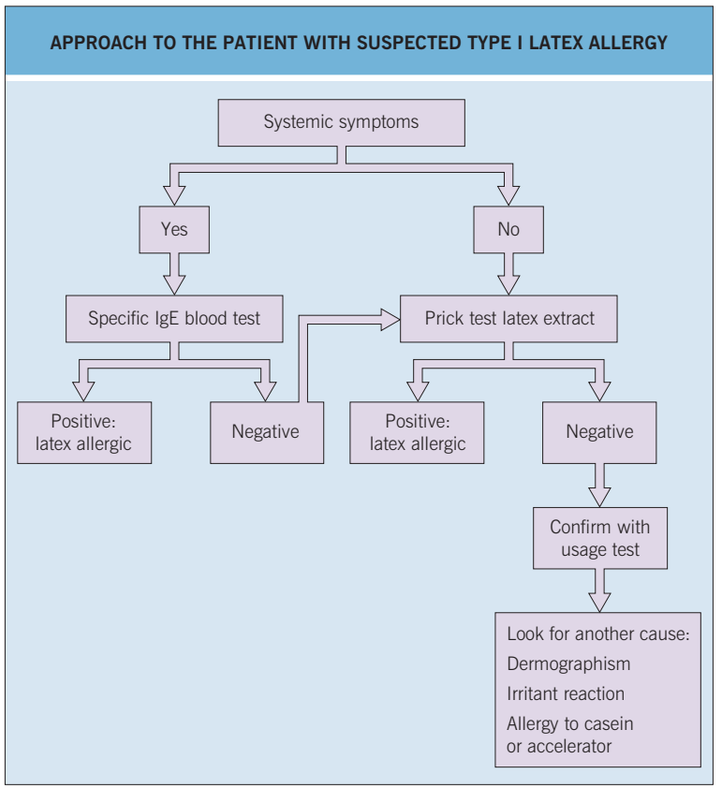

Fig. 16.11 Approach to the patient with suspected type I latex allergy. IgE-mediated immediate hypersensitivity is detected by prick tests, whereas delayed-type hypersensitivity which manifests as contact dermatitis is detected by patch testing. In the open usage test, the patient wears the suspect glove on a moistened hand.

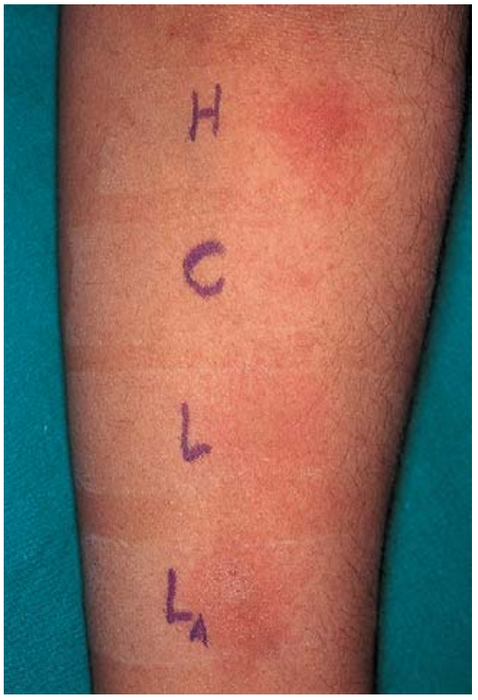

Fig. 16.12 Positive prick test with a commercial latex extract (L) and high ammoniated natural rubber latex (L_A). Histamine (H; 10 mg/ml) and saline (C) controls are appropriately positive and negative. The histamine-positive control confirms that the effects of previous medications (including antihistamines) are no longer an issue and the saline-negative control assesses for dermographism. When a standardized allergen is available for a prick test, a small drop is placed on the skin and the skin is pierced with a special lancet with a 1 mm tip. Surplus allergen is blotted off and a fresh lancet is used for each test substance to prevent cross-contamination. Reactions develop over 15 minutes and a wheal 3 mm larger than the negative control is considered positive.

Occupational Skin Cancer

Key features

- A skin cancer in which occupation has played a major role in the etiology
- In the workplace, the most important exposures are to UV radiation, ionizing radiation and carcinogenic chemicals (e.g. polycyclic hydrocarbons)

Introduction

Occupational skin cancers[20] have been estimated to account for less than 1% of all skin cancers. In a study of workers exposed to coal and diesel combustion products, the relative risk for developing

non-melanoma skin cancer was 1.5%[21]. The tumor most frequently associated with occupational chemical exposure is squamous cell carcinoma (SCC).

History

The first association between occupation and cancer was made in 1775. Sir Percival Pott, a surgeon at St Bartholomew's Hospital in London, described the occurrence of scrotal cancer in chimney sweeps. The latter was often preceded by keratotic lesions known as soot warts. In 1873, von Volkman described skin cancers from exposure to the distillation products of tar and pitch.

In the early 1800s, inorganic arsenic was associated with skin cancers, especially of the scrotum in smelter workers, but also from exposure in the mining industry and in users of end products (e.g. sheep dip). In the early twentieth century, ionizing radiation was recognized as a cause of radiodermatitis followed by skin cancer, particularly of the hands of medical workers administering radiotherapy.

Epidemiology

As carcinogens have become recognized and limits on occupational exposure introduced, solar UV exposure has risen to account for ~95% of cases of occupational skin cancer reported in the UK. In Australia, the most common cause of compensated occupational cancer (of all types) was UV exposure (22%), followed by asbestos (21%)[22]. It was estimated that 34 000 cases of non-melanoma skin cancer per year and 4% of cases of cutaneous melanoma in men were attributable to occupation.

Occupations at high risk of occupational skin cancer include:

- outdoor workers[23], especially in agriculture and building industries, and welders (UV exposure)
- workers exposed to polycyclic hydrocarbons (e.g. tars, pitches, oil fractionation products); in addition to direct skin contact, fumes may be inhaled
- workers exposed to arsenic in glass production, copper, zinc or lead smelting, and the production of pesticides, herbicides and semiconductors
- radiologists, dentists, X-ray technicians, and those who work with radioactive materials (ionizing radiation).

Pathogenesis

The major carcinogenic hazards include UV radiation, ionizing radiation and carcinogenic chemicals. Occupationally induced cancers are not pathologically different from those which arise spontaneously. However, the former tend to occur at an earlier age than spontaneous tumors at the same site. They arise following repeated or continuous exposure to the carcinogen, and there is a long latency period between the exposure to the carcinogen and appearance of the tumor.

While ionizing radiation results in DNA base changes and strand breaks, which lead to mutation through errors in repair, UV radiation acts as a "complete carcinogen" by initiating carcinogenesis and promoting tumor progression. Initiation begins with formation of thymine dimers, followed by erroneous base substitutions during DNA repair (see Ch. 86). In addition, UV radiation acts as a tumor promoter by driving a diverse array of cell-activating signal transduction pathways. This results in the production of growth factors and cells being driven through the cell cycle when they should have been arrested in the cycle in order to undergo DNA repair. This enforced cycling augments DNA replication errors involving critical genes normally involved in regulating growth, cell cycling and apoptosis (see Ch. 107).

There are two major classes of chemical carcinogens: (1) polycyclic aromatic hydrocarbons including benzo(a)pyrene; and (2) aromatic amines such as dichlorobenzidine, an intermediate in the dyestuffs industry. For many compounds, carcinogenic mechanisms are not well understood, but there are general analogies to UV-induced carcinogenesis. Alkylating agents damage DNA, resulting in base substitutions and errors during replication.

Clinical features and diagnosis

In evaluating a patient with suspected UV-related occupational skin cancer, a careful history is required to establish the relative contributions of work versus leisure exposure. The final judgment is essentially clinical.

With polycyclic aromatic hydrocarbons, a variety of skin changes may precede the development of cancer and aid in the clinical diagnosis. Associated changes include (in order of development) erythema and burning, folliculitis, poikiloderma, and keratotic papillomas (tar warts) within the poikilodermatous skin. The verrucous tumors may then develop into SCC, although basal cell carcinomas and keratoacanthomas also occur.

The clinical features and diagnosis of these cutaneous malignancies are discussed in detail in Chapters 108 and 113.

Pathology and treatment

The pathology and treatment of skin cancers are discussed in detail in Chapters 108 and 113.

Occupational Acne

Key features

- Open and closed comedones
- Non-inflamed nodules and cysts
- Inciting factors include exposures to oils, halogenated polycyclic hydrocarbons, and repeated frictional trauma

Introduction

Occupational acne is a form of acne resulting from various chemical exposures as well as particular environmental and physical factors. Chloracne is a rare acne-like skin condition caused by certain toxic chemicals (see later) and may be a cutaneous manifestation of systemic exposure.

History

Chloracne was first reported in 1897. In 1949, the first descriptions of human exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD)-contaminated chemicals were reported after a trichlorophenol reactor explosion in Nitro, West Virginia, USA. The majority of health effects have been reported among groups with high exposure, including occupational populations such as chemical production workers, pesticide applicators, and individuals who handled or were exposed to materials treated with 2,3,7,8-TCDD-contaminated pesticides. In addition, residents of communities contaminated with tainted waste oil (Missouri, USA) and industrial effluent (Seveso, Italy) have been affected[24]. During the Vietnam War, chloracne in US troops was ascribed to exposure to the defoliant Agent Orange.

Epidemiology

Oil acne is the most common form of occupational acne.

Pathogenesis

Continued exposure to oils results in reactive hyperkeratosis and subsequently follicular occlusion with typical manifestations of acne vulgaris.

Chloracne is caused by exposure to certain halogenated polycyclic hydrocarbons such as polychlorinated dibenzodioxins (PCDDs) and dibenzofurans (PCDFs)[25] which are most often found in fungicides, insecticides, herbicides and wood preservatives. It occurs within 2 months of exposure to chloracnegens and can persist for years despite cessation of exposure. The condition is always a sign of systemic exposure to the causal agent(s), but entry may occur via percutaneous absorption as well as from inhalation or ingestion of the chemicals. After exposure of workers in a large chemical factory to hexachlorobenzene[26], blood levels in those with chloracne were compared to the levels in workers without chloracne. Levels were calculated as toxicity equivalents of tetrachlorodibenzo-*p*-dioxin (TCDD). In the chloracne group, blood levels ranged from 1168 to 22 308 pg/g blood lipid. In the exposed but chloracne-free group, the range was from 424 to 662 pg/g. It was thus concluded that chloracne developed at blood levels between 650 and 1200 pg/g.

Fig. 16.13 Chloracne. Note involvement of retroauricular skin with numerous comedones (primarily closed) and cysts. The clinical differential diagnosis includes folliculotropic mycosis fungoides.

Clinical features

Oil acne and tar acne

Contact with acnegenic substances, such as creosote, oils and greases, can worsen existing acne. Oils used in industry, such as cutting oils (paraffin/oil mixtures), tars (pitch and creosote), and crude petroleum oils such as diesel oil, can all cause acne. Lesions may develop both in the usual sites for acne and in unusual sites such as the arms or abdomen. The latter are often the sites in contact with the oil, being beneath clothing that is saturated with the oils. Oils mists can also induce acneiform eruptions.

Acne mechanica

Acne mechanica is a form of acne, usually inflammatory, that is exacerbated by repeated frictional trauma that occludes the follicle. It is localized to sites of pressure, e.g. the back in long-distance drivers, the neck in violinists, and the chin in football players who wear helmets with chin straps.

Acne cosmetica

Certain cosmetic ingredients used by models and thespians can induce comedone formation, e.g. lanolin, petrolatum and some vegetable oils.

Chloracne

Chloracne is distinguished from ordinary acne vulgaris by the predominance of open (over closed) comedones and a concentration of lesions over the malar crescent and behind the ears (Fig. 16.13). The first sign of chloracne may be excessive oiliness of the skin. This is accompanied or followed by the appearance of numerous open comedones (i.e. blackheads). In mild cases, open comedones may be limited to the area around the eyes, extending across the temples to the ears. In more severe cases, they may appear more extensively on the body, especially in the malar region, other facial areas, behind the ears, and on the arms. The open comedones are usually accompanied by fluid-filled cysts and by an increased or darker growth of body hair.

As the disease progresses, milia form together with distinctive yellowish epidermoid inclusion cysts (some of which may become inflamed) on the face, behind the ears, and on the neck, buttocks, scrotum and thighs. Some authors have proposed using the term "metabolizing acquired dioxin-induced skin hamartomas" for these dioxin-induced cysts[27]. The skin may become thicker and even desquamate or peel. In severe cases, the acne can result in ulcerations and permanent scars. The condition fades slowly after exposure. Minor cases may disappear altogether, but more severe cases may persist for years. Chloracne is difficult to treat and can last for long periods without known additional exposure to chloracnegens. Sites of systemic involvement are the eyes, liver and nervous systems; some chloracnegens can be oncogenic.

Acne due to halogens

Chemicals that contain iodides, bromides and other halogens can induce an acneiform eruption similar to that of corticosteroid acne; however, the iodide-induced eruptions (i.e. iododerma) may be more severe. Patients with bromoderma may also have lesions that resemble pyoderma gangrenosum.

Pathology

Histologic features of comedones are reviewed in Chapter 36. Small infundibular cysts and dilated infundibula filled with orthokeratotic plugs are seen in chloracne. A disappearance of sebaceous glands has been described[27].

Treatment

Treatment consists primarily of avoidance of the cause, although some forms can be persistent and require treatments designed for acne vulgaris, e.g. topical or oral retinoids (see Ch. 36). However, chloracne is particularly recalcitrant.

Vibration White Finger

Synonyms: ■ Hand-arm vibration syndrome ■ Dead finger

Key features

- Development of a white finger or fingers in response to cold
- Associated transient loss of sensation
- Possible permanent finger neuropathy and pain in the affected limb
- Associated with exposures to vibrations between 30 and 300 Hz
- Workers at risk include operators of chainsaws and pneumatic tools

Introduction

Vibration white finger is a relatively frequent disorder among operators of chainsaws, pneumatic tools and hand grinders in cold climates[28]. Up to half of the exposed workforce can be affected.

History

Loriga first described the disorder in Italian marble-quarry workers in 1911. Six years later, this was followed by a description in sandstone cutters in Indiana, USA.

Epidemiology

Prevalence studies have suggested a relationship between symptoms and degree of exposure. This varies, however, with the type of tool and the work process involved. From 1972 to 1990, the prevalence amongst Finnish lumberjacks fell from 40% to 5%. This was attributed to a reduction in the weight and acceleration-induced vibration of their chainsaws[29].

It has been suggested that vibration white finger does not occur in countries with a warm climate. However, this may reflect the absence of the cold that serves as a trigger for symptoms rather than the absence of vibration-induced vascular changes.

Pathogenesis

Vibrations between 30 and 300 Hz are most strongly associated with development of this disorder. While increased activity of the sympathetic nervous system is viewed as the major cause of vibration white finger, it seems probable that local factors are also important. Vibration-induced damage to endothelial vasoregulatory mechanisms with alteration in α-adrenoceptors and impaired release of nitric oxide have been described.

OCCUPATIONAL INFECTIONS ACQUIRED FROM ANIMALS OR HUMANS WITH CUTANEOUS MANIFESTATIONS			
Occupation	**Infection**	**Organism**	**Animals/other humans**
Healthcare Sex industry Laboratory worker	Herpetic whitlow	HSV	Humans
	Scabies	*Sarcoptes scabiei*	
	Syphilis	*Treponema pallidum*	
	AIDS	HIV	
Farmer Abattoir* worker Veterinarian	Orf	Parapoxvirus	Sheep, goats, reindeer
	Milker's nodule	Parapoxvirus	Cows
	Brucellosis	*Brucella suis, B. abortus, B. melitensis*	Pigs, cattle, sheep
Farmer Wool sorter Dock worker Butcher	Anthrax	*Bacillus anthracis*	Cattle, sheep, goats, buffaloes, camels
Fisherman Tropical fish keeper Fish market worker	Fish tank granuloma	*Mycobacterium marinum*	Fish
Butcher Abattoir worker Meat and fish packers	Butcher's warts	Human papillomavirus, primarily types 2 and 7	Humans
	Impetigo	*Staphylococcus aureus*	
	Erysipelas	Group A streptococci	
Fisherman Abattoir worker Farmer Butcher, cook Veterinarian	Erysipeloid	*Erysipelothrix rhusiopathiae (insidiosa)*	Shellfish, fish, birds and mammals (esp. pigs)
Fisherman	Cellulitis	*Vibrio vulnificus*	Salt water
Farmer Veterinarian	Tinea corporis, capitis, barbae due to zoophilic species	*Microsporum canis*	Cats, dogs
		M. nanum	Pigs
		Trichophyton mentagrophytes var *mentagrophytes*	Small mammals
		T. verrucosum	Cattle
		T. gallinae	Chickens

*Slaughterhouse.

Table 16.7 Occupational infections acquired from animals or humans with cutaneous manifestations. Laboratory personnel can also acquire primary cutaneous forms of dimorphic fungal infections. HSV, herpes simplex virus.

Smoking is known to contribute to the development of the disorder, presumably because of the vasoconstrictive effect of nicotine.

Clinical features

Onset may occur within 3 months of beginning work but more frequently it takes 2–3 years to develop. Typically, a white patch of skin develops in response to cold-induced vasospasm. It is well demarcated from surrounding areas. Reduction in sensation occurs because the touch receptors are unable to function without adequate blood supply and this results in reduced dexterity. Episodes cease upon rewarming, often with the development of reactive hyperemia. Although caused by vibrating tools, attacks are not usually triggered by work with the vibrating tool.

The condition is graded according to the severity and frequency of symptoms, starting on the tips of the fingers (stage 1) and spreading to affect the whole digit (stage 3). In the most severe form, there are trophic changes and ulceration (stage 4). To aid in the diagnosis, finger skin temperature and finger systolic blood pressure can be measured in response to cold exposure, but the results are not discriminatory.

Pathology

The histologic features of vibration white finger include a significant reduction in the number of unmyelinated nerve fibers containing the neuropeptide calcitonin gene-related peptide (CGRP). There also may be hypertrophy of arterial smooth muscle. However, histology is not routinely utilized in the diagnosis of vibration white finger.

Differential diagnosis

In contrast to the symmetric distribution seen in Raynaud's disease, in vibration white finger the blanching is asymmetric and occurs on those digits most exposed to vibration; the thumbs are usually spared. However, Raynaud's phenomenon can also result from repeated occupational trauma, particularly in those who use tools that require a squeezing action, e.g. farmers and mechanics.

The hypothenar hammer syndrome results from occlusion of the ulnar artery as a consequence of repeated trauma to the palms and may be misdiagnosed as Raynaud's phenomenon.

Treatment

The prognosis for affected individuals is good: the disease regresses upon cessation of exposure. This is particularly true in the early stages, provided there are no other environmental or constitutional factors contributing to the disorder. As a consequence, no specific treatment may be required other than avoidance[30]. Therapeutically, topical nitroglycerin ointment or sustained-release glyceryl trinitrate patches are effective, but the condition relapses upon withdrawal. Various systemic agents used for Raynaud's disease, e.g. calcium channel blockers, have also been used for symptom control.

Infections

Many occupations, particularly those involving contact with animals, are associated with exposure to infectious agents. For example, individuals with occupations that involve wet work combined with rough physical conditions, such as butchers, slaughterhouse workers, and meat and fish packers, commonly develop infections with pyogenic bacteria and human papillomavirus (butcher's warts) through cuts and abrasions. Epidemics of methicillin-resistant *Staphylococcus aureus* infection have also occurred in professional football players in the US and these outbreaks are often difficult to control[31].

In the metal working industry, staphylococcal folliculitis can develop as a result of exposure to contaminated work materials such as coolant fluid. In addition, outdoor workers are exposed to environmental pathogens both by direct contact or implantation with soil or plants (e.g. mycetoma, chromomycosis) as well as following inoculation, most commonly via insect bites (e.g. Lyme disease, tularemia, typhus, spotted fevers).

Common infections may also occur more frequently as a result of environmental factors in the workplace. Increased humidity may lead to bacterial and fungal infections (due to dermatophytes or *Candida* spp.) in flexural body sites along with maceration of the skin. Pitted keratolysis caused by *Corynebacterium* spp. or *Micrococcus sedentaris* occurs on the soles in association with the use of occlusive footwear.

The main infectious organisms related to specific occupations are summarized in Table 16.7. Further information on these infections[32] can be obtained by reference to the relevant chapter in this book (Section Twelve).

ACKNOWLEDGMENT

I am grateful for the significant contribution of Peter Friedmann, MD, who collaborated in writing this chapter in previous editions.

Poaceae	Gramineae (Grass family)

Rhus ≠ Poison ivy or *Toxicodendron* (see text)
Non-immunologic urticaria = Toxin-mediated urticaria

INTRODUCTION

Plants and their products cause a variety of adverse cutaneous reactions, including the vast majority of cases of allergic contact dermatitis. This chapter describes the small minority of plants that cause such problems. (Reactions to members of the kingdoms Fungi and Protista are less common and will not be discussed here.) Plant dermatoses will be presented based on both their clinical features and the plant families that cause them. The major plants that cause allergic contact dermatitis (poison ivy, poison oak, chrysanthemums, and their relatives) are reviewed.

Plant reactions can be classified into urticaria (immunologic and toxin-mediated; see Chs 16 & 18), irritant dermatitis (mechanical and chemical), phototoxic dermatitis (phytophotodermatitis) and allergic contact dermatitis. Table 17.1 lists the most common plant reactions.

Botanical Aspects

To better understand the literature that addresses plant-related dermatoses, one should become familiar with basic botanical nomenclature[1].

Poison ivy as an example of nomenclature

It is occasionally necessary to alter the names of plants. As an example, the genus *Rhus* was once thought to be a cohesive, widespread genus with many species (including poison ivy, known previously as *Rhus radicans* or *Rhus toxicodendron*). Research in the 1950s and 1960s showed that poison ivy and its immediate relatives represented a distinct developmental lineage that should not be classified as *Rhus* but as a distinct genus[2]. The ICBN (International Code of Botanical Nomenclature) showed that the correct genus for the poison ivies and their relatives was *Toxicodendron*, and thus the correct scientific name for common poison ivy is *Toxicodendron radicans*.

Binomial nomenclature

The nomenclatural scheme of botany and zoology gives every entity two names: a generic name followed by a specific epithet, e.g. *Toxicodendron radicans* for poison ivy. It is customary to place after the binomial name a reference to the person (authority) who first published the specific epithet. The full binomial name of common poison ivy reads "*Toxicodendron radicans* (L.) O. Ktze". "(L.)" refers to Carl Linnaeus, who first named the plant with the specific epithet *radicans*. "O. Ktze" refers to Otto Kuntze, who transferred the epithet *radicans* from the genus *Rhus* into the genus *Toxicodendron*.

The genus, species and any infraspecific epithets are called the "minor categories of nomenclature" and these names are used when citing the name of a plant (Table 17.2). Genera are grouped into families, and if you know the family to which a plant belongs, you will probably be able to determine what kind of dermatologic manifestations (if any) it can cause.

Plant identification

Plant identification is difficult for the neophyte botanist (i.e. the vast majority of dermatologists). Therefore, the following recommendations should be followed to identify an unknown plant that you or your patient thinks is causing an eruption.

- *Collect specimens*. Herbs (low-growing plants with fleshy stems) should be collected in their entirety with their flowering and/or fruiting materials intact. For shrubs (low-growing plants with woody stems), the end of a branch (up to 60 cm) should be collected, with the leaves attached, and with any flowering or fruiting materials present. You may press plants before submitting them for identification, or you can put them into a plastic bag with *no water added* and submit them with data on (a) where that plant was collected and (b) a habitat description (cultivated in a garden, wild along a creek bank, in an open field, in high-elevation woodlands, etc.).
- *Involve a plant taxonomist*. Every US state and most Canadian provinces have an established mechanism for routine and rapid plant identification, and in most places the service is free. In suburban and rural areas, the county or regional agricultural extension service or farm advisors are knowledgeable about the procedures for immediate plant identification, and they have access to the regional herbaria. Urban areas have similar services, usually accessed through the urban horticulturist of the state extension service, or through the local garden center or botanical garden. In other countries, one should look for a nearby herbarium housing a collection of flora of the region. A botanist who works there would likely be willing to help identify an unknown plant.

Patch Testing

Details of patch testing are beyond the scope of this chapter (see Ch. 14). The reader is also referred to the excellent paper by Mitchell[3]. He rightly points out that identifying a plant causing a reaction in an individual patient is "a minor or even a major research exercise". He recommends collecting samples of all plants that a patient thinks could be causing his or her dermatitis. Then, all these plants must be identified by a plant expert. After that, one should start patch testing the patient to those plants known to cause allergic reactions. The most common allergenic plants and a proposed botanical screening tray are found in Table 17.3.

MOST COMMON PLANT DERMATOSES			
Binomial name	**Common name**	**Reaction type**	**Inciting agent**
Allium sativum	Garlic	ACD ICD Urticaria	Diallyldisulfide, allicin Probably the same Unknown
Alstroemeria spp.	Peruvian lily	ACD	Tulipalin A > B
Apium graveolens	Celery	Phytophotodermatitis	Furocoumarins, particularly in plants infected by "pink-rot" fungus
Capsicum annuum	Hot peppers	Erythema/edema/burning	Capsaicin
Citrus latifolia	Persian lime	Phytophotodermatitis	Furocoumarins
Dieffenbachia picta	Dumb cane	ICD	Calcium oxalate
Narcissus pseudonarcissus	Daffodils	ICD	Calcium oxalate
Opuntia spp.	Prickly pear and others	Mechanical irritant dermatitis	Glochids
Toxicodendron radicans	Poison ivy	ACD ICD (black-spot reaction)	Alkyl-catechols and resorcinols in urushiol
Toxicodendron diversilobum	Poison oak	ACD ICD (black-spot reaction)	Alkyl-catechols and resorcinols in urushiol
Tulipa spp.	Tulips	ACD ICD	Tulipalin A > B Coarse hair on bulbs
Urtica dioica	Stinging nettle	Urticaria	Histamine
X *Dendranthema* cultivars	Chrysanthemums	ACD	Sesquiterpene lactones

Table 17.1 Most common plant dermatoses. These are admittedly biased by the anecdotal and unscientific observations of the author. ACD, allergic contact dermatitis; ICD, irritant contact dermatitis.

THE BASIC NOMENCLATURAL SCHEME FOR PLANTS, USING COMMON POISON IVY AS THE EXAMPLE	
Kingdom	**Plantae (Metaphyta)**
Division	Magnoli<u>ophyta</u> (flowering plants)
Class	Magnoli<u>opsida</u> (dicots)
Subclass	Rosi<u>dae</u>
Order	Sapind<u>ales</u>
Family	Anacardi<u>aceae</u> (sumac or cashew family)
Genus	*Toxicodendron*
Species	*radicans*
(Author's name)	(L.) O. Ktze

Table 17.2 The basic nomenclatural scheme for plants, using common poison ivy as the example. The distinctive ending for each category is underlined. Note that the minor categories of nomenclature have no special endings.

MOST COMMON RELEVANT BOTANICAL ALLERGENS AND PROPOSED BOTANICAL SCREENING TRAY		
Plant name	**Plant family**	**Test solution**
Achillea millefolium (yarrow) *Arnica* spp. *Chrysanthemum* cultivars *Matricaria chamomilla* (chamomile) *Tanacetum parthenium* (feverfew)	Asteraceae	Compositae mix 6% in petrolatum
Cananga odorata	Anonaceae	Cananga (ylang-ylang) oil 2% in petrolatum
Citrus aurantium var. *amara*	Rutaceae	Neroli oil 4% in petrolatum
Lavandula spp.	Lamiaceae	Lavender (absolute) 2% in petrolatum
Lichens (fungus–alga dual organisms)		Lichen acid mix 0.3% in petrolatum
Melaleuca alternifolia	Myrtaceae	Tea tree oil 5% in petrolatum
Mentha spp.	Lamiaceae	Spearmint oil 5% in petrolatum
Pelargonium cultivars	Geraniaceae	Geranium oil (Bourbon) 2% in petrolatum
Rosa damascena	Rosaceae	Rose oil (Bulgarian) 2% in petrolatum
Santalum album	Santalaceae	Sandalwood oil 2% in petrolatum
Taraxacum officinale	Asteraceae	Dandelion 2.5% in petrolatum

Table 17.3 Most common relevant botanical allergens and proposed botanical screening tray. This list may be helpful to narrow down a potential botanical allergy in a patient who brings his or her specimens into your office to examine[4].

IMMUNOLOGIC CONTACT URTICARIA

Key features

- Atopic patients
- Frequent contact with fresh fruits and vegetables
- May present as urticaria, pruritus, burning or chronic dermatitis
- Oral allergy syndrome is mucosal contact urticaria to antigens similar to allergenic pollen
- Protein contact dermatitis represents an eczematous eruption arising from repeated urticarial reactions

Urticarial reactions due to plants are divided into immune and non-immune (toxin-mediated causes). Several cutaneous reaction patterns besides wheals are possible, e.g. erythema, dermatitis.

Epidemiology

Immunologic contact urticaria is fairly uncommon and classically affects individuals who are long-time food handlers and/or atopic. However, fully half of patients with "protein contact dermatitis" (an eczematous eruption arising from repeated urticarial reactions) are not atopic.

Examples of reported urticants include common vegetables, fruits, herbs, nuts, shrubs, algae, lichens, trees and grasses. Perhaps all plants are capable of causing immunologic urticaria, but only the ones handled most frequently cause problems clinically (Table 17.4). Celery (*Apium graveolens*) is the plant most likely to cause a generalized urticarial or anaphylactoid reaction.

SOME OF THE MANY PLANTS IMPLICATED AS CAUSES OF IMMUNOLOGICALLY MEDIATED URTICARIA		
Binomial name	**Common name**	**Notes**
Actinida chinensis	Kiwi	
Agave americana	Century plant	
Allium cepa	Onion	
Allium sativum	Garlic	
Allium schoenoprasum	Chives	
Ananas comosus	Pineapple	
Apium graveolens	Celery	Most common cause of systemic contact urticaria syndrome
Brassica oleraceae capaitata	Cabbage	
Brassica oleraceae botrytis	Cauliflower	
Carum carvi	Caraway	
Cichorium endiva	Endive	
Cichorium intybus	Chicory	
Cinnamomum spp.	Cinnamon	
Cirsium spp.	Thistle	
Citrus limon	Lemon	
Citrus paradisi	Grapefruit	
Citrus sinensis	Sweet orange	
Coffea arabica	Coffee	
Cucumis melo	Melon	
Cucumis sativus	Cucumber	
Daucus carota	Carrot	
***Dendranthema* spp.**	Chrysanthemum	
Ficus carica	Fig	
Foeniculum vulgare	Dill	
Hevea brasiliensis	Rubber tree	Numerous cross-reactors (see text)
Lactuca sativa	Lettuce	
Lycopersicon lycopersicum	Tomato	
Malus spp.	Apple	
Mangifera indica	Mango	
Medicago sativa	Alfalfa	
***Musa* spp.**	Banana	
Pastinaca sativa	Parsnip	
Petroselinum crispum	Parsley	
Prunus armeniaca	Apricot	
Prunus domestica	Plum	
Prunus persica	Peach	
Pyrus commuis	Pear	
Ricinus communis	Castor oil plant	
Solanum tuberosum	Potato	Most common cause in one review
Tulipa spp.	Tulip	
Zea mays	Corn	

Table 17.4 Some of the many plants implicated as causes of immunologically mediated urticaria. Those in bold have also been demonstrated to cause protein contact dermatitis. Any plant can probably cause urticaria, and this list probably reflects frequency of contact.

Pathogenesis (see Ch. 18)

The IgE-mediated release of vasoactive mediators from mast cells leads to local urticaria and, rarely, a "contact urticaria syndrome" that includes local wheals with systemic symptoms involving the nose, throat, lungs, gastrointestinal tract or cardiovascular system. The main factor seems to be histamine, but prostaglandins, kinins and leukotrienes probably augment the inflammatory response.

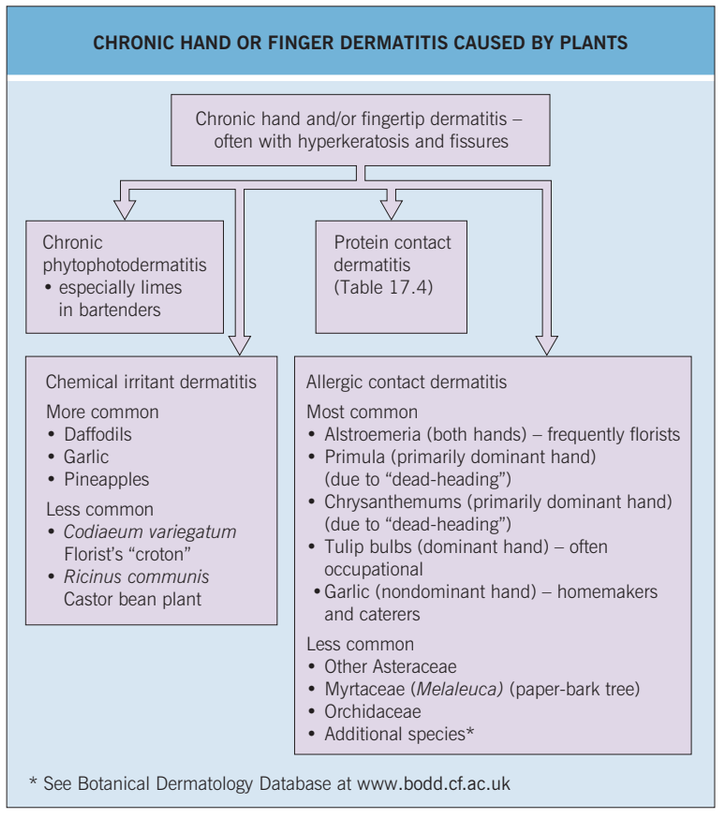

Fig. 17.1 Causes and types of chronic hand or finger dermatitis caused by plants.

Clinical Features

Within 30 minutes of contact with certain fresh foods, affected individuals experience pruritus, erythema, urticarial swelling, and even dyshidrotic-like vesicles. Sometimes, individuals experience only symptoms of pruritus, burning or tingling without objective findings[5]. Theoretically, any plant could cause contact urticaria, but continued exposure on the wet, macerated skin of food handlers has caused certain foodstuffs to be the most notorious offenders (see Table 17.4). Cooking, processing, deep-freezing or crushing fruits and vegetables generally reduces their allergenicity.

Some individuals become cross-sensitized to pollen and similar allergens in fruits or vegetables[6]. Upon eating a cross-reacting food, they experience sudden, IgE-mediated, oral cavity itching, stinging and pain. Edema of the lips, tongue, palate and pharynx typically ensue as the "oral allergy syndrome" (OAS) progresses. Gastrointestinal symptoms and anaphylaxis are possible if enough allergens are ingested. As an example, 70% of European patients with immediate hypersensitivity to birch pollen develop OAS while eating apples, pears, cherries, peaches, plums, apricots, almonds, celery, carrots, potatoes, kiwis, hazelnuts or mangoes. Pollen-associated foods are often, but not always, edible when heated.

The term "protein contact dermatitis" is used to describe a chronic dermatitis in which patch tests are typically negative but prick tests to large protein allergens are positive[7]. Patients develop a chronic dermatitis that acutely urticates within minutes of contact with the offending allergen. There are multiple mechanisms by which plants can cause chronic hand and fingertip eczema (Fig. 17.1).

Differential Diagnosis and Pathology

See Toxin-mediated (Non-immunologic) Contact Urticaria and Chs 16 & 18.

Treatment

Prevention is the preferred form of "treatment", but oral antihistamines are sometimes helpful. Parenterally administered epinephrine (adrenaline) is required for anaphylactic reactions.

TOXIN-MEDIATED (NON-IMMUNOLOGIC) CONTACT URTICARIA

Key features

- Anyone can be affected
- Stinging nettles (*Urtica* spp.) are most common cause
- Reaction can be subjective only
- Plants contain histamine, serotonin and acetylcholine within sharp hairs

History

Plants causing toxin-mediated urticaria have been used since antiquity as counterirritants in folk medicine. *Urtica dioica* parts have been used to produce homemade diuretics. Stem fibers were even used to make cloth until the early parts of the twentieth century. Native Americans used *U. dioica* subsp. *gracilis* to treat rheumatism, stomach upset, childbirth, paralysis, fevers, colds and tuberculosis.

Epidemiology

Members of the family Urticaceae cause the majority of plant-induced contact urticaria. Because all persons exposed to the toxins develop urticaria, toxin-mediated urticaria is far more common than immunologic urticaria. Because very few affected people seek medical attention, the true incidence of toxin-mediated urticaria is unknown. The most common culprit in the US is the stinging nettle (*Urtica dioica*) (Fig. 17.2A). It is now widely scattered throughout the northern hemisphere (except in lowland tropical areas), especially in moist woods, roadsides and on waste land. Other common urticating plants are listed in Table 17.5.

Pathogenesis (see Ch. 18)

Inciting plants possess sharp hairs (trichomes) on leaves (Fig. 17.2B) and stems (Fig. 17.2C). The proximal silicaceous hair is attached to a distal calcified portion that possesses a terminal bulb. When rubbed against, the bulb dislodges to reveal a beveled, hypodermic needle-like silicaceous hollow (Fig. 17.2D). These hollows release irritant chemical cocktails (histamine, acetylcholine, serotonin) that supposedly act as a defense mechanism against herbivores.

Clinical Features

Wheals achieve maximal size between 3 and 5 minutes after contact, and erythema, burning and itching last for 1–2 hours. A persistent tingling sensation may last 12 hours or more.

Reactions to stinging nettle pale in comparison to those elicited by members of the *Dendrocnide* genus of the Urticaceae family. Found mostly in eastern Australian rain forests, these trees grow up to 40 m in height. Young shoots are covered with stiff stinging hairs. Severe urticaria from these may last for weeks, and contact with water or cold objects reactivates the urticaria. Severe, intermittent, stabbing pains may follow the course of lymphatics. Many equine deaths and one human death due to contact with *Dendrocnide* have been documented.

Pathology (see Ch. 18)

Five minutes after contact with *Urtica dioica*, dermal edema and telangiectasias with or without mild spongiosis are seen. At 12 hours, the edema resolves but vasodilation persists. Some patients develop spongiosis plus neutrophilic and/or lymphocytic infiltrates. Mast cells are observed within the papillary dermis at 12 hours, but not at 5

THE MOST COMMON PLANTS CAUSING TOXIN-MEDIATED URTICARIA

Family	Genus	Species	Notes
Urticaceae (nettle family)	*Urtica*	*dioica, urens, pilulifera*	Stinging nettles – worldwide
	Laportea	*canadensis*	"Wood nettle", 5-foot-tall perennial herb – NE USA
	Dendrocnide	*gigas, moroides, photinophylla*	Potentially deadly stinging trees – eastern Australian rainforests
Euphorbiaceae (spurge family)	*Acidoton*	*urens*	Tropical Americas
	Cnidosculus	*stimulosus*	Spurge nettle – SE USA
		other species	Spurge nettles of tropical Americas
Hydrophyllaceae (water-leaf family)	*Wigandia*	*caracasana, urens*	Large-leafed shrubs – tropical Americas

Table 17.5 The most common plants causing toxin-mediated urticaria[8].

minutes[9]. Although histamine, acetylcholine and serotonin explain the early reaction (triple response of Lewis), they do not account for the persistent paresthesias.

Differential Diagnosis (see Ch. 18)

Although the evaluation of such patients is difficult, office testing of suspected allergens or toxin-containing plants may assume one of seven methods[5]. The most sensitive tests for immunologic contact dermatitis are the prick and scratch-chamber tests. For the scratch-chamber test, a 5-mm scratch is made on the back or forearm. Test material is applied and occluded with a Finn chamber for 15 minutes. The site is examined following Finn chamber removal and every 15 minutes for an hour. After reading, the chamber can be replaced for 48 hours to test for delayed hypersensitivity.

The method of choice for diagnosing toxin-mediated urticaria is the open application test: 0.1 ml of the suspected urticant is spread on a 3 × 3 cm area of skin. Dilution series are often used. The sites are observed every 10–15 minutes for an hour. Maximal erythema and edema typically occur 30–40 minutes after application. Test sites should be examined at 24 hours for irritant reactions.

For unusual plant products, 10–20 controls should be tested so that toxin-mediated urticaria and irritant dermatitis can be excluded as causes. Serologic tests such as the radioallergosorbent test (RAST) usually do not convey as much information as prick or scratch-chamber tests.

Treatment

Most stings are benign, self-limited, and require no treatment. Spines may be removed via glue or "sticking plaster" plus gauze as described in the next section. Topical agents, e.g. pramoxine, or oral analgesics may provide some relief of symptoms.

MECHANICAL IRRITANT DERMATITIS

Key features

- Large spines and thorns cause penetrating injuries and secondary infection
- Smaller emergences (glochids) act like small fishhooks and embed in skin
- Prickly pears are a cause of glochid dermatitis

Epidemiology

Mechanical irritant dermatitis can affect anyone. Most cacti and several other plants can inflict mechanical injury by large (spines) or small (glochids) emergences. Generally, the amount of damage to the skin is inversely proportional to the size of the emergence. Many of the plant families and genera that cause mechanical irritant dermatitis are found in Table 17.6.

Pathogenesis

Whereas cacti possess large spines, the smaller glochids cause more notorious dermatologic problems. The glochids – tufts of hundreds of short, barbed or hooked hairs – arise from pincushion-like structures named "areoles", from which larger spines, if present, also arise. The minute, barbed glochids (Fig. 17.3A) often point outward and backward like a fishhook and produce considerable irritation and pruritus after penetrating the skin. As an example, *Opuntia microdasys* ("polkadot cactus", "bunny ears cactus"), a house and garden favorite, bears disarming-appearing "fluffy" clusters of 100–200 glochids on its pads (see Fig. 17.13).

Clinical Features

Glochid dermatitis from prickly pears (*Opuntia* spp.) is a well-recognized entity[10]. One such species, *Opuntia ficus-indica* (the Indian or Barbary fig), causes "Sabra dermatitis". This pruritic, papular eruption occurs among prickly-pear pickers and those who unwarily stumble into burglar-proof hedges of this native Mexican plant (Fig. 17.3B). The fruit contains the highest concentration of glochids (Fig. 17.3C), and the latter can cause an eruption that is easily confused with fiberglass dermatitis or even scabies. There are some 200 species of *Opuntia*, all native to the New World, ranging from New England and British Columbia southward to the Straits of Magellan. Numerous species have become established in the Mediterranean basin, South Africa, South Asia and Australia.

Glochids may be transferred from clothing to other individuals. The prickly pear should be picked only when wetted, and picking should cease when it is windy, as the glochids can become airborne. As with the urticating plants, irritant hairs and thorns defend against plant-eaters.

Penetrating injuries can also lead to inoculation of microorganisms. *Clostridium tetani* and *Staphylococcus aureus* can be introduced by spines and thorns, and grasses, sphagnum moss and rose thorns can transmit *Sporothrix schenckii*. Atypical mycobacteria such as *Mycobacterium kansasii* (blackberries), *M. marinum* (cactus spines) and *M. ulcerans* (spiky tropical vegetation) have also added infectious insult to mechanical injury.

Treatment

Many intriguing methods of removing glochids have been recommended. Warm wax, glue, sticking plaster, facial gels and masks, or cellophane tape are applied to the affected area and the glochids are then quickly ripped off[11]. In perhaps the only controlled study (in rabbits), glochids (of *Opuntia ficus-indica*) were most effectively removed by first detaching the larger clumps with tweezers and then applying glue and gauze to the affected area. After the glue dried, the gauze was grasped and peeled off, resulting in the removal of 95% of implanted glochids.

COMMON PLANTS KNOWN TO CAUSE MECHANICAL IRRITANT REACTIONS

Family	Genus species	Notes
Araliaceae	*Hedera helix*	Common ivy – leaf-borne stellate hairs detach as leaves age
Asteraceae	*Carduus* and *Cirsium* spp.	Thistles
Asteraceae	*Lactuca serriola*	Prickly lettuce
Boraginaceae	*Borago officianalis*	Borage – sharp, stiff leaf and stem hairs
Cactaceae	*Opuntia* spp.	Prickly pears; "Sabra dermatitis"
Liliaceae	*Tulipa* spp.	Coarse fibers on tulip bulb tunics cause irritant component of "tulip fingers"
Moraceae	*Ficus* spp.	Figs – abrasive bristles on leaves and fruit
	Morus spp.	Mulberries – abrasive bristles on leaves and fruit
Poaceae	Many spp.	Grasses – fine hairs, prickly spikes, and cutting leaf edges
Proteaceae	*Grevillea* spp.	Terminal, sharp points on leaves – Australia
Rosaceae	*Rosa* spp.	Thorns can cause penetrating injuries, tenosynovitis and foreign body granulomata
Rubiaceae	*Galium aparine*	"Goose-grass" – hooked prickles on fruit, stems, leaves
Scrophulariaceae	*Verbascum thapsus*	"Mullein" or "flannel-plant" – woolly hairs on leaves used as facial rubefacient
Sterculiaceae	*Fremontodendron* spp.	"California glory" possesses stiff, stellate hairs

Table 17.6 Common plants known to cause mechanical irritant reactions. Although numerous plants possess irritant appendages, some of the well-known ones are listed here.

Fig. 17.3 Prickly pears (*Opuntia* spp.) and their glochids. A Microscopic appearance of glochids from *Opuntia microdasys*. **B** Prickly pear (*Opuntia ficus-indica*) habit. **C** Prickly pear (*Opuntia ficus-indica*) fruit. Fine spines and glochids are visible. *Courtesy, Dirk Elston, MD.*

CHEMICAL IRRITANT DERMATITIS

Key features

- Calcium oxalate in daffodils is a major cause of plant-related irritant dermatitis in florists and horticulturalists
- Spurges (including poinsettias) contain irritant phorbol esters in latex
- Capsaicin in hot peppers affects cutaneous nerves, but not the skin

History

Chemical irritants derived from plants have been well known for centuries. Native Mexican Indians once used smoke from burning peppers (*Capsicum*) as a weapon against enemies. Latex from the Manchineel tree (*Hippomane mancinella*, Euphorbiaceae) was used by Caribbean people as poison for arrow tips. Approximately 2000 years ago, Dioscorides gave careful instructions for making pills from spurges (Euphorbiaceae) because of the severe skin and eye irritation that could ensue after contact with the latex.

Epidemiology

Several major plant families contain chemical irritants (Table 17.7). These include crystalline calcium oxalate and a wide range of chemicals (e.g. phorbol esters, saponins) dissolved or suspended in plant latex or specific organelles.

Pathogenesis, Clinical Features and Treatment

(see Ch. 15)

Members of many plant families contain chemical irritants (see Table 17.7), and one of the most common irritants is calcium oxalate. A typical calcium oxalate-containing plant, *Dieffenbachia picta* (Araceae), decorates millions of homes and public places. Upon contact with a moist surface, the leaves release the water-insoluble calcium oxalate. If

PLANTS MOST COMMONLY IMPLICATED IN CAUSING CHEMICAL IRRITANT DERMATITIS

Family	Binomial name	Common name	Irritant chemical (location)
Agavaceae	*Agave americana*	Century plant	Calcium oxalate, saponins (latex throughout plant)
Alliaceae	*Allium sativum*	Garlic	Thiocyanates (bulbs)
Amaryllidaceae	*Narcissus* spp.	Daffodil, narcissus	Calcium oxalate (stems, leaves, bulbs)
Anacardiaceae	*Anacardium occidentale*	Cashew tree	Cashew nut shell oil (mesocarp [middle layer] of nut shell [irritant and allergenic])
Araceae	*Dieffenbachia picta*	Dumb cane	Calcium oxalate (leaves and fruits)
	Philodendron spp.	Philodendron	Calcium oxalate (leaves)
Brassicaceae	*Brassica nigra*	Black mustard	Thiocyanates (all parts)
	Raphanus sativus	Radish	
Bromeliaceae	*Ananas comosus*	Pineapple	Bromelain (stem > fruit) Calcium oxalate (all parts)
Euphorbiaceae	*Codiaeum variegatum*	Florist's "croton"	Phorbol esters (latex in stems, leaves, fruits)
	Euphorbia esula	Leafy spurge	
	Hippomane mancinella	Manchineel tree	
	Euphorbia pulcherrima	Poinsettia	
Liliaceae	*Hyacinthus orientalis*	Hyacinth	Calcium oxalate (bulbs)
Polygonaceae	*Rheum rhaponticum*	Rhubarb	Calcium oxalate (leaves)
Ranunculaceae	*Ranunculus* spp.	Buttercups	Protoanemonin (freshly damaged plant parts)
	Aquilegia spp.	Columbine	
	Caltha spp.	Marsh-marigold	
Solanaceae	*Capsicum annuum*	Hot pepper	Capsaicin (placenta of fruit [no dermatitis, only erythema, edema, burning])

Table 17.7 Plants most commonly implicated in causing chemical irritant dermatitis.

plant parts are chewed, salivation, burning, mucosal edema, and blistering ensue. This causes hoarseness or aphonia (hence "dumb cane"). Treatment includes parenteral corticosteroids, antacid mouthwashes, and analgesics. Antihistamines are of no benefit. The pain and edema wane over 4–12 days.

Calcium oxalate enhances the irritancy of other chemicals, such as the proteolytic enzyme bromelain (bromelin), found in pineapples. Pineapple workers often develop cracks, fissures, fingerprint loss, and microhemorrhages on their hands. Calcium oxalate-induced microabrasions allow bromelain to exert its proteolytic effect on dermal blood vessels. Gloves (e.g. nitrile) can be worn for protection.

Bulb dermatitis, though less dramatic, is more common[12]. Daffodil sap contains calcium oxalate and causes "daffodil itch", probably the most common dermatitis in florists. Dryness, scaling, fissures and erythema affect the fingertips, hands and forearms. Bulbs of several other plants (e.g. tulips, hyacinths) are also common causes of dermatitis; these include garlic, the allergens from which are also irritants at high concentrations (Fig. 17.4).

Spurges (Euphorbiaceae) are notorious for their irritant latex but derive their common name from the purgative properties of the seeds. The milky latex contains irritant phorbol esters, diterpenes and/or daphnane esters that may cause a painful, blistering dermatitis and even temporary blindness if the latex contacts the eye. The best-known family member, the poinsettia (*Euphorbia pulcherrina*), possesses a mildly irritating latex.

Buttercups (Ranunculaceae) contain the glycoside ranunculin that is converted to protoanemonin after plant injury. Protoanemonin causes severe, linear vesiculation that may resemble phytophotodermatitis, but without causing subsequent hyperpigmentation. Because protoanemonin rapidly polymerizes to the non-irritant anemonin, only freshly damaged plants cause reactions.

"Chili burns" or "Hunan hand syndrome" occurs commonly among those who remove the skins from large batches of roasted chili peppers (*Capsicum annuum*). The active principle is capsaicin, and when applied to the skin, it depolarizes nerves, causing vasodilation, smooth muscle stimulation, glandular secretion, and sensory nerve activation. Because only nerves are affected, dose-related cutaneous burning, irritation and erythema ensue without blistering. Symptoms may be delayed and last hours to days. The best home remedy for chili burns is handwashing with soap and water followed immediately by 1 hour of immersion in vegetable oil to help remove the fat-soluble capsaicin.

The "century plant" (*Agave americana*) grows in temperate, subtropical and tropical climates and forms rosettes of tough, sword-shaped leaves that often possess spiny margins. There was one report of ten Israeli soldiers who deliberately rubbed broken leaves on their skin and elicited a severe irritant dermatitis with erythema, confluent papulovesicles, and pustules[13]. The marked pruritus and stinging that follows within 5 minutes of contact with agave leaf is thought to be caused by latex-derived calcium oxalate crystals and saponins. Patients often develop a sore throat, headache, diarrhea and/or myalgias. Lesions can be purpuric.

PHYTOPHOTODERMATITIS

Key features

- Non-immunologic – it can happen to anyone
- Need UVA light plus topical or oral contact with photosensitizer
- Furocoumarins (psoralens and angelicins) are most common agents
- Limes, celery and rue are most common causes
- Potential photosensitizing plants of the family Apiaceae can be identified by umbel flower structure

Phytophotodermatitis connotes phototoxic reactions consisting of erythema (with or without blistering) and delayed hyperpigmentation. Phototoxicity implies an inflammatory reaction caused by the combination of a topical or oral photosensitizing agent followed by exposure to the appropriate wavelength of UV radiation. Because this is not an immunologic reaction, no prior sensitization is necessary and anybody can be affected.

Fig. 17.4 Erythematous, burning, edematous scrotum from irritant reaction after applying garlic (*Allium sativum*) to treat a "rash". *Courtesy, Martin Giandoni, MD.*

IMPORTANT MEMBERS OF THE APIACEAE FAMILY (FORMERLY UMBELLIFERAE) IMPLICATED IN PHOTOTOXIC REACTIONS

Scientific name	Common name(s)	Comments
Ammi majus	False Bishop's weed	Historical and economic importance
Angelica archangelica	Angelica	Candied portions used in cakes; characteristic Benedictine flavor
Angelica sylvestris	Wild angelica	
Anthriscus sylvestris	Cow parsley, wild chervil	"Strimmer dermatitis"*
Apium graveolens	Celery	Infected plants have more psoralens
Foeniculum vulgare	Fennel	
Heracleum laciniatum	Tromsø palm	Scandinavia
Heracleum lanatum	Cow parsnip	North America
Heracleum mantegazzianum	Giant Russian hogweed, wild rhubarb, hogweed tree	Giant weed naturalized across UK, Canada, US
Heracleum sphondylium	Common hogweed	Main cause of "strimmer dermatitis"*
Pastinaca sativa	Parsnip	Furocoumarins in leaves, roots, stem, fruits
Petroselinum crispum	Parsley	

*Strimmer = string-trimmer garden tool for cutting weeds.

Table 17.8 Important members of the Apiaceae family (formerly Umbelliferae) implicated in phototoxic reactions.

History[14]

As early as 2000 BC, vitiligo patients were encouraged to lie in the sun after picking *Ammi majus* from the Nile River valley and rubbing the juice on their skin. By 1400 BC, Indian doctors were using boiled extracts of *Psoralea corylifolia* (babchi or scurf-pea), from which we derive the term "psoralen". In 1897, Apiaceae-induced dermatitis was first reported, but the need for concomitant UV radiation went unnoticed. In 1942, Klaber introduced the term "phytophotodermatitis" to emphasize that a combination of plants and light is required for the reaction.

Epidemiology

Members of two plant families are the most common causes of phytophotodermatitis (Tables 17.8 & 17.9): Apiaceae (formerly Umbelliferae) and Rutaceae (includes the citrus fruits). Members of the mulberry family (Moraceae) and pea family (Fabaceae) also contain furocoumarins.

Apiaceae

Plants of the family Apiaceae cause more phytophotodermatitis than do plants of any other family (see Table 17.8). A distinctive floral umbel makes them easy to recognize: numerous small flowers are held in a simple umbel (a cluster of flowers on stalks of roughly equal length arising from a single point). Many small umbels can form "compound

PHOTOTOXIC MEMBERS OF THE FAMILY RUTACEAE	
Citrus aurantiifolia	Key lime
Citrus latifolia	Persian lime or seedless lime
Citrus aurantium	Bitter orange
Citrus bergamia	Bergamot orange
Citrus limetta	Sweet lemon
Citrus limon	Lemon
Citrus sinensis	Sweet orange
Citrus paradisii	Grapefruit
Cneoridium dumosum	Coast spice bush, berry rue
Dictamnus albus	Burning bush, gas plant
Phebalium argenteum	Blister plant
Pelea anisata	Mokihana
Ruta graveolens	Rue (UK)

Table 17.9 Phototoxic members of the family Rutaceae.

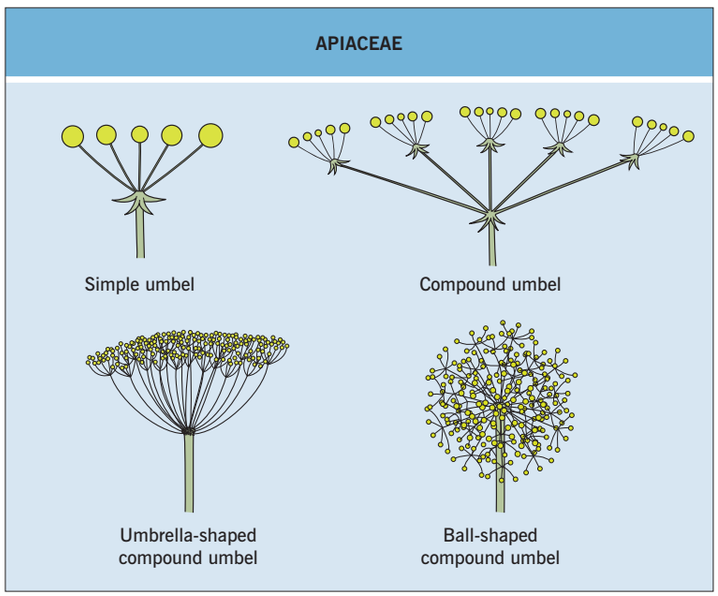

Fig. 17.5 Apiaceae. Compound umbels can be umbrella-shaped or ball-shaped.

umbels" (Fig. 17.5). Compound umbels may be umbrella-shaped or ball-shaped. The flower heads are sheathed at the base by one or more leaf-like bracts.

Heracleum sphondylium, common hogweed, is a major cause of phytophotodermatitis in Europe and North America. Once introduced into a new area, *Heracleum* species tend to grow out of control. The black seeds and leaves contain the highest concentrations of psoralens. The greatest threat from *Heracleum* occurs in the autumn, when the weather favors the development of many seeds. The hollow stems of *H. mantegazzianum and H. laciniatum* (Tromsø palm, Norway) used as peashooters and trumpets have caused perioral blisters in children.

Rutaceae

The Rutaceae family includes plants from tropical (*Citrus* spp.), subtropical, and temperate (*Ruta* spp.) climates and is the second most common family of plants reported to cause phytophotodermatitis (see Table 17.9). Many Rutaceae grow as shrubs or small trees, with flowers having four or five sepals (modified leaves that comprise a calyx) and petals as well as fleshy fruit. A major cause of phototoxic reactions in the US, especially in Florida and the desert southwest, is the rind of the Persian lime, *Citrus latifola*. Bartenders commonly develop vesicles on their index and middle fingers from squeezing limes to make cocktails. Although limes are notorious for this, even the sweet orange, *Citrus sinensis*, can cause a phototoxic cheilitis after contact with the rind.

Ruta graveolens, garden rue, is a native sub-shrub of the Mediterranean area with a long history as a folk medicine remedy for urticaria, warts and erysipelas. Its taste and smell are incredibly bitter. Extracts of the plant have been used to repel biting insects. It is probably the most common cause of phototoxicity acquired in English gardens. This plant contains 5-MOP (5-methoxypsoralen; bergapten), 8-MOP (xanthotoxin) and angelicins.

Dictamnus albus, the gas plant or burning bush, exudes an aromatic oil that can be ignited briefly without harming the plant. It has become a common yard plant in the US and Canada, and it grows wild in central and southern Europe, eastern Siberia and northern China. The seed pods have high concentrations of both 5-MOP and 8-MOP.

Moraceae

The mulberry family includes *Ficus carica* (the fig tree). This Middle Eastern native has been widely cultivated throughout warm, temperate regions of the world. Psoralens and 5-MOP are found chiefly in the sap of leaves and shoots[15]. Furocoumarins are generally not found in ripe or unripe fruit[15].

Fabaceae (Leguminosae)

The main source of psoralens for treatment of vitiligo in India is *Psoralea corylifolia*. It has been used to treat vitiligo since 1400 BC, and its seeds are still used for this purpose.

Other families

Other plant families have been reported to contain furocoumarins and other photosensitizing chemicals, but none have been shown to cause clinical phytophotodermatitis except St John's wort (*Hypericum perforatum*). In 11 of 23 (48%) HIV-infected patients receiving systemic hypericin as a potential antiretroviral agent, severe cutaneous phototoxicity developed.

Pathogenesis

Furocoumarins include linear (psoralens) and angular (angelicins) tricyclic structures. The most severe reactions occur with 5-MOP (bergapten), originally isolated from *Citrus bergamia* (Rutaceae), the bergamot orange, and 8-MOP (xanthotoxin), first isolated from *Fagara xanthoxyloides* (Rutaceae).

The first phase of phytophotodermatitis is an acute, oxygen-dependent skin injury. By electronic microscopy, cytoplasmic vacuolization and membrane rupture of keratinocytes are observed immediately following UVA irradiation of psoralen-exposed skin. Within 2 hours, desmosomal plaques have detached and degenerated[16]. It is known that UVA has the ability to excite psoralens to form covalent monoadducts with pyrimidines and interstrand DNA cross-links (see Ch. 134). Psoralen-induced hyperpigmentation occurs via increased melanocyte mitosis and dendricity, melanocyte hypertrophy, increased tyrosinase activity, and change in the size and distribution of melanosomes.

Furocoumarins appear necessary to defend plants from fungal attack. *Apium graveolens*, fresh celery, contains 10–100 mcg/g wet weight of psoralens in healthy plants, but may have 320 mcg/g when infected with *Sclerotinia sclerotium* (pink-rot disease). Disease-resistant celery unfortunately possesses high levels of furocoumarins concentrated in the leaf sap and stem sap.

Clinical Features

Cutaneous sensitivity to UV light peaks 30–120 minutes after contact with furocoumarins. Bizarre configurations of erythema, edema and bullae appear after 24 hours and peak at 72 hours (Fig. 17.6). These painful, non-pruritic reactions are more often seen in mid to late summer, when psoralen concentrations are highest in the offending plants and more skin is exposed to direct sunlight. To avoid misdiagnosis as poison ivy dermatitis, physicians must note that the initial erythematous and bullous reaction only occurs in sun-exposed areas. Hyperpigmentation appears 1–2 weeks later and lasts months to years. Occasionally, low-dose UVA and/or psoralens cause hyperpigmentation without a preceding vesicular or erythematous eruption (Fig. 17.7; see

Fig. 17.6 Bullous phase of phytophotodermatitis. There was associated burning but no pruritus, and the linear bullae were replaced by hyperpigmentation. *Courtesy, Jean L Bolognia, MD.*

Fig. 17.7 Phytophotodermatitis. Streaky hyperpigmentation due to contact with lime followed by exposure to sunlight. *Courtesy, Anthony J Mancini, MD.*

Ch. 67). Involved areas may remain hypersensitive to UV radiation for years. Wet skin, sweating and heat enhance the phototoxic response.

Furocoumarin exposure occurs in many settings (Table 17.10). Modern power tools such as a weed-whacker or strimmer (string trimmer) deliver a buckshot spray of weeds that may include Apiaceae members. "Strimmer dermatitis" appears 12–24 hours later as red, irregular macules and papules, not bizarre linear and angular streaks, on the anterior chest and arms. Implicated species, especially in Europe, include hogweed (*Heracleum sphondylium*), giant hogweed (*Heracleum mantegazzianum*) and cow parsley (*Anthriscus sylvestris*).

Berlock (or berloque) dermatitis comes from the German word "berlock" or the French word "berloque", meaning a trinket or charm. It described pendant-like streaks of pigmentation on the neck, face, arms or trunk after the application of colognes containing 5-MOP.

Phytophotodermatitis has been mistaken for child abuse. If parents touch plants or fruit containing furocoumarins, they can transfer them to their children. A week or more later, these children may develop digitate hyperpigmentation in sun-exposed sites of parental hand contact. Multiple hues are not seen in the skin lesions, as would be expected in healing bruises.

Xanthotoxin (8-MOP) is the most effective photosensitizer in limes, and it is over ten times more plentiful in the rind than in the pulp. Non-dermatologists frequently misdiagnose lime-induced phytophotodermatitis. In addition to child abuse, misdiagnoses include allergic contact dermatitis (e.g. poison ivy), impetigo, cellulitis, and infectious lymphangitis.

RISK ACTIVITIES FOR PHYTOPHOTODERMATITIS	
Cosmetics	Tan promoters or perfumes containing bergamot oil (berlock dermatitis) or a fig leaf decoction
Fruit and vegetable processing	Canning celery or stocking celery in grocery stores Making lemonade or limeade, especially if selling it outside Squeezing lime juice for margaritas and other drinks or guacamole
Gardening	Brushing against *Dictamnus* spp. ("gas plant/burning bush") (US, Europe, N China) or *Ruta* (UK) Cultivating celery, parsnip or parsley Clearing weeds with a "weed-whacker" (US) or "string trimmer" (UK) Pruning or harvesting figs Growing *Angelica* for herbal medicine (Korea), cake decorating (when candied), tonic and flavoring in wines (esp. Benedictine, US)
Hiking	Through fields and riverbanks (*Heracleum* spp.) (Pacific NW, Europe) Rolling in meadows Hiking in southern California and Baja California (*Cneoridium dumosum*, coast spice bush [Rutaceae])
Ingestion	Ingestion of massive quantities of psoralens (esp. celery) before UVA tanning Ingestion of *Chlorella* (an alga) (Japan)
Medications	Excessive exposure to UV radiation after taking or applying psoralens for PUVA Application of rue (*Ruta* spp.) as an insect repellant
Play	Making peashooters with *Heracleum* spp. Playing among rue bushes or Apiaceae Fighting with parsnips/celery Wearing leis of *Pelea anisata* (Hawaii)

Table 17.10 Risk activities for phytophotodermatitis.

Phototoxicity following the ingestion of naturally occurring psoralens is rare. Two fair-skinned "volunteers" ate 20 stalks of celery, 25 dried figs and 250 g of parsley, yet they developed no reaction after 30 minutes' exposure to midday sun. Oral ingestion of large quantities of celery broth 1–2 hours before UVA tanning or PUVA treatment has caused severe burns.

Celery harvesters and canners are at high risk for developing phytophotodermatitis. Only 1 mcg of 8-MOP/cm^2 of skin is necessary to produce blisters after 2.4 J/cm^2 (less than 10 minutes of summer sunlight in Colorado)! In one study of 320 randomly selected Michigan celery workers, 163 (51%!) displayed various stages of vesicular and bullous dermatitis on the fingers, hands and forearms[17]. In this study, the authors could not induce phytophotodermatitis except by using celery infected with pink-rot disease (*Sclerotina sclerotiorum*). The furocoumarins are concentrated in the leaf sap and stem sap.

Phytophotoallergic Contact Dermatitis

At least one photoallergic reaction to a plant (*Parthenium hysterophorus*) has been proven. Photoallergy due to plants is exceedingly rare.

Treatment

Prevention is the best treatment for phytophotodermatitis. Known furocoumarin-containing plants should not be planted near play areas. When using weed-whackers or strimmers, operators must cover their extremities. If one has been in contact with a suspected phototoxic plant, prompt washing with soap and water may prevent a reaction.

ALLERGIC CONTACT DERMATITIS (see also Ch. 14)

Key features

- Poison ivy/poison oak plant identification
  - Compound leaves with three leaflets
  - Flowers or fruit arise from axillary position
  - Black dots of urushiol often present on leaves and fruit
  - Common poison ivy climbs by aerials roots with "hairs"

Epidemiology

Anacardiaceae

Members of the family Anacardiaceae cause more allergic contact dermatitis than do all other plant families combined. Most allergenic family members belong to the genus *Toxicodendron*, including poison ivy, poison oak and poison sumac.

Toxicodendron identification[18]

Toxicodendron leaves are compound, possessing three or more leaflets. The old saying about poison ivy, "Leaves of three; leave them be", refers to each leaf having three leaflets. Flowers and fruit arise in an axillary position in the angle between the leaf and the twig from which it arises (Fig. 17.8). In contrast, the flowers and fruit of *Rhus* arise at the end of a branch. The leaf stalk is enlarged at its origin from the supporting twig and leaves a "U"- or "V"-shaped scar after it falls off. Green fruit turn off-white when mature. Plants cling to trees via "hairy" aerial rootlets.

Toxicodendron oleoresin contains urushiol and the enzyme laccase. Laccase oxidizes urushiol at temperatures of 68–86°F and humidity of 75–85%. The black, oxidized, plastic-like polymer has great tensile strength and is insoluble. Therefore, black spots are commonly found on the leaves of plants. The "black-spot test" helps identify toxic Anacardiaceae, but performing it also increases one's likelihood of contracting a nasty dermatitis! Use a stone to thoroughly crush plant contents, especially the leaf stalks, between folds of white paper. Urushiol turns dark brown within 10 minutes and black by 24 hours.

Allergenic Anacardiaceae

As noted in Table 17.11, there are two species each of poison ivy and poison oak and one species of poison sumac listed that are common to the US (Fig. 17.9). Some of these have multiple subspecies. Poison oak and poison ivy are weeds that grow along roads, trails or streams; they possess three leaflets (sometimes five) per leaf (compound leaves). Poison sumac contains 7–13 leaflets per leaf (see Fig. 17.8). Young leaves are frequently red in color, and the mature fruit (drupes) are tan or cream colored and have no hairs (the young drupes will have hairs). Classically, poison ivy leaves have pointed tips and are ovate (widest point below the center). Poison oak leaves usually have rounded ends. Western poison oak has oval leaves, whereas Eastern poison oak has variable leaf appearances that can mimic white oak leaves.

Remember that the non-leaf portions of the plant can induce dermatitis, even in the winter. The "winter" shape of poison ivy on fence posts resembles "Medusa heads" that are identifiable while driving down the highway. Strongly suspect any vine climbing by aerial rootlets

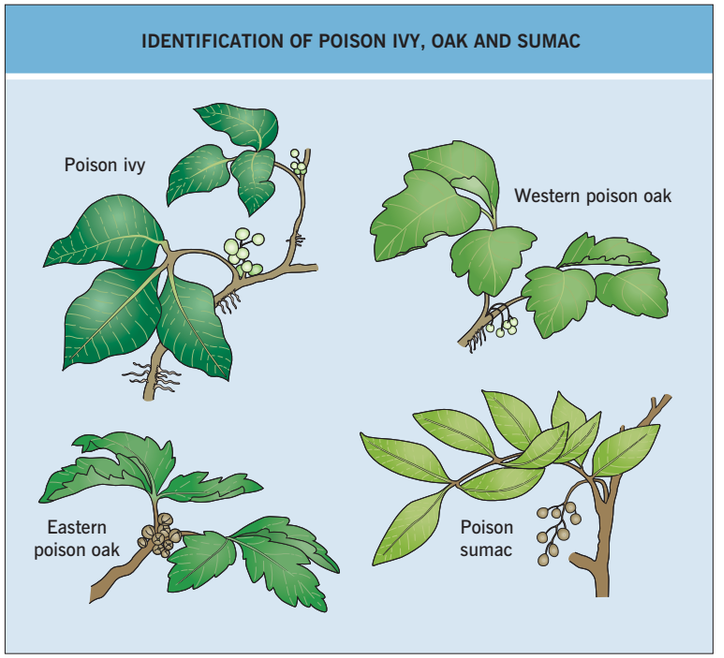

Fig. 17.8 Characteristic features useful for identifying poison ivy, poison oak and poison sumac. *With permission from the American Journal of Contact Dermatitis.*

MOST COMMON ALLERGENIC MEMBERS OF THE ANACARDIACEAE FAMILY AND MEMBERS OF TWO OTHER PLANT FAMILIES THAT ALSO CONTAIN URUSHIOL CROSS-REACTING CHEMICALS		
Binomial name	**Common name**	**Notes**
Toxicodendron radicans	Common or Eastern poison ivy	Eastern half of USA Climbs trees with aerial rootlets Some subspecies in Mexico, Japan, China
Toxicodendron rydbergii	Northern or Western poison ivy	Western half of USA (except CA) and northern border states Non-climbing shrubs
Smodingium argutum	South African poison ivy	South Africa
Toxicodendron toxicarium	Eastern poison oak	Southeast USA
Toxicodendron diversilobum	Western poison oak	Pacific Coast of USA Usually a shrub but can climb
Toxicodendron vernix	Poison sumac	Eastern third of USA Not a weed Grows in standing water
Anacardium occidentale	Cashew nut tree	Tropical Americas
Mangifera indica	Mango tree	Tropics
Metopium toxiferum	Poisonwood tree	Caribbean basin
Semecarpus anacardium	Indian marking nut tree	Southeast Asia, Pacific Islands, Australia
Toxicodendron verniciflua	Japanese lacquer tree	Japan and China
Gluta renghas	Rengas tree	Malaysia lumber source
Schinus terebinthifolius	Brazilian pepper tree or Florida holly	Native to South America, but now a problem in southern Florida, Hawaii, Central America, the Pacific Rim and Pacific Islands
	CROSS REACTORS	
Ginkgo biloba (Ginkgoaceae)	Ginkgo tree	Cultivated worldwide in temperate climates – only the seed coat is allergenic
Grevillea spp. (Proteaceae)	Spider flower, silk oak, Hawaiian tree, kahili tree	Widely cultivated Australian natives

Table 17.11 Most common allergenic members of the Anacardiaceae family and members of two other plant families that also contain urushiol cross-reacting chemicals.

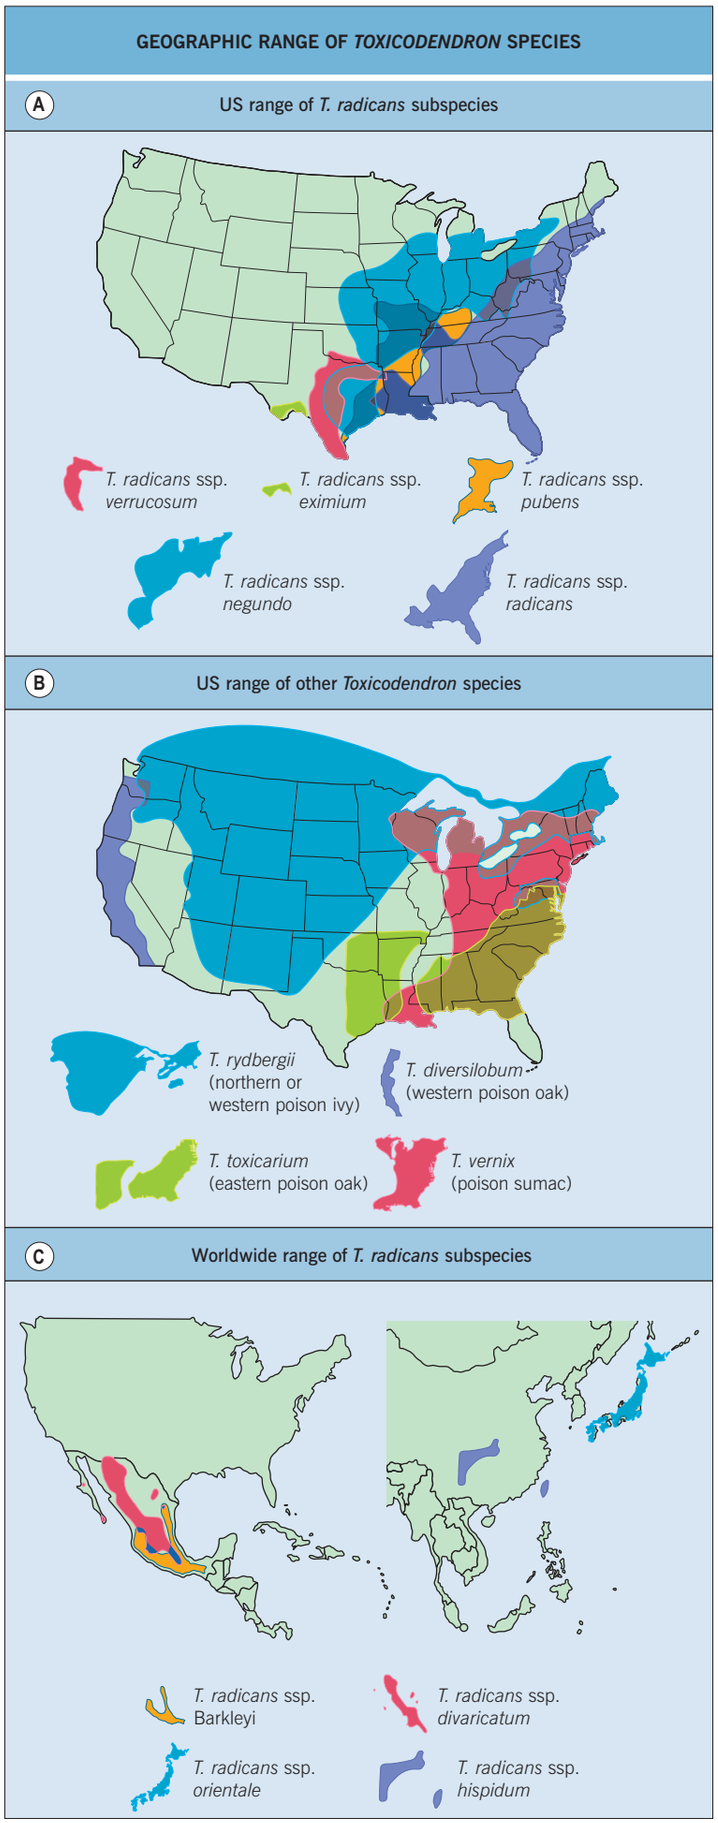

Fig. 17.9 Geographic range of *Toxicodendron* spp.

connected at the bottom to a tree or log. In snow, *T. rydbergii* grows so low to the ground that the upward, tine-like branches may be the only clue to its identification.

The cashew nut tree (*Anacardium occidentale*) grows in the tropics worldwide. The nuts contain an oily, brown juice between the two layers of its shell. The concentration of phenols in the nutshell and bark is so high that contact causes an immediate vesicant reaction. Africans have used cashew nut shell oil in ritual scarification. Any part of the tree, except the nut, can cause dermatitis.

Mango (*Mangifera indica*) is the most popular fruit tree in tropical and subtropical America, and some 35 species grow throughout Southeast Asia. The leaves, bark, stems and fruit skin contain sensitizing resorcinols. Peeling the fruit before eating it typically prevents allergic contact dermatitis, although allergy to mango pulp has been demonstrated; the pulp allergens appear to be distinct from the resorcinols. Hawaiian natives rarely react to mango, perhaps because early oral exposure induces immunologic tolerance.

The Florida holly (*Schinus terebinthifolius*, Brazilian pepper tree) is probably the most common cause of allergic contact dermatitis in southern Florida. The sap and crushed berries possess a variety of sensitizing phenols.

Although the mango, cashew and Brazilian pepper trees are incredibly common throughout Latin America, dermatitis to them there is rare, in contrast to the frequent reactions developed by US residents. The main allergens in toxicodendrons are catechols, whereas those in the listed trees are resorcinols. Of note, catechols possess greater allergenicity than resorcinols. Early cutaneous exposure to catechols may allow cross-reactions to other Anacardiaceae, whereas early oral exposure to resorcinols may induce a state of tolerance. However, some mango-allergic patients may also react to catechols in toxicodendrons.

The Japanese lacquer tree (*Toxicodendron vernicifluа*), 15–20 m in height, provides a thick, self-melanizing, viscous bark sap used for varnishing wood. Because polymerized urushiol remains in the lacquer, it has been known to maintain its allergenicity for many years. Patients allergic to poison ivy usually react to Japanese lacquer tree catechols. In a survey of 232 lacquer craftsmen, 189 (81%) developed dermatitis from the lacquer, but 83% of these reactions resolved with continued lacquer exposure (natural hyposensitization)[19]!

The black juice of the Indian marking tree nut (*Semecarpus anacardium*) is mixed with alum to mark laundry in India and Malaysia. Indian laundry workers (dhobies) often develop "dhobie mark dermatitis". During World War II, 15–20% of English soldiers stationed in India were affected after wearing marked garments.

Cross-reactors from other families

The seed of the Ginkgo tree (*Ginkgo biloba*), the only living member of the family Ginkgoaceae, possesses an allergenic ginkgolic acid. Because of the tree's large size, beauty and resistance to air pollution, it is widely grown in suburban North America and Europe. Only the male trees of this dioecious species are cultivated. The yellowish seeds of female trees disintegrate, forming butyric acid, which smells like rancid butter. Contact with the soft outer layer (pulp) of the seed is responsible for the vast majority of allergic reactions. Dermatitis following contact with the seed kernel, seed shell and leaves has been reported, but these parts likely cause only irritant reactions. Handling the intact seed (without the seed coat) (Fig. 17.10) supposedly does not cause dermatitis in sensitized individuals. The unique, fan-shaped leaf makes the ginkgo easy to recognize.

Fig. 17.10 Leaves and seeds of *Ginkgo biloba*. Only the fresh seed covering contains the allergen, ginkgolic acid, which typically cross-reacts with urushiol.

Grevillea (Proteaceae) includes 250 plant species common to Australia that contain pentadecylresorcinol. Having no side-chain double bonds, it is less allergenic than poison ivy and poison oak allergens. The flower of the Hawaiian kahili tree (*Grevillea banksii*) is a significant cause of allergic contact dermatitis in Hawaii.

Asteraceae and related families

Key features

- Asteraceae (Compositae) identification
  - Flower head with all strap-like florets (e.g. dandelion)
  - Flower head with small, central tubular florets and peripheral strap-like florets (e.g. daisy, sunflower)
  - Leaf-like bracts surround undersurfaces of flowers

Prevalence of sesquiterpene lactone allergy[20–22]

Up to 4.3% of European patch-test patients are allergic to members of the Asteraceae (Compositae) family. A sesquiterpene lactone (SQL) mix detected 16–65% of relevant allergies in various studies, and the Compositae mix detected 33–87%. Typically, the Compositae mix is two to three times as sensitive as the SQL mix. Feverfew (*Tanacetum parthenium*) extract usually detects Asteraceae-sensitive individuals who do not respond to the SQL mix. Ideally, patients who are thought to be sensitive to a particular member of the Asteraceae family should be tested to portions of the suspect plant. The next best option is to use both the SQL mix and Compositae mix. Finally, if this is not possible, patients should be tested to the SQL mix and feverfew extract.

Identification of Asteraceae[23]

The classic Asteraceae member has many tiny flowers (florets) clustered to form a flower head (capitulum) subtended by an involucre (whorl of bracts) (Fig. 17.11). In some plants (e.g. dandelions), all the florets are similar. In others (e.g. sunflowers), an inner "disc" of short, tubular florets is surrounded by long, strap-like "ray" florets.

Allergenic Asteraceae[23]

The daisy family includes many troublesome weeds, ornamentals, herbaceous perennials, and vegetables (Table 17.12). Over 200 species of Asteraceae are important causes of contact dermatitis worldwide. The florist's chrysanthemum belongs to a hybrid genus known as X *Dendranthema*, a segregate of the genus *Chrysanthemum*. Dermatitis occurs in amateur florists who "dead-head" plants to encourage larger blooms.

In 1956, *Parthenium hysterophorus* (the "Scourge of India") accidentally traveled with a consignment of US wheat to Poona, India, where it found an inviting ecologic niche without natural enemies. Within 7 years it became abundant in Poona, and it has now become a major urban and rural weed throughout India. Unlike South American *P. hysterophorus*, the Indian plant contains large amounts of SQLs.

Pathogenesis

Anacardiaceae allergens[25–27]

The allergenic substance urushiol derives its name from the Japanese word for the sap (kiurushi) of the Japanese lacquer tree (*T. verniciflua*). It contains a mixture of catechols (1,2-dihydroxybenzenes) and resorcinols (1,3-dihydroxybenzenes) that avidly binds to skin but is readily degraded by water.

Catechols and their alkyl side chains are immunologically inert. However, combining them produces potent sensitizers. The immunologic activity of alkyl side chains results from van der Waals forces, not ionic interaction, hydrogen bonding or covalent linkage. Longer side chains increase irritancy and allergenicity; location at position 3 of the catechol ring increases antigenicity, but placement at position 6 induces tolerance. Although virtually all individuals who are allergic to poison ivy react to the C15 catechol with two double bonds (a diolefin), only 37% respond to the C15 catechol with an unsaturated side chain (pentadecylcatechol). Therefore, pentadecylcatechol, which is easily synthesized, is an inappropriate patch-test allergen for Anacardiaceae sensitivity, because the diolefin is the major component in poison ivy and poison oak urushiols.

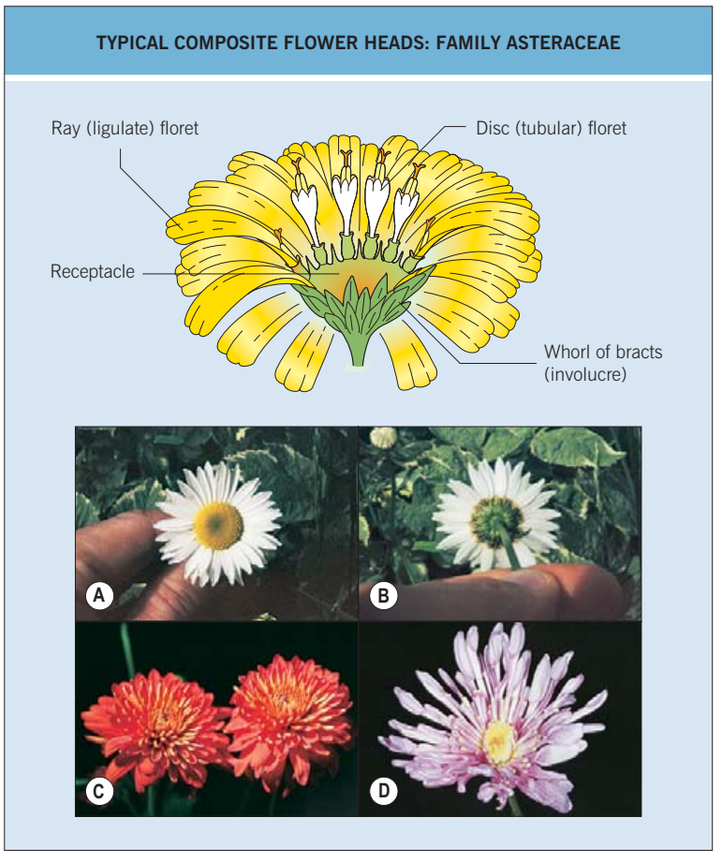

Fig. 17.11 Typical composite flower heads of members of the family Asteraceae (Compositae). Note the leaf-like bracts underneath the flower head. Daisy (*Leucanthemum* spp.), demonstrating composite flower head (**A**) and leaf-like bracts beneath the flower head (**B**) that are characteristic of flower heads of the family Asteraceae. **C** A cushion chrysanthemum (X *Dendranthema* cvs), demonstrating all ray, or strap-like, florets. **D** A composite chrysanthemum (X *Dendranthema* cvs), demonstrating central tubular florets and peripheral ray florets. This composite type of flower head gave rise to the former family name, Compositae.

Asteraceae allergens[23,28]

The major sensitizers, SQLs, are found in the leaves, stems and flowers, and are composed of a sesquiterpene ($C_{15}H_{24}$) and a lactone ring (cyclic ester). Over 1350 SQLs have been described, and the composition of SQLs produced by any species varies according to location and weather. An α-methylene group attached to the lactone ring increases allergenicity. Because SQL cross-reactivity follows no apparent rules, even the SQL patch-test mix (alantolactone, dehydrocostus lactone and costunolide) does not reliably screen for SQL allergy.

Clinical Features

Anacardiaceae dermatitis[25,29,30]

Key features

- Urushiol is a partially water-soluble allergen and must be washed off quickly
- Treat for at least 2 weeks, otherwise rebound phenomenon common
- Eruption "progresses" to "new areas" because of variability in antigen concentration and stratum corneum/epidermal thickness

Damage is usually required for plants to release urushiol, so lightly brushing against uninjured leaves is innocuous. However, in the late fall, plants release urushiol spontaneously. Urushiol may be spread by contaminated clothing, dogs, cats, lacquered furniture, sawdust and smoke. Allergen-containing smoke can cause severe respiratory tract inflammation, dermatitis, and even temporary blindness.

SOME OF THE MORE THAN 200 ALLERGENIC MEMBERS OF ASTERACEAE (COMPOSITAE) FOUND THROUGHOUT TEMPERATE WORLD CLIMATES			
Category	**Binomial name**	**Common name**	**Notes**
Wild flowers and weeds	*Achillea millefolium*	Yarrow, milfoil	A cause of allergic contact "strimmer" or "weed-whacker" dermatitis
	Ambrosia spp.	American ragweeds	Allergic contact dermatitis throughout growing season; allergic rhinitis only during pollen season
	Arnica montana	Arnica, mountain tobacco	
	Artemisia vulgaris	Mugwort	Grow in temperate climates worldwide
	Helenium autumnale	Sneezeweed	
	Iva spp.	Marsh elder, swamp weed	
	Parthenium hysterophorus	Wild feverfew	Scourge of India; Australian and Danish "bush dermatitis"
	Tanacetum cinerarilifolium	Pyrethrum	
	Tanacetum vulgare	Tansy	
	Tanacetum parthenium	Feverfew	Perhaps the best single plant to screen for SQL allergy
	Taraxacum officinale	Dandelion	Airborne contact dermatitis after mowing
Ornamental flowers	*Dahlia* spp.	Dahlia	
	X *Dendranthema* cultivars	Chrysanthemum	Most common cause of SQL dermatitis
	Helianthus annuus	Sunflower	Windblown trichomes can cause airborne contact dermatitis
	Rudbeckia hirta	Black-eyed Susan	
	Tagetes spp.	Marigold	Contain no SQLs
In herbal medicine	*Achillea millefolium*	Yarrow, milfoil	
	Arnica montana	Arnica, mountain tobacco	
	Calendula officinalis	Pot marigold	
	Chamaemelum nobile	Sweet/Roman chamomile	
	Helianthus annuus	Sunflower	
	Inula helenium	Elecampane	
	Tanacetum parthenium	Feverfew	
	Tanacetum vulgare	Tansy	
	Taraxacum officinale	Dandelion	
Vegetables	*Cichorium endiva*	Endive	
	Cichorium intybus	Chicory	
	Cynara scolymus	Globe artichoke	
	Lactuca sativa	Lettuce	

Table 17.12 Some of the more than 200 allergenic members of Asteraceae (Compositae) found throughout temperate world climates[24]. SQL, sesquiterpene lactone.

After contact with urushiol, a sensitized person typically develops an erythematous, pruritic eruption within 2 days (4–96 hours) that peaks within 1–14 days. However, dermatitis may occur up to 3 weeks after primary contact or within hours of secondary contact. Streaks of erythema and edematous papules typically precede vesicles and bullae (Fig. 17.12A,B). If the antigen load is lower, only erythematous, edematous reactions may be seen (Fig. 17.12C). Although allergic contact dermatitis is the most common cause of such a streaky, vesicular dermatitis, plants may cause this picture by other means (e.g. chemical irritant dermatitis or the initial phase of phytophotodermatitis). Patch tests of bulla fluid are routinely negative. The illusion that this fluid propagates the eruption results from variations in the time it takes for a clinical reaction to occur at different sites that receive differing antigen loads and have variable stratum corneum and epidermal thicknesses.

Erythema multiforme appears to be an underreported sequela of severe poison ivy reactions that may appear 2 weeks following onset of the dermatitis[31] (Table 17.13). Uncommonly, nephritis or eruptions resembling measles, scarlatina or urticaria develop and are ascribed to immune complex deposition. Without treatment, the allergic contact dermatitis lasts about 2–3 weeks. More severe peak reactions take longer to resolve. Prolonged postinflammatory hyperpigmentation may occur in darkly pigmented individuals.

Over 70% of the US population react to poison ivy allergens after patch testing, but only 50% react to plants in the field. Interestingly, only 15% of atopic persons are sensitive, and studies suggest that sensitivity is hereditary. Urushiol-sensitive AIDS patients with $CD4^+$ counts <200/mcl maintain sensitivity to poison ivy allergens[32]. The predominant effector T cells against poison ivy catechols are $CD8^+$.

In "black-spot" poison ivy dermatitis, urushiol acts as both irritant and allergen. An acute irritant contact dermatitis is superimposed on an acute allergic contact dermatitis[33]. Oxidized resin can be found on the skin, resulting in a black discoloration (Fig. 17.12D). If the lacquer stains clothes black, it cannot be washed off and will retain its allergenicity indefinitely. A more widespread spotted pattern in non-covered sites is seen if a patient has been weed-whacking areas of poison ivy (Fig. 17.12E).

PLANTS AND PLANT PRODUCTS THAT CAN LEAD TO ERYTHEMA MULTIFORME IN THE SETTING OF SEVERE ALLERGIC CONTACT DERMATITIS		
Common name (binomial name)	**Family**	**Notes**
Poison ivy, oak, sumac (*Toxicodendron* spp.)	Anacardiaceae	US and Canada
Tea tree oil (*Melaleuca alternifolia*)	Myrtaceae	Australia, exported products
Wild feverfew (*Parthenium hysterophorus*)	Asteraceae	India

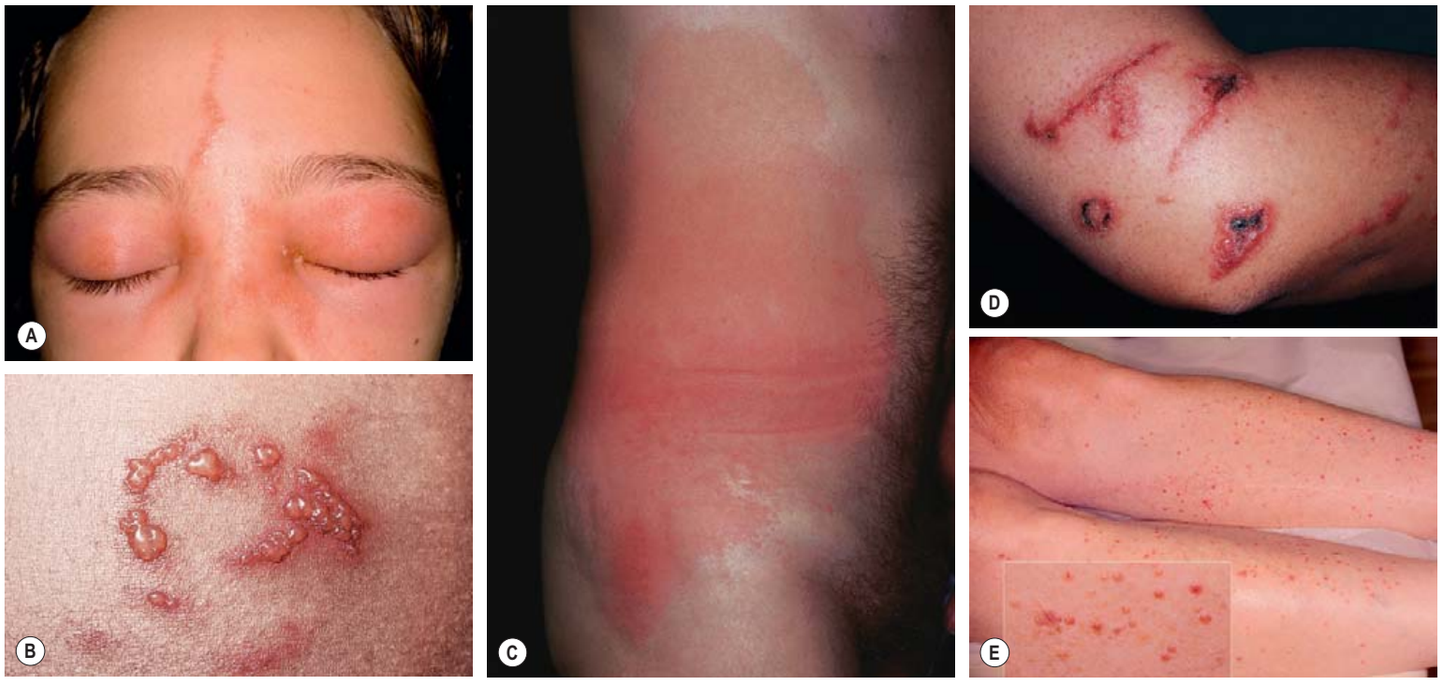

Fig. 17.12 Clinical manifestations of Anacardiaceae dermatitis. A Poison ivy (*Toxicodendron radicans*) dermatitis: erythema and edema of the eyelids as well as streaks of erythema plus tiny vesicles. **B** Poison ivy dermatitis: acute streaks of erythema with superimposed vesicles and bullae. **C** Widespread erythema and edema associated with intense pruritus after carrying logs of the poisonwood tree (*Metopium toxiferum*) of the family Anacardiaceae. **D** "Black-spot" poison ivy dermatitis: note the black discoloration in the central portion of the edematous plaques due to plant resin. **E** Weed-whacker dermatitis with widespread spotted pattern. *A, E, Courtesy, Louis A Fragola, Jr, MD; B, Courtesy, Fitzsimons Army Medical Center Dermatology slide teaching library.*

Asteraceae dermatitis[23]

Key features

- Caused by sesquiterpene lactones
- Most common cause is chrysanthemums
- Often presents with airborne contact pattern
- Patients frequently become photosensitive

Chrysanthemums are probably the most common house plant to cause allergic contact dermatitis (Fig. 17.13). The flowers and leaves are more potent sensitizers than are the stems.

The form of Asteraceae dermatitis that classically afflicts middle-aged men with a history of outdoor exposure typically resembles airborne contact dermatitis (ABCD) (Fig. 17.14). It has finally been demonstrated that SQLs (e.g. from feverfew [*Tanacetum parthenium*]), though not volatile, are bound to airborne trichomes in nature in sufficient concentrations to cause ABCD[34]. Typically, a single region of the body is involved for several years. The dermatitis flares in the summer during the plant's growing season and disappears in the winter. Later, all exposed areas develop a chronic pruritic and lichenified dermatitis (chronic actinic dermatitis [CAD]), presumably mediated by UV-induced antigens in the skin (see below). However, the eyelids, melolabial folds, retroauricular sulci and antecubital fossae are generally involved, unlike the situation in photosensitive dermatitis (see Fig. 87.16).

While ragweed (*Ambrosia artemisiifolia*) commonly causes immediate hypersensitivity ocular and airway reactions, it is a rare cause of allergic contact dermatitis. Type I allergic reactions are caused by high-molecular-weight, water-soluble antigens found in pollen. Although pollen can rapidly penetrate the skin[35], it contains no SQLs and has not been demonstrated to cause contact dermatitis. Cutaneous reactions to ragweed SQLs include ABCD (see above) and dyshidrotic eczema[36].

Parthenium hysterophorus (Congress weed, "Scourge of India") dermatitis in India affects adult men more than adult women or children, even though in India exposure is similar for all groups. Early studies estimated a male-to-female ratio of 20:1. The large male preponderance was not found in an American study demonstrating a 1.4:1 male-to-female ratio in those sensitive to Asteraceae. There is surprisingly little cross-reactivity between various Asteraceae family members.

Photosensitivity and Asteraceae allergy

SQLs possess neither phototoxic nor photoallergic properties, yet 85% of patients with chronic photosensitivity dermatoses may react to Asteraceae[37]. The development of abnormally low minimal erythema and minimal phototoxic doses following the onset of Asteraceae/SQL allergy has been demonstrated. The CAD that develops in some patients who are allergic to SQLs is thought to be an autoimmune photodermatosis mediated by sunlight-induced antigens in the skin. For example, the SQL isoalantolactone has been shown to be highly reactive with DNA in solution during UVA irradiation, and the UV action spectrum for CAD corresponds with the UV absorption peak for DNA. An interaction between SQLs and DNA in the presence of UV light may alter DNA to make it antigenic and trigger a CAD response[38].

Asteraceae-allergic individuals frequently react to plant allergens in perfumes, woods, balsam of Peru, colophony and lichens[39]. These allergies often precede the development of CAD. Although α-terthienyl and various polyacetylenes with phototoxic properties have been found in some Asteraceae, no link has been established between their presence and dermatitis[38].

Treatment

As soon as exposure to poison ivy or related plants is recognized, the entire body should be thoroughly washed with copious amounts of water. Soap may be used afterwards, but early use of soap or alcohol may expand the area of resin on the body since these are better solvents for urushiol than is water[40]. Fisher[41] has shown that urushiol (which is water-degradable) can be removed in significant amounts only if washed off very early. After 10 minutes, only 50% can be removed; after 15 minutes, only 25%; after 30 minutes, only 10%; and after 60 minutes, none of it can be removed.

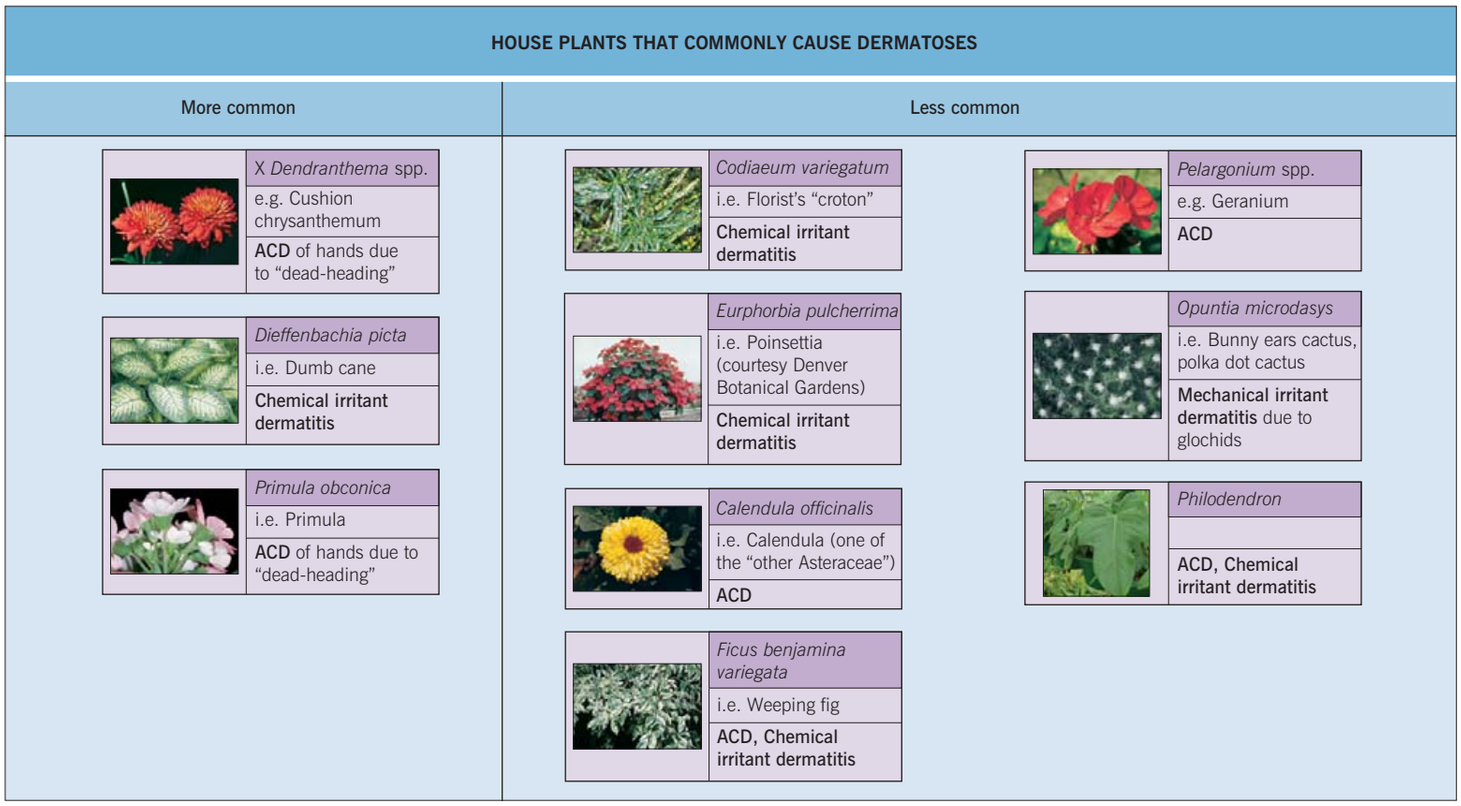

Fig. 17.13 House plants that commonly cause dermatoses. ACD, allergic contact dermatitis.

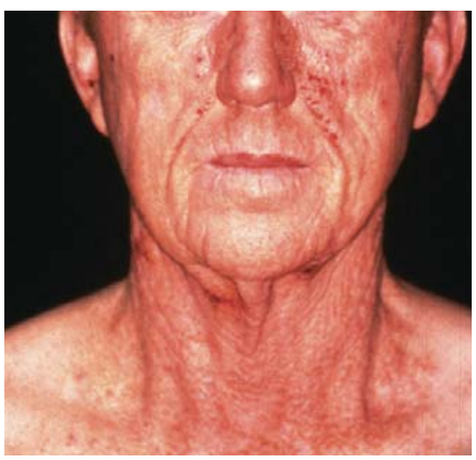

Fig. 17.14 Airborne contact dermatitis. Example of the airborne contact dermatitis pattern seen in a patient allergic to sesquiterpene lactones. Note involvement of the submental region and upper anterior neck, which would not be expected if this were a photodermatitis. *Courtesy, Dirk Elston, MD.*

For all causes of acute allergic contact dermatitis, the following general measures can be followed. Weepy lesions are best treated with tepid baths, wet-to-dry soaks, or bland shake lotions (calamine) that can dry the lesions. An astringent such as Burow's solution (aluminum subacetate) works well to cool and dry lesions when applied as a wet-to-dry dressing. Topical antihistamines, anesthetics containing benzocaine, and antibiotics should be avoided to prevent sensitization[40].

The most potent topical corticosteroids only help if applied during the earliest stages of the outbreak, when vesicles and blisters are not yet present. Abrupt discontinuation of these can lead to rebound inflammation. Both pimecrolimus and tacrolimus have been ineffective at treating urushiol-induced dermatitis. One surfactant product (Zanfel™) has been demonstrated to significantly relieve itch and erythema even after the eruption has been present for several days[42].

Systemic corticosteroids are extremely effective when indicated. These are best given in a dose of 1–2 mg/kg/day based upon ideal weight, gradually tapered over 2–3 weeks[43]. Many patients are referred for a "recurrence" of their poison ivy dermatitis after completing a short, 6-day course of oral corticosteroids, most commonly methylprednisolone given as a tapered "dose pack" (24 mg on day 1, decreasing by 4 mg each day over 6 days). As a result, the initial dose for an adult is often too low and the duration is too short. Soporific oral antihistamines can help patients sleep.

Hyposensitization programs for Anacardiaceae- and Asteraceae-allergic individuals have failed. Patients develop pruritus ani and/or generalized pruritus and urticaria and comment that the "treatment is worse than the disease". Natural desensitization probably occurs through early, oral ingestion of allergens. It appears that hyposensitization after becoming cutaneously sensitized to the potent allergens in poison ivy and poison oak is difficult, but not impossible, as demonstrated by Japanese lacquer craftsmen[20].

Marks and co-workers[44] demonstrated that 5% quaternium-18 bentonite lotion (Ivy-Block®) helps prevent poison ivy dermatitis in patch-test-positive individuals. Patients should realize that poison ivy allergens pass through rubber gloves, but not through heavy-duty vinyl gloves.

In CAD or other widespread Asteraceae-induced dermatitis, potent topical corticosteroids and oral prednisone are relatively ineffective unless employed early (before year-round dermatitis occurs). Azathioprine (2 mg/kg/day) or mycophenolate mofetil may be necessary for refractory disease (see Ch. 87). Low-dose PUVA therapy (with or without prednisone) may also prove helpful[23,45]. Whole-body application of mechlorethamine (nitrogen mustard) works, but only temporarily, and oral cyclosporine works, but the disease rapidly rebounds upon discontinuation[45].

Other Plant Families Causing Allergic Contact Dermatitis

Alliaceae

The genus *Allium* includes onions, garlic and chives. Garlic is the most frequent cause of fingertip dermatitis in homemakers and those who cook. It typically presents on the thumb, index and middle fingertips of the non-dominant hand with hyperkeratosis, desquamation and fissuring in an asymmetric pattern. Fresh garlic is a potent irritant that

Fig. 17.15 Allergic contact dermatitis in a florist. A Flowers of the Peruvian lily (*Alstroemeria* spp.). **B** Florist with fingertip *Alstromeria* allergic contact dermatitis showing how he holds Peruvian lily while cutting off the leaves. **C** Index finger of the same florist, showing the chronic, lichenified, hyperkeratotic dermatitis caused by allergy to Peruvian lily and tulipalin A (*Alstroemeria*). *B, C, With permission from the American Journal of Contact Dermatitis. 1999;10(3):172–6.*

has caused second- and third-degree burns when applied to injured skin (see Fig. 17.4). Therefore, patch testing to whole garlic should never be done. The irritants and allergens are thought to be diallyl disulfide (the most important one), allylpropyl disulfide and allicin. Onion (*Allium cepa*) dermatitis is rare. Common disposable gloves, such as vinyl, latex, polyethylene and nitrile, do not protect sensitized individuals who handle garlic or onions. Reusable domestic rubber gloves are protective.

Alstroemeriaceae and Liliaceae

"Tulip fingers" is a combined allergic and irritant contact dermatitis caused by tulip bulbs (*Tulipa* spp.). Erythematous, scaling plaques mark the fingertips and periungual skin, particularly on the first and second fingers of the dominant hand. Although this classic appearance can occur, most commonly a diffuse, dry hand dermatitis is seen. Pulpitis, paronychia, and spread of dermatitis to the face, neck, arms and anogenital area may ensue. Tuliposide A, a glycoside, is found in the white epidermis of bulbs. Acidic hydrolysis converts it to tulipalin A, the allergen. Tuliposide B (and therefore its hydrolytic product, tulipalin B), the α-hydroxy derivative of tuliposide A, is commonly found in tulips, and is a much weaker sensitizer.

Since their popularization in Holland in 1963, Peruvian lilies (*Alstroemeria auriantiaca* and *A. ligtu*) have become incredibly popular in floral arrangements (Fig. 17.15A). Handlers remove individual flowers, thread wire through the stems and/or cut off leaves (Fig. 17.15B). These workers often develop erythema, fissuring, vesicles, hyperkeratosis and exfoliation of the fingertips, greater on the dominant hand (Fig. 17.15C)[46]. Most frequently, it presents as non-inflamed distal finger fissuring and hyperkeratosis. Unfortunately, the allergen passes through vinyl (polyvinyl chloride) gloves[46]. Although nitrile (synthetic rubber) gloves are protective, few florists will wear them. Tuliposide A and B are found in virtually all portions of the plant. The flowers have more allergen than the stems, and the leaves have the least amount. Attempts are being made to grow hypoallergenic cultivars that contain only tuliposide B[46].

Myrtaceae

Tea tree oil distilled from the leaves of *Melaleuca alternifolia* Cheel has been increasingly reported as a cause of allergic contact dermatitis since 1991. At least two-thirds of Australians have been exposed to it, and approximately 7% of them are allergic to it. While tea tree oil possesses broad-spectrum antimicrobial and anti-inflammatory effects, at least 16 different constituents are strong sensitizers. Most sensitizers are degradation products formed after exposure of tea tree oil to light, warmth and moisture[47]. Fresh tea tree oil is a weak sensitizer. The most common sensitizers are terpinolene, ascaridol, α-terpinene and 1,2,4-trihydroxy menthane.

Botanical products

Hundreds of botanical extracts are added to numerous skin care products for fragrance and purported healing properties. When testing patients with a presumed contact allergy who were using products with botanical extracts, two studies demonstrated that 50–60% of patients had at least one relevant positive reaction. The most common culprit was tea tree oil, followed by feverfew and lichen acid mix (found in deodorants). Balsam of Peru (*Myroxylon pereirae*), fragrance mix, Compositae mix and SQL mix were poor screens for botanical allergy in that they uncovered only 33%, 30%, 20% and 7% of relevant allergic reactions, respectively. The authors of this study suggested creating a new botanical screen tray that included all items found relevant in at least two patients[4].

OCCUPATIONAL PLANT DERMATOSES

Florists[48,49]

Irritant dermatitis outweighs allergic contact dermatitis in frequency and importance. Estimates of hand dermatitis in florists range from an 8% point prevalence to a 25–30% annual incidence to a nearly 50% lifetime incidence, especially amongst floral designers. Most importantly, most cases of hand dermatitis are mild, periodic and self-limited. Because florists' hands are often wet, primary irritant reactions may lead to sensitization over long periods of time.

For florists, the most common sensitizers are sesquiterpene lactones, tulipalin A and primin (*Primula obconica*). Daffodil itch (caused by calcium oxalate), from handling daffodil stems and bulbs, is probably the most common cause of irritant contact dermatitis in florists.

Horticulturalists

Fully 10% of 250 horticultural workers were allergic to Asteraceae and one-third had urticaria[50]. An atopic family history increases one's likelihood of developing urticaria.

Grocery Store Workers

Among grocery store workers, two factors have been identified that raise the risk for phytophotodermatitis: the amount of exposure to fresh produce (especially celery) and the use of tanning salons (UVA exposure). The prevalence ratio of phytophotodermatitis is >40 for those with both risk factors compared to those with neither.

Outdoor Workers

Among outdoor workers, poison ivy and poison oak (*Toxicodendron* spp.) are the main causes of occupational contact dermatitis. *Toxicodendron* contact accounts for 10% of all lost-time injuries for the US Department of Agriculture Forest Service. Foresters, especially when fighting forest fires, have virtually no control over avoiding these plants. Up to 25% of firefighters need to leave the fire line because of severe *Toxicodendron* dermatitis. Forestry workers often suffer from "woodcutter's eczema", an allergic reaction caused by airborne SQLs in *Frullania* (liverworts) growing on tree trunks in the American and Canadian Pacific Northwest. The dermatitis is worse in wet winter months and presents in a pseudo-photodistribution, involving the upper eyelids but sparing the submental area. This suggests dispersal of oleoresin by rainwater.

Urticaria and Angioedema 18

Clive EH Grattan

Synonyms: ■ Wheals – hives, nettle rash ■ Angioedema – Quincke edema

Key features

- Urticaria is characterized by transient skin or mucosal swellings due to plasma leakage. Superficial dermal swellings are wheals, and deep swellings of the skin or mucosa are termed angioedema. Wheals are characteristically pruritic and pink or pale in the center, whereas angioedema is often painful, less well defined and shows no color change.
- There are several recognizable clinical patterns of urticaria and different causes. The latter include allergy, autoimmunity, drugs, dietary pseudoallergens, and infections. Many cases remain unexplained ("idiopathic") even after an extensive evaluation. C1 esterase inhibitor deficiency needs to be considered as a cause of recurrent angioedema without wheals.
- Diagnosis is based primarily on the history and clinical examination. Determination of the etiology or triggers, as well as exclusion of other diagnoses, may require further investigations, including blood tests, physical and dietary challenges, skin tests and skin biopsy.
- Urticaria is a common disorder that may cause considerable distress and last for years, but the associated symptoms can often be alleviated by appropriate management.

INTRODUCTION

Urticaria is a common reason for patients to present to primary care practitioners, emergency rooms, dermatologists and allergists. It is characterized by the rapidity of its fluctuation. As a rule, individual wheals last no more than 24 hours, but the whole attack usually lasts much longer. With nearly all clinical patterns of urticaria, wheals may be accompanied by angioedema, but the occurrence of isolated angioedema (without wheals) is of special significance because some of these patients will have a deficiency of C1 esterase inhibitor (C1 inh). The latter is a rare disorder that is often inherited and can prove fatal without treatment. Urticarial vasculitis is a systemic disease defined by damage to small blood vessels (see Ch. 24), but it may sometimes present with wheals or angioedema that, without confirming a duration of more than 24 hours (by serial examination of marked lesions) and a biopsy, are indistinguishable from other patterns of urticaria. While urticaria rarely progresses to anaphylaxis, it is often a feature of that condition. Good management of urticaria depends on a thorough understanding of etiologies, triggers and aggravating factors, in addition to the most appropriate drug therapies.

Definition of Urticaria

Urticaria is often used as a descriptive term for recurrent whealing of the skin, with angioedema being viewed as a separate entity. However, there is increasing acceptance that the term "urticaria" is more appropriately used to define a disease in which the clinical presentation is determined by the depth of swelling. Thus, urticaria may present with wheals, angioedema, or both. Similarly, the term "angioedema" may be used to describe a physical sign or a distinct clinical subgroup of urticaria characterized by deep swellings without wheals.

Wheals are pruritic, pink or pale swellings of the superficial dermis that may have an initial flare around them (Fig. 18.1). Lesions may be a few millimeters in diameter or as large as a hand, and the number can vary from a few to numerous. The hallmark of wheals is that *individual* lesions come and go rapidly, by definition, in general within 24 hours.

Angioedema swellings occur deeper in the dermis and in the subcutaneous or submucosal tissue. They may also affect the mouth and, rarely, the bowel. The areas of involvement tend to be normal or faint pink in color, painful rather than red and itchy, larger and less well defined than wheals, and often last for 2 to 3 days (Fig. 18.2).

EPIDEMIOLOGY

Estimates of the lifetime occurrence of urticaria range from less than 1% to as high as 30% in the general population, depending on the age range and method of sampling. The true figure is likely to be in the range of 1–5%[1]. The prevalence of specific types of urticaria, e.g. chronic idiopathic urticaria or cold urticaria, will be lower. There is no reliable literature on racial variation, but an estimate of prevalence in China was appreciably higher than that in European studies, at 23%[1]. Urticaria is a worldwide disease and may present at any age. The peak incidence depends on etiology. The proportion of cases due to different etiological agents is likely to relate to the frequency of environmental exposures, such as infections and allergens, in different countries, but estimates of this are not available. It is also often difficult to prove a cause and effect, and so an underlying condition may be inappropriately "blamed" for causing urticaria. Overall, urticaria is more common in women, with a female : male ratio of approximately 2 : 1 for chronic urticaria, but the ratio varies with the different physical urticarias. For example, women outnumber men in dermographism and cold urticaria, but more men develop delayed pressure urticaria[2]. Hereditary angioedema has an autosomal dominant inheritance pattern and occurs in approximately 1 : 50 000 individuals.

PATHOGENESIS

The Mast Cell

Distribution and diversity

The mast cell is the primary effector cell of urticaria. Mast cells are widely distributed throughout the body but vary in their phenotype and response to stimulation. This may explain why systemic features, such as those seen in anaphylaxis, do not accompany the activation of cutaneous mast cells in urticaria. The majority of mast cells in the skin and intestinal submucosa contain the neutral proteases tryptase and chymase (MC_{TC}), whereas those in the bowel mucosa, alveolar wall and nasal mucosa contain only tryptase (MC_T). Both types, however, express high-affinity IgE receptors (FcεRI) and are therefore capable of participating in IgE-dependent allergic reactions[3]. There is conflicting evidence on the number of cutaneous mast cells in chronic urticaria, but there is agreement that they may be more likely to degranulate in response to certain stimuli, such as intradermal codeine injection, and in this sense may be in general more "releasable". Little is known about the beneficial effects of mast cells, but there is some evidence that they may be involved in the innate immune response to infection, wound healing, and the neuroendocrine system. Recently, they have been

Fig. 18.1 Wheals. Wheals can be small or large in size (**A**) as well as annular (**B**), but they still retain the classic central pallor and erythematous flare. **C** Occasionally, more uniform edematous plaques are seen. *B, Courtesy, Julie V Schaffer, MD.*

Fig. 18.2 Angioedema. The swelling is deeper than wheals and may affect mucosal surfaces. Note the swelling of the lips and periorbital region and the lack of erythema.

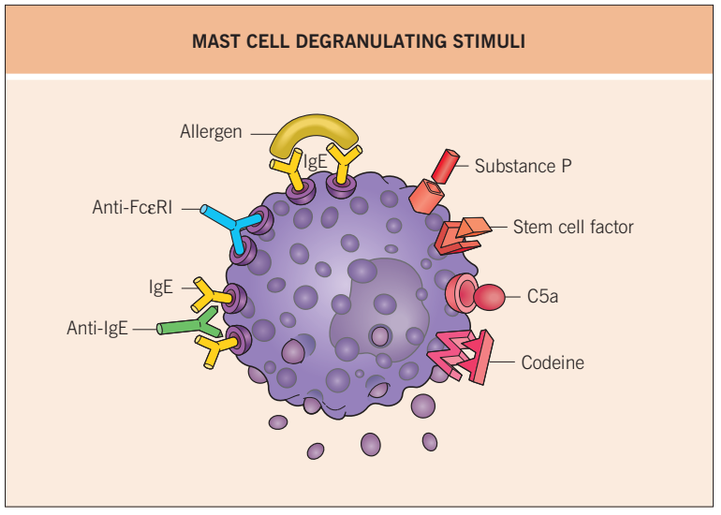

Fig. 18.3 Mast cell degranulating stimuli. Both immunologic and non-immunologic stimuli can lead to release of mediators. Stem cell factor is also known as KIT ligand.

shown to help initiate the extracellular matrix formation and angiogenesis required for neurofibroma development.

Degranulating stimuli

Cross-linking of two or more adjacent FcεRI on the mast cell membrane will initiate a chain of calcium- and energy-dependent steps leading to fusion of storage granules with the cell membrane and externalization of their contents. This is known as degranulation. Classic immediate hypersensitivity reactions involve binding of receptor-bound specific IgE by allergen. There are also several recognized immunologic degranulating stimuli that act through the IgE receptor, such as anti-IgE and anti-FcεRI antibodies (Fig. 18.3). Non-immunologic stimuli, including opiates, C5a anaphylatoxin, stem cell factor and some neuropeptides (e.g. substance P), can cause mast cell degranulation by binding specific receptors, independent of the FcεRI (see Fig. 18.3).

Proinflammatory mediators

Mast cell granules contain preformed mediators of inflammation, the most important of which is histamine (Fig. 18.4). A wide range of cytokines has been demonstrated in human mast cells from different tissues, including tumor necrosis factor-α (TNF-α), interleukins (IL)-3, -4, -5, -6, -8 and -13, and granulocyte–macrophage colony-stimulating factor (GM-CSF). Synthesis and secretion are upregulated following FcεRI stimulation. TNF-α is expressed constitutively in resting human cutaneous mast cells. Prostaglandins and leukotrienes are synthesized

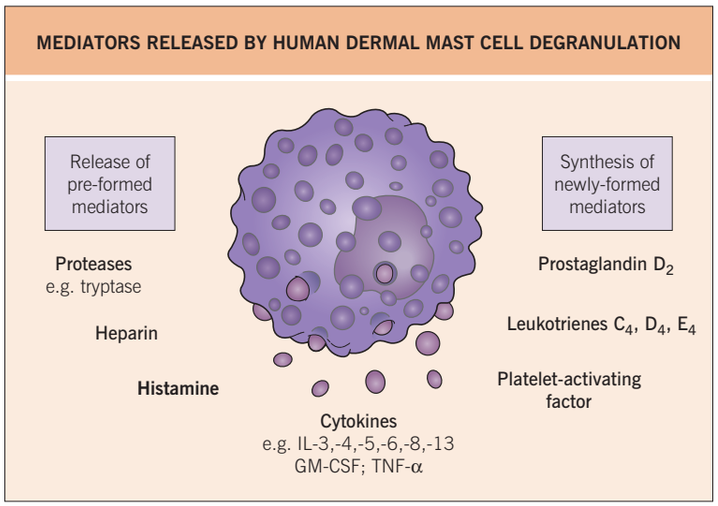

Fig. 18.4 Mediators released by human dermal mast cell degranulation. Both preformed and newly synthesized proinflammatory mediators are released from mast cells.

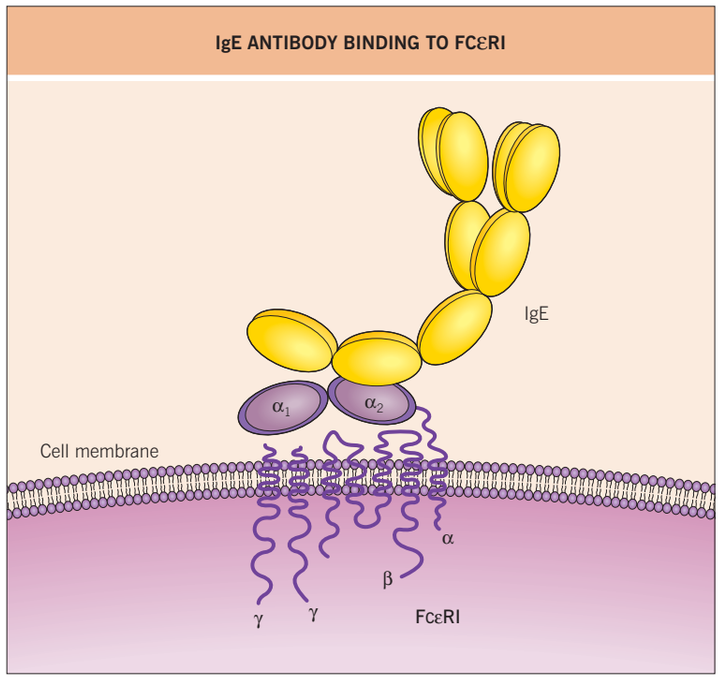

Fig. 18.5 Histamine-releasing autoantibodies bind the extracellular α subunit of the high-affinity IgE receptor (FcεRI). Autoantibodies directed against the terminal α_1 domain are able to bind the receptor in the presence of IgE and are therefore non-competitive, whereas those recognizing the α_2 domain compete with IgE for the binding site.

from arachidonic acid derived from cell membrane phospholipids (see Fig. 130.7). The most important proinflammatory eicosanoids are prostaglandin (PG) D_2 and the leukotrienes (LT) C_4, D_4 and E_4 (slow releasing substance of anaphylaxis). PGE_2 has inhibitory effects on immunologic mast cell degranulation and may therefore have a protective role in urticaria.

Blood Vessels

Histamine and other proinflammatory mediators released on degranulation bind receptors on postcapillary venules in the skin, leading to vasodilation and increased permeability to large plasma proteins, including albumin and immunoglobulins. Furthermore, histamine, TNF-α and IL-8 upregulate the expression of adhesion molecules on endothelial cells, thereby promoting the migration of circulating inflammatory cells from the blood into the urticarial lesion.

Blood

Autoantibodies

Functional IgG autoantibodies that release histamine (and other mediators) from mast cells and basophils have been detected in the serum of 30–50% of patients with chronic "ordinary" urticaria using *in vitro* assays[4]. The majority of these autoantibodies bind the extracellular α subunit of FcεRI. Those recognizing the α_2 domain compete with IgE for the binding site, whereas non-competitive autoantibodies directed against the terminal α_1 domain are able to bind the receptor in the presence of IgE (Fig. 18.5). Approximately 10% of chronic urticaria sera contain functional autoantibodies directed against the Fc portion of IgE itself (see Fig. 18.3). Binding of the autoantibodies to mast cells may initiate complement activation with the generation of C5a anaphylatoxin, which in turn facilitates or augments degranulation[5]. Other mast cell activating factors may also exist in urticaria sera: a non-IgG "mast cell-specific factor" has been described, although its identity remains unknown[6]. There is currently no evidence that characterized cytokines cause mast cell degranulation in urticaria.

The pathogenesis of urticarial vasculitis (see Ch. 24) is thought to involve circulating immune complexes, although the antigen has not been identified except in hepatitis B and C viral infections.

Leukocytes

The importance of peripheral blood leukocytes in the pathogenesis of urticaria is becoming clearer. Blood basophils in chronic ordinary urticaria patients are less responsive *in vitro* to the immunologic stimulus anti-IgE, possibly through desensitization, and these cells are reduced in number[7]. These patients can be classified into responders and non-responders based upon the release of histamine by their basophils in response to anti-IgE. The functional phenotype appears to remain stable during the course of the active illness, but then, during disease remission, the basophils become more responsive to anti-IgE[8]. Expression of the negative regulator SHIP (src homology 2-containing inositol phosphatase) is increased in the basophils from anti-IgE non-responders[9], although the significance of this to the pathogenesis of chronic urticaria is unknown. Evidence is emerging that basophils are recruited into urticarial wheals and may sustain the inflammatory response by releasing histamine and other mediators, analogous to the delayed phase of immediate hypersensitivity reactions.

Eosinophil, neutrophil and lymphocyte numbers are normal in the peripheral blood, but these cells are often present in biopsy specimens from spontaneous wheals. Eosinophils may contribute to the persistence of wheals by generating LTC_4, LTD_4 and LTE_4 and by releasing toxic granule proteins, including major basic protein (MBP), which can release histamine from basophils. The function of neutrophils and lymphocytes in urticaria has not been elucidated.

Nerves

Substance P and other neuropeptides release histamine from mast cells *in vitro* and can induce a wheal and flare reaction in human skin when injected intradermally. Vasoactive intestinal polypeptide (VIP) caused a greater wheal reaction in those with chronic urticaria than did other skin-tested neuropeptides[10], but the relevance of this to urticaria is still uncertain.

Mechanisms of Urticaria Formation

Mast cell-dependent urticaria

Potential mechanisms for mast cell-dependent urticaria are included in Table 18.1. Cross-linking of the Fab portion of specific IgE on mast cells by percutaneous or circulating allergen (see Fig. 18.3) undoubtedly accounts for some cases of acute or episodic urticaria but is probably never the cause of adult chronic continuous urticaria. Examples of the former would be contact urticaria from natural rubber latex and acute urticaria from foods, including nuts, fish and fruit. However, the majority of acute urticaria cases do not relate to allergen exposure.

IgE has been implicated in the pathogenesis of symptomatic dermographism, cold urticaria and solar urticaria, but the mechanism by

ETIOLOGIES AND PATHOMECHANISMS OF URTICARIAL LESIONS
IDIOPATHIC
IMMUNOLOGIC
• Autoimmune (autoantibodies against FcεRI or IgE) • IgE-dependent (allergic) • Immune complex (vasculitic) • Kinin- and complement-dependent (C1 esterase inhibitor deficiency)
NON-IMMUNOLOGIC
• Direct mast cell-releasing agents (e.g. opiates) • Vasoactive stimuli (e.g. nettle stings) • Aspirin, other nonsteroidal anti-inflammatory drugs, dietary pseudoallergens • Angiotensin-converting enzyme inhibitors

Table 18.1 Etiologies and pathomechanisms of urticarial lesions. It is often difficult to know the exact pathogenesis of individual cases of urticaria, and many cases remain idiopathic after evaluation. See figs 18.3 and 18.6.

which it renders skin mast cells more sensitive to physical stimulation is not certain[11]. It is proposed that the physical stimulus in these patients induces a neoantigen that reacts with specific IgE antibody bound to mast cells. An additional mechanism, such as neuropeptide release, could initiate or potentiate mast cell activation. Using electron microscopy, localized platelet clumping has been demonstrated in cold urticaria, and the release of platelet mediators, including platelet-activating factor (PAF) and factor IV, could contribute to the urticaria.

Cholinergic urticaria develops in response to stimulation of cholinergic sympathetic innervation of the sweat glands. How release of acetylcholine from the nerve endings leads to mast cell activation and histamine release is unknown. An allergy to sweat has been demonstrated by one group of investigators. It has been proposed that pressure-induced wheals may be due to a late-phase reaction, but an antigen has never been identified.

The initiating event for spontaneous urticaria wheals is unclear but may involve plasma leakage due to local factors such as heat or pressure, which allow the extravasation of autoantibodies, leading to mast cell degranulation and a subsequent urticarial response. As functional autoantibodies cannot be detected in approximately 40% of chronic urticaria sera by currently available tests, other mechanisms may operate in "non-autoantibody" urticaria, which, nevertheless, has a similar clinical presentation[12]. Increased plasma levels of prothrombin fragment 1 + 2 (F 1 + 2) and D-dimer (a measure of fibrinolysis) have been demonstrated in chronic urticaria[13] and relate to disease severity, but the contribution of coagulation abnormalities to the pathogenesis remains unclear.

A popular hypothesis is that dietary and drug pseudoallergens may cause urticaria through the diversion of arachidonic acid metabolism from prostaglandin to leukotriene formation. How this leads to urticaria is not clear, but it is known that intradermal injections of LTC_4, LTD_4 and LTE_4 cause whealing by a direct action on small blood vessels. There is some evidence from studies of rat peritoneal mast cells that PGD_2 and PGE_2 have inhibitory effects on immunologic mast cell degranulation[14], so a reduction in their formation may facilitate the latter. Aspirin can *aggravate* urticaria in up to 30% of patients with chronic disease[15], and while some clinical studies of dietary pseudoallergen avoidance have given encouraging results, the proportion of complete responders confirmed by rechallenge is small[16]. Aspirin allergy as a *cause* of urticaria is much less common, and the proportion of patients with urticaria due solely to pseudoallergens is probably low.

Understanding "idiopathic" urticaria remains an important challenge. From a clinical perspective, it should be regarded as a multifactorial problem, and searching for aggravating factors is just as important as looking for causes.

Mast cell-independent urticaria

There are several recognized circumstances where angioedema or wheals are due to mechanisms that do not involve mast cells. These need special consideration because their management and prognosis are different. For example, prostaglandins are involved in the pathogenesis of some patterns of non-immunologic contact urticaria (e.g. to sorbic acid), and the latter can be suppressed by nonsteroidal anti-inflammatory drugs (NSAIDs)[17]. In the cryopyrin-associated periodic syndromes (CAPS; see below), patients often develop urticarial lesions. The significant improvement that results from the administration of *anakinra*, an IL-1 receptor antagonist[18], *rilonacept* (IL-1 TRAP), a fusion protein that contains the extracellular domain of the IL-1 receptor (which binds IL-1)[19], or *canakinumab*, a human anti-IL-1β monoclonal antibody[20], points to the role of the cryopyrin inflammasome (see Fig. 45.1) and its production of IL-1β.

C1 esterase inhibitor (C1 inh) deficiency

C1 inh deficiency is usually hereditary, but may be acquired. Three types of hereditary angioedema (HAE) are now recognized (see Fig. 18.18). Types I and II are caused by mutations in one allele of the structural gene for C1 inh, resulting in reduced levels of C1 inh (85% of cases; type I) or reduced C1 inh function (15% of cases; type II). Because the mutations lead to levels of 5–30% of normal (rather than the expected 50%) in patients with type I HAE, it is thought that there is *trans* inhibition of the normal allele or increased catabolism of C1 inh.

Deficiency of C1 inh leads to loss of inhibition of Hageman factor (FXII), resulting in the generation of bradykinin by the action of kallikrein on high-molecular-weight kininogen (Fig. 18.6). Activation of the C1 component of complement by proteolytic enzymes, including plasmin and FXIIa, leads to low levels of C4 in the serum, which is an almost constant feature between and during attacks in untreated patients. Of note, type III HAE may be due to an *activating* mutation in one allele of the gene that encodes FXII, leading to increased formation of bradykinin. One possible explanation for the preponderance of women is the enhancement of transcription of this gene by estrogens. In addition, there is a positive feedback loop between kallikrein and FXII.

Acquired deficiency of C1 inh may result from persistent low-level activation of C1q by anti-idiotypic antibodies (directed against a paraprotein) in patients with B-cell lymphoproliferative disorders and plasma cell dyscrasias, or in autoimmune connective tissue diseases. This leads to *consumption* of C1 inh plus low serum levels of C1q as well as C4 (acquired, type I) or the formation of *inhibitory autoantibodies* directed against the C1 inh (acquired, type II).

Angiotensin-converting enzyme (ACE) inhibitor-induced urticaria is believed to result from the inhibition of endogenous kininase II (also known as ACE), which leads to increased production of bradykinin via inhibition of its metabolism (see Fig. 18.6). It usually presents with angioedema, which is often orofacial and may be life-threatening.

CLINICAL FEATURES

Clinical Diversity

It is important to distinguish *urticaria* from *urticarial dermatoses*, such as urticarial drug eruptions, eosinophilic cellulitis and bullous pemphigoid. The individual wheals of urticaria are "here today and gone tomorrow" (i.e. they generally last less than 24 hours), whereas with urticarial dermatoses, the individual lesions last for days or longer. Although urticarial vasculitis is often included in classifications of urticaria because the wheals resemble urticaria, it is actually an urticarial dermatosis. Clinically, the lesions last longer than 24 hours (as determined by circling and observing individual wheals), and histologically there is evidence of leukocytoclastic vasculitis (see Ch. 24).

Wheals may be small or large, single or multiple. In the physical urticarias, the distribution pattern and morphology can be helpful in separating the different clinical types (see Physical Urticarias). Angioedema can merge with wheals and these two can be difficult to separate, especially around the eyelids. Angioedema may also be a feature of anaphylaxis, if the throat is involved. In this sense, wheals, angioedema and anaphylaxis form parts of a clinical spectrum.

Classification

Because the etiology is often unknown at the time of the first consultation, the most practical classification of urticaria relies on clinical

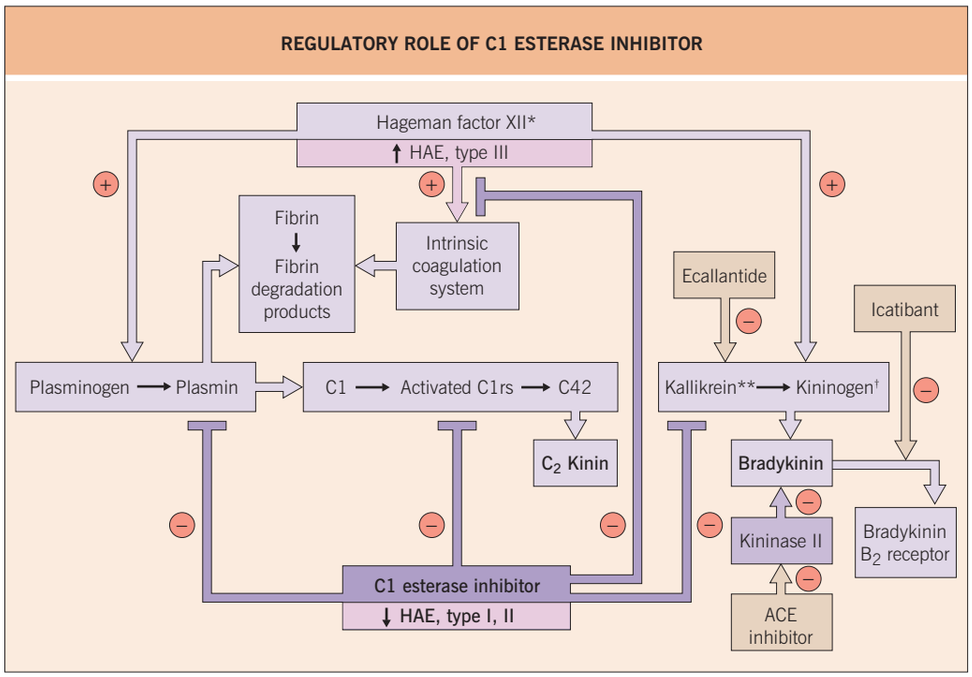

Fig. 18.6 Regulatory role of C1 esterase inhibitor on the fibrinolytic, coagulation, complement and kinin systems. Angiotensin-converting enzyme (ACE) inhibitor-induced urticaria is believed to result from the inhibition of endogenous kininase and a subsequent increase in bradykinin. Icatibant and ecallantide have recently been approved for the emergency treatment of hereditary angioedema (HAE). Icatibant, a decapeptide, is a specific bradykinin B_2 receptor antagonist. Ecallantide, a 60-amino acid recombinant protein, selectively inhibits kallikrein. *The active form of Hageman factor (XII) is XIIa. **Kallikrein is formed from prekallikrein. †High-molecular-weight.

CLINICAL CLASSIFICATION OF URTICARIA AND ANGIOEDEMA
• "Ordinary" (spontaneous) urticaria (all urticarias not classified below)
• Physical (inducible) urticarias (see Table 18.3)
• Urticarial vasculitis (defined by vasculitis on skin biopsy)
• Contact urticaria (induced by percutaneous or mucosal penetration)
• Angioedema without wheals
• Distinctive urticarial syndromes

Table 18.2 Clinical classification of urticaria and angioedema. All clinical patterns of urticaria can be acute, episodic or chronic.

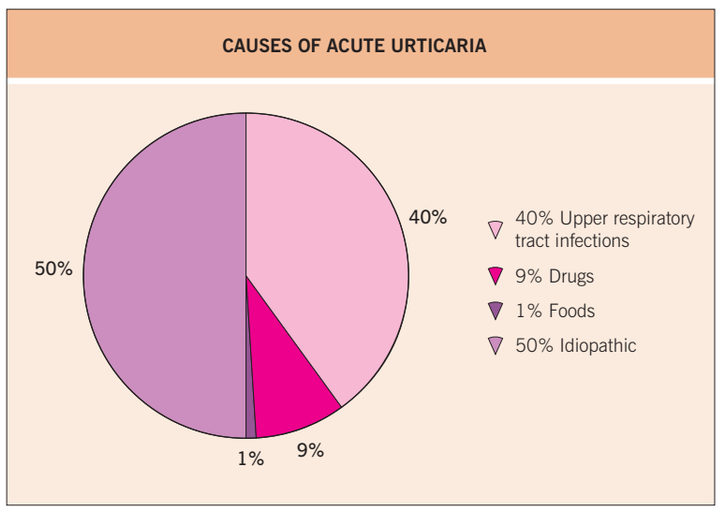

Fig. 18.7 Causes of acute urticaria. *Data from Zuberbier, 1996*[21].

characteristics rather than etiology to define groups of patients (Table 18.2). Most spontaneous urticaria can be considered to behave in an ordinary manner (i.e. fluctuating wheals which may be accompanied by angioedema) whatever its etiology or duration, unless it has a predominantly physical trigger, has evidence of vasculitis, or is caused by exogenous contact. If no cause for ordinary (spontaneous) urticaria can be defined, it is called idiopathic, but the use of this label as an automatic prefix to chronic urticaria is no longer tenable as a significant number of these patients will have autoimmune disease. It is worth separating angioedema without wheals from the other patterns of urticaria, because some of these cases will be due to HAE, acquired C1 inh deficiency, or drug reactions (e.g. ACE inhibitors, NSAIDs), and these are managed differently.

Acute versus Chronic Urticaria

All urticarias are acute initially. Some will become chronic after a period of time that is usually defined as 6 weeks or more. The term "chronic urticaria" should only be applied to continuous urticaria occurring at least twice a week off treatment. Urticaria occurring less frequently than this over a long period is better called episodic (or recurrent), because this presentation is more likely to have an identifiable environmental trigger. The causes of acute urticaria presenting to emergency dermatology clinics in one survey[21] are shown in Figure 18.7. Most of these patients probably fall into the ordinary category, because physical urticarias and urticarial vasculitis tend to persist beyond 6 weeks and contact urticarias would not normally present to the hospital. The high frequency of associated viral infections is notable, as is the lack of food allergy as a cause. The different clinical patterns of chronic urticaria and their causes (where known) are shown in Figure 18.8. These data reflect the experience of specialist urticaria clinics in dermatology departments and may not represent the experience of other medical practitioners, such as those in general practice, internal medicine, pediatrics and allergy.

"Ordinary" (Spontaneous) Urticaria

The condition can present at any age. Acute urticaria is common in young children with atopic dermatitis, but chronic urticaria peaks in the fourth decade. Multiple pruritic wheals of different sizes erupt anywhere on the body and then fade within 2–24 hours without bruising; angioedema lasts longer. Urticaria may occur at any time, but often appears in the evening or is present on waking. Irritation tends to be most intense at night and may disturb or prevent sleep. This, in turn, compounds the distress of the condition. Substantial impairment in quality-of-life measures, including self-image, sexual relationships and social interaction, has been demonstrated[22]. Women may describe premenstrual exacerbations. Systemic symptoms of fatigue, lassitude, sweats and chills, indigestion or arthralgias are common with severe attacks, but the occurrence of pyrexia or arthritis should alert the clinician to another explanation, such as urticarial vasculitis, Schnitzler's

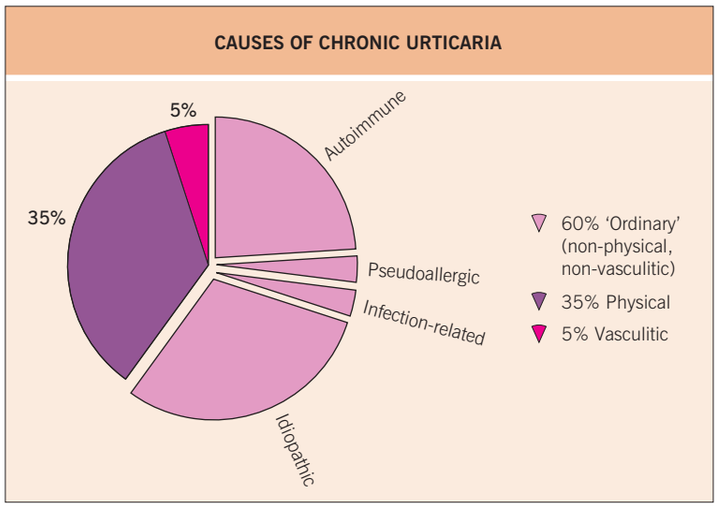

Fig. 18.8 Causes of chronic urticaria. Autoimmune represents those patients with functional autoantibodies against FcεRI or the Fc portion of IgE.

syndrome or cryopyrin-associated periodic syndrome (e.g. Muckle–Wells syndrome).

Associations

Chronic urticaria has been associated with autoimmune thyroid disease[23] and other autoimmune conditions, including vitiligo, insulin-dependent diabetes, rheumatoid arthritis and pernicious anemia[12]. Patients with demonstrable histamine-releasing autoantibodies have a very strong association with HLA-DR4 and its associated allele HLA-DQ8[24]. A possible association between *Helicobacter pylori* gastritis and chronic urticaria was suggested by a systematic review of therapeutic studies, which showed a higher frequency of urticaria remission when the infection was eradicated than when it was not[25]. Parasitic infections, such as intestinal strongyloidiasis, are an uncommon cause of urticaria in developed countries, but may be a significant problem where they are endemic. Acute urticaria due to gastric *Anisakiasis simplex* has been reported from Spain[26]. Possible associations between dental infections or gastrointestinal candidiasis and chronic urticaria have not been substantiated by large epidemiologic studies. Although there have been anecdotal reports linking urticaria to malignancy, no statistically significant association was found in a large Swedish survey[27].

Physical (Inducible) Urticarias

The physical urticarias represent a distinct subgroup of the urticarias that are induced by an exogenous physical stimulus rather than occurring spontaneously. Because cholinergic urticaria is triggered by factors that lead to sweating (e.g. a rise in core body temperature, stress or spicy foods), rather than an external physical stimulus, it is often classified separately from other inducible urticarias; for the sake of convenience, it will be included here. The physical urticarias are classified by the predominant stimulus that triggers wheeling, angioedema or anaphylaxis[28] (Table 18.3). Of all the urticarias, they may affect the quality of life most severely, particularly delayed pressure urticaria and cholinergic urticaria[29]. While the lesions of most physical urticarias occur within minutes of provocation and generally resolve within 2 hours, a few physical urticarias (e.g. delayed pressure urticaria, delayed dermographism) develop after a delay of several hours and persist for 24 hours or longer.

The wheals are usually localized to the stimulated area of skin. However, sometimes the physical stimuli need to produce a systemic effect, e.g. a rise or drop in core body temperature, to induce urticaria of a reflex type. Thus, generalized heating of the body can induce cholinergic urticaria (which is common), and generalized cooling, cold reflex urticaria (which is rare). Here, multiple small wheals occur on widespread areas of the body.

CLASSIFICATION OF PHYSICAL URTICARIAS
URTICARIA DUE TO MECHANICAL STIMULI

Dermographism
• Immediate
  • Simple
  • Symptomatic
• Delayed
Delayed pressure urticaria
Vibratory angioedema
• Inherited
• Acquired

URTICARIA DUE TO TEMPERATURE CHANGES

Heat

Cold
• Cold contact urticaria
  • Primary
  • Secondary (cryoglobulins, cryofibrinogen)

URTICARIA DUE TO SWEATING OR STRESS
Cholinergic urticaria Adrenergic urticaria Exercise-induced urticaria • Exercise-induced anaphylaxis • Food- and exercise-induced anaphylaxis
SOLAR URTICARIA
AQUAGENIC URTICARIA
Rare variants are not shown here for simplicity (see text).

Table 18.3 Classification of physical urticarias by the eliciting stimulus.

Angioedema may be seen with all the physical urticarias except with symptomatic dermographism. Vibratory angioedema manifests with subcutaneous swellings but not wheals. Also, several forms of physical urticaria can coexist in the same patient. Common combinations include symptomatic dermographism and cholinergic urticaria; cold and cholinergic urticaria; and delayed pressure urticaria and delayed dermographism. Delayed pressure urticaria may coexist with chronic urticaria. Some rare forms of physical urticaria, such as familial delayed cold urticaria, are beyond the scope of this chapter.

Urticaria due to mechanical stimuli

Dermographism (literally "skin writing") (syn. factitious urticaria)

Immediate dermographism

This is divided into simple or symptomatic. Simple immediate dermographism occurs in ~5% of normal people in response to moderate stroking of the skin and may be regarded as an exaggerated physiologic response.

Symptomatic dermographism[30] is the most common of the physical urticarias (Fig. 18.9). It manifests as linear wheals at sites of scratching or sites of friction, such as collars and cuffs of clothes. Wheeling occurs after gentle stroking of the skin in response to a shearing force. Patients, most frequently young adults, often complain of pruritus before the wheals appear and may not associate them with scratching. It is worst in the evening and often occurs in bouts. The lesions usually resolve within an hour. Mucosal involvement does not occur, but vulvar swelling during sexual intercourse has been reported. The general course is unpredictable, but usually there is a gradual tendency towards improvement over several years. Symptomatic dermographism occasionally follows scabies infestation and penicillin allergy. There is no association with systemic disease, atopy, food allergy or autoimmunity.

Rarer forms of dermographism

These include delayed dermographism, which appears at least 30 minutes after a stroking stimulus, red dermographism (in response to rubbing, not stroking, the skin), localized dermographism, cholinergic dermographism, and dermographism associated with mastocytosis. The blanching response seen in patients with atopic and other forms of dermatitis, known as white dermographism, is not a form of urticaria.

Fig. 18.9 Symptomatic dermographism within minutes of scratching. *Courtesy, Jean L Bolognia, MD.*

Fig. 18.10 Delayed pressure urticaria.

Delayed pressure urticaria

Delayed pressure urticaria (DPU) is important because it can interfere severely with quality of life; it may be underdiagnosed and its treatment is difficult[31]. DPU is characterized by the development of deep erythematous swellings at sites of sustained pressure to the skin, after a delay of 30 minutes to 12 hours (Fig. 18.10); sometimes it resembles angioedema. The swellings are usually pruritic, painful, or both, and may persist for several days, unlike the spontaneous wheals of ordinary urticaria. Sites frequently involved are the waistline after wearing tight clothing, below the elastic of socks, the feet in tight shoes, the palms after manual work, the soles after walking or climbing ladders, and the genitalia after intercourse.

Systemic features such as malaise, "flu-like" symptoms and arthralgias may occur. If the swellings occur over joints, the resulting restriction of motion may be mistaken for arthritis. The prognosis is variable, but the mean duration in different series was 6–9 years. Up to 37% of patients with chronic ordinary urticaria attending a hospital specialist clinic had associated DPU[32]. Conversely, nearly all patients with DPU have associated spontaneous wheals. Because of this association and the delayed onset, patients may not be aware of any relationship to pressure unless specifically questioned.

Vibratory angioedema

This is a very rare form of urticaria, where a vibratory stimulus induces localized swelling and erythema within minutes, lasting 30 minutes. Stimuli include jogging, vigorous rubbing with a towel, and the use of vibrating machinery such as lawnmowers and motorcycles. Avoidance of vibratory stimuli enables patients to live a normal life. Vibratory angioedema may be acquired or familial. The acquired form is often milder, and it may be associated with other physical urticarias such as DPU and immediate symptomatic dermographism. The familial form is dominantly inherited, and intense vibratory stimuli may induce generalized erythema and headache.

Urticaria due to temperature changes

Heat exposure

Heat contact urticaria

This is one of the rarest forms of urticaria, where, within minutes of contact with heat from any source, itching and whealing occur at the site of contact, lasting up to 1 hour. This must be distinguished from cholinergic urticaria. Patients can present after contact with hot water (e.g. washing dishes), but also after contact with radiant heat or warm sunlight. Systemic symptoms of faintness, headache, nausea and abdominal pain have occurred when the urticaria is extensive. There is an even rarer delayed form.

Cold exposure

Cold urticaria represents a heterogeneous group of conditions in which whealing occurs within minutes of rewarming after cold exposure[33].

Fig. 18.11 Cold urticaria. Wheals developed on the forearm after placement of an ice cube for 10 minutes, followed by rewarming. *Courtesy, Thomas Schwarz, MD.*

Primary cold contact urticaria

The most commonly encountered form is primary cold contact urticaria; it accounts for at least 95% of cases (Fig. 18.11). Although cold urticaria may follow respiratory infections, arthropod bites or stings, and perhaps HIV infection, the cause of most cases remains unknown (idiopathic). It may occur at any age, but is most frequently seen in young adults. Itching, burning and whealing occur in cold-exposed areas minutes after rewarming the skin. Commonly, primary cold contact urticaria occurs in rainy, windy weather and after contact with cold objects, including ice cubes. Patients often relate symptoms to changes in temperature as much as to the absolute external temperature. Systemic symptoms of flushing, headache, syncope and abdominal pain can develop if large areas are affected. Cold baths and swimming should usually be avoided as there is a potential risk of anaphylaxis. The mean duration was 6–9 years in one series, though primary cold contact urticaria may be more transient if it follows a viral infection.

Secondary cold contact urticaria

Cases due to serum abnormalities such as cryoglobulinemia or cryofibrinogenemia are rare, and are associated with other manifestations such as Raynaud's phenomenon or purpura. The wheals are usually similar to those of primary cold contact urticaria, but may last longer. The presence of circulating cryoglobulins or cryofibrinogen should be determined, and serum protein and immunofixation electrophoreses performed. Underlying causes, such as hepatitis B or C viral infections, lymphoproliferative disease or infectious mononucleosis, should be excluded.

Fig. 18.12 Cholinergic urticaria on the trunk after exercising and sweating.

Fig. 18.13 Urticarial vasculitis. Lesions look like ordinary urticaria but last longer and may bruise. An incidental finding is a skin graft donor site.

Reflex cold urticaria

In this form, generalized cooling of the body induces widespread wheal-ing. Patients with this disorder can experience life-threatening reactions from exposures such as diving into a cold lake. The ice cube test is negative, but placing the patient in a cold room at 4°C can reproduce lesions. This is no longer performed, as fatal anaphylaxis can occur.

Familial cold urticaria

Familial cold urticaria, also referred to as familial cold autoinflammatory syndrome, belongs to the group of disorders known as cryopyrin-associated periodic syndromes (see Table 45.2). The patients have mutations in *NLRP3,* which encodes the protein cryopyrin, and they develop cold-induced urticarial papules.

Urticaria due to sweating or stress

Cholinergic urticaria

Cholinergic urticaria is characterized by multiple, transient, papular wheals that are 2–3 mm in diameter and surrounded by an obvious flare. They occur within 15 minutes of sweat-inducing stimuli, such as any form of physical exertion, hot baths or sudden emotional stress (Fig. 18.12). Other eliciting stimuli include moving from a cold to a hot room, drinking alcohol and eating spicy food. It occurs more frequently in young adults with an atopic diathesis and is unusual in the elderly.

After the appropriate stimulus, pruritus is followed by the development of small, monomorphic wheals that are symmetrically distributed. They are most prominent on the upper half of the body, but can also affect the lower legs and forearms and even become generalized. Angioedema and systemic manifestations consisting of faintness, headache, palpitations, abdominal pain and wheezing may occur. Reduced forced expiratory volumes (in the absence of respiratory symptoms) have been recorded by spirometry. In more severely affected individuals, cholinergic urticaria can cause severe personal and occupational disability.

Cold urticaria, symptomatic dermographism or aquagenic urticaria may be associated with cholinergic urticaria. There is usually a gradual tendency towards improvement, but the condition may last for years. Rarer forms include cholinergic pruritus, cholinergic erythema (in which pruritic, symmetric, small erythematous macules appear to be persistent, but individual lesions actually last for up to 1 hour), and cholinergic dermographism. Severe exercise-induced cholinergic urticaria may sometimes progress to anaphylaxis.

Exercise-induced anaphylaxis (EIA)

This can occur without the typical wheals of cholinergic urticaria and appears to be a syndrome in its own right[34]. Food- and exercise-induced anaphylaxis (FEIA) is an increasingly recognized syndrome[35]. In FEIA, angioedema and/or anaphylaxis occur within minutes of exercise if it follows either prior ingestion of a specific food (e.g. α-gliadin in wheat), or sometimes within 4 hours of a heavy meal. FEIA may be due to priming of the mast cell by prior exposure to an allergen, or to an unknown mechanism. EIA is produced by exercise, but not by an increase in core temperature induced by other means capable of provoking cholinergic urticaria (e.g. a hot bath), and this distinction can be used to differentiate between the two conditions.

Adrenergic urticaria

Adrenergic urticaria can be distinguished from cholinergic urticaria by the presence of blanched vasoconstricted skin surrounding small pink wheals induced by sudden stress, as opposed to pale wheals surrounded by a pink halo. The lesions can be reproduced by intradermal injections of norepinephrine (noradrenaline).

Urticaria due to other exposures

Solar urticaria

Itching and whealing occur within minutes of exposure to UV or visible wavelengths of solar radiation specific to the patient (see Ch. 87).

Aquagenic urticaria

In aquagenic urticaria, contact with water of any temperature induces an urticarial eruption resembling a sparse form of cholinergic urticaria. Lesions occur most frequently on the upper part of the body and last for less than an hour. Other physical urticarias must be excluded and the condition must be differentiated from aquagenic pruritus (see Ch. 6).

Urticarial Vasculitis

Urticarial vasculitis is a clinicopathologic entity in which cutaneous lesions resemble urticaria clinically (but last longer than 24 hours) (Fig. 18.13) and histologically show evidence of leukocytoclastic vasculitis (Table 18.4; see Ch. 24)[37].

Contact Urticaria (see Ch. 16)

Contact urticaria is defined by the development of urticaria at the site(s) of contact with skin or mucosa, but contact erythema and even burning and stinging without erythema are sometimes embraced in the definition[17]. Percutaneous or mucosal penetration of the urticant may have distant effects, including acute urticaria or even anaphylaxis. Contact urticaria may be more common than reported, as patients often do not present to the hospital or tertiary care clinics, because the diagnosis can be self-evident.

Immunologic and non-immunologic forms are recognized, depending on whether the contact urticaria is due to allergen interaction with specific IgE or is IgE-independent. Allergic contact urticaria can be seen in children with atopic dermatitis who become sensitized to environmental allergens, such as grass, animals and foods, or in glove-wearers who are allergic to latex. In those individuals repeatedly exposed to latex via mucosal surfaces (e.g. urinary catheterization in spina bifida patients), allergic contact urticaria can be complicated by anaphylaxis. Non-immunologic (i.e. non-allergic) contact urticaria is due to direct effects of urticants on blood vessels, such as from exposure to sorbic

URTICARIAL VASCULITIS	
Epidemiology	Favors middle-aged women
Characteristics of urticarial lesions	>24 hours in duration; painful & burning sensation as well as pruritus; residual purpura as they resolve
Sites of involvement	Often occur at pressure points
Concurrent angioedema	Up to 40% of pts
Extracutaneous manifestations (% of pts affected)*	Arthralgias (50%) – transient, migratory GI involvement (20%) – abdominal pain, nausea, vomiting, diarrhea Pulmonary obstructive disease (20%) Renal (5–10%) – proteinuria, hematuria Ocular (unusual) – conjunctivitis, episcleritis, uveitis Other (unusual) – Raynaud's phenomenon, livedo reticularis, splenomegaly, lymphadenopathy, idiopathic intracranial HTN, pericardial or muscle involvement
Associated disorders	Systemic lupus erythematosus Sjögren's syndrome Serum sickness Cryoglobulinemia Infections – hepatitis B or C virus, Epstein-Barr virus Rarely, solar or cold urticaria, drugs, hypergammaglobulinemia
Laboratory evaluation	CBC with differential, platelet count; ESR, CRP; LFTs, BUN, crt Complement assays – C3, C4, CH50; if C4 low, C1q Urinalysis If indicated, PFTs, CXR, SPEP, IFE Tests for associated disorders, e.g. ANA, anti-Ro Ab
Disease course	Average of 3 years
Treatment (primarily based upon small case series and case reports; see Table 24.9)	Antihistamines for associated pruritus NSAIDs – improvement in 50% of pts Colchicine, dapsone, hydroxychloroquine, methotrexate, plasmapheresis Corticosteroids ± immunosuppressants†

*Higher incidence and greater severity in patients with hypocomplementemia.
†Especially for hypocomplementemic urticarial vasculitis.

Table 18.4 Urticarial vasculitis. In a series of 132 patients, an elevated ESR (28%), hypocomplementemia (18%) and an ANA titer >1 : 160 (11%) were the more common abnormalities[36]. Ab, antibodies; ANA, antinuclear antibodies; BUN, blood urea nitrogen; CRP, C-reactive protein; crt, creatinine; CXR, chest X-ray; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; HTN, hypertension; IFE, immunofixation electrophoresis; LFTs, liver function tests; NSAIDs, nonsteroidal anti-inflammatory drugs; PFTs, pulmonary function tests; pts, patients; SPEP, serum protein electrophoresis.

acid and benzoic acid in eye solutions and foods or cinnamic aldehyde in cosmetics; it may be mediated by PGD_2 and can be inhibited by NSAIDs. Percutaneous microinjection of vasomediators (e.g. histamine, acetylcholine, serotonin) via nettle stings or contact with histamine liberators that degranulate mast cells (e.g. dimethylsulfoxide, cobalt chloride) can lead to contact urticaria within minutes.

Food contact hypersensitivity syndrome

The oral allergy syndrome presents with itching and mild swelling of the mouth, tongue and soft palate within minutes of eating fresh fruits such as apples, pears, peaches and cherries, but not cooked fruit. It usually occurs in hayfever sufferers and represents a cross-reaction between panallergens in grass or birch pollens with fruit proteins. Angioedema and anaphylaxis are fortunately very rare. Recently, the term "food contact hypersensitivity syndrome" was proposed to include all forms of mucosal food contact reactions, including oral allergy syndrome[38].

Angioedema Without Wheals

Recurrent angioedema without wheals is in many instances idiopathic, but it is important to exclude a drug reaction and to consider the possibility of C1 inh deficiency. The latter can be inherited or acquired (e.g. B-cell lymphoproliferative disorders, plasma cell dyscrasias).

Drug reactions

A number of drugs can cause angioedema without wheals. The most common are NSAIDs[39] and ACE inhibitors[40]. Aspirin intolerance may present with angioedema alone, or with urticaria or anaphylaxis; cross-reactions with other NSAIDs can occur. A causative link to ACE inhibitors may be overlooked because angioedema can present over a year after starting the medication. For practical purposes, ACE inhibitors should be discontinued in favor of other antihypertensive medications if angioedema occurs without wheals. ACE inhibitors are contraindicated in patients with HAE and acquired C1 inh deficiency.

Hereditary angioedema, types I and II (inherited C1 inh deficiency)

The likelihood of inherited C1 inh deficiency as a cause of recurrent angioedema is increased if there is a family history or previous laryngeal edema or colicky abdominal pain (sometimes presenting as a surgical emergency). Trauma (emotional or physical) and estrogens can trigger attacks. The usual duration is 48–72 hours, and episodes are often followed by a refractory period. Some families with HAE describe a transient, prodromal erythematous eruption, but urticarial wheals does not occur and so a history of recurrent wheals effectively excludes the disorder.

Hereditary angioedema, type III

Type III HAE refers to individuals with a heterozygous gain-of-function mutation in the gene that encodes FXII (see above). Compared to patients with an inherited deficiency of C1 inh, the age of onset is later (usually in the second decade) and there is a higher frequency of facial angioedema.

Distinctive Urticarial Syndromes

Hereditary periodic fever syndromes (autoinflammatory syndromes)

Cryopyrin-associated periodic syndromes (CAPS)

The allelic disorders Muckle–Wells syndrome, familial cold autoinflammatory syndrome (familial cold urticaria), and neonatal-onset multisystem inflammatory disease (NOMID/CINCA) are now known to be

all due to mutations in *NLRP3*, which encodes the protein cryopyrin (see Table 45.2)[41,42]. These patients can develop wheals from an early age that may prove quite resistant to antihistamines.

Other syndromes

In hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) and TNF receptor-associated periodic syndrome (TRAPS), erythematous and edematous urticarial plaques can occur in addition to periorbital edema (TRAPS). The cutaneous lesions in familial Mediterranean fever are more erysipeloid in appearance (see Table 45.2).

Schnitzler's syndrome

Schnitzler et al.[43] in 1974 described an unusual variant of chronic urticaria characterized by recurrent, non-pruritic wheals plus intermittent fevers, bone pain, arthralgia or arthritis, an increased ESR and a monoclonal IgM gammopathy. The clinical presentation has many similarities to CAPS. Skin biopsy specimens usually show a neutrophil-predominant dermal infiltrate, but fully developed vasculitis is uncommon. Some clinicians believe that these patients are best considered as having a variant of urticarial vasculitis that simply requires additional biopsies to demonstrate fully developed leukocytoclastic vasculitis. Schnitzler's syndrome has been reported to respond very well to anakinra, and the use of rilonacept is currently under investigation.

Episodic angioedema with eosinophilia

A syndrome of episodic angioedema with hypereosinophilia, weight gain and fever has been described (Gleich syndrome). The cause is uncertain, but increased serum levels of IL-5 have been found[44].

Systemic capillary leak syndrome

Also known as Clarkson's syndrome, this rare acquired disorder is characterized by episodic massive plasma exudation from blood vessels, leading to potentially life-threatening hypotension, analogous to anaphylaxis. Angioedema may be a feature. It is associated with an IgG paraproteinemia. Medications, in particular IL-2, can also produce a systemic capillary leak syndrome.

PATHOLOGY

The histopathology of urticaria is characterized by upper dermal edema with a mild mixed perivascular infiltrate of lymphocytes, eosinophils and some neutrophils (Fig. 18.14). A predominantly neutrophilic pattern has been described in a minority of patients, but this does not appear to carry any diagnostic significance[45]. Previous reviews of biopsy specimens from large series of patients with chronic urticaria have emphasized a spectrum of changes, ranging from mild lymphocytic infiltrates with rare neutrophils to occasionally showing fully developed leukocytoclastic vasculitis[46], emphasizing the potential for confusion between chronic urticaria and urticarial vasculitis. Features of the latter include endothelial cell damage, a perivenular cellular infiltrate rich in neutrophils, and leukocytoclasis. Some extravasation of erythrocytes and fibrinoid deposits in and around blood vessels may also be seen.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The differential diagnosis of urticaria includes all dermatologic conditions with an urticarial component, including insect bite reactions (papular urticaria), acute febrile neutrophilic dermatosis (Sweet's syndrome), pre-bullous pemphigoid (i.e. urticarial bullous pemphigoid), acute facial contact dermatitis (versus angioedema), urticarial drug reactions (e.g. antibiotics) and the urtication that may occur when lesions of urticaria pigmentosa are rubbed. In all these conditions, the urticarial component is part of a more prolonged inflammatory process (or mast cell proliferation in the case of mastocytosis) than is true urticaria and should be readily distinguishable by the prolonged duration of individual lesions.

Diagnosis

A comprehensive history is essential in every patient with urticaria. It should cover the duration of disease, frequency of attacks, duration of individual lesions, associated illness, previous treatment, known adverse reactions, past and family history, occupation and leisure activities, and an assessment of the impact of the disease on the patient's quality of life. The use of a detailed questionnaire in conjunction with a complete blood count and ESR was found to be almost as good as a complete diagnostic evaluation[47]. A full physical examination looking for the morphology and duration (by circling individual lesions) of wheals, bruising, livedo reticularis and signs of systemic disease should always be undertaken, but it is often normal. The patient's own photographs can often be useful because it is common for urticaria to have cleared by the time of consultation. Investigation should be targeted at specific features identified in the clinical assessment, as outlined below, and may include blood tests, skin biopsy (obtained in all patients with lesions lasting more than 24 hours), challenges for physical urticarias, food additives and drugs, and, infrequently, skin tests for allergy and the measurement of histamine-releasing autoantibodies. Most patients with antihistamine-responsive urticaria do not need an extensive investigation. A diagnostic algorithm is given in Figure 18.15.

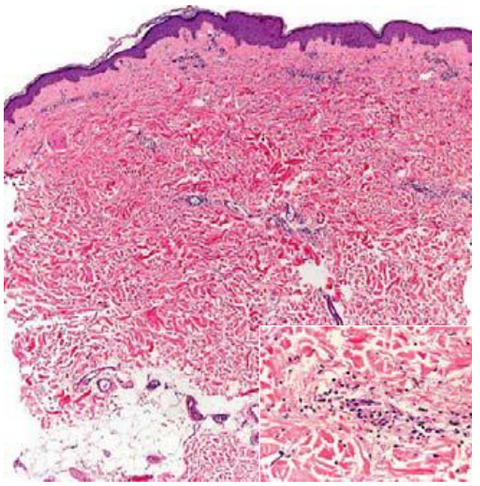

Fig. 18.14 Ordinary urticaria – histologic findings. A sparse, mainly perivascular inflammatory infiltrate and scant edema within the superficial and mid dermis. Note several neutrophils and a few eosinophils (insert). *Courtesy, Lorenzo Cerroni, MD.*

Acute urticaria

IgE-mediated reactions to environmental allergens as a cause of acute urticaria and contact urticaria can be confirmed by skin prick testing and serum radioallergosorbent tests (RAST). Results of both have to be interpreted in the clinical context.

Chronic urticaria

No investigations are routinely required for the majority of patients with mild disease that responds to antihistamines. A useful screening profile for non-responders with more severe disease could include a complete blood count and white cell differential (for instance, to detect the eosinophilia of intestinal parasitosis) and ESR (usually normal in chronic urticaria). The ESR may be elevated in urticarial vasculitis, and it is consistently high in the cryopyrin-associated periodic syndromes in which patients also have an elevated C-reactive protein level and an elevated serum amyloid A (SAA) protein level. Thyroid autoantibodies should be considered and thyroid function tests performed if indicated clinically. The prevalence of thyroid autoantibodies is higher in patients with chronic urticaria than in controls and may be an indicator of autoimmune urticaria. Tests for bowel parasites may be considered in the appropriate clinical setting.

Although the term "autoimmune" urticaria is increasingly being used for patients with evidence of functional serum autoantibodies (see Fig. 18.3), there is still a lack of agreement with regard to establishing such a diagnosis because of the lack of reliable, readily available or practical confirmatory tests. Demonstration of a localized wheal and flare response to intradermal injection of autologous serum (the autologous serum skin test; ASST) provides useful evidence of functional factors in the blood, but is not specifically a test for autoantibodies[48] (Fig. 18.16). A negative test, however, has very good negative predictive value for the absence of functional antibodies[49]. In the future, stricter regulatory guidelines regarding the handling of blood products will increasingly limit performance of this assay.

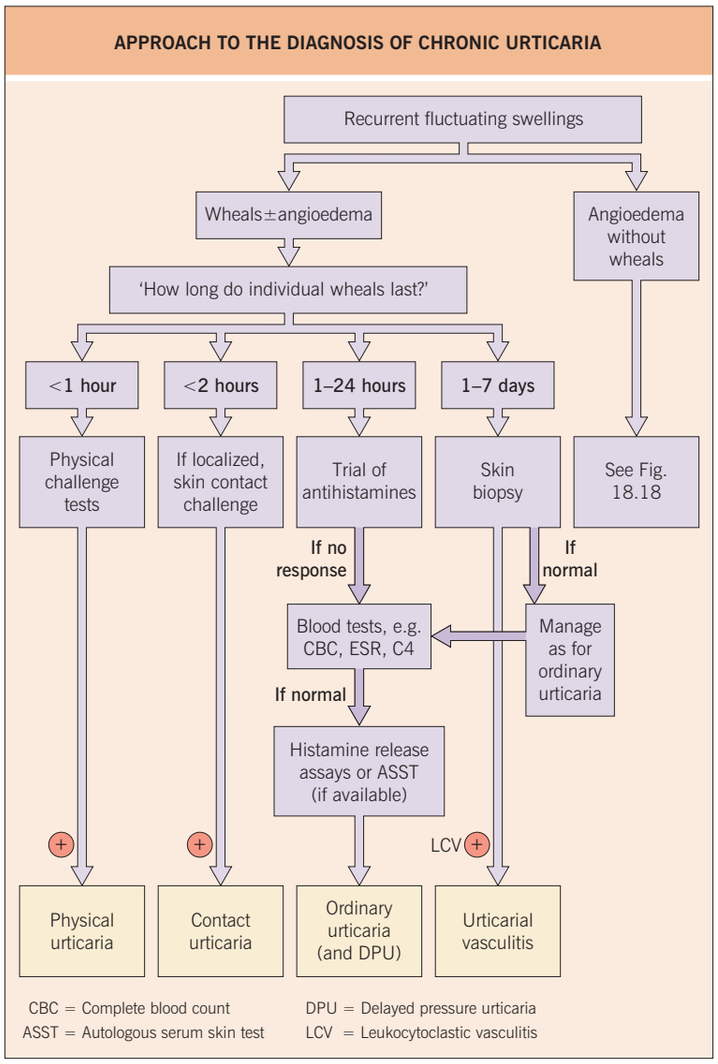

Fig. 18.15 Approach to the diagnosis of chronic urticaria.

Fig. 18.16 Autologous serum skin test (ASST). At 30 minutes, a red wheal response is present at the site of an intradermal injection of autologous serum, but not at that of a normal saline control. For the test to be positive, the wheal response at the serum injection site must be at least 1.5 mm greater in diameter than the control site. The ASST is a reasonably sensitive and specific screening test for functional autoantibodies as detected by the basophil release assay. Spontaneous wheals are also present at the venipuncture site and above the serum skin test.

Immunoassays for anti-FcεRI and anti-IgE antibodies (commercially available) do not necessarily correlate with basophil and mast cell histamine-releasing assays (sometimes commercially available) because non-functional as well as functional autoantibodies have been detected by Western blot and ELISA. The overlap between the ASST ("autoreactivity"), functional autoantibodies (detected via basophil or mast cell assays) and immunoassays ("immunoreactivity") is illustrated in Figure 18.17. The strongest evidence for an autoimmune etiology of urticaria is provided by demonstrating all three features, but many clinicians would accept a positive ASST and/or a positive functional assay as providing sufficient proof of autoimmunity to guide therapies and prognosis.

Physical urticarias

International standards for the diagnosis of physical urticarias and definitions of challenge testing have been proposed[28]. Symptomatic dermographism can be tested for simply by stroking the skin of the back lightly with the rounded edge of a wooden spatula. A calibrated instrument called a dermographometer, which is a spring-loaded stylus, the pressure of which can be adjusted to a predetermined setting (36 g/mm^2), can be used to quantify the sensitivity of the skin. Delayed pressure urticaria is confirmed if applying either a 2.5-kg weight to the thigh or back for 20 minutes (using a rod with a diameter of 1.5 cm) or a dermographometer set at 100 g/mm^2 for 70 seconds, results in a palpable wheal at 30 minutes to 8 hours (usually at 6 hours). Provocation tests for cholinergic urticaria include exercise to the point of sweating in an overheated environment, or partial immersion in a hot bath at 42°C for 10 minutes. A positive hot bath test excludes exercise-induced anaphylaxis. Cold contact urticaria is confirmed by the development of whealing at the site of application of an ice cube in a thin polyethylene bag or glove for 5 minutes (the most sensitive individuals may react after 30 seconds, with the least sensitive requiring up to 20 minutes of ice application; see Fig. 18.11).

Phototesting confirms the diagnosis of solar urticaria, with the development of wheals within minutes of exposure to natural or artificial radiation. The action spectra of the inducing wavelengths can be determined by narrowband monochromators (see Ch. 87). The diagnosis of aquagenic urticaria is made by inducing wheals after a bath or shower at body temperature, or under wet gauze applied at body temperature for 20 minutes. Localized heat urticaria is confirmed by applying a heated cylinder (temperature increments up to 45°C) to the skin for 30 seconds to 5 minutes.

Urticarial vasculitis

Lesional skin biopsy is essential and should be undertaken if circled lesions last more than 24 hours, in order to confirm the presence or absence of leukocytoclastic vasculitis histologically. The sampled lesion should have been present for 12–24 hours. Direct immunofluorescence microscopy is generally uninformative and should not be routinely performed. Patients with urticarial vasculitis need a full vasculitis screen (see Table 18.4 & Ch. 24).

Angioedema without wheals

Detection of a low serum level of C4 is a very sensitive, but nonspecific, screening test for types I and II HAE and acquired C1 inh deficiency (the level is normal in type III HAE). Measurement of the *amount* of C1 inh by immunochemical assay for type I HAE and C1 inh *function* to detect type II HAE should be performed if indicated by the history and supported by a low serum C4 level. Serum C1q levels are also reduced in acquired C1 inh deficiency (Fig. 18.18).

TREATMENT

Patients should be given advice and information on common precipitants, treatments and prognosis. Antipruritic lotions and the avoidance of aggravating factors, including NSAIDs, may be sufficient for some, but many will need additional interventions, including systemic medications. These can be stratified into first-, second- and third-line therapies (Fig. 18.19). The management of urticarial vasculitis (see Table 18.4) and that of C1 inh deficiency are considered separately because their pathogenesis and response to treatment are different. Patients must understand that although systemic corticosteroids may be the

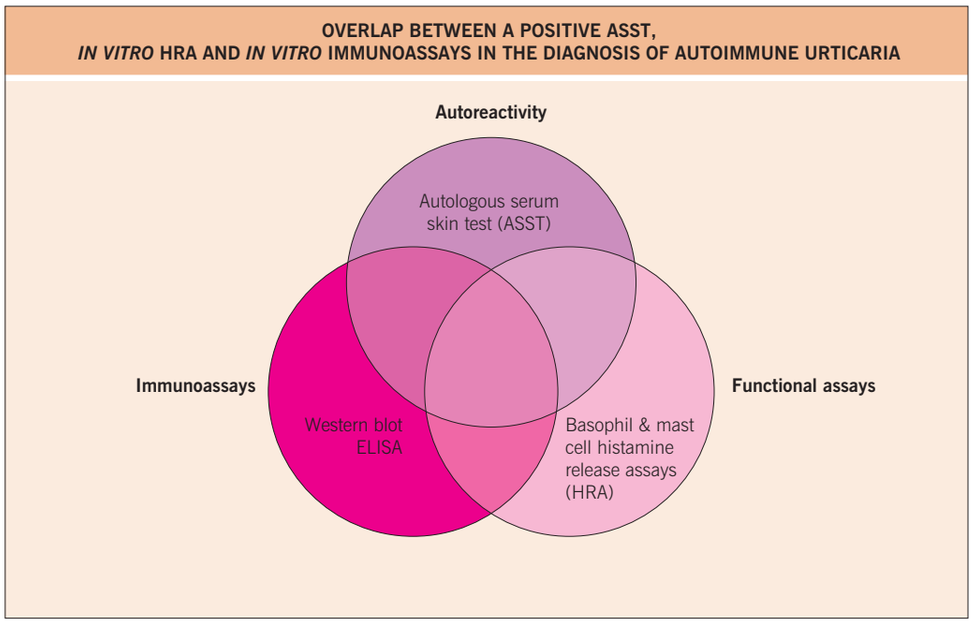

Fig. 18.17 Overlap between a positive autologous serum skin test (ASST), *in vitro* histamine release assays (HRA) and *in vitro* immunoassays in the diagnosis of autoimmune urticaria. The ASST will become increasingly difficult to perform in the future as regulations regarding blood products become more restrictive.

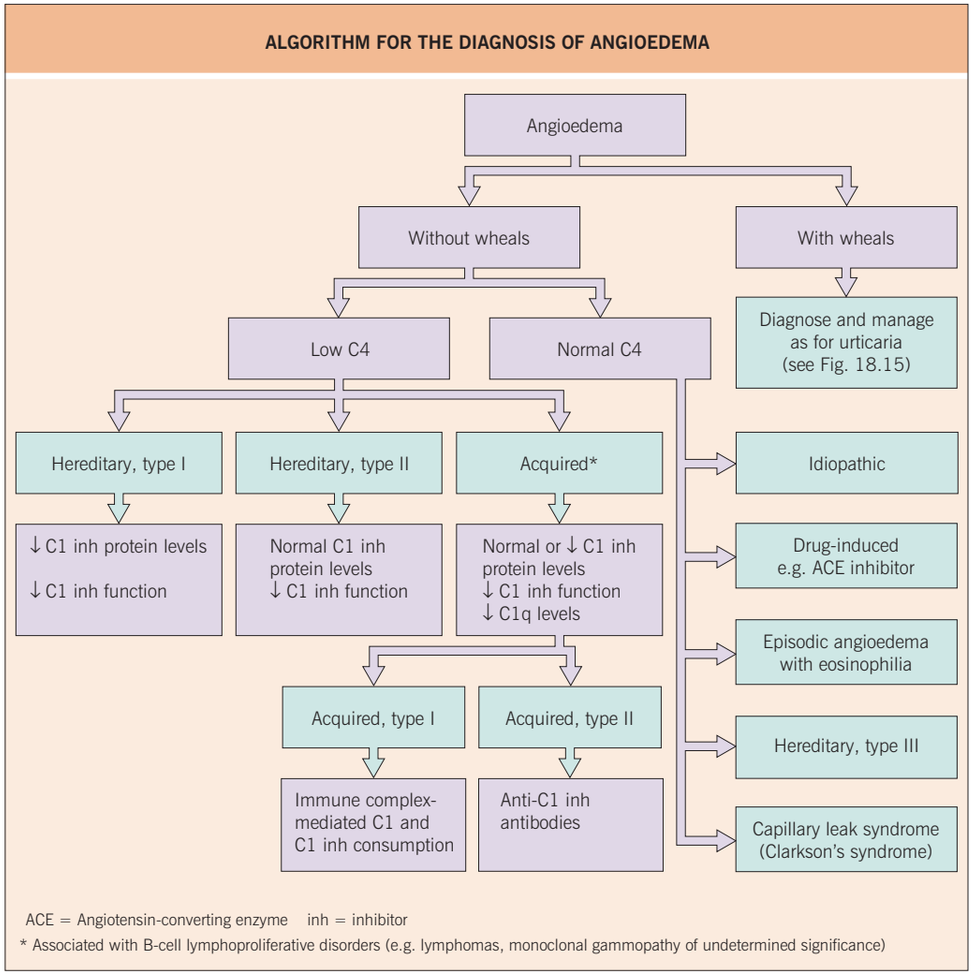

Fig. 18.18 Algorithm for the diagnosis of angioedema. Episodic angioedema with hypereosinophilia, along with weight gain and fever, is known as Gleich syndrome.

only treatment that completely eliminates their lesions, long-term use is unacceptable and combinations of other therapies can nearly always control symptoms and significantly improve quality of life.

Acute, Chronic and Physical Urticarias

First-line therapies

Antihistamines are the mainstay of management for most patients with urticaria, although not all patients will respond and only about 40% of those attending tertiary care clinics will clear or almost clear at licensed doses. Antihistamines reduce pruritus, flatten wheals, shorten wheal duration and reduce wheal numbers, even though they may not clear urticaria completely. It is worth discussing the relative benefit with patients who feel that "they haven't worked".

Antihistamines should be taken on a daily basis, the frequency depending on their half-life. In other words, they should not be taken only when the patient is symptomatic. As a general rule, antihistamines are safe and have few significant adverse effects. They can be

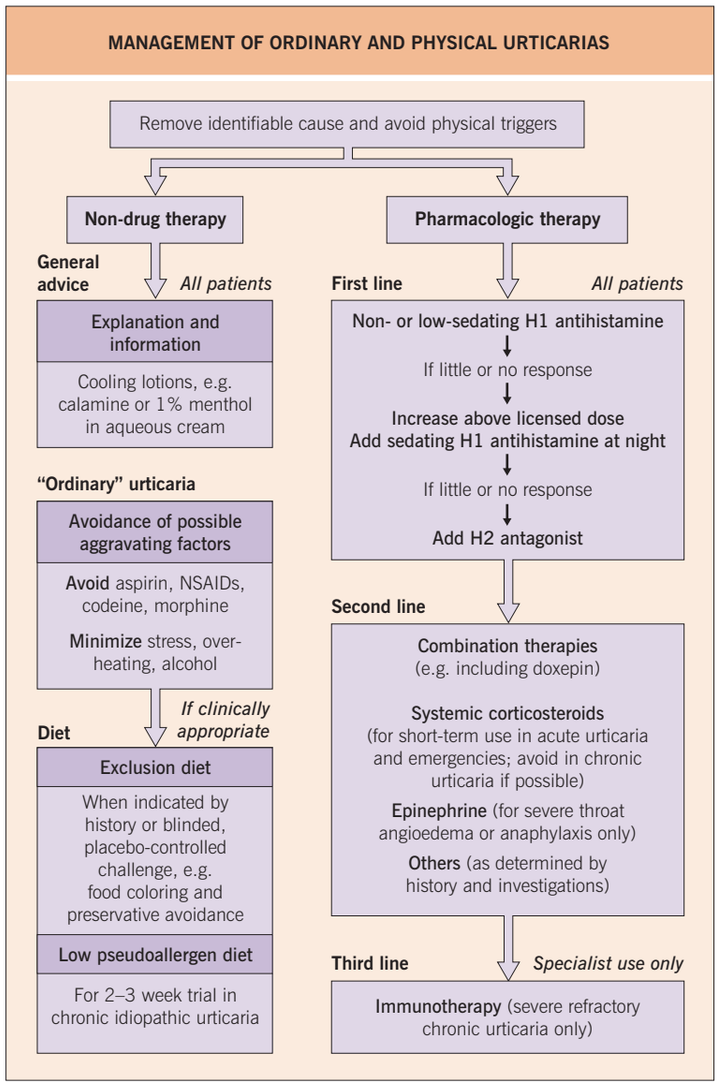

Fig. 18.19 Management of ordinary and physical urticarias.

grouped into first-generation (classic) antihistamines, second-generation (non- or minimally sedating) antihistamines and their derivatives, and the H_2 antagonists (Table 18.5). Combining drugs from the different groups can lead to better control of urticaria symptoms.

Classic antihistamines

Classic antihistamines are problematic because sedation and anticholinergic side effects are often dose-limiting. However, in combination with a daytime non-sedating antihistamine, they can be taken at night if sleep is disturbed by urticaria, but the following day they may interfere with skilled tasks (e.g. operating machinery and driving) or reduce the ability to concentrate at work or school. Chlorpheniramine is often chosen for pregnant women when antihistamines are essential, because it has a long safety record; however, it is not licensed for this indication and should be avoided in the first trimester if possible.

Second-generation antihistamines

Second-generation antihistamines are usually well tolerated, with the majority of patients requiring only once-daily oral dosing (see Table 18.5). For chronic urticaria, there is probably little distinction between the second-generation antihistamines when they are taken at the licensed dosages. A European consensus paper has recommended increasing the daily dose of second-generation H_1 antihistamines up to fourfold for difficult urticaria[50]. It is possible that their additional anti-allergic and anti-inflammatory properties may be clinically beneficial at these higher doses, but direct evidence for this is lacking and they do represent unlicensed dosages.

Fexofenadine is licensed for urticaria at 180 mg daily. It is the active metabolite of terfenadine, but does not appear to have the potential for ventricular arrhythmias of its parent drug at licensed doses. Desloratadine (an active metabolite of loratadine) and levocetirizine (the active enantiomer of cetirizine) probably offer no clinical advantage over their parent drugs at equivalent doses.

Clinically important drug interactions are infrequent, but coadministration of mizolastine with systemic erythromycin and ketoconazole is contraindicated because of concern about possible cardiac arrhythmias. Caution is also recommended with regard to other hepatic cytochrome P450 3A4 inhibitors or substrates (see Ch. 131), including cimetidine and cyclosporine, which may be used for urticaria in special circumstances.

Addition of H_2 antagonists to conventional H_1 antihistamines

The addition of H_2 antagonists to conventional H_1 antihistamines may be helpful in some patients with chronic urticaria, although the evidence for combining H_1 and H_2 antihistamines is poor and not all authorities recommend this therapeutic approach. H_2 antihistamines have no effect on histamine-induced pruritus and should not be used as monotherapy. Ranitidine is preferable to cimetidine because, unlike cimetidine, it does not interfere with hepatic metabolism of other drugs and does not bind androgen receptors. Nizatidine and famotidine have similar properties to ranitidine, but have not been evaluated in clinical trials for chronic urticaria and cannot be specifically recommended.

Second-line therapies (targeted interventions)

Second-line therapies may be considered when urticaria does not respond well to antihistamines, but high-quality evidence to support their use is lacking. They should usually be prescribed as additive therapies (to antihistamines) rather than as alternatives. The choice of second-line drugs should be guided by specific indications, summarized in Table 18.6. Here, the management of urticaria can be influenced considerably by a full clinical assessment and the experience of the clinician. It is unusual for children to need second-line therapies, except the occasional use of prednisolone for very severe acute exacerbations of chronic urticaria. Second-line drugs should be used with considerable care in pregnancy, and only after the risks have been carefully considered against the likely benefits. Non-drug interventions include diets, phototherapy and cold desensitization.

Drug therapies

Prednisone or *prednisolone* is effective for nearly all presentations of chronic urticaria, but often needs to be used at reasonably high doses (30–50 mg daily) to achieve good initial control of severe disease. It should be considered primarily for the short-term management of "crisis" urticaria and serious angioedema of the throat, when, often, a single dose or several daily doses will be sufficient to re-establish control with regular full-dose antihistamines. Regular treatment with oral corticosteroids should be avoided because of the usually prolonged duration of chronic urticaria and because of their predictable side effects (e.g. hypertension, weight gain, glucose intolerance, osteoporosis). Rebound is also a common problem and the long-term course of the urticaria is often not altered.

Epinephrine (adrenaline) by subcutaneous or intramuscular injection is the treatment of choice for anaphylactic shock or severe anaphylactoid reactions, whether due to an allergy, pseudoallergy or physical urticaria. Epinephrine may also be necessary for angioedema of the oropharynx in severe acute allergic urticaria and idiopathic angioedema, but it is rarely required for chronic urticaria and is not effective for HAE. Directing epinephrine mist from an aerosol inhaler onto mucosal angioedema may be helpful for minor episodes, but it is usually better to administer the drug intramuscularly or subcutaneously, if it is required. Side effects of epinephrine include tachycardia, anxiety and headache. It should be used with caution in patients with hypertension, ischemic heart disease, cerebrovascular disease and diabetes mellitus. Coadministration of tricyclic antidepressants (including doxepin) and β-blockers should be avoided. For reassurance, patients who are prone to severe acute allergic urticaria and idiopathic angioedema may carry a self-administered epinephrine pen and they need to be aware of side effects, drug interactions and potential rebound phenomenon.

Doxepin is a tricyclic antidepressant with very potent H_1 and H_2 antihistaminic properties. Although it has significant sedative and

ANTIHISTAMINES FOR URTICARIA			
Class	**Examples**	**Plasma half-life (hours)**	**Daily adult dose***
Classic (sedating) H_1 antihistamines	Chlorpheniramine (1)	12–15	4 mg three times daily (up to 12 mg at night)
	Hydroxyzine (1)	20	10–25 mg three times daily (up to 75 mg at night)
	Diphenhydramine (2)	4	10–25 mg at night
	Doxepin† (1)	17	10–50 mg at night
Second-generation H_1 antihistamines	Acrivastine‡ (1)	2–4	8 mg three times daily
	Cetirizine§(1)	7–11	10 mg once daily
	Loratadine (1)	8–11	10 mg once daily
	Mizolastine‖ (1)	13	10 mg once daily
Newer second-generation H_1 antihistamines	Desloratadine (1)	19–35	5 mg once daily
	Fexofenadine (1)	17	180 mg once daily
	Levocetirizine (1)	7–10	5 mg once daily
	Rupatadine (1)	6	10 mg once daily
H_2 antagonists¶	Cimetidine (1)	2	400 mg twice daily
	Ranitidine (2)	2–3	150 mg twice daily

*Current prescribing manuals should be consulted for details on doses in children.
†Possesses potent H_1 and H_2 antihistamine properties.
‡Only available in the US as a combination product with pseudoephedrine for seasonal allergic rhinitis.
§The active metabolite of hydroxyzine.
‖Not available in the US.
¶Used in combination with H_1 antagonists.

Table 18.5 Antihistamines for urticaria. A short-acting classic antihistamine may be added at night to a daily second-generation antihistamine, with or without the addition of an H_2 antagonist for maximal antihistamine blockade. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

SECOND-LINE MEDICATIONS FOR CHRONIC OR PHYSICAL URTICARIA				
Generic name	**Drug class**	**Route**	**Dose**	**Special indication/associated diseases**
Prednisone (2)	Corticosteroid	Oral	0.5 mg/kg daily	Severe exacerbations (days only)
Epinephrine (2)	Sympathomimetic	Subcutaneous, IM (self-administered)	300–500 mcg	Idiopathic or allergic angioedema of throat/ anaphylaxis
Montelukast (3)	Leukotriene receptor antagonist	Oral	10 mg daily	Aspirin-sensitive urticaria, ? delayed pressure urticaria
Thyroxine (2)	Thyroid hormone	Oral	50–150 mcg daily	Autoimmune thyroid disease
Colchicine (3)	Neutrophil inhibitor	Oral	0.5/0.6–1.5/1.8 mg* daily	Neutrophilic infiltrates in lesional biopsy specimens or urticarial vasculitis
Sulfasalazine (3)	Aminosalicylates	Oral	2–4 g daily	Delayed pressure urticaria

Table 18.6 Some second-line medications for chronic or physical urticaria. Current prescribing manuals should be consulted for details on dose, drug interactions and contraindications for individual patients. The stated doses represent guidelines only. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. *Available in doses of 0.5 mg or 0.6 mg, depending upon the country. IM, intramuscular.

anticholinergic properties, it may be valuable, especially when dosed at night in adult patients with chronic urticaria.

Montelukast, a leukotriene receptor antagonist (see Ch. 130), may be beneficial for aspirin-sensitive chronic urticaria[51], due to the likely involvement of leukotrienes in its pathogenesis. *Zafirlukast* has also been used. There have been anecdotal reports of responses in refractory chronic urticaria associated with delayed pressure urticaria, but clinical experience to date has been less encouraging. Side effects are uncommon, but urticaria, angioedema and anaphylaxis have been reported when it has been given for other indications.

Thyroxine supplementation has been reported to suppress chronic ordinary urticaria in biochemically euthyroid patients with elevated levels of antithyroid autoantibodies. Although there may be occasional successes from this approach, the results are inconsistent.

Sulfasalazine can be helpful for chronic urticaria when delayed pressure urticaria (DPU) symptoms predominate, providing it is tolerated. Otherwise, these patients often require systemic corticosteroids. The drug should be avoided in patients with aspirin sensitivity and glucose-6-phosphate dehydrogenase (G6PD) deficiency. Complete blood count and hepatic enzymes must be monitored monthly for the first 3 months, and then regularly during therapy. Stevens–Johnson syndrome, nephrotic syndrome and oligospermia have been reported. Dapsone can be considered in DPU patients who are sensitive to NSAIDs.

Colchicine may be beneficial for chronic urticaria when predominantly neutrophilic infiltrates are seen histologically ("neutrophilic urticaria") and it is also used for urticarial vasculitis. Possible side effects include nausea, vomiting and abdominal pain. Peripheral neuritis,

myopathy, alopecia and myelosuppression have been reported rarely with prolonged treatment. Patients with liver or renal disease who are receiving colchicine should avoid P-glycoprotein or strong CYP3A4 inhibitors.

Nonsteroidal anti-inflammatory drugs have been used to treat DPU, with conflicting results, but may exacerbate chronic urticaria.

Anabolic steroids, such as danazol, may be useful for severe cholinergic urticaria, but virilizing side effects and long-term concern regarding liver toxicity are disadvantages.

Miscellaneous drug therapies described for chronic urticaria include tranexamic acid, heparin and warfarin, but convincing evidence for their use is lacking and there are no specific situations where they appear to be better than other treatments.

Non-drug therapies

Exclusion of food additives and natural salicylates from the diet has been advocated in a number of reports. The high success rates in some series may have been due in part to the natural history of remission in chronic urticaria, as less than 20% of patients responding to low-pseudoallergen diets flare after double-blind placebo-controlled challenge with individual additives[52]. Diets nevertheless remain popular with chronic urticaria patients and are always worth considering when antihistamines have failed and second-line drugs are inappropriate. There is general agreement that food allergy as a cause of adult chronic urticaria is exceptional, and that investigation for relevant immediate hypersensitivity reactions should not be undertaken without a strong lead from the history.

Induction of tolerance by repeated frequent graduated exposures to the precipitating physical factor can be helpful for cold urticaria, solar urticaria and localized heat contact urticaria. The schedule is time consuming, not all patients can be rendered tolerant, and repeated daily exposures are necessary to maintain tolerance.

Ultraviolet therapy and photochemotherapy (PUVA) have been used for chronic urticaria, but the reported results have been inconclusive. A retrospective survey suggested that narrowband UVB (NB-UVB) phototherapy might be effective. There is limited evidence that PUVA and NB-UVB are helpful for highly symptomatic dermographism at doses usually administered for psoriasis.

Third-line therapies

The recognition that some patients with severe urticaria unresponsive to antihistamines have an autoimmune etiology has opened up the option of immunotherapy for selected cases of chronic autoimmune urticaria.

Plasmapheresis was used successfully in some patients with chronic autoimmune urticaria in a small, open, proof-of-concept study, but it is not recommended as monotherapy because of its expense, its potential morbidity, and the early relapse of the urticaria[53].

IVIg infusions (total of 2 g/kg over 5 days) were beneficial in the majority of chronic autoimmune urticaria patients in another small open study, with remissions in some lasting at least 3 years[54]. Expense and potential morbidity remain a concern for this approach, which has not been subject to controlled studies.

Cyclosporine (3–4 mg/kg/day) appears to clear or substantially benefit approximately two-thirds of patients with chronic autoimmune urticaria refractory to antihistamines. This benefit has been confirmed in a double-blind study of cyclosporine at 4 mg/kg/day for 4–8 weeks; there were no serious adverse effects (e.g. renal impairment)[55]. However, only 25% of responders remained clear or almost clear 4–5 months after discontinuing therapy, and symptomatic side effects (e.g. gastrointestinal) were common. In addition, the risk of maintaining the "impossible to wean" patient on long-term cyclosporine is potentially considerable, as is the risk of rebound after discontinuation. Optimal treatment protocols have yet to be confirmed.

Other *immunosuppressive therapies*, including methotrexate, mycophenolate mofetil, azathioprine and cyclophosphamide, may work for some patients with severe chronic urticaria, if cyclosporine fails. Responses to *methotrexate* may be seen in steroid-dependent chronic urticaria patients with and without evidence of functional autoantibodies[56].

Omalizumab (humanized anti-IgE monoclonal antibody) has been reported anecdotally to be effective for spontaneous and inducible urticarias at doses equivalent to those used in asthma. Its effectiveness in chronic spontaneous urticaria has been demonstrated in a double-blind study[56a].

Urticarial Vasculitis

Treatment options are outlined in Tables 18.4 and 24.9.

C1 Esterase Inhibitor (C1 inh) Deficiency

The treatment of C1 inh deficiency differs from that of other types of angioedema. C1 inh concentrate should be given in an emergency, as it may prove to be life-saving. Fresh frozen plasma may be given as an alternative to C1 inh concentrate if the latter is unavailable. Antihistamines, corticosteroids and epinephrine are not effective in patients with C1 inh deficiency[57]. To treat an acute life-threatening attack, patients with the acquired form of C1 inh deficiency often require much higher doses of C1 inh concentrate than the 20 units/kg recommended for HAE.

C1 inh concentrate may also be given as prophylaxis 1 hour before elective surgery, especially when intubation or tooth extraction is necessary. For minor surgical procedures, oral tranexamic acid (1 g four times daily in adults or 500 mg four times daily in children) for 48 hours before and after the procedure, or an increase in established maintenance doses of tranexamic acid or anabolic steroids, can be effective prophylaxis. Maintenance therapy is only necessary for patients with symptomatic recurrent angioedema or related abdominal pain.

Oral danazol is the treatment of choice for most patients, since stanozolol is now difficult to obtain. Virilizing side effects may occur even at the low doses needed for long-term maintenance therapy. Regular monitoring for hepatic inflammation and adenomas is essential. Oral tranexamic acid (an inhibitor of the activation of plasminogen to plasmin) may be used for maintenance, but it is contraindicated if there is a history of thrombosis. The manufacturer recommends regular eye examinations and liver function tests in the setting of long-term administration. ε-Aminocaproic acid has also been prescribed for some patients. Icatibant, a specific bradykinin B_2 receptor antagonist, and ecallantide, a kallikrein inhibitor, have recently been approved for the emergency management of HAE (see Fig. 18.6); both are administered as subcutaneous injections. Because HAE may be induced or exacerbated by estrogens in oral contraceptive pills or hormone replacement therapy, they should be avoided if possible.

PROGNOSIS

Most patients with chronic urticaria can expect to benefit from treatment, but the prognosis for complete recovery has probably changed little from that in a survey done over 40 years ago, which identified that 50% of patients attending a tertiary referral center with urticaria alone were clear within a year, but that 20% with urticaria and angioedema continued to have symptoms 20 years from the time of onset[58].

Figurate Erythemas 19

Agustín España

Chapter Contents

Erythema annulare centrifugum 307
Erythema marginatum 312
Erythema migrans 313
Erythema gyratum repens 316

INTRODUCTION

Erythemas represent a change in the color of the skin that is due to the dilation of blood vessels, especially those in the papillary and reticular dermis. The color, which is blanchable, can vary from pink to dark red to violaceous. Most erythemas last for days to months, but some may last only minutes (e.g. flushing). Although erythemas represent a broad and heterogenous group of cutaneous disorders, i.e. they can range from palmar erythema of pregnancy to a diffuse scarlatiniform eruption, the erythemas discussed in this chapter all share a common feature – a figurate configuration.

In figurate erythemas, the lesions have an annular, arciform or polycyclic appearance. While a wide range of cutaneous diseases can have an annular configuration (Table 19.1), there are four "classic" figurate erythemas: erythema annulare centrifugum, erythema marginatum (rheumaticum), erythema (chronicum) migrans, and erythema gyratum repens.

ERYTHEMA ANNULARE CENTRIFUGUM

Synonyms: ■ Superficial or deep gyrate erythema ■ Erythema perstans ■ Palpable migrating erythema

Key features

- Erythematous annular lesions that migrate centrifugally
- Superficial lesions have the classic "trailing" white scale, while the deep gyrate erythemas have a more infiltrated border
- The disorder occurs more commonly in adults, and superficial lesions favor the thighs and hips
- Individual lesions usually last for several days to a few months
- Although often idiopathic in nature, it can be associated with infections (e.g. tinea pedis) and anecdotally with other disorders or exposures

Introduction

The term "erythema annulare centrifugum" (EAC) has been applied to a broad spectrum of clinical findings. As a result, it has come to encompass more than just annular erythematous plaques with trailing scale. One explanation for this is that once the other three major figurate erythemas (with specific etiologies; see below) and the disorders listed in Table 19.1 are excluded, EAC often becomes a "default" diagnosis. Unfortunately, this has led to some confusion, but until a specific "trigger" can be identified for each individual patient, this situation will persist. As a consequence, some authors have come to the conclusion that EAC, especially the deeper form, represents a clinical reaction pattern rather than a specific clinicopathologic entity[1]. Adding to the confusion is the school of thought in which the term EAC is reserved for only the superficial form.

History

In 1881, Colcott-Fox described persistent, ring-shaped lesions with pruritus, to which he gave the name "erythema gyratum perstans". Twenty-five years later, Wende described "erythema figuratum perstans", which was characterized by recurrent lesions with scale-crust. The term "EAC" was actually introduced by Darier in 1916. Lastly, the name "erythema perstans" has been used by some authors to describe these various presentations[2]. It is now thought that all of these terms refer to clinical or pathologic variants of the entity now referred to as EAC[3]. However, Ackerman[4] preferred to call the two histologically different forms (superficial and deep) of EAC "superficial gyrate erythema" and "deep gyrate erythema", whereas Weyers et al.[5] believe that the superficial and deep forms of EAC are unrelated to one another and should not be referred to by the same name. These latter authors recommend that the term EAC be reserved for the superficial type, which in their opinion represents a specific clinicopathologic entity.

Epidemiology

Although EAC can appear in any age group, its peak incidence is during the fifth decade of life. There is no known gender difference. A rare dominantly inherited form of EAC has been described that has also been referred to as "familial annular erythema"[6]. The overall duration of the disorder can range from several days to decades[3], and an unusual form that recurs annually has been described.

Pathogenesis

It has been suggested that EAC, especially the superficial form with epidermal spongiosis histologically, represents a reaction pattern or "hypersensitivity" to one of many antigens. EAC has been associated with infectious agents, particularly dermatophytes, but also with other fungi (e.g. *Candida, Penicillium* in blue cheese[7]), viruses (e.g. poxvirus, EBV, varicella-zoster virus, HIV), parasites and ectoparasites (e.g. *Phthirus pubis*). Less commonly, EAC has been linked to drugs (e.g. diuretics, nonsteroidal anti-inflammatory drugs, antimalarials, gold, finasteride, amitriptyline, etizolam), pregnancy, particular foods, autoimmune endocrinopathies, hypereosinophilic syndrome and, occasionally, neoplasms (e.g. lymphomas, leukemias)[8]. However, these associations are anecdotal, and, in the last group, Curth's postulates have not been consistently fulfilled (see Ch. 53). There are patients with EAC who noted resolution of their lesions after the diseases that presumably triggered the EAC were successfully treated.

Another unresolved aspect of EAC is the mechanism by which the lesions migrate at their periphery. Localized areas of cutaneous inflammation are thought to reflect localized production of proinflammatory cytokines and vasoactive peptides. However, how and why this process spreads centrifugally remains an enigma[9]. The disappearance of EAC lesions after the administration of interferon suggests that TNF-α and IL-2 may have a role in its pathogenesis[10].

Clinical Features

The initial lesions of EAC begin as firm pink papules that expand centrifugally and then develop central clearing. An individual lesion can enlarge to greater than 6 cm in diameter over a period of 1 to 2 weeks. If expansion of the annular plaque is not uniform, incomplete arcs appear, as do polycyclic lesions, or simply festooned bands. In the superficial form, the lesions are minimally elevated, and there is desquamation at the inner margin, i.e. trailing scale (Fig. 19.1A).

DIFFERENTIAL DIAGNOSIS OF FIGURATE ERYTHEMA			
Disorders	**Clinical features**	**Histologic findings**	**Cross references**
TRANSIENT LESIONS (TYPICALLY LASTING <24 HOURS)			
Urticaria	Transient and recurrent wheals; pruritus	Superficial perivascular infiltrate of eosinophils and lymphocytes; occasionally neutrophils (then sometimes referred to as neutrophilic figurate erythema of infancy)	Ch. 18
Erythema marginatum	Polycyclic erythematous eruption; antecedent group A streptococcal infection; additional manifestations of acute rheumatic fever, e.g. arthritis and carditis	Scant perivascular infiltrate of neutrophils in the papillary dermis without vasculitis	See text
Erythema marginatum-like lesions of hereditary angioedema	Transient polycyclic erythematous eruption; favors trunk; precedes or accompanies episodes of angioedema	Minimal to no inflammatory infiltrate; dense perivascular and interstitial dermal deposits of bradykinin	Ch. 18
African trypanosomiasis	Annular erythematous patches on the trunk associated with fever spikes	Perivascular lymphocytic infiltrate; parasites are occasionally seen within the dermis	Ch. 83
Erythrokeratodermia variabilis	Transient gyrate or circinate erythematous patches (usually fade/migrate within a few hours); also fixed figurate hyperkeratotic plaques; *GJB4* mutations	Scant perivascular lymphocytic infiltrate; dilated capillaries	Ch. 57
URTICARIAL LESIONS LASTING >24 HOURS			
Allergic urticarial eruption	Annular edematous plaques; favors trunk	Superficial and deep lymphocytic infiltrate with eosinophils	
Annular erythema of infancy	Recurrent annular erythematous plaques, usually lasting a few days; typically affects infants 3–11 months of age (see Fig. 19.4)	Perivascular lymphocytes and eosinophils	
Wells' syndrome	Edematous erythematous plaques, often annular or arcuate with a greenish color centrally; pruritus; peripheral blood eosinophilia	Diffuse infiltrate of eosinophils; flame figures	Ch. 25
Urticarial vasculitis	Urticarial plaques, often annular, that may have a purpuric component; pain, burning and/or pruritus; systemic manifestations in hypocomplementemic form	Leukocytoclastic vasculitis	Ch. 24
Erythema migrans	Erythema slowly migrates from site of tick bite; influenza-like syndrome; secondary distant lesions	Superficial and deep perivascular lymphohistiocytic infiltrate; eosinophils and plasma cells in erythema migrans; mucin in LE tumidus and annular erythema of Sjögren's syndrome	See text and Ch. 74
Erythema annulare centrifugum (deep)	Annular erythema with raised borders		See text
Lymphocytic infiltrate of Jessner	Annular erythematous plaques; favors face and upper trunk		Ch. 121
LE tumidus	Annular erythematous plaques; favors face, upper trunk > extensor forearms		Ch. 41
Annular erythema of Sjögren's syndrome*	Annular erythematous plaques; favors face, arms, upper trunk; most common in Asian patients; anti-Ro antibodies		Ch. 45

*Considered by many authors to be a form of SCLE.

Table 19.1 Differential diagnosis of figurate erythema. Key clinical features and histologic findings are provided. Additional conditions that can present with figurate erythema include **Kawasaki disease (may be erythema marginatum-like), hereditary periodic fever syndromes (especially *T*NF *r*eceptor-*a*ssociated *p*eriodic *s*yndrome [TRAPS]; see Table 45.2), relapsing polychondritis, polymorphous light eruption, inflammatory vitiligo (including a papulosquamous variant), eosinophilic vasculitis, Sweet's syndrome, neutrophilic eccrine hidradenitis, pyoderma vegetans (expanding pustular lesions) and leukemia cutis**. AFB, acid-fast bacilli; BMZ, basement membrane zone; FTA-ABS, fluorescent treponemal absorption; GI, gastrointestinal; LE, lupus erythematosus; RPR, rapid plasma reagin; SCLE, subacute cutaneous LE.

DIFFERENTIAL DIAGNOSIS OF FIGURATE ERYTHEMA			
Disorders	**Clinical features**	**Histologic findings**	**Cross references**
GRANULOMATOUS LESIONS			
Granuloma annulare	Skin-colored to pink annular and arcuate plaques with borders composed of multiple papules; favors acral and extensor sites	Palisading granulomas with altered collagen and mucin	Ch. 93
Annular elastolytic giant cell granuloma	Pink annular plaques with atrophy and hypopigmentation centrally; favors sites of chronic sun exposure	Granulomatous infiltrate with elastophagocytosis by giant cells (border of lesion); absence of elastic fibers (center of lesion)	Ch. 93
Interstitial granulomatous dermatitis (IGD); interstitial granulomatous drug reaction (IGDR)	Annular erythematous plaques (or, in IGD, linear cords); favors axillae, groin, lateral trunk and legs; associated arthralgias/arthritis; IGDR is most often due to antihypertensive and lipid-lowering agents	Palisading granulomas surrounding tiny foci of degenerated collagen; neutrophils and eosinophils; little to no mucin	Ch. 45
Sarcoidosis	Red-brown annular plaques and papules; favors face; systemic manifestations	Sarcoidal granulomas ("naked tubercles")	Ch. 93
Borderline or tuberculoid leprosy	Annular plaques with raised erythematous borders and (in tuberculoid lesions) central hypopigmentation; asymmetric distribution; hypoesthesia, alopecia	Linear or oval perineural granulomas in the dermis; foamy macrophages and AFB in borderline lesions	Ch. 75
PAPULOSQUAMOUS LESIONS			
Erythema annulare centrifugum (superficial)	Annular lesions with trailing scale; favors thighs, hips and trunk	Superficial perivascular lymphocytes with focal parakeratosis and spongiosis; focal hemorrhage in pityriasis rosea	See text
Erythema gyratum repens	Concentric erythematous rings with wood-grain appearance; erythema moves ~1 cm per day; associated with cancer		See text and Ch. 53
Pityriasis rosea	Herald patch on trunk; oval annular papules and plaques with central fine scaling plus a collarette of trailing scale; Christmas-tree distribution on posterior trunk		Ch. 9
Pityriasis rubra pilaris	Appears as the primary "classic" lesions resolve; resembles erythema gyratum repens	Alternating vertical and horizontal ortho-and parakeratosis; follicular plugging with shoulders of parakeratosis	See text and Ch. 9
Tinea corporis	Annular plaques with scale (exception: tinea incognito); pustules in border; concentric lesions in tinea imbricata; KOH-positive	Dermatophytes in the stratum corneum	Ch. 77
Lichen planus (LP)	Violaceous annular plaques; gray-brown to brown hyperpigmentation centrally; mucosal involvement; photodistribution in actinic LP	Hypergranulosis, band-like lymphocytic infiltrate at dermal–epidermal junction, necrotic keratinocytes	Ch. 11
Annular LE (subacute > discoid), neonatal LE, mothers of boys with chronic granulomatous disease	Photosensitivity; favors face (discoid), extensor upper extremities/upper trunk (SCLE), periorbital area (neonatal LE); anti-Ro antibodies (SCLE, neonatal LE)	Vacuolar interface dermatitis; often periadnexal lymphohistiocytic inflammation	Ch. 41
Seborrheic dermatitis	Erythematous annular plaques with scaling; favors face and central chest	Psoriasiform epidermal hyperplasia, spongiosis, perivascular lymphocytes	Ch. 13
Psoriasis	Annular scaly plaques with slow expansion	Parakeratosis, diminished granular layer, elongated rete ridges, neutrophils migrating into epidermis	Ch. 8
Ichthyosis linearis circumflexa of Netherton syndrome	Serpiginous or circinate erythematous plaques bordered by double-edged scale; trichorrhexis invaginata; atopic diathesis, elevated serum IgE	Psoriasiform features	Ch. 57

Table 19.1 Differential diagnosis of figurate erythema (cont'd). Key clinical features and histologic findings are provided. Additional conditions that can present with figurate erythema include **Kawasaki disease (may be erythema marginatum-like), hereditary periodic fever syndromes (especially *T*NF *r*eceptor-*a*ssociated *p*eriodic *s*yndrome [TRAPS]; see Table 45.2), relapsing polychondritis, polymorphous light eruption, inflammatory vitiligo (including a papulosquamous variant), eosinophilic vasculitis, Sweet's syndrome, neutrophilic eccrine hidradenitis, pyoderma vegetans (expanding pustular lesions) and leukemia cutis.** AFB, acid-fast bacilli; BMZ, basement membrane zone; FTA-ABS, fluorescent treponemal absorption; GI, gastrointestinal; LE, lupus erythematosus; RPR, rapid plasma reagin; SCLE, subacute cutaneous LE.

Continued

DIFFERENTIAL DIAGNOSIS OF FIGURATE ERYTHEMA			
Disorders	**Clinical features**	**Histologic findings**	**Cross references**
LESIONS WITH ABSENCE OR VARIABLE PRESENCE OF SCALE			
Annular lichenoid dermatitis of youth	Red-brown annular patches or thin plaques with central hypopigmentation; favors groin and flanks; affects children and young adults	Lichenoid infiltrate; marked keratinocyte necrosis limited to the tips of rete ridges	
Secondary syphilis	Annular plaques with central hyperpigmentation; favors face; flu-like symptoms; additional cutaneous manifestations; positive for RPR and FTA-ABS	Perivascular and interstitial infiltrate with plasma cells; also lichenoid or granulomatous infiltrate, exocytosis	Ch. 82
Mycosis fungoides	Annular erythematous or hypopigmented plaques, some with scale; admixed with classic lesions; often with pruritus	Infiltrate of atypical lymphocytes in the dermis and clustering in the epidermis; also plasma cells and eosinophils	Ch. 120
PUSTULAR LESIONS			
Pustular psoriasis (annular pattern)	Rapid expansion with erythematous borders studded with pustules	Subcorneal and spongiform pustules; neutrophils in the epidermis	Ch. 8
Sneddon–Wilkinson disease, IgA pemphigus	Pustules in a circinate pattern; peripheral expansion with central clearing; axillae, groin, inframammary areas	Subcorneal pustules; neutrophils in the epidermis; intercellular epidermal IgA deposition in IgA pemphigus	Chs 8 & 29
Eosinophilic pustular folliculitis (Ofuji's disease)	Grouped follicular pustules and papulopustules in an annular or serpiginous configuration; favors the face, trunk and arms	Infundibular eosinophilic pustules	Ch. 38
EROSIVE/VESICULOBULLOUS LESIONS			
Erythema multiforme (EM), Stevens–Johnson syndrome	Association with HSV vs. drugs and *Mycoplasma*, respectively; target lesions more common in EM; mucosal involvement	Necrotic keratinocytes, vacuolar degeneration of the basal layer and variable inflammation	Ch. 20
Necrolytic migratory erythema	Erosion and crusting of advancing edge; periorificial involvement; glossitis; association with glucagonoma or liver/GI disorders (pseudoglucagonoma); constitutional symptoms	Pallor and edema of the upper epidermis; variable erosion	Ch. 53
Bullous pemphigoid, pemphigoid gestationis	Annular urticarial plaques; tense bullae; pruritus	Subepidermal bullae with eosinophils > neutrophils; linear deposits of IgG and/or C3 in BMZ	Ch. 30
Linear IgA bullous dermatosis	Annular urticarial plaques; vesicles and bullae within border ("string of pearls"); pruritus	Subepidermal bullae with neutrophils > eosinophils; linear deposits of IgA in BMZ	Ch. 31
Epidermolysis bullosa simplex (especially Dowling–Meara subtype)	"Herpetiform" blisters in figurate array; episodic flares of migratory circinate erythema and blistering (K5 mutations)	Split through basal layer of epidermis	Ch. 32
Annular epidermolytic ichthyosis	Migratory, annular or polycyclic, erythematous plaques with superficial blistering/peeling and scaling at the border; episodic flares; K1 or K10 mutations	Epidermolytic hyperkeratosis	Ch. 57
PURPURIC LESIONS[†]			
Purpura annularis telangiectoides	"Cayenne pepper" petechiae and telangiectasias in annular configuration; favors legs	Capillary dilation and tight perivascular infiltrate of lymphocytes; extravasated erythrocytes	Ch. 22
Acute hemorrhagic edema of infancy	Annular or targetoid, edematous, erythematous plaques that become purpuric; favors face, ears and extremities; febrile but non-toxic-appearing child <2 years of age	Leukocytoclastic vasculitis; perivascular IgA deposition in fewer than one-third of cases	Ch. 24
PERFORATING LESIONS			
Elastosis perforans serpiginosa	Peripheral edge composed of keratotic papules; favors neck and other flexural areas	Excess of elastic fibers in clumps in the superficial dermis with transepidermal elimination	Ch. 96

[†]Purpura can also occur in urticarial vasculitis.

Table 19.1 Differential diagnosis of figurate erythema (cont'd). Key clinical features and histologic findings are provided. Additional conditions that can present with figurate erythema include **Kawasaki disease (may be erythema marginatum-like), hereditary periodic fever syndromes (especially *T*NF *r*eceptor-*a*ssociated *p*eriodic *s*yndrome [TRAPS]; see Table 45.2), relapsing polychondritis, polymorphous light eruption, inflammatory vitiligo (including a papulosquamous variant), eosinophilic vasculitis, Sweet's syndrome, neutrophilic eccrine hidradenitis, pyoderma vegetans (expanding pustular lesions) and leukemia cutis** AFB, acid-fast bacilli; BMZ, basement membrane zone; FTA-ABS, fluorescent treponemal absorption; GI, gastrointestinal; LE, lupus erythematosus; RPR, rapid plasma reagin; SCLE, subacute cutaneous LE.

Fig. 19.1 Erythema annulare centrifugum. A Superficial form, with polycyclic plaque and delicate scale on the inner margin of the advancing edge (trailing scale). The scale is detached centrally. **B** Deep form, with obvious elevation of advancing edges and without trailing scale.

Fig. 19.2 A comparison of erythema annulare centrifugum and urticaria. The lesions in **A** have no scaling and may be confused with annular urticaria (**B**). However, individual lesions of urticaria are evanescent.

The scale may not be present in all the lesions in a particular patient (Fig. 19.2A). There may be associated pruritus, especially in lesions that histologically show spongiosis. Occasionally, vesicles develop within the peripheral margin, raising the clinical possibility of linear IgA bullous dermatosis. In deep gyrate erythema, the advancing edges are obviously elevated (Fig. 19.1B) and there is usually no associated scale. The majority of these lesions are non-pruritic.

As lesions resolve, there is no residual scarring, but postinflammatory hyperpigmentation can be seen and, on occasion, purpura. Although the lesions of EAC may be localized or generalized, they rarely, if ever, involve the palms, soles, scalp or mucous membranes. Individual lesions can persist for weeks to months, but there are usually no associated systemic manifestations. While new lesions can appear just as older ones resolve, there may be prolonged intervals of time between flares. When EAC is due to an underlying disorder, flares of the former may correlate with recurrences of the latter. Most patients with EAC do not have an underlying disorder that can be identified, nor can the onset, fluctuations or duration be related to a specific antigen.

Pathology

In superficial lesions of EAC, the findings are nonspecific, with mild spongiosis and microvesiculation with associated focal parakeratosis, as well as a mild superficial perivascular lymphohistiocytic infiltrate. These histologic features correspond to the scale on the inner margin of the advancing edge of the lesion. Characteristically, the inflammatory cells form a fairly tight aggregate around vessels, the so-called "coat sleeve" anomaly. Rarely, eosinophils are found in the perivascular infiltrate. The advancing edge, which is slightly raised, is the result of edema in the papillary dermis. The central area of clearing may contain dermal melanophages.

In deep lesions of EAC, the epidermis is usually unremarkable, and a mononuclear cell infiltrate with a sharply demarcated perivascular arrangement is present primarily within the mid and lower dermis. For this reason, the lesions are generally elevated and are more indurated than in the superficial form of EAC, and do not have trailing scale.

Differential Diagnosis

EAC must be differentiated from other annular erythematous lesions (see Table 19.1), particularly tinea corporis and annular psoriasis, when there is associated scale. Additional entities to consider include annular urticaria (Fig. 19.2B), allergic urticarial eruption, cutaneous lymphoid hyperplasia (pseudolymphoma), and lymphoma cutis. Patients with autoimmune disorders, including linear IgA bullous dermatosis, Sjögren's syndrome and lupus erythematosus (LE tumidus, subacute cutaneous LE), can also have erythematous annular, arciform and polycyclic lesions.

Treatment

If EAC is due to an underlying disorder, the skin lesions will usually resolve once the latter has been successfully treated. Topical corticosteroids applied to the advancing border of the lesions may be of benefit. Topical antipruritics and sedating antihistamines can be prescribed if there is associated pruritus. Even in the absence of an identifiable cause, some authors have advocated the empiric use of antibiotics or antifungal agents. Although systemic corticosteroids can induce a clinical remission, recurrences are common when the medication is discontinued. Based solely on case reports, the following have been reported as beneficial: topical tacrolimus, topical calcipotriene (calcipotriol), oral metronidazole, subcutaneous etanercept and subcutaneous interferon-α (2×10^6 IU three times per week)[10]. However, systemic approaches to therapy are seldom necessary.

ERYTHEMA MARGINATUM

Synonyms: ■ Erythema marginatum rheumaticum ■ Erythema annulare rheumaticum

Key features

- Migratory annular and polycyclic erythematous eruption
- Cutaneous manifestation of acute rheumatic fever
- Associated findings include carditis, migratory polyarthritis, Sydenham's chorea and subcutaneous nodules
- Seen more commonly in children than in adults

Introduction

Rheumatic fever is characterized by an abnormal immunologic response to a preceding infection with group A β-hemolytic streptococci and by the triad of fever, arthritis and carditis. Cutaneous manifestations include erythema marginatum and subcutaneous nodules, but they are seen in a minority of patients. Jones originally established the criteria for the diagnosis of rheumatic fever, and, in 1992, they were revised by the American Heart Association: major criteria are carditis, migratory polyarthritis, Sydenham's chorea, erythema marginatum and subcutaneous nodules. Minor criteria include fever, arthralgias and abnormal laboratory findings (elevated ESR, elevated C-reactive protein, or prolonged PR interval on an ECG). To establish the diagnosis of acute rheumatic fever, two major or one major and two minor criteria must be accompanied by evidence of an antecedent group A streptococcal infection, e.g. a positive culture or raised or rising antistreptolysin O or anti-DNase B titer[11]. More recently, a group of international experts on rheumatic fever reaffirmed the validity of the major and minor Jones criteria and recommended no further revisions[12].

History

In 1831, Bright noted the presence of annular erythematous lesions in patients with rheumatic fever. In 1889, Cheadle gave these lesions the name "erythema marginatum rheumaticum"[13]. Carol and van Krieken first described the histopathologic findings in 1935. Two years later, Perry reported that rapid migration of these lesions is a characteristic finding[14]. In 1944, Jones established the criteria for diagnosing rheumatic fever[15].

Epidemiology

Attacks of acute rheumatic fever are associated with antecedent group A β-hemolytic streptococcal infections of the pharynx. Approximately 3% of patients with untreated infections can develop acute rheumatic fever. It is estimated that in high-income countries, the incidence is 5 per 100 000, whereas in low-income countries, it ranges from 100 to 1000 per 100 000. Erythema marginatum is seen in less than 10% of patients with acute rheumatic fever. The higher incidence of erythema marginatum in children (as compared to adults[16]) reflects the predominance of rheumatic fever in children; the peak age-related incidence is between 5 and 15 years.

Pathogenesis

The mechanisms that underlie the appearance of cutaneous lesions of erythema marginatum are unknown. Presumably, there is an abnormal humoral and cellular immune response to one or more antigens associated with group A β-hemolytic streptococci (e.g. M protein). Antigenic mimicry may play a role in that epitopes cross-reacting with group A streptococcal antigens have been identified in human myosin, actin, tropomyosin, keratin, laminin, N-acetylglucosamine and vimentin[17]. Specific characteristics of certain strains of group A β-hemolytic streptococci, such as higher M protein content and mucoid colony formation, may facilitate the development of acute rheumatic fever[18]. Of note, there have been scattered reports of erythema marginatum-like lesions in association with cat scratch disease and psittacosis[19,20]. The latter may reflect an overlap between erythema marginatum and EAC.

Clinical Features

Following the initial streptococcal pharyngitis, there is usually a latency period of 2–5 weeks before the development of the acute attack of rheumatic fever. The lesions of erythema marginatum begin as erythematous macules that spread peripherally and become patches or plaques, but in the absence of associated scale. Erythema marginatum can also have a polycyclic arrangement (Fig. 19.3). The lesions are usually asymptomatic, and, over a period of 12 hours, they can migrate by 2–12 mm; in areas of previous involvement, the skin may appear pale or lightly pigmented.

The most common locations for erythema marginatum are the trunk, axillae and proximal extremities, with sparing of the face. New lesions usually last from a few hours to a few days and are often most noticeable during the afternoon. Recurrent crops can occur over a number of weeks. Erythema marginatum is associated primarily with the active phase of rheumatic fever, and, in general, it is seen in conjunction with the carditis. Of note, children less than 5 years of age appear to have a higher incidence of erythema marginatum as well as carditis and arthritis[21].

Subcutaneous nodules are another cutaneous manifestation of rheumatic fever. These lesions appear primarily over bony prominences, especially the wrists, elbows, knees and ankles, in patients with long-standing disease. The nodules are usually painless and they are rare during the initial attack of rheumatic fever. Similar nodules can be seen in patients with polyarticular juvenile idiopathic arthritis (see Ch. 45). In addition to the major and minor criteria (see Introduction), patients may also have malaise, chest or abdominal pain, epistaxis, tachycardia and anemia, as well as a nonspecific urticarial eruption[18].

Pathology

An interstitial and perivascular infiltrate composed predominantly of neutrophils without vasculitis is observed. There can be extravasation of erythrocytes in the later stages. Direct immunofluorescence microscopy for immunoglobulins and complement is negative. Although

Fig. 19.3 Erythema marginatum (rheumaticum). Polycyclic and evanescent annular lesions are seen on the trunk of this young patient.

Fig. 19.4 Annular erythema of infancy. Expanding annular urticarial plaques in a 6-month-old boy. *Courtesy, Julie V Schaffer MD.*

these histologic findings are not unique to erythema marginatum, they are helpful in excluding other entities in the differential diagnosis, such as annular erythema of infancy.

Differential Diagnosis

The differential diagnosis includes primarily annular urticaria, annular erythema of infancy (Fig. 19.4) and neutrophilic figurate erythema of infancy[22]. Less often, Still's disease, hereditary periodic fever syndromes (particularly *T*NF *r*eceptor-*a*ssociated *p*eriodic *s*yndrome [TRAPS]; see Table 45.2), EAC, Kawasaki disease and the other entities listed in Table 19.1 need to be considered. There is also an annular erythema with an appearance similar to erythema marginatum that precedes or accompanies episodes of hereditary angioedema[23].

Treatment

There is no specific therapy for this dermatosis. In general, its clinical course is unaltered by treatment of the underlying acute rheumatic fever; however, symptoms are usually mild and lesions resolve spontaneously.

ERYTHEMA MIGRANS

Synonyms: ■ Erythema chronicum migrans ■ Lyme borreliosis ■ Lyme disease ■ Afzelius' disease

Key features

- Annular erythema develops at the site of the bite of a *Borrelia*-infected tick
- Several species of *Ixodes* ticks are infected with different genospecies of *Borrelia burgdorferi*
- Erythema migrans represents the initial cutaneous manifestation of Lyme disease and is seen in 60–90% of patients diagnosed with the disease
- Multiple secondary lesions that are smaller in size can occur as a result of spirochetemia or lymphatic spread

Introduction

Lyme disease is an infection due to *Borrelia burgdorferi* spirochetes that are transmitted by bites from several species of *Ixodes* ticks (e.g. *I. scapularis, I. pacificus, I. ricinus*; see Ch. 85). Erythema migrans represents the initial cutaneous manifestation.

History

The first report of an annular erythema developing after a tick bite was by Afzelius in 1909 and he coined the term "erythema migrans". Lipschütz then referred to these cutaneous lesions as "erythema chronicum migrans". In the US, Steere described an epidemic form of childhood arthritis preceded by erythema migrans in several communities in the vicinity of Lyme, Connecticut. In the 1980s, Burgdorfer isolated a new spirochete in lesions of erythema migrans and the organism was subsequently named *B. burgdorferi*[24].

Epidemiology

Although Lyme disease has a worldwide distribution, it is seen most commonly in the US (northeast, midwest and west coast) and in Europe (Scandinavia and central Europe). The natural hosts for *Borrelia* are white-footed mice and white-tailed deer. In the Netherlands, the risk of developing both tick bites and erythema migrans was shown to be related to the proportion of the land covered by woods, sandy soil or dry uncultivated land, as well as the density of the sheep and cattle populations[25]. More than 28 000 cases of Lyme disease were reported in the US during 2008, and the actual number may be as high as 60 000 to 100 000. In Europe, the highest reported incidences are from middle Europe, in particular Germany, Austria, Slovenia and Sweden[26]. For example, in Poland, there was a notable increase from a few cases in 1969–1976 to 11.5 per 100 000 in 2005. However, not all patients who have had tick bites or positive serologic tests for *B. burgdorferi* develop Lyme disease. For example, in Switzerland, where the prevalence of a positive serology for this spirochete is 28%, only 4% developed Lyme disease, and in France, the figures were 15% and a very few cases, respectively.

Pathogenesis

In mice, *B. burgdorferi* has been shown to usurp a tick salivary protein, Salp15, as a means of enhancing transmission[27]. By binding to the outer surface protein C (OspC) of *B. burgdorferi*, Salp15 provides protection against antibody-mediated killing. In addition, Salp15 inhibits adaptive immune responses against both *Borrelia* and tick antigens[28]. Of note, one of the strategies for preventing Lyme disease in the future is the development of anti-tick vaccines that utilize tick salivary proteins.

Once the *Borrelia* organisms have entered the body, some of the spirochetal lipoproteins may trigger the innate immune system, with cytokines being produced by macrophages[29]. In addition, a Th1 response is triggered as part of the adaptive immune system. Both adaptive T-cell and B-cell responses facilitate the synthesis of antibodies against different antigens of *B. burgdorferi*. Spirochetemia is present in approximately 45% of patients at the time of their presentation with erythema migrans[30], and these organisms can disseminate widely due to their ability to resist elimination by macrophages, adhere to brain and epithelial cells, penetrate into the cytoplasm via intracellular junctions, and induce TNF-α production[31].

Even though the lesion expands centrifugally, *B. burgdorferi* organisms have been found both in the center and at the periphery of lesions of erythema migrans. The persistence of the spirochete in the skin for a long time after the tick bite may be due to an absence of the production of interferon-γ and an ineffective immune response[29]. Also, different immune responses to the various genospecies of the *B. burgdorferi* sensu lato complex (*B. burgdorferi* sensu stricto, *B. afzelii, B. garinii*) may lead to different clinical presentations[32] (e.g. borrelial lymphocytoma in Europe but not the US; see Ch. 74).

Clinical Features

Lyme borreliosis is divided into three clinical stages: (1) early localized disease; (2) early disseminated disease; and (3) chronic disease (Table 19.2). Erythema migrans is an important clinical feature of early disease. Typically, 7–15 days (range, 2–28 days) after tick detachment, an erythematous, expanding annular plaque appears that may have a

STAGES AND MAJOR ORGAN MANIFESTATIONS OF LYME BORRELIOSIS			
Organ	**Early localized disease**	**Early disseminated disease**	**Chronic disease**
Skin	Erythema migrans		Acrodermatitis chronica atrophicans (Europe)
	Disseminated erythema migrans Borrelial lymphocytoma (Europe)		
Nervous system		Meningo-polyradiculoneuritis Cranial neuritis Bell's palsy	Encephalopathy Encephalomyelitis Neuropathy
Musculoskeletal system		Arthralgias, arthritis Myositis	Chronic arthritis
Heart		Atrioventricular block Myopericarditis, pancarditis Tachycardia	
Lymphatic	Regional lymphadenopathy	Regional or generalized lymphadenopathy	
Other		Conjunctivitis, iritis Hepatitis Non-productive cough Microscopic hematuria or proteinuria

Fig. 19.5 Erythema migrans. Annular erythema that spreads centrifugally. The peripheral erythematous border may or may not be sharply demarcated and is usually 1–2 cm in width.

Fig. 19.6 Disseminated erythema migrans. Multiple circular and a few annular plaques are scattered on the lower extremities as well as the trunk (not shown). *Courtesy, Thomas Schwarz, MD.*

lighter-colored central area or a bull's-eye appearance (Fig. 19.5). The eventual diameter is usually at least 5 cm. Lesions of primary erythema migrans favor the trunk, axilla, groin and popliteal fossa. Occasionally, the advancing edge may be crusted or even vesicular. Untreated, the lesions usually last less than 6 weeks (median, 4 weeks). In 20–25% of patients, multiple lesions can appear due to multiple tick bites or as a result of disseminated disease secondary to spirochetemia or lymphatic spread[29]. Disseminated lesions tend to be smaller in size and less pronounced and usually appear days to weeks after the appearance of the primary erythema migrans (Fig. 19.6)[33].

Erythema migrans is seen in 60–90% of patients diagnosed with Lyme disease. In the US, the systemic manifestations of this initial phase tend to be more acute, with influenza-like symptoms, including fatigue, headache, arthralgias, myalgias and fever, as well as lymphadenopathy, conjunctivitis or hepatitis (see Table 19.2)[34,35]. In Europe, this initial clinical phase is usually less severe, and the lesions of erythema migrans tend to last longer. Of the patients with erythema migrans who are not treated, approximately 60% will go on to have monoarticular or oligoarticular arthritis (usually the knee) within weeks to months after the initial infection; approximately 10%, a neurologic manifestation (most commonly facial nerve palsy); and approximately 5%, a cardiac complication (usually varying degrees of atrioventricular block)[30]. For a discussion of borrelial lymphocytoma and acrodermatitis chronica atrophicans, see Chapter 74. Of note, *Ixodes* ticks may transmit more than one disease, in particular babesiosis (a malaria-like illness) and human anaplasmosis (see Ch. 85) as well as Lyme disease.

Pathology

The histologic features of erythema migrans are similar to those of a deep gyrate erythema (Fig. 19.7). While routine histology is often not specific, many specimens will contain eosinophils and plasma cells in the infiltrate. Immunohistochemical studies have shown a reduction in the number of Langerhans cells; in the dermis, the inflammatory infiltrate contains macrophages, $CD4^+$ helper T cells and $CD45RO^+$ memory T cells[36]. In addition, multiple apoptotic cells may be observed in the epidermis[37]. A silver stain such as the Warthin–Starry stain that has been used to detect *Treponema pallidum* can also demonstrate *Borrelia* spirochetes in the skin.

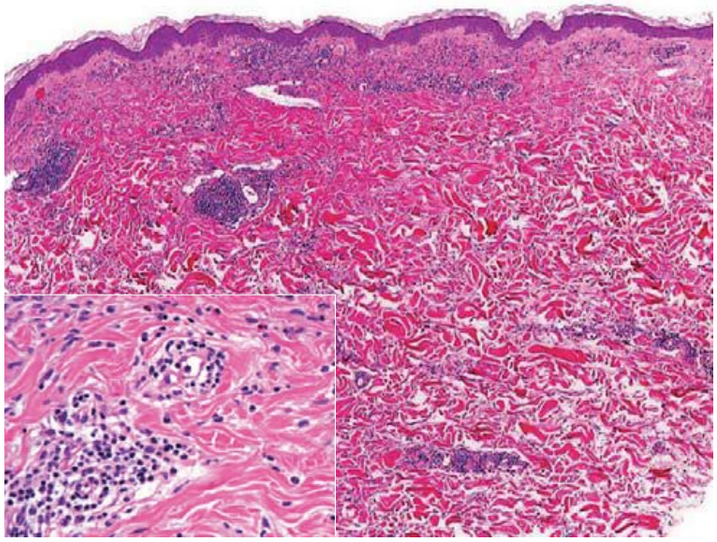

Fig. 19.7 Erythema migrans. A superficial and deep perivascular infiltrate is present within the dermis as well as a scattered interstitial pattern. The infiltrate is composed of lymphocytes and plasma cells (insert). *Courtesy, Lorenzo Cerroni, MD.*

2008 CDC LYME DISEASE SURVEILLANCE CASE DEFINITION
Definition of erythema migrans (EM)
A skin lesion that typically begins as a red macule or papule and expands over a period of days to weeks to form a large round lesion, often with partial central clearing. A single primary lesion must reach ≥5 cm in diameter. Secondary lesions also may occur. Annular erythematous lesions occurring within several hours of a tick bite represent hypersensitivity reactions and do not qualify as EM.
Confirmed
• A case of EM (as defined above) with a known exposure* • A case of EM with laboratory evidence of infection and without a known exposure • A case with at least one late manifestation† that has laboratory evidence of infection
Probable
• Any other case of physician-diagnosed Lyme disease that has laboratory evidence of infection
Suspected
• A case of EM where there is no known exposure and no laboratory evidence of infection
*Exposure is defined as having been (≤30 days before onset of EM) in wooded, brushy or grassy areas (i.e. potential tick habitats) in a county in which Lyme disease is endemic (in which at least two confirmed cases have been acquired or in which established populations of a known tick vector are infected with *B. burgdoferi*). ***A history of tick bite is not required.*** †Recurrent, brief attacks of joint swelling; lymphocytic meningitis, cranial neuritis (particularly facial palsy [may be bilateral]), radiculoneuropathy or, rarely, encephalomyelitis (requires CSF antibody production); acute onset of high-grade (2nd-degree or 3rd-degree) atrioventricular conduction defects that resolve in days to weeks and are sometimes associated with myocarditis.

Table 19.3 2008 CDC Lyme disease surveillance case definition. From www.cdc.gov/ncphi/disss/nndss/casedef/lyme_disease_2008.htm. CDC, Centers for Disease Control and Prevention.

TREATMENT OPTIONS FOR BORRELIOSIS			
	Antibiotic		
Clinical features	**First choice for adults and children ≥8 years*,†**	**First choice for children <8 years and pregnant women; second choice otherwise***	**Alternative choice***
Early localized disease	Doxycycline 100 mg (2 mg/kg) po q12h, 14–21 days‡	Amoxicillin 500 mg po q8h (50 mg/kg po per day divided q8h), 14–21 days§	Cefuroxime axetil 500 mg (15 mg/kg) po q12h, 14–21 days
Early disseminated disease or chronic disease, **mild** Cranial nerve palsy, 1st or 2nd degree heart block	Doxycycline 100 mg (2 mg/kg) po q12h, 14–28 days‡	Amoxicillin 500 mg po q8h (50 mg/kg po per day divided q8h), 14–28 days	Cefuroxime axetil 500 mg (15 mg/kg) po q12h, 14–28 days
	First choice	**Second choice**	**Third choice**
Early disseminated disease or chronic disease, **severe** Meningitis, radiculopathy, 3rd degree heart block	Ceftriaxone 2 g (75–100 mg/kg) iv once daily, 14–28 days	Cefotaxime 2 g (50–70 mg/kg) iv q8h, 14–28 days	Penicillin G 18–24 million units (200 000–400 000 units/kg) iv per day divided q4h, 14–28 days
*No comparative trials for early localized disease, so no established superior treatment; doxycycline also treats human anaplasmosis. †Avoid doxycycline in children <8 years and pregnant women. ‡In a randomized, double-blind, controlled trial, similar outcomes were observed for a 10-day versus 20-day course of doxycycline[42]. §Recommended for 21 days for pregnant women.			

Table 19.4 Treatment options for borreliosis[31]. Doses for children are in parentheses, with adult dose as maximum. A Jarisch-Herxheimer-like reaction with an increase in systemic symptoms and in the size or intensity of the inflammation of the erythema migrans lesion occurs in ~15% of patients within 24 hours after the initiation of antimicrobial therapy[30].

Differential Diagnosis

The recently revised CDC case definition for Lyme disease now includes three categories: "confirmed", "probable" and "suspected" (Table 19.3)[38]. Of relevance to dermatologists, a confirmed diagnosis of Lyme disease requires the presence of characteristic lesions of erythema migrans *plus* either a known exposure or laboratory evidence of infection. The latter includes the isolation of *Borrelia* from tissues (including lesions of erythema migrans) or fluids, or more commonly, the detection of anti-*Borrelia* antibodies by the two-test approach of an ELISA followed by a Western blot[34]. Of note, the peak specific IgM response (usually directed against the 41 kDa flagellar antigen) occurs 3–6 weeks into the infection[31]. As a result, a patient who presents with an early lesion of erythema migrans may not have elevated anti-*Borrelia* antibodies, and the false-negative rate may be as high as 60%[30].

Because antibodies often persist for months or years following infection, serologic tests can not accurately distinguish between active and past infections. In general, if the Western blot analysis yields negative results (even if there are positive findings by ELISA or indirect fluorescent antibody testing), the diagnosis of Lyme disease cannot be supported. This is especially true if the Western blot is performed more than 2 to 4 weeks after exposure. Lastly, positive serologic tests and a history of Lyme disease do not ensure protective immunity[39].

B. burgdorferi DNA can be detected via PCR in skin biopsy specimens and urine of patients with erythema migrans[31], but this is usually reserved for clinical trials[40]. Culture of tissue from the perimeter of erythema migrans lesions is essentially 100% specific and can distinguish live from dead organisms, but this diagnostic test is also not routinely performed. Both a special bacteriologic agar (modified Barbour–Stoenner–Kelly medium) and prolonged observation of cultures are required[41], making it impractical in the routine clinical setting.

Erythema migrans must be distinguished from exaggerated local arthropod reactions, erysipelas, cellulitis, allergic contact dermatitis and non-pigmented fixed drug eruption, and, less often, other entities outlined in Table 19.1. In addition, the southern tick-associated rash illness (STARI or Masters disease) that follows the bite of the *Amblyomma americanum* tick may have a similar-appearing lesion[30].

Treatment

Recommended antibiotic regimens are outlined in Table 19.4. It is estimated that in areas epidemic for this disease, only 1% of the

individuals who are bitten by ticks develop Lyme disease. This may be due to the observation that the tick must be attached for at least 24 hours for transmission to occur[43]. Therefore, routine treatment of tick bites with 2–3-week courses of antibiotics is not recommended. In patients from endemic areas (>20% of ticks infected) in whom the tick, identified as a nymphal or adult *I. scapularis*, has been attached for >36 hours and prophylaxis can be started within 72 hours of tick removal, a single 200 mg dose of doxycycline may decrease the risk of developing Lyme borreliosis (from 3.2% in the placebo group to 0.4% in the treatment group in one study)[44].

ERYTHEMA GYRATUM REPENS

Synonym: ■ Gammel's disease

Key features

- A figurate erythema that is migratory and composed of concentric rings with a wood-grain appearance
- It represents a paraneoplastic phenomenon and the most common underlying neoplasm is carcinoma of the lung
- The lesions may have associated pruritus and scale, and they characteristically exhibit rapid migration (up to 1 cm per day)
- The cutaneous lesions resolve when the neoplasm is successfully treated

Introduction

In the vast majority of patients, erythema gyratum repens represents a paraneoplastic figurate erythema. In theory, the cutaneous lesions arise as a result of an immune reaction against tumor-associated antigens with the subsequent recognition of similar antigens in the skin. There are, however, a number of other entities that can have an erythema gyratum repens-like appearance.

History

Erythema gyratum repens was first reported by Gammel in 1952, and his original description clearly identified its key clinical features.

Epidemiology

Erythema gyratum repens is a very rare disorder seen primarily in adults. Risk factors parallel those for the underlying neoplasms.

Pathogenesis

A leading hypothesis is that erythema gyratum repens represents an immune reaction in which there is a cross-reaction between tumor and cutaneous antigens[45]. In a few patients, direct immunofluorescence (DIF) has demonstrated deposits of IgG and C3 in the basement membrane zone (BMZ) of the skin, and, in isolated cases, similar deposits were seen in the associated neoplasm[46]. However, this could simply represent a nonspecific finding. Caux et al.[46] suggested that the tumor produces a modification in its basement membrane and this subsequently induces an immune response. Recognition of similar antigens in the BMZ of the skin then leads to the cutaneous eruption. The responsible antigen(s) is not known, but a curious finding is an accumulation of active Langerhans cells in the upper layers of the epidermis[47].

Clinical Features

Patients usually have multiple, annular, erythematous lesions that develop scale at their edges and advance at a rapid rate (up to 1 cm per day). This rate of peripheral spread is significantly faster than that of EAC. Lesions have a wood-grain or zebra-like pattern, due to the development of "rings within rings" (Fig. 19.8). In some patients, the eruption is also pruritic. Additional findings in patients with erythema gyratum repens include acquired ichthyosis, palmoplantar keratoderma and hypereosinophilia.

Fig. 19.8 Erythema gyratum repens. Multiple gyrate erythematous plaques, showing a wood-grain pattern. *Courtesy, Agustin Alomar, MD.*

Fig. 19.9 Resolving pityriasis rubra pilaris. The lesions can resemble erythema gyratum repens. *Courtesy, Irwin Braverman, MD.*

In at least 80% of patients, erythema gyratum repens is associated with an underlying neoplasm, most commonly of the lung, breast, esophagus or stomach[48,49]. The cutaneous lesions usually develop from 1 year prior to 1 year after the diagnosis of the neoplasm. Erythema gyratum repens may coincide with underlying pulmonary tuberculosis, and patients with other disorders (see below) can also have erythema gyratum repens-like lesions. However, occasionally, individuals are otherwise healthy.

Pathology

The histopathologic findings are nonspecific and include hyperkeratosis, focal parakeratosis, moderate patchy spongiosis and a mild, perivascular lymphohistiocytic infiltrate. In some cases, eosinophils and melanophages are seen in the dermis. By immunoelectron microscopy, DIF-detected immune deposits of IgG at the BMZ (see Pathogenesis) were shown in one patient to be beneath the lamina densa[46]. In addition, anti-EGF receptor, anti-vimentin and anti-α-actin staining was more intense in lesional skin and tumor tissue than in controls. Nevertheless, the meaning of these findings is unknown, given their anecdotal nature, and DIF is not required for confirmation of the diagnosis.

Differential Diagnosis

In addition to excluding the other types of figurate erythema, erythema gyratum repens-like lesions may be seen in patients with erythrokeratodermia variabilis and resolving pityriasis rubra pilaris (Fig. 19.9) as well

as bullous pemphigoid (both paraneoplastic and classic) and epidermolysis bullosa acquisita[50]. The differential diagnosis also includes erythema gyratum-like lesions due to mycosis fungoides, psoriasis, linear IgA bullous dermatosis, Sjögren's syndrome, cutaneous small vessel vasculitis (including urticarial forms), or hypersensitivity reactions to azathioprine. In certain regions of the world, tinea imbricata would also be included in the differential diagnosis.

Treatment

Erythema gyratum repens resolves when the associated neoplasm is successfully treated. There may be a return of cutaneous lesions in association with the development of metastases or local recurrences of the malignancy.

Erythema Multiforme, Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis

Lars E French and *Christa Prins*

Chapter Contents

Erythema multiforme 319
Stevens–Johnson syndrome and toxic epidermal necrolysis 323

Until recently, the nosology of severe acute bullous disorders due to infectious agents or drugs has been confusing. It has now become clear that Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are variants within a continuous spectrum of adverse drug reactions, whereas erythema multiforme (EM) is a distinct disorder with different clinical signs and precipitating factors, e.g. herpes simplex virus (HSV) infections. Therefore, EM will be discussed separately from SJS and TEN.

ERYTHEMA MULTIFORME

Synonym: ■ Erythema multiforme minor – erythema multiforme von Hebra

Key features

- A self-limited but potentially recurrent disease
- Abrupt onset of papular "target" lesions, with the vast majority of lesions appearing within 24 hours
- Two types of target lesions are recognized: (1) typical, with at least three different zones; and (2) atypical papular, with only two different zones and/or a poorly defined border
- Target lesions favor acrofacial sites
- Erythema multiforme minor: typical and/or occasionally atypical papular target lesions with little or no mucosal involvement and no systemic symptoms
- Erythema multiforme major: typical and/or occasionally atypical papular target lesions with severe mucosal involvement and systemic features
- A preceding HSV infection is the most common precipitating factor; occasionally, there are other preceding infections or, rarely, drug exposure
- Diagnosis of erythema multiforme requires clinicopathologic correlation and is not based solely on histologic findings
- Erythema multiforme does not carry the risk of progressing to toxic epidermal necrolysis

Introduction

Erythema multiforme (EM) is an acute, self-limited skin disease characterized by the abrupt onset of symmetric fixed red papules, some of which evolve into typical and/or occasionally "atypical" papular target lesions[1–4]. The eruption is often precipitated by an infection, particularly HSV. Two forms of EM are recognized – EM minor and EM major. Both are characterized by the same type of elementary lesions (targets), but are distinguished by the presence or absence of mucosal involvement and systemic symptoms (Table 20.1). In the vast majority of patients, EM can be distinguished clinically from SJS and TEN based upon the type of elementary skin lesions and their distribution[2,3,5].

History

EM was first described by the Austrian dermatologist Ferdinand von Hebra in 1860[6,7]. The disease he described was mild with a sudden onset of hundreds of red papules. By daily observation, von Hebra recognized that some of the original papules evolved into lesions with concentric zones of color change, which he termed "target" lesions. He mentioned that some of the target lesions resembled a "herpes iris". However, von Hebra described neither a prodrome nor the presence of mucosal lesions. He recognized that the condition could be recurrent and mentioned a "typus annuus" which recurred every spring.

EM was later divided into EM minor and EM major by Bernard Thomas in 1950[8]. Thomas considered von Hebra's disease to be EM minor, and severe mucosal necrosis with "EM-like" cutaneous lesions to be EM major. Since 1950, much confusion has developed regarding the definition of EM, in part because some authors, especially in the US, have stated that EM major includes SJS. However, recent investigations have clarified the situation by providing strong evidence that the term "EM minor" should be reserved for von Hebra's disease and the term "EM major" should be used for EM associated with mucosal lesions and systemic symptoms, but not for describing SJS, because SJS and EM major are distinct clinical disorders[2,3,5]. That said, because these are biologic processes, there can be patients where the distinction proves challenging.

Epidemiology

EM is predominantly observed in young adults and is very uncommon during childhood[5,9]. There is a slight male preponderance, but no racial bias. The exact incidence rate of EM is not known.

Pathogenesis

Current understanding suggests that EM is most likely, and in most patients, a mucocutaneous manifestation of a distinct skin-directed immune reaction that occurs in the setting of an infection in certain "predisposed" individuals. HSV is clearly the most common associated infectious agent, with *Mycoplasma pneumoniae*[10] (which also may be associated with SJS), *Histoplasma capsulatum* and parapoxvirus (orf) observed less frequently (Table 20.2). Histoplasmosis-associated EM has been said to occur more often in those patients with concomitant erythema nodosum. To date, evidence for EBV as a precipitating factor is incomplete[9]. Rarely, EM has been diagnosed as being due to drugs or systemic disease (see Table 20.2). Consequently, the possibility of SJS, generalized fixed drug eruption, polymorphous exanthematous drug eruption or urticaria[9,11] should be strongly considered if the presumed diagnosis is drug-induced EM. Of note, several physical agents such as trauma, cold, and UV and orthovoltage irradiation have been described as triggers for outbreaks of EM related to infectious agents, drugs or systemic disease.

To date, there is no clearly defined genetic predisposition for the development of EM. Several small studies of HLA antigen association have found different associations: HLA-DQw3 (specifically the DQB1*301 split), DRw53 and Aw33[12,13]. These HLA associations differ from those reported for SJS and TEN (see below).

COMPARISON OF ERYTHEMA MULTIFORME (EM) MINOR, EM MAJOR AND STEVENS–JOHNSON SYNDROME (SJS)						
	Type of skin lesions	**Distribution**	**Mucosal involvement**	**Systemic symptoms**	**Progression to TEN**	**Precipitating factors**
EM minor	• Typical targets • ± *Papular* atypical targets	Extremities (especially elbows, knees, wrists, hands), face	Absent or mild	Absent	No	• Herpes simplex virus • Other infectious agents
EM major	• Typical targets • ± *Papular* atypical targets • Occasionally bullous lesions	Extremities, face	Severe	Present	No	• Herpes simplex virus • *Mycoplasma pneumoniae* • Other infectious agents • Rarely, drugs
SJS	• Dusky macules with or without epidermal detachment • *Macular* atypical targets • Bullous lesions (<10% BSA detachment)	Trunk, face	Severe	Present	Possible	• Drugs • Occasionally, *Mycoplasma pneumoniae* • Rarely, immunizations

Table 20.1 Comparison of erythema multiforme (EM) minor, EM major and Stevens–Johnson syndrome (SJS). BSA, body surface area; TEN, toxic epidermal necrolysis.

Herpes simplex virus

In the majority of children and adults with EM, the disease is precipitated by HSV types 1 and 2[14–17]. Preceding herpes labialis is noted in approximately 50% of subjects with EM[14–17]. The herpes labialis may precede the onset of the cutaneous lesions, occur simultaneously, or be evident after the target lesions of EM have appeared. Most commonly, herpes labialis precedes target lesions of EM by 3–14 days. It is presumed that most cases in children and young adults are due to HSV type 1, but documented cases of HSV type 2 in adolescents and young adults have been reported[15,17].

Most of our current knowledge regarding EM is related to the study of HSV-associated EM. Not only are HSV-encoded proteins found within affected epidermis[14–17], but HSV DNA can be detected within the early red papules or the outer zone of target lesions in 80% of individuals with EM[7]. The presence of fragments of HSV DNA (most often comprised of sequences that encode its DNA polymerase) within the cutaneous lesions, as well as the expression of virally encoded antigens on keratinocytes, may be interpreted as evidence for replicating HSV within affected skin sites[14,15,18–20]. However, replication must be at a low level, because usually HSV cannot be cultured from EM lesions.

The inflammation within cutaneous lesions is believed to be a part of the HSV-specific host response[15]. Individuals with HSV-associated EM have normal immunity to HSV, but may have difficulty clearing the virus from infected cells; within sites of cutaneous lesions, HSV DNA may persist for 3 months after a lesion has healed[19]. Development of cutaneous lesions is initiated by the expression of HSV DNA sequences within the skin, and the recruitment of virus-specific T-helper type 1 (Th1) cells that produce interferon-γ in response to viral antigens within the skin[21]. This is thought to be followed by an "autoimmune" response resulting from the recruitment of T cells that respond to autoantigens released by lysed/apoptotic viral antigen-containing cells. Most recently it was shown that the HSV DNA fragments described above are transported (by peripheral blood $CD34^+$ Langerhans cell precursors) to the sites where EM skin lesions will develop prior to each eruption[22].

PRECIPITATING FACTORS IN ERYTHEMA MULTIFORME		
Infections (approx. 90% of cases)	Viral	• **Herpes simplex virus (HSV-1, HSV-2)** • Parapoxvirus (orf) • Vaccinia (smallpox vaccine) • Varicella zoster virus (chickenpox) • Adenovirus • Epstein-Barr virus • Cytomegalovirus • Hepatitis virus • Coxsackievirus • Parvovirus B19 • Human immunodeficiency virus
	Bacterial	• ***Mycoplasma pneumoniae**** • *Chlamydophila* (formerly *Chlamydia*) *psittaci* (ornithosis) • *Salmonella* • *Mycobacterium tuberculosis*
	Fungal	• *Histoplasma capsulatum* • Dermatophytes
Drugs (unusual)		Primarily: • Nonsteroidal anti-inflammatory drugs • Sulfonamides • Anticonvulsants • Other antibiotics, e.g. aminopenicillins • Allopurinol
Exposures (unusual)		• Poison ivy
Systemic disease (rare)		• Inflammatory bowel disease • Lupus erythematosus† (Rowell's syndrome) • Behçet's disease†

*Also precipitating factor for Stevens–Johnson syndrome and isolated oral mucositis.
†May be a pattern of cutaneous lesions in the disease rather than a precipitating factor.

Table 20.2 Precipitating factors in erythema multiforme. This is a *non-exhaustive* list based primarily on case reports and small series of cases. The most common causes are in bold.

Clinical Features

Due to a certain degree of clinical similarity, EM minor, EM major, SJS and TEN have, until quite recently, all been considered to be part of a single disease spectrum. However, as discussed previously, there is now strong evidence to support the concept that EM is a disease distinct from SJS and TEN at several levels – clinical, prognostic and etiologic. Clinical criteria allow the distinction of both forms of EM from SJS/TEN in the vast majority of patients[2,3,5]. These clinical criteria are as follows: (1) the type of elementary skin lesion; (2) the distribution of skin lesions (topography); (3) the presence or absence of overt mucosal lesions; and (4) the presence or absence of systemic symptoms (see Table 20.1).

Elementary skin lesions (Fig. 20.1)

The characteristic elementary skin lesion of EM is the *typical target lesion*. The latter measures <3 cm in diameter, has a regular round shape and a well-defined border, and it consists of at least three distinct zones, e.g. two concentric rings of color change surrounding a central circular zone that has evidence of damage to the epidermis in the form of bulla

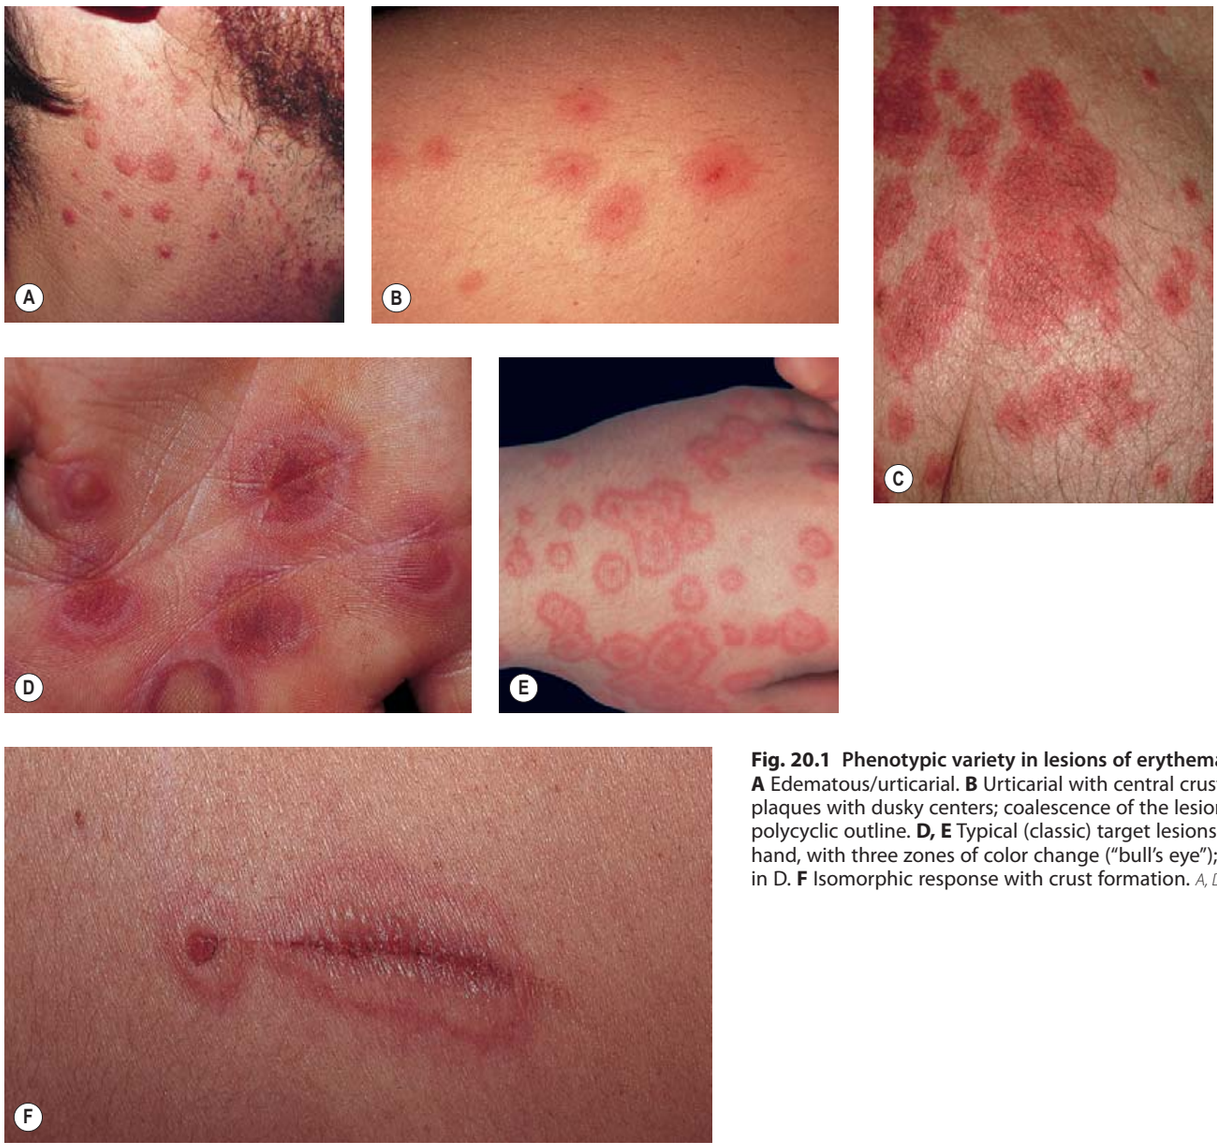

Fig. 20.1 Phenotypic variety in lesions of erythema multiforme. **A** Edematous/urticarial. **B** Urticarial with central crusting. **C** Erythematous plaques with dusky centers; coalescence of the lesions leads to a well-defined polycyclic outline. **D, E** Typical (classic) target lesions on the palms and dorsal hand, with three zones of color change ("bull's eye"); note the central vesicles in D. **F** Isomorphic response with crust formation. *A, D, F, Courtesy, William Weston, MD.*

formation or crust[2,3]. Frequently, this central circular zone also has a dusky appearance and over time, the lesion may resemble a "bull's eye".

While early target lesions often have a central dusky zone and a red outer zone ("iris" lesion), they can evolve to three zones of color change. Each concentric ring within the target lesion most likely represents one of a sequence of events of the same ongoing pathologic process. This may explain why some patients have only a limited number of fully developed, typical targets amidst a number of target lesions that are not yet typical or fully evolved, while in others all the lesions are at the same stage of development, thus creating a monomorphic clinical appearance. Given the possibility that only a few typical target lesions may present, a complete skin examination is essential.

In EM, elevated *atypical papular target lesions* can either accompany typical target lesions or constitute the primary cutaneous lesion. These particular lesions are defined as round, edematous, palpable and reminiscent of EM, but with only two zones and/or a poorly defined border. They must be distinguished from the flat (macular) atypical targets that are seen in SJS or TEN, but not EM. The latter are defined as round lesions that are also reminiscent of EM, but with only two zones and/or a poorly defined border, as well as being non-palpable (with the exception of a potential central vesicle or bulla).

Distribution of skin lesions (topography)

Although there is considerable variation from individual to individual, numerous lesions are usually present[9]. In general, lesions of EM develop preferentially on the extremities and the face; target lesions favor the upper extremities, as does the entire eruption of EM[9,17,23]. The dorsal aspects of the hands and the forearms are the most frequently involved sites, but the palms, neck, face and trunk (Fig. 20.2) are common locations as well[23]. Involvement of the legs is seen less frequently. EM lesions may also appear within areas of sunburn[9]. In addition, lesions tend to be grouped, especially on the elbows or knees[9,24].

The Koebner phenomenon may be observed, with target lesions appearing within areas of cutaneous injury such as scratches[9,24] (see Fig. 20.1F) or as erythema and swelling of the proximal nail folds at sites of chronic self-trauma. The injury must precede the onset of the EM eruption because the Koebner phenomenon does not occur once the EM lesions have appeared.

Mucosal lesions

Severe mucosal involvement is characteristic of EM major. Mucosal involvement is usually absent in EM minor, and, when present, lesions are few in number and mildly symptomatic[5,9,14,15,23–25]. The primary mucosal lesions of EM are vesiculobullous and rapidly develop into painful erosions that involve the buccal mucosa and lips (Fig. 20.3) and less commonly the ocular and genital mucosae. On the lips, the erosions rapidly become covered by painful crusts. Erosions of the anogenital mucosa are often large and polycyclic with a moist base.

Systemic symptoms

Systemic symptoms are almost always present in EM major and absent or limited in EM minor. In EM major, the systemic symptoms that

Fig. 20.2 Multiple lesions of erythema multiforme on the trunk. The dusky or crusted centers within the papules help to differentiate it from a morbilliform drug eruption.

Fig. 20.3 Mucosal involvement in erythema multiforme major. Typical target lesions are seen as well as serous crusting of the vermilion lips and eyelid margin. At the margin of the serous crusting of the lip, there are two zones of color with a polycyclic outline.

usually precede and accompany the skin lesions are fever and asthenia of varying degrees. Arthralgias with joint swelling have occasionally been described, as has pulmonary involvement resembling atypical pneumonia. Whether the latter is a pulmonary manifestation of EM versus one of the associated infections such as *M. pneumoniae* is unclear. Renal, hepatic and hematologic abnormalities in the context of EM major are rare[17].

By integrating these four clinical criteria, a distinction can be made between EM minor, EM major and SJS (see Table 20.1).

Natural history

In EM, a history of an abrupt onset of skin lesions is obtained, with almost all of the lesions appearing within 24 hours and full development by 72 hours[9,17]. Pruritic or burning sensations within the lesions may be described. The individual lesions remain fixed at the same site for 7 days or longer[6,7,26].

For most individuals with EM, the episode lasts 2 weeks and heals without sequelae[9,17]; one possible rare exception is ocular sequelae in the setting of EM major, which may occur if adequate eye care is not promptly instituted. Occasionally, postinflammatory hyper- or hypopigmentation is seen. Patients with EM usually have an uncomplicated clinical course, although recurrences, in the case of HSV-associated EM, are quite common[9,17,24]. One recurrence each spring, as described by von Hebra, may occur[6]. Most individuals with recurrent HSV-associated EM have one or two episodes a year, an exception being those receiving immunosuppressive drugs[17,24,27,28]. The use of immunosuppressive agents such as oral corticosteroids may be associated with more frequent and longer episodes of EM[9,17,25]. These individuals may have five or six episodes per year or even almost continuous disease in which one attack has not completely resolved before another occurs. The incidence of secondary bacterial infections also increases in the setting of prolonged corticosteroid use[9,17].

Pathology

EM is a clinicopathologic, not a purely histologic, diagnosis. Histologic findings are characteristic but not specific, and are most useful for excluding entities in the differential diagnosis such as lupus erythematosus (LE) and vasculitis[9,17,27]. In EM, the keratinocyte is the target of the inflammatory insult, with apoptosis of individual keratinocytes being the earliest pathologic finding (Fig. 20.4)[27]. As the process evolves, mild spongiosis and focal vacuolar degeneration of basal keratinocytes are observed. Superficial dermal edema and a perivascular infiltrate of mononuclear leukocytes and T lymphocytes with exocytosis into the epidermis are also seen.

Immunofluorescence findings are nonspecific[9]. Granular deposits of IgM and C3 around superficial blood vessels and focally at the dermal–epidermal junction have been described. Specific HSV antigens have been detected within keratinocytes by immunofluorescence, and HSV genomic DNA has been detected by PCR amplification of skin biopsy specimens[14,18,19].

Compared to SJS, the dermal inflammation component is more prominent in EM and the epidermal "necrolysis" component is more discrete[29]. Large sheets of epidermal necrosis are not seen in EM.

Differential Diagnosis

Many non-dermatologists overdiagnose EM by labeling individuals with giant urticaria as having EM (Fig. 20.5)[11]. The clinical criteria of Brice et al.[9] for distinguishing EM from urticaria should be strictly observed (Table 20.3). These include the presence of symmetrical fixed red papules or atypical papular target lesions, at least some of which evolve into typical target lesions. Particular attention should be given to the duration of individual lesions at a specific site and to epidermal damage in the center of the target lesions. EM papules are "fixed" at the same skin site for at least 7 days, whereas urticarial lesions last less than 24 hours at a particular site. The center of EM lesions demonstrates epithelial damage in the form of crusting or blisters, whereas the center of giant urticaria is characterized by normal skin or erythema without epidermal damage. Administration of subcutaneous epinephrine (adrenaline) will clear urticaria within 20 minutes, but will not change EM lesions. Edema of the face, hands and feet can be associated with urticaria, but is usually not observed in EM[9,11,17].

A number of conditions can sometimes have "target-like" lesions and mimic EM, including the aforementioned giant urticaria, fixed drug eruptions, subacute cutaneous LE, Kawasaki disease, erythema annulare centrifugum, and several forms of vasculitis[30]. A skin biopsy to exclude these entities is helpful. However, there is significant clinical and histologic overlap between EM and generalized fixed drug eruption. The total number of lesions is helpful, especially when there are hundreds, but it is also important to try to determine the number of lesions present in the first outbreak (i.e. fewer lesions in fixed drug eruption).

Recurrent EM during childhood may mimic polymorphous light eruption or juvenile spring eruption in that it may be sun-induced and develop with the first significant sun exposure in the spring[31]. In

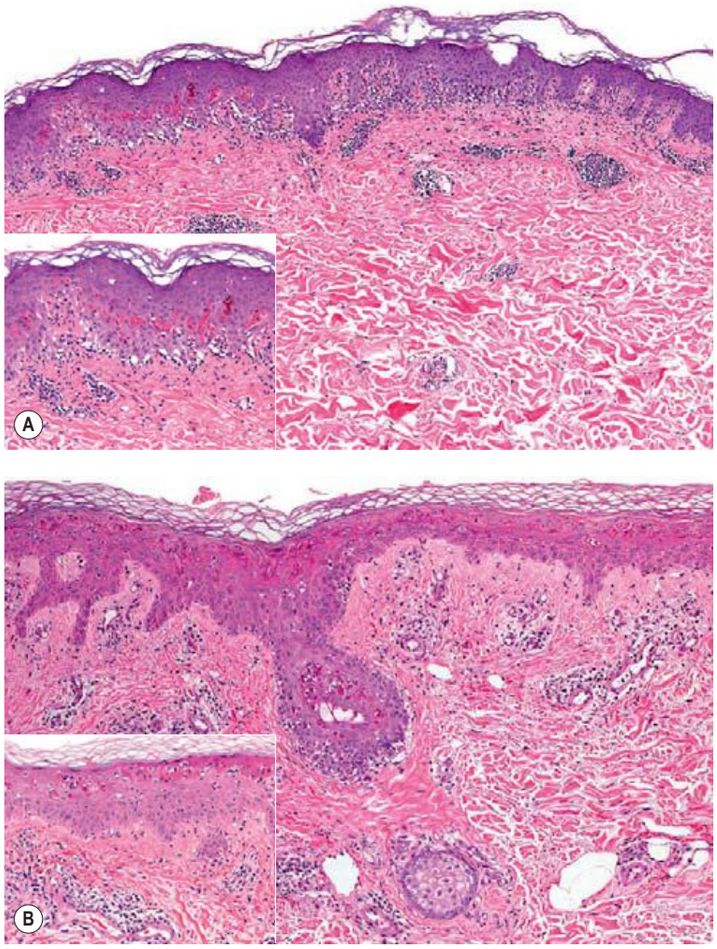

Fig. 20.4 Histopathologic features of erythema multiforme. A Early lesion – focal sites of apoptosis of keratinocytes with an interface dermatitis and vacuolar degeneration of the basal layer (insert). A perivascular lymphocytic infiltrate is also present. **B** Late lesion – more confluent necrosis of keratinocytes within the upper layers of the stratum spinosum (insert). The hair follicle still has evidence of an interface dermatitis. *Courtesy, Lorenzo Cerroni, MD.*

Fig. 20.5 Urticaria in an infant misdiagnosed as erythema multiforme. These migratory, annular plaques are markedly edematous. Some of the lesions have central erythema but there are no crusts or blisters. *Courtesy, Julie V Schaffer, MD.*

DIFFERENCES BETWEEN URTICARIA AND ERYTHEMA MULTIFORME	
Urticaria	**Erythema multiforme**
Central zone is normal skin	Central zone is damaged skin (dusky, bullous or crusted)
Lesions are transient, lasting less than 24 hours	Lesions "fixed" for at least 7 days
New lesions appear daily	All lesions appear within first 72 hours
Associated with swelling of face, hands or feet (angioedema)	No edema

Table 20.3 Differences between urticaria and erythema multiforme.

patients with systemic LE, occasional individual lesions will mimic true target lesions of EM, but other lesions characteristic of systemic LE are usually present[9]. Early lesions of vasculitis, particularly urticarial vasculitis, may mimic target lesions of EM. Histologic examination assists in distinction; additional clues include an elevated ESR, autoantibodies and low serum complement levels[9].

Treatment

Therapeutic options include topical and systemic treatment of the acute eruption as well as prophylactic treatment of recurrent disease. Topical therapy includes topical antiseptics for eroded skin lesions and antiseptic/antihistamine rinses and local anesthetic solutions for oral lesions. Administration of topical ophthalmic preparations should be done in conjunction with an ophthalmologist.

There are no double-blind or open trials of systemic therapies for the acute episode of EM[9,17]. When a precipitating factor can be identified (e.g. HSV or *M. pneumoniae*), specific therapy should be instituted; in the case of HSV, this represents chronic suppressive antiviral therapy (see below). As a rule, antiviral therapy has minimal impact if given after the appearance of the acute episode of EM. In most cases of EM, especially EM minor, symptomatic treatment will suffice. Oral antihistamines for 3 or 4 days may reduce the stinging and burning of the skin. In severe forms of EM with functional impairment, early therapy with systemic corticosteroids (e.g. prednisone [0.5–1 mg/kg/day]) or pulse methylprednisolone [20 mg/kg/day for 3 days]) should be considered, despite the absence of controlled studies and the long-existing controversy regarding increasing the risk of infectious complications[32].

In individuals with HSV-associated EM with frequent recurrences, prophylaxis for at least 6 months with oral acyclovir (10 mg/kg/day in divided doses), valacyclovir (500–1000 mg/day, with dose depending upon frequency of recurrences) or famciclovir (250 mg twice daily) should be considered. A double-blind, placebo-controlled study in young adults did demonstrate efficacy of acyclovir prophylaxis[28]. In addition to reducing the frequency of recurrences, occasionally the beneficial effect can continue even after the antiviral drug is discontinued. In non-responsive patients, the dose of the medication may be doubled, or a substitution made of the antiviral drug. Acyclovir or valacyclovir begun after symptoms appear is ineffective[17]. Obviously, in those patients in whom EM is precipitated by factors other than reactivation of HSV, antivirals will be of no benefit.

In patients with recurrent EM that is resistant to prophylactic antiviral therapy, especially severe cases of recurrent EM, several therapeutic approaches have been described; however, none have been validated by controlled trials and none are consistently effective or free of side effects. Among these are: azathioprine (100 mg/day for several months), prednisone (0.5 mg/kg/day for several months), thalidomide, dapsone, cyclosporine, mycophenolate mofetil and PUVA[17,33–36].

STEVENS–JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Synonym: ▪ Toxic epidermal necrolysis – Lyell's syndrome

Key features

- Prodrome of upper respiratory tract symptoms, fever and painful skin
- Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are two rare, potentially fatal, adverse cutaneous drug reactions of differing severity, characterized by mucocutaneous tenderness and erythema as well as extensive exfoliation
- SJS is characterized by <10% body surface area of epidermal detachment, SJS–TEN overlap by 10–30%, and TEN by >30%
- The medications most frequently incriminated are allopurinol, nonsteroidal anti-inflammatory drugs, antibiotics and anticonvulsants. TEN and SJS usually occur 7–21 days after initiation of the responsible drug
- The average mortality rate is 1–5% for SJS and 25–35% for TEN; it can be even higher in elderly patients and in those TEN patients with a very large surface area of epidermal detachment
- Exfoliation is due to extensive death of keratinocytes via apoptosis; the latter is mediated via the cytotoxic secretory protein granulysin and interaction of the death receptor–ligand pair Fas–FasL
- Optimal medical management of SJS and TEN requires early diagnosis, immediate discontinuation of the causative drug(s), and rapid initiation of supportive care and specific therapy
- Specific therapies that have the potential to selectively block keratinocyte apoptosis, such as high-dose IVIg, may provide added benefit over supportive care alone

CLINICAL FEATURES THAT DISTINGUISH STEVENS–JOHNSON SYNDROME (SJS), TOXIC EPIDERMAL NECROLYSIS (TEN), AND SJS–TEN OVERLAP

Clinical entity	SJS	SJS–TEN	TEN
Primary lesions	Dusky and/or dusky red lesions Flat atypical targets	Dusky and/or dusky red lesions Flat atypical targets	Poorly delineated erythematous plaques
			Epidermal detachment – spontaneous or by friction
			Dusky red lesions
			Flat atypical targets
Distribution	Isolated lesions	Isolated lesions	Isolated lesions (rare)
	Confluence (+) on face and trunk	Confluence (++) on face and trunk	Confluence (+++) on face, trunk and elsewhere
Mucosal involvement	Yes	Yes	Yes
Systemic symptoms	Usually	Always	Always
Detachment (% BSA)	**<10**	**10–30**	**>30**

Table 20.4 Clinical features that distinguish Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and SJS–TEN overlap. BSA, body surface area.

Introduction

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are rare, acute and life-threatening mucocutaneous diseases that are nearly always drug-related. They are a consequence of extensive keratinocyte cell death that results in the separation of significant areas of skin at the dermal–epidermal junction, producing the appearance of scalded skin. This extensive cell death also results in mucous membrane detachment, and it contributes to the characteristic symptoms of SJS and TEN, which include: high fever, moderate to severe skin pain, anxiety and asthenia. The disease runs an unpredictable course. An initially benign-appearing dermatosis can progress rapidly, and once overt skin detachment has occurred, it is difficult to determine when it will end. Several studies have addressed the clinical signs of SJS and TEN, and there is now a framework of diagnostic criteria. Risk of death can also be accurately predicted by applying a severity-of-illness score specifically developed for predicting the clinical outcome of TEN (SCORTEN; see below).

As prognosis is correlated with the speed at which the culprit drug is identified and withdrawn, it is crucial to establish the correct clinical diagnosis rapidly, so the causal drug(s) can be discontinued and appropriate medical treatment begun as soon as possible. Although TEN, and especially SJS, were historically considered to be part of a spectrum of diseases that included EM major (all of which have clinically similar mucosal lesions), these disorders should now be distinguished, as their cause, management and prognosis are usually distinct (Table 20.4; see Table 20.1). SJS and TEN should also be distinguished from dermatoses such as staphylococcal scalded skin syndrome, generalized fixed drug eruption, drug-induced linear IgA bullous dermatosis, toxic erythema of chemotherapy, and acute generalized exanthematous pustulosis, as their management and prognosis are also quite different.

High-quality supportive treatment, ideally in intensive care units with modern equipment and trained nursing staff, is the current standard of care and can improve outcome. No specific therapy for SJS and TEN has yet shown efficacy in prospective, controlled clinical trials (i.e. attained evidence-based medicine standards of acceptance). Their low prevalence and life-threatening potential make randomized clinical trials difficult to perform. Despite this, conceptually interesting approaches based upon known elements of the pathogenesis of SJS and TEN and small case series have been described (see below).

History

In 1922, two US physicians, Stevens and Johnson, described an acute mucocutaneous syndrome in two young boys. The condition was characterized by severe purulent conjunctivitis, severe stomatitis with extensive mucosal necrosis, and "EM-like" cutaneous lesions. It became known as Stevens–Johnson syndrome (SJS) and was recognized as a severe mucocutaneous disease with a prolonged course and occasional fatalities[2,5,37]. SJS was later designated as EM major by Bernard Thomas in 1950[8]. However, recent clinical investigations have made it clear that the term "EM major" should not be used to describe SJS as they are distinct disorders (see Table 20.1)[2,3,5,37].

In 1956, Alan Lyell described four patients with an eruption "resembling scalding of the skin objectively and subjectively", which he called "toxic epidermal necrolysis". "Toxic" referred to toxemia – circulation of a toxin – which was thought to be responsible for the constitutional symptoms and epidermal necrosis. Lyell coined the term "necrolysis" by combining the key clinical feature "epidermolysis" with the characteristic histopathologic feature "necrosis". He also described an attack on the mucous membranes as part of the syndrome, and noted that there was very little inflammation in the dermis, a feature that was later referred to as "dermal silence"[38]. This feature contrasted with the obvious inflammatory infiltrate of other blistering disorders such as EM, dermatitis herpetiformis and bullous pemphigoid. TEN was considered at the time to be a cutaneous reaction pattern to multiple stimuli, including drugs (e.g. sulfonamides) and microbes (e.g. *Staphylococcus*)[39].

The description of a subgranular epidermal split in neonatal mice following exposure to phage group II *S. aureus*, the subsequent discovery of a new staphylococcal exotoxin called epidermolytic toxin, and the absence of overt keratinocyte necrosis led to the distinction of TEN from what would come to be known as the "staphylococcal scalded skin syndrome" (SSSS; see Ch. 74)[40]. It should be noted here that one of Lyell's original patients actually represented SSSS, and, although by that time he had already noted the histologic differences between TEN and SSSS, they were attributed to different degrees of injury.

As more patients with TEN were reported in the years following Lyell's treatise, it became clear that certain drugs such as sulfonamides, pyrazolones, barbiturates and anticonvulsants were principally associated with TEN. At the same time, drugs were increasingly being incriminated as a cause of EM associated with severe stomatitis. Hence, EM epidermal type (as defined by Orfanos et al.[41]), SJS and TEN were, at the time, considered to be part of a continuous spectrum of cutaneous reactions. It was clear, however, that HSV was the major cause of EM,

and that this virus was not associated with cases of TEN. Recently, the group of Jean-Claude Roujeau has clarified this issue by providing clinical evidence that EM and SJS are clinically distinct disorders with different causes and prognoses[3,5]. Increasingly, SJS and TEN are considered to be two ends of a spectrum of severe epidermolytic adverse cutaneous drug reactions, differing only by the extent of skin detachment (see Table 20.4).

Epidemiology

SJS and TEN are rare diseases that affect women more often than men (Table 20.5). Certain patient groups have an increased risk of developing SJS/TEN, including those who have slow acetylator genotypes, are immunocompromised (e.g. HIV infection), are undergoing radiotherapy while concomitantly receiving anticonvulsants (see Fig. 139.10), or have specific human leukocyte antigen (HLA) alleles. Examples of the latter are HLA-B*1502 in Asians and East Indians (but not Europeans) who are exposed to carbamazepine and HLA-B*5801 in Han Chinese exposed to allopurinol. Consequently, the FDA recently recommended genotyping of all Asians for the allele HLA-B*1502 prior to the administration of carbamazepine. In individuals with AIDS, the risk of developing TEN is 1000-fold higher than in the general population[45].

Death rates reported in large case series in which supportive therapy was used alone are quite variable, and it is known that these rates are heavily dependent on factors such as patient age and extent of epidermal detachment. Nevertheless, mortality rates range from 25% to 50% (average, 25–35%) for patients with TEN, and they are reported to be approximately 5% for patients with SJS[43,48].

Use of medications is reported in over 95% of patients with TEN. A strong association between drug ingestion and development of the cutaneous eruption is observed in 80% of cases. Other rare causes include infections and immunizations. The literature reflects a less clear relationship between drugs and SJS, as only 50% of reported SJS cases are claimed to be drug-related. This is certainly an underestimation, however, and most likely is due, in part, to the confusion that previously existed regarding the diagnostic distinction between SJS and EM.

More than 100 drugs have been identified to date as being associated with SJS/TEN. The most frequently implicated drugs are listed in Table 20.6 and consist primarily of allopurinol, antibiotics, nonsteroidal anti-inflammatory drugs, and anticonvulsants. Among the antibiotics, sulfonamides are the most strongly associated with SJS/TEN; other antimicrobials include aminopenicillins, quinolones, cephalosporins, tetracyclines and antifungals. In general, the risk of developing SJS/TEN is reported to be highest during the initial week(s) of therapy. For the aromatic anticonvulsants, the risk is highest during the first 2 months of treatment[49]. Furthermore, drugs with long half-lives are more likely to cause drug reactions and a fatal outcome than those with short half-lives, even if they are chemically related[50].

STEVENS–JOHNSON SYNDROME (SJS) AND TOXIC EPIDERMAL NECROLYSIS (TEN): EPIDEMIOLOGY AND RISK FACTORS	
Annual incidence	1.2–6 per million (SJS) 0.4–1.2 per million (TEN)
Ratio women : men	1.5 : 1
Risk factors	Slow acetylator genotypes
	Immunosuppression (e.g. HIV infection, lymphoma)
	Concomitant administration of radiotherapy and anticonvulsants (most commonly, those with brain tumors)
	HLA-B*1502: Asians and East Indians exposed to carbamazepine
	HLA-B*5801: Han Chinese exposed to allopurinol
	HLA-A*3101: Europeans exposed to carbamazepine

Table 20.5 Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN): epidemiology and risk factors. Adapted from refs 55, 56, 56a.

Pathogenesis

To date, the precise sequence of molecular and cellular events that lead to the development of SJS/TEN is only partially understood. The proposed pathogenesis must take into account the rarity of the reaction and the involvement of specific types of drugs.

Compelling evidence suggests that SJS/TEN is associated with an impaired capacity to detoxify reactive intermediate drug metabolites. It is thought to be initiated by an immune response to an antigenic complex formed by the reaction of such metabolites with certain host tissues[48,51–54]. Genetic susceptibility may also play a role, as evidenced by the identification of specific drug-related HLA alleles as major susceptibility genes for the development of SJS and TEN[42,55,56]. In addition to the alleles listed in Table 20.5, the HLA-DQB1*0601 allele has been reported in a significantly disproportionate number of white patients with SJS *and* ocular complications, suggesting that this allele may confer an increased risk for this specific clinical phenotype[57].

Cytotoxic T cells expressing the skin-homing receptor, cutaneous lymphocyte-associated antigen (CLA), are seen early in the development of cutaneous lesions[58–62]. These are likely to be drug-specific cytotoxic T cells[63]. Important cytokines such as interleukin (IL)-6, TNF-α, interferon-γ, IL-18 and Fas ligand (FasL) are also present in the lesional epidermis and/or blister fluid of patients with TEN, and their actions could explain some of the constitutional symptoms of TEN as well as the frequently observed discrepancy between the extent of epidermal damage and the paucity of the inflammatory infiltrate[58,64,65]. Lastly, the typical interval between the onset of drug therapy and SJS/TEN is between 1 and 3 weeks, suggesting a period of sensitization and providing further support for the role of the immune system in their pathogenesis. This period ("memory") is considerably shortened in patients who are unfortunately re-exposed to a drug that previously resulted in SJS or TEN.

Recently, it has been clearly shown that the tissue damage described by pathologists as epidermal necrolysis is a reflection of massive keratinocyte cell death via apoptosis[66]. The apoptosis of individual keratinocytes is a hallmark of the early stages of SJS and TEN, and it is the first clear morphologic sign of specific tissue damage. The more classic histologic image of extensive epidermal "necrolysis" is, in fact, an image of the aftermath of keratinocyte apoptosis. Indeed, the apoptotic state of cells is transient in nature, and it is followed by necrosis if the apoptotic cells are not rapidly phagocytosed. In SJS and TEN, within hours, keratinocyte apoptosis becomes very abundant in lesional skin, thus

MEDICATIONS MOST FREQUENTLY ASSOCIATED WITH STEVENS–JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS
Allopurinol
Aminopenicillins
Amithiozone (thioacetazone)*,†
Antiretroviral drugs, especially NNRTIs
Barbiturates
Carbamazepine
Chlormezanone*,‡
Phenytoin anticonvulsants
Lamotrigine
Phenylbutazone*,§
Piroxicam
Sulfadiazine*,†
Sulfadoxine†
Sulfasalazine
Trimethoprim–sulfamethoxazole
*Not available in the US. †Antibacterial. ‡Sedative/hypnotic. §Nonsteroidal anti-inflammatory drug.

Table 20.6 Medications most frequently associated with Stevens–Johnson syndrome and toxic epidermal necrolysis. Amifostine may join this list. NNRTIs, non-nucleoside reverse transcriptase inhibitors (in particular, nevirapine, efavirenz, etravirine). For a complete updated list of drugs associated with SJS and TEN, refer to: Litt J, Litt JZ. Litt's Drug Eruption Reference Manual Including Drug Interactions. London: Informa Healthcare.

rapidly overwhelming the phagocytic capacity of the affected skin. Over a period of hours to days, these apoptotic keratinocytes become necrotic and lose their cohesion to adjacent keratinocytes as well as the basement membrane. The whole epidermis then loses viability, creating the familiar histologic image of full-thickness epidermal necrolysis.

Fas ligand (FasL, CD95L), a member of the TNF family of cytokines, has the ability to induce apoptosis by binding to its specific cell surface receptor, the Fas (CD95, Apo-1) death receptor[67]. Such death receptors function as cell surface sensors that detect the presence of specific extracellular death signals and rapidly trigger cellular destruction by apoptosis (Fig. 20.6). Notably, keratinocyte apoptosis within lesional skin of patients with TEN is associated with highly increased expression of keratinocyte FasL, together with conserved levels of keratinocyte Fas expression[64,65,68,69]. Overlaying cryostat sections of lesional skin with Fas-sensitive cells as targets has demonstrated that keratinocyte FasL is cytolytically active in TEN; cytolysis can be prevented by monoclonal antibodies that block the interaction of Fas and FasL.

In 2008, Chung et al.[70] provided evidence that another cytotoxic molecule plays a role in the keratinocyte apoptosis observed in SJS/TEN. High concentrations of granulysin, a secreted, cationic, cytolytic protein produced by cytotoxic T lymphocytes (CTLs), natural killer (NK) cells and natural killer T (NKT) cells, were found in blister fluid from patients with SJS/TEN. Moreover, injection of recombinant granulysin into mouse skin induced epidermal necrolysis and an inflammatory cell infiltrate.

The current model for the pathogenesis of SJS/TEN (Fig. 20.7) is as follows: upon exposure to certain types of drugs (see Table 20.6), an individual with particular predisposing factors (see Table 20.5) mounts a specific immune reaction to the drug or one of its metabolites. As a result of an interplay of cell types and cytokines that remains to be totally defined, there is a strong expression of the cytolytic molecule FasL on keratinocytes as well as granulysin secretion from CTLs, NK cells and NKT cells. This leads to FasL- and granulysin-mediated apoptosis of keratinocytes and subsequent epidermal necrosis and detachment.

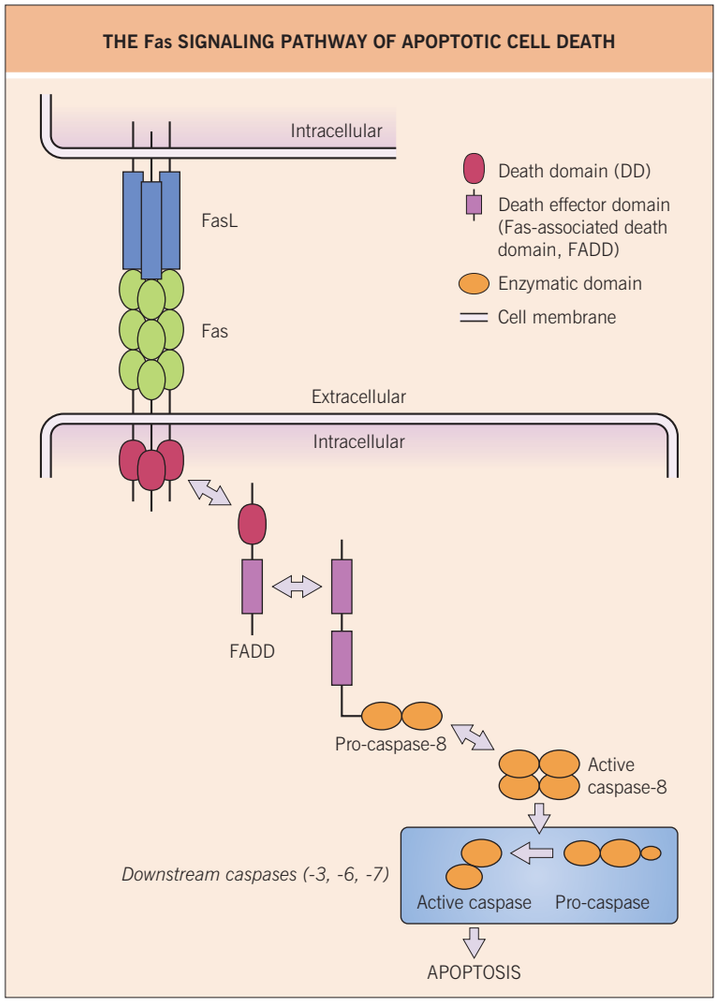

Fig. 20.6 The Fas signaling pathway of apoptotic cell death. The death receptor Fas and its ligand FasL are transmembrane proteins. Fas signaling is triggered in the target cells by receptor tri(multi)-merization, induced upon contact with membrane-bound FasL from an adjacent cell. Subsequently, recruitment of intracellular signaling proteins FADD and pro-caspase-8 leads to autoactivation of the protease caspase-8 as well as apoptosis due to subsequent activation of downstream effector caspases (caspases-3, -6, -7), which cause cellular disintegration and death. Stimuli that induce apoptosis include cellular stress, growth factor withdrawal, DNA damage and cytokines.

Clinical Features

Initial symptoms of both TEN and SJS can be fever, stinging eyes, and pain upon swallowing, any of which can precede cutaneous manifestations by 1 to 3 days. Skin lesions tend to appear first on the trunk, spreading to the neck, face and proximal upper extremities. The distal portions of the arms as well as the legs are relatively spared, but the palms and soles can be an early site of involvement. Erythema and erosions of the buccal, ocular and genital mucosae are present in more than 90% of patients (Fig. 20.8). The epithelium of the respiratory tract is involved in 25% of patients with TEN, and gastrointestinal lesions (e.g. esophagitis, diarrhea) can also occur[71]. The skin lesions are usually tender, and mucosal erosions are very painful. Additional systemic manifestations include fever, lymphadenopathy, hepatitis and cytopenias.

The morphology of the skin lesions has been studied in detail. First, lesions appear as erythematous, dusky red or purpuric macules of irregular size and shape, and they have a tendency to coalesce (Fig. 20.9). At this stage, and in the presence of mucosal involvement and tenderness, the risk of rapid progression to SJS or TEN should be strongly suspected. In the absence of spontaneous epidermal detachment, a Nikolsky sign should be sought by exerting tangential mechanical pressure with a finger on several erythematous zones. This sign is considered positive if dermal–epidermal cleavage is induced. In some patients, the macular lesions observed at the onset can have a dusky center, giving them a target-like appearance. However, such lesions lack the three concentric rings characteristic of typical target lesions (as originally described by Hebra) and are not papular as in atypical target lesions of EM.

As the epidermal involvement progresses toward full-thickness necrosis, the dusky red macular lesions take on a characteristic gray hue. This process can be very rapid (hours), or take several days. The necrotic epidermis then detaches from the underlying dermis, and fluid fills the space between the dermis and the epidermis, giving rise to blisters. The blisters have special features: they break easily (flaccid) and can be extended sideways by slight pressure of the thumb as more necrotic epidermis is displaced laterally (Asboe–Hansen sign). The skin resembles wet cigarette paper (see Fig. 20.12B) as it is pulled away by trauma, often revealing large areas of raw and bleeding dermis, which is referred to as "scalding" (Fig. 20.10). These patients must therefore be handled with extreme care. Tense blisters are usually seen only on the palmoplantar surfaces, where the epidermis is thicker and, therefore, more resistant to mild trauma.

When admitting such patients, the extent of necrolysis must be carefully and correctly evaluated, since it constitutes a major prognostic factor. The rules characteristically used to evaluate the surface area of thermal burns are appropriate for this purpose (see Ch. 88). Experience has shown that the extent of skin detachment is easily overestimated. Measurements should include detached and detachable epidermis (positive Nikolsky sign) but not purely erythematous areas (negative Nikolsky sign)[2]. The extent of skin detachment allows classification of the patient into one of three groups (Fig. 20.11; see Table 20.4):

- SJS: <10% of body surface area (BSA)
- SJS–TEN overlap (an intermediate category): 10–30% of BSA (Fig. 20.12)
- TEN: >30% of BSA.

Mucosal erosions are present in >90% of patients (Fig. 20.13). Patients complain of photophobia and painful micturition.

It is also important to distinguish between SJS and EM, which are now considered to be different illnesses with different prognoses (see above)[5]. Their histologic features are similar and, therefore, not helpful

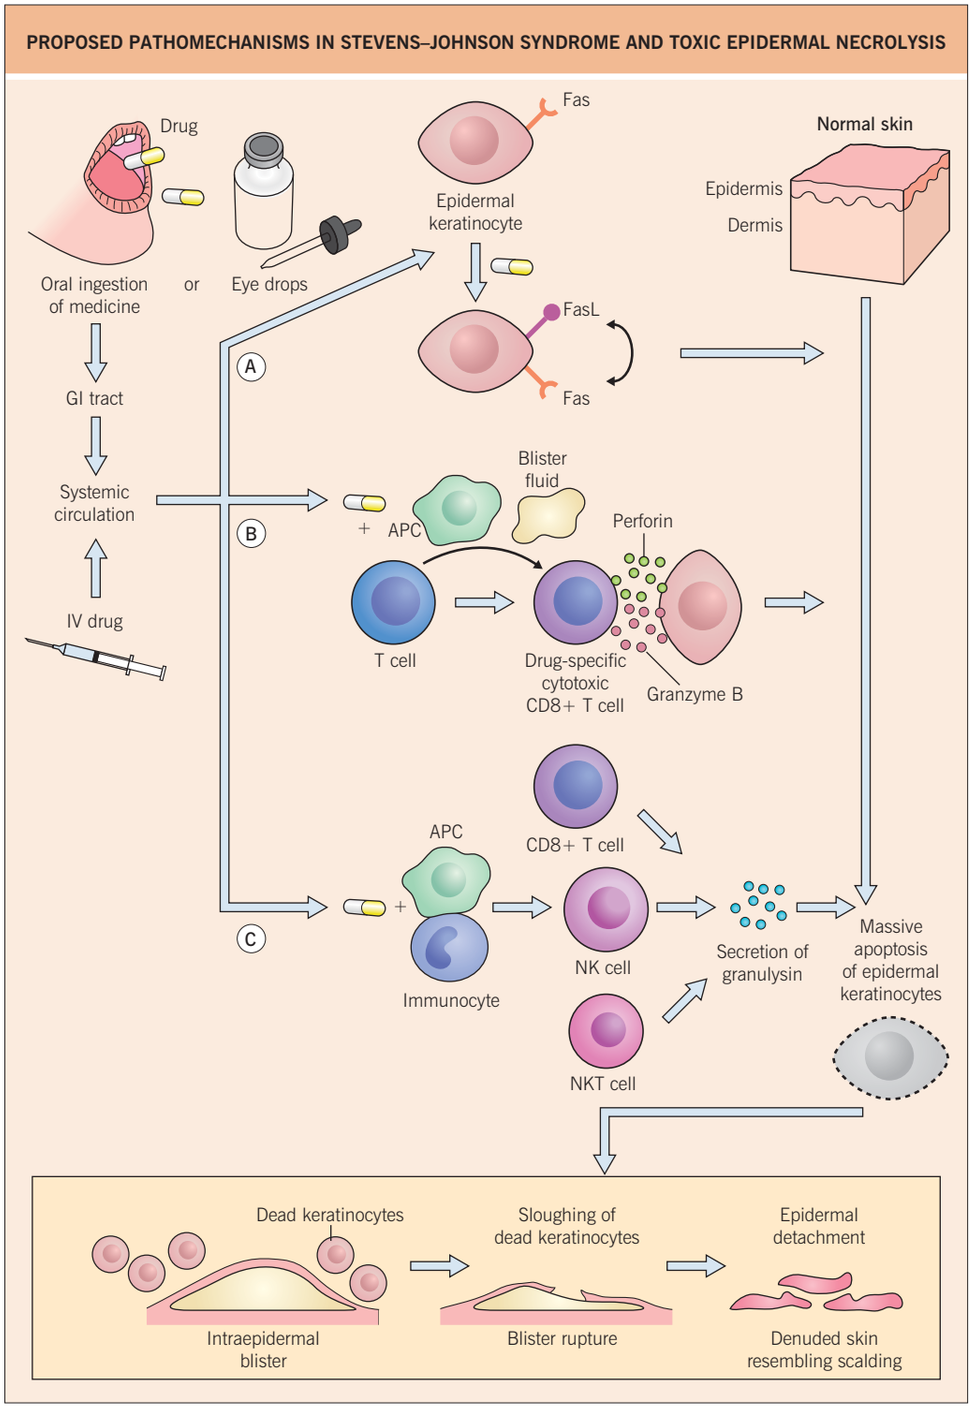

Fig. 20.7 Proposed pathomechanisms to explain apoptosis of epidermal keratinocytes in Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). A number of medications can trigger widespread apoptosis of epidermal keratinocytes in individuals with SJS or TEN, leading to skin blistering and denudation. Several theories have been proposed for this condition: (**A**) the medication might induce upregulation of FasL by keratinocytes constitutively expressing Fas, leading to a death receptor-mediated apoptotic pathway; (**B**) the drug might interact with MHC class I-expressing cells and then drug-specific $CD8^+$ cytotoxic T cells accumulate within epidermal blisters, releasing perforin and granzyme B that kill keratinocytes; and (**C**) the drug may also trigger the activation of $CD8^+$ T cells, NK cells and NKT cells to secrete granulysin, with keratinocyte death not requiring cell contact. IVIg contains antibodies against Fas that can block the binding of FasL to Fas. *From Nickoloff BJ. Saving the skin from drug-induced detachment. Fig. 20.10 Clinical features of toxic epidermal necrolysis (TEN). A Detachment of large sheets of necrolytic epidermis (>30% body surface area), leading to extensive areas of denuded skin. A few intact bullae are still present. **B** Hemorrhagic crusts with mucosal involvement. **C** Epidermal detachment of palmar skin.

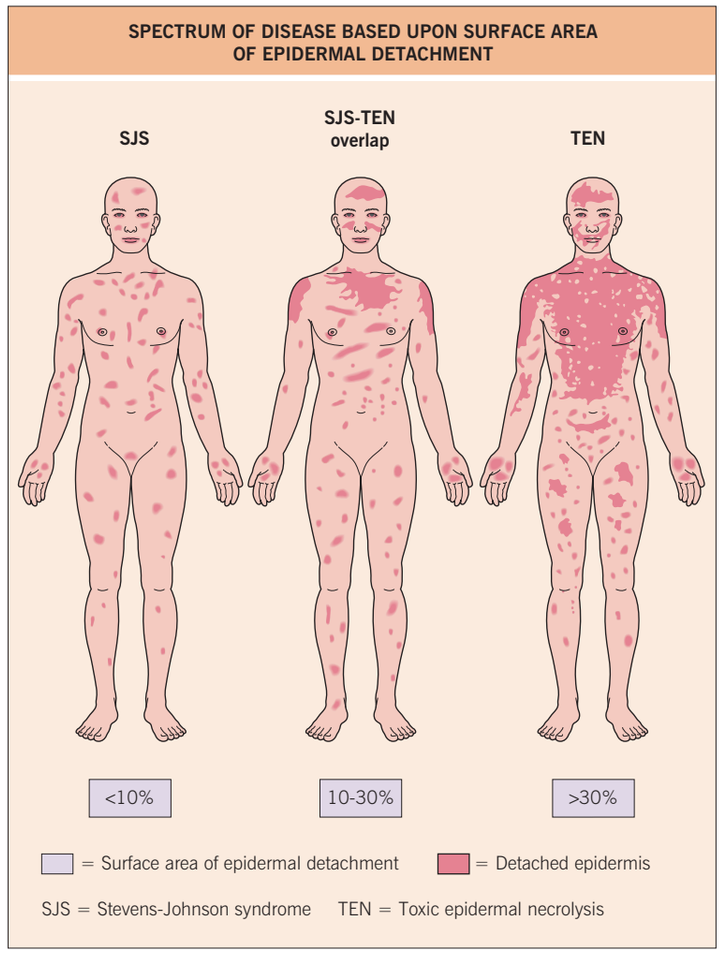

Fig. 20.11 Spectrum of disease based upon surface area of epidermal detachment.

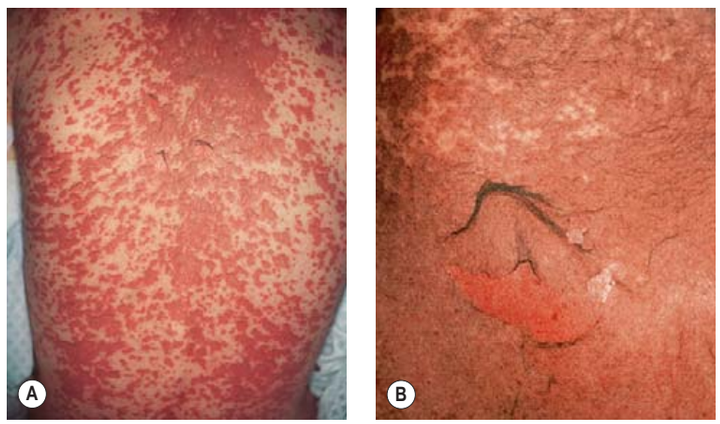

Fig. 20.12 Stevens–Johnson syndrome (SJS) versus SJS–TEN overlap. A In addition to mucosal involvement and numerous dusky lesions with flaccid bullae, there are areas of coalescence and multiple sites of epidermal detachment. Because the latter involved >10% body surface area, the patient was classified as having SJS–TEN overlap. **B** Close-up of epidermal detachment, whose appearance has been likened to wet cigarette paper.

in distinguishing between the two diseases. Differentiation is based primarily on clinical characteristics, especially the appearance of the target lesions and their distribution. To retain the diagnosis of EM, typical target lesions must exist, whereas SJS should be considered if target lesions are atypical (see Table 20.1). Unfortunately, criteria for predicting which patients with SJS are likely to progress towards full-blown TEN are currently unavailable.

In TEN, there are several factors that have been correlated with poor outcome, including increasing age and extent of epidermal detachment. In addition, the number of medications, elevation of serum urea, creatinine and glucose levels, neutropenia, lymphopenia and thrombocytopenia have been statistically linked to poor outcome. Late withdrawal of the causative drug is also associated with a less favorable outcome.

Table 20.7 SCORTEN. It represents a prognostic scoring system for patients with toxic epidermal necrolysis[72]. The score is based upon the number of prognostic factors in a particular patient. BSA, body surface area.

It has been estimated that prompt withdrawal of the offending drug reduces the risk of death by 30% per day[50]. A severity-of-illness score for TEN has recently been proposed (SCORTEN), in which seven parameters with equal weight have been integrated so as to make it possible to predict outcome (Table 20.7)[72,73].

On average, death occurs in every third patient with TEN, and it is mainly due to infections (*S. aureus* and *Pseudomonas aeruginosa*). Massive transepidermal fluid loss associated with electrolyte imbalance, inhibition of insulin secretion, insulin resistance, and onset of a hypercatabolic state can also be contributive factors. All these complications of TEN (that can also be observed in SJS) are best managed in intensive care units. They can unfortunately culminate in adult respiratory distress syndrome and multiple organ failure despite adequate supportive therapy.

Healing of areas of detached epidermis through re-epithelialization usually starts within days, and it is complete in most cases within 3 weeks. This process results from proliferation and migration of keratinocytes from "reservoir" sites, such as healthy epidermis surrounding denuded areas and hair follicles within the areas of detachment. Due to this conserved capacity for re-epithelialization, skin grafting is not required in SJS or TEN. Unfortunately, however, healing can be imperfect, and survivors may have sequelae such as symblepharon, conjunctival synechiae, entropion, ingrowth of eyelashes, cutaneous scarring, irregular pigmentation, eruptive melanocytic nevi, persistent erosions of the mucous membranes, phimosis, vaginal synechiae, nail dystrophy and diffuse hair loss. These can often be minimized by optimal skin care (see below), but, in TEN, up to 35% of survivors can have ocular symptoms ranging from sicca syndrome to blindness[48].

Identification of the offending drug is an important and difficult task, but it should be among the first priorities. As noted previously, delayed withdrawal of the causative drug(s) is associated with increased mortality. Currently, there is no reliable *in vitro* test for the rapid identification of causative drugs. Patch testing shows weak sensitivity in SJS/TEN, and it is not appropriate for identification purposes; re-exposing the patient to the proposed causative drug is obviously not an acceptable option in such severe drug reactions. The clinician, therefore, has to rely on previously reported associations and determine the probability (unlikely, possible, plausible, probable, very probable) for each medication based on the intrinsic ability of a particular drug to cause SJS/TEN (see Table 20.6 and reference therein) and extrinsic factors such as the onset of a given medication with respect to the onset of SJS/TEN. SJS and TEN usually occur 7–21 days after initiation of the causative drug in the setting of a first exposure to the drug, but can occur within 2 days in the case of re-exposure to a drug that previously caused SJS or TEN. In general, the medication list of patients with SJS and TEN should be reduced to a strict minimum, appropriate substitutions made, and drugs with short half-lives favored.

Pathology

Histopathologic examination of lesional skin is a very useful tool for confirming the diagnosis of SJS and TEN (Fig. 20.14), as the morphologic findings are distinct from those observed in SSSS (subcorneal blister with cleavage located in the granular layer of the epidermis) and acute generalized exanthematous pustulosis (AGEP; a rich neutrophilic infiltrate, superficial epidermal pustules and spongiosis, but no full-thickness epidermal necrolysis). Frequently, immediate analysis of frozen cryostat sections is sufficient for this purpose.

In early lesions of SJS and TEN, apoptotic keratinocytes are observed scattered in the basal and immediate suprabasal layers of the epidermis. This is most likely the histologic correlate of the dusky to gray color that clinicians familiar with SJS/TEN consider as a warning sign of pending full-blown epidermal necrolysis and detachment. At later stages, lesional biopsy specimens show a subepidermal blister with overlying confluent necrosis of the entire epidermis and a sparse

perivascular infiltrate composed primarily of lymphocytes. At an immunopathologic level, variable numbers of lymphocytes (usually $CD8^+$) and macrophages are observed within the epidermis, whereas lymphocytes in the papillary dermis are primarily $CD4^+$ cells[59,60].

Differential Diagnosis

The differential diagnosis of SJS and TEN consists primarily of EM (see above), SSSS, AGEP and generalized fixed drug eruption. Paraneoplastic pemphigus, drug-induced linear IgA bullous dermatosis (LABD), Kawasaki disease, LE, toxic erythema of chemotherapy, and severe acute GVHD can also be considered in some patients, depending upon the clinical setting. Patients with drug reactions with eosinophilia and systemic symptoms (DRESS) can sometimes develop vesicles and bullae due to dermal edema (see Ch. 21).

In most instances, SSSS and AGEP can be easily distinguished from TEN on clinical grounds. SSSS usually occurs in newborns and young children, but can also occur in adults who have renal failure or are immunosuppressed. SSSS is induced by a staphylococcal exotoxin (epidermolysin) that targets desmoglein 1 (see Ch. 74)[74]. The areas of erythema are tender and widespread, but spare the mucous membranes, palms and soles. The Nikolsky sign may be positive as in TEN, but it results in a superficial subcorneal cleavage, not a dermal-epidermal separation. Fragile bullous lesions then develop, and they are rapidly followed by exfoliation of sheets of epidermis. For the trained clinician, the exfoliation is clearly more superficial, leaving a bed of intact epidermal layers instead of the wet and bright red dermal tissue observed in TEN. Furthermore, in SSSS a purulent nasal discharge is frequently present. The distinction between TEN and SSSS is also very evident histologically, as the former results in full-thickness epidermal necrolysis, whereas the latter shows a subcorneal split with a normal underlying epidermis.

AGEP, also considered an important adverse cutaneous drug reaction, presents as large areas of erythema studded with multiple, small (<3 mm), non-follicular pustules. Neutrophilia and eosinophilia are frequently observed, and, together with the pustules, go against the diagnosis of TEN. The Nikolsky sign may be positive and is, therefore, not a good diagnostic marker in this situation. In addition, the pustules may coalesce into rather large lesions and then slough. Mucous membrane involvement occurs in approximately 20% of cases. Histology is a useful complement to clinical examination as it reveals a dense neutrophilic infiltrate and intraepidermal and subcorneal pustules, but no full-thickness epidermal necrolysis. Multiple mucocutaneous lesions of fixed drug eruption can overlap clinically and histologically with SJS; determination of the number of lesions present during the first outbreak may prove useful (see Ch. 21).

An acute onset of paraneoplastic pemphigus, drug-induced LABD, and acute severe GVHD can, in some circumstances, be reminiscent of TEN. However, the clinical context, as well as the histologic and immunohistochemical findings (by direct and indirect immunofluorescence microscopy), can rapidly aid in establishing the correct diagnosis. Vancomycin is the most common cause of drug-induced LABD and is an uncommon cause of SJS/TEN.

Kawasaki disease is sometimes confused with SJS in children[9]. In the former, the lips are red and dry ("chapped") and the hemorrhagic crusts and mucosal denudation observed with SJS are absent (see Ch. 81). The bulbar conjunctivae are injected in Kawasaki disease but there is no exudate as is seen in SJS. In Kawasaki disease, target-like lesions are seen occasionally but bullous lesions are generally not observed. However, there is an epidermal split which results in perineal peeling and peeling of the fingertips.

TEN-like vesiculobullous skin disease has been observed in patients with both acute and subacute LE as well as in individuals with systemic LE who are on no medications. Sontheimer and colleagues have proposed the term "acute syndrome of apoptotic pan-epidermolysis" (ASAP) to describe this clinical syndrome[75].

Thermal burns, phototoxicity, and coma bullae (see Ch. 33) can be associated with full-thickness epidermal necrosis, but the overall clinical setting is very different. Notably, the distribution of lesions and the patient's history are not compatible with TEN. In any patient receiving chemotherapy assigned the diagnosis of TEN, the possibility of extensive toxic erythema of chemotherapy needs to be considered (see Ch. 21). The bullae tend to be more tense and do not rupture as easily.

Treatment

Optimal medical management of SJS and TEN requires early diagnosis, immediate discontinuation of the causative drug(s), supportive care, and specific therapy (Fig. 20.15).

Supportive care is similar to that performed for severe thermal burns, and it is aimed at limiting associated complications, which are the main cause of mortality. These include hypovolemia, electrolyte imbalance, renal insufficiency and sepsis. Careful daily wound care, hydration and nutritional support are essential and, preferably, done in an intensive care unit if there is epidermal detachment involving 10–20% (or more) of BSA[76]. Use of a controlled pressure, thermoregulated bed and an aluminum survival sheet, instead of a regular bed and sheets, is recommended. All patient manipulations should be performed sterilely, and venous catheters should be placed, if possible, in a region of non-involved skin.

Wound care is best performed once daily with the help of, or in the presence of, a dermatologist. The patient should be manipulated as

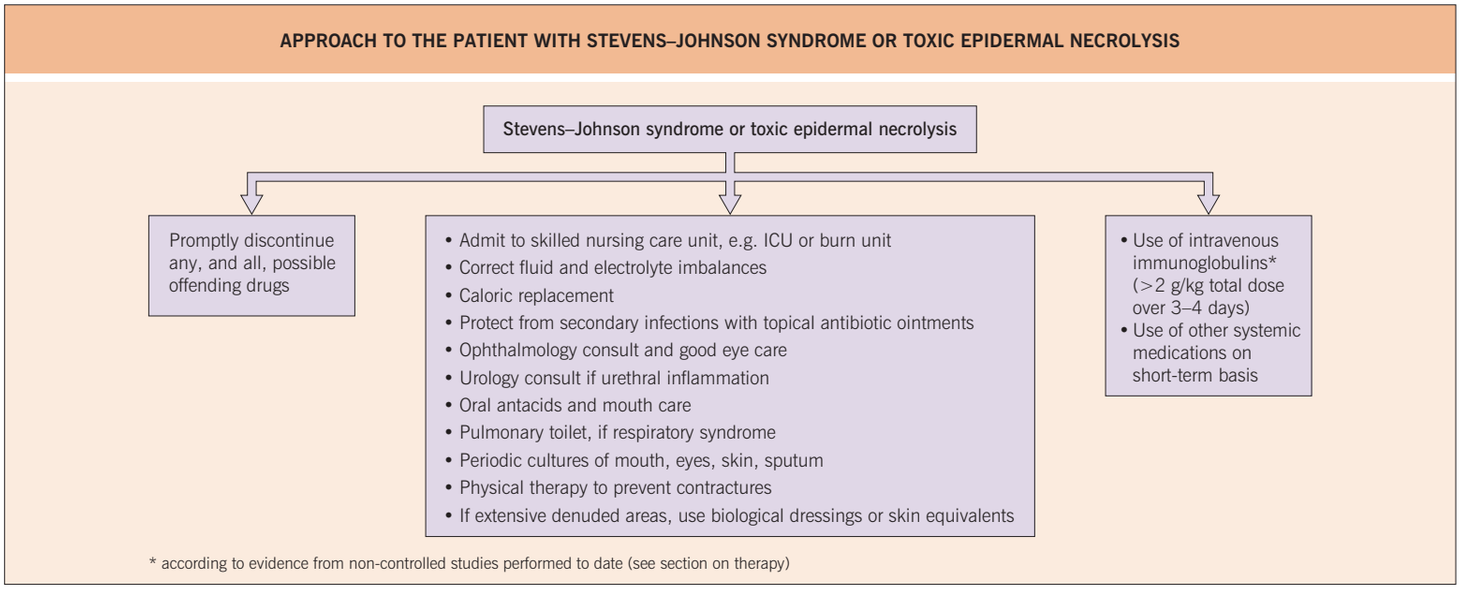

Fig. 20.15 Approach to the patient with Stevens–Johnson syndrome or toxic epidermal necrolysis. ICU, intensive care unit.

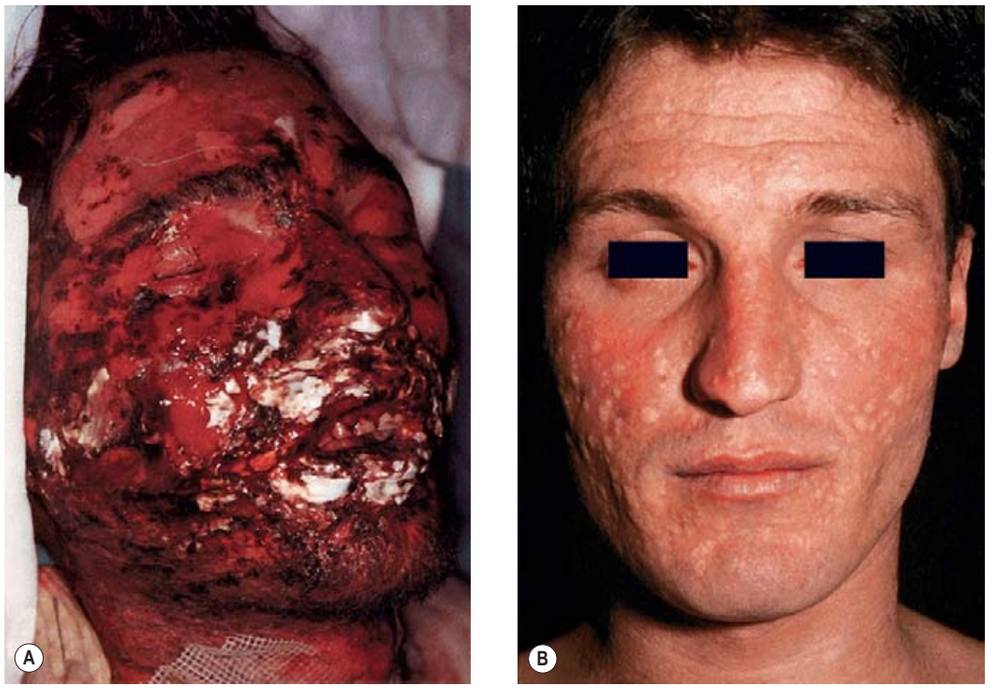

Fig. 20.16 Treatment of toxic epidermal necrolysis (TEN). Facial involvement of a patient with TEN (50% body surface area involvement) before (**A**) and 3 weeks after (**B**) treatment with IVIg (0.75 g/kg/day for 4 days).

Table 20.8 Published studies (with ≥10 patients) on the use of IVIg for the treatment of toxic epidermal necrolysis. The green boxes denote those studies where the actual mortality rate was less than the predicted mortality rate and the pink boxes represent those studies where the mortality rate was greater than the predicted mortality rate. For SCORTEN scoring system, see Table 20.7 and for APACHE scoring system, see ref 86a. BSA, body surface area; C, controlled; NC, non-controlled; Prospect, prospective; Retro, retrospective; — information not available.

little as possible, as every movement is a potential cause of epidermal detachment. Cutaneous care should concentrate on the face, eyes, nose, mouth, ears, anogenital region, axillary folds and interdigital spaces. Non-detached areas are kept dry and not manipulated. Detached areas, particularly on the back and pressure sites in contact with the bed, should be covered with Vaseline® gauze until re-epithelialization has occurred (see Ch. 145). For the face, serous and/or bloody crusts can be cleaned daily with isotonic sterile sodium chloride solution. An antibiotic ointment (e.g. mupirocin) should be applied around orifices (ears, nose, mouth), and silicone dressings can be used to cover erosive denuded areas of skin. The silicone dressing does not need to be changed and can be left in place until re-epithelialization occurs, but its surface must be cleansed daily with isotonic sterile sodium chloride solution. Another option is to place a large non-adherent layered dressing (e.g. Exu-Dry™) over the patient and on the bed.

For the eyes, regular examination by an ophthalmologist is recommended. Eyelids should be gently cleansed daily with isotonic sterile sodium chloride solution, and an ophthalmic antibiotic ointment applied to the eyelids. In addition, antibiotic eyedrops should be administered three times a day to the cornea to reduce bacterial colonization, which can lead to scarring. Nostrils should be cleaned daily with a sterile cotton swab, moistened with isotonic sterile sodium chloride solution, and then the same procedure used to apply a little antibiotic ointment (e.g. mupirocin). The mouth should be rinsed several times a day using a syringe with isotonic sterile sodium chloride solution, and then aspirated if the patient is unconscious. In the anogenital region and interdigital spaces, cutaneous care is performed daily by short applications of silver nitrate solution (0.5%) in the case of maceration, or simply sterile sodium chloride solution if there is no maceration.

To date, no specific therapies for SJS and TEN have shown efficacy in prospective, controlled clinical trials, i.e. attained evidence-based medicine standards of acceptance. In general, therapy for severely affected patients with SJS has mirrored therapy for TEN, while those patients with milder non-progressive forms of SJS may receive only supportive care. The low prevalence of SJS and TEN makes randomized clinical trials hard to perform. As a consequence, the literature for the most part consists of case reports and small uncontrolled series. In such studies, several treatments, including cyclosporine (3–4 mg/kg/day), cyclophosphamide (100–300 mg/day), plasmapheresis, N-acetylcysteine

(2 g/6 h), and TNF-α antagonists (e.g. etanercept, infliximab) have shown promising results[58,77–83]. Systemic corticosteroids have been a mainstay of therapy for decades, but their use remains controversial[84], despite a recent study suggesting efficacy when administered acutely and over a short period of time as pulse therapy (intravenous dexamethasone 1.5 mg/kg for three consecutive days)[85]. Recently, a controlled study using thalidomide was interrupted because of higher mortality in the thalidomide group compared with the placebo group[86].

In theory, therapies that have the potential to selectively block keratinocyte apoptosis have significant potential for treating SJS and TEN. The demonstration that Fas-mediated cell death (induced *in vitro* by lesional skin from patients with TEN) can be abrogated by monoclonal antibodies against FasL or by Fas : Fc (soluble form of Fas receptor) suggested that blocking antibodies might be useful in the treatment of TEN. Approximately 10 years ago, we observed that commercial preparations of IVIg contained antibodies against Fas that are able to block the binding of FasL to Fas[64]. Furthermore, IVIg, by blocking Fas, inhibited cell death mediated by recombinant FasL *in vitro*. When used in high doses (0.75 g/kg/day for four consecutive days) to treat patients with TEN, IVIg consistently and rapidly blocked the progression of epidermal detachment and disease in 10 of the 10 patients treated in a preliminary pilot study[64] (Fig. 20.16). To date, numerous case reports and 10 additional case series (that included at least 10 patients) have analyzed the therapeutic effect of IVIg in TEN (Table 20.8). Taken together, although each study has its potential biases, 8 of the 11 studies suggest that IVIg (at a total dose of >2 g/kg administered over 3–4 days) may reduce TEN-associated mortality[87–90].

Detailed analyses of studies published to date strongly suggest that total doses of ≤2 g/kg may be insufficient for obtaining an optimal therapeutic effect. In a recently published systematic review of the literature, higher doses of IVIg correlated with an increased survival rate and lower mortality rate[91]. Furthermore, for every additional 1 g/kg increase in the total dose of IVIg, there was a 4.2-fold increase in the survival rate. Therefore, our currently recommended treatment regimen is 1 g/kg/day of IVIg for three consecutive days, thus giving a total dose of 3 g/kg (this total dose is equivalent to that used in our first pilot study[64]). Some authors who reported successful results used an even higher total dose of 4 g/kg over 4 days[88]. In conclusion, high-dose IVIg appears to be a reasonable and relatively safe choice among the selective therapies currently available and previously tested. Further trials are required, however, to firmly establish its efficacy.

21 Drug Reactions

Jean Revuz and Laurence Valeyrie-Allanore

Key features

- The skin is one of the most common targets for adverse drug reactions
- To determine the cause of the eruption, a logical approach based on clinical characteristics, chronologic factors and a literature search is required
- Exanthematous eruptions and urticaria are the two most common forms of cutaneous drug reactions
- When an exanthematous eruption is associated with fever, lymphadenopathy, and/or edema of the face, the possibility of drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) must be considered and an evaluation for systemic involvement conducted
- Less common drug reactions include fixed, lichenoid, pustular, photo-, bullous and vasculitic reactions, as well as Stevens–Johnson syndrome and toxic epidermal necrolysis
- Early withdrawal of all potentially responsible drugs is essential, particularly in the case of severe drug reactions

INTRODUCTION

The skin is one of the most common targets for adverse drug reactions[1]. Eruptions are observed in 0.1% to 1% of patients enrolled in premarketing trials of most systemic drugs. In the case of medications such as antibiotics (e.g. aminopenicillins, sulfonamides) and anticonvulsants, at least 1%, and sometimes more than 5%, of patients receiving these drugs may develop a skin eruption. Approximately 2% of all drug-induced skin reactions are considered "serious" according to the following World Health Organization (WHO) definition: "if it results in death, requires hospitalization or prolongation of existing hospital stay, results in persistent or significant disability/incapacity, or is life-threatening". Toxic epidermal necrolysis (TEN) and drug reaction with eosinophilia and systemic symptoms (DRESS; also referred to as drug-induced hypersensitivity syndrome [DIHS]) are examples of such "serious reactions". Roujeau and Stern[2] estimated that 1 of every 1000 hospitalized patients has a serious cutaneous drug reaction. Prompt identification of severe cutaneous adverse reactions (SCARs) is an important goal, as it is a necessary step prior to discontinuing the offending agent and thus decreasing morbidity (Table 21.1).

It may be tempting to consider most eruptive cutaneous drug reactions, especially the severe ones, as various presentations of a "hypersensitivity syndrome". However, in order to begin to understand these entities, it is more useful to examine the specificity of the clinical, pathologic and biologic patterns, thus eventually allowing classification of each type of adverse cutaneous reaction as a single entity with a well-defined and specific mechanism[3].

This chapter focuses on adverse cutaneous reactions due to systemically administered medications. In addition, several specific types of drug reactions are discussed in other chapters (Table 21.2).

SEVERE CUTANEOUS ADVERSE REACTIONS (SCARs)
Anaphylaxis
Anticoagulant-induced skin necrosis
Acute generalized exanthematous pustulosis (AGEP)
Drug rash with eosinophilia and systemic symptoms (DRESS)/Drug-induced hypersensitivity syndrome (DIHS)
Generalized fixed drug eruption
Stevens–Johnson syndrome and toxic epidermal necrolysis

Table 21.1 Severe cutaneous adverse reactions (SCARs).

EPIDEMIOLOGY

Cutaneous reactions to drugs are responsible for approximately 3% of all disabling "injuries" that occur during hospitalization. In departments of dermatology, they represent 2% of consultations and approximately 5% of the admissions to an inpatient dermatology department. The incidence of fatalities due to drug reactions (systemic and cutaneous) among inpatients is between 0.1% and 0.3%[4].

Risk factors for developing an adverse drug reaction include an older age and female gender, and, as expected, the risk increases with the number of drugs taken by the patient. Paradoxically, the incidence of most immunologically mediated drug eruptions is increased in the setting of immunosuppression; e.g. in patients with AIDS ($CD4^+$ <200/mm^3), the risk of developing an exanthematous eruption to sulfamethoxazole is 10- to 50-fold greater than in the general population[5]. Whether an atopic diathesis acts as a risk factor remains debatable[6]. More recently, morbilliform drug reactions to hydroxychloroquine were observed more commonly in patients with dermatomyositis as compared to those with lupus erythematosus (LE).

Guaifenesin	2.9
Furosemide	2.6
Phytonadione	0.9
Flurazepam	0.5
Chloral hydrate	0.2

Table 21.3 Skin reactions to "drugs" received by at least 1000 patients[1].

DRUGS RECEIVED BY MORE THAN 1000 PATIENTS WITH NO SKIN REACTIONS (RATES ESTIMATED TO BE ≤3 PER 1000)
• Potassium chloride • Milk of magnesia • Digoxin • Meperidine hydrochloride • Dioctyl sodium sulfosuccinate • Magnesium hydroxide • Aluminum hydroxide • Acetaminophen • Multivitamins • Bisacodyl • Diphenhydramine hydrochloride • Aspirin • Aminophylline • Prochlorperazine • Ferrous sulfate • Thiamine • Prednisone • Atropine • Codeine • Vitamin B complex and ascorbic acid • Pentazocine • Hydrochlorothiazide* • Phosphate enema • Castor oil • Tetracycline* • Morphine • Regular insulin • Warfarin • Spironolactone
*Notably phototoxic reactions were not included.

Table 21.4 Drugs received by more than 1000 patients with no skin reactions (rates estimated to be ≤3 per 1000)[1].

The epidemiology of common adverse cutaneous drug reactions is still in its infancy. As a result, the incidence of drug reactions is difficult to establish precisely. Pre-marketing clinical trials, conducted before a new drug is licensed, include a limited number of patients, thus preventing a clear estimate of the true incidence. It is usually after several months or years of greater utilization that a more precise profile of the side effects of a newly released drug is established. Moreover, available information must be interpreted with caution, depending upon the method of data collection[1].

One preferred method of determining rates of cutaneous reactions to drugs is a prospective systematic survey such as the Boston Collaborative Drug Surveillance Program, which included 22 000 monitored patients[7]. This program allowed the potential risk of skin reactions to specific drugs to be determined (Tables 21.3 & 21.4). Reaction rates to commonly administered drugs have been confirmed by several prospective studies; however, the latter have been limited to inpatients[8]. In one series, adverse skin reactions occurred in 2.7% of 48 000 patients hospitalized over a 20-year period on a general internal medicine service; maculopapular exanthemas (91.2%), urticaria (5.9%) and vasculitis (1.4%) were the reactions most commonly observed. The primary responsible drugs were penicillins, sulfonamides and nonsteroidal anti-inflammatory drugs (NSAIDs).

Except for studies in hospitalized populations and those focusing on the most severe reactions, data regarding the incidence of cutaneous drug reactions in the general population are minimal, in part due to the absence of comprehensive post-marketing surveillance programs. In a retrospective cohort study from the Netherlands of 13 679 patients from general practices, the most frequently reported skin reactions to antimicrobials were due to trimethoprim–sulfamethoxazole (2.1% of users), fluoroquinolones (1.6%) and penicillins (1.1%).

PATHOGENESIS

Common eruptive cutaneous drug eruptions are hypersensitivity reactions with an underlying immunologic mechanism. Drugs or their metabolites may act as haptens, inducing a specific cell-mediated or humoral response. Cutaneous reactions also may arise as a result of non-immunologic mechanisms (Table 21.5). Some of these reactions are predictable given their relationship to the dose and/or the pharmacologic properties of the drug. However, the responsible pathophysiology may be difficult to identify simply on the basis of clinical appearance as the skin responds to a wide variety of stimuli through a limited number of morphologic reaction patterns. This may explain, at least in part, why the underlying mechanism of many cutaneous drug eruptions is still unknown.

Immunologically Mediated Drug Reactions

- *IgE-dependent drug reactions* (formerly type I, Gell–Coombs classification): urticaria, angioedema and anaphylaxis.
- *Cytotoxic drug-induced reactions* (antibody against a fixed antigen; formerly type II): petechiae secondary to drug-induced thrombocytopenia.
- *Immune complex-dependent drug reactions* (formerly type III): vasculitis, serum sickness and certain types of urticaria.
- *Possible delayed-type, cell-mediated drug reactions* (formerly type IV; sometimes not well defined): exanthematous, fixed and lichenoid drug eruptions, as well as Stevens–Johnson syndrome (SJS) and TEN.

The precise mechanisms have not yet been clearly defined for all of these reactions, and attempting to identify a unique mechanism for every drug eruption can certainly prove difficult. It has also become clear that the Gell–Coombs classification of immune reactions is an oversimplification when applied to drug reactions in which there is a mixture of humoral and cellular effectors. Also, additional types of reactions, e.g. granulomatous, acneiform, pseudolymphomatous, have been described.

Non-immunologic Mechanisms

Overdose

The clinical manifestations are predictable and represent an exaggeration of the drug's pharmacologic actions. It may occur as a consequence of a prescribing error or deliberate excess by the patient. In addition, drug overdoses can be observed in patients given the usual dose of a medication, but in whom there are differing rates of absorption, metabolism or excretion. An example would be methotrexate toxicity in elderly patients with reduced renal function.

MECHANISMS OF CUTANEOUS DRUG-INDUCED REACTIONS	
Immunologic mechanism (unpredictable)	• IgE-dependent drug reactions • Cytotoxic drug-induced reactions • Immune complex-dependent drug reactions • Cell-mediated reactions
Non-immunologic mechanisms (sometimes predictable)	• Overdose • Pharmacologic side effects • Cumulative toxicity • Delayed toxicity • Drug–drug interactions • Alterations in metabolism • Exacerbation of disease
Idiosyncratic with a possible immunologic mechanism (unpredictable)	• DRESS (DIHS) • TEN/SJS • Drug reactions in the setting of HIV infection • Drug-induced lupus erythematosus

Table 21.5 Mechanisms of cutaneous drug-induced reactions. DIHS, drug-induced hypersensitivity syndrome; DRESS, drug reaction with eosinophilia and systemic symptoms; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

LOGICAL APPROACH TO DETERMINE THE CAUSE OF A DRUG ERUPTION	
DRUG RESPONSIBILITY ASSESSMENT	
Clinical characteristics	• Type of primary lesion (e.g. urticaria, erythematous papule, pustule, purpuric papule, vesicle or bulla) • Distribution and number of lesions • Mucous membrane involvement, facial edema • Associated signs and symptoms: fever, pruritus, lymph node enlargement, visceral involvement
Chronological factors	• Document all drugs to which the patient has been exposed (including OTC and complementary) and the dates of administration • Date of eruption • Time interval between drug introduction (or reintroduction) and skin eruption • Response to removal of the suspected agent • Consider excipients (e.g. soybean oil) • Response to rechallenge*
Literature search	• Bibliographic research (e.g. Medline) • Drug Alert Registry or Medwatch • Data collected by pharmaceutical companies • In the case of more recently released medications, extrapolation based on the class of drug and in particular the first drug released in the class
*Often inadvertent.	

Table 21.6 Logical approach to determine the cause of a drug eruption. OTC, over-the-counter.

Pharmacologic side effects

These reactions include undesirable or toxic effects that cannot be separated from the desired pharmacologic actions of the drug. For example, chemotherapeutic agents target rapidly dividing cells and their side effects include alopecia, mucositis and pancytopenia.

Cumulative toxicity

Prolonged exposure to a medication may lead to cumulative toxicity. For example, the accumulation of drugs such as silver, minocycline and amiodarone or their metabolites within the skin can lead to distinctive discoloration of the skin. Methotrexate can also lead to hepatic fibrosis.

Delayed toxicity

This corresponds to a toxic, dose-dependent effect that occurs months to years after the discontinuation of a medication. Examples would be arsenic and the development of squamous cell carcinomas and palmoplantar keratoses, or alkylating agents and acute leukemia.

Drug–drug interactions

Interactions between two or more drugs administered simultaneously may occur at several different steps: (1) intestinal drug interactions; (2) displacement from binding proteins or receptor sites; (3) enzyme stimulation or inhibition; and (4) altered drug excretion (see Ch. 131). Examples of each include the interactions between tetracycline and calcium, methotrexate and sulfonamides, cyclosporine and azoles, and methotrexate and probenecid, respectively.

Alterations in metabolism

Drugs may induce cutaneous changes by their effects on the nutritional or metabolic status of the patient. Bexarotene may induce severe hypertriglyceridemia and eruptive xanthomas, while isoniazid may be associated with pellagra-like changes.

Exacerbation of disease

A variety of drugs can exacerbate pre-existing dermatologic disease, such as androgens in patients with acne vulgaris or lithium and interferon in patients with psoriasis.

Idiosyncratic with Possible Immunologic Mediation

Idiosyncratic drug eruptions represent reactions that are unpredictable and cannot be explained on the basis of the pharmacologic properties of the drug. For several of these reactions, an immunologic mechanism is suspected and supporting evidence is available (see below). Reactive metabolites of drugs can bind covalently to proteins, and the altered protein, considered as foreign, then induces an immune response. However, the way in which a drug is metabolized into a reactive species (or fails to be metabolized) differs in nature and amount depending upon the patient's specific metabolic pathways. These variations are genetically influenced (see Ch. 131). Examples would be the increased incidences of the procainamide-induced systemic lupus syndrome and sulfonamide-induced TEN in slow acetylators as opposed to rapid acetylators. In addition, certain HLA alleles increase the risk of adverse drug reactions, e.g. the association of HLA-B*5701 with hypersensitivity reactions to abacavir and HLA–B*1502 with SJS/TEN in Han Chinese.

The pathophysiology of drug-induced skin reactions such as exanthematous drug eruptions, DRESS (DIHS), acute generalized exanthematous pustulosis (AGEP) and TEN, as well as the increased susceptibility of HIV-infected patients, may be partially explained by an interplay between immune mechanisms and genetic predisposition.

DIAGNOSTIC FEATURES

Drug eruptions, both suspected and unsuspected, are a frequent reason for consultation, and it is often (although not always) possible to categorize a drug as having a high, medium or low probability of being responsible. A logical approach begins with an accurate description of the skin lesions and their distribution as well as associated signs and symptoms (Table 21.6). Data regarding all the drugs taken by the patient, including prescription, non-prescription/over-the-counter and complementary or alternative treatments, as well as the dates of administration and doses need to be collected. The chronology of drug administration is of paramount importance (Table 21.7). The time between initiation of the drug and the onset of the skin eruption is a key element in identifying the offending drug, as most immunologically mediated reactions occur within 8 to 21 days after initiation of a new medication.

Evolution after drug withdrawal may be helpful, as the cutaneous eruption usually clears when the suspected drug is discontinued. However, this assessment may prove difficult in the case of drugs with a long half-life or "persistent" drug reactions such as lichenoid and photoallergic eruptions or drug-induced pemphigus foliaceus and subacute cutaneous LE.

The suspect drug should be withdrawn as soon as possible. The usual practice is to discontinue all drugs that are non-essential. However, in some instances, it is necessary to weigh the risks versus the benefits

CHARACTERISTICS OF MAJOR DRUG-INDUCED ERUPTIONS				
Clinical presentation	**Percentage that are drug-induced (%)**	**Time interval**	**Mortality (%)**	**Selected responsible drugs**
Exanthematous eruption	Child: 10–20 Adult: 50–70	4–14 days	0	Aminopenicillins Sulfonamides Cephalosporins Anticonvulsants Allopurinol
Urticaria	<10	Minutes to hours	0	Penicillins Cephalosporins NSAIDs Monoclonal antibodies Contrast media†
Anaphylaxis	30	Minutes to hours	5	
Fixed drug eruption	100	First exposure: 1–2 weeks Re-exposure: <48 hours, usually within 24 hours	0	TMP-SMX NSAIDs Tetracyclines Pseudoephedrine*
Acute generalized exanthematous pustulosis (AGEP)	70–90	< 4 days	1–2	β-Lactam antibiotics Macrolides Calcium channel blockers
Drug reaction with eosinophilia and systemic symptoms (DRESS)/ Drug-induced hypersensitivity syndrome (DIHS)	70–90	15–40 days	5–10	Anticonvulsants (aromatic) Sulfonamides Allopurinol Lamotrigine (especially in combination with valproate) Minocycline
Stevens-Johnson syndrome (SJS)	70–90	7–21 days	5	Sulfonamides Anticonvulsants (aromatic) Allopurinol NSAIDs Lamotrigine
Toxic epidermal necrolysis			30	

*Non-pigmenting.
†Often anaphylactoid reaction.

Table 21.7 Characteristics of major drug-induced eruptions. NSAIDs, nonsteroidal anti-inflammatory drugs; TMP-SMX, trimethoprim–sulfamethoxazole.

for each drug and to determine if a similar-acting, but non-cross-reactive, drug is available as a substitute.

In the process of identifying the responsible drug, access to drug databases is very helpful[9–11]. However, if application of these databases is too rigid, then a new or unusual drug reaction may not be identified. Moreover, the drug most frequently associated with adverse reactions may be innocent in a particular patient, and the physician dealing with a suspected drug reaction must remain open-minded.

With the exception of assays for IgE antibodies, diagnostic or confirmatory tests to establish the responsible drug are not available. A number of *in vitro* tests have been designed, including the migration inhibition factor test, the lymphocyte toxicity assay, the lymphocyte transformation test and the basophil degranulation test[12]. However, their sensitivity and specificity have not been assessed in a reliable way with relevant controls. As a result, they are of little help in the clinical setting.

Patch testing has been used in the diagnosis of the anticonvulsant-associated drug hypersensitivity syndrome, but with inconsistent results[13]. Barbaud et al.[14] emphasized the importance of delayed readings of prick, intradermal and patch tests in amoxicillin-induced morbilliform eruptions. Unfortunately, investigations involving series of patients with several different types of drug reactions have shown heterogeneous results. Of note, cutaneous patch tests with the offending agent are frequently positive (80% of patients) after recovery from AGEP, but are positive in only a minority of cases of SJS or TEN[15]. In general, these tests, when positive, may be helpful in preventing readministration of the offending drug, but except for patch tests in AGEP, their specificity and sensitivity are low.

Rechallenge carries the risk of inducing a more severe reaction, thus limiting its use for both ethical and medico-legal reasons. Furthermore, the recurrence rate is not 100% with rechallenge (e.g. there are refractory periods) and a negative result may give an erroneous sense of security. Even with these limitations, in patients with fixed drug eruptions, topical provocation or rechallenge may prove helpful.

CLINICAL FEATURES

Exanthematous Drug Eruptions

Synonyms: ■ Morbilliform drug eruption ■ Maculopapular drug eruption ■ Urticarial drug eruption

Exanthematous or morbilliform eruptions are the most common adverse drug reactions affecting the skin. They are often referred to as maculopapular drug eruptions or, in the case of non-dermatologists, "drug rashes".

The major underlying mechanism is probably immunologic, and they are often considered to be cell-mediated hypersensitivity reactions. However, the pathophysiology is likely to be more complex. The drug hapten presented by dendritic cells to T lymphocytes can bind covalently or non-covalently to MHC II–peptide complexes[16]. $CD4^+$ and $CD8^+$ T cells, strongly expressing perforin and granzyme, are recruited. Both cell types have cytotoxic activity leading to death of keratinocytes. Certain drugs such as sulfamethoxazole may actually bind directly to the MHC–peptide complex and T-cell receptor in a non-covalent way[17,18]. Furthermore, viral infections may increase the incidence of drug reactions, e.g. aminopenicillin-induced exanthematous eruptions in patients with infectious mononucleosis is close to 100% (see Ch. 80). One theory is that reactive drug metabolites disturb the balance between cytotoxic and regulatory phenomena, allowing cytotoxicity against virally infected cutaneous cells[19].

The cutaneous eruption classically begins 7 to 14 days after the start of a new medication and can even occur a few days after the drug has been discontinued. However, the eruption may develop sooner, especially in cases of inadvertent rechallenge. The lesions begin as erythematous macules in a symmetric distribution that sometimes become slightly palpable. The eruption begins on the trunk and upper

extremities and progressively becomes confluent (Fig. 21.1A). It is typically polymorphous with morbilliform or sometimes urticarial lesions on the limbs, confluent areas on the thorax (Fig. 21.1B), and purpuric lesions on the ankles and feet. Mucous membranes are usually spared. Pruritus and low-grade fever are often present. On the trunk, the eruption may appear scarlatiniform. Annular plaques (Fig. 21.1C) or atypical, irregularly-shaped "target" lesions may be present, leading to the misdiagnosis, and therefore overdiagnosis, of erythema multiforme. The eruption disappears spontaneously after 1, sometimes 2, weeks, without complications and/or sequelae.

Clinical features that can alert the clinician to the possibility of a more severe drug-induced eruption include edema of the face or a marked peripheral blood hypereosinophilia (suggestive of DRESS [DIHS]) and mucous membrane lesions or painful or dusky skin, which may announce TEN or SJS. Histologic examination of morbilliform eruptions is not particularly helpful, as it shows nonspecific changes consisting of a mild superficial perivascular and interstitial lymphocytic infiltrate; eosinophils may be present (~30% of cases) as well as interface changes (~50% of cases)[20].

The major entity in the differential diagnosis of morbilliform drug reactions is a viral exanthem (e.g. Epstein-Barr virus, enteroviruses, adenovirus, early HIV, human herpesvirus type 6 [HHV-6], parvovirus B19), which is often indistinguishable (see Fig. 81.2). The polymorphic nature of the cutaneous eruption as well as the presence of peripheral blood eosinophilia favor a drug reaction. In the absence of definite evidence, a drug etiology is favored in adults, whereas a viral cause is favored in the pediatric population. Moreover, viral infections may enhance the risk of a drug eruption (see above)[19]. Toxic shock syndromes, scarlet fever, acute GVHD, Kawasaki disease and Still's disease should be excluded on the basis of associated clinical features.

Treatment is largely supportive. Topical antipruritics and corticosteroids may help to alleviate pruritus. Discontinuing the offending agent is the first therapeutic measure. "Treating through", i.e. continuing the drug despite the cutaneous eruption, can be considered when the suspected drug is of paramount importance for the patient and there is no satisfactory substitute drug. Usually, the eruption will disappear, but a few patients may experience a progressive worsening, leading to erythroderma. Whether continuation of the drug can lead to SJS is debatable. Early morbilliform lesions and early target lesions often have a similar appearance and the possibility exists that although the eruptions appear to be "leaving the same station", they may be on different tracks from the beginning. Another approach which has been used successfully in HIV-infected patients requiring sulfonamides is desensitization.

Many drugs induce an exanthematous eruption in approximately 1% of patients. However, the following classes of drugs have a significantly higher incidence: aminopenicillins, sulfonamides, cephalosporins and anticonvulsants.

Fig. 21.1 Exanthematous drug eruptions. Numerous pink papules on the trunk due to a cephalosporin (**A**). Confluence of lesions on the trunk (**B**) and annular plaques on the forehead (**C**) secondary to phenobarbital.

Urticaria, Angioedema and Anaphylaxis (see Ch. 18)

Several different mechanisms may be responsible, with dramatic outbreaks of acute urticaria usually representing an immediate hypersensitivity reaction mediated by IgE antibodies, especially when the urticaria is associated with angioedema and/or anaphylaxis. This type of anaphylactic reaction is frequently due to penicillin and occurs within minutes of the drug exposure. "Anaphylactoid" reactions may mimic IgE-induced histamine release, but are secondary to a non-immunologic liberation of histamine and/or other mediators of inflammation. Clinically, it can be difficult to distinguish between anaphylaxis and an anaphylactoid reaction.

Urticaria

Urticaria is characterized by transient erythematous and edematous papules and plaques that are usually associated with pruritus. Central pallor can be seen as in the wheal-and-flare reaction to histamine. The lesions vary in size and number and may assume a figurate or polycyclic configuration (Fig. 21.2). They can appear anywhere on the body, including the palms, soles or scalp.

The duration of an individual lesion is usually a few hours to 24 hours; when the urticaria resolves, the skin is normal in appearance. Urticarias are considered "acute" when they last for less than 6 weeks and "chronic" when they persist for longer periods of time. Although drugs are thought to be responsible for <10% of all cases of urticaria,

Fig. 21.2 Urticaria secondary to penicillin. Several of the lesions have a figurate appearance.

CUTANEOUS SIDE EFFECTS OF INSULIN INJECTIONS
Immediate hypersensitivity
Local reaction (erythema, pruritus)
Urticaria, angioedema
Anaphylaxis (rare)
Delayed hypersensitivity
Reaction at injection sites (erythema, induration)
Morbilliform eruption (rare)
Acute generalized exanthematous pustulosis (AGEP) (rare)
Exfoliative dermatitis (rare)
Lipodystrophy
Lipoatrophy (occurs less frequently with rapidly absorbed analogue insulins, e.g. insulin lispro)
Lipohypertrophy

Table 21.8 Cutaneous side effects of insulin injections. Use of an insulin pump also carries the risk of scarring and abscess formation.

they are more often associated with acute rather than chronic urticaria. Nonetheless, any evaluation of a patient with chronic urticaria should include a review of all medications. Patients with chronic urticaria should avoid acetylsalicylic acid (ASA; aspirin), as well as other NSAIDs, as they can lead to an exacerbation.

Immunologic assays, e.g. radioallergosorbent tests (RAST), for the detection of specific IgE antibodies and skin tests (prick tests) can be useful in confirming the diagnosis. However, the number of drugs for which there are commercially available assays is limited, consisting primarily of penicillin, aminopenicillin, cephalosporin and insulin (Table 21.8). Because prick tests can occasionally induce an anaphylactic reaction, they must be performed with caution in an appropriate clinical setting. Clinicians will often withhold medications based on patients' self-reports, but in sone series, only 10% to 20% of patients reporting a history of penicillin allergy were truly allergic when assessed by skin testing[21]. Thus, patients with a compelling need for penicillin who have a history of an immediate type (IgE-mediated) reaction to penicillin should undergo skin testing.

A number of drugs can induce acute urticaria, with lesions appearing within minutes to days of drug administration, depending upon whether there has been prior sensitization (immediate versus accelerated) and whether the mechanism is immunologic or non-immunologic. The major drugs responsible for immunologically based urticaria are antibiotics, especially penicillins and cephalosporins, and, less often, sulfonamides and tetracyclines (in particular minocycline). As the use of monoclonal antibodies for neoplastic and inflammatory diseases increases, so will cases of urticaria (and vasculitis; see below) due to these exogenous proteins (see Ch. 128). Acetylsalicylic acid is the classic example of a drug that induces an anaphylactoid reaction; the majority of urticarial reactions to radiocontrast media are non-immunologic (Table 21.9), as are many, but not all, reactions to NSAIDs (e.g. ibuprofen, naproxen). Allergic reactions to latex in gloves or medical devices can induce local or generalized urticaria, especially in the case of direct contact with mucosal surfaces (see Chs 16 & 18).

ADVERSE REACTIONS TO RADIOCONTRAST MEDIA
IODINATED
Immediate (<1 hour)
Urticaria (usually non-immunologic), angioedema
Anaphylactoid reaction
Delayed (1 hour to 1 week)
Morbilliform eruption
Acute generalized exanthematous pustulosis (AGEP)
Symmetrical drug-related intertriginous and flexural exanthema (SDRIFE)
Iododerma (also >1 week)
GADOLINIUM
Urticaria, erythema (rare)
Anaphylactoid reactions, anaphylaxis (rare)
Nephrogenic systemic fibrosis (in the setting of renal insufficiency; see Ch. 43)

Table 21.9 Adverse reactions to radiocontrast media.

The most important step in the treatment of drug-induced urticaria is withdrawal of the causative agent. Treatment consists primarily of H_1 antihistamines. Additional therapeutic options are discussed in Chapter 18.

Of note, the clinical differential diagnosis of urticaria includes urticarial lesions due to vasculitis and/or serum sickness. In the latter disorders, there is antigen–antibody formation with deposition of immune complexes within postcapillary venules. This leads to activation of the complement cascade with liberation of vasoactive amines and proinflammatory cytokines that increase vascular permeability and attract polymorphonuclear cells (see Ch. 24), resulting in the histologic features of leukocytoclastic vasculitis. These immune complexes may also induce the formation of anaphylatoxins which trigger the direct release of mediators from mast cells and basophils, leading to urticaria as well as the clinical and pathologic features of serum sickness.

Angioedema

Angioedema is a reflection of transient edema of the deep dermal, subcutaneous and submucosal tissues. It is associated with urticaria in 50% of cases and may be complicated by life-threatening anaphylaxis. Angioedema occurs in 1 to 2 per 1000 new users of angiotensin-converting enzyme (ACE) inhibitors, a rate that is probably higher than the risk associated with penicillin[22]. The most severe cases of angioedema may start within a few minutes after drug administration. However, in the case of ACE inhibitor-induced angioedema, lesions may appear from 1 day to several years after starting the drug; most appear within the first year. African-Americans and those with a history of idiopathic angioedema are at increased risk for developing ACE inhibitor-induced angioedema.

The clinical picture of angioedema is that of an acute pale or pink subcutaneous swelling, usually of the face (eyelids, lips, ears, nose), and less often of the extremities or genitalia. The areas of involvement are frequently unilateral or asymmetric. Involvement of the larynx, epiglottis and surrounding tissues may impair swallowing and lead to upper airway obstruction (stridor). Edema of the oropharynx (including the buccal mucosa and tongue) can also occur. Occasionally, in drug-induced angioedema, there is edema of the intestinal wall with abdominal pain, nausea, vomiting and diarrhea.

The major drugs implicated in angioedema, besides penicillins and ACE inhibitors, are NSAIDs, radiographic contrast media and, more recently, monoclonal antibodies (see Ch. 128). It is important to note that drug-induced angioedema may actually represent an unmasking of another cause for angioedema, e.g. acquired C1 inhibitor deficiency due to autoimmune or lymphoproliferative disorders. In patients with ACE inhibitor-induced angioedema, substituting angiotensin II receptor

antagonists may not be the answer, even though the antagonists represent a different class of drugs which do not increase levels of bradykinin (see Fig. 18.6). The receptor antagonists are also associated with angioedema, albeit less frequently.

Anaphylaxis

Anaphylaxis consists of an acute life-threatening reaction that can result from exposure to a number of drugs. It occurs in about 1 per 5000 exposures to penicillin and combines skin (urticaria and/or angioedema) with systemic manifestations such as hypotension and tachycardia. Occasionally, there is hypotension in the absence of cutaneous lesions. In severe cases, the patient becomes unconscious as a result of cardiovascular shock and may die. Serious cases of anaphylactic shock tend to appear shortly (within minutes) after drug administration and are more commonly seen with parenteral administration as compared to oral ingestion.

Prompt discontinuation of the offending drug is mandatory, as is strict avoidance of the drug in the future. Patients who have serious angioedema or an anaphylactic reaction should be hospitalized and monitored. Systemic corticosteroids are often prescribed, and, in cases of life-threatening angioedema or anaphylaxis, subcutaneous epinephrine (adrenaline). Patients who have been receiving β-blockers may have a stunted response to the epinephrine.

Antibiotics, in particular penicillin, are the major causes of drug-induced anaphylaxis. Anaphylaxis can also be seen following exposure to latex (see Ch. 16) and anaphylactoid reactions are seen with radiographic contrast media. Rarely, anaphylaxis occurs following cutaneous injections (e.g. local anesthetics) or topical applications of medications (e.g. bacitracin, chlorhexidine).

Photosensitivity (see Ch. 87)

Cutaneous photosensitivity disorders may be idiopathic, due to endogenous photosensitizers (e.g. porphyrins), or result from exogenous photosensitizers (e.g. medications). The combination of light plus drug can lead to several forms of cutaneous inflammation. The photosensitivity drug reactions are classically divided into two major types: phototoxic and photoallergic[23]. The former is more common than the latter.

Phototoxicity

Phototoxic reactions are fairly common and usually predictable. They can occur in any person who receives a sufficient amount of a phototoxic drug together with sufficient exposure to ultraviolet radiation (UVR). There is a direct interaction of the UVR with the drug (or its metabolite) in the skin such that an unstable singlet or triplet state is created, leading to the generation of reactive oxygen species. The latter are responsible for cellular damage.

Clinically, a phototoxic drug reaction usually has the appearance of an exaggerated sunburn (Fig. 21.3), but after a shorter-than-expected exposure time. It is limited to sun-exposed areas and is followed by hyperpigmentation. Histologically, phototoxicity is characterized by necrotic keratinocytes, edema, a sparse dermal lymphocytic infiltrate and vasodilation.

Photo-onycholysis and pseudoporphyria are less common clinical presentations. In the former, the nail plate separates from the nail bed of several digits, with minimal nail bed changes. Fragility, erosions and vesicles of the dorsal hands and face are observed in pseudoporphyria, but plasma porphyrins are normal (see Ch. 49).

The drugs most commonly responsible contain ringed structures and include the tetracyclines (particularly doxycycline and demeclocycline), the NSAIDs (especially propionic acid derivatives) and the fluoroquinolones. Additional drugs that can produce phototoxic reactions include amiodarone, psoralens and phenothiazines (see Table 87.6). In the case of pseudoporphyria, the most likely culprit is naproxen (see Table 49.5).

For drugs with a short half-life, administration of the drug in the evening may be enough to decrease the risk below the clinical threshold for phototoxicity.

Photoallergy

Photoallergic reactions occur as a result of cell-mediated hypersensitivity to an allergen activated or produced by the effect of light on a drug (or its metabolite). UVR is required to convert the drug into an immunologically active compound (photoallergen) that induces the immune response. These reactions are idiosyncratic and can be maintained in the absence of excessive sun exposure.

Fig. 21.3 Phototoxic reaction in a patient receiving methotrexate. The erythema and bullae are obviously limited to sun-exposed sites and resemble an exaggerated sunburn. Patients on methotrexate can also experience a "sunburn-recall" phenomenon.

Fig. 21.4 Photolichenoid drug eruption due to hydrochlorothiazide. The lesions favored the extensor surfaces of the forearms.

Photoallergic eruptions are more chronic in nature than phototoxic reactions. Clinically, the lesions are pruritic and resemble dermatitis or lichen planus (Fig. 21.4; see Ch. 11), but are primarily in sun-exposed sites. Over time, lesions may spread to non-sun-exposed areas. The associated pruritus can lead to superimposed lichenification. Chronic exposure to photoallergic drugs can, in an occasional patient, lead to extreme photosensitivity that persists for months to even years after the responsible drug is eliminated. These patients then fall within the spectrum of chronic actinic dermatitis (see Ch. 87). Phototesting can be useful in the clinical evaluation.

Several classes of drugs are commonly associated with photoallergic reactions; they include thiazide diuretics, sulfonamide antibiotics, sulfonylureas and phenothiazines, all of which contain a sulfur moiety (Fig. 21.5). Additional medications that have been reported as photoallergens include quinine, quinidine, tricyclic antidepressants, antimalarials and NSAIDs.

In photoallergic reactions, drug withdrawal is recommended, given the risk of exacerbation even with relatively low-dose exposures to UVR plus the risk of chronicity. Topical corticosteroids, physical barriers, reduced sun exposure, and broad-spectrum sunscreens may prove useful.

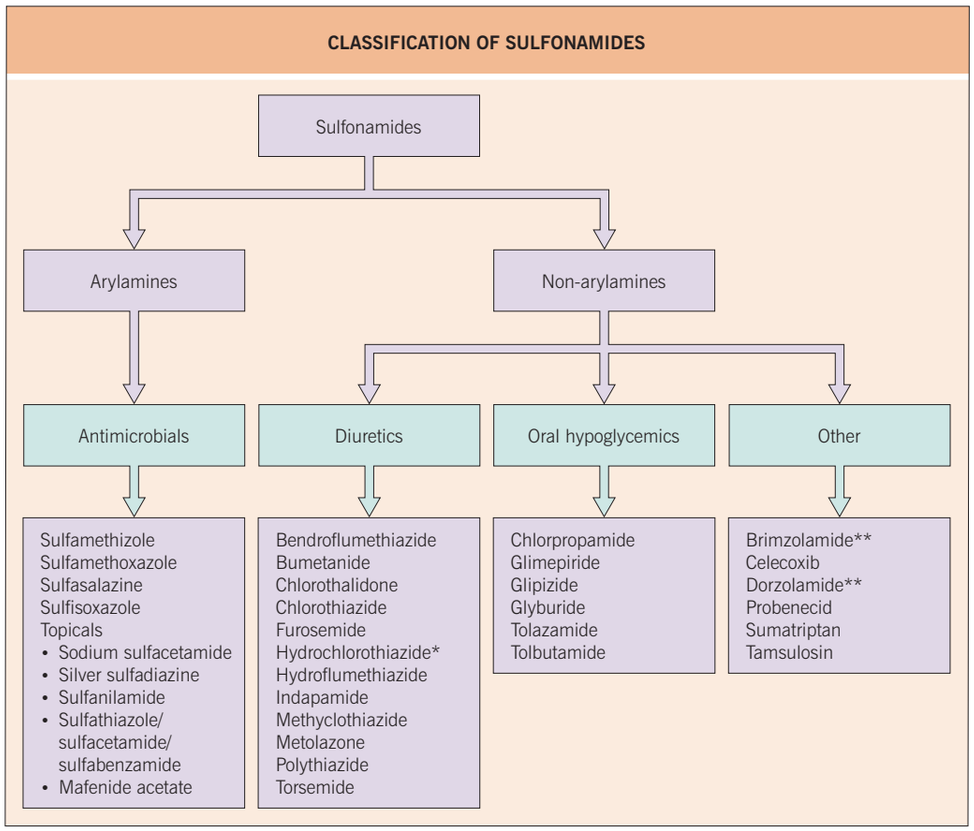

Fig. 21.5 Classification of sulfonamides. *Often combined with other antihypertensives, e.g. triamterene, angiotensin-converting enzyme inhibitors, β-blockers. Approximately 10% of the patients with a history of a drug reaction to antimicrobial sulfonamides will also react to the non-arylamine sulfonamides. However, this is thought to be a reflection of a predisposition to allergic reactions rather than cross-reactivity. **Eyedrops.

Vasculitis (see Ch. 24)

Although many cases of cutaneous small vessel vasculitis (CSVV) are idiopathic, secondary causes such as infections, autoimmune connective tissue diseases, and drugs (~10% of cases) need to be considered. Drug-induced vasculitis typically involves small vessels (but can involve medium-sized vessels) and is thought to be triggered by deposition of immune complexes.

Clinically, drug-induced CSVV usually presents as purpuric papules, primarily on the lower extremities. Urticaria-like lesions, hemorrhagic blisters, pustules, digital necrosis and ulcers may also be seen. Systemic involvement is very unusual, but suggestive symptoms are fever, myalgias, arthralgias and/or headache. Internal manifestations include arthritis, nephritis, peripheral neuropathy and gastrointestinal bleeding. Histopathologic examination of early lesions should be performed.

Vasculitis usually occurs 7 to 21 days after drug administration and less than 3 days following rechallenge. Systemic corticosteroids may benefit patients with systemic involvement; otherwise, they are not indicated. Additional management options are discussed in Chapter 24.

The primary medications associated with drug-induced CSVV include penicillins, NSAIDs (both oral and topical), sulfonamides and cephalosporins; additional drugs are propylthiouracil, thiazide diuretics, furosemide, allopurinol, phenytoin, fluoroquinolones and biologic agents (e.g. granulocyte and granulocyte–macrophage colony-stimulating factors [G-CSF, GM-CSF], interferons). ANCA-positive vasculitis with anti-myeloperoxidase antibodies has been associated with several drugs, including propylthiouracil, hydralazine and minocycline, and polyarteritis nodosa has been observed following hepatitis B vaccination[24].

Neutrophilic Drug Eruptions

Acute generalized exanthematous pustulosis

Synonyms: ■ Pustular drug eruption ■ Toxic pustuloderma

Acute generalized exanthematous pustulosis (AGEP) is an acute febrile drug eruption characterized by numerous small, primarily non-follicular, sterile pustules, arising within large areas of edematous erythema[25]. The incidence of AGEP has been underestimated and many cases have been confused with pustular psoriasis. More than 90% of cases of AGEP are drug-induced[26]. Occasionally, it may be due to other causes, e.g. an enteroviral infection or exposure to mercury.

HLA-B5, -DR11 and -DQ3 have been found more frequently in patients with AGEP[27]. A prior sensitization (including a contact sensitization) would explain the short interval (<4 days) between drug administration and the onset of the eruption, as this suggests an immunologic recall phenomenon. The percentage of positive patch tests to the incriminated drugs is high (up to 80%) (Fig. 21.6A)[15,28]. Blood neutrophilia and the accumulation of neutrophils within the lesions suggest the release of neutrophil-activating cytokines by drug-specific T lymphocytes (e.g. IL-3, IL-8, G-CSF), but the precise underlying mechanisms of AGEP are still unknown.

Clinically, AGEP is characterized by a high fever, with lesions beginning on the face or in the major intertriginous zones (i.e. axillae and groin) and then disseminating over a few hours. Numerous small (<5 mm), non-follicular, sterile pustules arise within large areas of edematous erythema (Fig. 21.6B,C). There may be associated burning or pruritus or both. Edema of the face and hands, purpura, vesicles, bullae, erythema multiforme-like lesions and mucous membrane involvement are additional findings observed in approximately 50% of patients[26]. The lesions last 1 to 2 weeks and are followed by a superficial desquamation.

Histologically, spongiform pustules are seen within the most superficial layers of the epidermis, beneath the stratum corneum (Fig. 21.6D). Edema of the papillary dermis and a perivascular mixed infiltrate with neutrophils and some eosinophils are usually present. CSVV and necrotic keratinocytes are unusual findings. A marked leukocytosis with an elevated neutrophil count is frequently seen. Additional laboratory abnormalities include mild to moderate eosinophilia, transient renal dysfunction, and hypocalcemia.

AGEP must be differentiated from acute pustular psoriasis of the von Zumbusch type. The pustules are clinically indistinguishable, but additional skin lesions such as petechiae, purpura, atypical target-like lesions and vesicles are more frequently observed in AGEP. Histologically, massive edema in the superficial dermis, exocytosis of

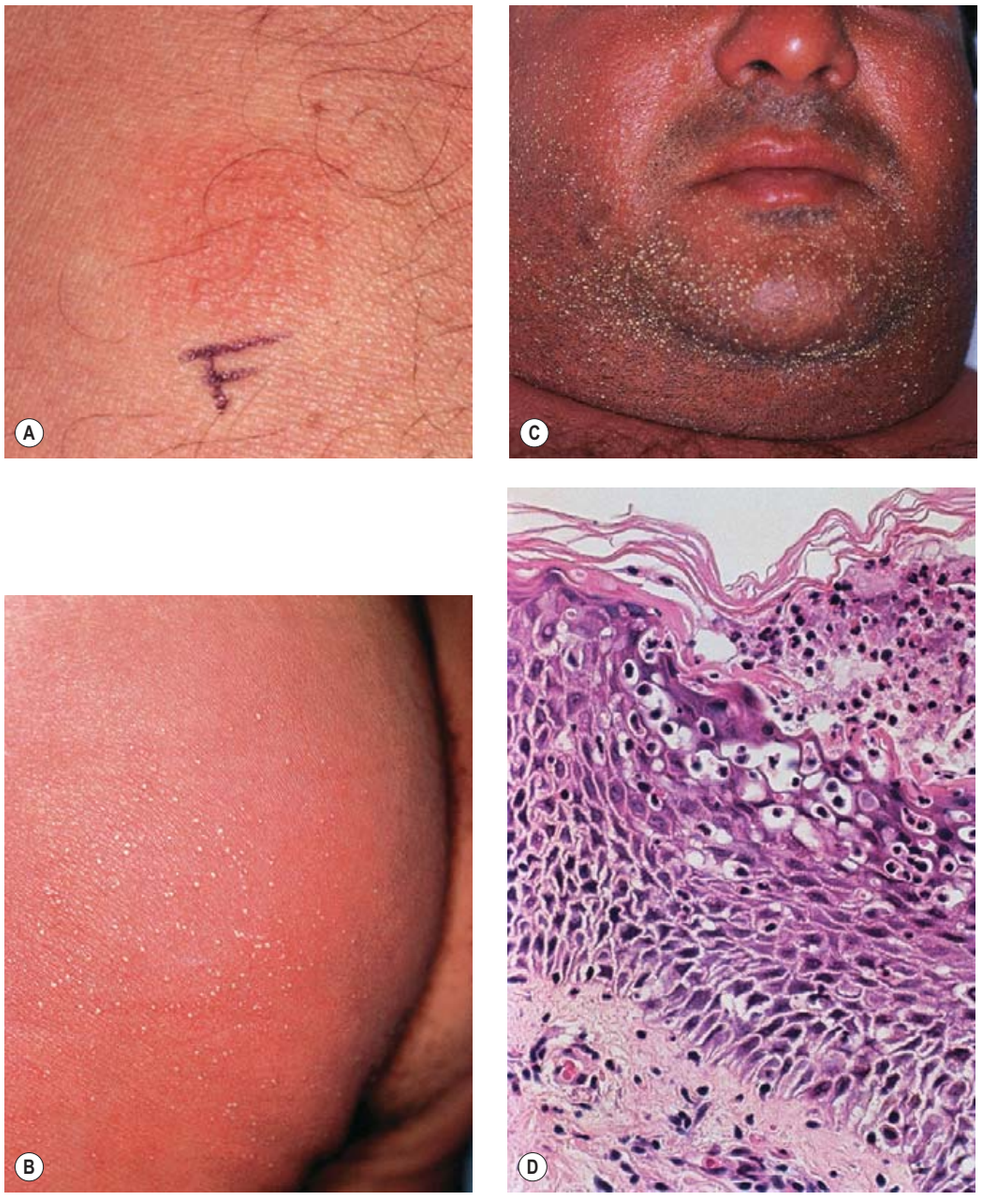

Fig. 21.6 Acute generalized exanthematous pustulosis (AGEP). A A positive patch test result 4 days following the application of 0.75% metronidazole in a patient with a previous pustular drug eruption to that medication. Diffuse erythema of the buttock (due to cephalosporin, **B**) and face (due to metronidazole, **C**) studded with sterile pustules. Spongiform pustules are seen within the epidermis of lesional skin (**D**). *A & C, Courtesy, Kalman Watsky, MD.*

eosinophils, vasculitis, and necrosis of keratinocytes are all suggestive of AGEP, whereas acanthosis is more characteristic of pustular psoriasis. The two major differences are the acuteness of the disease and the history of drug exposure in AGEP. However, AGEP may occur more frequently in patients with a history of psoriasis, thus making the distinction even more difficult.

Common exanthematous drug eruptions may have a few pustules, but they are usually follicular. In severe forms of AGEP, the confluence of the pustules may lead to confusion with TEN. However, the presence of subcorneal pustules in biopsy specimens allows one to distinguish between the two entities. In addition to facial edema, pustules may also be observed in DRESS (DIHS), but the prolonged evolution, atypical lymphocytosis, marked hypereosinophilia, and visceral involvement usually permit differentiation.

Antibiotics are the primary drugs implicated in AGEP. Beta-lactam antibiotics (e.g. penicillins, aminopenicillins, cephalosporins) and macrolides are the most frequently responsible medications[29], followed by calcium channel blockers (in particular diltiazem) and antimalarials. Additional cases have been associated with carbamazepine, acetaminophen (paracetamol) and a wide range of antimicrobials (e.g. terbinafine, metronidazole, isoniazid, vancomycin, doxycycline). As recognition of this clinical entity has increased, so has the number of implicated drugs. Both a literature search and an open mind are required in the evaluation of a patient with AGEP, as this eruption has been associated with ingestion of lacquer chicken and chromic picolinate as well as exposure to icodextrin during peritoneal dialysis. The withdrawal of the responsible drug is the main treatment, in conjunction with topical corticosteroids and antipyretics.

Sweet's syndrome (acute febrile neutrophilic dermatosis)

(see Ch. 26)

Since a limited number of cases of Sweet's syndrome have been reported as drug reactions, they probably represent <5% of all cases. This syndrome is characterized by fever, peripheral blood neutrophilia, and painful erythematous plaques that favor the face and upper extremities and contain dense neutrophilic dermal infiltrates. There are also reports of the lesions being limited to a lymphedematous extremity. In drug-induced Sweet's syndrome, neutrophilia is often absent, probably due to the fact that a number of these cases are related to the use of hematopoietic growth factors to reverse chemotherapy-induced neutropenia. The lesions of drug-induced Sweet's syndrome usually develop about a week after the onset of drug administration[30]. Although the differential diagnosis includes malignancy-associated Sweet's syndrome, it would be very unlikely for malignancies to recur 2–3 weeks post appropriate chemotherapy.

After withdrawal of the responsible drug, the fever abates in 1 to 3 days and the lesions disappear within 3 to 30 days[31]. Systemic corticosteroids may be required in severe cases. The major drugs associated

with drug-induced Sweet's syndrome are: (1) all-*trans*-retinoic acid; and (2) G-CSF or GM-CSF, which facilitate the differentiation and the proliferation of neutrophils, respectively[32]. Neutrophilic infiltrates can be seen elsewhere, including the muscles and lung. Additional cases attributed to trimethoprim–sulfamethoxazole[30], norfloxacin, furosemide, celecoxib and tetracyclines have been reported.

Halogenoderma

Bromoderma, fluoroderma and iododerma are rare dermatoses that develop following exposure to bromides, fluorides, iodides and iodine-containing compounds. The latter two groups are used as radiation protectants, in combination therapy for hyperthyroidism, and as expectorants (saturated solution of potassium iodide; SSKI). Dermatologists are familiar with SSKI as a treatment for erythema nodosum (see Ch. 100) and sporotrichosis. Systemic exposure to iodine-containing contrast media, irrigation of wounds with povidone-iodine, ingestion of iodide-containing supplements and the use of amiodarone are additional causes of iododerma. Bromides act as sedatives, and, outside the US, potassium bromide is sometimes prescribed for the treatment of seizures.

Some authors have suggested that halogenodermas represent hypersensitivity reactions. However, accumulation of the halogenide does seem to be an important factor. For example, one risk factor for the development of these reactions is acute or chronic renal failure.

Halogens may induce acneiform eruptions and pustules, and, less commonly, granulomatous or vegetative plaques, ulcers and even bullae (Fig. 21.7). Although cutaneous lesions often appear after long-term exposure, they can appear in as quickly as a few days. Histologically, an accumulation of neutrophils within the dermis is seen and exocytosis of neutrophils into the epidermis can lead to intraepidermal abscesses. In longer-standing lesions, papillomatosis develops.

Bromodermas and iododermas must be differentiated from folliculitis, dimorphic fungal infections (e.g. blastomycosis), pyoderma gangrenosum, Sweet's syndrome, blastomycosis-like pyoderma, and pemphigus vegetans. Histologic evaluation and measurement of blood levels of iodine (40–92 mcg/l = normal range) and bromide (5–10 mg/dl = normal range) aid in establishing the diagnosis. Halogenodermas may persist for weeks after drug withdrawal because of the slow elimination rate of iodides and bromides. Topical and systemic corticosteroids, in addition to diuretics, may hasten resolution, and, in severe cases, cyclosporine may be administered.

Other neutrophilic eruptions

Neutrophilic eccrine hidradenitis is characterized by erythematous papules and plaques due to neutrophilic infiltrates around and within eccrine glands (Fig. 21.8). It is most commonly seen in patients with acute myelogenous leukemia receiving cytarabine and less often in those receiving other chemotherapeutic agents (e.g. bleomycin, anthracyclines, methotrexate, cyclophosphamide). G-CSF can also induce lesions of neutrophilic eccrine hidradenitis, as can acetaminophen. Neutrophilic eccrine hidradenitis can also precede acute and chronic myelogenous leukemia, and, occasionally, it has been observed in conjunction with infections due to Gram-negative bacilli, streptococci, staphylococci and HIV.

In patients with chemotherapy-induced neutropenia, neutrophils may be absent from the biopsy specimens, so an alternative name, "chemotherapy-induced eccrine hidradenitis", has been suggested. Neutrophilic eccrine hidradenitis may reflect a toxic insult to eccrine glands and ducts and it can be a histologic finding, along with eccrine squamous syringometaplasia, in patients with toxic erythema of chemotherapy. Of note, neutrophilic eccrine hidradenitis can be seen in sites of bleomycin injections.

Drug-induced pyoderma gangrenosum is quite rare. There are scattered case reports linking pyoderma gangrenosum with G-CSF, GM-CSF and isotretinoin; questionable associations exist for methotrexate, azathioprine and hydralazine.

Drug Reaction with Eosinophilia and Systemic Symptoms (Drug-Induced Hypersensitivity Syndrome)

The acronym DRESS, for *d*rug *r*eaction with *e*osinophilia and *s*ystemic *s*ymptoms, has been advocated as a more specific term for what was previously referred to as systemic hypersensitivity syndrome[2,33]. More recently, another acronym has been proposed, DIHS, which stands for *d*rug-*i*nduced *h*ypersensitivity *s*yndrome. To aid in the diagnosis of this disorder, a scoring system has been put forth (Table 21.10)[34].

The underlying mechanisms probably include a specific alteration in the metabolism of particular drugs; for example, a defect in the detoxification of anticonvulsants and sulfonamides has been demonstrated in patients recovering from DRESS (DIHS). For anticonvulsants, the inability to detoxify toxic arene oxide metabolites is probably a key factor; cross-reactivity between phenytoin, carbamazepine and phenobarbital is well documented, both *in vivo* and *in vitro*[35]. Risk factors for developing DRESS (DIHS) secondary to sulfonamides include acetylator phenotype and the susceptibility of the patient's lymphocytes to the toxic metabolite hydroxylamine.

Immune mechanisms are also implicated: IL-5, released by activated T lymphocytes, contributes to the generation of eosinophilia, a key feature of this syndrome[36]. A possible role for viruses such as HHV-6 and HHV-7 in the pathogenesis of DRESS (DIHS) has been proposed[37–39]. Increased titers of antiviral antibodies and active viral replication have been observed, pointing to a potential role for the viral infection. However, this could just represent nonspecific activation of a ubiquitous virus.

Fig. 21.7 Iododerma. Edematous erythematous vesicopustules on the buttocks with central crusts.

Fig. 21.8 Neutrophilic eccrine hidradenitis. Erythematous plaques on the leg, which may be confused with Sweet's syndrome.

DIAGNOSTIC SCORING SYSTEM FOR DRESS/DIHS			
Criteria	**No**	**Yes**	**Unknown/ unclassifiable**
Fever (≥ 38.5°C)	–1	0	–1
Lymphadenopathy (≥ 2 sites; > 1 cm)	0	1	0
Circulating atypical lymphocytes	0	1	0
Peripheral hypereosinophilia	0		0
0.7–1.499 × 10^9/L - *or* - 10–19.9%*		1	
≥ 1.5 × 10^9/L - *or* - ≥ 20%*		2	
Skin involvement			
– Extent of cutaneous eruption > 50% BSA	0	1	0
– Cutaneous eruption suggestive of DRESS**	–1	1	0
– Biopsy suggests DRESS	–1	0	0
Internal organs involved†	0		0
One		1	
Two or more		2	
Resolution in ≥ 15 days	–1	0	–1
Laboratory results negative for at least three of the following (and none positive): (1) ANA; (2) blood cultures; (3) HAV/HBV/ HCV serology; and (4) *Chlamydia* and *Mycoplasma* serology	0	1	0
Final score: < 2, no case; 2–3, possible case; 4–5, probable case; >5, definite case			

*If leukocytes < 4.0 x 10^9/L

**At least two of the following: edema, infiltration, purpura and scaling.

†Liver, kidney, lung, muscle/heart, pancreas, or other organ and after exclusion of other explanations.

Table 21.10 Diagnostic scoring system for DRESS (drug reaction with eosinophilia and systemic symptoms)/DIHS (drug-induced hypersensitivity syndrome. Proposed by the RegiSCAR-group[34]. ANA, antinuclear antibody; BSA, body surface area; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus.

Fig. 21.9 Drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS). Multiple edematous papules are present. *Courtesy, Kenneth Greer, MD.*

The incidence of DRESS (DIHS) has been estimated to be between 1 in 1000 and 1 in 10 000 exposures to drugs such as anticonvulsants (e.g. phenytoin, carbamazepine, phenobarbital) and sulfonamides. The incidence may be higher in African-Americans and patients from the Caribbean basin. In Northern European populations, the presence of the HLA-A*3101 allele significantly increases the risk of developing carbamazepine-induced hypersensitivity syndrome[39a].

Clinically, this hypersensitivity syndrome develops 2 to 6 weeks after drug initiation, later than most other immunologically mediated skin reactions. Fever and a cutaneous eruption are the most common symptoms, seen in 85% and 75% of patients, respectively. Cutaneous involvement usually begins as a morbilliform eruption, which later becomes edematous, often with a follicular accentuation. Additional manifestations include vesicles, tense bullae induced by dermal edema, follicular as well as non-follicular pustules, erythroderma and purpuric lesions. The face, upper trunk and extremities are usually the initial sites of involvement (Fig. 21.9). Edema of the face is a frequent finding and is a hallmark of DRESS (DIHS).

Lymph nodes are often enlarged, and sometimes arthralgias or even arthritis may be seen. The most common (and usually the most severe) site of visceral involvement is the liver. The hepatitis is sometimes fulminant and is responsible for the majority of deaths associated with this syndrome (~10% of cases). Myocarditis, interstitial pneumonitis, interstitial nephritis, thyroiditis and even infiltration of the brain by eosinophils may be observed. In the case of DRESS (DIHS) due to allopurinol, gastrointestinal bleeding can occur. The cutaneous and visceral involvement may persist for several weeks or months after drug withdrawal, and additional sites of involvement (e.g. cardiac) may develop weeks or months later, including following a taper of corticosteroids.

Prominent eosinophilia is common and is a very characteristic feature. It is often accompanied by mononucleosis-like atypical lymphocytosis. Elevation of hepatic enzymes can be a worrisome finding and requires serial evaluation. Evidence of thyroid or cardiac dysfunction (as detected by an echocardiogram) are additional abnormalities in some patients. Histologic examination of the skin demonstrates a mild to dense lymphocytic infiltrate in the superficial dermis associated with eosinophils and dermal edema. If the rash persists, the dermal infiltrate may become quite dense, as in pseudolymphoma.

The differential diagnosis includes other cutaneous drug eruptions, acute viral infections, hypereosinophilic syndrome, lymphoma and pseudolymphoma[37,38]. Involvement of multiple viscera differentiates DRESS (DIHS) from the more common morbilliform eruptions. Serum sickness-like reactions and drug-induced vasculitis are usually easily differentiated from DRESS (DIHS).

In addition to the most common etiologies – the aromatic anticonvulsants (phenobarbital, carbamazepine and phenytoin), lamotrigine (especially when co-administered with valproate) and the sulfonamides – minocycline, allopurinol (in particular, full doses in the setting of renal dysfunction), gold salts and dapsone may also induce this syndrome, as well as drugs used to treat HIV infection, e.g. abacavir. Early withdrawal of the offending drug is, of course, mandatory, but may not be sufficient for obtaining a rapid full recovery. Corticosteroids represent the first line of therapy. In milder cases, topical high-potency corticosteroids may be helpful. Systemic corticosteroids are recommended for life-threatening involvement of the lung and heart because the inflammation is responsive to corticosteroids. The latter are not particularly useful for reversing kidney and/or liver disease. Relapse can occur when the dosage is tapered, and, as a result, steroid therapy sometimes has to be maintained for several weeks and even months.

Bullous Eruptions

Fixed drug eruption

In fixed drug eruptions (FDE), the lesions develop 1 to 2 weeks after a first exposure. With subsequent exposures, they appear within 24 hours. Clinically, one or a few, round, sharply demarcated erythematous and edematous plaques are seen (Fig. 21.10A), sometimes with a dusky, violaceous hue, central blister or detached epidermis (Fig. 21.10B,C). The lesions can be found anywhere on the body, but favor the lips, face, hands, feet and genitalia. An erosion may develop centrally (Fig. 21.10D,E) and the lesions progressively fade over several days, often leaving a residual postinflammatory brown pigmentation (Fig. 21.10F). Upon readministration of the causative drug, the lesions recur at exactly the same sites. With each recurrence, additional sites of involvement may appear or the number of lesions may remain constant. The

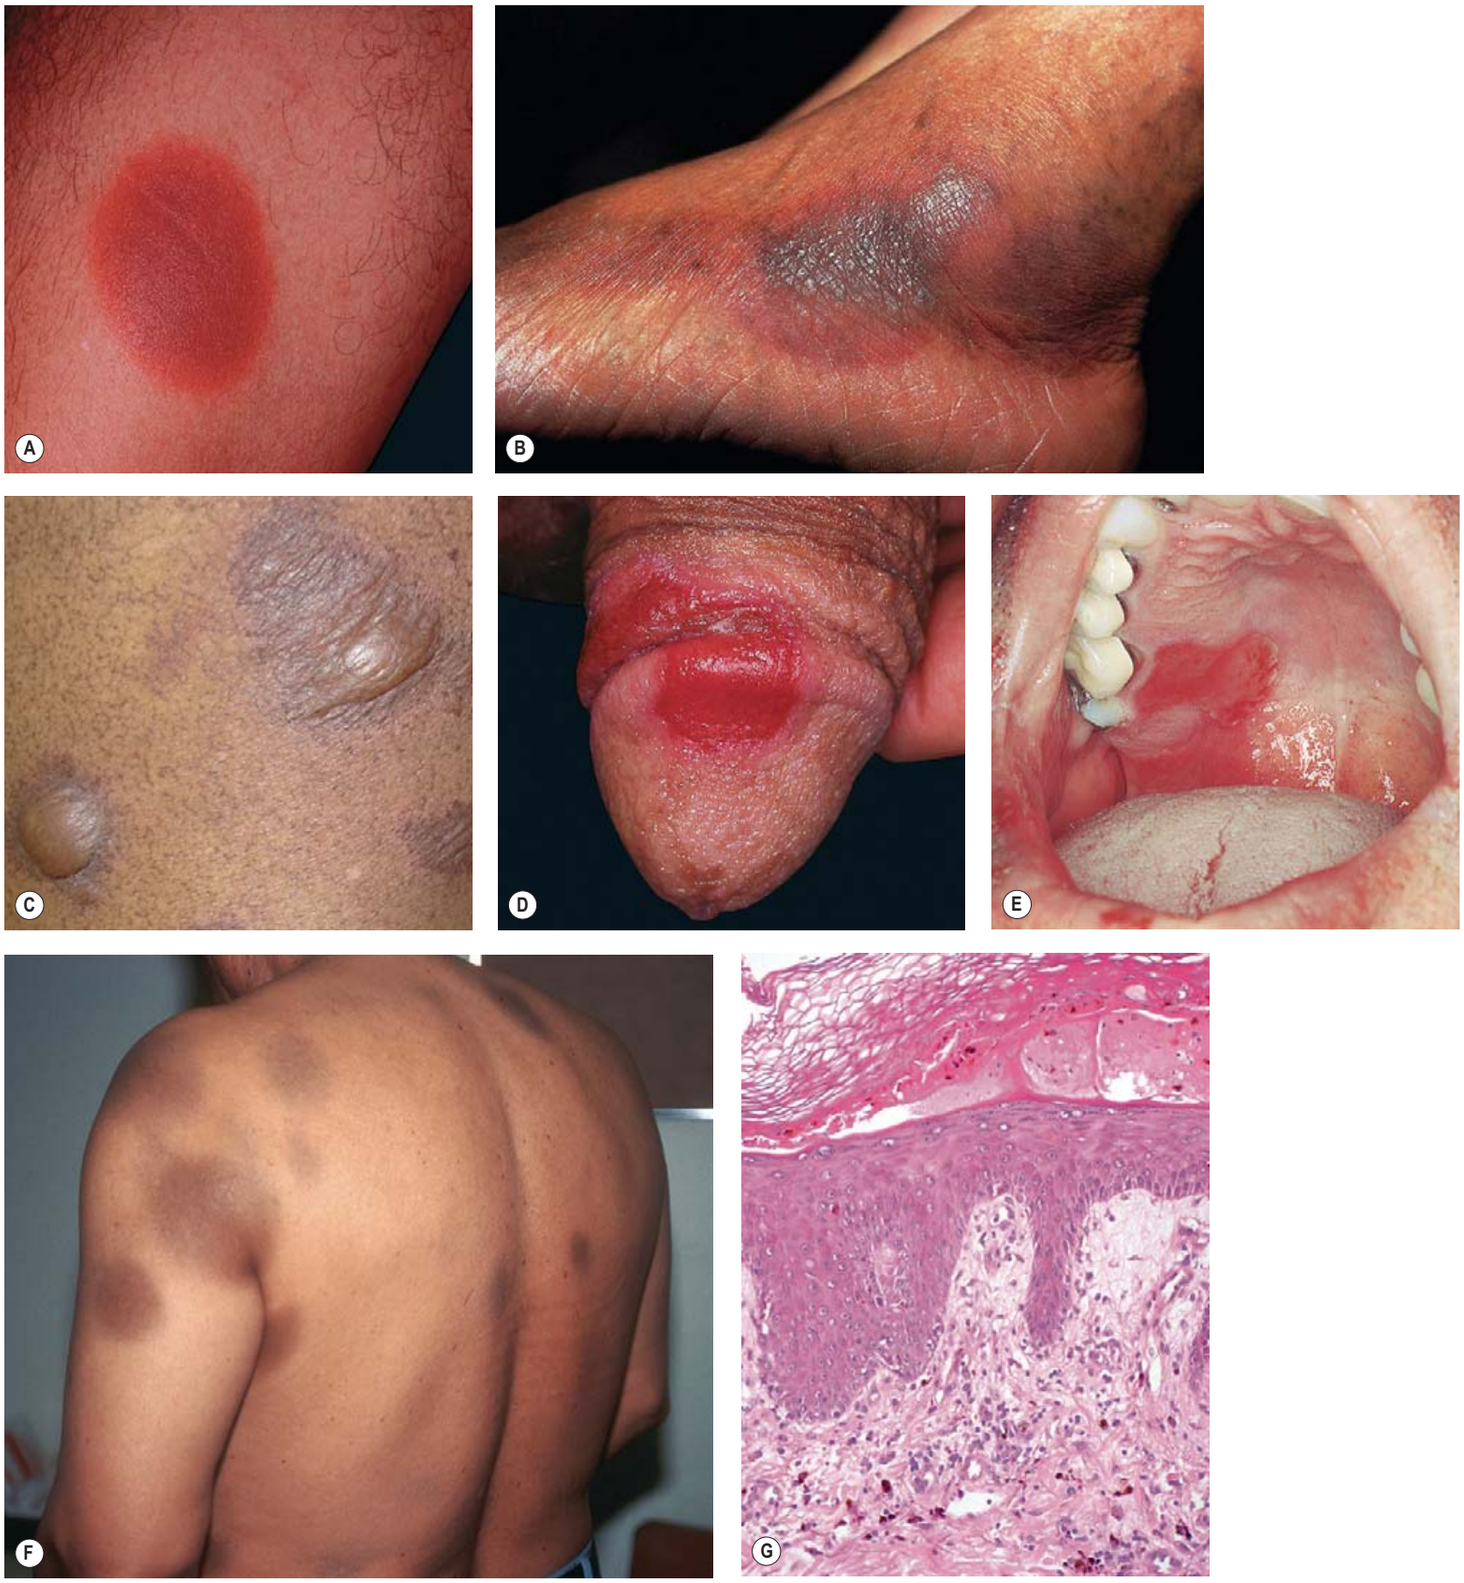

Fig. 21.10 Fixed drug eruptions. Well-demarcated erythematous (**A**) to violet–brown plaques that can develop a detached epidermis (**B**), bulla (**C**) or erosion (**D,E**) centrally. As lesions heal, circular or oval areas of hyperpigmentation are commonly seen (**F**). Histologically, serous crust, a few necrotic keratinocytes, mild vacuolar changes at the dermal–epidermal junction, papillary dermal edema and melanophages can be seen as well as a mononuclear infiltrate (**G**). Responsible drugs were phenolphthalein (**A**), naproxen (**B**), ciprofloxacin (**D**), allopurinol (**E**) and trimethoprim–sulfamethoxazole (**F**). *D & E, Courtesy, Kalman Watsky, MD. F, Courtesy, Mary Stone, MD.*

presence of numerous lesions is referred to as generalized FDE, and it may be difficult to distinguish from erythema multiforme or SJS (when the oral mucosa is also involved).

A non-pigmenting variant of FDE, with large erythematous edematous plaques has also been described, occurring primarily after administration of pseudoephedrine. It has been also observed with other drugs, e.g. NSAIDs, acetaminophen, tetrahydrozoline (eyedrops). Linear FDE is a rare variant and could be confused with linear lichen planus.

Histopathology reveals a superficial and deep interstitial and perivascular infiltrate within the dermis, composed of lymphocytes, eosinophils and sometimes neutrophils. There may be necrotic keratinocytes in the epidermis (Fig. 21.10G). Dermal melanophages are often the only histologic finding in non-inflammatory lesions.

The drugs most frequently associated with FDE are sulfonamides (in some series, up to 75% of cases), NSAIDs (in particular, phenazone derivatives), barbiturates, tetracyclines and carbamazepine[40,41]. Phenolphthalein-induced FDE is seen less commonly because it has been removed from a number of laxative preparations. Sometimes, the inducing drug can be readministered without exacerbation, and there may be a refractory period after the occurrence of a fixed eruption. Provocation via patch testing in a previously *involved* site may be useful in determining the responsible drug (as long as not performed during the refractory period).

When there is a single lesion, the differential diagnosis includes a spider or arthropod bite reaction, and when there are many lesions, erythema multiforme or SJS. On the genitalia, herpes simplex viral infections are often considered and a periungual lesion can be mistaken for paronychia.

Linear IgA bullous dermatosis

Linear IgA bullous dermatosis is an autoantibody-mediated subepidermal blistering disease that may be associated with drug exposure. Tense vesicles and bullae appear 24 hours to 15 days after the offending medication is begun. The blisters often have an annular configuration, as in the idiopathic version of the disease (see Ch. 31), but there are reports of a TEN-like presentation. Histologic examination shows subepidermal bullae with neutrophils in the dermis. Direct immunofluorescence reveals linear deposition of IgA in the basement membrane zone, within the lamina lucida or rarely below the lamina densa. Most patients lack circulating IgA autoantibodies[42]. Resolution follows within 2 to 5 weeks of discontinuation of the responsible medication. The major implicated drugs are vancomycin[43], followed by β-lactam antibiotics, captopril, NSAIDs, phenytoin, rifampin, sulfonamides, amiodarone, furosemide, lithium and G-CSF (see Table 31.5).

Drug-induced bullous pemphigoid

Drug-induced bullous pemphigoid can resemble the "classic" form of this autoimmune disorder, (see Ch. 30) or the cutaneous lesions may have an erythema multiforme-like appearance. Responsible drugs include furosemide, penicillin and its derivatives, and sulfasalazine. Because the histologic and direct immunofluorescence findings are similar to those observed in bullous pemphigoid, it is the clinician who has to consider the diagnosis of drug-induced disease, especially in younger patients (<60 years of age). The differential diagnosis also includes the inflammatory form of epidermolysis bullosa acquisita and erythema multiforme.

Drug-induced pemphigus

Drug-induced pemphigus is an autoimmune blistering disease whose exact pathogenesis is unknown, but appears to be multifactorial. The binding of an active thiol (sulfhydryl) group of a drug to the desmosomal antigen complex could act as a hapten and induce a humoral immune response directed against the desmosomes. The latter then results in acantholysis and intraepidermal blisters.

The clinical, histologic and immunofluorescent microscopy findings in drug-induced pemphigus are similar to those in the spontaneous form of the disease, except that direct immunofluorescence of perilesional skin is positive in only 90% of cases[44]. Circulating antidesmoglein autoantibodies are found in 70% of patients.

In developed countries, up to 10% of cases of pemphigus could be drug-induced. Lesions characteristic of pemphigus foliaceus or pemphigus vulgaris appear several weeks or months after the responsible drug is begun. Approximately 80% of cases are due to drugs that contain a thiol group, such as penicillamine, ACE inhibitors (e.g. captopril), gold sodium thiomalate and pyritinol. Non-thiol drugs include antibiotics (especially β-lactams), pyrazolone derivatives, nifedipine, propranolol, piroxicam and phenobarbital. A spontaneous remission after drug withdrawal is not always observed, especially in patients whose pemphigus is due to drugs that do not contain a thiol moiety.

Stevens–Johnson syndrome and toxic epidermal necrolysis (see Ch. 20)

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are considered rare, life-threatening, drug-induced skin reactions within a clinical spectrum (Fig. 21.11)[45] and early detection is essential.

Fig. 21.11 Stevens–Johnson syndrome. Flaccid bullae leading to epidermal detachment (<10% body surface area). Note the resemblance to wet cigarette paper.

SYMMETRICAL DRUG-RELATED INTERTRIGINOUS AND FLEXURAL EXANTHEMA (SDRIFE) – CLINICAL CRITERIA
• Exposure to a *systemically* administered drug*, occurring with either the initial or a repeated dose (excluding contact allergens)
• Sharply demarcated erythema of the gluteal/perianal area and/or V-shaped erythema of the inguinal/perigenital area
• Involvement of at least one other intertriginous site/flexural fold
• Symmetry of affected areas
• Absence of systemic symptoms and signs
*Not a chemotherapeutic agent so as to not confuse with toxic erythema of chemotherapy.

Table 21.11 Symmetrical drug-related intertriginous and flexural exanthema (SDRIFE) – clinical criteria. This entity is also referred to as drug-induced intertrigo, flexural drug eruption and baboon syndrome. The latter term is also used to describe a form of systemic contact dermatitis.
Adapted from Häusermann P, Harr Th, Bircher AJ. Baboon syndrome resulting from systemic drugs: is there strife between SDRIFE and allergic contact dermatitis syndrome? Contact Derm 2004;51:297–310.

An interesting phenomenon is the markedly increased incidence of TEN in individuals with AIDS[46]. Three explanations have been proposed: (1) an increased number of drugs are given to AIDS patients; (2) the HIV infection itself is responsible; and (3) the paradoxical increase (in the setting of immunodeficiency) is due to an alteration in the balance between $CD4^+$ and $CD8^+$ T lymphocytes.

These diseases are discussed in detail in Chapter 20.

Other Drug-Induced Cutaneous Reactions

Symmetrical drug-related intertriginous and flexural exanthema

In symmetrical drug-related intertriginous and flexural exanthema (SDRIFE), sharply demarcated, symmetrical areas of erythema develop in the anogenital region following exposure to a systemically administered drug, usually an aminopenicillin or cephalosporin and less often other antibiotics or contrast media (Table 21.11). Typically, there is involvement of at least one other flexural site. Confusion arises because some patients with systemic contact dermatitis may have erythema of the buttocks and upper inner thighs, with both the latter clinical presentation – as well as SDRIFE – sometimes referred to as baboon syndrome. The differential diagnosis also includes toxic erythema of chemotherapy due to drugs such as intravenous busulfan, but the history of chemotherapy administration 2–4 weeks earlier is usually easily obtained.

Pseudolymphoma (see Ch. 121)

Synonym: ▪ Cutaneous lymphoid hyperplasia

Fig. 21.12 Heparin-induced thrombocytopenia with thrombosis syndrome. **A** Ischemia and necrosis of the foot. **B** Petechiae due to thrombocytopenia and an irregular area of cutaneous necrosis due to thrombosis. *A, Courtesy, Kalman Watsky, MD. B, Courtesy, Jean L Bolognia, MD.*

DRUG-INDUCED ALOPECIA	
Telogen phase	– **Anticoagulants:** heparin > warfarin – Anticonvulsants: carbamazepine, valproic acid, phenytoin, lamotrigine – Antidepressants: imipramine, desipramine, maprotiline, fluoxetine – Antihypertensive agents: • **β-blockers:** timolol, acebutolol, propanolol • ACE inhibitors: captopril, enalapril, ramipril • Diuretics: spironolactone – Antimicrobials: terbinafine, gentamicin, thiamphenicol, fluconazole – Antithyroid drugs: carbimazole, thiouracils – Colchicine – **Interferons** – Lipid-lowering agents: clofibrate, cholestyramine – **Lithium** – NSAIDs: piroxicam, naproxen, indomethacin, ibuprofen – Oral contraceptives (discontinuation) – **Retinoids** – Others: allopurinol, cimetidine, L-dopa, amphetamines, pyridostigmine, bromocriptine, buspirone
Anagen phase	– Antineoplastic agents (see Table 21.13) – Others: arsenic, bismuth, gold, thallium

Table 21.12 Drug-induced alopecia. The more commonly incriminated medications are in bold. ACE, angiotensin-converting enzyme.

Fig. 21.13 Serum sickness due to antithymocyte globulin. The purpuric lesions are due to small vessel vasculitis in this patient with aplastic anemia. *Courtesy, Jean L Bolognia, MD.*

Drug-induced pseudolymphoma represents an insidious disease which simulates lymphoma clinically and histologically[47]. It has a benign biological behavior and does not satisfy the criteria for non-Hodgkin lymphoma. Although this disorder was originally thought to represent a hypersensitivity reaction, current evidence indicates that the responsible drugs may depress immunologic functions and impair immunosurveillance, leading to an abnormal proliferation of lymphocytes, increased T-cell activity and hypogammaglobulinemia.

Pseudolymphoma develops months or even years after the incriminated drug is begun. The cutaneous lesions may be solitary or multiple, localized or widespread, and consist of erythematous to violet papules, plaques or nodules. Numerous generalized tumors are rare. An erythroderma simulating Sézary syndrome has also been described[48]. There is often associated lymphadenopathy, but it may be an isolated finding[33].

Histologically, a dense lymphocytic infiltrate is seen within the dermis that can mimic a T- or B-cell lymphoma. In some patients, the lymphocytic infiltrate is band-like, resembling mycosis fungoides. Atypical nuclei with a cerebriform outline and epidermotropism may also be observed. The lymphocytes are predominantly T cells and are polyclonal in most cases. In the lymph nodes, focal necrosis and eosinophilic and histiocytic infiltrates may destroy the normal architecture. Atypical lymphoid hyperplasia may also be observed.

Complete recovery occurs within a few weeks after withdrawal of the responsible drug. The majority of drug-induced pseudolymphomas have been reported with anticonvulsants (phenytoin, phenobarbital, carbamazepine), antipsychotics (chlorpromazine, promethazine), imatinib mesylate, and angiotensin II receptor antagonists (see Table 121.1).

Granulomatous reactions

There are granulomatous drug reactions that can mimic interstitial granulomatous dermatitis and granuloma annulare and they are discussed in Chapter 45. In addition, sarcoidal reactions can be seen in patients with hepatitis C viral infections receiving interferon-α and ribavirin.

Anticoagulant-induced skin necrosis

Anticoagulant-induced skin necrosis is a rare, sometimes life-threatening reaction induced by warfarin (Coumadin®) or heparin. Lesions of warfarin necrosis typically begin 2 to 5 days after therapy is initiated and coincide with the expected early drop in protein C function (see Ch. 23).

Clinically, erythematous painful plaques evolve into hemorrhagic blisters and necrotic ulcers as a consequence of ischemic infarcts. The latter are due to occlusive thrombi within blood vessels of the skin and subcutaneous tissue[2]. The most common sites of involvement are the breasts, thighs and buttocks. One in every 10 000 individuals who receives warfarin will develop this phenomenon and those with hereditary deficiency of protein C are at highest risk. Therapy includes discontinuing warfarin and administering vitamin K, heparin (as the anticoagulant), and intravenous infusions of protein C concentrate. Warfarin necrosis should not be confused with anticoagulant-induced cholesterol emboli, which, despite the name "warfarin blue toe syndrome", is not restricted to this medication.

MUCOCUTANEOUS SIDE EFFECTS OF CHEMOTHERAPEUTIC AGENTS	
Reactions	**Responsible drugs**
Alopecia, reversible	Alkylating agents: cyclophosphamide, ifosfamide, mechlorethamine Anthracyclines: daunorubicin, doxorubicin, idarubicin Taxanes: paclitaxel, docetaxel Topoisomerase 1 inhibitors: topotecan, irinotecan Etoposide, vincristine, vinblastine, busulfan, actinomycin D, gemcitabine
Alopecia, irreversible	Busulfan
Mucositis	Daunorubicin, doxorubicin, high-dose methotrexate, high-dose melphalan, topotecan, cyclophosphamide, taxanes, continuous infusions of 5-fluorouracil (5-FU) and prodrugs of 5-FU
Extravasation reactions (e.g. chemical cellulitis, ulceration)	Anthracyclines, carmustines, 5-fluorouracil, vinblastine, vincristine, mitomycin C
Chemotherapy recall (tender sterile inflammatory nodules at sites of previous chemotherapy extravasation or administration)	5-fluorouracil, mitomycin C, paclitaxel, doxorubicin, epirubicin
Hyperpigmentation (see Ch. 67)	Alkylating agents: busulfan, cyclophosphamide, cisplatin, mechlorethamine Antimetabolites: 5-fluorouracil (5-FU), capecitabine (5-FU prodrug), methotrexate, hydroxyurea Antibiotics: bleomycin, doxorubicin
Serpentine supravenous hyperpigmentation	5-Fluorouracil, doxorubicin, docetaxel, vinorelbine
Mucosal hyperpigmentation	Busulfan, 5-fluorouracil, hydroxyurea, cyclophosphamide
Nail hyperpigmentation	5-Fluorouracil, cyclophosphamide, daunorubicin, doxorubicin, hydroxyurea, methotrexate, bleomycin
Onycholysis	Paclitaxel, docetaxel
Radiation recall	Methotrexate, doxorubicin, daunorubicin, taxanes (e.g. paclitaxel, docetaxel), dacarbazine, melphalan, capecitabine, gemcitabine, cytarabine, pemetrexed
Radiation enhancement	Doxorubicin, hydroxyurea, taxanes, 5-fluorouracil, etoposide, gemcitabine, methotrexate
Photosensitivity	5-Fluorouracil (5-FU) and 5-FU prodrugs (e.g. capecitabine, tegafur), methotrexate, hydroxyurea, dacarbazine, mitomycin C, docetaxel
Inflammation of "keratoses"	*Actinic keratoses*: 5-fluorouracil (5-FU) and 5-FU prodrugs (e.g. capecitabine), pentostatin *Seborrheic keratoses*: cytarabine, taxanes *Disseminated superficial actinic porokeratosis*: 5-fluorouracil (5-FU) and 5-FU prodrugs, taxanes
Toxic erythema of chemotherapy: – Acral erythema (erythrodysesthesia) – Eccrine squamous syringometaplasia – Pseudocellulitis Neutrophilic eccrine hidradenitis	 Cytarabine, anthracyclines, 5-fluorouracil (5-FU) and 5-FU prodrugs, taxanes, methotrexate, busulfan, cisplatin Cytarabine, busulfan, cyclophosphamide, carmustine, taxanes Gemcitabine, clofarabine Cytarabine, bleomycin, anthracyclines, cyclophosphamide, cisplatin, topotecan
Ulcerations	Hydroxyurea (lower extremities)
Nodulosis	Methotrexate (but usually in patients with rheumatoid arthritis)
Flushing	Asparaginase, high-dose BCNU, mithramycin
Others:	*Urticaria*: asparaginase, bleomycin, chlorambucil, cyclophosphamide, daunorubicin *Exanthematous eruption*: bleomycin, carboplatin, cytarabine, methotrexate, liposomal doxorubicin, paclitaxel, cladribine, gemcitabine, pemetrexed, bortezomib *SJS/TEN*: bleomycin, busulfan, cyclophosphamide, doxorubicin, etoposide, methotrexate, docetaxel *Cutaneous vasculitis*: gemcitabine, busulfan, cyclophosphamide, hydroxyurea, levamisole, pemetrexed *Dermatomyositis-like eruption*: hydroxyurea *Pseudoscleroderma tous reaction (especially extremities)*: paclitaxel, gemcitabine *Palmoplantar hyperkeratosis*: capecitabine, tegafur *Acquired cutaneous adherence*: doxorubicin (plus ketoconazole)

Table 21.13 Mucocutaneous side effects of chemotherapeutic agents. The mucocutaneous side effects of kinase inhibitors and blocking antibodies are reviewed in Table 21.14. Cutaneous squamous cell carcinomas are most commonly associated with fludarabine, hydroxyurea, and topical BCNU. SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

Heparin-induced cutaneous necrosis is due to antibodies that bind to complexes of heparin and platelet factor 4 and induce platelet aggregation and consumption (see Ch. 23). Platelet counts are usually depressed, but, unless the baseline platelet count is known, this may not be appreciated. In addition to relative thrombocytopenia, heparin can induce thrombosis and cutaneous necrosis, both at the site of injection and at distant sites (Fig. 21.12) as well as in internal organs (e.g. CNS). This is sometimes referred to as heparin-induced thrombocytopenia with thrombosis syndrome. Discontinuation of the heparin and administration of anticoagulants, such as argatroban, danaparoid or lepirudin, is recommended.

Serum sickness-like eruption

This syndrome is more commonly observed in children and typically includes fever, arthralgias, arthritis, a rash (urticarial, morbilliform) and lymphadenopathy[2,3]. It occurs 1 to 3 weeks after drug exposure. Unlike in "true" serum sickness due to non-human proteins (e.g. antithymocyte globulin, tositumomab, infliximab; Fig. 21.13), hypocomplementemia, circulating immune complexes, vasculitis and renal disease are absent. This reaction occurs in approximately 1 in 2000 children given cefaclor. Other drugs associated with serum sickness-like reactions are penicillins, NSAIDs, bupropion, phenytoin, sulfonamides, minocycline and propranolol.

Drug-induced lupus

There are several theories regarding the pathogenesis of drug-induced lupus. Reactive drug metabolites interacting with nuclear histones could act as haptens and activate the complement cascade. As an example, procainamide-induced systemic LE occurs more frequently in patients who are slow acetylators as compared to rapid acetylators.

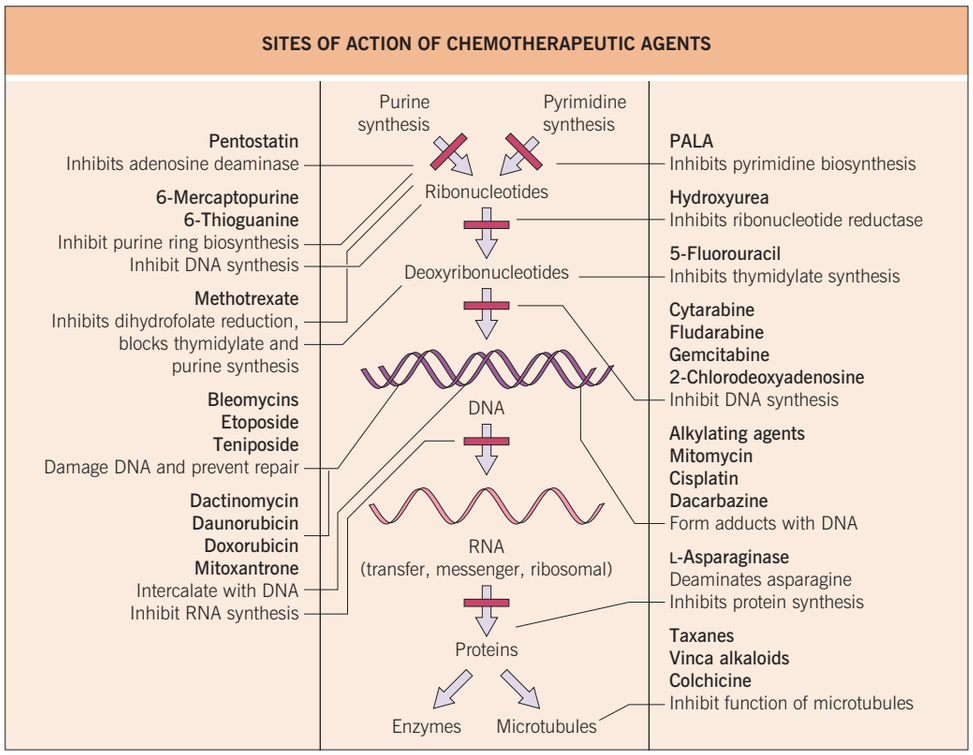

Fig. 21.14 Sites of action of chemotherapeutic agents. PALA, N-phosphonoacetyl-<H>L-aspartate; TMP, thymidine monophosphate. *Modified with permission from Brunton L, Lazo J, Parker K (eds.). Goodman & Gilman's The Pharmacological Basis of Therapeutics, 11th edn. New York: McGraw-Hill Medical, 2005.*

Drug-induced *systemic* LE is associated with fever, weight loss, pericarditis and pleuro-pulmonary inflammation; it has no gender predilection. Cutaneous involvement is rare, but includes a malar erythema, photoeruptions, and discoid or erythema multiforme-like lesions. Vasculitis and renal or neurologic involvement are also rare. The symptoms usually develop more than a year after the medication was initiated.

Drug-induced systemic LE is characterized by the presence of antihistone antibodies in up to 95% of cases, but these antibodies are not specific and may be seen in patients with idiopathic systemic LE. Antibodies against double-stranded DNA are typically absent. The seroconversion from negativity to positivity for antinuclear antibodies alone is not sufficient to discontinue a particular medication. However, if symptoms develop, the offending drug should be withdrawn. The clinical symptoms usually resolve within 4 to 6 weeks, but positivity for antinuclear antibodies may persist for 6 to 12 months. Responsible drugs include procainamide and hydralazine, followed by chlorpromazine, isoniazid, methyldopa, propylthiouracil, quinidine, practolol, D-penicillamine, and PUVA. Minocycline's association with this disorder is well described, but patients may not have antihistone antibodies[49]. Several patients with drug-induced lupus attributed to minocycline have had antineutrophil cytoplasmic antibodies, which may be directed against myeloperoxidase or elastase.

Drug-induced *subacute cutaneous* LE presents with psoriasiform and annular lesions, usually of the upper trunk and extensor surfaces of the arms, that are clinically and histologically indistinguishable from those seen in the idiopathic form of the disease (see Ch. 41). Anti-Ro/SSA and anti-La/SSB antibodies can be present. Responsible drugs include hydrochlorothiazide, calcium channel blockers, terbinafine, NSAIDs, griseofulvin, docetaxel, PUVA and interferon. Resolution of the eruption may or may not occur after discontinuation of the responsible drug.

In the case of TNF-α inhibitors, antinuclear and anti-DNA antibodies can develop (see Ch. 128) and patients may develop cutaneous lesions of chronic (discoid), subacute and acute cutaneous LE.

Mucosal ulceration

Stomatitis with erosions and ulcerations may occur either as part of a drug-induced mucocutaneous syndrome (e.g. fixed drug eruption, pemphigus, TEN) or as a direct side effect. Agents used for immunosuppression or as chemotherapy are the major drugs associated with the development of stomatitis, including methotrexate, doxorubicin and 5-fluorouracil (see below)[50]. Severe ulcerative stomatitis has also been observed with metamizole, phenylbutazone, oxyphenbutazone, D-penicillamine and gold therapy, sometimes in the setting of drug-induced neutropenia and agranulocytosis. Allergic reactions to dental materials and exposure to metals such as mercuric chloride or copper sulfate may cause stomatitis.

In a prospective study of 100 patients treated with nicorandil, a potassium channel activator, five individuals developed chronic buccal ulcerations with severe dysphagia, whereas none were observed in the 100 control patients. This side effect may be seen in up to 14% of patients treated with this drug[51]. A more recent review of the literature on drug-induced mucosal ulcerations identified eight different compounds as "plausible" causes: niflumic acid (topical use), captopril, nicorandil, phenindione, piroxicam, gold salts, phenobarbital and sodium hypochlorite (topical antiseptic). Penile ulceration can also be observed secondarily to contact toxicity by secreted drugs such as foscarnet.

Drug-induced hair loss and hair growth

A considerable number of medications have been reported to induce hair loss[52]. They affect the hair follicles via two major mechanisms: anagen effluvium and telogen effluvium. In the former, hair loss occurs within 2 to 3 weeks of drug administration, whereas in telogen effluvium, the delay is usually 2 to 4 months. Clinically, both are classified as diffuse non-scarring alopecias (see Ch. 69). The prevalence and severity of drug-induced alopecia depend upon the drug as well as an individual's predisposition, and the hair loss is usually reversible after discontinuation of the responsible agent. Diagnosis of drug-induced telogen effluvium can be difficult, as confirmation requires an appreciation of an improvement after the suspected drug has been withdrawn. Table 21.12 lists a number of the drugs associated with alopecia, including β-blockers, lithium, retinoids and heparin.

With regard to drug-induced hair growth, it is important to distinguish between hypertrichosis and hirsutism. The associated medications for both entities are discussed in Chapter 70.

Reactions to chemotherapy

Chemotherapeutic agents may induce local or systemic skin toxicity. There is a wide range of cutaneous manifestations of chemotherapy,

Fig. 21.15 Cutaneous side effects of chemotherapeutic agents. A Ulceration due to extravasation of doxorubicin. **B** Horizontal melanonychia due to 5-fluorouracil. **C** Erythema of the ears due to cytarabine (cytosine arabinoside), sometimes referred to as "Ara-C ears"; the petechiae are due to thrombocytopenia. **D** Toxic erythema of chemotherapy due to cytarabine, with obvious acral erythema involving the plantar surface. **E** Inflammation surrounding a seborrheic keratosis in a patient receiving paclitaxel. **F** Necrosis of psoriatic plaques due to an "overdose" of methotrexate. **G** Raynaud's phenomenon and digital necrosis due to systemic bleomycin. *B–F, Courtesy, Jean L Bolognia, MD.*

from benign to life-threatening[50] (Table 21.13), as well as a wide diversity of drugs used to treat neoplastic disease (Fig. 21.14).

Alopecia

One of the most common adverse reactions to chemotherapy is alopecia due to anagen effluvium in which there is an abrupt cessation of mitotic activity. The alopecia involves primarily the scalp hairs, but other sites may be affected, such as the eyebrows and axillary and pubic regions. The hair loss is almost always reversible, and the severity of alopecia depends primarily upon the specific drugs administered. Occasionally, patients with straight hair will develop curly hair when it regrows.

Stomatitis

Mucositis of the oral and gastrointestinal mucosae is a major, often dose-limiting, cause of morbidity in patients receiving chemotherapy. Stomatitis occurs in approximately 40% of patients, and there are two possible underlying mechanisms:

- Direct drug-induced cytotoxic effects on the oral epithelial cells, which have a high mitotic index. Mucosal involvement appears 4 to 7 days after the drugs are administered, and the erythematous, edematous and ulcerated oral mucosa produces symptoms of pain, burning and xerostomia. Spontaneous healing is observed within 2 to 3 weeks.
- Indirect effects on the oral mucosa due to superimposed infections (e.g. *Candida*, herpes simplex virus) and/or hemorrhage, reflections of bone marrow suppression. These effects are typically observed at the therapeutic nadir of the white blood cell count. However, the prophylactic use of antivirals (e.g. acyclovir) and antifungals (e.g. fluconazole) as well as colony-stimulating factors (which reduce the duration of neutropenia) have decreased the impact of this second mechanism.

Preventive measures include maintaining oral hygiene via the use of soft toothbrushes and rinsing with water and sodium bicarbonate.

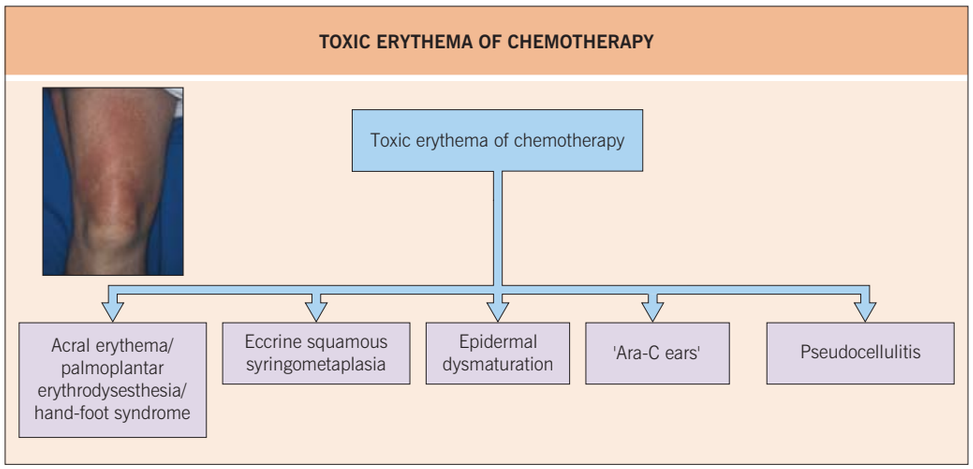

Fig. 21.16 Toxic erythema of chemotherapy. Use of a number of terms (especially those based on histologic findings), including palmoplantar erythrodysesthesia, eccrine squamous syringometaplasia and epidermal dysmaturation, has created some confusion for clinicians. There is considerable overlap in the appearance of the symmetric erythematous patches which can develop edema, erosions, desquamation or purpura (depending on the patient's platelet count), whether they favor acral sites, intertriginous zones, or the elbows and knees. "Toxic erythema of chemotherapy" has been suggested as an encompassing term that allows simplification. In addition, there is no need to implicate additional diagnoses when lesions are not limited to the hands and feet. *Courtesy, Jean L Bolognia, MD.*

In addition to specific antimicrobial agents, topical anesthetics may be helpful; in some patients, systemic analgesics are required. More recently, palifermin (keratinocyte growth factor) has been introduced to treat mucositis due to high-dose chemotherapy ± total body irradiation. However, administration of palifermin is associated with the appearance of a white coating of the tongue and transient keratoses within areas of cutaneous inflammation.

Other reactions

Chemotherapeutic agents are also responsible for other mucocutaneous reactions such as ulcerations at sites of extravasation of intravenous medications (Fig. 21.15A), skin, oral and nail hyperpigmentation (Fig. 21.15B), and acral erythema (Fig. 21.15C,D), also known as erythrodysesthesia. The frequency of extravasations has been markedly reduced by the use of "permanent" central venous catheters, whereas the incidence of acral erythema has increased in the setting of prolonged infusions of drugs and the chronic use of oral kinase inhibitors.

A variety of terms have been used to describe the cutaneous toxic effects of chemotherapy, e.g. "palmoplantar erythrodysesthesia", "hand–foot syndrome", "eccrine squamous syringometaplasia" "intertrigo eruption of chemotherapy" and "epidermal dysmaturation", creating some confusion. There is considerable overlap in the appearance of the symmetric erythematous patches which can develop edema, desquamation or purpura (depending on the patient's platelet count), whether they favor acral sites, intertriginous zones, the scrotum, or the elbows and knees. "Toxic erythema of chemotherapy" has been suggested as an encompassing term that allows simplification (Fig. 21.16).

Additional reactions to chemotherapy include radiation recall or enhancement, photosensitivity, inflammation of actinic or seborrheic keratoses (Fig. 21.15E), necrosis of plaques of psoriasis (Fig. 21.15F) or mycosis fungoides, Raynaud's phenomenon with digital necrosis (Fig. 21.15G), and neutrophilic eccrine hidradenitis (see above; Fig. 21.8). Long-term administration of hydroxyurea is associated with the development of painful ulcerations of the malleolar region of the lower extremities. The ulcers may be difficult to heal unless the hydroxyurea is discontinued.

The cutaneous side effects of the more recently introduced kinase inhibitors overlap with those of "standard" chemotherapy, including alopecia and toxic erythema of chemotherapy. However, there are also more unique side effects such as hypopigmentation of the skin and hair and periorbital edema from those that block c-KIT and platelet-derived growth factor receptor (PDGFR) as well as folliculitis due to inhibitors of epidermal growth factor receptor (EGFR; Table 21.14).

Fig. 21.17 Psoriasiform eruptions due to TNF-α inhibitors. A Widespread papulosquamous lesions in a patient being treated with infliximab for gastrointestinal GVHD. Histologically, there was no evidence of cutaneous GVHD. **B** Sterile pustulosis of the plantar surface developed in this patient with rheumatoid arthritis who had received infliximab for the previous 5 years. Neither patient had had a reduction in immunosuppression prior to the onset of the psoriasiform eruption. *A, Courtesy, Dennis Cooper, MD. B, Courtesy, Chris Bunick, MD.*

Drug reactions in HIV infection

Patients with HIV infection are at increased risk for drug eruptions (see Ch. 78). For example, the incidence of SJS-TEN in HIV-infected patients is 1/1000 per year (versus 1/1 000 000 per year in the general population) and this increase has been reported since the beginning of the AIDS epidemic[46]. An acquired glutathione deficiency in HIV-infected patients could contribute to an altered metabolism of trimethoprim–sulfamethoxazole (TMP-SMX) and therefore increase the risk of cutaneous reactions to that drug combination. However, this would not explain the multitude of drug eruptions to a variety of medications.

This increased susceptibility to drug reactions is most commonly observed in patients whose $CD4^+$ count is between 100 and 400/mm^3. It has been proposed that drugs or their metabolites disturb the balance between cytotoxic and regulatory phenomena, allowing a resurgence of cytotoxicity against virally infected cutaneous cells[19]. The target of the cytotoxic reaction would be viral antigens rather than drug haptens.

The major offending drugs include TMP-SMX, aminopenicillins, dapsone, abacavir, nevirapine and anticonvulsants. For example, up to

40% of HIV-infected patients may develop a "rash" during treatment with TMP-SMX[53]. These adverse cutaneous reactions, especially when severe, necessitate discontinuation of the drug. In the case of mild reactions, "treating through", i.e. continuing the drug despite the cutaneous eruption, is possible and has been followed by the disappearance of the rash. Corticosteroids may lower the rate of reactions to sulfonamides in AIDS patients[54]. Desensitization has been performed in these patients with varying results.

Drug-induced psoriasis

Drugs may be associated with the precipitation or exacerbation of psoriasis. A drug can affect the patient with psoriasis or a psoriatic diathesis in several ways: (1) exacerbation of pre-existing psoriasis; (2) induction of lesions of psoriasis in clinically normal skin in a person with psoriasis; (3) precipitation of psoriasis *de novo*; and (4) development of treatment resistance[55]. In addition, in sites of involvement by other cutaneous drug reactions (e.g. exanthematous), psoriatic lesions may appear secondary to the Koebner phenomenon, and plaques may develop at sites of injections of interferon.

The clinical manifestations of drug-induced psoriasis span the spectrum of psoriasis, from limited or generalized plaques to erythroderma and pustulosis of the palms and soles. Nail changes and scalp involvement may also be seen. The latency period depends on the offending drug. It can be categorized as short (<4 weeks), intermediate (4 to 12 weeks), and long (>12 weeks); examples of drugs that have been categorized in this manner are terbinafine and NSAIDs (short), antimalarials and ACE inhibitors (intermediate), and lithium and β-blockers (long)[56]. Lesions of drug-induced psoriasis usually regress within weeks to a few months of discontinuing the inciting drug. However, psoriasiform eruptions, including palmoplantar pustulosis, may be more persistent in patients receiving TNF-α inhibitors (see Ch. 128). The latter occur not just in individuals with psoriasis or rheumatoid arthritis, but also in patients being treated for other conditions, e.g. GVHD or inflammatory bowel disease, who have no personal or family history of psoriasis (Fig. 21.17). These eruptions may or may not follow a reduction in immunosuppression.

Histologic findings are not always characteristic. They may suggest psoriasis or be more compatible with a lichenoid drug eruption.

CUTANEOUS SIDE EFFECTS OF KINASE INHIBITORS AND BLOCKING ANTIBODIES

	Sorafenib	Sunitinib	Vemurafenib	Erlotinib, gefitinib, cetuximab (MoAb)	Imatinib	Dasatinib	Nilotinib

REACTIONS LOCALIZED TO SITES OF INJECTIONS OF MEDICATIONS	
Etanercept*	Erythematous plaques, vasculitis, eosinophilic cellulitis
Adalimumab	Erythematous or urticarial plaques
GM-CSF*, G-CSF*	Pustular reaction, urticarial plaque
Interferon*	Vasculopathy with necrosis, development of plaque of psoriasis
Interleukin-2	Lobular panniculitis, granulomas
Vitamin K	Erythematous plaque, often annular (Fig. 21.19); morpheaform plaque (Texier's disease)
Heparin	Necrosis, ecchymosis (see Ch. 23)
Low-molecular-weight, calcium-containing heparin	Calcinosis cutis
Glatiramer acetate	Fibrosis, panniculitis, lipoatrophy, vasospasm, Nicolau syndrome
Iron	Brown discoloration, hyperpigmentation
Hyaluronic acid, silicone	Swelling, granulomatous reaction (see Ch. 94)
Corticosteroids	Dermal atrophy, lipoatrophy, telangiectasias, deposits, hypopigmentation
Vitamin B_{12}	Pruritus, morpheaform plaque
Enfuvirtide	Erythematous or morpheaform plaque
VACCINES	
Aluminium-containing vaccine	Nodules, foreign body reaction

*Discussed in Chapter 128.

Table 21.15 Reactions localized to sites of injections of medications (in addition to extravasation of those administered intravenously). See Table 21.8 and Table 89.3 for reactions to insulin and illicit drugs, respectively. CSF, colony stimulating factor; G, granulocyte; GM, granulocyte–macrophage

Acneiform eruptions (including folliculitis)

Acneiform eruptions represent approximately 1% of drug-induced skin eruptions. Clinically, papules and/or pustules are seen primarily on the face and upper trunk, the same sites favored by acne; comedones are usually absent. The interval between drug exposure and the acneiform eruption depends on the offending agent. The major drugs implicated in acneiform eruptions include corticosteroids, androgens, hydantoins, lithium, halogenides, and oral contraceptives (more often those that contain progestins with androgen-like effects). Less commonly, azathioprine, quinidine and adrenocorticotropic hormone are the culprits. With the introduction of blocking antibodies and inhibitors of EGFR (see Table 21.14), follicular eruptions are increasingly seen by dermatologists (see Fig. 36.15).

Pigmentary changes

Drug-induced cutaneous hyperpigmentation may result from a variety of mechanisms, including enhanced melanin production, deposition of drugs or their metabolites (sometimes complexed with melanin or iron, and, in some instances, better described as discoloration), and simply postinflammatory changes. The hyperpigmentation may be more pronounced in sun-exposed areas. The drugs most commonly implicated in cutaneous hyperpigmentation (or discoloration) include minocycline, antimalarials, amiodarone (Fig. 21.18), oral contraceptives, imipramine, chemotherapeutic agents and clofazimine (see Ch. 67). Exposure to heavy metals such as silver and gold as well as arsenic may also induce darkening of the skin, and bleomycin can lead to linear "flagellate" hyperpigmentation.

Hypopigmentation can occur with the chronic use of several topical medications, including retinoic acid and corticosteroids; depigmentation is associated primarily with the application of monobenzyl ether of hydroquinone or exposure to catechols, phenols or quinones (i.e. contact or occupational leukoderma; see Ch. 66). Cutaneous hypopigmentation can result from tyrosine kinase inhibitors, in particular imatinib.

A few drugs are capable of changing the color of hair. For example, chloroquine, imatinib, dasatinib and sunitinib (see Table 21.14) can lead to lightening or even depigmentation. Imatinib can also lead to darkening of the hair.

Eruptions induced by vaccines

With the discontinuation of vaccinations for smallpox in the general population, the incidence of significant cutaneous side effects due to

vaccines is now low[57] (see Ch. 81). Local inflammatory reactions consisting of erythema, swelling and tenderness can be seen, as well as urticaria, angioedema and anaphylaxis; the latter occurs primarily with live measles vaccines. Lichenoid eruptions[58], erythema multiforme and occasionally autoimmune reactions, e.g. polyarteritis nodosa, have been observed[24]. Vaccination with BCG can lead to a benign, self-limited local reaction consisting of a plaque, pustule or even ulcer (see Ch. 75). Occasionally, local abscess formation may follow vaccination of strongly reactive individuals, administration of a large amount of vaccine, or a deep injection.

Localized reactions to injected medications

In addition to the cutaneous reactions to vaccines discussed previously, Table 21.15 outlines cutaneous reactions that are localized to the sites of injections of medications. Table 21.8 reviews the side effects of insulin injections.

TREATMENT

Only a small fraction of drug eruptions are life-threatening or lead to disabling sequelae. Management begins with the withdrawal of the suspect drug as soon as possible[59]. Frequently, however, several drugs may be incriminated. As there is no clinical or laboratory test which permits identification of the offending agent with certainty, the decision is usually made to discontinue all drugs that are non-essential as well as the "high-probability" drugs. Appropriate substitutions may also be required; for example if phenytoin is discontinued, then levetiracetam or valproate would be prescribed rather than phenobarbital or carbamazepine.

For mild drug eruptions, topical corticosteroids and antihistamines may be helpful. In the case of "acute skin failure" as in TEN, management must be undertaken in specialized intensive care units. Supportive interventions include warming of the environment, correction of electrolyte disturbances, high caloric supplementation, and prevention of sepsis.

The hypothesis of an immunologic etiology for drug eruptions has led to the use of systemic corticosteroids, immunosuppressives and anticytokine therapies. Although corticosteroids have been advocated by some clinicians, there is minimal evidence for their usefulness either as a preventive or as a therapeutic agent in the most common forms of drug reactions, e.g. exanthematous. In patients with mild reactions that occur during the treatment of a severe disease, it is sometimes possible to "treat through" the rash and continue the incriminated drug. In this situation, systemic corticosteroids may be helpful, as has been recently observed with TMP-SMX in previously intolerant patients who had AIDS-associated *Pneumocystis jiroveci* pneumonia[54]. However, there is no agreement regarding this clinical approach and, in the case of severe reactions, administration of systemic corticosteroids as a preventive measure may prove detrimental. Of note, corticosteroids can improve the cutaneous and visceral (lung, heart) manifestations of DRESS (DIHS) and may be life-saving; however, relapses are often observed when the corticosteroids are tapered.

Finally, after recovery, patients should be advised to avoid the drug thought to be responsible for the reaction and all chemically related compounds.

Purpura: Mechanisms and Differential Diagnosis

22

Warren W Piette

PURPURA

Introduction

The differential diagnosis of purpura is extensive, but the evaluation of a patient with purpura can be greatly facilitated by categorizing purpuric lesions into morphologic subsets[1]. This chapter serves as an introduction to a method to evaluate and classify patients presenting with this important dermatologic sign. Purpura is defined as visible hemorrhage into the skin or mucous membranes. The differential diagnosis presented in this chapter is directed toward syndromes of primary purpura, where the hemorrhage is an integral part of lesion formation, rather than secondary hemorrhage into established lesions (e.g. stasis dermatitis, dependent cellulitis). Purpuric lesions are divided into six subsets: (1) petechiae (Fig. 22.1A, Table 22.1); (2) macular purpura (Table 22.2); (3) macular ecchymoses (Fig. 22.1B, Table 22.3); (4) palpable purpura (Fig. 22.1C, Table 22.4); (5) non-inflammatory retiform purpura (Fig. 22.1D; Table 22.5); and (6) inflammatory retiform purpura (Table 22.6). Lesions in the first three groups are categorized on the basis of size, while those in the last three groups can range in size from a few millimeters to several centimeters in diameter. The relevance of these morphologic subsets in sorting through the differential diagnosis is outlined in Figure 22.2.

Two major causes of purpura, microvascular occlusion syndromes and vasculitis, will be discussed in Chapters 23 and 24, respectively. The former are important to recognize because they may mimic vasculitis but require a very different approach to diagnosis and therapy. The most typical presentation of microvascular occlusion syndromes is non-inflammatory retiform purpura (see Table 22.5). Early lesions seldom show much erythema, and in the uncommon instance in which early erythema is present, purpura or necrosis typically comprises at least two-thirds of the lesion.

In the skin, livedo reticularis is a reflection of the physiologic anatomy of slow flow states (see Ch. 106). It is the three-dimensional structure and flow regulation of the dermal and subcutaneous vasculature that gives rise to the violaceous or bluish net-like pattern of livedo reticularis, and this flow pattern is reproducible in any given individual. The diameter of the almost-circular individual units within the net-like grid varies from 2 cm or larger on the back to 5 mm or less on the palms or soles.

Retiform purpura morphology results from occlusion of the vessels that produce the livedo reticularis pattern (see Fig. 23.5), but the two entities can be distinguished based upon the presence or absence of purpura, respectively, hence the term "retiform purpura". Given the size of dermal vessels, the clot within the vessel is often too small to be seen grossly. What is actually observed is hemorrhage around the vessel within the dermis, presumably due to ischemia with hemorrhage prior to complete occlusion of the vessel. The shape of such a hemorrhagic lesion is determined by the anatomy of the slow flow network, though a complete reticulate pattern is very rarely seen. Instead, the morphology of retiform purpura is composed of "puzzle pieces" of the livedo reticularis pattern. Some lesions might be called river-like or serpentine purpura because of their likeness to a winding river or snake, and others could be referred to as branching purpura because of their likeness to the angled course of a tree branch. However, very few of these lesions are truly stellate, i.e. characterized by a central area of necrosis or hemorrhage with radiating extensions.

Retiform lesions should be carefully examined to confirm the presence of purpura, and it is important to inquire about the duration of the lesions. Inflammatory retiform purpura (see Table 22.6) may have a reticulate or branching morphology, but (unlike non-inflammatory retiform purpura) early lesions typically exhibit prominent erythema. However, just as the wound healing response can eventually lead to erythema and leukocytoclasis in lesions initiated by non-inflammatory occlusion, vasculitis sometimes produces lesions that show minimal early inflammation. Among the inflammatory disorders that can result in retiform purpura, the ANCA-positive vasculitides (especially Wegener's granulomatosis and microscopic polyangiitis) are the ones most likely to present with lesions that are difficult to distinguish from retiform purpura due to occlusion. Despite this overlap of clinical presentations, careful examination of early lesions to determine whether there is a substantial inflammatory component can greatly aid in focusing the differential diagnosis and directing the evaluation.

This morphologic approach to the differential diagnosis of purpura represents a departure from traditional categorization by pathophysiology. Because the pathophysiology of purpuric syndromes is what the clinician is attempting to ascertain, sorting by pathophysiology is of limited clinical utility. The morphology-based method is designed to streamline the process of generating clinical hypotheses (i.e. most likely diagnoses) to facilitate a rapid, efficient and accurate evaluation to prove or disprove the suspected diagnosis.

The Time Course of Purpura

The three subsets of macular (non-palpable) purpura (see Tables 22.1–22.3) cause purpura primarily through mechanisms of simple hemorrhage, with extravasated red blood cells and minimal inflammation observed in biopsy specimens. As such, these lesions have a very simple evolution, from initial hemorrhage to steady clearing of red blood cells and hemoglobin. Clinically, this correlates with fading of lesions and, in larger lesions, transition of color from red–blue or purple to green, yellow or brown before complete fading.

In syndromes of inflammatory hemorrhage, such as cutaneous small vessel vasculitis, and in microvascular occlusion, the evolution and clearing of lesions is more complicated. This is outlined in Figure 22.3. Because of the different evolution patterns of these two processes, it is possible for a biopsy specimen of a late lesion of vasculitis to resemble an early lesion of occlusion histologically. Conversely, a late lesion of occlusion with some resulting dermal necrosis may on histologic examination show features characteristic of leukocytoclastic vasculitis. This means that the biopsy specimen of a purpuric lesion must be interpreted within the context of the lesion's age and clinical setting. The clinical and histologic assessment of purpuric lesions are equally important in properly evaluating and diagnosing a purpuric syndrome.

COAGULATION

Primary hemostasis consists of the formation of a platelet plug, and this is sufficient for the many daily minor injuries to the microvascular system. When a platelet plug is inadequate due to the size of the vessel or the size of the injury, secondary hemostasis with clot formation is needed. The control of clot formation is critically important: too little clotting can lead to death by hemorrhage; inappropriate clotting produces thrombosis, embolus or necrosis; and uncontrolled clotting with fibrinolysis can produce both thrombosis and hemorrhage, as in disseminated intravascular coagulation. Therefore, a thrombus must form rapidly at sites of injury, it must not extend beyond where it is needed,

Fig. 22.1 Clinical examples of petechiae and purpura. A Round to oval petechiae, <3 mm in diameter. **B** Actinic (solar) purpura and pseudoscars, both in sites of actinic damage plus trauma. **C** Palpable purpura due to cutaneous small vessel vasculitis (inflammation plus hemorrhage). **D** Non-inflammatory (bland) retiform purpura as well as hemorrhagic bullae in a patient with disseminated intravascular coagulation (DIC). *D, Courtesy, Judit Stenn, MD.*

and clotting factors that escape the local injury site must be prevented from triggering clotting at distant sites. As might be expected for a system that requires exquisite regulation to perform properly, the control of coagulation is multifaceted and still not completely understood[2,3]. Basal coagulation encompasses the constant low-level activation of some components of the procoagulant, natural anticoagulant and fibrinolytic pathways, so that these systems are ready for a rapid response when needed. An overview of the controls and interconnections of these pathways is shown in Figure 22.4.

The initiation stage of clot formation generates small amounts of thrombin (factor IIa) via formation of a tissue factor–factor VIIa complex that activates factor IX to IXa and factor X to Xa (a process formerly referred to as the extrinsic pathway of coagulation)[2,3]. This phase may take place on any cell that expresses tissue factor and is exposed to plasma; inflammatory cells and injured endothelial cells are common sites. Only small amounts of these factors are released in this phase, usually insufficient to produce a clot. However, these small amounts are critical for triggering the propagation/amplification phase of coagulation. The thrombin released during initiation activates platelets. Platelet membrane surfaces are then inverted to expose phospholipids (especially phosphatidyl serine) critical for localizing membrane procoagulant complexes, starting with the binding of factors VIIIa and Va (cofactors for factors IXa and Xa, respectively). Thrombin molecules also stimulate the release of factor V from platelet granules and activate factor V as well as factor VIII, freeing the latter from von Willebrand factor. Finally, thrombin activates factor XI to XIa (which leads to further activation of IX to IXa). As shown in Figure 22.4, the activated platelet surface is now the site of complexes capable of rapid amplification of thrombin generation, which then catalyzes the cleavage of fibrinogen to fibrin with subsequent polymerization of fibrin monomers into a clot.

Classically, factor XII and the contact activation complex have been considered as part of the coagulation cascade (formerly referred to as the intrinsic pathway). However, while patients deficient in factor XII, high-molecular-weight kininogen or prekallikrein may have prolonged activated partial thromboplastin times (APTT), they do not bleed excessively and may actually be prone to thrombosis. These findings, plus other recent investigations, have challenged traditional concepts of the role of the contact activation system[4,5]. Factor XII may play a role in clot propagation, particularly in pathologic states, but the contact activation system seems more targeted toward other physiologic functions.

The contact activation complex is formed by the assembly of high-molecular-weight kininogen (HMWK) and prekallikrein (PK) on a multiprotein receptor complex on endothelial cell membranes; this complex consists of cytokeratin 1, the globular head of the C1q receptor and the urokinase plasminogen activator receptor. Binding of HMWK, PK and sometimes factor XII to this receptor complex results in the production of the powerful vasodilator bradykinin and other vasoactive mediators. In addition, fibrinolytic activity is generated through both activation of single- and two-chain urokinase-like plasminogen activator and release of tissue plasminogen activator, which subsequently convert plasminogen to plasmin. C1 esterase inhibitor, well known in controlling complement reactions, also has a major role in regulating this pathway. Of note, the episodic edema of hereditary angioedema is probably due more to deficient C1 esterase inhibitor-mediated down-regulation of bradykinin production than to deficient inhibition of complement (see Ch. 18). The contact activation system is likely

DIFFERENTIAL DIAGNOSIS OF MACULAR PETECHIAE (≤4 MM IN DIAMETER)
PATHOPHYSIOLOGY: HEMOSTATICALLY RELEVANT THROMBOCYTOPENIA (<50 000/mm³)*
Major etiologies†
1. Idiopathic thrombocytopenic purpura 2. Thrombotic thrombocytopenic purpura 3. Disseminated intravascular coagulation 4. Other acquired thrombocytopenias, including drug-related a. Peripheral destruction (e.g. quinine, quinidine) b. Drug-induced decreased production, idiosyncratic or dose-related (e.g. chemotherapy) c. Bone marrow infiltration, fibrosis or failure
PATHOPHYSIOLOGY: ABNORMAL PLATELET FUNCTION
Major etiologies†
1. Congenital or hereditary platelet function defects 2. Acquired platelet function defects a. Aspirin, NSAIDs b. Renal insufficiency c. Monoclonal gammopathy 3. Thrombocytosis secondary to myeloproliferative disorders (often >1 000 000/mm³)
PATHOPHYSIOLOGY: NON-PLATELET ETIOLOGIES
Major etiologies†
1. Spiking elevations of intravascular venous pressure (Valsalva maneuver-like, e.g. repetitive vomiting, childbirth, paroxysmal coughing, seizure) 2. Fixed increased pressure (e.g. stasis, ligatures) or intermittent pressure (e.g. blood pressure cuff – Rumpel–Leede sign) 3. Trauma (often linear) 4. Perifollicular (vitamin C deficiency) 5. Mildly inflammatory conditions a. Pigmented purpuric eruptions b. Hypergammaglobulinemic purpura of Waldenström
*Most patients do not have petechiae until platelets ≤20 000/mm³. †Partial list.

Table 22.1 Differential diagnosis of macular petechiae (≤4 mm in diameter). NSAIDs, nonsteroidal anti-inflammatory drugs.

DIFFERENTIAL DIAGNOSIS OF INTERMEDIATE MACULAR PURPURA (5–9 mm)
MAJOR ETIOLOGIES*
1. Hypergammaglobulinemic purpura of Waldenström 2. Infection/inflammation in patients with thrombocytopenia 3. Rarely, minimally inflamed cutaneous small vessel vasculitis (usually dependent distribution)
*Partial list.

Table 22.2 Differential diagnosis of intermediate macular purpura (5–9 mm).

responsible for some of the fibrinolysis and refractory hypotension seen in sepsis, following cardiopulmonary bypass ("post-pump" systemic inflammatory response syndromes), and in other settings where contact activation is likely to be extensive.

Natural anticoagulant control of clot extension is likewise complex[2,3]. The initiation phase of clotting is down-regulated by *tissue factor pathway inhibitor* (TFPI) and *antithrombin III* (ATIII). TFPI and ATIII are bound to heparan sulfate molecules on the surface of endothelial cells, and their presence in close proximity to sites of desired clot formation allows them to capture activated clotting factors and prevent them from leaving the area. TFPI can inactivate factor Xa, and the TFPI–factor Xa complex can efficiently bind to and inhibit factor VIIa (which is found in a complex with tissue factor); in the absence of factor Xa, TFPI reacts with factor VIIa at a much slower rate. ATIII can

DIFFERENTIAL DIAGNOSIS OF MACULAR ECCHYMOSES (≥1 cm)
PATHOPHYSIOLOGY: PROCOAGULANT DEFECT PLUS MINOR TRAUMA
Major etiologies*
1. Anticoagulant use 2. Hepatic insufficiency with poor procoagulant synthesis 3. Vitamin K deficiency 4. Disseminated intravascular coagulation (some)
PATHOPHYSIOLOGY: POOR DERMAL SUPPORT OF VESSELS PLUS MINOR TRAUMA
Major etiologies*
1. Actinic (solar, senile) purpura 2. Corticosteroid therapy, topical or systemic 3. Vitamin C deficiency (scurvy) 4. Systemic amyloidosis (light chain-related, some familial types) 5. Ehlers–Danlos syndrome
PATHOPHYSIOLOGY: PLATELET PROBLEMS PLUS MINOR TRAUMA
Major etiologies*
1. Platelet function defects, including von Willebrand disease and those induced by medications and metabolic diseases 2. Acquired or congenital thrombocytopenia
*Partial list.

Table 22.3 Differential diagnosis of macular ecchymoses (≥1 cm).

PALPABLE PURPURA: INFLAMMATORY PURPURA WITH PROMINENT EARLY ERYTHEMA
I. PATHOPHYSIOLOGY: LEUKOCYTOCLASTIC VASCULITIS DUE TO IMMUNE COMPLEX DISEASE
A. Small vessels only
1. Idiopathic, infection- or drug-associated IgG or IgM complexes 2. Idiopathic IgA complexes (HSP), or IgA complexes associated with drugs or infection 3. Hypergammaglobulinemic purpura of Waldenström 4. Urticarial vasculitis: often minimally purpuric 5. Pustular vasculitis (e.g. bowel bypass syndrome)
B. Small- and medium-sized (macroscopic) vessels may be involved
1. Mixed cryoglobulinemia 2. Rheumatic vasculitides (LE, RA), Sjögren's syndrome
II. PATHOPHYSIOLOGY: PAUCI-IMMUNE LEUKOCYTOCLASTIC VASCULITIS
A. ANCA-associated
1. Wegener's granulomatosis 2. Microscopic polyangiitis 3. Churg–Strauss syndrome
B. Other
1. Erythema elevatum diutinum 2. Sweet's syndrome (vasculitis unusual)
III. PATHOPHYSIOLOGY: NOT LEUKOCYTOCLASTIC VASCULITIS
