The mid 1970s marked the beginning of the modern era of clinical PDT when Dougherty and colleagues combined systemically administered hematoporphyrin derivative with visible light to treat cutaneous and subcutaneous malignancies in humans; they also confirmed the role of singlet oxygen[2,3]. With the advent of lasers and fiberoptic-equipped endoscopes, the use of PDT was extended to carcinomas of the lung, bladder and esophagus. PDT finally gained regulatory approval by the US Food and Drug Administration (FDA) in 1995, but not for skin. Although the skin is obviously relatively easy to illuminate with light, there were two major limitations in using hematoporphyrin derivative or its more purified, commercially available form (porfimer sodium [Photofrin®]) for cutaneous malignancies. Firstly, both of these photosensitizers require intravenous administration, and secondly, they induce marked generalized cutaneous photosensitivity that lasts 6–8 weeks, necessitating strict avoidance of outdoor light.

Because they are relatively large molecules, the percutaneous absorption of porphyrins is rather poor. The breakthrough in developing PDT as a practical treatment option in dermatology can be attributed to the Canadian team of Kennedy and Pottier, who noted in the 1980s that a naturally occurring porphyrin precursor, 5-aminolevulinic acid (ALA), could photosensitize the skin by inducing *local intracutaneous* production of protoporphyrin IX (PpIX; see Fig. 135.1). Their successful treatment of non-melanoma skin cancers with topical ALA plus broadband red light abrogated the two major disadvantages associated with systemic photosensitizers (see above)[4]. The elegance of using topical ALA for PDT consists of how it takes advantage of the endogenous porphyrin biosynthetic pathway (which is present in all nucleated cells) in order to generate PpIX from ALA. The simplicity of this approach greatly facilitated clinical research, with the bulk of clinical studies and experience emanating, to date, from Europe. Although almost a century passed from when Raab and Von Tappeiner conducted their seminal studies to the initial regulatory approval of porfimer sodium, the use of topical ALA (Levulan®) plus blue fluorescent light (Blu-U®) for the treatment of actinic keratoses was approved by the US FDA in 1999, just one decade after the first original publication by Kennedy and colleagues[4]. More recently, topical methyl aminolevulinate (mALA; Metvixia®), an esterified congener of ALA, in combination with red LED (light-emitting diode) light (Aktilite®), has been approved in a number of countries for dermatologic PDT.

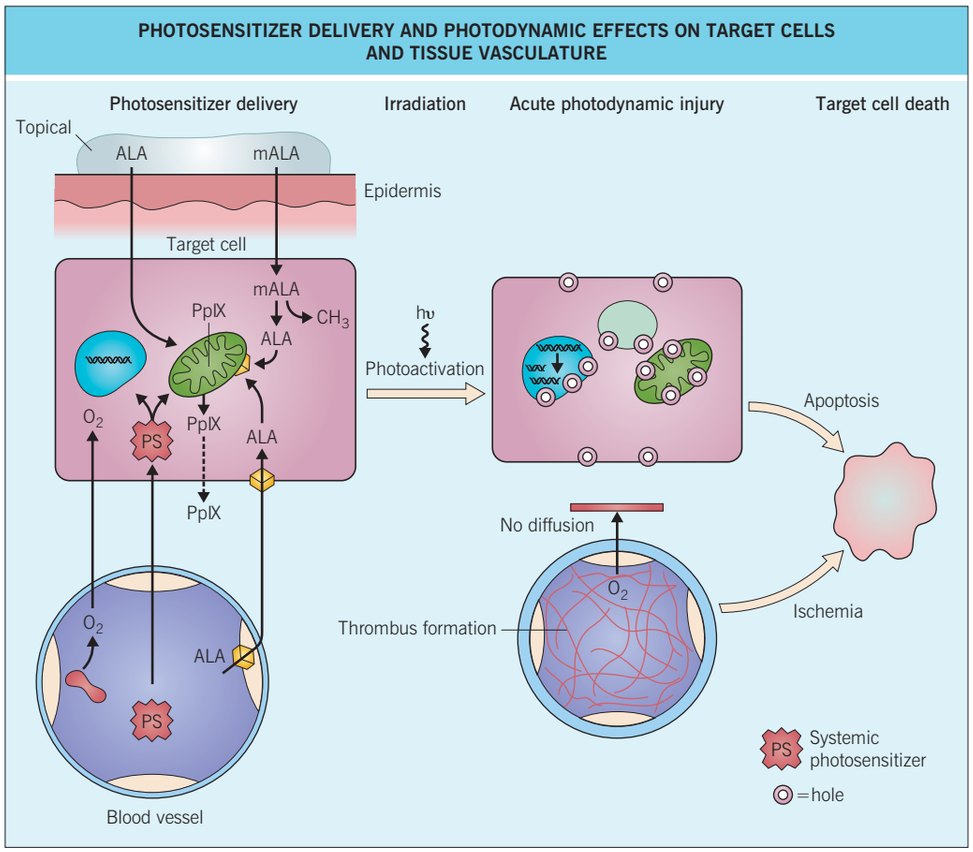

Fig. 135.1 Photosensitizer delivery and photodynamic effects on target cells and tissue vasculature. Topical photosensitizers 5-aminolevulinic acid (ALA) and methyl aminolevulinate (methyl-esterified ALA; mALA) diffuse through the stratum corneum into target epithelial cells. Systemic photosensitizers arrive through the bloodstream. Oxygen is delivered via erythrocyte circulation. ALA derived from any source is converted to protoporphyrin IX (PpIX) within mitochondria. PpIX then leaks from the mitochondria to other cellular structures. Systemically delivered photosensitizers concentrate within endothelial cells and diffuse through the interstitium to target cells. After there has been sufficient time for photosensitizer partitioning to subcellular structures, target tissue is irradiated with photoactivating light. During acute photodynamic injury, plasma and nuclear membranes lose integrity. Acute injury in endothelial cells leads to thrombus formation and vascular collapse. Target cell and tissue oxygen delivery cease. Both apoptosis and ischemic necrosis contribute to irreversible target cell injury and death.

PDT – PHOTOCHEMISTRY, PHOTOBIOLOGY AND MECHANISM OF ACTION

PDT is superficially analogous to PUVA (psoralen plus UVA light) therapy to the extent that both of these treatment modalities involve the administration of photosensitizers followed by exposure to specific wavelengths of light. Mechanistically, both involve exogenous chromophores that transfer photon energy from light to drive specific photochemical reactions within the skin. Nevertheless, there are important differences between PDT and PUVA (Table 135.1), the most fundamental of which is the fact that, by definition, PDT generates singlet oxygen.

PDT Photochemistry

The transfer of energy from light to tissue can be illustrated diagrammatically by considering the resting and excited states of the molecules involved in photochemical reactions (Fig. 135.2). The photosensitizer is delivered to or generated within the target tissue in its ground, lower-energy resting state. Its efficiency as a chromophore for absorbing light energy is governed by its absorption spectrum (Fig. 135.3). If light of an appropriate wavelength is used to irradiate the photosensitizer within tissue, photon absorption occurs and the photosensitizer is excited to a higher-energy "singlet" state. The excited singlet is short-lived, lasting nanoseconds, and then undergoes intersystem crossing to a more stable "triplet" state which has a lifetime on the order of microseconds. The "triplet" photosensitizer species can transfer its energy to molecular oxygen, yielding singlet oxygen ($^1O_2$), and as a result, returns to its resting ground state. Photochemical reactions that are mediated by oxygen are referred to as type II photochemical or photosensitized reactions. The singlet oxygen thus generated reacts with a variety of cellular components, including lipids, proteins and nucleic acids. The efficiency by which a given photosensitizer generates singlet oxygen from light can be expressed as its quantum yield; photosensitizers with a high quantum yield are better suited for clinical PDT.

Singlet oxygen is by no means the only active intermediate generated by the triplet photosensitizer. A variety of other reactive oxygen species, including peroxides (H_2O_2), superoxide anion (O_2^-) and hydroxyl radicals (.OH), are generated from molecular oxygen and undoubtedly contribute to the overall biologic effect. Singlet oxygen and other reactive oxygen species can also interact chemically with the photosensitizer itself, leading to its inactivation by a process known as photobleaching. In this way, the PDT process can in part shut itself off automatically.

Light within the visible spectrum is typically used for PDT. This is because ultraviolet light has limited tissue penetration and infrared radiation (>850 nm) does not possess sufficient photon energy to trigger the transformation of molecular oxygen into singlet oxygen via an excited photosensitizer intermediary.

When PDT photosensitizers are excited to their singlet states, they can alternatively return to their ground state via the emission of a

PHOTODYNAMIC THERAPY VERSUS PUVA THERAPY	
SIMILARITIES	
• Chromophore is an exogenous drug • Photosensitizer can be topical or systemic • Specific wavelengths of light are used to activate photosensitizer within tissue • Broad range of potential dermatologic applications	
DIFFERENCES	
PDT	**PUVA**
• Topical photosensitization based on ALA and its derivatives relies on the endogenous metabolism of prodrugs	• Topical psoralen is active in its native form as administered
• Systemic PDT photosensitizers are administered parenterally	• Systemic psoralens are administered orally
• Visible light used for photosensitizer activation	• UVA light activates psoralens
• Type II photochemical reactions convert molecular oxygen to singlet oxygen	• Type I photochemical reactions generate covalent adducts between psoralens and DNA
• Can be used to treat non-melanoma skin cancer	• Carcinogenic

Table 135.1 Photodynamic therapy (PDT) versus PUVA (psoralens plus UVA light) therapy.

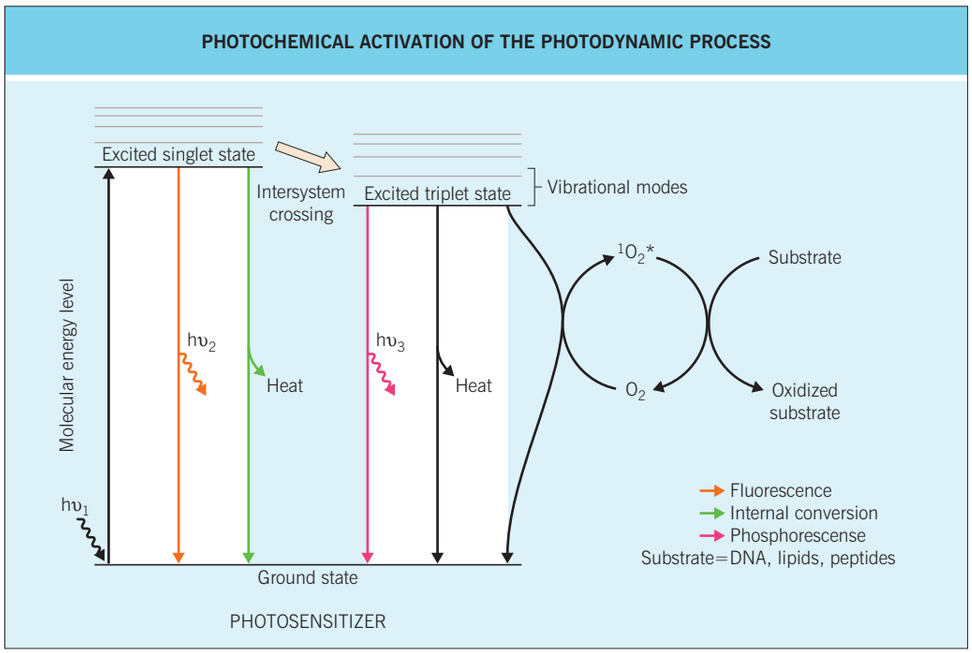

Fig. 135.2 Photochemical activation of the photodynamic process and the generation of reactive singlet oxygen: the Jablonski energy state diagram. The photosensitizer is delivered to or generated within the target tissue in its ground, lower-energy resting state. If light of an appropriate wavelength is used to irradiate the photosensitizer within tissue, photon absorption occurs and the photosensitizer is excited to a higher-energy "singlet" state. The excited singlet is short-lived, lasting nanoseconds, and then undergoes intersystem crossing to a more stable "triplet" state which has a lifetime on the order of microseconds. The "triplet" photosensitizer species can transfer its energy to molecular oxygen, yielding singlet oxygen ($^1O_2$), and as a result, returns to its resting ground state. See PDT Photochemistry section for additional details. *Excited state.

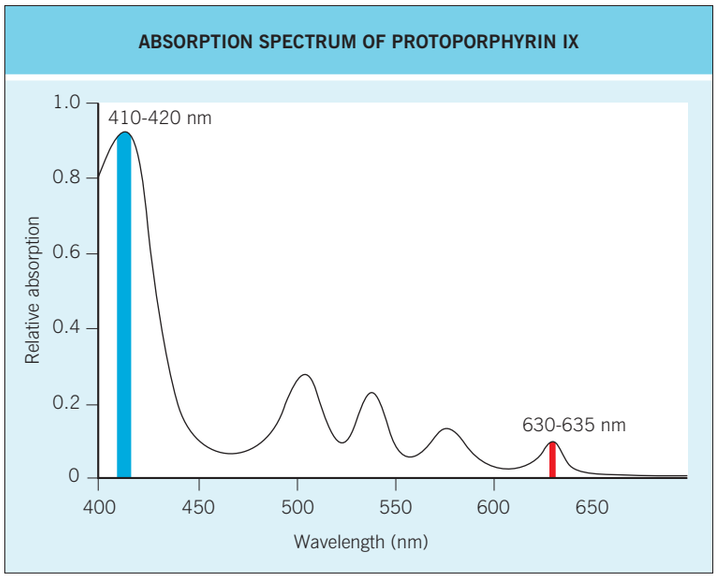

Fig. 135.3 Absorption spectrum of protoporphyrin IX (PpIX). The absorption spectrum depicts the efficiency of absorption of light as a function of wavelength. It reveals the major absorption (photoactivation) peaks of PpIX. The blue (410–420 nm) and red (630 nm) wavelengths are typically used to activate PpIX in photodynamic therapy.

photon. This emission of light by the photosensitizer is termed fluorescence and the latter property permits, with Wood's lamp illumination (365 nm), direct visualization of photosensitizer accumulation or photobleaching within tissue. Because of minor energy dissipation during the singlet state, the actual energy of the emitted fluorescence photon is typically slightly lower than that of the initially absorbed photon; therefore, the fluorescence signal is of a higher wavelength (red- or "Stokes"-shifted) than the ultraviolet-A (UVA) light emitted by a Wood's lamp. Another pathway whereby an excited singlet can return to the ground state is non-radiative decay in which heat is released. This latter photothermal pathway is the primary mechanism of action for lasers and intense pulsed light (IPL) sources.

By way of comparison to PUVA, UVA absorption by a psoralen molecule elevates it to an excited state. The latter then reacts directly with biomolecules such as DNA without any requirement for oxygen as an intermediary. These non-oxygen-dependent processes are customarily termed type I photochemical or photosensitized reactions.

Photobiologic Mechanisms of Action

As previously noted, type II photochemical (photosensitized) reactions require oxygen in order to generate reactive oxygen species, with singlet oxygen being the most important reactive oxygen species in PDT. The net biologic effects of singlet oxygen are presumably dependent upon the extent and location of its production. Although the exact and most relevant molecular sequence of reactions initiated by singlet oxygen has not been determined, oxidative damage (including to cellular membranes) is known to trigger cellular injury and apoptosis. For a given PDT clinical effect or indication, the specific mechanism of action depends on the target tissue, the photosensitizer and its mode of delivery, subcellular photosensitizer localization, and the overall drug–light dose delivered. For example, systemic photosensitizers are known to preferentially localize to the vascular bed of tumors. Light activation then leads to vascular collapse and ischemic tumor necrosis (see Fig 135.1)[5]. In contrast, when topical ALA is applied to an epidermal carcinoma such as Bowen's disease, PpIX accumulates within the actual tumor cells, with direct cytotoxicity upon light activation.

At a high drug–light dose, greater levels of singlet oxygen are presumably generated during PDT, leading to necrotic tissue damage. With lower levels of drug and/or light, damage is more limited, with apoptotic changes in a fraction of the cells. Because PDT is oxygen-dependent, target tissues that are hypoxic may prove relatively resistant to the desired therapeutic effect.

Tissues exposed to PDT can become inflamed as a result of normal host responses to injury as well as activation of specific immunologic reactions. As with the underlying mechanism of action, the type of immunologic reaction varies depending upon the target and mode of PDT delivery. In animal models of contact hypersensitivity, PDT suppresses local and systemic immune responses in addition to reducing epidermal Langerhans cells[6]. There is also evidence that the photosensitizers used in PDT can target activated T cells[7,8], providing one rationale for using PDT to treat inflammatory disorders such as psoriasis. Microbes, including viruses, bacteria, fungi and parasites, may be susceptible to singlet oxygen, and there is a growing number of clinical studies attesting to the potential utility of PDT in the treatment of skin infections.

PDT Selectivity

PDT was initially conceived and developed as a method for achieving selective tumor destruction. Several factors lead to this selectivity (Table 135.2). In neoplasms, where cellular metabolism is higher than normal, local factors such as enhanced perfusion, vascular and lymphatic hyperpermeability, pH and lipoprotein receptors on target cells may lead to preferential accumulation and retention of photosensitizers within the

MECHANISMS FOR ACHIEVING SELECTIVITY DURING PHOTODYNAMIC THERAPY	
Photosensitizer effects	**Light effects**
• Selective photosensitizer retention • Selective photosensitizer biodistribution and uptake • Ability to limit surface area of photosensitizer application (non-systemic drugs) • Variation of the time between drug administration and light exposure	• Spatial confinement of irradiation to the target • Wavelength dependence for light penetration into skin • Photobleaching of photosensitizer • Interstitial delivery of light via fiberoptic probes

Table 135.2 Mechanisms for achieving selectivity during photodynamic therapy.

tumor. With topical PDT, the surface area of drug application can be confined, thus limiting the zone of photosensitization. There are also inherent differences in the permeability barrier of skin lesions such as basal cell carcinomas, actinic keratoses, and psoriasis that facilitate the uptake of ALA-like prodrugs into the epidermis and dermis. In addition, the temporal differences in how photosensitizers are partitioned between diseased versus normal tissue can be exploited to enhance selectivity; by varying the time delay (that is typically required between drug administration and light exposure), a more advantageous photosensitizer ratio between diseased and normal skin can be achieved. Determining the optimal time for this delay or incubation period is usually a matter of systematic empiric testing.

Selectivity is also achieved by manipulation of the light component of PDT (see Table 135.2). At the simplest level, this entails restricting the area of light exposure on the skin, usually with the lesion in the center plus a limited margin of adjacent normal-appearing skin. Most clinical photosensitizers exhibit multiple absorption maxima across the visible spectrum (see Fig. 135.3). Because light propagation within tissue is wavelength-dependent, the use of shorter wavelengths, i.e. blue light, will confine the PDT effect to primarily the epidermis, while red light will exert a deeper effect. For deeper targets within the skin, fiberoptic probes can be implanted interstitially in the dermis or subcutaneous tissue to deliver light.

Photobleaching is another mechanism by which PDT can exert selectivity. A certain threshold "drug–light PDT dose" exists for effects such as tissue necrosis. If the level of photosensitizer within *normal* tissue is below this threshold, light exposure will induce predominantly photobleaching rather than generating sufficient singlet oxygen to damage tissue. On the other hand, within the adjacent target site where the photosensitizer concentration is presumably above the required threshold, singlet oxygen generation will prevail.

Photosensitizer selectivity can readily be demonstrated given that PDT molecules usually have high fluorescence quantum yields that can actually be visualized (Fig. 135.4). Via fluorescence examination with a Wood's lamp, the margins of skin tumors can be delineated and this technique has been proposed as a diagnostic approach to non-melanoma skin cancers irrespective of any PDT intervention[9]. More accurate tumor delineation can be very helpful in planning treatment approaches to non-melanoma skin cancer. However, the fluorescence intensity, as assessed visually or by instrumentation, does not necessarily correlate with the ensuing PDT reaction or ultimate clinical outcome. Immediately, at the conclusion of the light exposure stage, the phenomenon of photobleaching can be confirmed visually by the absence or marked reduction of fluorescence.

Fig. 135.4 Fluorescence of intratumor protoporphyrin IX (PpIX) when illuminated by a Wood's lamp (365 nm). A Superficial basal cell carcinoma (BCC). **B** Following application of topical methyl aminolevulinate (mALA) for 3 hours under occlusion, the BCC demonstrates red fluorescence due to accumulation of PpIX.

Advantages and Limitations of PDT

Advantages of PDT include its relative conceptual simplicity as well as the accessibility of the skin to direct application of photosensitizing drugs and activating light. PDT photosensitizers typically have minimal dark toxicity (i.e. toxicity in the absence of light) and are therefore relatively safe. PDT can also be used in patients with a variety of comorbidities, including those who are anticoagulated, and general anesthesia is rarely required or even used for cutaneous PDT. There is a broad range of potential clinical applications and an ability to fine-tune and modulate the therapeutic effect by altering any one of several different treatment parameters, including drug dose, incubation time, light fluence, exposure time or field size. When used to treat actinic keratoses and superficial non-melanoma skin cancer, PDT has been shown to lead to better cosmesis than conventional approaches such as cryotherapy and surgery; perhaps this is due to its selective properties.

Nonetheless, PDT is far from being a perfect therapeutic modality as it has inherent limitations. The generation of singlet oxygen within the target site is critically dependent on the ability to deliver both photosensitizer and light to this site in the presence of oxygen. Systemic administration results in more widespread distribution of photosensitizer, which is advantageous when treating extensive areas of involvement or for delivering drug to thicker lesions such as invasive carcinomas. However, systemic drug delivery is via the intravenous route, and as a consequence, there is generalized cutaneous photosensitivity. Topical photosensitization is limited by drug penetration into the epidermis and dermis, while light delivery by surface illumination is limited by the depth of penetration of visible light. Although wavelengths such as infrared are more penetrating, they do not have

sufficient photon energy to generate singlet oxygen. Thus, PDT is useful primarily for superficial cutaneous tumors and diseases.

The fact that there are multiple treatment parameters can also be a disadvantage in that the multiplicity of combinations and permutations makes it complicated to determine the conditions necessary for optimal clinical outcomes. Moreover, the literature is replete with an array of different reported parameters, making it difficult to standardize treatment regimens and evaluate clinical evidence of efficacy, even for the same indication. The commercially recommended treatment parameters are based on strict clinical trial protocols and do not afford much flexibility in terms of dosing. From the patient perspective, intraoperative local pain at the site of light exposure can be intense and even intolerable, and for many patients this represents a significant disincentive for repeat treatments. Finally, commercially available PDT systems (i.e. photosensitizers and light sources) incur significant cost, thereby posing a practical barrier to accessing a treatment that is fundamentally based on a naturally occurring compound combined with visible light.

COMPONENTS OF PDT

In PDT, the physician provides two of the three essential components – the photosensitizing drug and light. A wide range of photosensitizers (Fig. 135.5) have been developed and evaluated along with a multiplicity of different light sources and delivery systems. Of these, only two commercial systems are currently approved for use by the US FDA: ALA plus blue light and mALA plus red light.

Photosensitizers

Topical photosensitizers

Although topical photosensitizers based on the porphyrin backbone have been developed and evaluated, none to date have become practical, on a clinical or commercial level, for dermatologic use. For practical purposes, topical PDT relies primarily on the ALA prodrug approach.

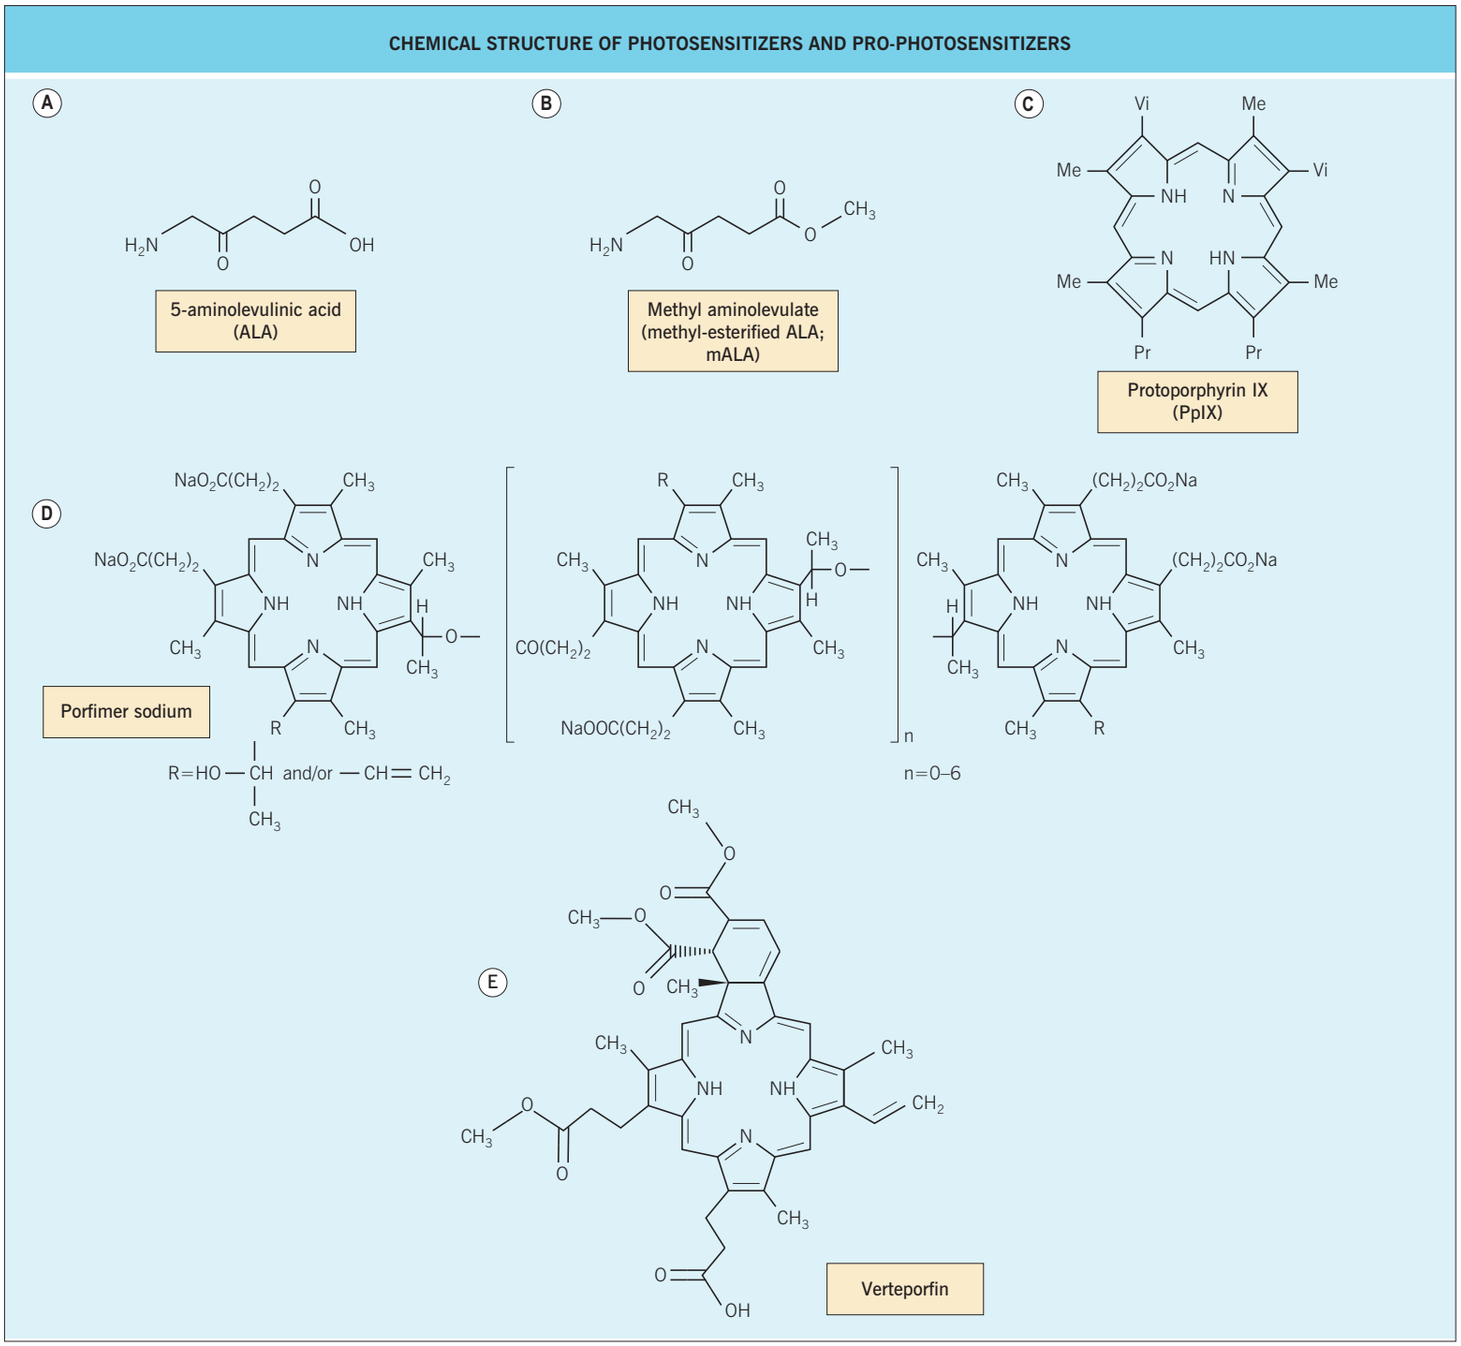

Fig. 135.5 Chemical structures of photosensitizers and pro-photosensitizers. A 5-aminolevulinic acid (ALA). **B** Methyl aminolevulinate (methyl-esterified ALA; mALA). **C** Protoporphyrin IX (PpIX). **D** Porfimer sodium. **E** Verteporfin. Me, methyl; Pr, propionic acid; Vi, vinyl.

TOPICAL PHOTOSENSITIZER PRODRUGS USED FOR DERMATOLOGIC PHOTODYNAMIC THERAPY		
Drug – generic name	5-aminolevulinic acid HCl (ALA)	Methyl aminolevulinate (methyl-esterified ALA; mALA)
Drug – trade name® and formulation	Levulan, 20% hydroalcoholic solution	Metvixia, 16.8% cream
Photosensitizer produced	PpIX	PpIX
Treatment λ (nm)	417, 630	630
Time period between administration and irradiation (incubation time)	14–18 h, but often reduced to 1–4 h with retention of efficacy and less phototoxicity	3–4 h under occlusion
Light source	Blue fluorescent lamp* Various other sources also used	Red LED (light emitting diode) lamp* Various other light sources also used
Cutaneous FDA-approved indications†	AKs	AKs
Common off-label uses	BCC, Bowen's disease, mycosis fungoides, photoaging, acne	BCC, Bowen's disease, mycosis fungoides, photoaging, acne

*FDA-approved light source.
†At the time of writing.

Table 135.3 Topical photosensitizer prodrugs used for dermatologic photodynamic therapy. AKs, actinic keratoses; BCC, basal cell carcinoma; FDA, Food and Drug Administration; PpIX, protoporphyrin IX.

Aminolevulinic acid (ALA) and methyl aminolevulinate (mALA) prodrugs

Aminolevulinic acid (ALA) and methyl aminolevulinate (mALA) represent prodrugs that are converted within the skin into PpIX (Table 135.3). A familiarity with porphyrinogenesis in mammalians aids in understanding the pharmacology of ALA and its congeners. ALA (5-aminolevulinic acid, δ-aminolevulinic acid) is synthesized in all nucleated cells, and it is an intermediate compound in the heme biosynthetic pathway (see Fig. 49.1); ALA synthase catalyzes the formation of ALA from succinyl-CoA and glycine. The latter reaction represents the rate-limiting step in this pathway and is inhibited by heme.

When pharmacologic quantities of ALA are supplied to cells as in PDT, this regulatory step is bypassed, leading to an intracellular accumulation of PpIX, which is photodynamically active. The formation of PpIX is the penultimate step in the *de novo* synthesis of heme, with the formation of heme requiring the addition of Fe^{2+} to PpIX via ferrochelatase. The effect of topical ALA can be enhanced by using an iron chelator to decrease heme formation, thereby allowing unfettered ALA synthase activity (due to a lack of feedback inhibition). The net result is a greater concentration of PpIX and an enhanced PDT effect[10]. Of note, PpIX is synthesized within mitochondria (see Fig. 135.1) and then diffuses to cellular membrane systems such as the endoplasmic reticulum and the plasma membrane.

ALA can be administered via topical, oral or parenteral routes, and for cutaneous indications, the topical approach is preferred due to its simplicity. Unlike fully formed porphyrin molecules that are relatively large, ALA is small and simple and crosses the surface permeability barrier readily via active transport mechanisms. Within the skin, the absorbed ALA induces porphyrinogenesis, thereby inducing a porphyric state at the cellular level. Since the skin's barrier function is often impaired in diseased states, there can be selective PpIX generation due to enhanced ALA absorption. In some PDT applications, the skin is first prepared by gentle curettage of excess surface scale and crust, and this may also promote topical drug absorption. Within the skin, PpIX accumulates in the epidermis and sebaceous glands due to its lipophilicity[11].

The carboxyl moiety of ALA can be esterified by a variety of alkyl groups, the simplest of which results in methyl aminolevulinate (mALA). Substituted ALA congeners are absorbed into the skin by passive and active mechanisms different from those of ALA, and upon their uptake into cells, these substituents are hydrolyzed to yield free ALA (see Fig. 135.1). Esters other than mALA are currently investigational agents only, with the exception of hexyl-aminolevulinate which is used for bladder carcinoma in Europe. Both ALA and mALA are considered prodrugs or pro-photosensitizers since the skin actually generates the active photosensitizer from these exogenous compounds. The relative merits of ALA versus mALA as a topical photosensitizer have been actively debated on various theoretical grounds, but there are no clear results from clinical studies to settle this issue.

ALA has been compounded in a variety of different vehicles for topical application, and in North America it is commercially available in a 20% preparation marketed as Levulan®. The latter is a topical hydroalcoholic solution that is freshly prepared immediately prior to application. Its labeled use is for treating actinic keratoses, although multiple off-label applications have been explored and described (see Table 135.3). Time is required to allow ALA to be absorbed and converted to PpIX, with a recommended incubation period of 14–18 hours without occlusion prior to exposure to blue fluorescent light. Many clinicians typically use a shorter incubation period of 1–4 hours, instead of the recommended 14–18 hours which was based primarily on controlled clinical trials.

Mechanistically, mALA is similar in principle to ALA; it is available in a 16.8% cream formulation (Metvixia®) that must be stored in a refrigerator. mALA is applied for 3–4 hours under occlusion prior to exposure to red light from an LED. mALA has also been used for multiple different applications but its labeled use is only for actinic keratoses and superficial non-melanoma skin cancers in various countries (see Table 135.3).

Photochemically, PpIX has an absorption spectrum similar to that of other porphryins (see Fig. 135.3). There is a prominent, broad blue Soret absorption band along with four smaller "Q" bands between 500 and 635 nm. PpIX will be converted to its singlet and triplet states more efficiently if pumped by light at one or more of these absorption maxima.

Systemic photosensitizers

Hematoporphyrin derivative and porfimer sodium are considered first-generation PDT photosensitizers. Both are preferentially retained by neoplastic tissue and thus provide some degree of treatment selectivity. Hematoporphyrin derivative and porfimer sodium are complex mixtures of covalently linked esters and ethers of dimeric and oligomeric hematoporphyrin subunits that have a relative absorption maximum near 630–635 nm (see Fig. 135.5). Unfortunately, these first-generation agents also persist in the skin for several weeks, resulting in marked photosensitivity to ordinary outdoor light.

Second-generation porphyrin photosensitizers were developed with pharmacokinetic profiles that favored more rapid elimination from the skin, resulting in shorter periods of generalized photosensitivity, e.g. 1–3 days in the case of verteporfin[12]. Systemic second-generation photosensitizers are pure substances that have a defined composition and are based on the tetrapyrrole porphyrin backbone. They exhibit absorption maxima that are at longer wavelengths (660–700 nm) than those of the first-generation agents, thus allowing a more penetrating light to be used for drug activation. Second-generation photosensitizers have been explored in limited studies for non-melanoma skin cancer, psoriasis and port-wine stains, but the only FDA-approved second-generation agent is verteporfin and its indication is for PDT of age-related macular degeneration. Although systemic porphyrins are not used to any great extent for treating skin disease, dermatologists should nonetheless be familiar with their medical use given their propensity to cause phototoxic cutaneous drug reactions.

Light Sources

Choosing a light source for PDT depends fundamentally on three considerations. First, the spectral output of the light should include a waveband that corresponds to one or more of the peaks in the absorption spectrum of the photosensitizer. Next, the desired depth of effect determines which photosensitizer absorption peak should be chosen. For PpIX, red light activation will provide a deeper clinical effect as compared to blue light. The surface area to be treated must also be taken into account. For example, while lasers can provide precise

LIGHT SOURCES FOR PHOTODYNAMIC THERAPY (PDT)			
Light source	**Spectral output**	**Commercial name**	**Properties and comments**
Sunlight	Broadband	–	• Universally accessible, although highly variable • Difficult to standardize light dose • Significant risk of excess phototoxicity
Incandescent	Broadband	–	• Optical filters used to produce specific wavebands • Slide projector is an example
Arc lamp	Broadband	–	• Optical filters used to produce specific wavebands
Metal halide lamp	Broadband	–	• Optical filters used to produce specific wavebands
Fluorescent lamp	Broadband	Blu U®	• Blue output to match the Soret band • Recommended fluence of 10 J/cm^2 • FDA-approved for use with ALA to treat actinic keratoses
Light-emitting diodes (LED)	Narrowband	Aktilite®	• Red output • Recommended fluence of 37 J/cm^2 • FDA-approved for use with mALA to treat actinic keratoses; also approved in other countries for treating superficial BCC and Bowen's disease
Lasers	Monochromatic	Various	• Relatively expensive • May generate photothermal effects in addition to PDT • Small exposure field • Output can be continuous or pulsed
Intense pulsed light (IPL)	Broadband	Various	• Relatively expensive • May generate photothermal effects in addition to PDT

Table 135.4 Light sources for photodynamic therapy (PDT). ALA, 5-aminolevulinic acid; BCC, basal cell carcinoma; FDA, Food and Drug Administration; mALA, methyl aminolevulinate.

irradiation, they may be impractical for treating broad or extensive surfaces.

Several different types of light sources have been used for PDT (Table 135.4), but only two of these are approved by the FDA. These commercial devices are relatively simple to use and can be powered by standard electrical outlets. Although lasers are essential for endoscopic PDT applications in which fiberoptic probes are required, they are optional when treating the skin. For PDT, continuous wave lasers are usually configured as argon- or KTP-pumped dye lasers emitting red light; pulsed dye lasers have been used primarily for the treatment of actinic keratoses with ALA. Of note, non-monochromatic sources are simpler, cheaper and more efficient than lasers for PDT. In theory, natural sunlight can also be used for drug activation in PDT since it contains all of the appropriate wavelengths, and pilot clinical studies have demonstrated its potential efficacy[13]. The main drawback to sunlight is the inability to accurately control the light dose delivered to the skin and the increased risk of excessive phototoxicity. Therefore, at present, it is not routinely recommended outside of a research setting.

Regardless of the specific light source, in PDT the light dose is measured and delivered in a manner analogous to conventional phototherapy. The ***irradiance*** of the lamp is specified in units of W/cm^2, and this represents the power density over a surface area unit. Irradiance (or power density) depends on the light source itself, and irradiance can vary based on the lamp's age, overall operating conditions, and the distance from the lamp to the skin target. The absolute light dose used to activate the photosensitizer is also known as the ***fluence*** and is measured in J/cm^2. The ***exposure time*** in seconds required to deliver a specified fluence can be determined from the formula:

$$\text{exposure time} = \frac{\text{fluence (J/cm}^2\text{)}}{\text{irradiance (W/cm}^2\text{)}}$$

PDT Dosimetry

Although PDT is deceptively simple in concept, there is a multitude of considerations in determining the appropriate doses of photosensitizer and light. Current clinical PDT dosing guidelines have been determined by systematic as well as semi-empiric clinical investigations; nevertheless, they are based on several basic concepts unique to PDT. The net production of singlet oxygen depends on both the amount of photosensitizer and the fluence of light delivered to the target. A certain degree of reciprocity exists between these two components, in that a high photosensitizer level combined with a low fluence can in theory produce the same amount of singlet oxygen as a low concentration of photosensitizer activated by a high fluence. The overall "PDT dose" can thus be viewed mathematically as a "drug × light dose" product so that an equivalent clinical effect can be achieved using different combinations of drug and light. However, for topical PDT, there are upper limits as to the amount of photosensitizer that can actually be delivered to the skin, due to absorption issues.

Another important limit to the principle of drug–light dose reciprocity relates to the irradiance of the activating light. At very high irradiances, there is significant heat production due to both non-radiative photosensitizer absorption/relaxation and nonspecific light absorption by other tissue chromophores. This leads to photothermal effects superimposed on the PDT process itself. For example, utilization of a yellow pulsed dye laser to activate PpIX within actinic keratoses will induce a combination of PDT plus photothermal reactions since each laser pulse has a very high peak irradiance[14]. In some instances, these added photothermal effects may possibly be desirable, but to date this approach has not been systematically studied for cutaneous PDT. At lower irradiances, on the other hand, there is evidence that the pain associated with PDT might be reduced[15].

Other factors that can influence the PDT effect include the waiting period between drug administration and light exposure and the mode by which the light is delivered. There must be a sufficient "incubation" time for the photosensitizer to specifically accumulate within the target sites prior to activation. A longer incubation time for topical ALA or mALA may achieve a higher level of photosensitization without the need for a higher prodrug concentration. An interesting and potentially useful variation in light delivery is to fractionate the total light dose into a series of two or more separate exposures, each punctuated by defined intervals. The potential net effect of fractionating the light dose is achieving a greater overall PDT effect even without applying more drug[16]. Mechanistically, there are several reasons why this can happen. During PDT, molecular oxygen is consumed, and a pause in light exposure allows oxygen to be replenished via vascular reperfusion and diffusion. Likewise, this pause may also allow more photosensitizer to be either: (1) synthesized *de novo* from the residual ALA that may still be present within viable skin cells (following topical application); or (2) delivered via the bloodstream (systemic photosensitizers).

INDICATIONS

The applications of PDT in dermatology have extended far beyond its initial use for eradicating skin cancers. Although the ever-expanding use of PDT has been partly random and empiric, certain pharmacologic properties provide a rational basis for many of these proposed and accepted indications. PDT agents can photosensitize neoplastic, inflamed and vascular tissues, modulate immunologic processes, localize to the pilosebaceous unit, and cause lethal damage to microbes. Historically, the field has evolved from myriad scattered case reports to larger controlled trials. To date, good-quality clinical evidence outside of cutaneous oncology is limited; for the most part,

Paired comparison to topical 5-FU[19]	14 (hand AKs)	ALA 20% under occlusion	4 h	Red light (580–740 nm) at 150 J/cm^2 and mean irradiance of 86 mW/cm^2	Total surface area of AKs reduced by 70% (73% for 5-FU)	• 5% 5-FU cream was applied twice daily for 3 weeks • Assessed over 6 months • Pain and erythema similar in two groups*
Comparison with cryotherapy[20]	193 (95 cryotherapy controls)	mALA 16% under occlusion	3 h	Red light (570–670 nm) at 75 J/cm^2	69% (75% for cryotherapy)	• Prior to PDT or cryotherapy, superficial curettage was performed • Two cycles of cryotherapy • Excellent or good cosmetic outcome: PDT, 98%; cryotherapy, 91%
Comparison to cryotherapy or vehicle[21]	204	mALA 16% under occlusion	3 h	Red light (570–670 nm) at 75 J/cm^2	91% at 3 months (68% for cryotherapy and 30% for vehicle alone)	• Two cycles of PDT • Single freeze–thaw cryotherapy • Superior cosmesis with PDT versus cryotherapy
Comparison to vehicle[22]	80	mALA 16% under occlusion	3 h	Red light (570–670 nm) at 75 J/cm^2	89% at 3 months (38% for vehicle alone)	• Two cycles
Vehicle-controlled[23]	243	ALA 20%	14–18 h	Blue fluorescent lamp at 10 J/cm^2	89% at 12 weeks (13% for vehicle alone)	• Two sessions of PDT allowed
Vehicle-controlled in organ transplant recipients[24]	17	mALA 16% under occlusion	3 h	Red light (600–730 nm) at 75 J/cm^2	90% at 16 weeks (0% for vehicle alone)	• Two sessions of PDT
Comparison to cryotherapy; right–left intra-individual design[17]	119	mALA 16% under occlusion	3 h	Red LED light (near 630 nm) at 37 J/cm^2	89% at 24 weeks (86% for cryotherapy)	• PDT retreatment at 12 weeks allowed • Double freeze–thaw cryotherapy • Superior cosmesis with PDT
Vehicle-controlled[25]	49	mALA 16% under occlusion	3 h	Red LED light (near 630 nm) at 37 J/cm^2	86% at 3 months (52% for vehicle alone)	• Two sessions of PDT
Comparison to topical imiquimod on extremities[26]	30	ALA 20% under occlusion	4 h	Red light (570–670 nm) at 75 J/cm^2	65% at 6 months (56% for imiquimod)	• Two sessions of PDT • Imiquimod three times per week for 4 weeks; second 4-week course of imiquimod allowed 4 weeks after end of first course
*Pain and erythema was maximal at the start of therapy for PDT and at the end of therapy for 5-FU.						

Table 135.5 Prospective controlled studies of topical photodynamic therapy (PDT) of actinic keratoses (AKs). Unless noted otherwise, each patient received a single PDT session. ALA, 5-aminolevulinic acid; 5-FU, 5-fluorouracil; h, hours; LED, light-emitting diode; mALA, methyl aminolevulinate (methyl-esterified ALA).

non-oncologic uses of PDT are off-label or investigational in virtually all jurisdictions. The overwhelming majority of indications in dermatology involve photosensitization via the topical route with an ALA-type prodrug, as no systemic photosensitizers are currently approved for dermatologic use.

Oncologic

PDT is an accepted and approved treatment for actinic keratoses (AKs). For superficial carcinomas such as superficial basal cell carcinoma (BCC) and Bowen's disease (*in situ* squamous cell carcinoma), there are controlled trials on the use of topical PDT and licensed approvals vary according to country. PDT is not used for treating melanoma because of the competition between melanin and photosensitizer for light absorption.

Based on biophysical considerations alone, AKs can be treated with blue or red light, whereas only red light should be used for non-melanoma skin cancer. Multiple studies have documented that cosmesis following PDT can be superior to that following conventional therapies[17,18]. One of the ideal aspects of PDT is that it seems to be particularly practical and well suited for patients with multiple synchronous AKs or cutaneous carcinomas or evidence of field cancerization. In patients with an extensive burden of many superficial, disseminated tumors, the availability of a systemic photosensitizer would be advantageous.

Actinic keratoses (AKs)

Being superficial, AKs would not be expected to pose any major obstacles to efficacy, and clinical trials have demonstrated that up to 90% of AKs can be cleared with topical PDT[17,19–26] (Table 135.5, Fig. 135.6). Hypertrophic AKs may prove more difficult to eradicate due to drug and light penetration issues; so, prior to PDT, curettage debridement of scale is often recommended. For hypertrophic AKs, multiple treatment sessions may be required to achieve a satisfactory overall result.

AKs can be treated on a lesion-by-lesion basis, or by applying photosensitizer to a broad area of photodamaged skin harboring active lesions. A more brisk and extensive reaction may occur when applying topical ALA or mALA to a broad field and it may be reasonable to consider a shorter incubation period. The latter approach allows for concomitant treatment of subclinical AKs[27]. Actinic cheilitis represents an excellent potential PDT application since alternative treatment approaches such as surgical vermilionectomy or laser vaporization are more complicated and morbid[28].

Basal cell carcinoma (BCC)

Superficial BCCs respond well to PDT, with an expected primary clearance rate of 87% with a follow-up of 3–36 months[29] (Table 135.6, Fig. 135.7). Nodular BCCs do not appear to be as well suited to PDT as a

Fig. 135.6 Photodynamic therapy (PDT) of facial actinic keratoses. A Pre-treatment. **B** Three months following PDT utilizing topical methyl aminolevulinate (mALA; 3 hours under occlusion) plus irradiation with red light from an LED (light-emitting diode), resulting in clearing of lesions.

PROSPECTIVE CONTROLLED TRIALS OF TOPICAL PHOTODYNAMIC THERAPY OF BASAL CELL CARCINOMA						
Comparator and design (ref.)	**No. of patients or lesions**	**Topical photosensitizer (concentration)**	**Incubation time**	**Light source**	**Response rate**	**Comments**
SUPERFICIAL BCC						
Comparison with cryosurgery[30]	36 lesions (21 PDT; 15 cryotherapy)	ALA (20%) under occlusion	6 h	635 nm laser at 60 J/cm^2 and 60–100 mW/cm^2	61% for PDT at 1 year (93% for cryosurgery)	• Response rate based on histologic evaluation at 1 year • Prior to PDT, crusts, stratum corneum and lipids removed • Cryosurgery consisted of two 25–30-sec freeze–thaw cycles with a 2–4-min interval
Comparison with cryotherapy[31]	118 patients	mALA (160 mg/g) under occlusion	3 h	Red light (570–670 nm) at 75 J/cm^2	5-year recurrence rate 22% (20% recurrence rate for cryotherapy)	• Up to two additional PDT sessions if incomplete response at 3 months • Cryotherapy performed with two freeze–thaw cycles • Better cosmesis with PDT
Comparison with surgery[32]	196 patients	mALA (160 mg/g) under occlusion	3 h	Red LED light at 37 J/cm^2	12-month recurrence rate 9.3% (0% for surgery)	• PDT: two sessions 7 days apart; two sessions repeated in 3 months if incomplete response • Better cosmesis with PDT
NODULAR BCC						
Comparison to excisional surgery with ≥5 mm margins[18]	101 patients	mALA (160 mg/g) under occlusion	3 h	Red light (570–670 nm) at 75 J/cm^2	83% at 1 year (96% for surgical excision)	• PDT: two sessions 7 days apart • If incomplete response at 3 months, second course (two sessions) of PDT given • Prior to PDT, superficial curettage was performed • Better cosmesis with PDT

Table 135.6 Prospective controlled trials of topical photodynamic therapy (PDT) of basal cell carcinoma (BCC). Unless noted otherwise, each patient received a single PDT session. ALA, 5-aminolevulinic acid; h, hours; LED, light-emitting diode; mALA, methyl aminolevulinate; min, minutes; sec, seconds.

lower response rate of 53–71% has been observed[29]. More than one session of PDT may be required to treat a given BCC. Multiple BCCs arising in the context of cancer-prone genodermatoses such as nevoid basal cell carcinoma syndrome are probably a good application for PDT since multiple lesions can be treated during one session[33]. Difficult-to-treat BCCs (e.g. recurrent, sclerosing type, large volume) are probably best dealt with by Mohs micrographic surgery or radiotherapy because of the importance of achieving deep margin control.

Bowen's disease

Bowen's disease (BD) is confined, by definition, to the epidermal compartment and is thus eminently within the therapeutic range of PDT (Table 135.7). Many PDT experts consider BD to be an ideal indication since PDT can be used to treat multiple lesions as well as large, extensive plaques[37]. Tumors that behave clinically like BD but with microinvasive histology also seem to respond to PDT[38]. Invasive squamous cell carcinomas are ill-suited to PDT and clinical experience confirms this statement. BD of the genital region and extramammary Paget's disease can be appropriate targets for PDT.

Mycosis fungoides

Activated and malignant T cells can be selectively sensitized by exogenous ALA, and this is why PDT has been used to treat the mycosis fungoides form of cutaneous T-cell lymphoma. Interestingly, these lymphocytes express high levels of transferrin and have a corresponding low intracellular level of iron, conditions that favor PpIX accumulation

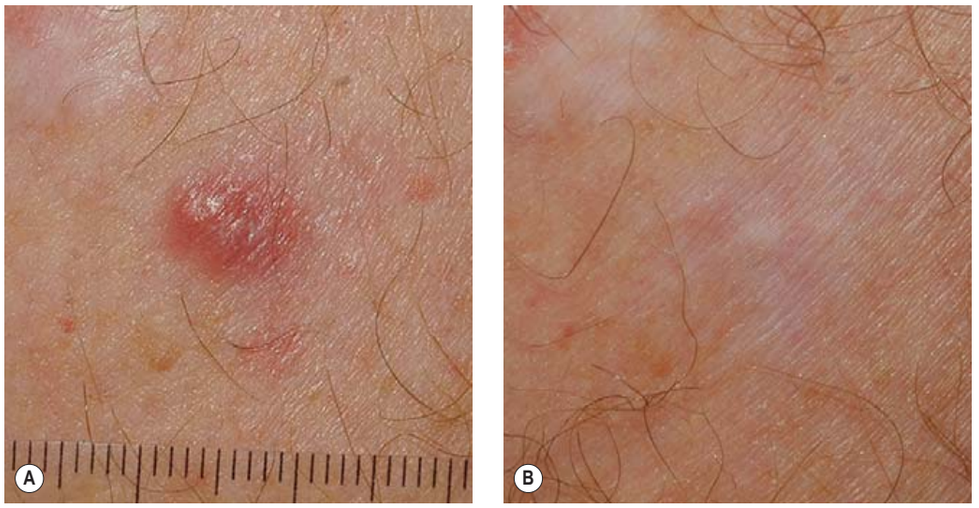

Fig. 135.7 Photodynamic therapy (PDT) of a superficial basal cell carcinoma (BCC). **A** Superficial BCC prior to treatment. **B** Two years following PDT utilizing topical methyl aminolevulinate (mALA; 3 hours under occlusion) plus irradiation with red light from an LED (light-emitting diode; 37 J/cm^2), with complete clinical resolution.

PROSPECTIVE CONTROLLED TRIALS OF TOPICAL PHOTODYNAMIC THERAPY OF BOWEN'S DISEASE (*IN SITU* SQUAMOUS CELL CARCINOMA)

Comparator and design (ref.)	No. of patients or lesions	Topical photosensitizer (concentration)	Incubation time	Light source	Response rate	Comments
Comparison with cryotherapy[34]	40 lesions (<2 cm)	ALA (20%)	4 h	Red light (615–645 nm) at 125 J/cm^2 and 70 mW/cm^2	75% [15/20 at 1 year] (50% [10/20] for cryotherapy)	• Cryotherapy (cryo) was a 20-second freeze–thaw cycle • PDT: one session • For complete clearance of non-responding tumors, cryo-treated group required 2–3 more cryo treatments (2 recurrences at 1 year) and PDT-treated group required 1 more PDT treatment (0 recurrences)
Comparison with 5-FU[35]	40 patients	ALA (20%)	4 h	Red light (615–645 nm) at 100 J/cm^2	82% at 1 year (48% for 5-FU)	• 5-FU daily for 1 week followed by twice daily for 3 additional weeks • PDT repeated after 6 weeks if necessary
Comparison with 5-FU and cryotherapy[36]	225 patients	mALA (160 mg/g) under occlusion	3 h	Red light (570–670 nm) at 75 J/cm^2	80% at 1 year (69% for 5-FU and 67% for cryotherapy)	• PDT repeated in 1 week; if necessary, additional PDT (1 cycle [2 sessions]) in 3 months • 5-FU applied for 4 weeks • Single freeze–thaw cycle for cryotherapy

Table 135.7 Prospective controlled trials of topical photodynamic therapy (PDT) of Bowen's disease (*in situ* squamous cell carcinoma). Unless noted otherwise, each patient received a single PDT session. ALA, 5-aminolevulinic acid; BD, Bowen's disease; 5-FU, 5-fluorouracil; h, hours; mALA, methyl aminolevulinate.

(see above)[7]. Because sufficient topical ALA can reach the target T cells within the epidermis and dermis, an appreciable clinical effect can be observed. Comparative studies are lacking, although some case series are quite encouraging[39].

Cutaneous metastases

PDT's historical roots in dermatology lie in its initial use during the 1970s to treat intracutaneous metastases[2]. Such treatment is palliative, and, depending on the thickness of the nodule, systemic rather than topical photosensitization may be preferable. In the past, PDT was often employed to treat advanced cancers, but it is now widely accepted that PDT is far more appropriate for treating superficial carcinomas.

Non-oncologic PDT Applications

Acne

Not only did early studies demonstrate that exogenous ALA could induce PpIX formation within the skin, they also noted the preferential accumulation of active photosensitizer and selective phototoxicity within the pilosebaceous unit[11]. In addition, singlet oxygen exerts antibacterial and anti-inflammatory effects. These effects, plus the increasing practical impediments to using oral isotretinoin, have provided a powerful impetus to developing PDT regimens for acne. The initial systematic study was published in 2000, where sustained improvement for 20 weeks following treatment with ALA and red light was observed[40]. The therapeutic effect correlated histologically with sebocytopenia, suggesting that sebaceous gland involution was a desirable and achievable endpoint. Since then, a variety of different treatment regimens have been described, but to date there have been no comparative trials with conventional acne therapies. Published clinical studies have focused primarily on high-dose or low-dose treatment regimens with reports of varying results and putative mechanisms[41]. High-dose PDT is associated with more durable responses but at the expense of increased pain and local reactions (Fig. 135.8), whereas with low-dose PDT, improvement is more modest and transient. There remains no consensus as to the optimum treatment parameters for achieving either type of anti-acne effect.

Parenthetically, it should be noted that *Propionibacterium acnes* produces cutaneous porphyrins, which can be readily demonstrated by Wood's light examination of any sebaceous-dense area, including normal skin. Exposure to high-intensity blue light alone, in the absence of any exogenous PDT drug, can lead to clinical improvement of up to two-thirds of inflammatory acne lesions after eight treatment sessions[42].

Photoaging

When used to treat non-melanoma skin cancer and AKs, subjectively PDT is thought to produce cosmetically favorable results, including improvement of sun-damaged skin (Table 135.8). Well-designed trials directly comparing PDT to non-PDT treatments in which photoaging

Fig. 135.8 Use of photodynamic therapy (PDT) for moderate but recalcitrant acne vulgaris. This patient declined the use of oral isotretinoin and had failed therapy with topical agents and oral antibiotics. **A** Baseline. **B** Three days after PDT utilizing topical 20% 5-aminolevulinic acid (ALA; 3 hours incubation) followed by irradiation with red light from an LED (light-emitting diode; 630 nm; 37 J/cm^2; 70 mW/cm^2); intense inflammation and pustulation is limited to treated sites. **C** Two months after single treatment session. *Courtesy, Sunil Kalia, MD.*

is the primary focus are sparse relative to the extent that this treatment approach is advocated in clinical practice. Nonetheless, two separate studies of ALA-based PDT combined with IPL showed superiority for IPL alone in a side-by-side design involving 20 patients and 16 patients, respectively[44,45]. At the molecular level, PDT appears to stimulate the production of dermal collagen[46], while another study demonstrated expression of matrix metalloproteinases in photodamaged skin after PDT[47].

Psoriasis

In theory and practice, psoriatic plaques can be readily photosensitized by topical agents used in PDT. Lesional clearing has been observed with various light sources, including UVA and red light. High levels of PpIX within treated plaques correlated with significant and often dramatic pain upon light exposure. Pain, combined with the need for multiple treatments and a controlled trial demonstrating results inferior to narrowband UVB phototherapy[48], have made PDT a much less attractive option for psoriasis when compared to existing therapies, including targeted molecular therapies (biologics).

Cutaneous infections

There are several mechanisms by which PDT can treat infectious diseases. Singlet oxygen may destroy the microbes directly or it may activate host immunologic reactions against the microorganisms. In addition, PDT can induce necrosis of infected tissue, for example, in the treatment of verrucae or condylomata. Conditions that have been shown in controlled trials to improve with PDT include verruca vulgaris[49], condyloma acuminata[50,51], and leishmaniasis[52]. The emergence of drug-resistant bacteria has also motivated investigations into the treatment of bacterial skin infections with PDT[53].

Vascular anomalies

Systemic photosensitizers are biodistributed via the peripheral circulation and it stands to reason that intravascular drug activation with light would be useful in inducing the involution of abnormal vascular

SELECTED STUDIES OF TOPICAL PHOTODYNAMIC THERAPY FOR THE TREATMENT OF PHOTOAGING

Type of study (ref.)	No. of patients	Topical photosensitizer (concentration)	Incubation time	Light source	Response	Comments
Prospective, randomized, varying incubation times[27]	18	ALA (20%) solution	1, 2 or 3 h	Blue light (417 nm) at 10 J/cm^2	Improvement in skin quality, fine wrinkling and sallowness of facial skin	• 90% of treated hypertrophic AKs also responded
Case series, varying incubation times and light doses[43]	3 (phototypes I–III)	ALA (20%)	30 or 60 min	IPL (28 J/cm^2 or 26 J/cm^2 for skin types I/II and III, respectively)	Possible synergistic photo-rejuvenation due to potentiation of PDT by concomitant hyperthermia, but there were no PDT-alone or radiofrequency-alone controls	• IPL-based PDT was combined with radiofrequency (20 J/cm^2) • Erythema seen with 60-min incubation times but not with 30-min incubation times
Prospective, randomized, split-face, with comparison to IPL alone[44]	20	ALA (20%) solution applied twice after an acetone scrub	30–60 min	IPL (515–1200 nm) at 23–28 J/cm^2 (single pass; 2.4 ms pulse/15 ms delay/4 ms pulse)	Four weeks after the last treatment, in the ALA/IPL-based PDT group, global photodamage and mottled pigmentation were improved*; fine lines and pigmentation were successfully treated†	• Three treatments at 3-week intervals • All patients received two additional full-face IPL treatments • Contact cooling was used • Blinded observer • ALA/IPL-based PDT vs IPL – similar effects on tactile roughness and sallowness
Prospective, split-face, with comparison to IPL alone[45]	16	ALA (20%)	30–60 min	IPL (550/570–1200 nm) at 34 J/cm^2, double pulsing	Three months after final treatment, greater improvement with PDT: 55% vs 29.5% for IPL (crow's feet), 60% vs 37% for mottled pigmentation, 85% vs 54% for telangiectasia; greater clearance of AKs with PDT: 78% vs 54%	• Three treatments at monthly intervals

*Improved defined as a decrease in score by 1 point (5-point scale).
†Successful treatment defined as a decrease in score to 0 or 1.

Table 135.8 Selected studies of topical photodynamic therapy (PDT) for the treatment of photoaging. ALA, 5-aminolevulinic acid; AKs, actinic keratoses; h, hours; IPL, intense pulsed light; min, minutes; ms, milliseconds.

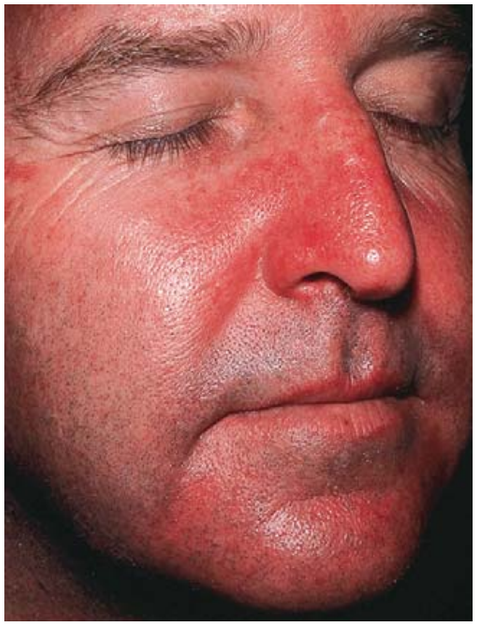

Fig. 135.9 Photosensitivity after oral 5-aminolevulinic acid (ALA). This patient sustained a phototoxic reaction 24 hours earlier by walking in bright sunlight several hours after oral ALA administration. The reaction resolved several days later. *Courtesy, Whitney Tope, MD.*

structures. Nowadays, this effect is clearly operative in two clinical situations: (1) vascular bed damage and ischemic necrosis following systemic photosensitization of carcinomas; and (2) destruction of hyperproliferative retinal blood vessels in age-related macular degeneration with systemic verteporfin-based PDT. Vascular malformations such as port-wine stains have been shown to respond to systemic PDT with results that appear to be at least equivalent to those achieved with conventional pulsed laser therapy[54]. Experience with this technique is largely from China, where hematoporphyrin-type preparations are used systemically.

ADVERSE EFFECTS AND COMPLICATIONS

PDT agents (prodrugs or photosensitizers) and visible light ordinarily possess minimal inherent toxicity, and the adverse effects related to PDT are largely an extension of the photochemical and photobiologic reactions that involve the generation of reactive oxygen moieties, especially singlet oxygen. Interestingly, erythropoietic protoporphyria could be considered a possible toxicity model for ALA and its congeners, since both clinical scenarios result in the overproduction of PpIX. The primary difference is that with erythropoietic protoporphyria, PpIX excess is constitutive, whereas with ALA-based PDT, the effect is transient.

Photosensitivity

Depending on the drug delivery method, cutaneous photosensitivity is generalized or localized. Systemic photosensitizers carry a greater risk of photosensitization and the risk depends on the particular agent and its dose. Photosensitivity manifests as varying degrees of erythema (Fig. 135.9), edema and/or blistering of any exposed site, with subjective symptoms of pain, a burning sensation, lightheadedness and photophobia. Patients receiving systemic PDT photosensitizers must be instructed to strictly avoid outdoor light as well as bright indoor light. Appropriate opaque clothing must be worn. Conventional chemical sunscreens, even those with a high sun protection factor, are not useful in managing at-risk patients since the action spectrum extends throughout the visible spectrum, which is not blocked by sunscreens. Complete avoidance of all light is unnecessary, since regular indoor light exposure provides a safe means by which low-level photobleaching can hasten the clearance of photoactive agents from the skin. In the case of topical PDT, applying an opaque covering to the treatment site during the incubation period will prevent inadvertent activation.

STEPS IN ADMINISTERING TOPICAL PHOTODYNAMIC THERAPY AND PRACTICAL CONSIDERATIONS
PREOPERATIVE PHASE
• Confirm that the patient is a good candidate for PDT: appropriate indication, assess comorbidities; consider PDT especially in the setting of: – Field cancerization – Multiple synchronous or metachronous superficial tumors – Skin cancer-prone genodermatosis – Organ transplant recipient • Select treatment site(s) and confirm diagnosis by histologic examination if necessary • Exclude contraindications: porphyria, photosensitivity disorder, pregnancy, photosensitizer hypersensitivity • Provide patient with counseling and education in terms of expectations and precautions • Determine the photosensitizer, light and treatment parameters that will be employed • Determine the number of PDT sessions to be given and the time interval; for non-melanoma skin cancer, two separate PDT sessions one week apart are recommended
INTRAOPERATIVE PHASE
Topical drug application
• Confirm treatment site(s) • Consider degreasing the treatment surface with topical acetone or by microdermabrasion • Prepare treatment site(s); gently curette excess stratum corneum or scale-crust if appropriate • Apply topical photosensitizer to the target treatment site(s) (i.e. ALA solution or mALA cream); occlusion and coverage by opaque material are optional • Incubate the photosensitizer for 1–4 hours (or up to 18 hours), depending on the indication and specific prodrug • Remove the medication; confirm the presence of PpIX fluorescence by Wood's lamp illumination (optional)
Light administration/drug activation
• Provide protective eyewear to patient and staff • Position patient and lamp(s) for uniform exposure and patient comfort; if necessary, consider covering certain skin sites with opaque material to limit light exposure to the target of interest • Confirm light dose to be given, and then initiate light exposure (Blu-U®: 10 J/cm^2 of blue light, ~ 16 minutes; Aktilite®: 37 J/cm^2 of red LED light, ~ 7–9 minutes); a healthcare professional should ideally remain with the patient for the duration of the light exposure • At the completion of the light exposure, confirm the photobleaching of PpIX by Wood's lamp illumination (optional)
Pain management during light exposure
• Assemble tools and devices for pain control; consider premedication with analgesics or sedatives • The physical presence of a healthcare professional is very important for providing reassurance and monitoring; constant verbal reassurance and distraction are essential • Reinforce to the patient that the sensation of pain indicates that the appropriate PDT reactions are occurring • Additional specific strategies for managing pain include: – Applying an ice cube or ice pack near the treatment site – Spraying cold water over the treatment site – Applying a fan that can be held by the patient – Directing forced cold air towards the treatment site – Interrupting the light exposure temporarily – Infiltration or nerve block anesthesia
POSTOPERATIVE PHASE
• Apply wound dressing if there is an acute exudate • Reduce swelling by using ice packs • Prescribe oral analgesics to be taken if necessary • If patient has been given a systemic photosensitizer, provide detailed photoprotection instructions • Arrange follow-up, including next PDT session if appropriate; for non-melanoma skin cancer, a repeat course/cycle of PDT may be appropriate 3 months after the first course/cycle if there is clinical evidence of residual disease

Table 135.9 Steps in administering topical photodynamic therapy (PDT) and practical considerations. ALA, 5-aminolevulinic acid; LED, light-emitting diode; mALA, methyl aminolevulinate; PpIX, protoporphyrin IX.

Pain

The incubation period, which follows application of the topical photosensitizer, is generally uneventful, but within seconds to minutes of illumination of the skin with light, patients will often experience a range and series of unpleasant sensations at the site of light exposure. A variety of terms are used by patients to describe these sensations, including pain, warmth, burning, stinging, smarting and stabbing. The intensity will usually build with time and there can be spread of the discomfort beyond the actual treatment field. This pain does not necessarily correlate with the intensity of visible fluorescence present at the end of the incubation period and prior to light exposure. The rate of light delivery can sometimes influence the degree of pain, with lower irradiances being more tolerable[15]. Sometimes, temporary interruption of the light exposure will allow the pain to dissipate temporarily. A variety of practical strategies have been designed to manage the pain of PDT (Table 135.9). For some patients, the pain can be so intense that they will not be willing to undergo more than one treatment session.

Inflammation

At the end of the light exposure, the treated site will exhibit an immediate wheal and flare reaction. Over the next 24–48 hours, there may be edema, induration, purpura and blistering, along with exudation and crusting. Depending on the indication and the PDT drug–light dose, frank tissue necrosis may supervene accompanied by erosions and ulceration. Local reactions evolve over the ensuing 1–6 weeks and any wounds will heal by second intention.

Other Local Reactions

As with any physical modality, PDT can induce scarring and postinflammatory hyper- and hypopigmentation. Development of these complications depends primarily on the extent of the iatrogenic injury and the patient's constitutive injury and wound healing propensity.

Photosensitizer Allergy

Multiple case reports have documented contact hypersensitivity to mALA. In a controlled trial, contact sensitization to mALA was observed in as many as 35% of patients who had *previously* undergone five or more mALA-based PDT sessions; only 1.7% of the control subjects who had not previously undergone PDT demonstrated sensitization[55].

PRACTICE AND TECHNIQUES

The practical administration of PDT requires attention to a number of details during the preoperative, intraoperative and postoperative stages (see Table 135.9). Although the commercial PDT systems for dermatology come with officially recommended and approved protocols, the practice of PDT is not uncommonly off-label, both in terms of indications and specific procedural steps guided by the individual practitioner's experience and empiric preferences. One round of drug plus light administration can be considered a single PDT session, and a "course" or "cycle" of PDT may involve one or more PDT sessions separated by a set time interval. What should not be underestimated is the time and staffing necessary to provide appropriate patient counseling and education as well as intraoperative support during the light exposure phase.

FUTURE DIRECTIONS

Although PDT predates the discovery of antibiotics, corticosteroids, Mohs micrographic surgery and lasers by many years, only during the past decade did it become an accepted therapeutic modality in dermatology. Previous limitations to exploiting light-generated singlet oxygen were solved by the development of the topical ALA prodrug methodology, thereby fulfilling the promise of PDT as a simple and practical treatment. Controlled trials and cumulative clinical experience have defined the current spectrum of applications. Ongoing challenges include managing intraoperative pain, increasing the effective depth, and further simplifying the therapy in order to make it more accessible and practical.

On the horizon are novel ways of delivering ALA, including new formulations and a topical ALA-impregnated patch, which has shown efficacy in the treatment of actinic keratoses[56]. Adhesive, wearable, light-emitting patches have also been considered for PDT[57]. Since the latter operate at low irradiances, there may be less pain associated with these devices. In terms of innovative applications, it appears that PDT can be effective for managing field cancerization beyond just clearing visible and subclinical actinic keratoses. There is direct evidence that skin sites treated with topical PDT will develop new lesions at a slower rate, raising the possibility of PDT for photochemoprevention[58,59]. The fortunate irony is that light can now be used to effectively treat and even prevent the neoplasia that were induced by light in the first place.

Synonym: ■ LASER – light amplification by stimulated emission of radiation

Key features

- Laser surgery works by precise tissue heating when optical energy is absorbed within the skin
- Heat is created exactly where light is absorbed by molecules called chromophores
- The major chromophores for visible and near-infrared light are melanin and hemoglobins. Water is the major far-infrared chromophore
- Red and near-infrared wavelengths are deeply penetrating.
- Wavelength(s) of lasers or intense pulsed light (IPL) sources are often matched for absorption by chromophores in skin targets such as blood vessels, hair follicles, melanin-containing cells, tattoo ink or tissue layers
- Selective heating and damage of targets can occur when a pulse of selectively absorbed light is delivered faster than the targets can cool by heat conduction
- The time for a tissue target to cool is its thermal relaxation time, equal in seconds to approximately the square of the target size in millimeters
- Very short (nanosecond) laser pulses, produced by Q-switched lasers, can precisely damage small targets such as individual melanocytes
- Millisecond lasers and IPLs selectively affect multicellular targets such as blood vessels, hair follicles and tissue layers
- Fractional laser treatments create an array of microscopic thermal injury zones
- Radiofrequency electrical current, traditionally used for skin surgery, has been re-configured for aesthetic applications
- High-intensity, focused ultrasound can heat a precise focus within or below the skin
- Laser microscopy of live, intact skin is an emerging diagnostic tool for dermatology

INTRODUCTION

Modern dermatology is inextricably linked to photomedicine, which includes all diagnostic and therapeutic uses of light. The last century took us from Einstein's insight into the quantum nature of light, to the invention of the ruby laser in 1960, to the wide spectrum of lasers available today. In particular, the principle of selective photothermolysis guided the development of pulsed lasers that target specific skin structures such as blood vessels, melanosomes and hair follicles. Laser dermatology is a dynamic field and a steady source of therapeutic innovation.

LASERS

LASER is an acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation, and this describes the physical process by which, in accordance with Einstein's principles of electromagnetic radiation[1], lasers produce light[2]. Electromagnetic radiation is a basic form of energy that exhibits both wave and particle properties. The quantum of electromagnetic energy is called a photon, and a photon can stimulate an excited atom to emit another photon with the same energy, wavelength and phase. The idea of lasers was envisioned by Charles Townes, followed in 1960 by the actual demonstration of a laser utilizing a flashlamp-excited ruby crystal[3]. Soon thereafter, Dr Leon Goldman initiated dermatologic application of laser technology.

All laser systems are composed of four essential components (Fig. 136.1), including: (1) a gas, liquid or solid medium (Table 136.1) that can be excited to generate light; (2) a source of pump energy to excite the medium; (3) mirrors at the ends of the laser, forming an optical cavity that favors the amplification process; and (4) a delivery system.

Stimulated emission occurs when more than half of the atoms within the laser medium are excited by the pump energy source; this ensures that photons traveling in the laser medium are more likely to encounter an excited atom (leading to stimulated emission) than a resting atom that can simply absorb the light. Light is amplified as it travels back and forth between the laser's mirrors, and a very high intensity can be achieved.

Laser light has several properties that are different from other light sources[4]. *Monochromicity* refers to emission of a well-defined wavelength, rather than a band of wavelengths. *Coherence* describes light waves that travel in phase, both in time and space, similar to a column of soldiers marching in step. *Collimation* refers to a very parallel beam of light. Coherence and collimation allow lasers to be focused to very small spot sizes (see Fig. 136.1).

Lasers may emit a continuous beam or pulses of light. Continuous lasers usually have limited power, whereas extremely high peak power can be emitted during a short laser pulse[5]. Q-switched lasers produce short pulses at very high peak power. "Q" refers to a quality factor for light traveling across the laser cavity, which can be changed suddenly to produce a short, intense burst of light. Dermatologic Q-switched lasers are designed to produce pulses of 10–100 nanoseconds, with fluence (energy density) typically in the 2–10 J/cm^2 range. These short, high-power pulses are particularly useful for selective removal of tattoos and pigmented lesions[6].The repetition rate for pulsed lasers is expressed in hertz (Hz). Of note, some lasers emit a rapid train of low-energy pulses that behave surgically like continuous-wave lasers and are called quasicontinuous.

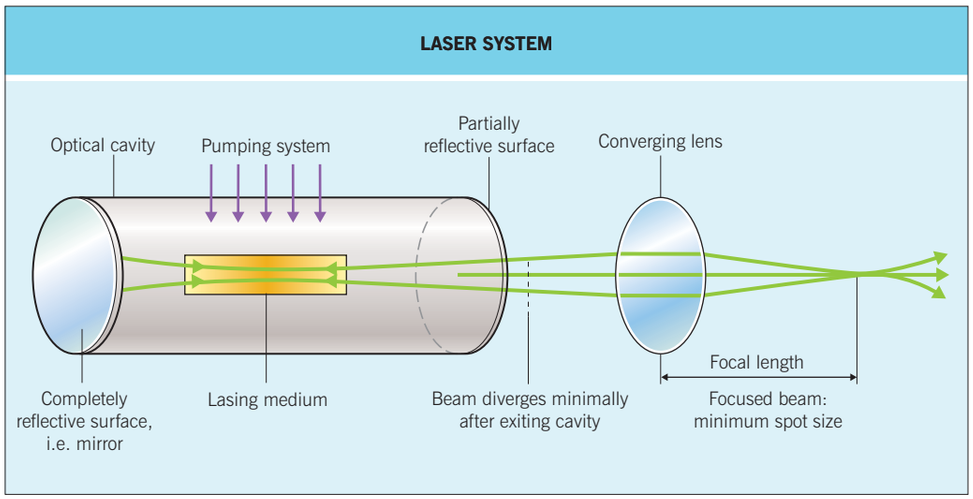

Fig. 136.1 Laser system. The pumping system stimulates the lasing medium to emit photons. The mirrors at the ends of the cavity reflect this light back and forth along one axis, leading to amplification of the stimulated emission process; one of the mirrors is only partially reflective, allowing the laser light to exit. Lasers produce beams of light with low divergence (spread) that are close to being collimated (i.e. parallel light waves). This then allows the beam to be tightly focused by a converging lens or mirror as focusing is required to produce a specific spot size.

TYPES OF LASER MEDIA

Gas	Liquid	Solid
Argon Carbon dioxide Copper vapor Helium–neon Krypton Xenon chloride*	Rhodamine dye dissolved in organic solvent†	Crystal • Alexandrite • Erbium-doped yttrium aluminum garnet (YAG) • Holmium-doped YAG • Neodymium-doped YAG • Potassium titanyl phosphate • Ruby Semiconductor • Diode (e.g. aluminum gallium arsenide)

*In excimer lasers.
†In pulsed dye lasers.

Table 136.1 Types of laser media. Lasers are often named for the medium contained within their optical cavity.

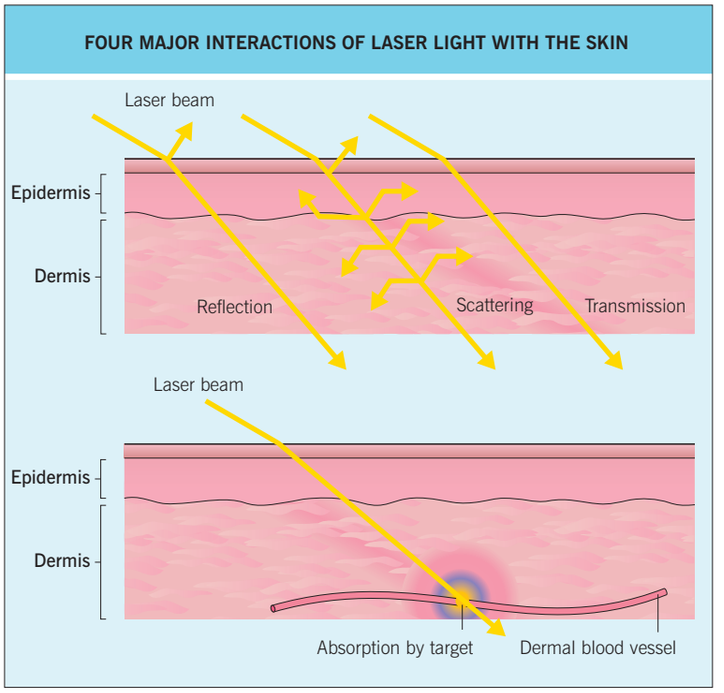

Fig. 136.2 Four major interactions of laser light with the skin. These are reflection, scattering, transmission and absorption.

SKIN OPTICS

At the skin surface, 4–7% of light is typically reflected because of the difference in the refractive index between air (n = 0) and stratum corneum (n = 1.45)[7]. This is termed the Fresnel reflectance because it follows Fresnel's equations relating reflectance to the angle of incidence, plane of polarization, and refractive index[8]. The remaining 93–96% of incident light enters the skin, where it is primarily scattered and/or absorbed (Fig. 136.2). Scattering occurs when photons "bounce" off particles and fibers within the skin, leading to diffusion of the incoming beam of light and limiting its depth of penetration. Tissue effects occur only when light is absorbed.

The *absorption coefficient* is defined as the probability per unit path length that a photon at a particular wavelength will be absorbed, and it depends on the concentration of chromophores (absorbing molecules) present. When absorption occurs, the photon surrenders its energy to a chromophore. Once absorbed, the photon ceases to exist and the chromophore becomes excited.

Three primary skin chromophores are water, hemoglobin and melanin (Fig. 136.3). Chromophores exhibit characteristic bands of absorption at certain wavelengths. It is this fact that allows for the delineation of specific targets for laser activity. While melanin absorbs broadly across the visible and ultraviolet (UV) spectrum, the oxyhemoglobin and reduced hemoglobin in blood exhibit strong bands in the UV, blue, green and yellow regions. Water has strong absorption in the infrared (IR) region (Fig. 136.4).

Optical properties of the epidermis and dermis are different. In pigmented epidermis, melanin absorption is usually the dominant process over the majority of the optical spectrum (200–1000 nm) (see Fig. 136.3). In the dermis, there is strong, wavelength-dependent scattering by collagen fibers, which attenuates penetration of light. This scattering varies inversely with wavelength. In general, between 280 and 1300 nm, the depth of penetration increases with wavelength (see Fig. 136.5). Above 1300 nm, penetration decreases due to the absorption of light by water. The most deeply penetrating wavelengths are 650–1200 nm, while the least penetrating wavelengths are within the far-UV and far-IR regions.

THERMAL INTERACTIONS

Most laser interactions involve heat. As temperature is raised, many essential molecules within cells are denatured, including proteins, DNA, RNA and cell membranes. This results in loss of function via unfolding and coagulation of macromolecules. Thermal coagulation yields cell necrosis and, if widespread, a burn. Laser skin surgery requires precise control over the placement and amount of heat-induced injury.

Most human cells can easily withstand temperatures of up to 40°C. Whether a given cell population can survive higher temperatures is dependent upon both exposure time and temperature. This is because the rate of thermal denaturation depends upon temperature: heat increases the rate at which molecules denature. In most organisms, exposure to sub-lethal heat induces a cellular reaction termed the heat shock response. Normal protein synthesis is replaced by synthesis of proteins called heat shock proteins, which confer some resistance to thermal injury[9]. Laser-induced thermal injury is well described by an Arrhenius model[10] – the rate of denaturation is exponentially related to temperature. Thus, accumulation of denatured material rises exponentially with temperature and proportionally with time[11]. Near a critical temperature (which is different for different tissues), rapid coagulation occurs; this is what accounts for the well-defined histologic boundaries of dermal coagulation in laser and other burn injuries. In the dermis, type I collagen plays a primary role in thermal coagulation, whereas elastin is extremely thermally stable and can survive boiling without apparent injury. Fibrillar type I collagen has a sharp melting transition at 60–70°C. At or above this temperature range, scarring becomes likely. Selective photothermolysis permits selected heating of targets within the dermis, such as blood vessels or hair follicles, with preservation of dermis between targets. However, even with selective photothermolysis, there is an absolute need to keep the bulk skin temperature below ~60–70°C.

When laser light, intense pulsed light (IPL), radiofrequency (RF) waves or other form of energy is absorbed by tissue, most of the absorbed energy is converted to heat; the latter then begins to diffuse into the surrounding tissue. Heat diffusion via conduction is also called thermal relaxation. *Thermal relaxation time* (TRT) is defined, for a given tissue structure, as the time required for the heated tissue to cool halfway towards its initial temperature. The key to clean ablation of tissue is to ablate it quickly, before much heat is conducted into surrounding tissue[12].

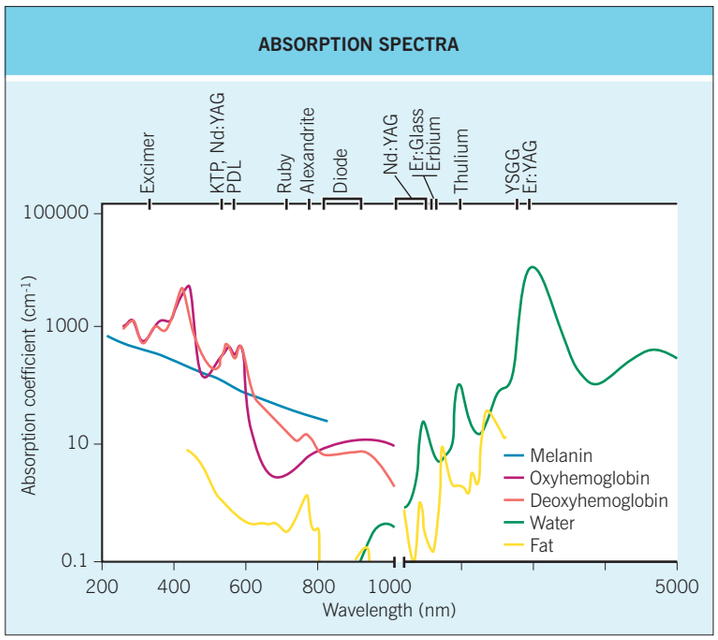

Fig. 136.3 Absorption spectra. The heterogeneous absorption spectra of chromophores allow selective photothermolysis to work. Er, erbium; KTP, potassium titanyl phosphate; Nd:YAG, neodymium-doped yttrium aluminum garnet; PDL, pulsed dye laser; YSGG, yttrium scandium gallium garnet.

SELECTIVE PHOTOTHERMOLYSIS

The concept of selective photothermolysis[13] first arose to guide the design of a laser for treating pediatric port-wine stains. Selective, localized heating (with focal destruction of "target" structures) is achieved by a combination of selective light absorption and a pulse duration shorter than or approximately equal to the TRT of the targets. Choice of wavelength(s) must correspond to absorption by chromophores within the skin targets. The wavelength must also penetrate to the anatomic depth of the skin targets.

The TRT of a target is proportional to the square of its size (Table 136.2). Thus, for a given material and shape, an object half the size will cool in one-quarter of the time. For most tissue structures, TRT (in seconds) is approximately equal to the square of the target dimension (in millimeters). Shape also affects TRT, and for a given thickness, spheres cool faster than cylinders, which cool faster than planes.

In general, the optimal pulse duration for *selective photothermolysis* is approximately equal to the TRT. Selective photothermolysis typically utilizes pulsed (rather than continuous) sources[14]. Blood vessels encompass a wide range of TRTs, including capillaries (tens of microseconds), large venules of adult port-wine stains (up to tens of milliseconds) and leg veins (hundreds of milliseconds). Small pigmented targets (e.g. melanosomes within pigmented melanocytes in a nevus of Ota) are best treated with short (sub-microsecond) pulses, while larger pigmented targets (e.g. hair follicles) have longer TRTs and are best treated with longer (millisecond) pulses[15].

PHOTOMECHANICAL EFFECTS

Pulsed lasers can also cause mechanical effects[16]. Sudden heating induces thermal expansion with consequent acoustic and/or shock waves. These waves can rupture or increase permeability of cell membranes. Cavitation, the violent formation and collapse of steam bubbles, may also occur. The latter is the dominant mechanism of vessel rupture by pulsed dye lasers emitting pulses less than ~20 milliseconds[17].

A number of parameters control laser–tissue effects, including wavelength, fluence, irradiance, spot size, and pulse duration (Table 136.3). With smaller spot sizes, scattering leads to a more rapid loss of photons from the beam as it penetrates the skin, whereas a large spot size allows more photons to remain within a beam's diameter. The greatest effec-

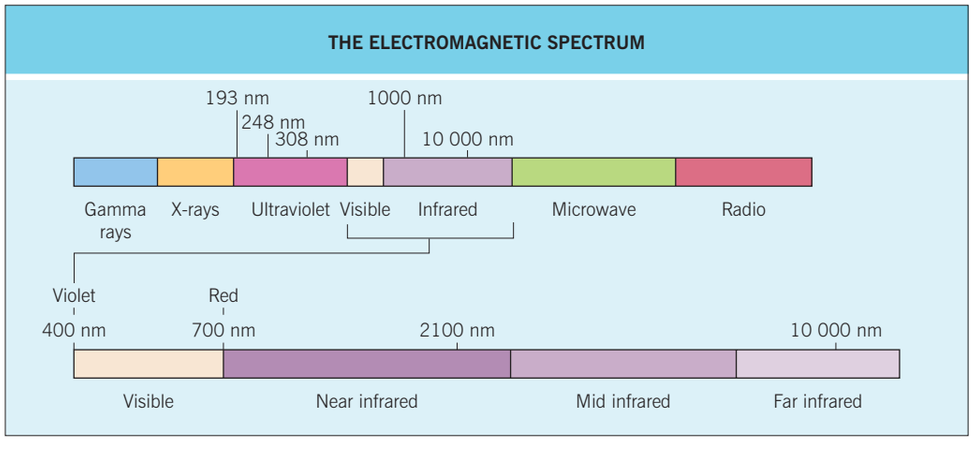

Fig. 136.4 The electromagnetic spectrum. The visible portion is only a small range of the spectrum.

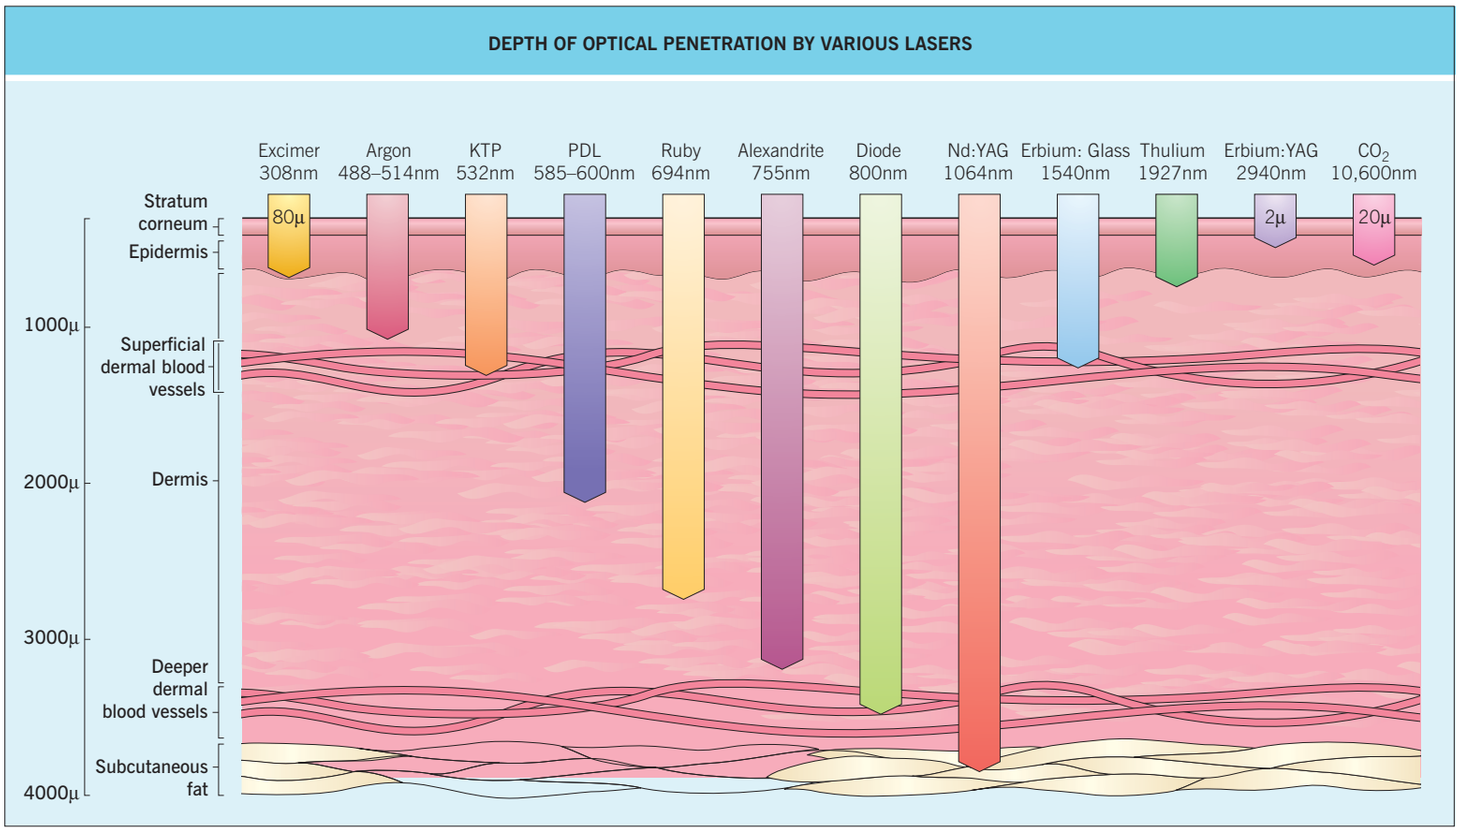

Fig. 136.5 Depth of optical penetration by various lasers. It should be noted that the treatment depth can greatly exceed the optical penetration depth for ablative lasers. On the face, the fat can be present at depth of 2–3 mm. For example, the depth of optical penetration for CO_2 lasers is only ~20 microns, but fractional CO_2 lasers can vaporize nearly full-thickness microchannels through the dermis. KTP, potassium titanyl phosphate; Nd, neodymium; PDL, pulsed dye laser; YAG, yttrium aluminum garnet.

PULSE DURATIONS AND TARGETS OF SELECTIVE PHOTOTHERMOLYSIS

Chromophore	Diameter	TRT	Typical laser pulse duration
Tattoo ink particle	0.1 micron	10 ns	10 ns
Melanosome	0.5 micron	250 ns	10–100 ns
PWS vessels	30–100 microns	1–10 ms	0.4–20 ms
Terminal hair follicle	300 microns	100 ms	3–100 ms
Leg vein	1 mm	1 s	0.1 s

Table 136.2 Pulse durations and targets of selective photothermolysis. m, milli; n, nano; s, second; PWS, port-wine stain; TRT, thermal relaxation time.

LASER AND LASER DERMATOLOGY TERMS

Term	Definition	Unit
Energy	Fundamental unit of work	Joules (J)
Power	Rate at which energy is delivered	Watts (W)
Fluence	Amount of energy delivered per unit area	J/cm^2
Irradiance	Power delivered per unit area	W/cm^2
Pulse duration (pulse width)	Laser exposure duration	Seconds (s)
Spot size	Diameter of the laser beam on the skin surface	mm
Chromophore	Medium that absorbs light	
Thermal relaxation time	Time required for heated tissue to lose 50% of its heat through diffusion	Seconds (s)

Table 136.3 Laser and laser dermatology terms.

tive penetration depth into skin occurs with a combination of a penetrating wavelength (600–1300 nm; Fig. 136.5) and a large spot size.

SKIN COOLING

Epidermal melanin is an undesired chromophore when treating dermal targets. Epidermal damage can be minimized through the use of skin cooling, and this is especially important with darkly pigmented skin. All cooling methods extract heat at the skin surface via a cooling agent (gas, liquid or solid). For spray cooling, a cold *liquid* is used, e.g. liquid fluorocarbon is sprayed on the skin. *Solid* contact cooling often consists of a cold sapphire window held against the skin, through which laser or IPL energy is delivered. *Cold air* or *cold gels* can also be applied for passive skin cooling.

There are three basic types of skin cooling: precooling, parallel cooling and post-cooling, which correspond to extracting heat from the skin before, during and after the laser exposure, respectively[18]. For pulse durations shorter than ~5 milliseconds (e.g. many pulsed dye and all Q-switched lasers), there is not enough time for parallel cooling to extract much heat, but precooling provides some protection. For short pulsed lasers, cryogen spray cooling represents the most aggressive and effective form of precooling.

Parallel cooling is effective for pulses longer than ~5 milliseconds. Solid contact cooling with a cold sapphire window pressed against the skin just before and during a long laser pulse allows safer delivery of high fluences, even in darkly pigmented skin[19]. Bulk skin cooling before and after laser treatments (e.g. with ice or cold air) is useful for minimizing pain, erythema and edema[15].

APPLICATIONS OF LASER PRINCIPLES

Currently available medical lasers are outlined in Table 136.4 and their applications are discussed in Chapter 137.

LASERS IN MEDICINE							
Laser	**Wavelength (nm)**	**Mode**	**Average power (W)**	**Average energy per pulse (J)**	**Pulse duration (sec)**	**Pulse rep. rate (Hz)**	**Target chromophore**
Excimer (ArF)	193	Pulsed	10	0.1	10^{-8}	100	Proteins
Excimer (XeCl)	308	Pulsed	10	0.1	10^{-7}	100	Proteins
Argon	488, 514	CW	1–10				Hemoglobins, melanin
Copper vapor	511, 578	Quasi-CW	1–10	10^{-3}	10^{-8}	2×10^{3}	Hemoglobins, melanin
KTP	532	Quasi-CW	1–10	10^{-4}	10^{-8}	104	Hemoglobins, melanin
Q-switched, frequency-doubled Nd:YAG	532	Pulsed (ns)	1–3	0.2^{-1}	10^{-8}	5–10	Melanin, red tattoos
Pulsed dye	585–600	Pulsed	10	5	$(0.45–40) \times 10^{-3}$	2	Hemoglobins
Argon dye	630	CW	0.5–2				Photosensitizing drugs
Ruby	694	Pulsed	30	30	10^{-3}	1	Melanin
Q-switched ruby	694	Pulsed (ns)	2	2	3×10^{-8}	1	Melanin, black and green tattoos
Alexandrite	755	Pulsed	30	30	10^{-3}	1	Melanin, deoxyhemoglobin
Q-switched alexandrite	755	Pulsed	5	0.5–5	10^{-7}	1–10	Melanin, black and green tattoos
Diode (AlGaAs)	~800	CW/pulsed	5–3000	5–100	$(5–400) \times 10^{-3}$	1–2	Melanin, hemoglobins
Nd:YAG	1064	CW	10–100				Hemoglobins
Q-switched Nd:YAG	1064	Pulsed (ns)	5–10	1	10^{-8}	5–10	Black tattoos
Long-pulsed Nd:YAG	1064	Pulsed	1–50	1–50	$(1–200) \times 10^{-3}$	0–10	Hemoglobins, melanin

Ablative (Vaporizing) Skin Resurfacing

The ablative lasers are far-IR CO_2 (10 600 nm) or erbium:yttrium aluminum garnet (Er:YAG; 2940 nm) devices which emit wavelengths strongly absorbed by water. Pulsed and/or scanned focused beams are used to precisely vaporize superficial tissue, causing a "plume" of material leaving the skin. Most of the heat is removed during vaporization, but a thin layer of residual thermal damage remains that is useful for hemostasis. Laser resurfacing is very useful for treating photoaging, scars, and lesions such as epidermal nevi and seborrheic keratoses. Resurfacing removes the old epidermis and stimulates contraction and remodeling of the dermis for many months after treatment. Being a controlled partial-thickness burn, meticulous technique and wound care are important in order to avoid infection and other complications. Scarring, transient hyperpigmentation, delayed-onset permanent hypopigmentation, prolonged erythema, and bacterial, viral and fungal infections have been reported after laser resurfacing[20].

Interactions During Treatment of Vascular Lesions

A peak of absorption by oxyhemoglobin occurs at 577 nm within the yellow spectrum (see Fig. 136.3). Flashlamp-pumped *pulsed dye lasers* (PDLs) are frequently used to treat microvascular lesions and they emit 585–600 nm light (i.e. within this absorption band), with pulse durations ranging from 0.45 to 40 milliseconds. Because of the range of target vessel sizes and associated TRTs (see above), variable pulse duration PDLs are now widely employed. Despite this and other improvements (e.g. skin cooling), the majority of port-wine stains require six or more treatments in order to achieve stable improvement, and only a minority can be fully removed. Resistance appears to be primarily attributable to vessels deeper than 1.5 mm (see Fig. 136.5).

For the treatment of deeper vessels, high-fluence, millisecond-domain, *pulsed neodymium:YAG* (Nd:YAG) lasers (1064 nm) may offer an improvement when compared to PDLs, but the former has a variable and narrow range of safe and effective fluence. *Alexandrite* lasers (755 nm, ~3 millisecond pulse duration) are also effective for treating hypertrophic and/or PDL-resistant vascular lesions, with a better range of safe and effective fluence. This difference may be due to preferential absorption by oxyhemoglobin at 1064 nm, in contrast to preferential absorption by deoxyhemoglobin at 755 nm. Other lasers with wavelengths in the near-IR range (e.g. 980 nm and 810 nm diode lasers) have been utilized to target larger, deeper vessels (e.g. leg veins).

Currently, the 585–600 nm flashlamp PDL is a standard treatment for cutaneous microvascular lesions, including port-wine stains, telangiectasias, erythematous scars, and, when indicated, hemangiomas. The treatment fluence is decreased for more deeply pigmented skin, and the principal side effect is purpura, which is dependent on pulse duration, fluence and spot size[21]. Purpura is the result of microvascular hemorrhage, subsequent thrombosis and delayed appearance of vasculitis. When the pulse duration (or dwell time) exceeds ~20 milliseconds, there is little or no immediate purpura because cavitation and vessel rupture are avoided. It should be noted, however, that delayed purpura can still occur due to a phase of vasculitis several days after treatment, even when no immediate post-treatment purpura is observed.

Continuous- and quasicontinuous-wave green or yellow lasers as well as various IPL devices have less vascular specificity than PDLs, but they offer the advantage of markedly less post-treatment purpura because of longer pulse duration or dwell time. *Copper vapor* or *copper bromide* lasers emit either green light at 511 nm or yellow light at 578 nm. With their high pulse repetition rates, tissue effects are comparable to those of continuous-wave lasers. Minimal swelling and crusting can occur, with resolution within 1 week[22].

Potassium titanyl phosphate (KTP) lasers, at a wavelength of 532 nm (with variable pulse durations in the millisecond domain), have also been introduced for treating telangiectasias, again with less resultant purpura than with PDLs. In combination with parallel skin cooling windows, these lasers are versatile for vascular lesion treatment.

IPLs are filtered xenon flashlamps which emit a wide range of wavelengths. Compared with most vascular lasers, IPLs are less selective and less powerful but still useful for selective photothermolysis of telangiectasias and poikiloderma.

Interactions During Treatment of Pigmented Lesions and Tattoos

Melanosomes are melanin-containing organelles that range from ~0.5 to 1.0 micron in size, and they can act as a primary target for selective photothermolysis of pigmented lesions[23]. Melanin has a broad absorption spectrum (see Fig. 136.3), which lends itself to possible targeting by a wide variety of lasers[24]. Choice of treatment wavelength is based on avoiding absorption by other chromophores and on matching depth of penetration to the depth of the lesion. In general, red and near-IR lasers are the most selective and penetrating devices for pigment cell targeting. The TRT of melanosomes is about 70–250 nanoseconds[13], and therefore Q-switched lasers are excellent for targeting melanosomes. When the fluence threshold for melanosome disruption is reached, the pigmented cell dies. Q-switched lasers selectively attack individual pigmented cells, so when the goal is to also remove adjacent, non-pigmented cells (e.g. during hair removal), millisecond pulses are used in order to allow heat transfer from pigmented to adjacent non-pigmented cells.

Treatment of tattoos with Q-switched lasers fragments the ink particles and selectively kills pigment-containing cells, with resultant ink particle release. Subsequent removal of tattoo ink particles can occur via an epidermal crust and/or lymphatic transport, and some particles are re-phagocytosed by dermal cells[25]. Of note, different laser wavelengths are needed for different ink colors (see Table 136.4).

Q-switched ruby and *alexandrite* lasers are very useful for epidermal and dermal pigmented lesions (e.g. lentigines, nevus of Ota) as well as for black and green tattoos (see Ch. 137). Café-au-lait macules and melanocytic nevi may respond to treatment with Q-switched ruby lasers (or, for nevi, long-pulsed ruby lasers that target nests of melanocytes), but recurrences are common and residual dermal melanocytes remain in laser-treated nevi[26,27]. Laser treatment of congenital melanocytic nevi is usually considered when surgical options are limited. However, laser removal of acquired melanocytic nevi is quite controversial given the potential risk for partial removal of a subtle early melanoma. Of note, postinflammatory hyperpigmentation and melasma respond poorly to laser treatment[28].

The *Q-switched Nd:YAG* laser emits at 1064 nm, with typical pulse durations of 10 nanoseconds. Its primary use is in the treatment of black tattoos and dermal melanocytoses such as nevus of Ota in darkly pigmented skin. Frequency-doubling to produce 532 nm visible green light is generally available in the same device, which can effectively remove epidermal melanin pigment as well as red tattoos.

Interactions During Hair Removal

Hair removal is the most popular laser procedure, and it probably requires damage to follicular stem cells in the bulge region of the outer root sheath and/or the dermal papilla at the base of the hair follicle. These are non-pigmented targets, located away from the pigmented hair shaft. High-energy, millisecond-domain pulses of wavelengths in the red to near-IR region of the spectrum (i.e. deeply penetrating) are used, from *ruby*, *alexandrite*, *diode* and *Nd:YAG* lasers. None of these sources works well for blond or white hair due to the paucity of melanin.

Since light must first travel through the pigmented epidermis to reach hair follicles, skin cooling is essential for safe permanent removal of hair in individuals with darkly pigmented skin. The primary mechanism for *temporary* hair loss is induction of catagen, which can occur at very low fluences; an 810 nm diode laser source intended for home use has been reported to reliably induce temporary reduction of pigmented terminal hair[29]. However, *permanent* loss of terminal hair typically requires either miniaturization to produce vellus-like hairs or complete degeneration with local fibrosis. For unknown reasons, an unwanted stimulation of a vellus-to-terminal hair transition can occur after laser or IPL treatments, particularly on the face in Mediterranean women.

Fig. 136.6 Histologic findings following ablative fractional photothermolysis. A microthermal zone (MTZ) of injury (arrow) is apparent after use of a CO_2 laser (10 600 nm) at 100 mJ/pulse. E, epidermis; D, dermis. *Courtesy, Wellman Center for Photomedicine.*

Interactions During Non-ablative Skin Rejuvenation

Non-ablative facial rejuvenation for the treatment of fine lines and non-dynamic rhytides uses mid-IR lasers (e.g. 1320 nm Nd:YAG, 1450 nm diode and 1540 nm erbium:glass lasers) and IPL sources (see below). These work by subtle thermal effects on the dermis, presumably stimulating a wound healing response. Responses to non-ablative rejuvenation are usually gradual and subtle, and well-controlled studies are lacking.

Fractional Photothermolysis

Fractional photothermolysis (FP) represents a treatment strategy in which many thousands of nearly invisible, microscopic zones of thermal injury are created (Fig. 136.6), stimulating turnover and remodeling of both the epidermis and dermis[29]. *Non-ablative* FP uses focused mid-IR laser microbeams to create a pixilated pattern of small columns of thermal damage, called microthermal treatment zones (MTZs). Typically, up to 1 million MTZs are placed per full-face treatment. Pattern density and depth of thermal damage are separately controlled. Density affects coverage whereas energy per MTZ is used to control depth of treatment (up to about 1.5 mm). In general, the depth of treatment should correlate with the depth of skin pathology being treated.

Tissue spared around each MTZ initiates rapid repair and stimulates remodeling. Desquamation of the epidermal portion of each MTZ removes some basal layer pigment and a small amount of papillary dermal debris. Non-ablative FP has been reported to improve

several skin conditions, including scars, fine rhytides, telangiectasias, dermatoheliosis and poikiloderma. There are a myriad of commercially available non-ablative FP devices (see Ch. 137).

Ablative FP uses carbon dioxide or erbium (Er:YAG) lasers to vaporize a similar pattern of small vertical channels that can extend deeply into the skin. Because remodeling is provided by tissue between the columns of ablation, the depth of ablation can be far deeper than with traditional ablative resurfacing procedures. However, care must be taken to avoid scarring, particularly in the infraorbital and neck regions where thin skin overlies a muscle (platysma). In theory, ablative FP may also be an effective mechanism for topical drug delivery, by providing many channels directly into the dermis.

Laser-Based Diagnostics

Laser technology has been instrumental in the development of biological microscopy and tissue imaging. Optical coherence tomography (OCT) uses near-IR, low-coherence light for high-resolution cross-sectional imaging of body tissues. OCT is a standard procedure in ophthalmology, is emerging as a means of rapidly imaging coronary arteries[30], and may have applications in dermatology[31]. For example, a Doppler version has been shown to be capable of imaging blood flow before and after laser treatment of vascular lesions[32].

Laser confocal microscopy captures light scattered or emitted from a thin plane "section" inside skin. Reflectance confocal microscopy is able to view the skin *in vivo* with histology-like resolution down to a depth of approximately 0.3 mm. Because histochemical stains are not used, confocal microscopy of skin tumors reveals diagnostic features that are different from those of conventional histology. For example, microvascular blood flow and trafficking of lymphocytes can be observed. In a preliminary study, the sensitivity and specificity of *in vivo* confocal microscopy for differentiating melanocytic nevi and seborrheic keratoses from cutaneous melanoma and basal cell carcinoma were 94% and 98%, respectively[33].

PRINCIPLES OF LASER SAFETY

The principles of laser safety are outlined in Table 136.5[34].

PRINCIPLES OF LASER SAFETY
POTENTIAL EYE INJURIES (PATIENTS AND DERMATOLOGISTS)
Blindness occurs rapidly and painlessly
• Blindness can occur even if only 1% of the beam is reflected into the eye from shiny metal, glass or plastic surfaces • Highest risk of eye injury and blindness with near-infrared Q-switched lasers • Lasers and IPL sources used for hair removal can target the retina and uveal tract • Anterior eye injury from lasers or IPL sources usually occurs with treatment of the lower eyebrow or vascular lesions near the eye (without an eye shield properly in place) • An opaque laser eye shield covering the patient's cornea will not prevent damage if the laser or IPL directly impacts exposed sclera • Long-pulse near-infrared laser light can penetrate through the eyelid to damage the eye
PREVENTION OF EYE INJURIES
Proper use of laser-protective eyewear (including eye shields)
• Wrap-around glasses and goggles are rated by optical density (OD) at specific wavelengths (corresponding to various lasers): OD = log (1/T), where T is transmittance of light through the eyewear; OD = 6 implies transmittance through the goggles is 10^{-6} • After determining wavelength of laser, check goggles for required OD and wavelength ranges of protection (printed directly on eyewear) • For dermatological lasers, proper protection is an OD ≥4 at the wavelength of the laser being used • Color of the goggles is not an indication of protection
FIRE HAZARDS
• Drapes, clothing, dry hair and plastic materials, including endotracheal tubes, can be ignited, especially when oxygen is in use • Greatest risk is with the CO_2 and erbium:YAG lasers used for skin resurfacing and ablative fractional treatments
PREVENTION OF FIRES
• Remember to place the laser in STANDBY mode when not actually treating the patient • Avoid inadvertently activating the laser foot-switch • Moisten any hair near the treatment field; remove mascara and eye makeup when working around eyelids • Alcohol, acetone or other flammable skin-cleaning solutions must be allowed to completely dry before laser use • Reduce intraoperative oxygen concentration to <40% • A fire extinguisher and water should be readily available
POSSIBLE CUTANEOUS BURNS
• Can occur with essentially all dermatological laser, IPL, RF or therapeutic ultrasound devices • Primarily due to improper device, dosimetry and/or treatment technique
PREVENTION OF CUTANEOUS BURNS
• Knowledge and careful observation of specific clinical endpoint responses for a particular laser–lesion combination
INHALATION OF LASER-GENERATED "PLUME" MATERIALS
• Particularly with resurfacing or vaporization of hair during its removal; latter can release irritating sulfur and other oxides
PREVENTION OF LASER "PLUME" BIOHAZARDS
• Smoke evacuator and good ventilation are most effective measures • Sub-micrometer surgical filter masks provide some protection when worn properly • Q-switched lasers capture particulate material in plastic cones

Table 136.5 Principles of laser safety. IPL, intense pulsed light; RF, radiofrequency.

NON-LASER ENERGY SOURCES

Flashlamps

Filtered xenon flashlamps, also referred to as intense pulsed light (IPL) sources, are also used for non-ablative skin rejuvenation, hair removal, and the treatment of vascular and pigmented lesions. By utilizing filters, different wavelength bands can be chosen, which are delivered in millisecond-domain pulses. Compared with lasers, IPLs are generally less target-selective, as they are unable to deliver the very short pulses needed for selective photothermolysis of very small targets such as the pigmented cells of tattoos or nevus of Ota. Attempts to remove tattoos with an IPL are inappropriate (despite advertising or FDA approvals to the contrary), as this often leads to burns and/or scarring. In a side-by-side comparative study, IPL was inferior to PDL for the treatment of port-wine stains.

Radiofrequency

Radiofrequency (RF) is a rapidly alternating electric current that locally heats tissue, based on both local current density and electrical resistance of the tissue. The energy deposited at a certain site is proportional to the local tissue impedance multiplied by the square of the local current density. As the name implies, RF generators operate at frequencies similar to AM and FM radio bands. The current is delivered from one or more electrodes held in contact or close proximity to the skin. The number of treatment electrodes defines an RF device as monopolar, bipolar or multipolar. In monopolar RF devices, one pole is located on the treatment handpiece, while the other (if present at all) is a large "passive" electrode placed remotely on the patient's body (Fig. 136.7A). Bipolar RF devices have two active electrodes held in contact with the tissue, and current flows between them (Fig. 136.7B). Because electrode size and spacing have a strong influence, the pattern and depth of heating can be adjusted to some extent.

Unlike most lasers and IPLs, there is little or no intrinsic selectivity to the deposition of energy from an RF source. The single relevant exception is lipid-rich tissue such as subcutaneous fat, which has substantially higher electrical impedance due to lower water content. As with lasers, skin cooling is useful with RF devices, in order to minimize the risk of burns near the delivery electrode.

While many monopolar and bipolar RF devices have been described for skin "tightening" and removal of cellulite or fat, the quality of clinical study-based evidence is generally poor. Because improper electrode

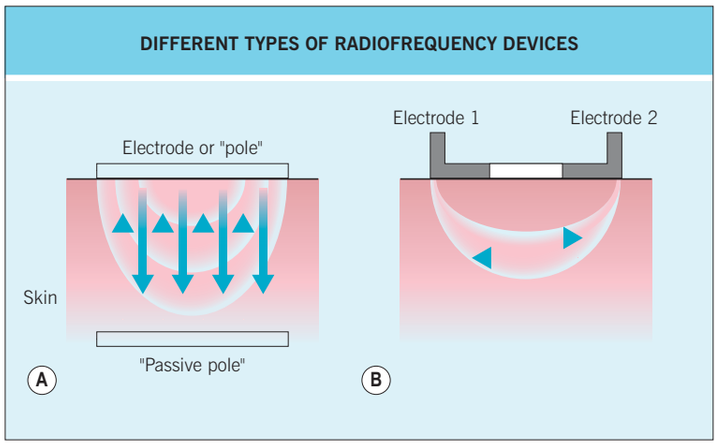

Fig. 136.7 Different types of radiofrequency (RF) devices. A A monopolar RF device has one pole located on the treatment handpiece, while the other (if present at all) is a larger "passive" electrode placed remotely on the patient's body. **B** A bipolar RF device has both poles located within the treatment handpiece and current flows between the electrodes, often in a banana-shaped pattern.

contact with skin is a common cause of injury (e.g. burns), some devices have sensors that monitor proper electrode–skin contact and/or integral skin cooling systems. The RF devices intended for "tightening" are designed to produce partial denaturation of type I collagen, which occurs at temperatures above ~60°C and leads to some immediate tissue contraction and subsequent new collagen synthesis[35].

At high frequencies, RF waves can also be transmitted across a dielectric (insulating) material, similar to radio transmissions through air. RF transmission to the skin from an emitting electrode is called capacitive coupling, and capacitive coupling electrodes have recently been described as "unipolar" RF. At the high frequencies utilized with capacitive coupling, a combination of induced current and rotational oscillations in water molecules produces tissue heating[36].

Fat lobules have higher electrical impedance than skin, fibrous septae or muscle. Thus, the lobules of fat can act as an electrical insulator. A large RF electrode configured to deliver a current path through subcutaneous fat could, in theory, preferentially heat fibrous septae, because these septae must carry a higher current density than the lobules which surround them. Cellulite improvement has been described by different authors following large-electrode, monopolar or bipolar RF. However, the apparent improvement in the appearance of cellulite does not correspond to fat destruction[36,37].

Ultrasound

High-frequency acoustic waves are routinely used for diagnostic medical imaging, at frequencies from ~20 kHz to 10 MHz. Ultrasound is an oscillating pressure (stress) wave that propagates at the speed of sound[38,39], with minimal scattering in soft tissues. The minimal scattering implies that ultrasound waves can be focused deeply in most tissues. Intensity is concentrated near the focal point, to the extent that tissue damage can occur by one or more of three mechanisms – heating, cavitation or shock waves. Heating is favored at high ultrasound frequencies while cavitation (a rapidly expanding gas bubble) is favored at low ultrasound frequencies; shock waves are high pressure, supersonic pressure waves that can be very destructive. Therapeutically, focused ultrasound can be used to destroy targets (e.g. kidney stones by shock waves, tumors by heating, thrombus by cavitation), and it can also promote tissue remodeling or membrane translocations (used in gene therapy)[40–42]. The attenuation (absorption) of ultrasound is greater at higher frequencies, and different materials have different attenuation coefficients[39].

Invasive ultrasonic liposuction probes were introduced over a decade ago to mechanically and thermally assist removal of fat, but with an additional risk of tissue burns (see Ch. 156)[43,44]. Non-invasive, unfocused ultrasound devices are also available, which operate at moderate power levels and are used for physical therapy of the skin (via warming and mechanical stimulation). A focused, pulsed ultrasound device capable of locally destroying subcutaneous abdominal fat was introduced and widely used in Europe, but results were inconsistent.

A non-invasive, focused ultrasound device, operating at megahertz (MHz) frequencies, was recently cleared in the US for the indication of brow lift. However, limited data regarding safety and efficacy are currently available. This device focuses millisecond-domain pulses at the level of the deep dermis and/or superficial fascia, up to a depth of ~4.5 mm. A small focal zone of thermal damage is produced with each pulse, sufficient to achieve tissue contraction at the focus. The treatment transducer is also used for imaging, in order to verify positioning and treatment at a proper tissue plane. This is the first combined diagnostic and therapeutic ultrasound device intended for dermatology.

Low Level Light Therapy (LLLT)

Over the past 50 years, lasers and light-emitting diode (LED) sources have been used for medical "biostimulation", mainly outside the US. Moderate irradiances of light, at certain visible and near-IR wavebands, have long been reported to modulate metabolism in mammals. The FDA mandate to balance risks and benefits is such that devices that pose no known risk are sometimes cleared for sale, with little or no evidence of efficacy. Most sources sold for LLLT do not have specifically approved indications.

That said, the FDA has cleared low power red lasers (continuous, milliwatt power, 630–800 nm wavelength) for treatment of carpal tunnel syndrome and for stimulating hair growth in male pattern alopecia, based on evidence from clinical trials. Moreover, scientific and clinical evidence is mounting in support of LLLT having bona-fide photobiologic effects. Stimulation of mitochondrial activity via light absorption is thought to occur. Mitochondrial signaling pathways affected by light include those that are redox-sensitive, ATP- and cyclic AMP-dependent, and regulated by nitric oxide[45,46].

LLLT may be appropriate as adjunctive therapy in the setting of ischemia, hypoxia or oxidative stress. These conditions exist in many primary cutaneous disorders, as well as after surgery and various laser treatments. The levels of light emitted by available LLLT devices are considered safe during exposure of unprotected skin and eyes.

The advancements in laser and light therapies over the past three decades are built upon the foundation of Albert Einstein's *The Quantum Theory of Light*. In these prescient 1917 writings, he proposed, amongst other concepts, that light consists of quanta of energy, and he hinted at the notion of amplification. In 1958, Townes and Schalow described Microwave Amplification by Stimulated Emission of Radiation (MASER). This was further refined by Thomas Maiman as Light Amplification by Stimulated Emission of Radiation (LASER)[1]. Early laser devices, however, were functionally limited by their lack of selectivity. Anderson and Parrish developed the concept of selective photothermolysis whereby laser energy could be used for targeted destruction of skin components (see Ch. 136). Their 1983 treatise continues to support our understanding of laser–tissue interactions and still drives new therapeutic applications of lasers in dermatology.

This chapter will consider laser and light applications for both medical and aesthetic purposes as related to the skin. Given the multiplicity of lasers available, the laser surgeon must understand the capabilities and limitations of each device so that the appropriate system can be selected and the parameters tailored to treat the intended target (Fig. 137.1). Safe and effective laser therapy is achieved when the operator understands the nature of the target, its location in the skin, and the potential collateral damage.

TYPES OF LASERS AND INTENSE PULSED LIGHT

The earliest lasers used by dermatologists were applied to vascular lesions and consisted of continuous or quasi-continuous wave lasers which emitted a constant beam of light. These included argon (488, 514 nm), argon pumped tunable dye (488–638 nm), copper vapor and copper bromide (511 nm, 578 nm), potassium titanyl phosphate (KTP, 532 nm), and krypton (568 nm) lasers. Although these lasers had wavelengths that corresponded to the hemoglobin absorption spectrum, the nature of their continuous beams generally induced nonspecific thermal damage to surrounding structures, leading to scarring and dyschromia. The root of the problem, a mismatch between the laser pulse duration and the thermal relaxation time of the target tissue (see Ch. 136), was effectively resolved once it was understood that laser pulse duration should approximately match the thermal relaxation time of the targeted tissue.

Pulsed Dye Laser

The pulsed dye laser (PDL) is considered to be the laser of choice for the treatment of many cutaneous vascular lesions, especially port-wine stains (PWS), superficial hemangiomas, poikiloderma of Civatte, facial telangiectasias and rosacea[2]. Hypertrophic and keloidal scars, psoriasis and warts are also amenable to treatment with PDL. While the initial PDL systems emitted 577 nm yellow light, slightly longer wavelength PDL devices (585 or 595 nm) were subsequently adopted to allow deeper tissue penetration of up to 1.2 mm.

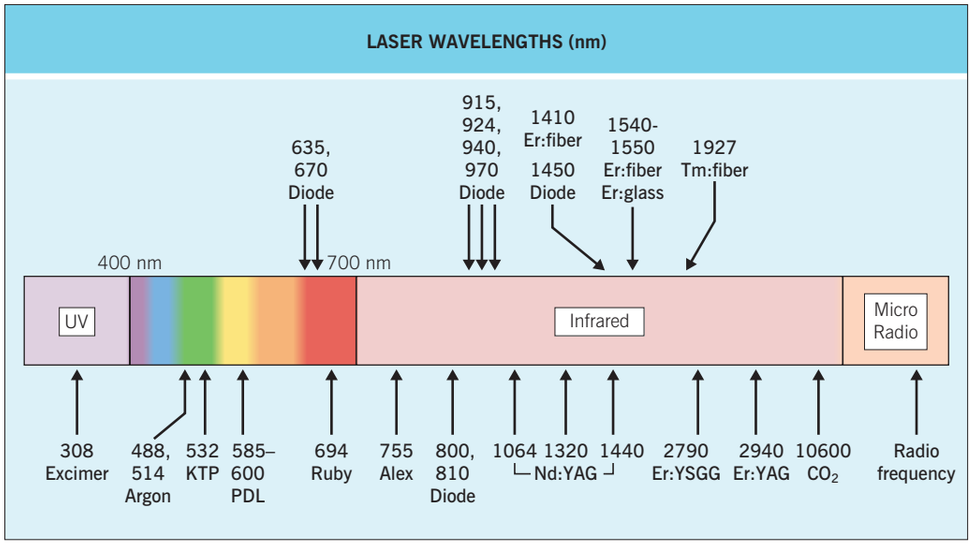

Fig. 137.1 Laser wavelengths (nm). Laser wavelengths lie predominantly within the ultraviolet, visible and infrared portions of the electromagnetic spectrum. Alex, alexandrite; Er, erbium; KTP, potassium titanyl phosphate; Micro, microwaves; Nd, neodymium; PDL, pulsed dye laser; Radio, radio waves; Tm, thulium; UV, ultraviolet; YAG, yttrium-aluminum-garnet; YSGG, yttrium-scandium-gallium-garnet.

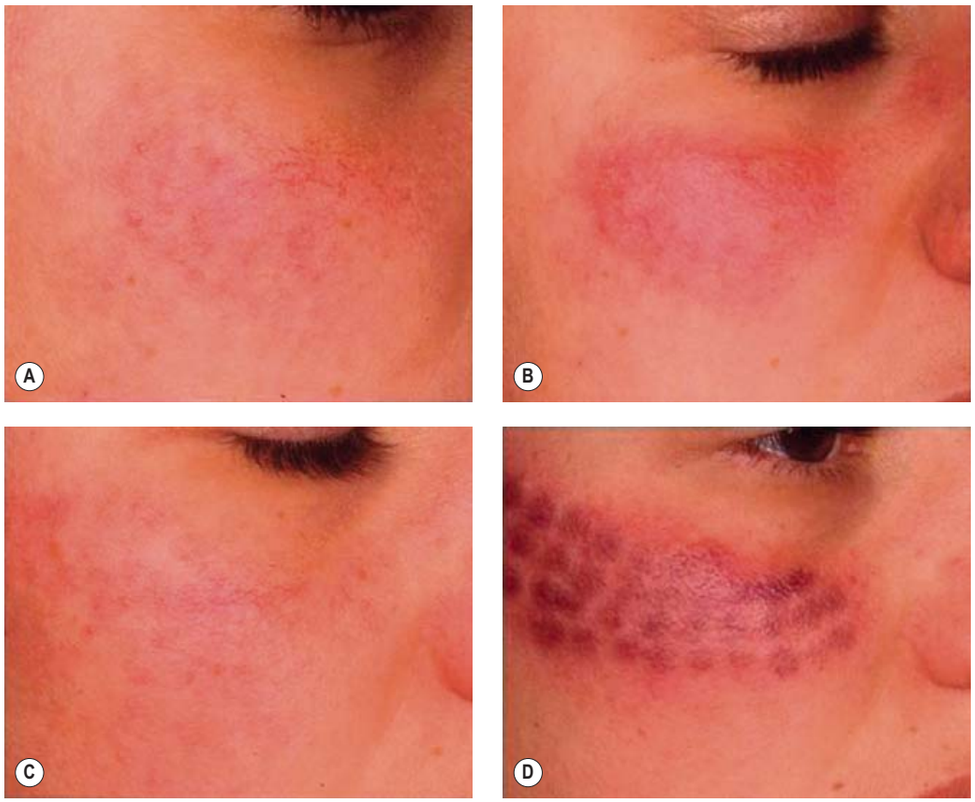

Fig. 137.2 Treatment of facial telangiectasias – potassium titanyl phosphate (KTP) laser versus pulsed dye laser (PDL). A, **C** Pretreatment. Mild erythema follows KTP therapy (**B**) compared to circles of purpura after PDL (**D**).

The choice of appropriate PDL parameters affects tissue response, in terms of both efficacy and appearance. Short pulse durations (0.45–3 millisecond [ms]) cause a purpuric reaction related to intravascular coagulation (Fig. 137.2). While very effective for telangiectasias, the bruised appearance is not cosmetically acceptable to many patients. Although slightly less effective, longer pulse durations (6–10 ms) with "pulse stacking" (application of a rapid succession of pulses to a particular location with cooling to achieve "purpura-free" treatments) is quite effective and less noticeable. The latest generations of PDL modulate this approach by dividing each pulse into eight micro-pulses. This is said to be more selective, to provide uniform vascular heating with a reduction in purpura, and to be more comfortable[3].

Epidermal protection during laser treatments, including those with PDL, is critical. Cooling helps to reduce blistering, crusting, and subsequent dyspigmentation (i.e. hypo- and hyperpigmentation). The most common cooling strategies are contact cooling, forced cold air, and cryogen spray. The Candela PDL systems incorporate cryogen spray cooling (Dynamic Cooling Device™) which is deployed immediately before the light pulse, while Cynosure systems use forced cold air. In addition to protecting the epidermis from non-selective thermal damage, cooling allows for the use of higher fluences, with improved efficacy.

KTP Laser (Frequency-Doubled Nd:YAG Laser)

KTP 532 nm laser light is produced by passing 1064 nm light from an Nd:YAG (neodymium-yttrium-aluminum-garnet) laser through a potassium titanyl phosphate (KTP) crystal, which effectively halves the wavelength and doubles the frequency. Since this wavelength closely corresponds to the first absorption peak of hemoglobin at 542 nm, the KTP laser can be used to effectively treat some vascular lesions (e.g. telangiectasias) in a purpura-free manner (see Fig. 137.2). In addition, this laser is a popular device for the removal of lentigines and other epidermal pigmented lesions. While this laser is best employed in patients with skin phototypes I–III, it can used in darker skin types (IV–VI) for unique applications, such as dermatosis papulosis nigra.

Nd:YAG Laser

The deeply penetrating Nd:YAG 1064 nm laser has significantly less hemoglobin absorption than the wavelengths of the PDL or KTP laser. However, its absorption by melanin is also very limited. The latter property enhances the safety profile of the 1064 nm laser in patients with darker phototypes. Also, this laser can be used to treat deeper vascular lesions and spider veins up to 3 mm in size[4]. Because of its poor coefficient of absorption by hemoglobin, much higher fluences are required to produce transmural heating of blood vessels. As a consequence of the higher fluences and longer pulse widths, this wavelength has a narrow window of safety, with the potential for volumetric heating and collateral damage; in addition, it tends to be quite painful. Cooling is critical for epidermal protection and pain control, as well as to reduce the risk of scarring from nonspecific thermal injury.

Intense Pulsed Light

Intense pulsed light (IPL) systems emit filtered polychromatic light with wavelengths ranging from visible to near infrared (500–1200 nm). Sophisticated filtering and pulsing systems prevent unwanted wavelengths from damaging the skin, and they have made this device more specific and quite versatile. Handpiece cooling is a useful feature present in some devices, and it can be employed to provide epidermal protection, while at the same time allowing greater fluences to reach deeper targets. IPL systems can be used to treat a number of conditions, including rosacea, PWS, hemangiomas, poikiloderma of Civatte and lentigines, as well as provide overall photorejuvenation. The new IPL devices are fast, reliable, and durable.

Cold ultrasound gel or aloe vera gel should be applied as a supplementary technique in order to diffuse surface heat and to act as a "heat sink" away from the epidermis. The gel also reduces the refractive index between air and skin, thus allowing better penetration and absorption of light. In addition, it enhances gliding of the handpiece from one location to the next.

In spite of these measures, thermal injury to the epidermis can still occur, leading to blistering, scarring and permanent pigmentary alterations. This is generally operator-dependent, with a greater risk when treating patients with a tan or darker skin phototypes (Fig. 137.3). IPL is most commonly used for patients with phototypes I–III with chronic photodamage or for hair removal. For treatment of more darkly pigmented patients, longer wavelength filters or lower fluences plus longer pulse widths can be used (Fig. 137.4).

The authors' preferred technique is to deliver multiple passes to a particular treatment area, with each subsequent pass oriented at

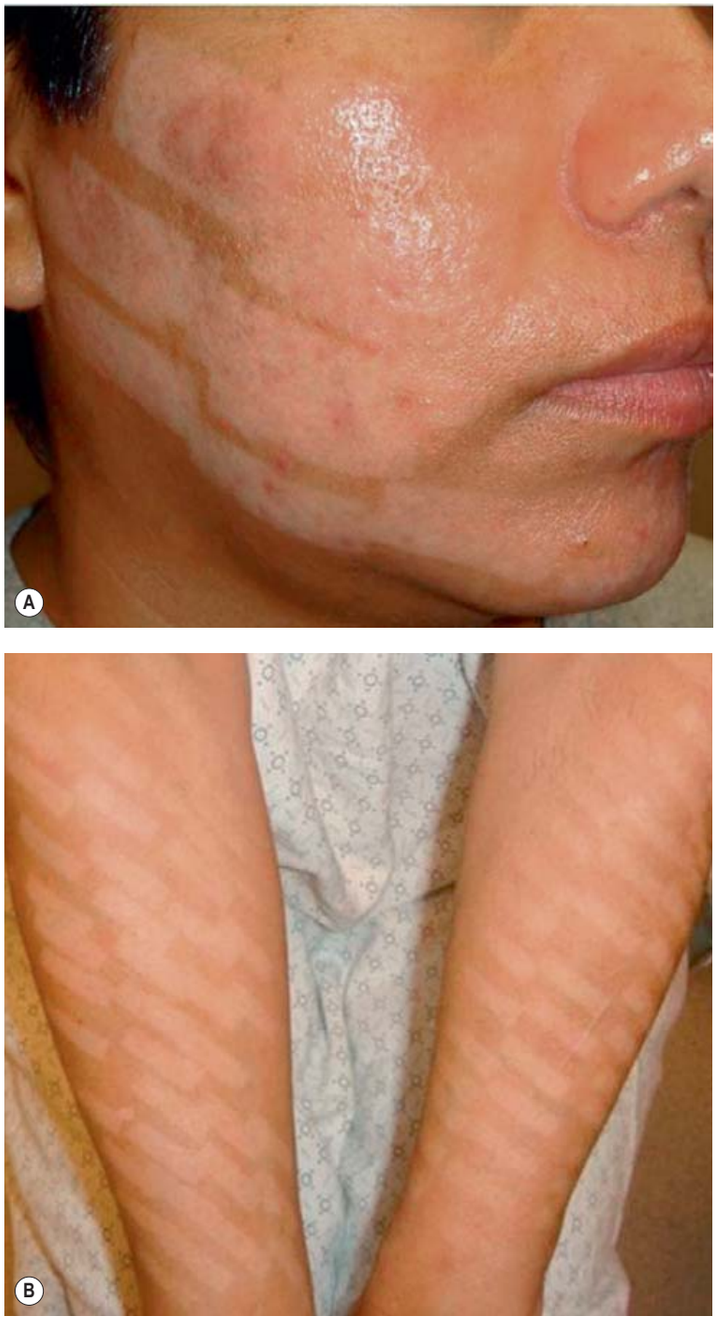

Fig. 137.3 Dyspigmentation and potential scarring due to inappropriate intense pulsed light (IPL) treatments in two patients with darker skin phototypes.

a different angle. This allows for uniform, consistent coverage and prevents zebra-like pigmentary irregularities and skip areas. If double or triple pulses are utilized in any one area, adequate time for epidermal cooling should be allowed between passes. The observable endpoints of IPL treatment are darkening of lentigines (see Fig. 137.4C) and either a disappearance or a darker blue appearance of telangiectasias.

As with any of these devices, the initial pulses should be assessed in terms of the tissue response. Potential problems that should be avoided are excessive blanching, bruising, and production of the Nikolsky sign or other signs of excessive non-selective heating. If cooling is being used, it should be assessed for efficacy. Additionally, care must be taken to avoid inadvertent photoepilation of eyebrows, and, for men, bearded skin.

TREATMENT OF VASCULAR LESIONS

Although patients most commonly present with telangiectasias and rosacea, one should also be familiar with the latest techniques available for the treatment of PWS and hemangiomas. The target chromophore in vascular lesions is oxyhemoglobin[5], with absorption peaks at 418, 542 and 577 nm (see Fig. 136.3). While the primary target is hemoglobin, the structurally dynamic nature of the skin does not allow for simplistic "targeting". Factors such as blood vessel depth, thickness, and skin phototype are also highly relevant considerations when treating vascular lesions.

Equally important considerations are the structures that the laser surgeon wishes to avoid, such as normal epidermal melanocytes, hair follicles, and the epidermis as a whole. Therefore, while the above wavelengths allow for maximal absorption, longer wavelengths are associated with less melanin absorption and deeper penetration. The most commonly used devices for the treatment of vascular lesions include IPL and the 532 nm KTP, 595 nm PDL, and 1064 nm Nd:YAG lasers. Other systems such as the 755 nm alexandrite and the 940 nm diode lasers also play an important role in the treatment of vascular lesions (Table 137.1).

Clinical improvement is best achieved by photothermal vascular damage[6]. As the pulse width approximates or exceeds the thermal relaxation time of the target vessel (approximately 1.5 ms), photothermal damage results. This induces *intravascular* thrombosis and subsequent collagenous fibrosis of the blood vessel wall and adjacent tissues[6]. These changes result in an immediate purpuric reaction (see Fig. 137.2D). Given the unwanted cosmetic appearance of the latter, which can last for 2 weeks, longer pulse widths (>6 ms) are often used, as they produce more gentle heating of the target vessel and avoid bruising altogether. However, some degree of intravascular thrombosis may be a prerequisite for clinical improvement and resolution of vascular lesions, as is the case in PWS.

Port-Wine Stains (PWS)

One of the first clinical applications of laser therapy was treatment of congenital vascular lesions, namely port-wine stains (PWS). PWS are capillary malformations that involve primarily the mid to superficial dermis; they occur in up to 0.5% of newborns and initially present as faint, light pink patches. These vascular anomalies are cosmetically and psychologically problematical as they are frequently located on the face. Approximately 5–10% of patients with unilateral PWS involving V1 have Sturge–Weber syndrome, with associated ocular and neurologic involvement. When located on the extremities, patients may develop Klippel–Trenaunay syndrome with soft tissue hypertrophy, especially when there is a sharply demarcated geographic stain (see Ch. 104).

Prior to laser therapy, PWS were treated via destructive modalities such as cryosurgery, dermabrasion, and X-ray radiation. These therapies often resulted in disfiguring scars. An early and relatively successful treatment of PWS utilized the continuous wave argon laser (488 and 514 nm). Despite the wavelength's relative specificity for its vascular target, this laser caused marked scarring in up to a third of patients[7]. The latter was caused by nonspecific thermal injury due to the exposure time of the beam (~ 200 ms) being in dramatic excess of the thermal relaxation time of the PWS vessels (~ 1–10 ms)[8].

A therapeutic paradigm shift evolved with the concept of selective photothermolysis and the development of the PDL, which was specifically designed to treat PWS. The first study, conducted by Tan et al.[9], demonstrated significant fading in all 35 patients (ages 3 months to 14 years) after an initial treatment and complete clearance after an average of 6.5 treatments. Most remarkably, the sequelae were minor, with some patients experiencing short-term hyperpigmentation and only two patients developing shallow depressed scarring. Although subsequent studies found significantly lower clearance rates, this initial study demonstrated a pattern of safety and efficacy of PDL for treatment of PWS.

While the early PDLs emitted a 577 nm wavelength, the current PDL systems deliver 585 and 595 nm, allowing targeted delivery of laser energy deeper into the skin with increased efficacy. These longer wavelengths are less well absorbed by hemoglobin, but they penetrate deeper into the vascular malformation, inducing a more even heating of the PWS[10]. Addition of the Dynamic Cooling Device™ (DCD) has allowed for the use of much higher fluences. Commonly used settings range from fluences of 4 to 15 J/cm^2 with pulse widths of 1.5–10 ms with a 7–12 mm spot size[11]. Larger spot sizes are associated with deeper energy penetration, but the fluence should be moderated with increasing beam diameter in order to avoid thermal damage related to the

Fig. 137.4 Intense pulsed light (IPL) treatment of lentigines in a patient with Fitzpatrick phototype IV skin. Because of the more darkly pigmented skin, lower energy and a longer pulse duration were carefully employed. **A** Preoperative. **B** Lentigines are appropriately slightly darker immediately following IPL. **C** Dry crusting of the skin 3 days postoperatively. **D** Excellent improvement of facial lentigines at 10 days.

Gaussian distribution of energy (i.e. the beam is hotter in the center than laterally, see Ch. 136).

For both technical and psychological reasons, early treatment of PWS is recommended. As compared to infantile hemangiomas, the dilated and ectatic vessels of PWS are not proliferative nor do they self-involute. Their surface area becomes proportionately larger as the child grows and many become thicker (with soft tissue hypertrophy), darker in color and deeper. As such, their treatment becomes clinically more challenging and often requires use of lasers with longer wavelengths, along with higher fluences and longer pulse durations to effectively treat the deeper and thicker vessels. Studies support this notion and have demonstrated that the extent of clearance is dependent on lesion size and depth[12]. From the psychological standpoint, PWS have been shown to impact childhood social and cognitive development and can have lasting repercussions on adult social relationships[13,14]. In addition, early treatment permits shorter treatment sessions (as the lesions are smaller), fewer sessions, and may allow resolution of the vascular anomaly prior to the child developing memory of the treatment and its associated stressors. Lastly, laser treatment in children younger than 6 months of age has been demonstrated to be safe and effective[15].

While 70% of PWS will have good or very good improvement (Fig. 137.5), a minority (<10%) will have very modest or no improvement. The degree of PWS clearance is dependent on the size of the lesion and its anatomic location[16]. For example, centrally located facial lesions (i.e. medial cheeks, upper lip and nose) require multiple sessions for improvement and tend to be more treatment-resistant as compared to lesions located in the periorbital region or on the forehead, lateral cheeks, or chin. Classically, treatment-resistant areas of PWS, which may correspond to more deeply situated vessels, are distributed within the second branch of the trigeminal nerve (V2). Likewise, PWS on distal extremities are more treatment-resistant and require a more aggressive approach. Although remarkable responses can be obtained after one laser treatment, treatment of PWS typically requires multiple sessions.

Given that PWS are composed of various-sized blood vessels, each with their own required treatment parameters, the PDL may prove inadequate in eliminating the entire capillary malformation. Poor responses may be related to poor laser penetration, a mismatch of parameters to vessel size, inadequate vascular heating, or scarce or poor chromophore uptake[17]. Given the limitations of the PDL, resistant

LASERS AND OTHER DEVICES USED FOR THE TREATMENT OF VASCULAR LESIONS

components of PWS may also be treated with the alexandrite and Nd:YAG lasers or IPL.

Infantile Hemangiomas

Representing the most common tumor of infancy, hemangiomas have a predilection for the head and neck region (60%), followed by the trunk and the extremities. They are present in 1–2% of neonates and there is a higher incidence in premature infants. These tumors are classically absent or very small at birth, but then appear and/or grow rapidly within the first few weeks of life. Infantile hemangiomas may have both superficial and deep components, with the superficial portions appearing red and the deeper components appearing blue. They can be categorized as segmental or focal (see Ch. 103)[17]. Their natural maturation involves a proliferative phase, a static phase, and an involutional phase. According to the classic teaching, 50% regress by age 5 years, 70% by age 7, and >90% by adolescence. Although hemangiomas can regress leaving the affected skin with normal texture and color, many heal with hyper- or hypopigmentation and atrophy or fibrofatty change (see Fig. 103.11).

Treatment of infantile hemangiomas, if any, should be tailored to the specific lesion, with consideration of its location, size, proliferative rate, and whether it is likely to produce a functional or anatomic deficit. Complicated infantile hemangiomas require a multidisciplinary approach, involving dermatology, pediatrics, interventional radiology, otolaryngology, plastic surgery, and ophthalmology. Common therapeutic options include monitoring, intralesional corticosteroids, systemic corticosteroids, surgical excision, and laser therapy. However, multiple recent studies have demonstrated the efficacy of propanolol in producing regression[18]. To date, the use of β-blockers appears to be relatively safe and propranolol is becoming a mainstay of treatment regimens for large or functionally significant hemangiomas.

Although the role of laser therapy in the treatment of infantile hemangiomas is controversial, PDL can be used and it may decrease the risk of ulceration and scarring. A retrospective study demonstrated a distinct improvement in 50% of infants with painful, ulcerated infantile hemangiomas (18% had no response and 5% were made worse) following therapy[19]. While some authors maintain that treatment with PDL can moderate the proliferative phase of infantile hemangiomas, this issue is contentious and debatable[20]. In the largest study of hemangiomas in children, abruption in growth was demonstrated in 96.6% of 692 lesions after PDL[21]. While these results seem extremely optimistic,

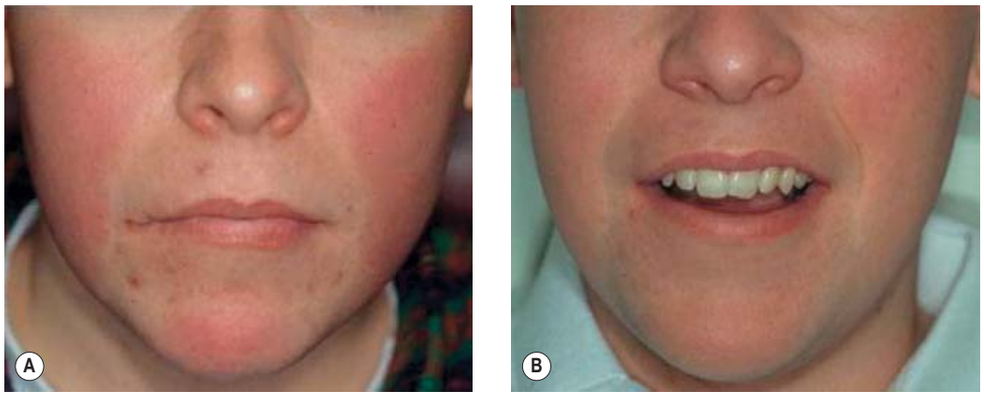

Fig. 137.6 Erythematotelangiectactic rosacea. Improvement of facial erythema and flushing 2 months following pulsed dye laser (PDL) therapy.

they do balance the opposing view that the PDL has limited benefit in children with hemangiomas. Other options that may be beneficial for these hemangiomas are IPL and, for deeper hemangiomas, the Nd:YAG (1064 nm) laser, although the latter can induce significant scarring.

Epidermal protection is critical in the treatment of infantile hemangiomas. Among the most significant side effects of laser therapy are scarring and pigmentary changes, both of which can be minimized by appropriate epidermal cooling mechanisms (e.g. contact cooling, cryogen spray cooling, forced cold air). These not only protect the epidermis, but also allow the use of higher fluences.

Telangiectasias

Patients frequently present with facial telangiectasias. These are most commonly associated with rosacea and chronic photodamage, but are also seen in the setting of liver disease, autoimmune connective tissue disorders, surgical scars, and misuse of topical corticosteroids. They are typically located on the nose, cheeks and chin and measure 0.1–1.0 mm in diameter. Facial lesions of this caliber are commonly treated with the KTP laser, IPL and PDL systems. When the PDL is used with short pulse durations, significant clearance can be achieved, albeit with significant bruising (see Fig. 137.2D). Clearance of facial vessels can be achieved with *non-purpuric fluences* or treatments that employ fluences ranging from 6.5 to 8.5 J/cm^2 with longer pulse durations (10–16 ms) using 10–12 mm spot sizes. At these settings, multiple passes and/or pulse-stacking techniques are typically employed to improve efficacy. Additionally, multiple treatment sessions may be required[22,23]. These techniques can be particularly beneficial for patients with recurring flushing and central facial erythema (Fig. 137.6).

Treatment of telangiectasias with the KTP laser with a small (0.2 to 2 mm) beam diameter induces few side effects, with little or no bruising and less swelling, pain and redness than is seen with the PDL (see Fig. 137.2). Larger-caliber, darker, deeper facial vessels can be effectively treated with the Nd:YAG laser, particularly in dark-skinned patients. However, to compensate for the diminished absorption of 1064 nm light by hemoglobin (nearly 10-fold less compared with 595 nm light), an increased fluence is required, making vigorous cooling necessary both for epidermal protection and to reduce patient discomfort. Finally, IPL is commonly used for purpura-free treatment of facial telangiectasias utilizing a 550 or 560 nm cut-off filter. The treatment endpoint for telangiectasias is vessel spasm or the change of the vessel color to a more dusky appearance.

Poikiloderma of Civatte

Poikiloderma of Civatte is a hallmark reflection of photodamage and involves the lateral aspects of the cheeks, neck and upper chest. While a prominent component is telangiectasias, there is also epidermal atrophy and actinic dyspigmentation. Comprehensive treatment requires consideration of each component. Options include IPL, PDL and KTP laser; new devices such as the fractionated ablative and nonablative lasers can also be used. When there is insufficient overlap of adjacent PDL pulses, a persistent "honeycomb-like" appearance may occur, with circles of improvement in color, texture and tone surrounded by a network of relatively untreated skin (Fig. 137.7). This

Fig. 137.7 "Footprinting" on the cheek of a young girl following pulsed dye laser (PDL) therapy of a port-wine stain. There is a honeycomb-like appearance due to circles of improvement surrounded by a network of relatively untreated skin.

mottled look can require multiple treatments to eradicate, and it is due to the Gaussian distribution of the light beam in which the center of the beam produces greater clearance than the edges.

Since IPL can favorably improve both dyspigmentation and telangiectasias, this system is perhaps more ideally suited to treat poikiloderma of Civatte. Several studies have reported 50–75% improvement in both the vascular component and the actinic dyspigmentation, with a low side-effect profile[24]. The pertinent short-term side effects are transient erythema and intentional darkening of lentigines, which all disappear in about a week. Although "footprinting" is possible with IPL, it is far less common than with PDL, given the larger size of the crystal IPL handpiece. Additionally, use of a multiple-pass technique applied in different orientations tends to minimize this unintended "footprint" consequence.

Telangiectasias and Venulectasias of the Leg ("Spider" Leg Veins)

"Spider veins" of the legs affect approximately 80% of men and women in the US[25]. These telangiectasias and venulectasias are red and blue in color, measure 0.2 to 2 mm in diameter, and develop in dependent areas, predominantly the legs. While a number of spider veins appear independently of deeper vascular disorders, a surprisingly high percentage can be improved by treating deeper underlying venous disease. While the superficial venous plexus is located in the skin, subcutaneous tissue and superficial fascia, the deep venous plexus is located within underlying muscle, with the two plexuses interconnected by perforating veins[26]. Whether as a consequence of age, hormonal or genetic factors, or trauma to the vessel wall, venous valvular incompetence produces increased hydrostatic pressure and ultimately vessel dilation (see Ch. 155).

Whereas facial telangiectasias are generally superficial, small in caliber, and have normal hydrostatic pressures, leg veins are larger in diameter, thicker in caliber, and are situated more deeply in the skin[27]. Additionally, as in any treatment site, there is heterogeneity in the size,

color and caliber of ectasias. These properties make treatment of leg veins even more challenging. While sclerotherapy is still the first-line therapy for spider veins (see Ch. 155), laser treatment is a viable option in a minority of patients (see Table 137.1). The latter include those with needle phobias, telangiectatic matting, ankle veins, and lack of a favorable response to sclerotherapy[27]. Also, laser therapy may be advisable in patients with a previous history of adverse reactions to sclerosing agents. The PDL and KTP laser can be used to treat small-caliber pink and red vessels which are too fine to cannulate with sclerotherapy needles, e.g. the telangiectatic matting that can be a consequence of prior sclerotherapy.

The target chromophore for leg veins is hemoglobin. While the 532 nm KTP laser, 585–595 nm PDL, and IPL are well absorbed by this target, the more limited depth of penetration does not allow for consistent treatment of vessels >1 mm in width located at depths >1.0 mm[28]. The results with IPL devices are inconsistent, unpredictable and vary depending on the selected parameters. Furthermore, these devices have more unfavorable side effects compared to sclerotherapy. Hyperpigmentation following PDL occurs in 20–40% of patients and can persist for 3 months or longer. This side effect may be related both to red cell extravasation and to epidermal cryogen spray injury. Many laser surgeons (including the authors) have used the long-pulsed Nd:YAG laser for the treatment of larger, deeper leg veins. While there is no doubt that some leg veins can be cleared, the pain, postinflammatory hyperpigmentation, and potential for scarring have many clinicians avoiding this device for this indication.

Given that leg veins are heterogeneous in their color, size, caliber and depth, and that many result from venous valvular incompetence, ultrasound investigation can assist in determining the most appropriate treatment strategy. Combination therapy using endovenous lasers, ambulatory phlebectomy, and sclerotherapy may represent the best approach for long-term, successful treatment of lower extremity ectasias. Synergistic improvement has been demonstrated when these treatments were used in combination (see Ch. 155)[4].

Verrucae

Verruca vulgaris is caused by the human papillomavirus, which induces epidermal hyperplasia and neovascularization in affected skin. The use of lasers is said to be based on the principle of targeting their vascular component which is evident histologically as dilated blood vessels in the dermal papillae. Early on, successful treatment was reported with the copper vapor laser, presumably by its inducing vascular coagulation of these reactive vessels[29]. Use of the PDL has been shown to induce intravascular thrombosis and vessel wall necrosis in patients with verrucae[30]. However, the nonspecific heat effect from lasers is likely the main mechanism for wart clearance with laser therapy. "Laserthermia" of warts, particularly with the Nd:YAG laser, has produced clearance in 75% of patients[31]. The mechanism may involve coagulation of epidermal proteins and blood vessels, with stimulation of a reactive inflammatory response. Although a similar tissue response is likely caused by carbon dioxide ablation of verrucae, response rates have been more variable, ranging from 30% to 80%[32]. Most notably, scarring and onychodystrophy can result from treatment of periungual verrucae with such ablative laser therapies[33,34].

Currently, the PDL is the most commonly used laser for the treatment of recalcitrant verrucae. A notable lack of bleeding and scarring makes this laser a favorable choice. Given the limited penetration of the PDL, hyperkeratotic portions of the wart are first pared down without inciting bleeding. Then, the lesions are treated until a dusky gray color is seen. However, rather high fluences are used, making this treatment quite painful, especially on the fingers. Depending upon the pain tolerance of the patient, digital nerve blocks may be needed. This procedure is repeated every 2 weeks until clinical resolution.

Clearance rates vary from 20% to 95%, and this range has been attributed to the variability (between studies) in the number and frequency of treatments as well as applied fluences. Despite these data, absolute benefit of the PDL over "conventional therapy" (consisting of cryotherapy and cantharidin) was not established in a prospective randomized trial. In fact, the two arms of the trial were similar in the percentage of patients with complete verruca clearance and the number of treatments needed for complete responses[33]. While laser therapy for verrucae is not exclusively beneficial, it does supplement the dermatologist's armamentarium in the treatment of these recalcitrant lesions.

Pyogenic Granulomas

Pyogenic granulomas (PG) are idiopathic, abruptly presenting, vascular neoplasms that tend to grow rapidly and bleed easily. Over 50% of these lesions recur after electrocoagulation, presumably because such desiccative treatments fail to ablate the deeper vascular components[35]. Both the argon and CO_2 lasers have been used to treat these neoplasms. More specific targeting of the vascular nature of PG has been attempted with the PDL, whether used directly on the lesion or in combination with glass slide diascopy to blanch out superficial components. Greater success may be achieved with antecedent removal of the papular component (by shave or electrodesiccation techniques) prior to PDL of the more deeply situated vessels. While shave removal followed by desiccation is still the first-line treatment for most patients, less scarring is noted with the PDL, when used either with modest fluences (1.5 ms pulses) *without cooling* or multiple stacked pulses (5–10 ms) *with cooling*.

Venous Lakes

Venous lakes are commonly seen on the lips or ears as gray–blue to purple compressible papulonodules and represent dilated venules in the superficial dermis. While innocent biologically, these lesions are brought to the attention of dermatologists because of cosmetic concerns or a history of periodic bleeding. Traditionally, electrocoagulation has been used, but scarring and recurrence are common sequelae. IPL, the argon laser, PDL, Nd:YAG laser and infrared coagulator have all been used successfully. It is likely that the alexandrite laser would also be effective.

Pain Considerations

PDL treatment can be associated with significant discomfort and has been typically described as a "hot rubber band" snapping on the skin. Whereas this procedure is generally well tolerated by adults, children typically require topical anesthesia for localized lesions. More diffuse vascular processes in children may require local or general anesthesia. KTP laser therapy is associated with fleeting stinging on the skin as the laser is applied onto the skin. IPL treatments can be performed with or without topical anesthesia. Forced cold air or ice chilling is an effective method for reducing discomfort and protecting the epidermis at the same time. Vibration distraction (gate theory) can also be effective. Nerve blocks are simple and effective for digital procedures.

TREATMENT OF TATTOOS

A tattoo is the deposition of an exogenous pigmented material into the skin. Although the most common purpose for tattooing is artistic and cosmetic, it has also been utilized in the medical field, in particular as radiation port markers. Additionally, tattoo pigment composed of lead, asphalt, gunpowder or coal can be induced explosively or traumatically. Once embedded, the exogenous pigment is taken up into lysosomes within dermal fibroblasts, macrophages and mast cells. These pigment granules measure 2–400 nm, but generally average about 40 nm in diameter. Regardless of the inciting cause or initial motivation, removal of such pigment is a common patient demand. Prior to advancements in laser technology, the removal of tattoos was frequently associated with disfiguring scarring. Methods utilized were excision, dermabrasion, salabrasion, laser ablation and electrodesiccation. With the evolution of the Q-switched laser, pigment eradication can be more safely achieved, with less scarring and/or pigmentary changes.

Q-switched lasers are characterized by having extremely short, nanosecond pulses of energy. The latter induce photomechanical and photoacoustic laser–tissue interactions. The exceptionally short pulse duration limits the thermal damage to just the lysosome. The rapid pulse induces an exponential increase in temperature to 200–300°C within nanoseconds, causing dramatic expansion within the organelle, followed by an equally catastrophic contraction/collapse of the same compartment, leading to *cavitation* of the lysosome. Clinically, the laser tissue reaction is seen as immediate epidermal whitening, which is essentially water vapor within the epidermis (Fig. 137.8). Mechanical damage results in cell membrane rupture and the release of exogenous

Fig. 137.8 Immediate tissue whitening following treatment of a tattoo with the Q-switched alexandrite laser. *Courtesy, Roy Grekin, MD.*

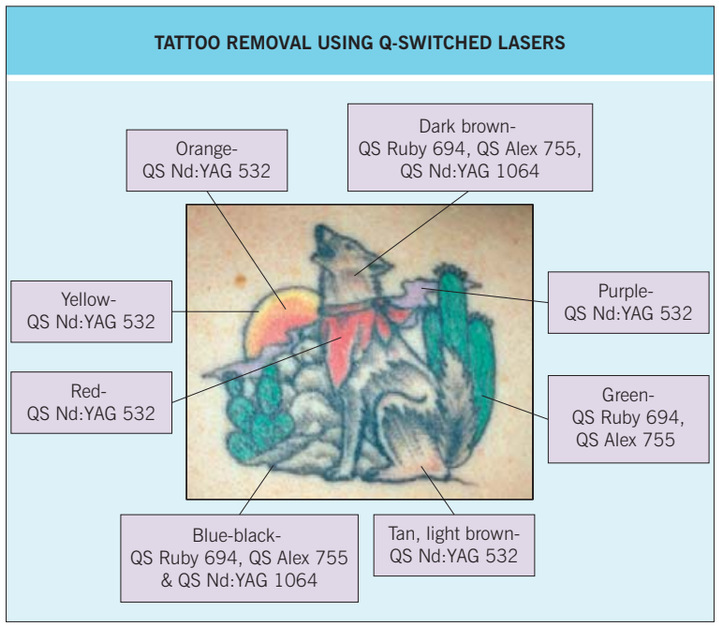

Fig. 137.9 Tattoo removal using Q-switched lasers. The Q-switched (QS) Nd:YAG (532 nm) laser can be used to try to remove red, orange, yellow, purple and tan/light brown pigments. The QS alexandrite (Alex; 755 nm) and QS ruby (694 nm) lasers can be employed to remove green tattoo ink, while the QS Alex, QS ruby and QS Nd:YAG (1064 nm) lasers can remove blue–black and dark brown tattoo ink. See Table 137.2 for details. *Courtesy, Jean L Bolognia, MD.*

pigment into the extracellular space. The pigment is then removed predominantly via lymphatic drainage, or it is simply re-phagocytosed.

Selection of the appropriate Q-switched laser is determined by the colors of tattoo pigment to be targeted (Fig. 137.9). Based on "complementary matching" of tattoo pigment, green tattoo pigment is most effectively removed by a red laser (694 nm), and red tattoo pigment is best removed with a green laser (532 nm). Blue and black pigments are removed with all three Q-switched lasers – ruby, alexandrite and Nd:YAG. More difficult to remove are yellow and orange pigments, as these are not well absorbed by currently commercially available laser light.

Although the advancements in laser technology and the refinement of Q-switched lasers have made pigment removal more safe and effective than before, absolute eradication of the pigment can be quite difficult (Table 137.2). Whether the tattoo was placed by an amateur or a professional tattoo artist is an important factor in how completely the tattoo can be removed. Amateur tattoos often incorporate blue–black pigments that are carbon-based, such as India ink. Given that these tattoos have only a few colors, and coupled with the observation that they may be placed more superficially in the skin, amateur tattoos are relatively easy to remove. Professional tattoo artists incorporate a wider spectrum of colors and deposit the pigments within the deep papillary and superficial reticular dermis. Hence, removal of these more complex professional tattoos can be problematic, even with the best devices.

Complications of tattoo removal include both hyper- and hypopigmentation. While hypopigmentation is observed with the ruby and alexandrite lasers, hyperpigmentation is common in more darkly pigmented patients. It has often been said that the Q-switched lasers removed tattoo pigment without scarring. While this is often true, there can be significant textural changes after multiple treatments with high-fluence devices. Additionally, inflammatory reactions to tattoo ink have been reported, including eczematous, granulomatous and lichenoid reactions. When systemic reactions occur after laser treatment, they are the consequence of mobilized antigens.

Paradoxical darkening of skin-colored tattoo ink is a common phenomenon following treatment with any of the Q-switched lasers. This unfortunate event happens immediately after a single laser pulse and is caused by a shift from an oxidized state to a reduced state in the tattoo pigment. This was classically reported as darkening of red "lip liner" to dark brown or black pigment as the ferric oxide tattoo was reduced to ferrous oxide (Fig. 137.10). Similar color changes can be seen in tattoos with titanium dioxide, a common agent used to lighten tattoo pigments; when a Q-switched laser is applied to titanium, it can change from white to blue–black. Although this problematic side effect can be improved via continued treatment with any of the Q-switched lasers, a test spot is wise with such tattoos, particularly on the face.

Fig. 137.10 Paradoxical tattoo darkening reaction following Q-switched laser removal of pink tattoo at the lip margin.

TREATMENT OF MELANIN-CONTAINING LESIONS

Ephelides and Lentigines

Since melanin has a broad absorption spectrum (see Fig. 136.3), many lasers can be used to treat melanin-containing lesions. At the lower end of the therapeutic window, the penetration of green lasers is limited to

TATTOO PIGMENTS, LASERS USED FOR THEIR REMOVAL, AND POTENTIAL COMPLICATIONS			
Color/ etiology	**Pigment**	**Lasers**	**Complications**
Traumatic	Lead, dirt, gunpowder, other	QS ruby, QS alexandrite, QS Nd:YAG (1064)	Hypopigmentation, micro-explosions (gunpowder)
Amateur black	India ink, carbon	QS ruby, QS alexandrite, QS Nd:YAG (1064)	Hypopigmentation
Professional black	Carbon, iron oxide, logwood extract	QS ruby, QS alexandrite, QS Nd:YAG (1064)	Hypopigmentation
Blue	Cobalt aluminate (azure blue)	QS ruby, QS alexandrite, QS Nd:YAG (1064)	Hypopigmentation
Green	Chromium oxide (casalis green), hydrated chromium sesquioxide (guignet green), malachite green, lead chromate, ferro-ferric cyanide, curcumin green, phthalocyanine dyes (copper salts with yellow coal tar dyes)	QS ruby, QS alexandrite	Hypopigmentation, allergic reactions (chromium)
Red	Mercury sulfide (cinnabar), cadmium selenide (cadmium red), sienna (red ochre; ferric hydrate and ferric sulfate), azo dyes	QS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening, allergic reactions (mercury sulfide, cadmium, azo dyes)
Yellow	Cadmium sulfide (cadmium yellow), ochre, curcumin yellow	QS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening, allergic reactions (cadmium)
Brown	Ochre	Tan/light brown: QS Nd:YAG (532) Dark brown: QS ruby, QS alexandrite, QS Nd:YAG (1064)	Hypopigmentation, tattoo ink darkening
Violet	Manganese violet	QS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening
White	Titanium dioxide, zinc oxide	QS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening
Skin colored	Iron oxides	QS Nd:YAG (532)	Hypopigmentation, tattoo ink darkening

Table 137.2 Tattoo pigments, lasers used for their removal, and potential complications. Hyperpigmentation and textural changes also occasionally occur as complications. Hypo- and hyperpigmentation are more common in individuals with darkly pigmented skin, and they are best treated with the Q-switched (QS) Nd:YAG (1064) laser to reduce this risk.

the superficial papillary dermis. These lasers are best utilized for epidermal pigmented lesions. Thus, the frequency-doubled Nd:YAG (532 nm), either Q-switched or normal mode, effectively treats lentigines and ephelides in most skin types with limited recurrence[36]. Additional lasers, e.g. the 800 nm diode, as well as IPL can also be used to treat epidermal pigmented lesions (Table 137.3). While the PDL is most commonly used for vascular lesions, 595 nm light is also well absorbed by melanin and can be used to treat pigmented lesions. By incorporating compression, the vascular component of the skin is blanched out and melanin-containing lesions can be targeted. Newer PDL systems have incorporated such a "compression handpiece".

In general, the Q-switched ruby and alexandrite lasers are more effective for treatment of more deeply situated pigmented lesions (e.g. nevus of Ota), as these wavelengths have an increased depth of penetration. Q-switched ruby (694 nm) laser light is better absorbed by melanin than is alexandrite (755 nm) laser light, which might be an advantage in lighter-skinned individuals, but problematic in darker-skinned patients, given the increased likelihood of nonspecific heating of normal epidermal melanin. Nd:YAG laser light is much less well absorbed by melanin, but reaches deeply into the skin; therefore, it is primarily used to treat dermal pigmented lesions. For the treatment of lentigines, ephelides, and café-au-lait macules as well as nevus of Ota, understanding these profiles allows one to choose the optimal device. The clinical response of pigmented lesions to Q-switched lasers is determined by where the pigment is localized (epidermal, dermal or mixed), whether it is intracellular or extracellular, and what the pigment is composed of (usually melanin)[37].

Benign Melanocytic Nevi

Laser removal of acquired and congenital nevi is controversial since no specimen is submitted for tissue diagnosis and margin assessment. Furthermore, the future biologic behavior of laser-resistant cells and the effect (if any) of laser thermal injury on these cells is unknown. Since the clinical standard of care is excision for any atypical pigmented lesion, laser treatment of melanocytic lesions should only be considered for clinically banal lesions in patients with no personal or family history of melanoma.

Both acquired and congenital melanocytic nevi have been treated with Q-switched ruby, alexandrite and Nd:YAG lasers[38]. The 694 and 755 nm devices can improve the appearance of acquired junctional melanocytic nevi without scarring[39]. In general, smaller and thinner lesions are typically more treatment-sensitive. While congenital lesions can be lightened, complete eradication is much more difficult and recurrence is common. Laser therapy decreases the number of the pigmented nevomelanocytic cells in the papillary dermis, but is unlikely to treat deeper seated non-pigmented cells that are closely associated with adnexal structures. This has been demonstrated histologically as persistent nevomelanocytic nests in the mid papillary and deeper dermis at depths of 0.16–0.44 mm. Deeper components of these nevi located in muscle or under fascia will remain unaffected by laser surgery.

The normal mode (non-Q-switched) long-pulsed ruby and alexandrite lasers have also been used to treat acquired nevi. Some of the clinical lightening observed has been attributed to fibroplasia of the dermis overlying the residual nevomelanocytes. Although fibroplasia may be cosmetically useful, this change potentially hides early signs of malignant transformation and might cause a delay in diagnosis. Therefore, patients who have any melanocytic nevi treated with lasers should understand that they need to report subsequent changes in color, shape or size. As long-pulse lasers deposit a lot of energy into the tissue, the potential for nonspecific thermal injury increases, with an associated increased risk of scarring. Lastly, the clinician must remember that early cutaneous melanoma can have a subtle clinical appearance.

Café-au-Lait Macules and Nevus Spilus

Café-au-lait macules (CALM) are tan–brown patches which histologically correspond to hypermelanosis of the basal melanocytes and

LASERS AND OTHER LIGHT-BASED DEVICES USED FOR THE TREATMENT OF PIGMENTED LESIONS				
Laser/device	**Wavelength (nm)**	**Fluence (J/cm²)**	**Pulse duration**	**Applications**
Q-SWITCHED LASERS (HIGHLY PIGMENT-SPECIFIC)				
Q-switched Nd:YAG, frequency-doubled	532	0.4–6	5–10 ns	Lentigines
Q-switched ruby	694	3–12	20–40 ns	Lentigines, nevi*
Q-switched alexandrite	755	1–12	50–100 ns	Lentigines, nevi*
Q-switched Nd:YAG	1064	3–12	5–10 ns	Nevi*
IPL, LONG-PULSED LASERS AND PDL WITH COMPRESSION (LESS PIGMENT-SPECIFIC)				
Intense pulsed light (IPL)	500–1200	Up to 30	5–10 ms	Lentigines, nevi*
Long-pulsed ruby†	694	5–30	Up to 4 ms	Nevi*
Diode	800	5–50	5–100 ms	Lentigines, nevi*
Nd:YAG	1064	Up to 300	1–100 ms	Nevi*
PDL with compression	595	3–5	0.45–1.5 ms	Lentigines
Long-pulsed alexandrite	755	25–50	0.5–300 ms	Lentigines, nevi*

*Treatment of pigmented melanocytic nevi (especially acquired lesions) is controversial.
†No longer being manufactured.

Table 137.3 Lasers and other light-based devices used for the treatment of pigmented lesions. Q-switched lasers are most effective for treating pigmented lesions due to their very short pulse durations, which effectively target the melanosome. In addition to the lasers listed above, pigment non-selective ablative lasers, such as CO_2 (10 600 nm) and erbium:YAG (Er:YAG; 2940 nm), can remove superficial pigmented lesions via nonspecific destruction. Parameters are dependent upon skin phototype, skin cooling technology and morphologic features; a test site is recommended.

keratinocytes. While these lesions can be seen in genodermatoses such as neurofibromatosis and McCune-Albright syndrome (see Chs 61 & 112), they are typically isolated benign lesions. Cosmetic improvement can be achieved with the Q-switched ruby, alexandrite and KTP lasers[40]. However, CALM can be resistant to laser therapy, and they are prone to a high rate of recurrence. Use of the long-pulsed alexandrite laser for the treatment of CALM has been reported to have a lower incidence of recurrence[41].

Nevus spilus consists of multiple melanocytic nevi superimposed on a background CALM. Although the treatment of these lesions is very similar to that of CALM, these are typically more resistant and require multiple sessions. They may respond to normal-mode laser wavelengths or IPL. Rarely, malignant transformation has been described in nevus spilus, and thus cautious laser or light therapy is advised[42].

Nevus of Ota and Nevus of Ito

Clinically, nevus of Ota and nevus of Ito are seen as gray–blue patches which correspond histologically to spindled pigment-producing melanocytes in the papillary dermis. These entities differ only in their anatomic location. Nevus of Ota involves the face (primarily V1/V2 distribution), while nevus of Ito corresponds to the distribution of the posterior supraclavicular and lateral brachial nerves. Both have been successfully treated with Q-switched ruby, alexandrite and Nd:YAG lasers[43]. Generally, high fluences are required, with multiple treatments spaced at least 6 weeks apart. A drawback of the Q-switched ruby laser is the tendency for hypopigmentation, which is a consequence of increased absorption by normal epidermal melanin. Hypopigmentation is observed less often with Q-switched alexandrite lasers (755 nm), which also achieve deeper penetration into the dermis[44].

Near-infrared lasers, namely the Q-switched Nd:YAG (1064 nm), have even deeper penetration into the skin but are less well absorbed by melanin. Although these characteristics appear to negate each other, they allow for safer use in patients with darker skin and also allow for clearance of more deeply seated pigment.

Blue nevi share some histologic features with nevi of Ota and Ito but are well-circumscribed gray-blue to blue-black papules (common) and plaques (cellular). As such, laser treatment of these lesions is similar to that of nevi of Ota and Ito[45]. While blue nevi are clinically benign, rare malignant transformation has been reported in cellular blue nevi.

Melasma

Melasma is a complex and therapeutically challenging disorder with both intrinsic (e.g. genetic, hormonal) and extrinsic (e.g. ultraviolet light) factors (see Ch. 67). It most commonly involves the face and presents as tan to dark brown patches with sparing of photoprotected sites. The majority of those affected are women and hormonal stimuli, including pregnancy and oral contraceptive use, tend to aggravate the condition. Medical and procedural therapeutic strategies include topical retinoids, hydroquinone, chemical peels and laser therapy. While treatment regimens boast varying degrees of improvement, recurrence is the norm despite precautionary measures such as strict sun protection.

Clinically, melasma is often categorized by distribution pattern and location of excess melanin. In epidermal melasma, melanin is localized to the basal and suprabasal epidermal layers, and in dermal melasma melanin is deposited within melanophages. The mixed variant includes features of both epidermal and dermal types. These subtypes are said to be distinguishable by Wood's lamp illumination, which accentuates epidermal pigmentation, but histologic and confocal microscopy studies have shown an admixture of both types within a single lesion. Of note, dermal deposits of melanin respond poorly to commonly prescribed topical therapeutic agents.

Since melasma is a disorder of hyperpigmentation due to increased melanin within epidermal melanocytes and dermal melanophages, it may seem intuitive that melasma should respond favorably to Q-switched lasers. However, this assumption has been demonstrated to be less than accurate. Although the melanophages present in dermal melasma can be selectively damaged by Q-switched lasers, the subsequent epidermal response frequently induces an inflammatory process and perpetuates or aggravates the problem[46]. Attempts at improving melasma by superficial laser resurfacing with Er:YAG may lead to temporary improvement, only to be followed by problematic postinflammatory hyperpigmentation[47].

Non-ablative, fractionated laser systems (see below) were initially touted to be a breakthrough therapy for melasma, with predictable and reproducible improvements. A preliminary case report described significant clinical improvement of treatment-resistant facial melasma after two treatments[48], with a subsequent study demonstrating that 60% of patients with skin phototypes III–V achieved 75–100% improvement[49]. The clinical improvements seemed to be paired with appropriate histologic findings of melanin extrusion in the dermal and epidermal necrotic debris[50]. Although the precise explanation for how the photothermal energy improves melasma is not clear, the clinical improvements may be the direct consequence of increased hydroquinone absorption into the epidermis and dermis (to affect dermal melanophages) via the microscopic tunnels. Despite this novel application of these fractionated lasers, melasma tends to recur and well-established regimens of topical retinoids, bleaching agents, and diligent sun protection remain the mainstay of therapy.

Becker's Nevus (Melanosis)

Becker's nevi are hamartomas that typically present during childhood or early adolescence as light to dark-brown patches or plaques on the shoulder, upper back or lateral arm (see Ch. 112). They are associated with variable amounts of hypertrichosis as well as smooth muscle hamartomas. Because melanin is located in both the epidermis and the dermal follicular matrix, treatment of Becker's nevus may require targeting of both these components. The basal layer melanin component requires nanosecond range pulse durations, and successful lightening has been accomplished with Q-switched ruby and alexandrite lasers[51]. In contrast, the follicular melanin responds more favorably to the millisecond pulse durations that characterize photoepilation systems. While these simplistic distinctions allow for methodical treatment, Becker's nevi are typically somewhat resistant to therapy. Often,

cosmetic improvement is more reasonably and realistically approached with the objective of photoepilation alone, as opposed to comprehensive eradication of the hamartoma

Postinflammatory or Drug-Induced Hyperpigmentation and Post-Sclerotherapy Discoloration

Postinflammatory hyperpigmentation (PIH) is a common side effect of many dermatologic procedures, both medical or cosmetic. For patients with darker skin phototypes, PIH should be anticipated and a treatment plan promptly initiated. Common topical therapies include corticosteroids, retinoids and bleaching creams. A newer treatment strategy is the use of fractionated photothermolysis with a low density and low energy. The fine, deep columns (referred to as microthermal or microablative zones; see below) serve as a drug delivery system and increase the penetration of these topical agents into the skin. For treatment-resistant patients, Q-switched ruby, alexandrite and Nd:YAG lasers have been used to expedite resolution of PIH. However, since PIH can be caused by these devices, circumspection is appropriate.

As opposed to PIH, which is due to excess melanin, discoloration that results from sclerotherapy is a consequence of vessel destruction, erythrocyte extravasation, and interstitial hemosiderin deposition. The Q-switched ruby laser has been used successfully to treat this common sequela from sclerotherapy, with a reported 92% improvement rate[52], but the success rate is quite variable.

Drug-induced hyperpigmentation or discoloration represents deposition of drug metabolites, hemosiderin, melanin, or a combination of these components in the dermis and/or epidermis (see Ch. 67). The resultant color depends on the initiating medication and can range from blue-gray or brown to yellow or red. Use of Q-switched ruby, alexandrite, and 1064 nm Nd:YAG lasers has led to improvement of minocycline-, amiodarone-, and imipramine-induced hyperpigmentation or discoloration[39].

TREATMENT OF STRIAE DISTENSAE

Striae distensae are common after pregnancy, growth spurts in adolescence, or rapid weight gain. Histologically, there is thinning of the epidermis and atrophy of the dermis. In their early inflammatory stages, they appear pink to purple in color and are called striae rubra. The latter mature and take on a more pallid color and then are termed striae alba (see Ch. 99).

Although treatment of striae is not medically necessary, many patients seek cosmetic improvement. PDL, pulsed CO_2, 308 nm excimer, and non-ablative 1450 nm lasers as well as IPL have been used with varying degrees of success with regard to the color and texture of striae[53–56]. More targeted studies have correlated clinical improvement with increased elastin remodeling or formation. Specifically, low-fluence 585 nm PDL (3 J/cm^2) has been demonstrated to dramatically stimulate elastin production[57]. Recently, fractionated photothermolysis was shown to improve atrophic scars[58]. Specifically, a pilot study of striae in patients with skin phototypes IV–VI demonstrated epidermal thickening and remodeling of collagen and elastin fibers after 1550 nm fractionated photothermolysis[59]. In spite of these reports, in clinical practice, the results of striae treatment with lasers have been quite disappointing.

ABLATIVE LASERS: CARBON DIOXIDE AND Er:YAG

Both the CO_2 and Er:YAG lasers have wavelengths in the infrared portion of the electromagnetic spectrum (see Fig. 137.1), and thus the chromophore is predominantly water. Selective photothermolysis of the epidermis and dermis is accomplished as nearly 80% of the skin is composed of water.

For CO_2 lasers, the depth of tissue ablation is very superficial, in the range of 20 microns. Based upon the heat vaporization of water and the energy absorbed per volumetric unit, the minimum fluence necessary to produce tissue ablation has been calculated to be 5 J/cm^2. Below this fluence, tissue is not vaporized, rather it is coagulated. However, both vaporization and coagulation are useful in the treatment of skin disease, and these wavelengths can be manipulated so as to achieve an appropriate balance of the two. When using the short-pulse or scan-type resurfacing CO_2 lasers, the coagulative or photothermal effect extends the depth of injury to 100–150 microns.[60], and this is responsible for the hemostasis, collagen rejuvenation, skin tightening, and, by extension, many of the complications such as scarring, seen with CO_2 lasers[61].

To achieve selective photothermolysis with the CO_2 laser, it has been suggested that the ideal pulse duration is ≤1 ms. The development of high-powered, short-pulsed CO_2 lasers (as compared to their continuous wave predecessors) has allowed for more selective control of tissue vaporization and thermal injury. The first pass of the high-energy, short-pulsed CO_2 laser induces localized tissue vaporization with surrounding coagulation/desiccation. Since this residual carbonized tissue acts as a heat sink, subsequent CO_2 laser pulses tend to vaporize less and heat more, causing non-selective damage. Thus, second and subsequent passes should only be applied after removal of the desiccated "charred" material at the surface of the skin[61].

The Er:YAG laser emits light at 2940 nm, with the water affinity being nearly 15 times greater than that of the CO_2 laser. This allows the Er:YAG laser to vaporize tissue more efficiently, leaving only a small residue of coagulated tissue. As a consequence of the limited photothermal effects, hemostasis and collagen contraction are significantly reduced with Er:YAG lasers. Coagulation settings, achieved by lengthening the laser pulse duration, have been incorporated into newer modulated Er:YAG laser systems (e.g. Sciton), inducing more hemostasis and resulting in better tissue contraction. While pure Er:YAG lasers demonstrated only modest tissue tightening as compared to CO_2 lasers, modulated Er:YAG systems have produced comparable resurfacing results, e.g. with settings on the Sciton laser of 50% overlap, 25–100 microns of ablation (depending on the regional thickness of the treated skin) and 50–100 microns of coagulation[62].

Use of the Er:YAG laser requires more skill and technical finesse than does use of the CO_2 laser as the clinical endpoints allowing the laser surgeon to gauge depth when resurfacing with the CO_2 laser are not seen with Er:YAG laser ablation. With the CO_2 laser, a chamois color is seen with ablation of the papillary dermis and further penetration into the reticular dermis produces a "water-logged cotton thread" appearance. These typical visual markers are lacking with Er:YAG laser resurfacing. Furthermore, the plateau response of diminishing ablation characteristic of the CO_2 laser is not seen with the Er:YAG[61]. There is significant energy absorption of 2940 nm light by residual desiccated tissue and the less skilled laser surgeon can unintentionally drill deep wounds into the skin. Therefore, it is critical that the operator constantly be aware of the depth of vaporization. Additionally, in contrast to the CO_2 laser, the desiccated tissue need not be wiped off. This barrier allows for faster healing and decreased risk of postoperative pigmentary changes.

The CO_2 laser remains the gold standard for photorejuvenation, wrinkle reduction and skin tightening. To date, nothing can beat the results obtained by an experienced laser surgeon using one of the high-energy short-pulsed CO_2 lasers. Specifically, even deep, coarse and fixed perioral and periorbital rhytides can be significantly diminished or eliminated (Fig. 137.11)[63]. Redundant skin is tightened by thermal coagulation as well as wound healing with associated fibroplasia, which can cause collagen contraction. However, this dramatic improvement comes at the expense of slow healing, prolonged erythema, permanent and patchy loss of pigmentation, and other complications. A split-face study of Er:YAG and CO_2 laser resurfacing demonstrated this duality; the side treated with the CO_2 laser had 63% improvement with 7.7 days of crusting, compared to the Er:YAG laser-treated side which had 48% improvement with an average of 3.4 days of crusting[64].

In general, more significant clinical improvement has gone hand in hand with more thermal damage, leading to more discomfort, more extensive wound care, and longer healing times. Additional side effects include persistent erythema for 3+ months, risk of scarring, a 20% chance of delayed-onset permanent hypopigmentation, and a line of demarcation between treated and untreated areas. All patients with actinic bronzing will note an improvement or lightening of their skin pigmentation in the treated areas. To avoid any demarcation lines in these regions, it is prudent to treat entire anatomic areas. This is particularly true for skin phototypes I and II. Skin phototypes IV–VI tend

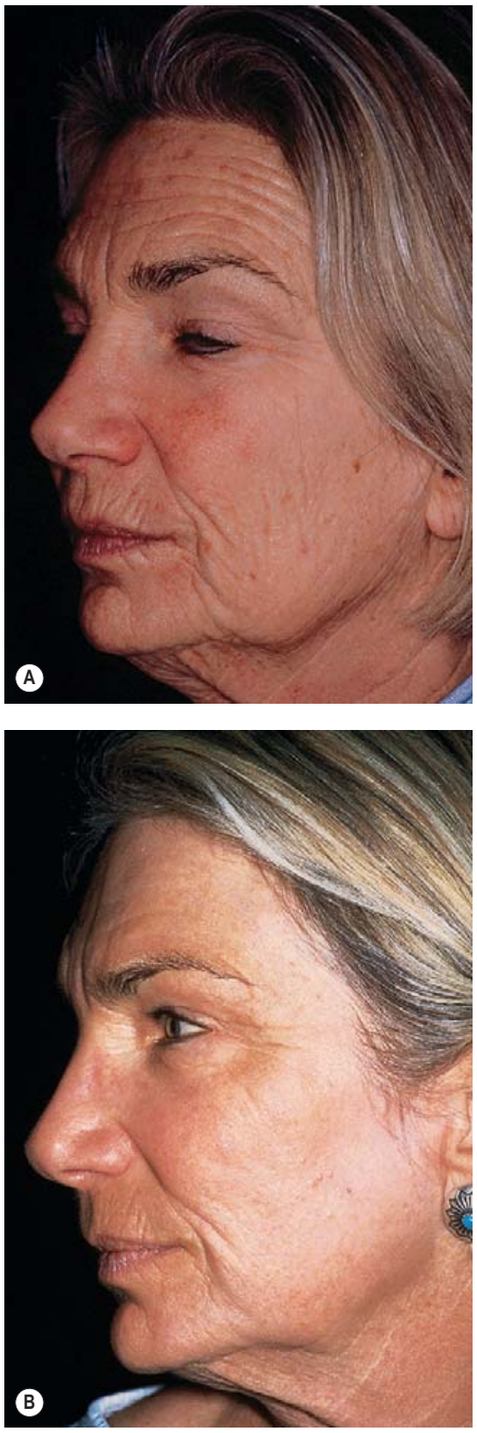

Fig. 137.11 Ablative CO_2 laser resurfacing. **A** Before treatment. **B** One year after resurfacing. *Courtesy, Jeffrey Dover, MD, and Kenneth Arndt, MD*

not to have actinic bronzing and hence focal or geographic areas can be treated.

Treatment of acne scarring is a common indication for ablative lasers. In general, more improvement of acne scarring is seen after CO_2 laser resurfacing than with the traditional Er:YAG laser. However, the dual mode or "hot" Er:YAG laser is equivalent to the CO_2 laser in many respects, and is preferred by many laser surgeons. Elevated or distensible acne scars are most amenable to resurfacing, compared to ice-pick and non-distensible scars, which are often resistant[65]. Focal ablation has been effectively used for resurfacing elevated, irregular epidermal lesions such as seborrheic keratoses, epidermal nevi, and verrucae; actinic keratoses and actinic cheilitis can also be significantly improved[66]. Additionally, benign hyperplasias or neoplasms with an elevated component can be "debulked", e.g. hypertrophic scars, rhinophyma, lymphangioma, adnexal tumors (including syringomas and angiofibromas), and xanthomas. Based upon more limited experience and case reports, effective treatment of balanitis xerotica obliterans, lichen sclerosus, porokeratosis, keratoderma, chondrodermatitis nodularis helicis, and Hailey–Hailey disease has been observed. Other possible indications for both the CO_2 and Er:YAG lasers include treatment of hidroadenomas, colloid milia, eruptive hair cysts, and onychodystrophy[61].

Among the most significant risks with ablative resurfacing is infection, whether by bacteria, viruses or fungi. Specifically, and especially if the treated region involves perioral skin or adjacent areas, antiviral medications (e.g. valacyclovir, famciclovir) should be initiated prophylactically (even in the absence of prior herpetic infection) to prevent the possibility of a generalized herpetic infection in the denuded skin. Antibiotic coverage, especially against staphylococci, may be prudent but is much debated. Desiccated, proteinaceous skin debris that results from resurfacing is a favorable culture medium for pathogens. Antiviral prophylaxis should be commenced the day prior to or at least the morning of the procedure and continued for 15 days. Antifungal prophylaxis with fluconazole (a single-dose 200 mg tablet) given during the early postoperative period has been demonstrated to prevent candidal infection, and may promote re-epithelialization[67].

FRACTIONATED LASERS

Traditional laser resurfacing yielded impressive facial photorejuvenation and significant tissue tightening. However, these outcomes were often at the cost of delayed healing, persistent redness and swelling, infection, unpredictable pigmentary changes (hypo- or hyperpigmentation) and scarring. In 2004, fractionated photothermolysis (FP) was introduced (Table 137.4) The development of fractionated lasers has changed the way laser surgeons practice. One can be aggressive in terms of depth and density, and yet relatively safe in terms of patient downtime, postoperative recovery, and complications. In contrast to traditional lasers where the spot size of the device defined the smallest treatment unit on the skin, hundreds of controlled microscopic zones of coagulative or ablative injury are delivered to the skin with each scan or stamp of the fractional device[68]. These areas of microscopic thermal injury are defined as microscopic treatment zones (MTZs; also referred to as microthermal zones). While MTZs appear to be minute dots on the skin, they actually represent exact columns or cylinders of epidermal and dermal thermal damage (see Fig. 136.6)[50]. MTZs are deliberate and calibrated such that the resultant depth, width and density are defined. Each microdot or cylinder of damage is surrounded by normal, unaffected skin, which acts as a reservoir for healing and enables these microwounds to resolve quickly, with minimal discomfort (Fig. 137.12). These healing wounds appear histologically as microscopic epidermal necrotic debris (MENDs); they are composed of fragmented and damaged skin components, including epidermis, dermis, melanin and elastin[69]. The skin surface heals within 7 days with extrusion of the MENDs.

Non-ablative Fractional Photothermolysis

The first system to be approved for clinical use was the Fraxel® SR750 (Reliant Technologies), which is a 1550 nm erbium-doped fiber fractionated laser that targets water as its chromophore. The laser handpiece employs a scanning system (Intelligent Optical Tracking System [IOTS]), allowing for uniform deposition of MTZs. The second-generation system (Fraxel re:store®) allows for adjustment of the MTZ energies up to 70 mJ with a depth of injury down to 1500 microns and treatment densities of 5–50%. The depth of these MTZs is an operator-dependent parameter and can be adjusted to match the thickness of skin or entity being treated.

Collagen remodeling is induced with this fractionated heating of the skin. The very nature of FP allows for the safe application of incredibly high fluences to narrow tissue columns, which if applied to confluent areas would certainly cause delayed healing and tissue scarring.

As the technology of fractionated systems is enhanced, a unique "telescoping mechanism" has been developed such that minor changes in beam diameter make a major impact on epidermal injury and depth of thermally altered tissue. More specifically, this device provides wider beam diameters the higher the energy. There is a "sweet spot" in terms of beam diameter at which epidermal disruption is minimized and

TYPES OF FRACTIONATED LASER DEVICES				
Laser type	**Wavelength (nm)**	**Laser name™,® (examples)**	**Energy of MTZ or macrofluence**	**MTZ depth (microns)**
		ABLATIVE		
Rolling scanner				
CO_2	10 600	Fraxel re:pair	5–70 mJ/MTZ	200–1500
Stamping scanner				
CO_2	10 600	Deep FX	2.5–50 mJ/MTZ	50–1500
YSGG	2790	Pearl Fractional	60–320 mJ/MTZ	1000
Er:YAG	2940	Lux 2940	<15 mJ/MTZ	50–300
Er:YAG	2940	Pixel	14–27 mJ/MTZ	30–70
Er:YAG	2940	Pro-Fractional	<400 J/cm^2	1000
		NON-ABLATIVE		
Rolling scanner				
Erbium fiber	1550	Fraxel re:store	4–70 mJ/MTZ	500–1400
Erbium/thulium fiber	1550/1927	Fraxel Dual	4–70 mJ/MTZ	500–1400/200
Erbium fiber	1410	Fraxel re:fine	5–20 mJ/MTZ	650
Stamping scanner				
Diode/bipolar RF	915 and bipolar RF	Matrix IR	<70 J/cm^2	500
Nd:YAG	1440 ± 1320	Affirm	8–12 mJ/MTZ	200–300
Er:Glass	1540	Fractional 1540	15–50 mJ/MTZ	125–850
Er:Glass	1540	Mosaic	5–40 mJ/MTZ	1000
Er:Glass	1540	Matisse	<250 J/cm^2	30–150

depth of dermal coagulation is maximized. Many laser companies are now producing fractionated non-ablative devices (see Table 137.4), and the prospective buyer should take the time to review in detail the various options, including power, speed, reliability and science in addition to the cost of the device and its consumables.

New indications and applications for this novel technology are evolving rapidly and include patients with chronic photodamage, skin laxity, rhytides, and multiple types of scarring, including acne scars, hypopigmented scars, and traumatic and surgical scars (Fig. 137.13). One of the first clinical applications of FP was treatment of facial melasma. While initial studies were promising with near-complete clearance of melasma after a few treatments, this early exuberance has been tempered by a more considered and lengthy assessment of response, with the tendency of melasma to recur.

Ablative Fractional Photothermolysis

Following the success of fractionated *non-ablative* rejuvenation came the development of fractionated *ablative* rejuvenation. The first commercially available system was Fraxel re:pair® (Reliant Technologies). This was a scanning fractionated CO_2 laser with the ability to place 2000 microablative MTZs per second. At the present time, no other scanning device can match this rate, though there are other devices that can provide the same clinical outcomes. Indeed, many other companies have produced their own fractionated ablative devices using

Fig. 137.12 Photodamage treated with fractionated ablative CO_2 laser. **A** Preoperative. **B** Characteristic pin-point bleeding from microscopic treatment zones (MTZ; also referred to as microthermal zones) immediately following laser therapy. **C** Improvement of lentigines, solar elastosis and fine static rhytides 3 months postoperatively.

Fig. 137.13 Non-ablative fractionated laser therapy for scar remodeling. **A** Patient at presentation with traumatic hypertrophic and fibrotic scarring. **B** After three treatments with Fraxel re:store®. **C** Marked improvement of scarring after five treatments performed over 6 months.

CO_2, Er:YAG and YSGG (2970 nm) wavelengths (see Table 137.4). For example, the re:pair® system creates MTZs approximately 120–150 microns wide and 200–1500 microns in depth (depending on the operator's selected parameters). The speed of delivery corresponds to the speed at which the operator moves the handpiece over the skin. The fluence of each laser microbeam can be adjusted up to 70 mJ/MTZ by the operator and the density ranges from 10% to 70% of the skin surface. A very equivalent system, the Lumenis DeepFX™ creates a pattern of MTZs 110 microns wide and 50–1500 microns deep (depending on parameters) with a galvanic scanner that creates a square template of MTZs[70]. The operator then advances the scanner onto adjacent untreated skin and repeats the process. This device can create identical tissue effects to the re:pair® system but is significantly slower.

Er:YAG- and YSGG-based fractionated ablative systems can also provide significant improvements in texture, tone, wrinkling and scars. Because of space limitations, a more detailed description of all of these systems is not possible, but references 71 and 72 provide additional information.

The fractional devices, both ablative and non-ablative, have made inroads into the traditional indications for laser resurfacing such as improvement of rhytides, scar revision and acne scarring (Fig. 137.14). Initial studies utilizing re:store® for the treatment of periorbital rhytides showed mild improvement in 12% of patients, noticeable improvement in 30%, and moderate to significant improvement in 54% after one to four treatments[68]. Settings of pulse energy and treatment density should be tailored for the individual patient, for the specific problem being addressed, and considering the anatomic site. However, in general, fractional treatments using a higher treatment density appear to impart greater improvement in texture, tone and dyspigmentation, while increased pulse energies lead to more significant improvements in rhytides and scarring. Collective experience has also shown that fine to moderate rhytides respond more favorably than deeper rhytides, and that less dramatic improvement should be expected compared to fully ablative resurfacing[73].

When used for acne scarring, fractional deep dermal ablation (FDDA™) treatment has demonstrated significant efficacy. In a study of 30 patients with moderate to severe acne scarring who underwent one to three treatments[74], mild to moderate overall improvement was noted with energies ranging from 20 to 100 mJ and densities of 600–1600 MTZ/cm^2. With further experience, it is clear that for a given beam diameter, very high energy (70 mJ) associated with very high density (70%) will be more efficacious than low energy and low density

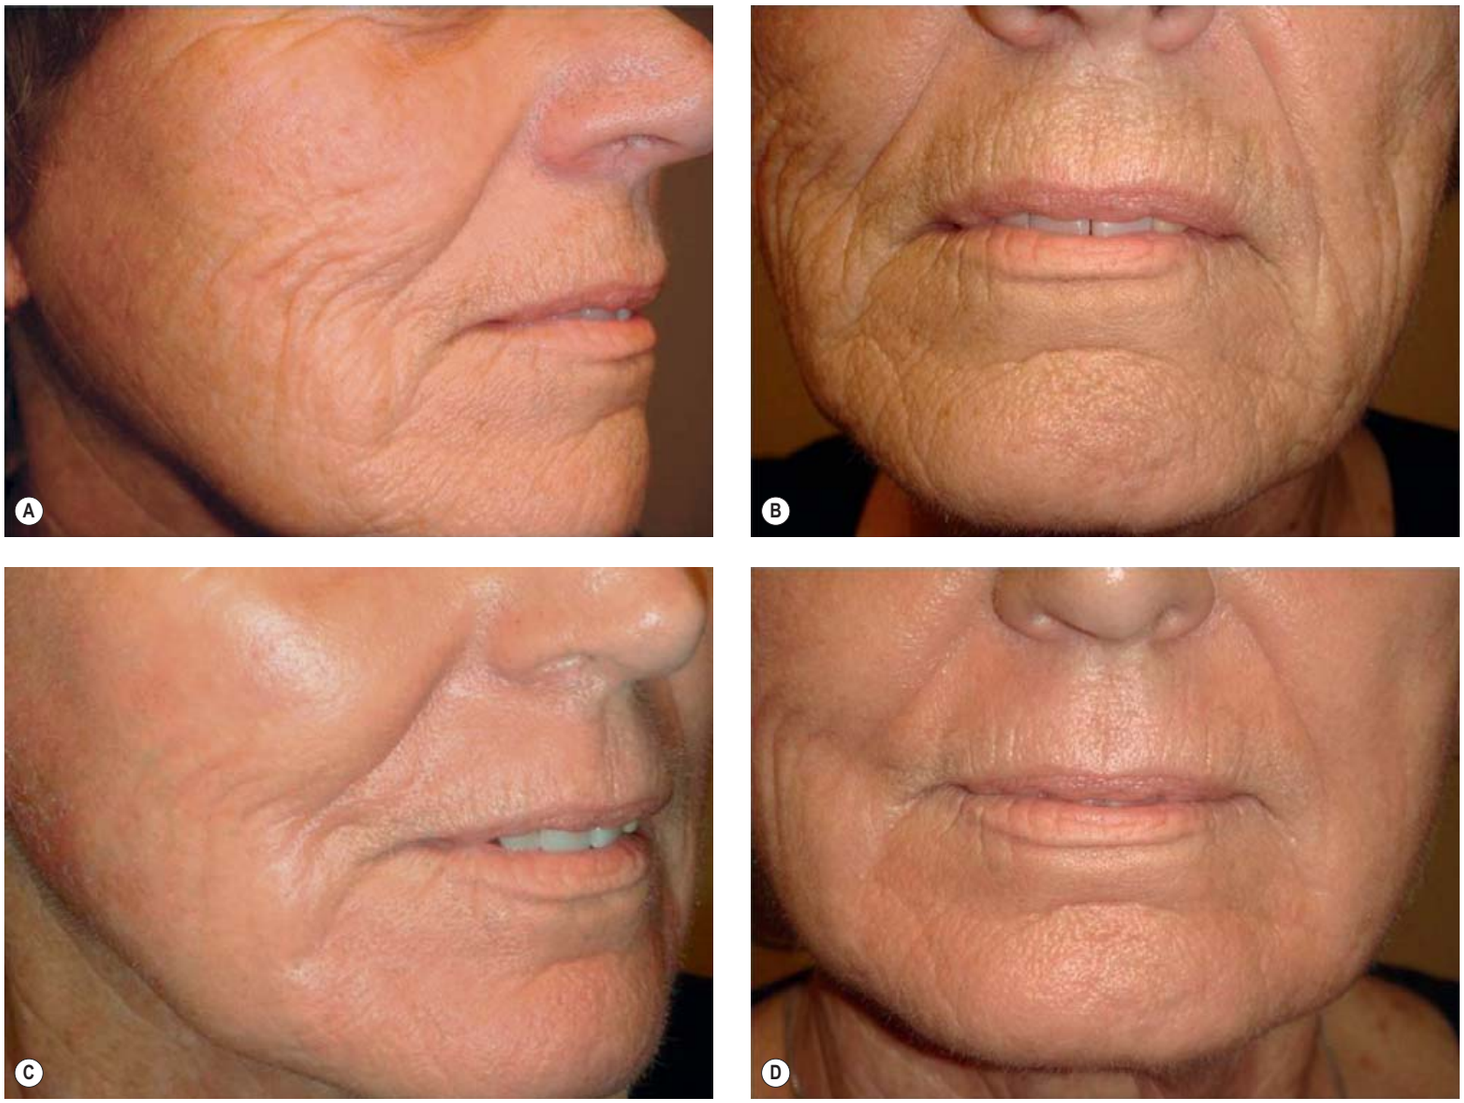

Fig. 137.14 Fractionated CO_2 laser (Fraxel re:pair®). A, B Coarse rhytides and solar elastosis. **C, D** Significant improvement in color, texture, tone and wrinkling following one treatment. Mild residual erythema and edema persist at 1 month.

when treating skin laxity and acne scarring. Although some patients may initially view multiple treatments as inconvenient, the benefits of rapid skin healing (generally within 7 days) and remarkably little discomfort compared to traditional laser resurfacing are distinct advantages (Fig. 137.15). Furthermore, sequential FDDA™ therapy may produce amplified benefit as collagen remodeling and skin contraction are enhanced with subsequent treatments.

Ablative FP offers the opportunity for relatively safe treatment of anatomic regions that were notoriously difficult to rejuvenate with conventional ablative resurfacing. Areas such as the neck and upper chest can now be more easily treated, albeit at reduced energy and density. Another advantage of fractionated systems is the ability to safely treat all skin types, including very darkly pigmented patients.

Evidence that fractionated laser therapies induce neocollagenesis is supported histologically. Increased expression of collagen remodeling markers such as heat shock proteins (47, 70 and 72), collagen III, proliferating cell nuclear antigen, and α-smooth muscle actin have been demonstrated within treatment areas[75,76]. More specifically, expression of heat shock proteins 47 and 72, which is required for collagen remodeling and maturation, has been detected within 1 week of an FP treatment and has persisted for nearly 3 months[76]. In addition to inducing neocollagenesis, ablative fractionated systems induce *volumetric tissue reduction* dermal plumping[76,77]. Taken collectively, the vaporization volume of millions of tiny-diameter cylinders of skin adds up. A standard aggressive fractionated CO_2 laser treatment can remove 5–7 cm^3 from the skin of the face[78]. As such, regular or intermittent treatments will improve skin laxity and could possibly prevent or delay the need for future facelift procedures.

Preoperative Considerations

Prior to any laser procedure (especially ablative), an appropriate medical history should be obtained, including allergies and medications. Physicians should specifically elicit any history of cosmetic procedures. Patients with a history of autoimmune connective tissue disease, diabetes, or drug, alcohol or tobacco abuse should be treated cautiously, as wound healing may be impaired. Those who have used isotretinoin during the past 6 months or those with a history of keloids may be at increased risk for scarring.

During the consultation, the patient and laser surgeon must mutually identify the problem(s) to be treated and establish reasonable expectations for improvement. Whereas one ablative fractionated procedure may achieve marked improvement in rhytides and acne scarring, three to six treatments may be required with a non-ablative system if little "downtime" is required. Potential risks of laser therapy are reviewed, which may include scarring, blistering, infection, hyper- or hypopigmentation, and milia/acne formation. If an ablative fractional laser treatment is planned, then there is a thorough discussion of postoperative wound care (see below).

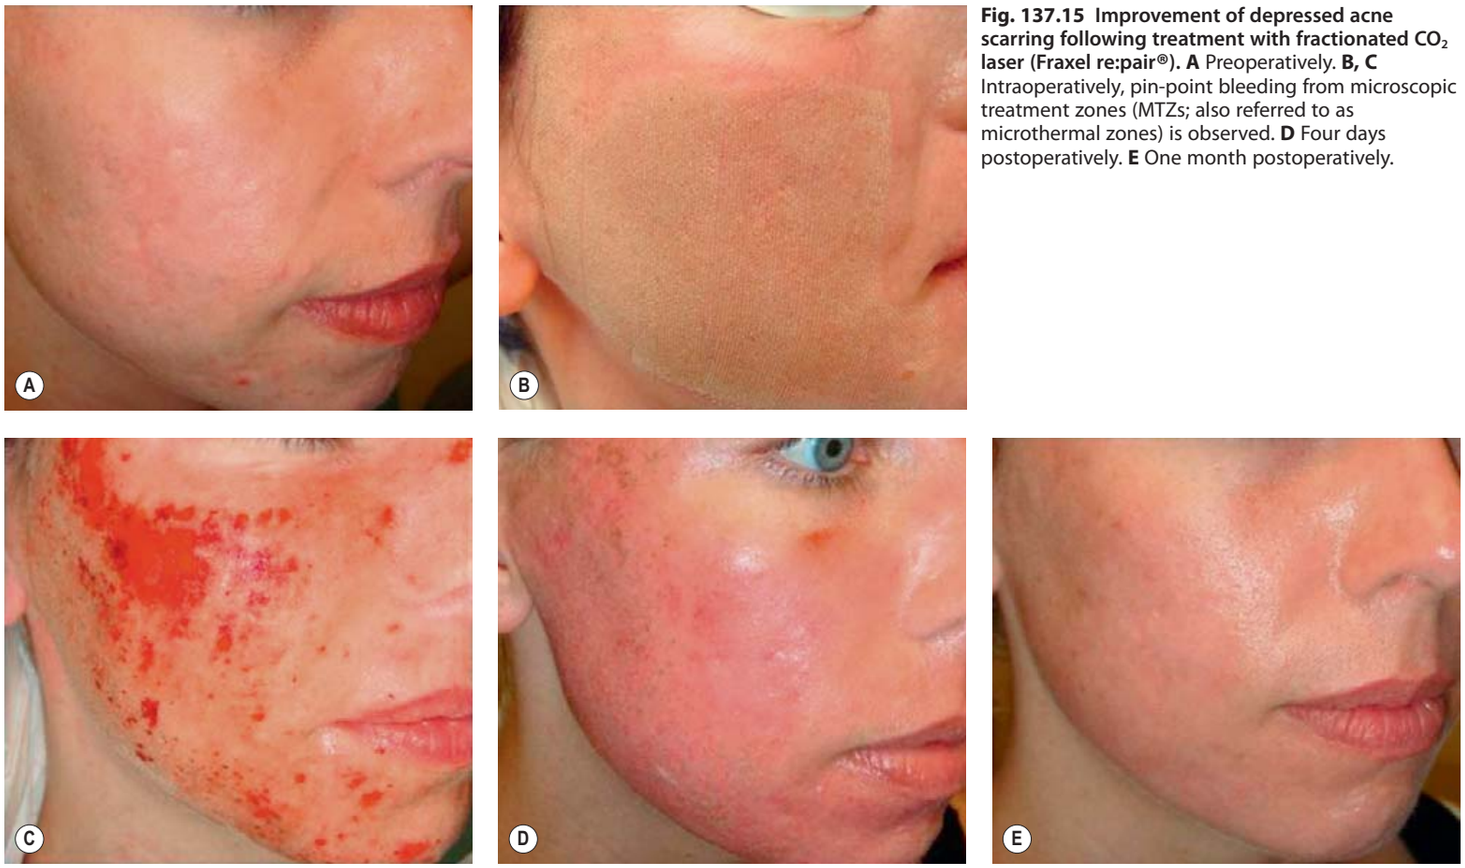

Fig. 137.15 Improvement of depressed acne scarring following treatment with fractionated CO_2 laser (Fraxel re:pair®). A Preoperatively. **B, C** Intraoperatively, pin-point bleeding from microscopic treatment zones (MTZs; also referred to as microthermal zones) is observed. **D** Four days postoperatively. **E** One month postoperatively.

Anesthesia

Both ablative and non-ablative fractional resurfacing can be quite painful without appropriate anesthesia, particularly when using high energies with a high density. Application of topical anesthetics in a lipophilic ointment base or under occlusion for approximately 1 hour after thorough skin cleansing is a simple and effective method for increasing patient comfort. Cooling strategies such as forced cold air or contact cooling can enhance patient tolerance. For more aggressive ablative procedures, supplementary anesthesia with nerve blocks, tumescent anesthesia, systemic narcotics, or anxiolytics is often used.

Post-therapy Considerations, Side Effects and Complications

Following ablative fractional resurfacing, punctate bleeding and serosanguineous drainage are normal side effects (see Figs 137.12 & 137.15), which dry into a thin keratinous crust within 24–48 hours. Patients are encouraged to minimize this crusting and aid in its exfoliation by applying dilute vinegar–water soaks to the treated sites every couple of hours. This is followed by a thin coat of white petrolatum ointment or generous amounts of a bland moisturizing cream until re-epithelization is completed.

Significant edema and erythema of treated skin is observed with both ablative and non-ablative fractionated therapies, though the latter is quite limited[79]. Topical application of a potent corticosteroid (e.g. fluocinonide ointment) immediately following the procedure can reduce these side effects. By using the MTZs as a drug delivery mechanism, very high local cutaneous concentrations of the corticosteroid can be achieved and the risks of systemic corticosteroid administration can be avoided (R Rox Anderson, personal communication, 2009). Non-ablative FP typically requires little or no "downtime" for healing, and the edema and erythema resolve within 24–48 hours. For ablative FP, the erythema dramatically improves within 1 week, but mild erythema and edema can persist for 3–6 weeks (see Fig. 137.15). Most patients are able to return to their normal activities, including work, and to apply makeup around 7 days following ablative FP, depending on the depth and density of treatment. Well-documented side effects of generalized and persistent erythema or delayed hypopigmentation that are seen with traditional resurfacing have not been reported to date with fractionated lasers. The exceptions here are some incidents of angulated erythema and infection related to poor technique leading to bulk heating and slow healing. Additionally, lines of demarcation are easily avoided by feathering the transitional skin between treated and untreated regions with near-minimal fluence and density settings.

Because only minute areas of damage are induced and the skin heals rapidly, fractionated ablative systems offer an unparalleled safety margin as compared to traditional ablative lasers. However, infection is still the most significant complication and it can lead to permanent scarring. It is essential that all patients begin oral antiviral therapy from at least the morning of the procedure and early on have frequent postoperative skin evaluations. Use of oral antibiotics and antifungal agents can be decided on a case-by-case basis.

Although scarring is an infrequent event, recent case reports have alerted laser surgeons to be cautious in "underpriviledged" areas such as the neck and chest[80]. Whereas skin on the cheek with its thicker dermis and abundant adnexal structures can tolerate high energies and up to 70% ablation for certain indications, more modest energy and significantly less ablation density should be employed on thinner, finer, and less privileged areas. As such, the laser surgeon must possess comprehensive knowledge of skin thickness at various locations on the face and also appreciate the composition of the skin structures in those locations.

Another noteworthy consideration for minimizing the risk of scarring is avoidance of immediate and direct overlap of treatment areas. Use of a non-overlapping technique allows the treated skin sufficient time to cool before the application of the subsequent pass. This prevents bulk heating, a likely cause of scarring in fractional laser therapy. While ancillary cooling is not necessary, forced cold air is recommended as it facilitates heat dissipation and further minimizes the potential for non-selective heat injury. Cooling also enhances patient comfort.

Postinflammatory hyperpigmentation is a near certain side effect when treating darker skin phototypes. This predictable event can be mitigated with early application of 4% hydroquinone cream twice a day

starting immediately post-therapy for non-ablative procedures. For those who have undergone ablative FP, this topical treatment can be started once the serosanguineous discharge of the immediate postoperative period has ceased. Patients with a prior history of melasma or other pigmentary disorders might be pretreated with hydroquinone prior to the procedure.

PLASMAKINETIC RESURFACING

Plasmakinetic resurfacing is another approach to skin rejuvenation. This technology converts nitrogen gas into a highly energized state (called *plasma*). Specifically, nitrogen gas is ionized as electrons are excited and plasma is created. The energy contained in the plasma is released from the device and aimed at the skin surface, but no direct contact is made between the skin and the device. The plasma energy can be adjusted (ranging from 1.0 to 4.0 J) by the operator. The spot diameter is 10 mm. Plasmakinetic energy heats the skin directly and there is no target chromophore as with lasers. Therefore, there is uniform heating of the skin surface without ablation. Although this indirect heating produces epidermal necrosis, the epidermis remains in place for several days and serves as a biologic dressing. By adjusting the energies, differential depths (from superficial to deep dermal heating) can be achieved for targeted therapies.

Several studies have been performed to compare plasmakinetic resurfacing with traditional ablative laser resurfacing clinically and histologically, and they have found comparable results. However, plasmakinetic resurfacing has the advantage of a favorable side-effect profile and more rapid recovery[81]. The FDA approved this technology (Portrait, Rhytec, Inc.) for the treatment of facial rhytides, acne scarring, and superficial lesions (e.g. actinic and seborrheic keratoses). Despite clinical success, the company producing the device has gone out of business.

OTHER PHOTOREJUVENATION DEVICES

While the ablative lasers can produce dramatic improvement in skin laxity and photodamage, their short-term side effects of discomfort, extended healing times, persistent erythema, postinflammatory hyperpigmentation, and the potential risks of scarring and permanent dyspigmentation have led to a shift toward non-ablative laser therapies. Photorejuvenation by "subsurface remodeling" is designed to induce dermal remodeling and volume restoration via selective dermal injury alone. Early incidental findings of modest rhytide improvement in patients undergoing PDL for facial telangiectasias suggested that selective photothermolysis of dermal vasculature stimulated collagen remodeling. Although the precise mechanism of this process is unclear, the photothermal energy emitted by non-ablative systems has been shown to stimulate a cascade of wound healing responses, including the release of collagenase and platelet-derived growth factor which promotes fibroblast activity and type I collagen formation[82]. These molecular changes offered early evidence to substantiate the use of non-ablative lasers for photorejuvenation and scar amelioration.

Photorejuvenation of the skin entails improvement of actinic telangiectasias, lentigines, solar elastosis and wrinkling. To a broader extent, it involves enhancing the color, tone and texture of the skin. The laser surgeon must appreciate the science and physics behind the energy delivery, rather than base his or her assumptions on a manufacturer's often exaggerated claims. Complete photorejuvenation often requires targeting hemoglobin, melanin and water, and no one laser or wavelength meets all of these objectives on its own. Given that laser and IPL applications for telangiectasias and pigmented lesions were previously reviewed, the use of PDL, Nd:YAG and KTP lasers or IPL for photorejuvenation will only be briefly discussed here. Instead, there will be a more detailed review of devices that improve skin texture and tone; such lasers emit infrared light, which is absorbed primarily by water and leads to collagen remodeling. The devices most frequently used within this group are the 1320, 1450 and 1540 nm lasers and, more recently, the fractionated 1550 nm laser.

Visible light lasers are effectively used to treat the telangiectasias and dyspigmentation associated with photodamaged skin. In addition to specifically improving pigmentation, KTP and Nd:YAG lasers have also been shown to cause a 20–40% improvement in texture and 20–30% improvement in rhytides[83]. The long-pulsed PDL can be used with a multiple-pass technique for photorejuvenation. It is worthy to note that both the 585 and 595 nm PDLs have received FDA clearance for treatment of periocular wrinkling. While collagen remodeling has been demonstrated histologically, clinical improvement of wrinkles is variable and modest.

Likewise, IPL is frequently used to improve photoaging. Its broad range of wavelengths allows the telangiectatic and pigmentary aspects of photoaging to be addressed simultaneously. In a study of 135 patients with poikiloderma of Civatte, IPL treatment of the neck and/or upper chest led to >75% clearance of telangiectasias and hyperpigmentation after a mean of three treatments[24]. While the emitted light is broad, IPL filters allow for more targeted treatments. It has been postulated that the shorter wavelengths are responsible for the improvement in pigmentation and telangiectasias, while the longer wavelengths are responsible for collagen remodeling via thermal effects on tissue water[83].

Infrared lasers whose wavelengths are absorbed almost exclusively by water are the 1320 nm Nd:YAG, 1450 nm diode, and 1540 nm erbium glass lasers. Of these, the 1320 nm Nd:YAG laser has the least affinity for water, and, consequently, the absorbed energy is scattered throughout the dermis. This characteristic permits penetration to at least 500 microns, and potentially up to 2 mm into the skin[84]. The 1320 nm laser has an incorporated cryogen spray (CoolTouch3) which can be set for pre-cooling, mid-pulse cooling, and post-laser pulse cooling. These options, like other cooling strategies with non-ablative lasers, provide epidermal protection and reduce epidermal injury.

Both the 1320 nm Nd:YAG laser and the 1450 nm diode laser, which decrease the activity of sebaceous glands, have received FDA clearance for the treatment of acne. Furthermore, the 1450 nm laser has been reported to be useful for the treatment of sebaceous hyperplasia. When used for the treatment of wrinkles, the 1450 nm diode laser produced only modest improvement and the improvement was not as clearly appreciated by study patients.

RADIOFREQUENCY (RF)

A huge amount of research and development went into constructing a radiofrequency-based skin tightening device. Monopolar RF energy generates heat in a manner which is directly related to tissue impedance. The first commercially available monopolar RF device was ThermaCool TC™ (Thermage) which delivered high-frequency RF energy to the skin via a thin coupling electrode handpiece with active cooling. *In vivo* studies demonstrated that RF energy produced collagen contraction after disrupting hydrogen bonds of the collagen triple-helix structure[85].

After RF tissue tightening received FDA approval for periorbital rhytide reduction in 2002, it was more widely used on the face and neck for improvement of skin laxity. A split-face study demonstrated average brow elevation of 2–4 mm, superior palpebral crease elevation of 1.9 mm, and reduction of jowl surface area by 22%[80]. Although other early studies reported similar conclusions, results in clinical practice were far more variable and unpredictable, and the treatments were associated with significant patient discomfort[86]. Aside from transient erythema and edema, irregular depressions ("mattress-top" irregularities) were seen, which were attributed to excessive treatment (outside the recommended parameters) causing localized fat atrophy. New algorithms were developed, which increased both the reproducibility of the results and patient comfort. They included the use of lower energies over a larger tip in a multiple-pass technique[70]. The most recent development is the CPT (Comfort Pulse Technology) Thermage device. It has been designed to reduce discomfort and increase the efficacy of tissue tightening. The CPT device provides a transcutaneous electrical nerve stimulation (TENS)-like interruption of RF energy interspersed with hot/cold skin stimulation, as well as vibration (acting on the gate theory of pain), a modulated RF profile, and a more distributive electrode.

Bipolar RF devices create localized heat by conducting current between the two electrodes on the skin surface (see Fig. 136.7). Studies purport to have shown a 25–50% improvement in wrinkles, skin smoothness and texture[87]. Recently, RF technologies combined with light have been introduced into the marketplace (e.g. Polaris™, ReFirme™). The objective of these combined light and bipolar RF devices is to create more

efficient tissue heating. The synergistic effects may increase the efficacy of each, but no studies have been performed to substantiate a benefit beyond RF alone. There are reasons to believe that the bipolar devices are not as efficient as monopolar devices in their ability to tighten tissue.

HAIR REMOVAL

Hair removal remains as popular as ever. According to the American Society for Aesthetic Plastic Surgery (ASAPS), laser hair removal was only second to botulinum toxin A injections as one of the most requested cosmetic procedures in 2008. While the distribution, density and color of hair is related to gender and genetic background, the acceptability and desirability of hair are often related to societal and cultural norms. Markedly excessive hair can be a marker for an underlying endocrinopathy or a medication side effect, and a possible etiology should be investigated prior to photoepilation (see Ch. 70). While most patients who undergo photoepilation have the cosmetic objective of decreasing unwanted hair, there are several medical applications of laser hair removal, such as treatment of pseudofolliculitis barbae.

Although the patient's ultimate desire may be to achieve total hairlessness in an anatomic region, complete eradication of hair is often an unattainable objective. In this regard, permanent hair removal, as defined by the FDA in 1998, is "…the long-term, stable reduction in the number of hairs re-growing after a treatment regime…and does not necessarily imply the elimination of all hairs in the treatment area"[88]. Realistic expectations are key and the laser surgeon should clearly and specifically communicate these objectives to the patient. For some patients with particularly coarse, dense unwanted hair, a successful outcome might be a transition to finer, lighter hair. Potential side effects should be reviewed, including pigmentary changes (hyper- or hypopigmentation), erythema, edema, discomfort, and very rarely scarring.

Photoepilation is based on selectively delivering energy to the hair follicle, specifically to the bulge region where follicle stem cells reside, causing their destruction while minimizing non-selective injury to the surrounding tissues. Additional melanin targets are located in the follicular hair shaft, the outer root sheath of the infundibulum, and the hair bulb matrix (see Ch. 68)[89]. Three mechanisms have been proposed to explain hair follicle destruction. These include photothermal injury to the follicle via direct heating of the follicle, photomechanical injury by induction of shock waves and violent cavitation, and photochemical injury by production of toxic intermediaries such as singlet oxygen or free radicals[90]. The ultimate objective of laser or IPL hair removal is seen after heat-induced change of the follicular structures and immediate surrounding tissues. These follicular changes are described as either transient growth arrest or permanent hair removal[91]. Whereas transient hair arrest occurs by induction of catagen, long-term removal is achieved as terminal hairs undergo either follicular fibrosis or miniaturization into vellus hairs.

Although the absorption of melanin corresponds to wavelengths from 400 to 1200 nm, the best lasers for photoepilation have wavelengths between 600 and 1100 nm, a range where there is more selective absorption by melanin and the light penetrates relatively deeply into the skin. Given this relatively broad therapeutic spectrum, many laser systems have been utilized, including the ruby (694 nm), alexandrite (755 nm), diode (800–810 nm) and Nd:YAG (1064 nm) lasers in addition to a variety of IPL systems with different cut-off filters. The optimal wavelength is probably in the ruby laser range (694 nm), but longer pulsing beyond 3 to 4 milliseconds is problematic, which has led to the utilization of alternative wavelengths. However, the safety and efficacy of laser hair removal is dependent on the operator's sophisticated knowledge regarding the practical application of laser–tissue interactions and the principles of selective photothermolysis. From a practical perspective, this entails accurate selection of: the laser system, the optimal pulse duration, and the appropriate fluence to achieve hair removal while protecting the epidermis and minimizing non-selective dermal heat injury. Inappropriate selection can result in permanent scarring and dyspigmentation.

Selection of the appropriate pulse duration is critical for effective photoepilation. As the thermal relaxation time of a hair follicle is 10–50 ms, the pulse duration should be adjusted to match these parameters[92]. However, extension of the pulse duration beyond the thermal relaxation time of the follicular unit could promote delivery of thermal damage to the surrounding non-pigmented stem cells and might induce more consistent follicular destruction[89]. This notion is illustrated by the relative ineffectiveness of Q-switched lasers for hair reduction; although their nanosecond pulse durations can deliver energy to individual pigmented cells, the pulse duration of Q-switched lasers is insufficient to permanently affect the follicular unit as an entity. In general, the ideal pulse duration would be between the thermal relaxation time of the epidermis (1 ms) and the hair follicle. Coarser, thicker and darker hairs may have relatively longer thermal relaxation times compared to thinner, finer hairs[90]. The ideal patient for hair removal is one with lighter skin (phototypes I–III) and dark brown to black hair (Fig. 137.16).

In general, higher fluences achieve greater hair reduction. However, since overzealous fluence might induce excessive collateral heat, a conservative selection of parameters is recommended. Typical danger zones are the chin and lip (where there is a greater density of hair follicles) as well as pigmented genital or inguinal skin. Fluence should be titrated up, if necessary, with each treatment. As a final note of caution, parameters are not interchangeable between devices, even those with the same laser or IPL wavelength. It is incumbent on the operator to know how to operate each system that he or she uses.

Laser hair removal in patients with darker skin can be more problematic as epidermal melanin competes with the follicular target. For patients with skin phototypes IV–VI, the long-pulsed Nd:YAG laser is

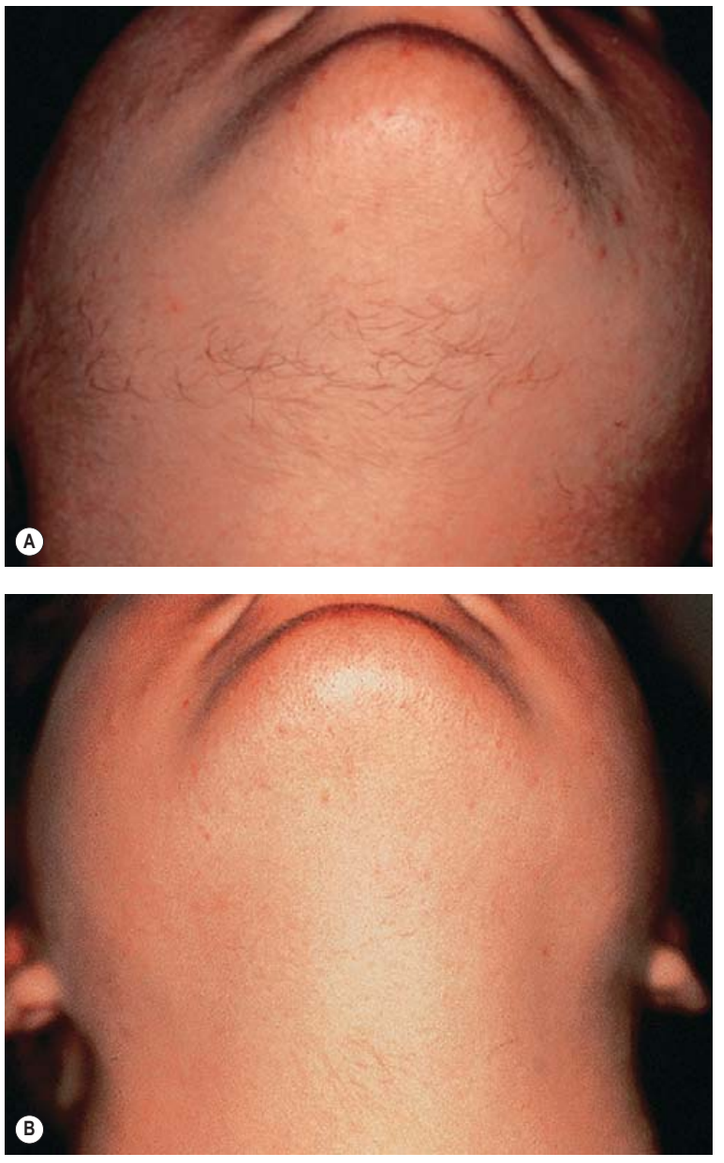

Fig. 137.16 Laser hair removal. A Before treatment. **B** Two years after three long-pulsed diode laser treatments; there is almost complete and long-term hair growth reduction. *Courtesy, Jeffrey Dover, MD, and Kenneth Arndt, MD.*

generally regarded as the safest system. However, the most common criticism of the long-pulsed Nd:YAG laser is the associated pain and relative lack of overall efficacy.

While IPL was initially designed for the treatment of vascular lesions, it has also been modified specifically for laser hair removal. With appropriate use of longer wavelength cut-off filters, short wavelengths can be eliminated and (relatively) more melanin-selective treatments can be delivered. Additionally, use of multiple synchronized pulses allows for heat retention within the hair shaft to produce selective thermal damage. This notion has been termed thermokinetic selectivity[93].

Appropriate cooling of the epidermis is critical with these hair removal devices. Cooling can be applied immediately prior to (pre-cooling), during (parallel cooling), or after laser pulsing (post-cooling). Aside from protecting the epidermis from excessive heat, contact cooling handpieces allow compression of the skin and facilitate delivery of more laser energy to the targeted hair follicles.

Although commercial laser and IPL companies might argue otherwise, no system is inherently superior for photoepilation. However, given a certain hair color, or skin type, there are differential decisions to be made regarding which system to purchase. In general, lighter skin phototypes (I–III) respond better to treatment with the 755 nm alexandrite or the 800 nm diode laser, while darker skin phototypes (IV–VI) respond better to treatment with the 1064 nm Nd:YAG laser. Most studies have shown comparable efficacy rates when sufficient fluence is used and multiple treatments are performed. Regardless of the laser or IPL system utilized, serial treatments are required for significant, long-term hair reduction. Typically, three to eight treatments spaced at 6–10-week intervals are recommended. Response rates of 70–90% hair reduction at a 6-month follow-up have been reported[94]. As stated previously, the "ideal" patient for photoepilation is one who has light skin and dark hair. Long-term efficacy of laser hair removal correlates with higher concentrations of eumelanin[95]. Recent attempts have been made to treat non-pigmented, gray or white hair, but so far there is little evidence of benefit.

Paradoxical hypertrichosis following the use of hair removal devices is a common and well documented side-effect of photoepilation. This has generally been described in patients with Mediterranean, Hispanic or Asian backgrounds and phototypes III or IV and dark lanugo hair. Of note, it can occur with any of the laser or IPL hair removal systems. Initial reports suggested that affected patients should be evaluated for hyperandrogenemia[96]. However, the largest retrospective analysis to date of 750 patients found that the overall incidence of paradoxical hypertrichosis was 4.5%, and it occurred most often on the face and neck of patients with skin phototypes III and IV. These authors postulated that the hair induction occurred at the borders of the treated areas, perhaps because of sub-therapeutic fluences during laser therapy and local inflammatory responses following photoepilation[97]. In the authors' experience, paradoxical hypertrichosis can be reversed using a photomechanical approach with a Q-switched Nd:YAG laser at high fluence.

Proper pre-treatment preparation of the skin prior to photoepilation allows for optimal treatment results. Failure to recognize the need to avoid treating suntanned skin has resulted in numerous burns, scarring, and permanent pigmentary changes. In sunny climates, patients should be advised to apply broad-spectrum sunscreens for weeks prior to laser therapy and to avoid tanning both before and after photoepilation, in order to prevent postinflammatory hyperpigmentation. Secondly, patients should avoid plucking, waxing, threading, and electrolysis prior to laser treatment as these will remove the target chromophore. Patients can be advised that shaving or depilatory creams are acceptable. Shaved hair (or at least hair cut flush with the skin surface) also minimizes inadvertent heat transfer to the epidermis during laser therapy. Finally, given that photoepilation is often associated with some degree of discomfort, topical anesthetics can be applied prior to treatment. While increasing patient comfort during the procedure is an important objective, several deaths have been reported with misuse of strong topical anesthetics in unsupervised situations.

During the procedure, the laser surgeon should constantly assess the skin's reaction to this or any other laser energy, and adjust parameters if necessary. The operator should expect to observe appropriate follicular reactions (such as perifollicular erythema and focal edema) indicating proper parameter selection, and should be critically inspecting the skin frequently for evidence of whiteness, blistering or crusting. A most ominous finding is a grey or white epidermal discoloration. This reflects dermal heat injury and is a marker of an inappropriately high fluence. Blister formation and epidermal necrosis may ensue, and in severe cases, may result in dermal necrosis and marked scarring.

While office-based laser photoepilation currently predominates, home-based systems have reached the marketplace. These systems offer a low-cost treatment alternative, abundant privacy, and convenience to the patient. Concerns have been raised by physicians about the safety of home systems and the ability of the lay operator to use them correctly. Although little peer-reviewed literature is available, one small office-based study demonstrated that nearly all of the patients were able to correctly administer their own treatments. Additionally, the observed side effects of hyper- and hypopigmentation, crusting and blistering were transient and had resolved by the conclusion of the study[98]. Use of these devices on inappropriate skin phototypes and tanned skin is clearly contraindicated. The patients need to assume a high degree of responsibility with these devices. There will be complications, but we should not underestimate the ability of the public to use (or abuse) these devices, just as with any other device such as a hair curler, which is arguably a significantly more dangerous piece of equipment.

TREATMENT OF PSORIASIS AND VITILIGO

Psoriasis affects nearly 2% of the US population and often commits patients to a lifetime of treatment. The range of therapies includes topical corticosteroids and vitamin D_3 analogues, systemic retinoids, methotrexate, phototherapy, and newer targeted immunomodulators ("biologic agents"; see Ch. 8). Despite the variety of treatment options available, some psoriatic plaques are recalcitrant. Application of laser therapy may represent a new approach to resistant lesions, particularly those in "problem areas" such as the scalp and intertriginous zones. The most commonly used laser for psoriasis is the 308 nm XeCl excimer laser. As a localized narrowband UVB therapy, the excimer laser has been demonstrated to clear psoriatic plaques by impeding epidermal cell proliferation and perhaps inducing localized immunosuppression. Compared to conventional UVB phototherapy, treatment with the excimer laser cleared psoriatic plaques two times faster and with lower cumulative UVB doses[99]. Additionally, PDL has been used to treat psoriasis by targeting the underlying abnormal vasculature. While both systems are beneficial, the excimer laser has been demonstrated to yield more favorable improvement[100]. The excimer laser has also been shown to produce impressive improvement of vitiliginous skin when used as adjuvant therapy, especially when combined with topical tacrolimus[101]. In the authors' opinion, the excimer device plays an important role in the photobiology section of the dermatologist's practice. Lastly, the excimer laser has been used to repigment some of the patients who developed delayed-onset permanent hypopigmentation following standard CO_2 or Er:YAG laser resurfacing procedures.

CONCLUSIONS

Increasingly, we are asking the question, "Lasers: what's the truth"? This reality check is necessary so that we start to ask the right questions and are critically aware of the answers. Laser engineers are very insightful, and they can provide us with semi-intelligent laser, light and other energy systems that can more precisely target the correct structures, and induce the correct healing responses. We should celebrate the enormous energy that goes into newer and more sophisticated devices, just as we should criticize and reject devices which under perform and over promise. Those of us who are involved in new technology development know that, just around the corner, advances are going to bring us smarter, cheaper, more durable, more tunable devices. Total internal reflection of spontaneous emission of radiation (TRASER) devices, which are neither lasers nor IPL, are more efficient than lasers and are tunable. New wavelengths are becoming available, targeting structures important in the control of acne or for body contouring. Our hope is that as this new technology comes online, there will be a continued attempt to answer the ongoing tough questions pertaining to both surgical and medical dermatology. In this regard, lasers and IPL should just be considered as "drugs", i.e. something that can be manipulated to ease the burden of those suffering from skin diseases.

Synonyms: ■ Cryotherapy ■ Contact therapy ■ Freezing

Key features

- Versatile modality for benign, premalignant and malignant lesions on all areas of the body
- Entails fast freezing and slow thawing, with a single freeze–thaw cycle for benign lesions and a double freeze–thaw cycle for malignant ones
- A tissue temperature of –50°C to –60°C is needed for destruction of malignant lesions, while lesser degrees of freezing are needed for benign lesions
- Because of its lower boiling point (–196°C), liquid nitrogen is preferred as the cryogen over nitrous oxide, carbon dioxide and fluorinated hydrocarbons
- Depth dose is determined by observation, palpation, freeze time, thaw time, lateral spread of freeze, and measurement of the tissue temperature. Cancer depth dose is achieved when these factors have reached the desired endpoint
- The tissue reactions are predictable, including crust or bulla formation after treatment of a benign lesion, and exudation, edema and sloughing after treatment of a malignant one
- Melanocytes are more sensitive to freezing than are keratinocytes, thus cryosurgery can lead to depigmentation

INTRODUCTION AND BACKGROUND

Cryosurgery is a treatment modality that is used frequently, to one degree or another, by all dermatologists. It is useful either as a primary or as an alternate form of treatment (Table 138.1). The word cryotherapy is often used interchangeably with cryosurgery, although the latter is a more accurate description of the destruction that is attainable with this modality.

The objective of cryosurgery is to cause selective necrosis of tissue, the extent of which depends on the type of lesion and the volume of freezing required. Tissue alterations are caused by reduction of the skin temperature with consequent freezing of cells[1]. The rate of heat transfer is a function of the temperature difference between the skin and the heat sink, or liquid nitrogen. Because the difference between the skin temperature and the temperature of liquid nitrogen is great, rapid heat transfer away from the skin results.

The tissue response ranges from an inflammatory reaction, as in the treatment of acne, to mild destruction for a benign lentigo, or even more destruction as for actinic keratoses. A greater amount of necrosis is needed for eradication of malignant lesions[2,3]. The mechanisms of injury in cryosurgery can be attributed to the direct effects of freezing tissue and to vascular stasis. Freezing tissue results in intracellular and extracellular ice crystal formation, disruption of cell membrane integrity, pH changes, impairment of multiple homeostatic functions, and thermal shock. This damage is enhanced during subsequent thawing of the tissue by the development of vascular stasis, which leads to failure of the local microcirculation. Slow cooling produces extracellular ice, but this is not as damaging as rapid cooling, which produces intracellular ice. Therefore, rapid cooling of the target tissue is desirable. On the other hand, the rate of rewarming, or thawing, should proceed slowly. With repeated freeze–thaw cycles, maximum destructive effects are produced. The tissue reactions that ensue after either light or deep freezing are predictable, and the underlying stroma provides a structural framework for wound repair.

Liquid nitrogen is the coldest medical cryogenic agent (–196°C boiling point) with the greatest freezing capability. It can be used for cutaneous malignancies as well as for small benign lesions. Although other cryogenic agents are available, including nitrous oxide, carbon dioxide and fluorinated hydrocarbons (latter phased out due to hydrochlorocarbon ban for ozone protection), they are not recommended for skin cancer but rather for lesions that require lesser degrees of freezing. Modern cryosurgery uses an apparatus that employs liquid nitrogen in a closed system that permits continuous and rapid extraction of heat from tissue. The dominant apparatus for dermatologic use is a hand-held unit that can be used either with a spray-tip accessory or with a closed cryoprobe (also known as contact therapy). Although the same equipment is used for a wide variety of conditions, the volume of liquid nitrogen, the technique of treatment, the duration of cooling and the amount of tissue being destroyed varies. Other techniques still in use include a cotton-tipped applicator and crushed carbon dioxide. Home freezing products that contain dimethyl ether and propane are occasionally effective for warts (although this may represent the natural history), but are inadequate for treating skin cancer.

INDICATIONS AND CONTRAINDICATIONS

Cryosurgery is a versatile modality that is used for many benign, premalignant and malignant lesions. The indications are related to the nature of the lesion and to the type of patient.

More than 50 benign conditions are amenable to cryosurgical management (Table 138.2). This is in addition to premalignant lesions and *in situ* malignancies including actinic keratoses, actinic cheilitis, lentigo maligna, Bowen's disease and erythroplasia of Queyrat.

Various sizes and subtypes of basal and squamous cell carcinomas can be treated, including papulonodular, cystic, superficial, ulcerative, keratotic and exophytic tumors[4,5]. The general indications for cryosurgery of tumors are outlined in Table 138.3. While not the usual initial therapeutic approach, cryosurgery has been used for selected recurrent tumors and ones that are fixed to cartilage or bone. However, many dermatologists feel that cryosurgery is not a good choice for treating most recurrent tumors.

Contraindications for cryosurgery include patients who have cold urticaria, cold intolerance, cryofibrinogenemia or cryoglobulinemia. Tumors with indistinct or ill-defined borders (e.g. morpheaform or infiltrative histologic subtypes), as well as deeply penetrating and very aggressive lesions, are best treated by other modalities. Cryosurgery is not considered to be a standard treatment for invasive melanoma.

ADVANTAGES OF CRYOSURGERY
• Versatility – treatment of diverse conditions
• Treatment of any area of the body
• Safe and relatively simple procedure
• Low cost
• Excellent cosmetic results
• Suitable for office, nursing home, or outpatient facility; operative suite not required
• No general anesthesia; local anesthesia optional
• Usually no restriction of work or sports
• Safe during pregnancy
• For patients who are fearful of undergoing surgery
• For poor-surgical-risk patients
• No age limitations – excellent for the very elderly
• Suitable for wheelchair and stretcher patients
• When other methods are impractical or undesirable

Table 138.1 Advantages of cryosurgery.

BENIGN CONDITIONS AMENABLE TO CRYOSURGERY	
• Acne cysts	• Lichen sclerosus (of vulva)
• Acne keloidalis nuchae	• Lymphangioma
• Acne vulgaris	• Cutaneous lymphoid hyperplasia (lymphocytoma cutis)
• Acquired perforating disorder	• Molluscum contagiosum
• Angiofibroma	• Mucocele
• Angiokeratomas, including of Fordyce	• Myxoid cyst
• Cherry angioma	• Nevoid hyperkeratosis of the nipple
• Chondrodermatitis nodularis helicis	• Orf
• Chromoblastomycosis	• Pearly penile papules

GENERAL INDICATIONS FOR CRYOSURGERY OF TUMORS
• Lesions with well-delineated borders
• Any anatomical site, including the eyelids
• Tumors difficult to treat by other methods
• Patients are elderly, debilitated, or have limited mobility
• Patients with pacemakers, defibrillators, and/or coagulopathies
• Inoperable tumors or for palliation

Table 138.3 General indications for cryosurgery of tumors.

Caution should be observed when confronted with patients who have darkly pigmented skin, since freezing of skin can result in hypopigmentation. Also, cryosurgery of facial lesions in patients with telangiectasias and facial erythema due to photodamage and/or rosacea can lead to obvious treatment sites. While overfreezing should be avoided in the case of benign and premalignant lesions, undertreatment of malignancies can lead to inadequate destruction or recurrence. Also, lesions that overlie superficial nerves, such as on the fingers or ulnar fossa, should

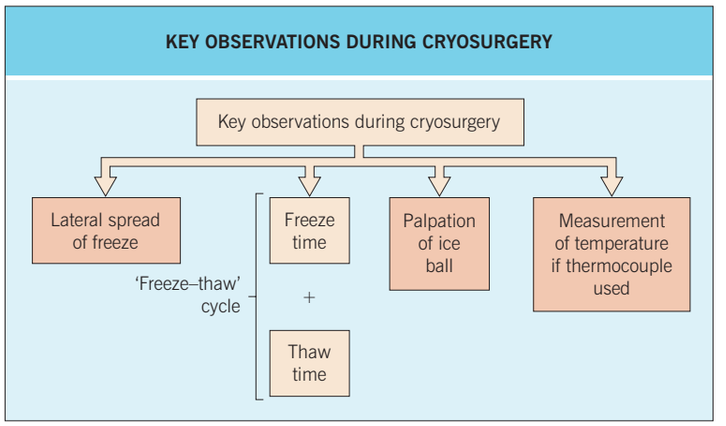

Fig. 138.1 Key observations during cryosurgery.

be carefully treated. Some anatomic areas where cryosurgery should be undertaken cautiously include the corners of the mouth, the vermilion margin of the lips, eyebrows, inner canthi, the free margin of the ala nasi, and the auditory canal, since scarring or retraction of the tissue can occur. Lesions in which treatment might lead to functional compromise or an unsightly cosmetic appearance are best treated by other means. Patients may also opt for another form of treatment when faced with the prospect of a long healing period.

PREOPERATIVE HISTORY AND CONSIDERATIONS

In planning treatment, consideration should be given to the characteristics of the lesion, which technique of cryosurgery to employ, and the expected results. An explanation of the procedure and the anticipated response of the tissue to freezing, including exudation, crusting, re-epithelialization and healing time, should be discussed with the patient.

TREATMENT FACTORS

When tissue is frozen, the surface freezing and extension of the ice ball is visible, yet the depth of freeze cannot be seen. Therefore, the amount of freezing and the temperature reached beneath and surrounding the lesion must be determined by the surgeon. This is referred to as the depth of freeze (depth dose) and consists of measuring certain clinical factors, including observation, palpation, freeze time, thaw time and lateral spread of freeze, as well as the tissue temperature (Fig. 138.1). The proper depth dose estimation is achieved when clinical observations and the tissue temperature, if measured, have reached the desired endpoint[6].

Freeze Time

The freeze time refers to the duration of cooling. It is shorter for a benign lesion than it is for a malignancy, e.g. about 5–7 seconds of freeze time with the open-spray technique will eliminate an actinic keratosis, whereas a freeze time of 45 seconds *and* a double freeze–thaw cycle may be required for a small basal cell carcinoma. The freeze time can be altered by the thickness of the lesion and by the amount of liquid nitrogen being emitted from the spray tip. Spray tips are available with varying aperture diameters and selection is influenced by the freeze time required. When the cryoprobe technique is used, the freeze time is approximately two to three times longer than with the open-spray technique. After freezing with either technique, the tissue is permitted to thaw spontaneously. The thaw time is usually two to three times longer than the freeze time.

Lateral Spread of Freeze

The lateral spread of freeze refers to the freezing of the tissue beyond the margins of the lesion. For some benign lesions, such as verrucae or dermatofibromas, it should reach 2 to 3 mm for the treatment to be successful. For basal cell and squamous cell carcinomas, the lateral spread of freeze should extend at least 3 to 5 mm or more beyond the tumor.

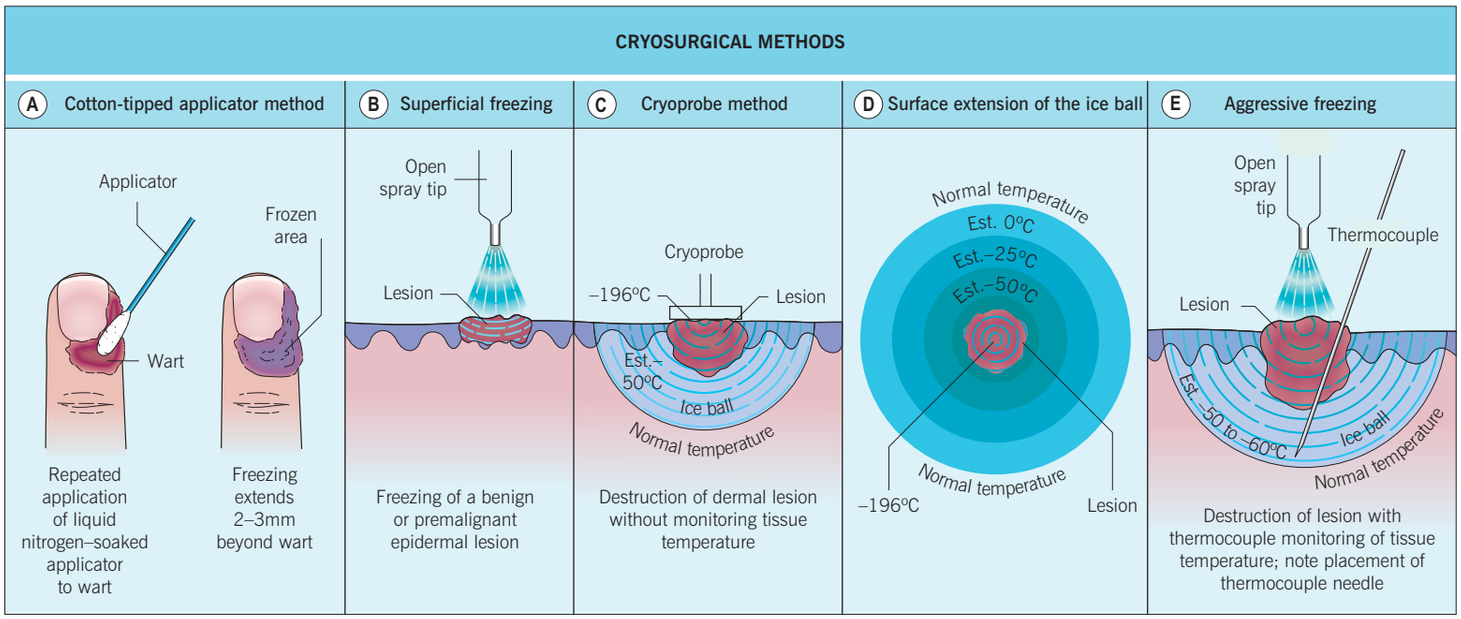

Fig. 138.2 Cryosurgical methods. A The cotton-tipped applicator method used in the treatment of verrucae vulgares, including periungual warts. **B** Superficial freezing used for treating benign lesions and actinic keratoses. **C** Cryoprobe method which is useful for round lesions and those on flat surfaces. **D** Surface extension of the ice ball: note the diminution of the temperature as the ice ball progresses outwards; this can be determined with palpation. **E** Aggressive freezing is deeper and employs thermocouple monitoring of tissue temperature.

Freeze–Thaw Cycle

A freeze–thaw cycle refers to the actual freezing and thawing of the lesion. A single cycle is usually sufficient for benign and premalignant conditions, while a double cycle is recommended for malignant lesions to ensure greater lethality to cancerous cells.

Temperature at the Base of the Tissue

To supplement the clinical estimation, one can measure the temperature at the base of a malignancy with the use of a thermocouple that is mounted in the tip of a 25- to 30-gauge needle. It is inserted into the skin at a 25° to 30° angle, from a point lateral to the lesion, with the tip coming to lie beneath the lesion (Fig. 138.2). This is useful for those lesions that lie more than 3 mm below the skin surface and for medicolegal reasons. Since the temperature recorded is very localized, more than one thermocouple may need to be inserted for a large lesion. The recommended temperature that should be achieved at the base of a malignancy is between –50°C and –60°C (see below).

DESCRIPTION OF TECHNIQUES

There are six techniques of cryosurgical treatment, and the choice of which is employed depends on the lesion and operator preference.

Dipstick Technique

The dipstick technique is the oldest method that employs liquid nitrogen. It consists of application of a saturated, cotton-tipped applicator onto the lesion (Fig. 138.2A). It is a method preferred by the authors for verrucae.

Solidified Carbon Dioxide

A less commonly performed method is crushed solidified carbon dioxide, contained in a disposable towel, and secured around a pestle. It is dipped in acetone and applied lightly onto the skin for mild freezing and exfoliation. This is known as slush therapy and can be used for acne vulgaris, acne cysts, rosacea and flat warts.

Open Spray

The open-spray method is the most frequently used technique, employing liquid nitrogen within a cryosurgical unit that has spray-tip attachments (Fig. 138.2B&E). It is suitable for diverse conditions, including seborrheic keratoses, acne cysts, lentigines, verrucae, dermatofibromas, condyloma acuminatum, actinic keratoses, actinic cheilitis, keratoacanthoma, lentigo maligna, basal cell carcinoma and squamous cell carcinoma. A fine spray of liquid nitrogen is directed at the lesion from a distance of approximately 1 to 2 cm. It is particularly useful for superficial, irregular, or multiple lesions and for those on a curved surface. An intermittent spray of liquid nitrogen of 60 seconds or more is used for malignant lesions, to allow for a deeper freeze.

Cryoprobe

The cryoprobe technique, also known as contact therapy, employs a cryosurgical unit and consists of application of a flat, pre-cooled metal tip that is placed firmly onto the lesion. It is useful for round lesions and those on flat surfaces (Fig. 138.2C). Venous lakes[7], hemangiomas, dermatofibromas, myxoid cysts, sebaceous hyperplasia, xanthelasma, condylomata acuminata, and basal cell and squamous cell carcinomas are examples of lesions that can be managed with this technique. The freeze time can range between 15 and 20 seconds for the benign lesions and up to several minutes for malignancies.

Confined Spray

The confined-spray technique is a variation of the open-spray in which the liquid nitrogen spray is confined within a cone that is held against the skin. Both plastic otoscope cones and specifically designed polycarbonate cones can be used to precisely localize the spray. The freeze time is the same as for the open-spray technique.

Closed Cone

The closed-cone technique also confines the spray, but the freeze time is half that of the open-spray since there is concentration of the liquid nitrogen to a very focal area of skin. This accessory is attached directly to the cryosurgical unit at one end, allowing the nitrogen to enter the cone. It is held against the skin, enabling it to rapidly freeze the lesion.

TREATMENT

Benign Lesions

Freezing is carried out after determination of the type of lesion and selection of the technique of treatment. For benign lesions, one may choose between the cotton-tipped applicator method, a spray technique or the cryoprobe.

For verrucae vulgares and periungual warts, the dipstick or open-spray techniques can be used[8]. The authors prefer the former because of greater control and exactness of the freeze, as well as for its predictability. The cotton-tipped applicator is repeatedly dipped into a cup of liquid nitrogen and applied directly onto the wart until a 2 to 3 mm halo forms around it (see Fig. 138.2A). Large lesions that encircle the nail are also treatable. The freeze time ranges between 20 and 60 seconds. A local anesthetic can be used to alleviate the stinging associated with this type of treatment. A bulla develops after several hours that should extend beyond the wart for treatment to be successful. The blister is caused by separation at the dermal–epidermal junction. The authors recommend sterile puncture of the bulla (approximately 12 hours following freezing) and washing of the site. Healing occurs within 3 weeks, without scarring or damage to the nail plate, and the cosmetic results are excellent. If a lesion recurs, it can be retreated in a similar manner.

Filiform warts are easily eradicated with this technique. They need only freezing of the lesion itself, with no halo, since vesicle formation is not necessary.

Acne comedones, closed or inflamed, can be diminished and improved by short freezing times using an acne spray tip. Small and large acne cysts can be reduced by spraying them between 5 and 15 seconds.

Keloids can be treated with the open-spray technique, alone or in combination with intralesional corticosteroid injections.[9] Deep freezing of the keloid leads to necrosis, crusting, and eventually diminution of the lesion, but multiple treatments may be required. When combined with intralesional corticosteroids, cryotherapy (freeze time of ~20–60 seconds) is performed 1–2 minutes prior to the injection. This prevents freezing of the triamcinolone acetonide suspension and the resulting edema "softens" the keloid, facilitating the injection. Caution is advised when treating keloids in patients with darkly pigmented skin, as depigmentation can occur.

Myxoid cysts are treated by deroofing and freezing for 15 to 20 seconds. One author (EK) reported a cure rate of 76.7% for these cysts, with excellent cosmetic results, using either the open-spray or cryoprobe technique[10].

Lentigines can be eradicated with a very brief freezing of 3 to 4 seconds. Overfreezing should be avoided to prevent hypopigmentation. Studies have shown that judicious use of liquid nitrogen cryotherapy can be as safe and effective as laser treatment for lentigines.

Cryosurgery is effective for eradication of dermatofibromas following shave removal of the surface of the lesion. The freeze time is approximately 15 seconds and either the open-spray or cryoprobe technique can be used.

Premalignant Lesions

Premalignant lesions are treated with one of the spray techniques or a cryoprobe. A local anesthetic and dressings are optional. The prototype lesion for the open-spray technique is an actinic keratosis (see Fig. 138.2B). A shallow crust forms and falls off within 2 weeks (Fig. 138.3). Multiple lesions can be easily treated at one visit[11]. The freeze time for actinic cheilitis ranges between 10 and 20 seconds. Bowen's disease can be treated with a single freeze–thaw cycle and a freeze time of approximately 20 seconds for a small lesion.

Malignant Lesions

In the treatment of malignant lesions, the same volume of tissue must be destroyed by freezing that would have been removed by conservative local excision if that had been the chosen procedure. Complete destruction is possible with cryosurgery. Lesions are treated aggressively using one of the spray techniques or the cryoprobe. Several preoperative biopsy specimens can be obtained to delineate the margins of a tumor. The target site is cleansed and a local anesthetic can be injected. Thermocouple needles can be implanted at this time. The entire tumor is generally frozen in one session using a double freeze–thaw cycle. Through palpation one can ascertain the extent of the ice ball (Fig. 138.2D). The recommended temperature is between –50°C and –60°C at the base of the tumor, and the freeze time is approximately 45 seconds for a 1 cm lesion. During the past two decades, there has been an increased use of colder temperatures, greater use of debulking techniques, and a trend toward more aggressive treatment for basal and invasive squamous cell carcinomas. At the conclusion of treatment, a dry gauze dressing is applied and instructions given to the patient for postoperative care.

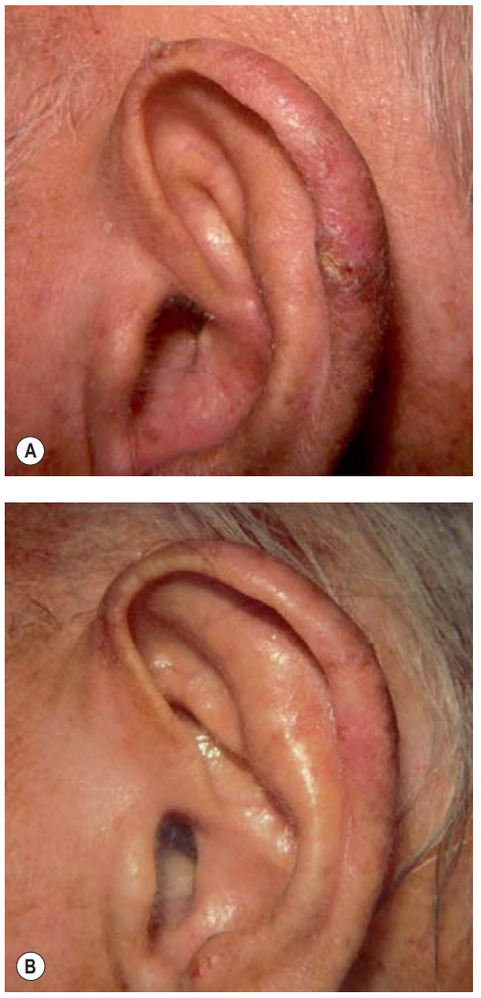

Fig.138.3 Actinic keratoses treated with cryosurgery (open-spray technique). A Prior to treatment. **B** Two to three weeks later.

One author (EK) reported a 5-year cure rate of 99% for 522 primary non-melanoma skin cancers[12]. The overall 30-year cure rate was 98.6% for 4406 basal cell, squamous cell and basosquamous cell carcinomas. Other investigators have obtained similar results[13–15]. Graham[16] had a combined cure rate of 98% for 3593 primary basal cell carcinomas using mostly the open-spray technique. Zacarian[17] reported an 18-year cure rate of 97.4% in the treatment of 4228 carcinomas. A 5-year follow-up study by Nordin et al.[18] of 50 patients with large primary basal cell carcinomas on the nose reported only one recurrence.

Cryosurgery is useful as an alternative modality for lentigo maligna (Fig. 138.4). Aggressive treatment using the open-spray technique is recommended, including freezing to –40°C to –50°C and a 1 cm lateral spread of freeze. With this technique, a recurrence rate of 6.6% was observed[19].

After treatment of a malignancy, the tissue responds in a predictable manner that leads to healing of the wound by second intention. The reactions that ensue after freezing include erythema, vesiculation, edema, exudation and sloughing (Fig. 138.5). Benign and premalignant lesions usually heal within 2 to 4 weeks. Malignant lesions on the face, eyelids, nose, ears and neck generally require 4 to 6 weeks to heal. Large tumors and those on the trunk and extremities take longer to heal, sometimes up to 14 weeks. The cosmetic results after cryosurgery are often equal or superior to those achieved by other modalities. Wounds reproduce natural skin contours and keloid formation typically does not occur. Cryosurgery is advantageous for tumors on the ears and nose because cartilage is relatively resistant to freezing damage and the architecture of the structure is preserved. Lesions on the eyelids and in the vicinity of the lacrimal duct are good candidates for cryosurgery, as the likelihood of ectropion is small and damage to the lacrimal outflow system is rare (Fig. 138.6)[20,21].

Fig. 138.4 A lentigo maligna on the forehead of a 72-year-old man. A The lesion measures 3.1 × 2.5 cm. **B** Cryosurgery to the entire lesion. Note the wide lateral spread of freeze. **C** The healed cryosurgical site 5 months after treatment.

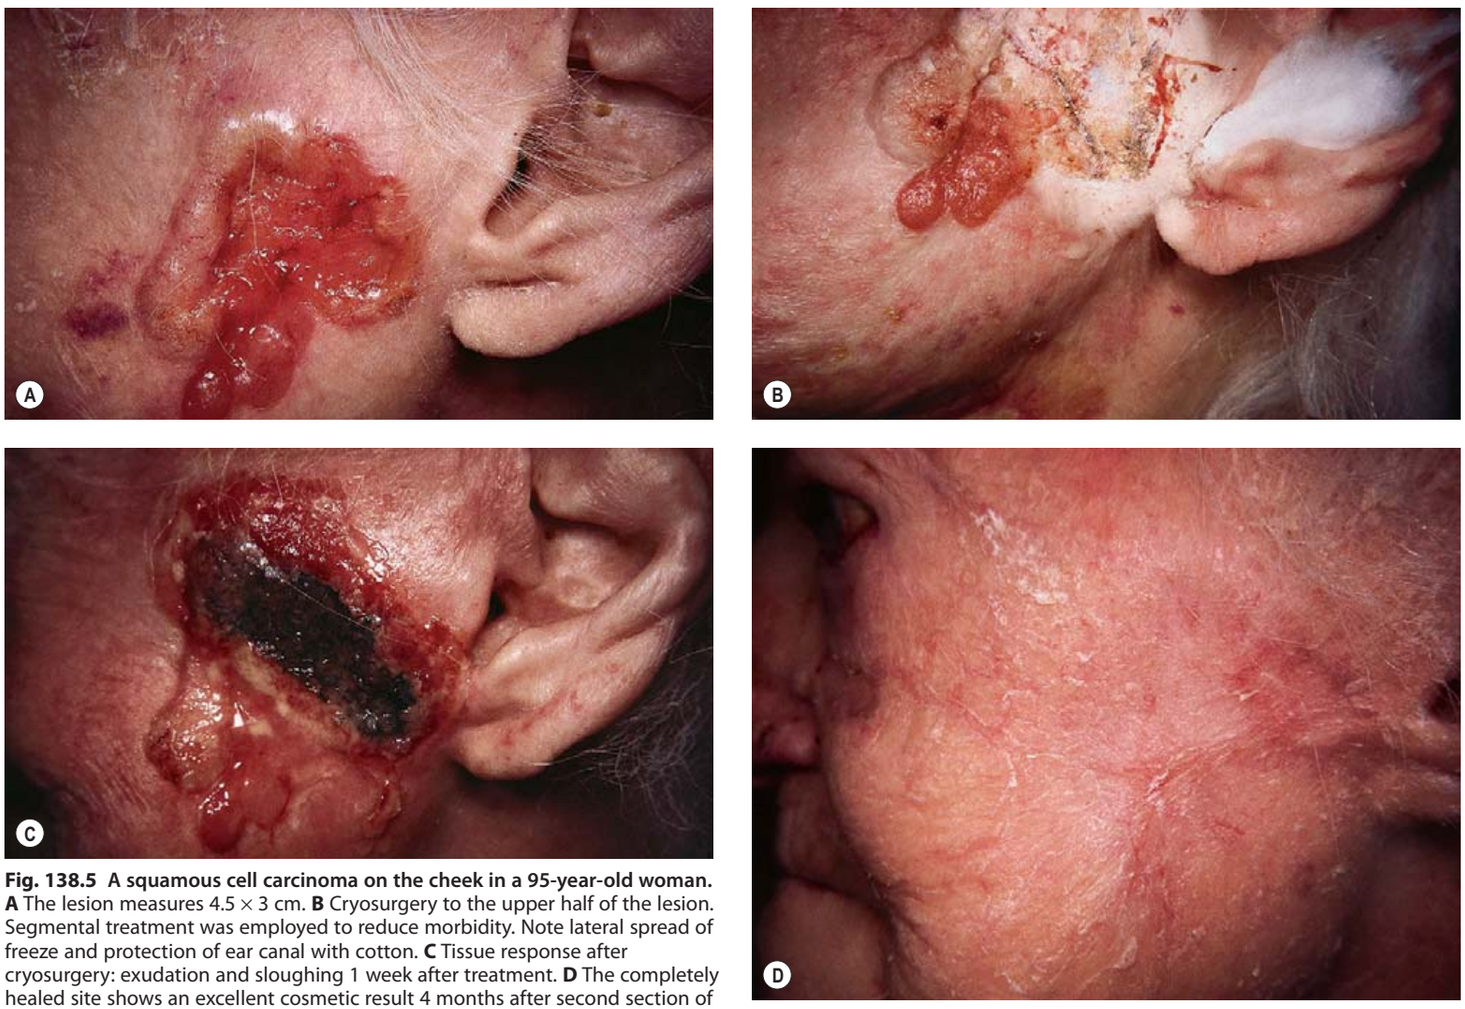

Fig. 138.5 A squamous cell carcinoma on the cheek in a 95-year-old woman. A The lesion measures 4.5 × 3 cm. **B** Cryosurgery to the upper half of the lesion. Segmental treatment was employed to reduce morbidity. Note lateral spread of freeze and protection of ear canal with cotton. **C** Tissue response after cryosurgery: exudation and sloughing 1 week after treatment. **D** The completely healed site shows an excellent cosmetic result 4 months after second section of tumor was treated.

A Papular lesion with telangiectasias on the eyelid margin of an 82-year-old woman. **B** Cryosurgery to lesion: note placement of thermocouple needle and protection of eye. **C** The healed cryosurgical site 6 months after treatment. Excellent cosmetic result; note loss of cilia.

VARIATIONS AND UNUSUAL SITUATIONS

If a lesion is thick or bulky, it is beneficial to reduce it to a shallow one by debulking with a curette, scissors or electrosurgery. This is done because the mass is detrimental to proper treatment, either by hindering the advancement of the ice ball, misjudging the placement of thermocouple needles or by prevention of proper assessment of the lateral margins and base of the lesion. After debulking, hemostasis must be obtained before proceeding with cryosurgery.

It is sometimes beneficial to inject lidocaine under a lesion for the purpose of lifting it away from underlying tissue or superficial nerves. Examples include the treatment of warts or actinic keratoses on the fingers and hands, and malignancies on the head, neck and scalp.

Selected large basal or squamous cell carcinomas are amenable to cryosurgery using segmental treatment (see Fig. 138.5). A lesion is treated in stages after being divided into sections and can be treated either on the same day or at subsequent visits. Each section is treated according to its characteristics and depth. Wound healing is not hindered by overlapping treatment at the margins.

POSTOPERATIVE CARE

Postoperative care varies according to the lesion, location and depth of freeze. Most benign lesions require little or no aftercare except for ordinary washing. A shallow eschar develops that falls off spontaneously. In some instances, a watery exudate may develop beneath an eschar or excessive granulation tissue may develop. This can be treated by debridement with a curette or simply cleansed with soap and water. An antibiotic ointment can be applied.

In the case of cutaneous malignancies, extensive exudation begins within 24 hours and diminishes in an orderly manner as the wound heals and re-epithelializes. The authors recommend washing with soap and water four times daily in the exudative stage and less often during the granulating period. A dry gauze dressing is initially applied, and, as the wound begins to heal, an antibiotic ointment is used. In some instances, oral antibiotics are beneficial, such as for lesions on the legs and ears, or where otherwise indicated. Bullae may form at the periphery of a large lesion and this is not a complication. The bullae are drained and healing is not affected.

COMPLICATIONS

The incidence of complications after cryosurgery is low. It is important to distinguish between expected sequelae and untoward results. A complication may arise in several ways: (1) as an unexpected event (e.g. infection); (2) as an unsatisfactory cosmetic result (e.g. hypertrophic scarring); and (3) as a more pronounced response of the tissue to freezing than had been anticipated (e.g. residual hypopigmentation).

Temporary complications may develop during the healing stage or after completion of treatment and generally resolve spontaneously. Commonly described examples include edema of the eyelids or ears and hypertrophic scarring. Edema, particularly periorbital, can be minimized or ameliorated with open wet compresses, corticosteroid cream or a short course of systemic corticosteroids. One author (EK) reported using an intramuscular injection of 4 mg betamethasone sodium phosphate 30 minutes before treatment, followed by an adult dose of oral prednisone (20 mg/day for 3 days)[22]. Occasionally, hypertrophic scarring may develop, particularly after treatment of a large lesion, but this always improves and resolves with time, usually within months. Intralesional corticosteroid injections can hasten resolution. Uncommon reactions include delayed bleeding, headache, paresthesia, neuropathy, secondary infection, syncope, nitrogen gas insufflation (gas bubbles in skin), milia, hyperpigmentation and pyogenic granuloma.

Permanent complications include tissue retraction (e.g. lips, eyebrows, ala nasi), tissue defect, depigmentation, notching, ectropion, alopecia and contour defects. Improvement sometimes occurs, especially in elderly patients with skin laxity.

FUTURE TRENDS

Cryosurgery is an old technique that will remain very popular for the treatment of actinic keratoses and warts. The technique has remained relatively unchanged for several decades. It is far less commonly performed than excision and Mohs surgery for cutaneous malignancies, and the expert use of cryoprobes has become an art performed by a limited number of dermatologists. The authors feel that new instrumentation and techniques may be forthcoming, e.g. "fractional" cryosurgery, the ability to measure the skin surface temperature during cryotherapy.

139 Radiotherapy

Michael Veness and Shawn W Richards

Chapter Contents

Radiotherapy of benign skin disorders *2293*
Radiotherapy of *in situ* cutaneous malignancies *2294*
Palliation *2298*

Synonyms: ■ Radiation treatment ■ Radiation therapy ■ X-ray therapy

Key features

- Radiotherapy is an important modality in the treatment of patients with skin malignancies
- Radiotherapy may reduce morbidity (as compared to surgery), decrease the risk of recurrent disease, and even be life-saving
- Although most patients with skin cancer are adequately treated by modalities other than radiotherapy, there are factors that may favor its recommendation (e.g. comorbidities, location)
- Modern radiotherapy has an established role as a definitive, adjuvant or palliative treatment
- Treating benign skin disease with radiotherapy must always be carefully considered in light of the risk of radiation-induced malignancy, especially in younger patients

BASICS OF RADIOTHERAPY

Indications

In dermatology, the primary role of radiotherapy is to treat basal cell carcinoma (BCC) and cutaneous squamous cell carcinoma (SCC; see Ch. 108)[1]. It is also used to treat less common, but potentially aggressive, cutaneous malignancies and, occasionally, benign diseases. The former include Merkel cell carcinoma, Kaposi sarcoma (AIDS- and non-AIDS-related), angiosarcoma, adnexal carcinoma, lymphoma and melanoma (especially lentigo maligna).

While the majority of skin cancers are amenable to excision or other treatment modalities (e.g. electrodessication and curettage) which are often more cost-effective, there are clinical settings where radiotherapy is favored. For example, *definitive* radiotherapy is often recommended when the outcome (functional and/or cosmetic) is likely to be better with radiotherapy than with surgery, especially in the situation where the clinician is constrained by the site or size of the tumor. Likewise, elderly patients with advanced lesions for whom complex surgery is best avoided are also excellent candidates for radiotherapy. The aim of *adjuvant* radiotherapy is to reduce the risk of recurrence, whereas *palliative* radiotherapy plays an important role in patients with advanced and/or incurable disease.

Mechanism of action

X-rays are a powerful form of ionizing electromagnetic radiation and the lethal damage they produce within double-stranded DNA represents the basis for radiation therapy[2]. When X-rays (often referred to as photons) are absorbed by biological matter, an electron may be ejected from an atom with the local release of large amounts of energy. The result is that replicating, i.e. more rapidly dividing, malignant cells undergo a mitotic death. Although normal adjacent tissues maintain mechanisms for repair following sublethal damage, there are limitations as to the dose of ionizing radiation normal tissue can tolerate, beyond which late reactions arise (see below). Enhancement of the difference in the response of malignant cells versus normal tissue is accomplished via delivery of the radiation in small divided doses (referred to as fractions).

Treatment machines

In the modern era of radiation oncology, high-energy megavoltage (mV) photons (6–25 mV) are generated by a linear accelerator (LINAC) located within a heavily shielded concrete bunker. One of the advantages of megavoltage radiotherapy is its ability to treat deep-seated internal malignancies with relative skin sparing. However, when treating cutaneous lesions, deep beam penetration and skin sparing are usually not desirable. The delivery of *low-energy* kilovoltage (kV) photons (50–300 kVp) by a *superficial/orthovoltage* machine is preferable, as it avoids both skin sparing and the irradiation of deeper tissues. With low-energy photons, tissue penetration is measured in millimeters to centimeters. Shielding is achieved by applying 3–4 mm of lead either directly onto the skin or by using an internal (e.g. eye or mouth) shield.

Terminology

The International Unit of radiotherapy is a Gray (Gy)[3]. One Gy is equivalent to 100 cGy or 100 rads (in the older terminology). A fraction of radiotherapy refers to the dose delivered in one treatment. A typical course of radiotherapy for a cutaneous malignancy in an otherwise healthy patient is 50 Gy delivered in 20 daily (Monday through Friday) fractions (2.5 Gy/fraction). Historically, patients were often administered only two or three fractions per week. At the very least, this latter schedule simply protracted the overall treatment period, but in some cases may have resulted in decreased local control. The daily outpatient irradiations are only minutes in duration and treatment regimens usually consist of 10 to 30 weekday visits.

Radiotherapy doses

Hypofractionation refers to the delivery of larger doses per fraction (4–7 Gy). However, when the dose per fraction is increased, the total dose delivered is then decreased. For example, commonly prescribed dose fractionation schedules are 45 Gy in 15 (3 Gy) fractions, 40 Gy in 10 (4 Gy) fractions, and 35 Gy in 5 (7 Gy) fractions. Using a 2 Gy per fraction equivalent, this variation in the total dose results when the biological effective dose (BED) needed for eradicating a tumor is calculated[4]. Despite this, the data suggest that, at least for small (≤2 cm) SCCs and BCCs, there is not a marked dose–response, and local control is similar whether a patient receives 40 Gy in 10 fractions (47 Gy BED) or 50 Gy in 20 fractions (52 Gy BED). However, when the tumors are larger or more infiltrative, better local control is achieved with a BED of around 60 Gy. Of note, late effects increase as the total dose and dose per fraction increase and it is these late effects that will impact on cosmesis and late tissue damage (necrosis).

Radiation physics

The qualities and "hardness" of a superficial/orthovoltage photon beam are determined by the placement of filters within the radiation beam[5]. In radiation physics, a standard term is the "half value layer" (HVL) which refers to the thickness of a material (often copper [Cu] or aluminum [Al]) that is required to reduce the beam intensity by 50%. The

filter serves to remove the softer photon component and improve the penetration quality of the beam. A second concept is half value depth (D½) and here filters are used to achieve radiation with a D½ that corresponds to tumor depth. For each superficial and orthovoltage beam, at least one to two filters should be available.

Low-energy photons (superficial/orthovoltage) and common cutaneous protocols

A typical 100 kVp superficial photon beam with an HVL of 7 mm of aluminum will deliver 100% of prescribed dose to the surface, 85% at 5 mm, and 70% at 10 mm. A 250 kVp orthovoltage beam with an HVL of 2.5 mm of copper will deliver 95% of prescribed dose at 5 mm and 90% at 10 mm. Most superficial lesions (<5 mm depth) will be adequately treated by a 100 kVp beam with an HVL of 6–8 mm aluminum (or similar). Deeper, more invasive lesions (5–10 mm in depth) are adequately encompassed by a 250 kVp orthovoltage beam with an HVL of 2–4 mm copper.

Some clinicians estimate tumor thickness and then choose an appropriate beam energy and HVL that will achieve 90–95% of the prescribed dose at the depth of the tumor. However, this latter approach requires an accurate estimate of tumor thickness.

The photoelectric effect is a phenomenon whereby underlying bone or cartilage receives a higher dose of radiation when low-energy photons are used. This is not the case with electrons (see below) and is used by some clinicians as a justification for the use of electrons when treating lesions in close proximity to bone or cartilage. However, there are no convincing data that the late effects in these tissues are markedly increased when low-energy photons are used instead of electrons[6].

Grenz ray treatment

Grenz rays are very-low-energy (5–15 kVp) photons that penetrate only superficially (0.5–1 mm)[7]. Nowadays, the use of this modality is very limited, but, in the past, several inflammatory dermatoses (e.g. chronic hand dermatitis) were treated with grenz rays. The latter are reported to be relatively safe in lifetime doses of up to 50 Gy to treated areas. Nevertheless, grenz rays should *never* be viewed as first-line therapy. Worldwide, the machines used to generate these very soft X-rays are rare and are not utilized in modern departments of radiation oncology.

Electrons

A linear accelerator can also generate electrons and they are utilized in a variety of treatment settings. Unlike X-rays, electrons are a particulate radiation that carries a negative charge. Low-energy electrons (6–8 MeV [million electron volts]) offer an alternative to low-energy photons when treating cutaneous tumors, but the former do have some disadvantages[8]. For example, electron beams are relatively skin-sparing (Fig. 139.1), and, as a result, a tissue equivalent bolus needs to be placed on the skin surface (Fig. 139.2). Also, utilizing electron beams for small treatment fields (<4 cm^2) may result in tumor underdosing at the deepest extent of the tumor.

Electrons offer the advantage of a rapid linear decline in dose beyond a well-defined tissue depth that is a function of the selected beam energy (see Fig. 139.1). For example, a 6 MeV electron beam provides some of its dose (~87%) at the surface, but deposits 100% of the specified dose at a depth of approximately 1 cm. Using a higher-energy beam will result in deposition of a higher percentage of the dose at the skin surface, but with a higher dose to subcutaneous tissues. On the other hand, if a tissue equivalent bolus of 1 cm is applied in conjunction with a 6 MeV beam, close to 100% of the desired dose will be obtained at the skin surface (see Fig. 139.2). All of the deposition of dose will be brought 1 cm closer to the skin surface, further minimizing the dose to underlying structures.

In addition, tumors treated with electrons require 10–20 mm margins as a consequence of a wider penumbra (dose drop-off at the field edge). Electrons also have a lower relative biological effectiveness (RBE) in comparison to photons, leading some clinicians to recommend a 10–15% increase in total dose to compensate.

In summary, there are data to suggest that local control of skin tumors may not be as good with electrons when compared to low-energy photons. However, this may reflect an under-appreciation by some clinicians of the intricacies of using small field electrons to treat skin cancers.

Brachytherapy

Brachytherapy is a type of radiotherapy that is delivered by the direct application of a radioactive source to involved tissues. In the vast majority of clinical settings, radioactive molds and implants offer little advantage over the range of energies of external beam photons and electrons currently available. As a result, they are rarely used nowadays to treat BCCs and SCCs. Nonetheless, some clinicians have advocated using radioactive molds for areas with poor vascularity and slow rates of healing (e.g. the anterior lower limb or dorsum of the hand)[9]. However, suitable lesions need to be superficial (<3–4 mm in depth) and there are radiation safety issues if this approach is utilized.

Office-based radiotherapy

Office-based superficial radiotherapy was once the standard modality by which dermatologists treated skin cancer[10]. Typical machines delivered photons of 70–100 kVp with a depth dose suitable for most patients with cutaneous malignancies. However, in the past two decades, the rising cost of radiotherapy machines combined with increased enthusiasm and training in dermatologic surgery have led to a significant decline in office-based radiotherapy. Nowadays, radiotherapy for skin cancer is performed almost exclusively by radiation oncologists. However, this does not diminish the need for dermatologists to understand the role of radiotherapy and to become familiar with its indications and treatment regimens, since dermatologists frequently diagnose skin cancer and outline therapeutic options.

Advantages of radiotherapy

Radiotherapy offers the advantage of a non-surgical approach, thereby avoiding surgical morbidity, scarring and the need for reconstruction. In situations where reconstruction with grafts or flaps is required, improved cosmesis may result from radiotherapy[11]. Radiotherapy fields

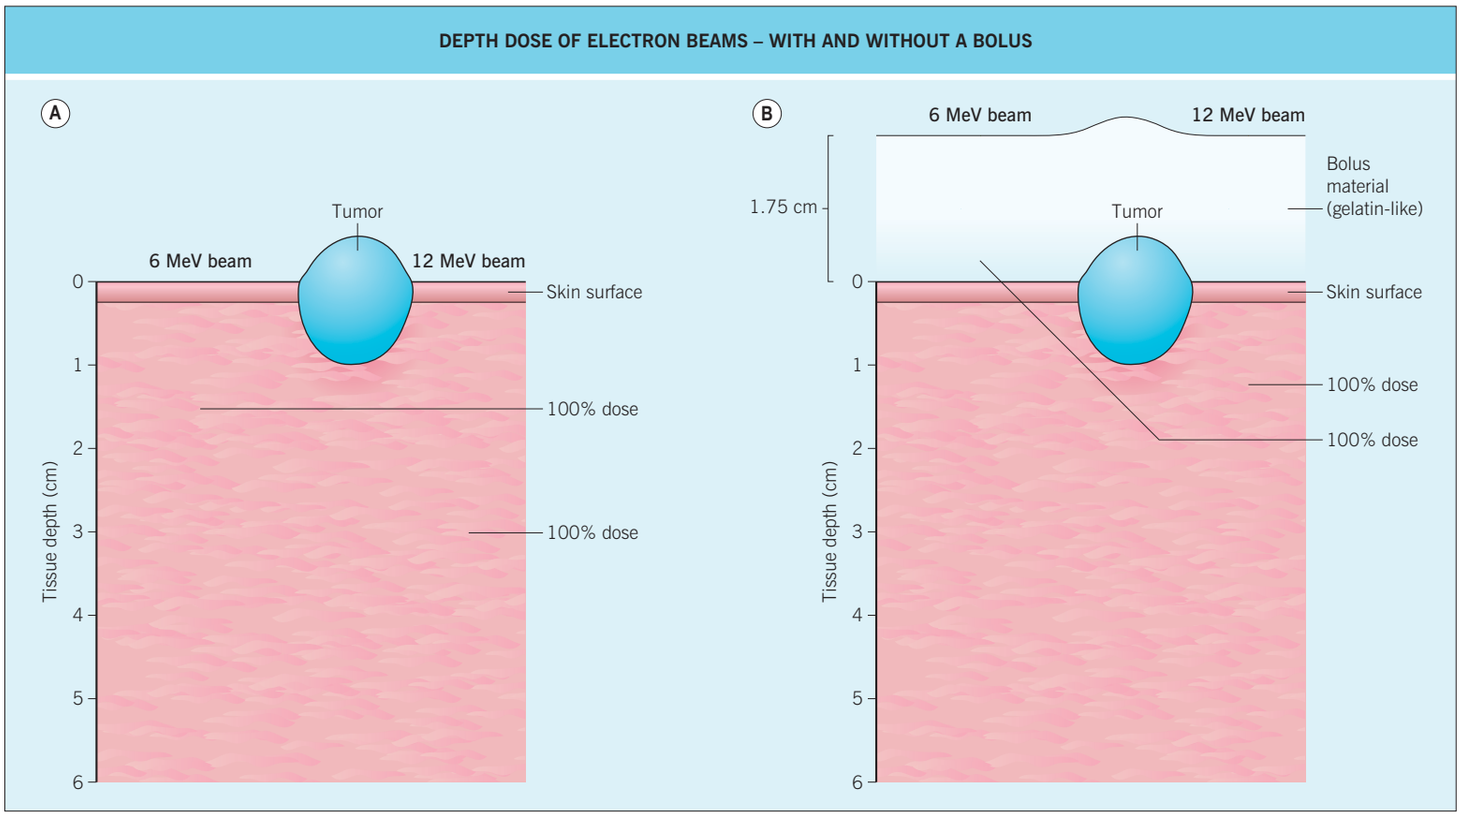

Fig. 139.2 Depth dose of electron beams – with and without a bolus. A Beams with a dose of 6 MeV and 12 MeV. **B** Demonstration of the bolus effect whereby a more appropriate dose of radiation is obtained at the skin surface. *Courtesy, Lynn Wilson, MD.*

can also be tailored with generous margins in order to encompass "at-risk" areas (e.g. possible sites of clinically inapparent tumor extensions) that, if surgically approached, would require involved and complex surgery. In addition, standard oncologic excision margins in certain sites are often difficult to achieve without causing surgical morbidity; such sites include the midface triangle, i.e. the periorbital region (especially the medial canthus), the lower eyelid, nose (especially the ala nasi and nasal tip), nasolabial fold, lip and chin.

Disadvantages of radiotherapy

Radiotherapy does have its disadvantages; in particular, most patients require a protracted course of treatment compared to what is often a simple outpatient excision. Patients should also be informed that because of the risk of serious late effects such as soft tissue and cartilage necrosis, a second course of definitive radiotherapy cannot be delivered to the same site. In addition, the reduced "quality" of irradiated skin makes subsequent surgery difficult if the tumor recurs or persists following radiation therapy. Lastly, individuals with xeroderma pigmentosum or nevoid basal cell carcinoma syndrome should not be irradiated owing to their marked predisposition for developing multiple and recurrent skin cancers, often at a young age.

Lesions that have deeply invaded cartilage or bone often do better with a combination of excision plus adjuvant radiotherapy, although definitive radiotherapy still remains an option (local control 60–70%). Radiotherapy of lesions located on the foot, anterior lower leg or dorsum of the hand, although not contraindicated, should be avoided if possible; lesions in such sites are best treated with excision. Unfortunately, radiotherapy to poorly vascularized, edematous tissues is often associated with poor healing. Skin cancers arising in sites of chronic ulceration, trauma or thermal burns should not be irradiated if at all possible. These sites often have poor vascularity and consequently poor healing. Patients with scleroderma and other causes of cutaneous fibrosis are also best treated by surgical means, as radiotherapy may enhance the fibrosis and lead to poor healing.

Radiotherapy has a very small (~1 in 1000) risk of causing a radiation-induced in-field malignancy (often soft tissue/bone sarcoma) 10–15 or more years after exposure[12]. However, these data were obtained from studies involving many different malignancies treated by various techniques and dosing schedules. It is likely that with modern radiotherapeutic techniques as well as the smaller volumes being irradiated when treating skin cancers, a figure of 1 in 1000 represents an overestimate of the real risk, which is actually rare. Despite this, in younger patients (<50 years of age), this is an important issue and patients must be informed of the risk.

RADIOTHERAPY OF BENIGN SKIN DISORDERS

Background

The role of radiotherapy in treating benign disorders has markedly diminished over the past several decades. It is no longer ethically acceptable to offer radiotherapy as a treatment for acne, warts, hirsutism or tinea capitis. The role of radiotherapy in treating inflammatory skin conditions (e.g. dermatitis, psoriasis, lichen planus) is primarily historical due to efficacious alternative treatments (e.g. corticosteroids, phototherapy) and the risk of exposing patients to ionizing radiation. Previous studies suggested that low-dose (8–12 Gy) soft X-rays often resulted in satisfactory resolution of symptoms, especially in eczematous conditions, but clinicians must carefully weigh the risks versus the benefits before recommending radiotherapy. Specific guidelines have been published regarding the risk/benefit ratio and obtaining informed consent when radiotherapy for benign disorders is being considered[13].

Keloids

Recurrent keloids, often refractory to re-excision and intralesional corticosteroid injections, can have significant cosmetic and psychologic sequelae for patients, many of whom are young women. The addition of low-dose (12–16 Gy) adjuvant radiotherapy delivered in three to four fractions, beginning within 24–48 hours following surgery, can markedly and safely reduce the incidence of recurrence[14]. A common site is the earlobe and patients can be treated with low-energy photons plus lead shielding of surrounding tissues. Young patients with keloids of the lower anterior neck (in close proximity to the thyroid gland) should not be irradiated.

Pseudolymphomas

Cutaneous pseudolymphoma (cutaneous lymphoid hyperplasia) often arises on the face (see Ch. 121). When lesions fail to respond to intralesional corticosteroids, low-dose fractionated radiotherapy (10–15 Gy in five fractions) utilizing low-energy photons is an efficacious treatment option with minimal, if any, side effects.

Scleredema

There are a few case reports of the use of electron beam therapy for patients with scleredema. Obviously, it would be reserved for those with recalcitrant disease and functional impairment.

RADIOTHERAPY OF *IN SITU* CUTANEOUS MALIGNANCIES

Squamous cell carcinoma *in situ* (Bowen's disease)

Radiotherapy can be used, albeit infrequently, to treat SCC *in situ*. The malignancy is limited to the epidermis and its appendages, arises more commonly in sun-exposed sites, and usually presents as a slowly growing scaly erythematous plaque. A biopsy is important to exclude the possibility of eczema or psoriasis. Only a small minority (<5%) become invasive SCCs, although this may be higher (10–30%) in genital lesions such as erythroplasia of Queyrat. Patients are treated with 40–50 Gy in 10–20 fractions using superficial low-energy photons (110–150 kVp), with reported local control rates of 98–100%[15].

Patients with widespread actinic keratoses have been treated with radiotherapy under special circumstances. Given that other very effective therapies are readily available (see Ch. 108), radiotherapy should not be considered a first-line treatment modality.

Lentigo maligna

Lentigo maligna (melanoma *in situ* arising within photodamaged skin) often presents as a longstanding and large-sized hyperpigmented patch on the face of elderly patients (see Ch. 113). The size and location often preclude simple excision, and radiotherapy remains a well-established option with excellent control rates (Fig. 139.3)[16]. Reported doses range from 35 to 100 Gy administered in 5–10 fractions, i.e. large doses per fraction. However, dose fractionation schedules of 40–50 Gy in 10–20 fractions would also be efficacious[17].

Fig. 139.3 Lentigo maligna (melanoma *in situ*). A An 82-year-old man with a lentigo maligna on his right cheek. **B** Three months after superficial radiotherapy (45 Gy in 15 daily fractions, 120 kVp, HVL 4.2 mm Al).

RADIOTHERAPY OF INVASIVE CARCINOMAS, SARCOMAS AND LYMPHOMAS

Basal Cell Carcinoma

Definitive radiotherapy

BCCs – in particular, primary tumors <2 cm in diameter – can be treated with a number of therapeutic modalities. However, there is a paucity of randomized controlled trials comparing these different modalities. In a recent Cochrane Review, the authors analyzed the published results of seven different treatment categories[18]. Although they suggested the need for further research, surgery and radiotherapy appeared to be the two most efficacious modalities, with surgery probably leading to the lowest recurrence rates[18]. Of note, Mohs micrographic surgery is said to result in some of the highest cure rates.

While local control rates (90–95%) for either excision or radiotherapy are probably similar, management decisions are often based on other factors (Table 139.1). For example, radiotherapy would be favored in an elderly patient with a BCC located on the nasal tip or nasal alae (Fig. 139.4). In the locations outlined in Table 139.1, excision followed by primary closure is often difficult to accomplish and grafts or flaps are frequently required if surgical excision is chosen (Fig. 139.5). In addition, achieving negative deep margins via excision may be difficult in these locations. Although larger lesions (>20 mm) can still be eradicated via definitive radiotherapy (see below), with increasing size and depth of invasion, local control rates decrease. Therefore, surgery combined with adjuvant radiotherapy is often recommended in order to try to achieve better local control.

Superficial BCCs that involve large areas are also treated with radiotherapy (Fig. 139.6), although alternatives such as photodynamic therapy, curettage and topical imiquimod are reasonable options. It is important to note that tumors can take many weeks to completely regress after radiotherapy and, therefore, early re-biopsy is not recommended. Dose fractionation schedules vary and are determined by patient and tumor factors (see below).

PATIENT FACTORS AND TUMOR CHARACTERISTICS THAT FAVOR RADIOTHERAPY	
Patient factors	Older age (>70 years)
	Patient preference (avoidance of surgery)
	Receiving medications that affect coagulation and platelet function
	Significant medical comorbidities
Tumor characteristics	Site: Ala nasi, nasal tip, nasal bridge, lower eyelid, medial canthus, helix
	Size/depth: Extensive and superficial
	Stage: Locally advanced requiring complex surgery

Table 139.1 Patient factors and tumor characteristics that favor radiotherapy. Many of these indications are relative.

Fig. 139.4 Superficial pigmented basal cell carcinoma. A 77-year-old woman with a 1 cm superficial pigmented basal cell carcinoma (BCC) on the nasal tip, a location where excision followed by primary closure can be difficult. The BCC was treated with superficial energy photons (45 Gy in 15 daily fractions, 100 kVp, HVL 7 mm Al).

Fig. 139.5 Nodular basal cell carcinoma. A A 56-year-old woman with a 1.5 cm nodular basal cell carcinoma of the right medial canthus. The patient received 55 Gy in 25 daily fractions using orthovoltage energy photons (250 kVp, HVL 2.5 mm Cu) following pre-treatment insertion of an internal eye shield. **B** A 10 mm radiotherapy field margin has been placed around the patient's tumor in order to encompass both macroscopic disease and possible surrounding microscopic (subclinical) spread. **C** At completion of radiotherapy, the tumor has regressed markedly. Note the confluent erythema demarcating the treatment field.

Fig. 139.6 Extensive basal cell carcinoma. A An elderly woman with a large basal cell carcinoma occupying much of the left temple region. **B** Three months after 40 Gy in 10 daily fractions using superficial energy photons (100 kVp, HVL 7 mm Al).

Adjuvant (postoperative) radiotherapy

A recommendation for radiotherapy is often made in the setting of incomplete excision of a BCC. A positive deep margin is always a concern, especially when a local flap has been used for reconstruction, because deep recurrences can be difficult to detect. In particular, undetected deep recurrences of tumors located within the midface and periorbital region may be associated with significant local morbidity. It is accepted that at least 20–30% of incompletely excised BCCs will recur[19] and re-excision is often recommended in order to achieve a negative margin[20]. In one study, for example, residual BCC was found in 45% of the re-excised specimens[19]. However, in some circumstances, the involved margin precludes simple re-excision (e.g. the periosteum of the nose). In these situations, radiotherapy is an option. The aim of adjuvant radiotherapy is to reduce the incidence of local recurrence by eradicating residual microscopic BCC. One study of 33 patients with a medial canthus BCC (and positive excisional margins) reported a 100% local control rate with adjuvant radiotherapy[20]. In a Canadian trial, the addition of adjuvant radiotherapy improved the 5-year local control rate from 61% to 91%[21]. Not surprisingly, the 10-year local control rates were similar (92% vs 90%), as the majority of recurrences were successfully salvaged via surgery.

Squamous Cell Carcinoma

Definitive radiotherapy

The approach to treating patients with cutaneous SCC is influenced by the small risk (<5%[22] to <1%) of metastatic spread to regional lymph nodes and the need to achieve local control. Of note, some patients can be considered as having high-risk SCC when certain unfavorable features are present; these include thickness >2 mm and especially >6 mm, diameter >2 cm, recurrent tumor, high-grade (i.e. poorly differentiated) histology, neurotropism, location on or around the ear or lower lip, and immunosuppressed host. These SCCs have a greater risk of developing recurrences and metastatic nodal disease[23,24].

In general, high-risk patients should have lesions excised with wider margins (see below) and be followed closely for at least 5 years[25]. However, depending upon the circumstances (see Table 139.1), some patients are treated with definitive (or adjuvant) radiotherapy. To date, there is no consensus as to which high-risk patients should be offered elective treatment (e.g. surgical, radiotherapy) of regional lymph nodes, but future sentinel lymph node biopsy studies may help resolve this issue. Patient stratification, based upon depth of invasion, may also influence recommendations. In a recent study of 615 patients with SCC followed for an average of 43 months, no metastases were seen with tumors ≤2 mm in depth, while metastases developed in 16% of those patients with tumors >6 mm in depth[26].

The aim in excising any SCC is to achieve adequate margins, taking into consideration cosmesis and function. Surgical excision of SCC is often more extensive than for BCC, with wider margins (>5 mm) usually recommended[27], and it may entail the Mohs micrographic surgical technique or wide local excision under general anesthesia with flap/graft reconstruction. In a study of cutaneous SCCs <2 cm in diameter, the investigators reported that with a 4 mm excision margin, 95% of the tumors were removed with negative margins. For SCCs >2 cm, a 6 mm excision margin led to negative margins in 95% of the cases[28]. Of note, the local control rate for SCCs is, on average, 10–15% lower than for equivalent-sized BCCs[1,4,29].

It is generally not appropriate to merely observe an incompletely excised SCC. Recurrent SCC is associated with a higher incidence of regional metastases (compared to the initial presentation), with rates of up to 25–45%, depending on the tumor location[22]. Both recurrent BCC and recurrent SCC are associated with a control rate that is lower by at least 10% (compared to untreated lesions of equivalent size), again emphasizing the need to reduce the risk of local relapse[4,28].

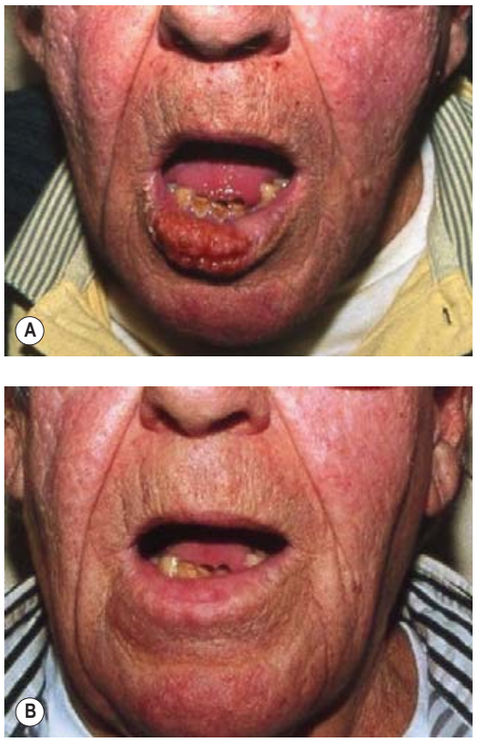

Fig. 139.7 Squamous cell carcinoma. A A 67-year-old man with a squamous cell carcinoma occupying much of the lower lip. The patient received 50 Gy in 20 daily fractions using orthovoltage energy photons (250 kVp, HVL 2.5 mm Cu) and oral cavity lead shielding to protect the teeth and mandible. **B** An excellent cosmetic and functional outcome has been achieved.

Definitive radiotherapy of cutaneous SCC is an excellent treatment option, especially in the clinical settings outlined in Table 139.1. For example, multiple medical comorbidities may preclude patients from having extensive surgery. In addition, in sites such as the lower lip, radiotherapy can result in excellent maintenance of function (even with more extensive tumors; Fig. 139.7) as well as cure rates comparable to surgery (see section on lip SCC)[30].

Keratoacanthomas

A keratoacanthoma (KA) typically presents as a rapidly enlarging papulonodule with a central keratin plug. Difficulty often arises in distinguishing these tumors histologically from well-differentiated SCCs, and many authorities consider most KAs to be a well-differentiated variant of SCC. Although KAs often regress spontaneously, a significant number become large and unsightly. Radiotherapy is an efficacious treatment option if excision is not contemplated. Regimens consisting of 25 Gy in five fractions have been reported to lead to a durable regression. Despite this, if the diagnosis of KA versus well-differentiated SCC is uncertain, a dose fractionation schedule appropriate for a SCC should be prescribed (40–50 Gy in 10–20 fractions; see section below on dose fractionation schedules).

Adjuvant (postoperative) radiotherapy

Adjuvant radiotherapy is an option when excision of an SCC is incomplete and re-excision is not considered possible. It is imperative that every pathology report documents and quantifies margin status, and a patient with an incompletely excised SCC, i.e. positive or close margin, remains at risk of local recurrence. While there is no consensus with regard to the most appropriate surgical margin for cutaneous SCCs, published recommendations range from 3 to 10 mm[31], often depending upon size (see above). In one series of patients with SCC of the lip, a 37% local recurrence rate was observed in patients who underwent excision alone (27% close/positive margins) versus a 6% local recurrence rate in patients treated with surgery plus adjuvant radiotherapy (94% close/positive margins)[32].

Special clinical situations

SCC of the lip

In regions of the world that have a high incidence of non-melanoma skin cancer (e.g. Australia), SCC of the lip is considered a skin cancer, not an oral cancer[30]. Compared to oral SCC, there is a lower propensity for spread to regional nodes. Nearly all lesions arise on the lower lip, usually as a consequence of chronic sun exposure.

As with small to moderate-sized SCCs of the skin, the outcome with surgery versus radiotherapy is similar. The laxity of the lip means that wedge excision (± vermilionectomy) is the procedure of choice, with primary closure often possible. When >30–50% of the lip is involved, excision with appropriate margins is usually not achievable without risking function (e.g. oral competency). Complex reconstruction is an option, but insensate tissue may be needed for reconstruction, again with an impact on function. Radiotherapy is therefore an excellent treatment option for SCC of the lip. The lower lip lends itself very well to treatment with orthovoltage photons following insertion of a 3 mm intraoral lead shield to protect the mandible and teeth (see Fig. 139.7). Doses are similar to those for any other equivalent-sized SCC, with a recommended total dose of 50–55 Gy in 20–25 fractions[32].

Lymph node metastases of SCC

Patients with metastatic SCC involving regional lymph nodes (usually of the head and neck) are best referred to a multidisciplinary cancer service[33]. Metastases within the cervical lymph nodes can be due to an occult SCC of the oropharynx or a previously treated cutaneous SCC. Parotid lymph nodes represent a common site for metastases from a previously treated scalp, forehead or ear SCC; in such cases, surgery (parotidectomy ± neck dissection) is required.

Adjuvant radiotherapy is nearly always recommended in patients with nodal metastases in order to improve locoregional control, as the risk of nodal relapse remains high despite surgery[34]. Even patients with multiple unfavorable features (e.g. involvement of multiple nodes, extranodal spread, close margins) can still expect a 5-year disease-free survival of 70–75% with the combination of surgery and adjuvant radiotherapy[34].

Perineural invasion of SCC and BCC

Perineural invasion is an uncommon but serious consequence of SCC and, to a lesser extent, BCC[35]. Up to 2% and 5% of excised BCCs and SCCs, respectively, are noted to have incidental perineural invasion, and a minority (30–40%) of these will present with, or eventually develop, neurologic signs (e.g. motor deficit) or symptoms. Formication (sensation of ants crawling) may herald the diagnosis of perineural invasion, but dysesthesias, paresthesias, numbness and pain are all suggestive symptoms. The diagnosis is frequently delayed because perineural invasion is often not suspected.

A consensus is lacking regarding the most appropriate treatment following the diagnosis of perineural invasion. Patients with limited disease usually undergo surgery plus adjuvant radiotherapy, while radiotherapy alone is often recommended for those with advanced disease extending into the cranial cavity. Prognosis is poor once signs (e.g. craniopathies) or symptoms develop, with 5-year survival rates reported to be around 50%. When periorbital SCCs, especially those in the supraorbital area, are associated with perineural invasion, further treatment should definitely be considered[36]. Retrograde spread of SCC along the first division of the trigeminal nerve towards the orbital apex can occur. In addition, both the second division of this nerve and the facial nerve are potential conduits for spread back to the CNS.

In some circumstances, additional surgery, often extensive, may be undertaken to explore and dissect out potentially involved nerves. Alternatively, radiotherapy, often requiring multi-field megavoltage photons to treat neural pathways to the brainstem as well as first echelon lymph nodes, can be recommended[35–37]. While radiotherapy has the advantage of avoiding surgery, there is some risk of late radiation damage to orbital and CNS structures. Doses of 50–70 Gy (2 Gy/fraction) are often utilized, although late complications can occur (10–35% of patients). Hyperfractionated radiotherapy (i.e. delivery of smaller-than-usual doses per fraction) and concomitant chemotherapy may improve outcome and decrease late reactions[37].

Immunosuppressed hosts

Immunosuppression in the setting of solid organ transplantation (usually renal or cardiac) may be associated with significant morbidity due to the development of malignancies, especially lymphomas and skin cancers. In some transplant populations, the risk of developing a cutaneous SCC exceeds 50%, and there is a greater risk of metastatic spread (compared to the general population). An interesting phenomenon is

the higher incidence of SCCs compared to BCCs. Transplant patients also have an increased incidence of cutaneous melanoma, Merkel cell carcinoma and Kaposi sarcoma. Additional patients at increased risk for developing aggressive cutaneous SCCs are individuals infected with HIV and those with chronic lymphocytic leukemia, especially when undergoing therapy (e.g. fludarabine, alemtuzumab). A subset of the SCCs that arise in immunosuppressed patients are clearly aggressive, with rapid growth and the development of regional and distant metastases[38]. There is some evidence that reducing the level of immunosuppression may be beneficial, although this potentially puts the patient at risk of organ rejection. The role of chemoprophylaxis (retinoids) in reducing the future development of skin cancers is unclear, although there is recent evidence to suggest a possible benefit. However, tolerability of dose-related side effects remains an issue.

The basic tenets of obtaining adequate surgical margins and examining for perineural invasion are of particular importance in this group of patients. Whilst prophylactic treatment to regional lymph nodes cannot be recommended, adjuvant radiotherapy to incompletely excised tumors or those with perineural invasion should be strongly considered. Transplant patients usually tolerate radiotherapy quite well, with no greater degree of acute toxicity[39].

Dose fractionation schedules and fields

An appropriate dose fractionation schedule depends upon both patient and tumor factors. However, decisions should not be based on age alone, as the presence or absence of relevant comorbidities must also be considered. As a generalization, smaller lesions (2–3 cm) in older patients (>70 years of age) are adequately treated by using 40–45 Gy in 10–15 daily fractions, resulting in acceptable local control and cosmesis (Table 139.2). Elderly or infirm patients may be best served by prescribing single large fractions (see palliation below) or even three to five fractions of 6–7 Gy. For larger invasive lesions (>3–4 cm) and/or younger patients, a lower fraction size (2–2.5 Gy) and a "hotter" total dose of 50–60 Gy are recommended in order to optimize local control and produce acceptable late effects. Some clinicians administer a higher dose for cutaneous SCCs than for equivalent-sized BCCs. However, the data to support this practice are conflicting, and, in the opinion of the authors, this is not required. Also, the dose for different subtypes or grades of BCC or SCC does not need to vary nor does the dose prescribed in the adjuvant setting.

A field margin of 5–10 mm beyond macroscopic disease or a surgical site is usually adequate (see Fig. 139.5B). For a small, well-defined BCC, a 5 mm field margin is adequate if superficial photons are used. For SCCs and infiltrative BCCs, a wider margin of 10–15 mm is required in order to encompass surrounding subclinical spread. Ideally, adjuvant treatment should start within 6–7 weeks of excision. Whilst some clinicians are reluctant to administer radiotherapy to a grafted site, it is uncommon for a healed skin graft to be lost because of radiotherapy[40]. Occasionally, poorly vascularized or infected grafts, especially on the scalp, do not tolerate radiotherapy.

SUGGESTED DOSE FRACTIONATION SCHEDULES FOR BASAL CELL CARCINOMAS AND SQUAMOUS CELL CARCINOMAS

Dose fractionation schedule	Indication	Biological effective dose*
Single 12–20 Gy fraction	Elderly, infirm (palliation)	
35 Gy in 7 fractions of 5 Gy	Elderly, medical comorbidity	44 Gy
40 Gy in 10 fractions of 4 Gy	Older, otherwise well	47 Gy
45 Gy in 15 fractions of 3 Gy	Older, otherwise well	49 Gy
50 Gy in 20 fractions of 2.5 Gy	Younger and/or lesion <2–3 cm	52 Gy
60 Gy in 30 fractions of 2 Gy	Younger and/or large lesion	60 Gy

*Calculated by converting to 2 Gy/fraction using the linear quadratic equation.

Table 139.2 Suggested dose fractionation schedules for basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs).

Merkel Cell Carcinoma

Merkel cell carcinoma is a primary cutaneous neuroendocrine (small cell) carcinoma that most often arises in the head and neck region (see Ch. 115)[41]. These tumors often lack diagnostic clinical features but usually have grown rapidly. Merkel cell carcinomas are aggressive, having a high propensity for locoregional relapse and distant spread, and patients need to be appropriately evaluated prior to instituting therapy. Merkel cell carcinoma is both a radio- and chemo-responsive carcinoma. Currently, wide local excision of the primary lesion with margins of at least 10–20 mm or Mohs micrographic surgery is recommended. Some clinicians also advocate sentinel lymph node biopsy, and treatment of the regional lymph nodes must always be considered (see below). When adjuvant locoregional radiotherapy is administered, there is evidence that extensive local surgery may not necessarily lead to a better outcome[42]. In patients considered medically or technically inoperable, radiotherapy alone (50–55 Gy in 20–25 fractions) can result in excellent in-field control in most patients, with death usually from distant relapse[43].

Although there are proponents of surgery alone for selected cases of Merkel cell carcinoma, adjuvant locoregional radiotherapy should nearly always be considered and represents "best practice" in the opinion of the authors[44–46]. Treatment should include the excision site, in-transit tissue (because of the risk of in-transit metastases), and regional lymph nodes. In an attempt to reduce the risk of locoregional relapse (which occurs in 40–50% of patients treated with surgery alone), a typical dose fractionation schedule would be 50 Gy in 20–25 daily fractions, usually requiring megavoltage photons or moderate-energy (9–12 MeV) electrons plus bolus[47]. Because of insufficient data, the role of adjuvant chemotherapy (cisplatin or carboplatin ± etoposide) is currently unresolved. In advanced or metastatic disease, both palliative radiotherapy and chemotherapy can offer effective symptom improvement.

Angiosarcoma

Most angiosarcomas present as violaceous plaques on the scalp and face of older adults (see Ch. 114). These tumors often extend well beyond the clinically evident/apparent margins[48] and locally extensive disease is usually present at the time of diagnosis. Unfortunately, excision alone is usually followed by local recurrences because of the multicentric and insidious nature of this tumor. Relapses can occur at the periphery of treated sites as well as regionally.

Angiosarcomas tend to be radio-responsive and therefore can be treated with radiotherapy. Patients with limited and operable disease may undergo excision followed by *adjuvant* radiotherapy. Alternatively, *definitive* radiotherapy is also an option, with a reasonable likelihood of obtaining in-field control[49]. In the case of scalp involvement, a technique can be used that encompasses the entire scalp and combines matching photon and electron fields[48]. Other options include multiple static electron fields or electron arcs. Lastly, single-agent chemotherapy with paclitaxel may be helpful in patients with recurrent disease.

Kaposi Sarcoma

Kaposi sarcoma (KS) is a type of spindle cell malignancy that arises from the vascular endothelium, usually presenting as violaceous papules and plaques (see Ch. 114). Classic KS favors the legs of elderly men of Mediterranean or Jewish origin[50], whereas AIDS-associated KS has a more widespread distribution pattern, including the oral cavity (see Ch. 78).

While the role of radiotherapy for AIDS-related KS has markedly diminished with the advent of antiretroviral therapy (ART; formerly referred to as highly active antiretroviral therapy [HAART]), it is a radio-responsive tumor and various dose fractionation schedules have been used to effectively treat cutaneous lesions. Regimens range from a single 8 Gy irradiation to 30–40 Gy in 10–20 daily fractions[51]. Because patients often develop acute painful reactions from radiotherapy to the oral cavity and the plantar surface, they should undergo radiotherapy to only one foot at a time.

Classic KS usually has a long and indolent clinical course. Patients with localized resectable tumors that are symptomatic may undergo excision, but the multifocal nature of the disease must be kept in mind.

Fig. 139.8 Kaposi sarcoma. A A 53-year-old man with a localized plaque of Kaposi sarcoma on the lateral aspect of the distal lower leg. **B** Two months after 50 Gy in 25 daily fractions using megavoltage photons plus a tissue equivalent bolus. There is erythema within the radiation field and residual brown discoloration.

Radiotherapy is also an effective modality for palliating areas of symptomatic disease. Single small doses of 8–12 Gy are reported to result in symptom relief and tumor reduction in most patients; however, in some circumstances, higher, more-fractionated doses may be considered to sites of limited disease (Fig. 139.8). Occasionally, there is a sense of chasing the disease, as lesions gradually appear at the periphery of irradiated sites. For patients with widespread disease, total skin electron beam therapy (see below) has been utilized.

Cutaneous Lymphomas

Cutaneous lymphomas are exquisitely radio-sensitive. However, with the exception of primary cutaneous B-cell lymphoma (see Ch. 119) and selected patients with cutaneous T-cell lymphoma (CTCL; see Ch. 120), the role of radiotherapy is essentially palliative. Patients with sites of symptomatic local disease (lymph nodes, dermal nodules and plaques, ulcers) can be palliated with doses of 20–30 Gy, often requiring orthovoltage or megavoltage energy photons. In primary cutaneous B-cell lymphoma, a form of indolent extranodal non-Hodgkin lymphoma, local radiotherapy with doses of 36–40 Gy may be curative[52].

Total skin electron beam therapy

Selected patients with mycosis fungoides and Sézary syndrome may be treated with total skin electron beam therapy (TSEBT) to a dose of 36 Gy over 9 weeks[53]. This treatment, which is complex and usually delivered by specialized centers of radiation oncology, has particular advantages:

- comprehensive coverage of the entire skin surface
- can be repeated should other modalities fail to control the CTCL
- an acceptable toxicity profile when given over a 6–9-week period.

While TSEBT can be offered to patients with all stages of disease, it is usually reserved for more advanced stages (IIB, III, IV) and/or disease that has failed to respond to less aggressive therapies (e.g. phototherapy, topical alkylating agents).

Treatment consists of a 4–6 MeV beam (see Fig 139.1), with patients often treated in the standing position at a distance of 7 m from the linear accelerator. Irradiation is administered 4 days per week for 9 weeks (i.e. 36 fractions). To some degree, X-ray contamination is always a feature of electron beam therapy. Typically, if using a 4–6 MeV electron beam, X-ray contamination is less than 2% of the dose. Each week, the entire skin surface receives two cycles of treatment and a total of 2 Gy is given to the entire skin surface each cycle. The perineum, plantar surface and scalp receive supplemental "boosts", as these areas are not adequately treated with the patient in the standing position. Lead contact lenses are used to shield the eyes during the initial 18 fractions of TSEBT, and external shielding of the eyelids is done during the second portion of the treatment; hands and feet are also shielded 50% of the time during TSEBT. Patients with tumor stage disease often receive supplemental boosts via orthovoltage or electrons at the completion of the TSEBT.

As there is no significant dose of radiation to the bone marrow or viscera[54], patients receiving TSEBT should not have systemic sequelae (e.g. cytopenias, nausea, vomiting, diarrhea). However, alopecia, dyspigmentation and hypohidrosis often occur and in many patients are permanent side effects. A repeat course of TSEBT may be given months to years later for those who develop recurrent treatment-resistant disease. The most suitable candidates for repeat TSEBT are individuals with longer intervals between courses (>6 months) and those who had a longer disease-free interval following the first course.

Adnexal Carcinomas

Adnexal (appendageal) carcinomas, such as microcystic adnexal carcinomas and sebaceous, eccrine or apocrine carcinomas, are rare and therefore any treatment approach needs to be individualized (Ch. 111). Many of these tumors are aggressive in nature, with a propensity to develop regional and distant metastases. While patients with operable cancers should have them excised with appropriate margins, inoperable lesions may respond to radiotherapy[55]. Adjuvant radiotherapy may also be recommended in the setting of incomplete excision. Doses similar to those for equivalent non-melanoma skin cancers should be administered (see Table 139.2).

PALLIATION

Locally Advanced Tumors

Occasionally, elderly, debilitated or mentally ill patients present with advanced and neglected skin cancers, which, though not curable, can be palliated. Such tumors are often painful, bleeding and infected, causing problems for both the patient and the caregiver. With the addition of a bolus (see Fig. 139.2), single large fractions of 12–20 Gy can be given quickly (within minutes) using megavoltage photons. Uncooperative patients may require mild sedation prior to treatment. These large single fractions are well tolerated with minimal toxicity. Alternative regimens include multiple medium-sized fractions given once or twice a week (e.g. 8 Gy × 3). In elderly patients who are otherwise well, higher total dose fractionation schedules such as 35 Gy in 5–7 fractions or 40 Gy in 10 fractions (Fig. 139.9) may be more appropriate and can be considered more radical in intent. These are often given as two or three fractions per week.

Metastases

Dermal-based metastases occur most frequently in patients with lung and breast cancer, and, in general, are associated with a poor prognosis (see Ch. 122). Both in-transit metastases and distant dermal metastases can develop in patients with cutaneous SCC, Merkel cell carcinoma, and melanoma. Cutaneous metastases may also present as rapidly enlarging subcutaneous masses with intact overlying skin.

Ulceration and bleeding are complications of cutaneous metastases that do respond to palliative radiotherapy. Orthovoltage photons or megavoltage photons (with a bolus) administered as a single 8 Gy fraction or as 20 Gy in five fractions are effective regimens. Metastatic

Fig. 139.9 Metastatic squamous cell carcinoma involving the parotid lymph nodes. A An 85-year-old man with advanced and inoperable SCC of his right parotid lymph nodes. **B** Following a 2-week course of palliative radiotherapy (40 Gy in 10 daily fractions using 12 MeV electrons plus a tissue equivalent bolus), he experienced a complete clinical response.

deposits elsewhere (e.g. skeletal) are also palliated with a similar dose fractionation schedule.

REACTIONS AND COMPLICATIONS

Acute Reactions

Acute morbidity from skin-directed radiotherapy is usually minimal (in-field cutaneous erythema and desquamation) and limited to a small area (Table 139.3). Systemic side effects such as fatigue, nausea and vomiting do not occur. The daily application of a bland emollient, aloe vera or vitamin E cream is recommended while receiving radiotherapy. Most patients can expect to have local discomfort and moist desquamation by the conclusion of the radiation therapy (Fig. 139.10), which then lasts for a few weeks. Hemorrhagic crusting can also develop and re-epithelization usually occurs by week 3 or 4 following completion of radiotherapy. During the healing phase, patients are advised to keep the irradiated tissue clean and dry (after washing). Delayed healing (beyond 6–8 weeks) is uncommon, as is associated soft tissue infection.

Late Reactions

The late effects of radiotherapy (e.g. telangiectasia, epidermal atrophy, dyspigmentation; see Table 139.3 & Fig. 139.10) often appear months to years later. They are more likely to appear with continued unprotected sun exposure, when a large dose per fraction (>3–4 Gy) was delivered, if the total dose was >55 Gy, and when large fields were irradiated. Chronic non-healing, radiation-induced ulcers represent poorly vascularized tissue that requires the importation of well-vascularized tissue to enable healing. The latter usually consists of local skin flaps or sometimes staged skin–muscle or axial pedicle flaps of non-irradiated tissue; grafts do not take well on irradiated tissue due to the poor vascular bed.

In a review of over 400 patients treated with radiotherapy, 92% were considered to have a good or excellent cosmetic result[1]. However, 36% of those receiving >60 Gy in ≤2 Gy fractions had only a fair (16%) or poor (20%) cosmetic result. Smaller treatment fields (2–3 cm) tolerate hypofractionation better than do larger areas, but, even so, if cosmesis is an important consideration, larger fractions should be avoided. Patients should also be warned of the small risk (<5%) of late soft tissue and cartilage necrosis, which are related to larger tumor size and larger doses per fraction.

RADIOTHERAPY REACTIONS AND COMPLICATIONS	
	Reaction or complication
Acute	Dry desquamation, moderate erythema Moist desquamation and mild bleeding
Late*	Hypo- or hyperpigmentation† Telangiectasia† Epidermal atrophy† and fragility Permanent epilation/alopecia, sweat gland atrophy Necrosis of soft tissue, cartilage and/or bone Subdermal fibrosis Radiation-induced malignancy‡ – SCC, BCC, angiosarcoma; malignant fibrous histiocytoma

*Many late effects are uncommon.
†Components of poikiloderma; a *TP53* haplotype containing two variant alleles was associated with almost a twofold increase in risk for telangiectasia. Variants in the *TP53* gene may therefore modify the risk of late skin toxicity after radiotherapy.
‡Many reports have been in patients whose dose fractionation schedules and techniques are now historical in nature.

Table 139.3 Radiotherapy reactions and complications. BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

DISEASES INDUCED BY RADIATION THERAPY
DISEASE NOT CONFINED TO THE SITES OF IRRADIATION
• Erythema multiforme • Bullous pemphigoid • Pemphigus foliaceus, pemphigus vulgaris • Brunsting–Perry mucous membrane (cicatricial) pemphigoid • Paraneoplastic pemphigus • Herpes zoster
DISEASE LIMITED TO SITES OF IRRADIATION
• Bullous pemphigoid • Erythema multiforme • Comedonal acne, folliculitis • Graft-versus-host disease • Lichen planus • Lichen sclerosus • Morphea (localized scleroderma) • Pseudosclerodermatous panniculitis • Urticaria pigmentosa • Digitate keratoses (also referred to as postirradiation minute digitate hyperkeratosis)
LESIONS THAT SPARE IRRADIATION SITES
• Exanthematous drug eruption

Table 139.4 Diseases induced by radiation therapy. Neoplasms are listed in Table 139.3.

Younger Patients

When irradiating younger patients, better long-term cosmetic results are more likely if a low dose per fraction (2 Gy/fraction) is administered. A typical dose for a small BCC would be 50–54 Gy delivered in 25–27 daily fractions[56]. However, even with this dose fractionation schedule, patients can still expect some degree of in-field hypopigmentation and telangiectasia; the latter can be addressed via pulsed dye laser treatment. Other options, therefore, should be considered prior to recommending radiotherapy to younger patients. The risk of a radiotherapy-induced in-field malignancy arising decades after high-dose therapeutic skin-directed radiotherapy is rare and poorly documented in the literature (see Table 139.3).

Cutaneous Diseases Induced by Radiation Therapy

Table 139.4 outlines the cutaneous disorders that are induced by radiotherapy, with some occurring outside the field of radiation[57] and others limited to the site of irradiation.

Fig. 139.10 Acute and chronic cutaneous side effects of radiation therapy. A Confluent moist desquamation and marked edema in a patient near completion of radiation therapy for a squamous cell carcinoma with neurotropism. **B** Stevens–Johnson syndrome localized to multiple radiation ports in a patient receiving phenobarbital. **C** Dry desquamation and erythema of the neck 10 days following radiation therapy for a pharyngeal Hodgkin lymphoma. **D** In-field telangiectasias; note the square distribution pattern. **E** In-field hypo- and hyperpigmentation 10 years after radiotherapy for a basal cell carcinoma. **F** In-field poikiloderma, fibrosis and ulceration; nowadays, this is seen much less often. **G** Spindle cell carcinoma within a radiation port. FUTURE TRENDS

Modern radiotherapy has entered a new and exciting era. Accurate conformal radiotherapy is being delivered via sophisticated three-dimensional CT-based planning and treatment systems. Intensity-modulated radiotherapy (IMRT) is allowing tumor doses to escalate and normal tissue doses to decrease. The integration of MRI and functional imaging such as positron emission tomography (PET) into planning systems will further enhance the accurate delivery of radiotherapy.

Synonym ■ Radiosurgery

Key features

- Electrosurgery encompasses a group of procedures by which tissue is removed or destroyed through the application of electrical energy
- True electrocautery uses direct current to create a red-hot tip, which can be safer for patients with pacemakers and implantable cardioverter-defibrillators
- In modern electrosurgery, high-frequency alternating current is converted to heat within the treated tissues as a result of resistance to its passage
- Electrodesiccation is superficial ablation by touching the tissue with a monoterminal device
- Electrofulguration is superficial ablation by use of a monoterminal device whose electrode is held at a slight distance from the tissue, allowing a spark to jump to the tissue
- Electrocoagulation uses a biterminal device for deeper coagulation
- Electrosection uses a biterminal device to cut while achieving hemostasis by mild lateral heat spread
- In order to minimize adverse sequelae, lateral heat spread should be kept to a minimum by using the appropriate waveform, power setting and electrode size

INTRODUCTION AND BACKGROUND

Definition

Modern electrosurgery is a group of techniques by which high-frequency alternating electrical current is applied to living tissues in order to achieve superficial coagulation, deep coagulation, or cutting of the skin. Since living tissue is a poor conductor of electricity, the flow of electrical current is hampered and builds up at the site of application. This resistance to the flow of electricity results in its conversion to heat. The use of different varieties of electrosurgical current, each characterized by a distinctive waveform, results in unique biologic outcomes, including desiccation, coagulation or section of treated skin.

Electrocautery

The forerunner of modern electrosurgery was electrocautery (from Greek *kauterion*, branding iron)[1]. In electrocautery, invented in 1875, a metal wire is heated by resistance to the flow of direct current electricity, as in an electric toaster. Hemostasis (even in a wet field) can be obtained with electrocautery, but the resulting third-degree burn may result in prolonged healing times and may cause inferior cosmetic outcomes.

Of note, electrocautery, with its hot element (Fig. 140.1), is different from modern electrosurgery, in which high-frequency alternating current is applied via an unheated electrode. Electrocautery units are of value for providing hemostasis for surgical patients with pacemakers and implantable cardioverter-defibrillators (ICDs), because external electromagnetic fields may compromise the function of these devices. A number of electrocautery units are currently produced; among them is the Thermal Cautery Unit (Geiger Medical Technologies Inc.).

Historical Aspects

Although used by most dermatologists on a daily basis, high-frequency electrosurgery (often referred to as "radiosurgery") could not have been developed if several major advances in the knowledge of electricity had not occurred. In order for alternating current electricity to be utilized for medical purposes, it was necessary for high-frequency currents to be produced. A generator that could provide such current was developed in 1889 by Thompson, who noted heat in his wrists when current was passed through his hands when immersed in saline solution[2]. Experiments conducted by Jacques Arsene d'Arsonval in 1891 established that the application, in human subjects, of electric currents with frequencies greater than 10 000 cycles per second (10 KHz) failed to cause neuromuscular stimulation and the associated tetanic response[3,4]. Also in the 1890s, Oudin, following some modifications to d'Arsonval's equipment, was able to generate a spray of sparks that caused superficial tissue destruction.

At the turn of the twentieth century, Rivière conceived the notion of using very small treatment electrodes in order to concentrate the current density. This would enable one to treat a skin lesion with an electric spark[5]. Walter de Keating-Hart and Pozzi[6] in 1907 introduced the term "fulguration" (from Latin *fulgur*, lightning), referring to the superficial carbonization that resulted when the spark from the Oudin coil was used to treat skin. They claimed that this modality was ideal for treating skin cancer and that the spark could selectively destroy tumor cells by interfering with their source of nutrition.

In 1909, Doyen[7] introduced the term "electrocoagulation" (from Latin *coagulare*, to curdle) to describe a different form of electrosurgery in which tissue was touched directly with the treatment electrode and an indifferent electrode was added to the circuit. The indifferent electrode allowed for direct removal of the electricity entering the patient and caused the latter to flow back into the electrosurgical device. By removing this static energy build-up, shocks were avoided in surgeons and other bystanders. The amperage was effectively increased while the "recycling" of electrical current allowed for lower voltages to be utilized. The current produced with this biterminal arrangement penetrated more deeply than fulguration and directly coagulated tissues rather than causing only surface carbonization. Doyen claimed that this more deeply penetrating current was more likely to be effective in the destruction of tumor cells.

William Clark, in 1911, reported on the use of an electrosurgical output that caused dehydration of tissue without carbonization at the surface[8]. He substituted a multiple spark gap for the usual single one in a monoterminal Oudin current generator. This provided a smoother current that resulted in the production of fine sparks as opposed to the

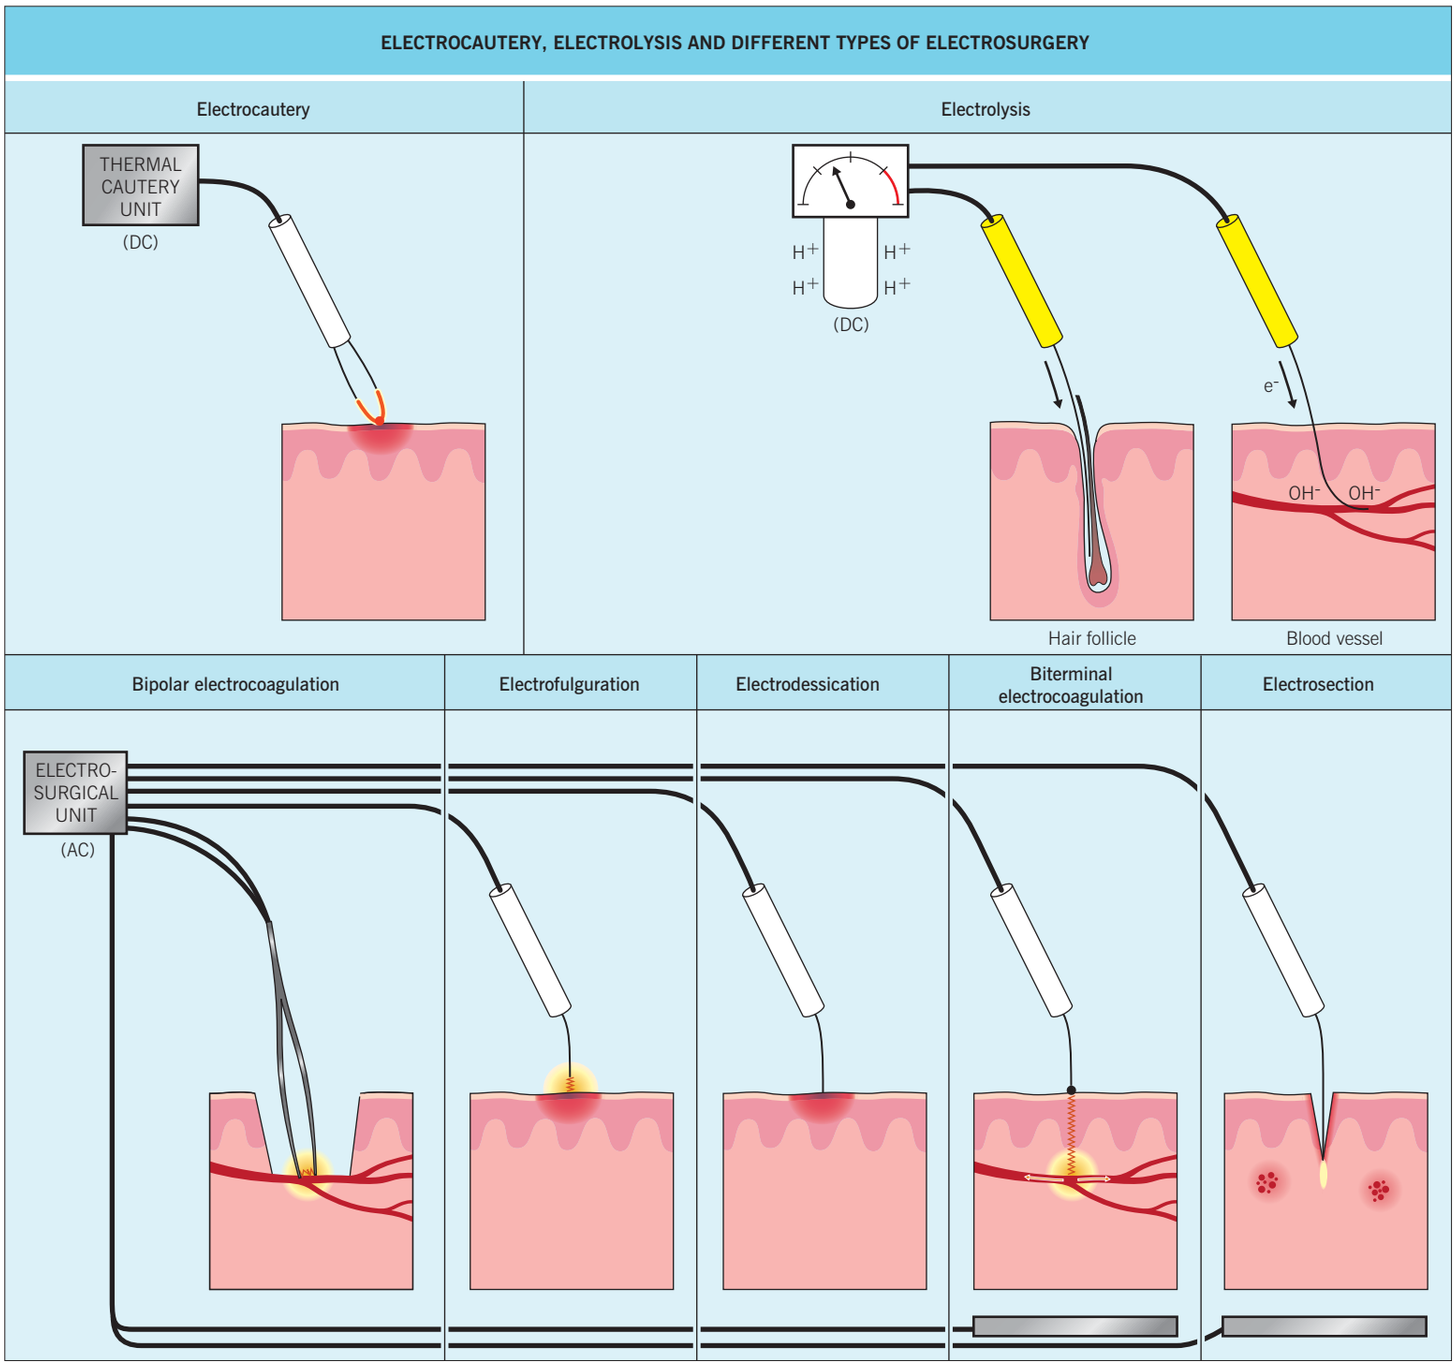

Fig. 140.1 Electrocautery, electrolysis and different types of electrosurgery. AC, alternating current; DC, direct current; e^-, electron; H^+, proton; OH^-, hydroxide ion.

long, thick sparks seen with electrofulguration. Clark used the term "desiccation" (from Latin *desiccare*, to dry out) to describe this action.

The next major event in the development of electrosurgery came in 1923 when Dr George A Wyeth, a noted tumor surgeon, used electrosurgery for cutting tissues[9]. His apparatus, which he termed an "endotherm knife" (Greek *endo*, within; *thermē*, heat), used a thermionic vacuum tube instead of a spark gap[10]. Wyeth called the technique "electrothermic endothermy". He believed that the technique was particularly applicable to tumor surgery since it sealed off not only the smaller blood vessels but also the lymphatics that might otherwise provide for dissemination of metastatic disease.

A Harvard physicist, William Bovie PhD, probably made the most important contribution to the development of electrosurgery. With financial assistance from the Liebel-Flarsheim Company of Cincinnati, he built an operating room electrosurgical device that offered both coagulation and cutting currents[11]. Dr Harvey Cushing, a distinguished neurosurgeon, became quite interested in these techniques and, with Bovie at the controls, began using electrosurgery for controlling bleeding and cutting through tissues during surgical procedures at Peter Bent Brigham Hospital in 1926. Dr Cushing's favorable impressions of electrosurgery assured acceptance of this technique by the surgical world. The subsequent impact of Bovie's machine upon medicine was so great that the word "bovie" is still often used generically as a noun to refer to an electrosurgical apparatus or even as a verb to describe the act of performing electrosurgery[12].

Electrosurgical Devices and Outputs

The circuitries of all electrosurgical instruments share certain design features necessary for production of suitable electrical outputs for electrosurgery. Standard household current first passes through a transformer which alters the voltage, providing the levels and characteristics required for the instrument's various circuit functions. The current

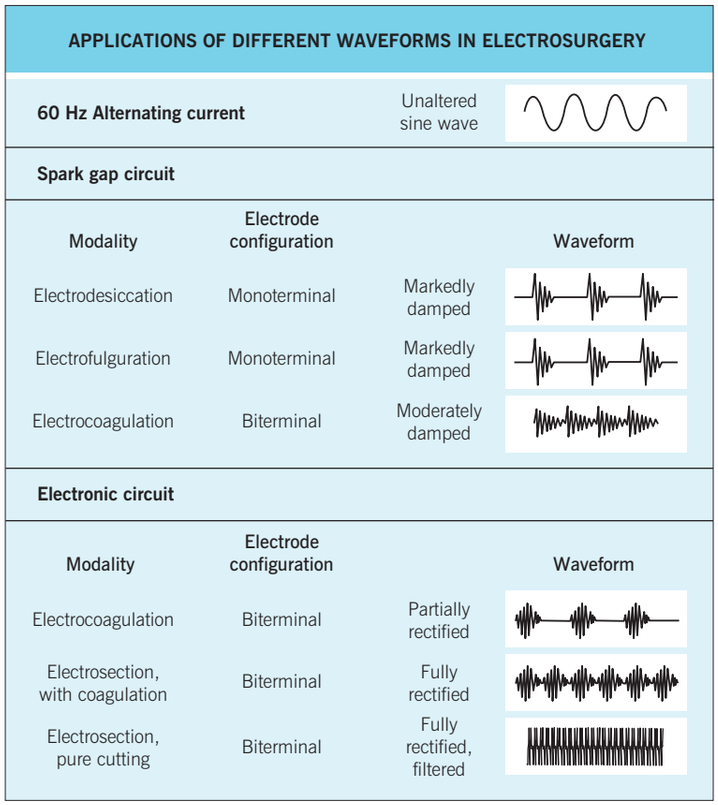

Fig. 140.2 Applications of different waveforms in electrosurgery.

next travels through an oscillating circuit that may employ a spark gap, a thermionic vacuum tube, or solid state transistors to increase electrical frequency. Finally, this altered electrical energy is delivered to the treatment electrode.

Each electrosurgical current produces its own unique wavy pattern of current flow, or *waveform*. The latter may be either *damped* or *undamped*, depending on the type of oscillating circuit used. In general, damped waveforms provide electrodesiccation and electrofulguration, whereas the application of moderately damped and undamped currents results in electrocoagulation and cutting currents, respectively (Fig. 140.2). The spark gap generator produces a damped wave, consisting of bursts of energy in which successive wave amplitudes gradually return to zero. This occurs due to the resistance to energy flow presented by the gap.

Use of a thermionic tube results in a more uniform output. The valve tube circuit is able to neutralize the internal resistance responsible for the damping effect seen in the spark gap circuit, and the amplitude of output therefore remains unchanged. Depending on the circuitry used, the output can be moderately damped (partially rectified) or slightly damped (fully rectified). A filtered, fully rectified output is essentially continuous and uniform, similar to an undamped wave. The different types of waveforms each result in different biologic outcomes and are, therefore, used for different electrosurgical procedures.

Terminology: Monopolar, Bipolar, Monoterminal and Biterminal

The terms *monopolar* and *bipolar* denote the number of tissue contacting tips at the end of the surgical electrode. When the surgical electrode has only one tip projecting from its end, it is a monopolar electrode. If it has two tips, it is a bipolar electrode. Therefore, an electrosurgical forceps (that plugs into two ports on the electrosurgical device) is considered to be bipolar, as opposed to a pointed electrode, which is monopolar (and plugs into one port on the device).

Monoterminal refers to the use of a treatment electrode without an indifferent or dispersive electrode ("ground plate"). *Biterminal* denotes that both treatment and indifferent electrodes are used (see Fig. 140.1). Such is the case with electrocoagulation and electrosection, in which use of the indifferent plate, although not *technically* necessary for the machine to work, will definitely enhance the efficiency of the electrosurgical apparatus. In biterminal electrosurgical applications, there is "recycling" of the energy that comes out of the treatment electrode, passes through the patient and is then removed from the patient via the indifferent electrode. Electrodesiccation and its variant, electrofulguration, are monoterminal procedures in which the indifferent electrode serves no purpose and, in most instances, is not even connected to the patient.

A simple way to visualize this is to think of the wires coming out of the machine as terminals. If only one wire (the handpiece for the electrode) is attached to the machine, then the application is monoterminal in nature. If, in addition, a "ground plate" is used, requiring a second wire to be attached to the machine, then the procedure is biterminal (see Fig. 140.6).

When a ball electrode is used to electrocoagulate a bleeding vessel, one is using biterminal, monopolar electrosurgery. In the case of bipolar forceps in which the electrode is connected to both the active and the dispersive electrode termini, we are using a biterminal, bipolar modality.

INDICATIONS/CONTRAINDICATIONS

The simplest way to think of electrosurgical applications in the clinical setting is to consider the three major capabilities of electrosurgery units. These include superficial tissue destruction (electrodesiccation), deep tissue destruction (electrocoagulation) and cutting (electrosection)[13,14]. Destruction or excision of skin lesions by electrosurgery should be accomplished with the smallest possible amount of damage to normal tissues. Whether electrosurgery, cryosurgery or CO_2 laser surgery is used, the greater the penetration of the destructive modality into the skin, the greater the likelihood that unacceptable scarring will result. Because the destructive effects of electrocoagulation extend more deeply than those of electrodesiccation, the clinician must consider the histologic characteristics of the lesion to be treated when selecting the appropriate current. A partial list of dermatologic conditions that are commonly treated by each electrosurgical modality is found in Table 140.1.

There are no absolute contraindications to the use of electrosurgery, but precautions should be taken during the treatment of patients with pacemakers or ICDs (see Variations/unusual situations, below).

PREOPERATIVE HISTORY AND CONSIDERATIONS

The preoperative assessment of patients undergoing electrosurgery should concentrate on potential hazards to either the patient or the treatment team. A patient history of previous allergic reactions to skin cleansers, anesthetics, or postoperative topicals and dressings should be sought. Electrosurgery should be used with care in patients with cardiac pacemakers and ICDs.

Smoke evacuation equipment should always be available to safely remove the smoke plume when extensive electrosurgery, particularly electrosection, is performed. In such procedures, the operator and assistants should wear masks and use eye protection to prevent exposure to smoke-borne microbes. Gloves should always be worn when electrosurgical procedures are performed.

Preparatory to electrosurgery, the lesion and surrounding skin should be cleansed with a non-alcoholic skin cleanser such as chlorhexidine or povidone iodine. There is a potential for alcohol to ignite with electrosurgery, so it should be avoided or allowed to thoroughly dry prior to therapy.

Local anesthesia, usually via 1% lidocaine with epinephrine (adrenaline), is almost always used when performing electrosurgery. The usual exception is in the treatment of small facial telangiectasias, in which anesthesia is omitted. Local infiltration is most often used for anesthetizing localized surface lesions, whereas field blocks and/or nerve blocks should be considered when performing larger electrosurgical procedures such as rhinophyma repair. When a local anesthetic is used prior to treatment of a dome-shaped lesion, such as a large angioma, it is helpful to massage the swollen anesthetized treatment site prior to electrosurgery, in order to flatten it. This prevents the development of a depressed scar subsequent to the procedure.

Prior to activating the electrosurgery unit, the operator should determine that the appropriate current and power settings for the particular

COMMON DERMATOLOGIC INDICATIONS FOR ELECTROSURGERY
ELECTROFULGURATION/ELECTRODESICCATION (SUPERFICIAL SKIN ABLATION)
Acrochordon
Actinic keratosis
Angioma (small)
Epidermal nevus
Hemostasis (capillary bleeding)
Lentigo
Seborrheic keratosis
Verruca plana
ELECTROCOAGULATION (DEEP SKIN ABLATION)
Angiofibroma
Angioma (large)
Basal cell carcinoma
Bowen's disease
Hemostasis (arterial bleeding)
Hirsutism (electroepilation)
Ingrown toenail matrixectomy
Banal melanocytic nevi
Sebaceous hyperplasia
Squamous cell carcinoma
Syringoma
Telangiectasia
Trichoepithelioma
Verruca vulgaris (all locations)
ELECTROSECTION (SKIN INCISION/EXCISION)
Acne keloidalis nuchae
Blepharoplasty incision
Debulking procedures
Hair transplant strip harvesting
Rhinophyma repair
Rhytidectomy incisions and undermining
Scar revision
Shave removal of benign skin lesions (fibromas, nevi, etc.)
Skin flap incisions and undermining
Skin resurfacing
Surgical excision of malignant or benign skin lesions

Table 140.1 Common dermatologic indications for electrosurgery.

procedure have been selected, that the dispersive electrode has been properly placed and that the correct treatment electrode has been chosen. Sterile sleeves that slip over the handle of the wand and disposable electrode tips are often utilized. It is unacceptable to use the same electrode tip on multiple patients without sterilization, erroneously assuming that heat will destroy pathogens.

DESCRIPTION OF TECHNIQUES

Electrodesiccation and Electrofulguration

For very superficial lesions, such as those involving only the epidermis, electrosurgical destruction by *electrodesiccation* can be achieved with little, if any, scarring. The markedly damped, high-voltage current generated by spark gap electrosurgical units causes superficial tissue damage by dehydration of the treatment site. It is delivered in a monoterminal (concentrative) fashion (see Fig. 140.1). If the electrode is held at a slight distance from the tissue, a spark is formed between the electrode and the tissue. This technique, termed *electrofulguration*, achieves very superficial destruction because the surface carbonization it produces insulates the underlying tissues from thermal heat spread.

Dermatologists who employ a Hyfrecator® or similar device often utilize this type of waveform. As the surface becomes charred by sparking at the surface, it is common for blood to appear in droplets that penetrate through the surface char. This is because the electrical current does not penetrate deeply enough to seal nearby blood vessels. Therefore, when surgical excision is undertaken, electrocoagulation is a better current to employ in order to provide hemostasis (see below). However, for treatment of very superficial epidermal lesions, electrofulguration should be considered the waveform of choice.

Electrodesiccation is the method of choice when the most superficial type of tissue destruction is desired. For example, it is ideal for treatment of epidermal lesions such as seborrheic or actinic keratoses (Fig. 140.3), acrochordons, verrucae planae or small epidermal nevi. Hemostasis of mild capillary bleeding can also be achieved by use of electrodesiccation. A standard technique for treating keratoses by this method is to move the electrode slowly across the surface of the lesion (for small lesions) or to insert it directly into the lesion (for larger lesions), while applying current at a low power setting. After a few seconds, the lesion bubbles as the epidermis separates from the underlying dermis. It can then be easily removed with a curette or simply by rubbing a piece of gauze across the treatment site. The clinical endpoint in treating epidermal lesions is punctate bleeding, which is controlled with pressure, by spot electrocoagulation, or by topical hemostatic agents such as aluminum chloride. More profuse bleeding indicates probable damage to the dermis, with a greater likelihood of subsequent scarring. Extremely small superficial lesions can be treated by electrofulguration, which causes the least amount of damage to adjacent tissues.

Electrocoagulation

In electrocoagulation, a moderately damped current is applied in a *biterminal* manner (both concentrative and dispersive electrodes are used). This current is of higher amperage and lower voltage than that utilized for electrodesiccation. Because this type of current penetrates more deeply, it has the potential for greater tissue destruction.

Electrocoagulation is particularly useful for deep tissue destruction and surgical hemostasis. It is our preferred modality for treating small and uncomplicated primary basal cell and squamous cell carcinomas, as well as other lesions such as trichoepitheliomas, which extend into the dermis. Much of the literature refers to "curettage and electrodesiccation (C&E)" or "electrodessication and curettage (ED&C)", but, in fact, electrocoagulation may be the preferred electrosurgical waveform for all but the most superficial tissue destruction.

When performed properly, electrosurgery plus curettage yields cure rates of 90–95% for uncomplicated basal cell carcinomas and superficial squamous cell carcinomas, making it an efficient, cost-effective treatment. Thorough curettage is likely the key element affecting success. Initially, a large curette (4–6 mm) is used to debulk the tumor, followed by a smaller curette (2 mm). The curette should be scraped across the surface of the treatment site in every direction, from superior to inferior, inferior to superior, left to right and right to left, using fairly firm downward pressure. In this way, all tumor extensions are eradicated.

After thorough curettage, the electrode is brought into direct contact with the tissue to be treated and is moved slowly around the periphery and across the curetted portion of the lesion, which eventually becomes charred. A curette may then be used to gently remove the charred tissue. For treatment of skin cancers, this procedure is repeated two or more times in an attempt to remove any small tumor extensions (Fig. 140.4). During the last curettage, a very small curette (1 mm) may be used to remove the final tiny "roots" of the tumor. Scarring must be expected with this procedure, and wounds following curettage and electrosurgery are allowed to heal by second intention.

Electrocoagulation is also effective for treatment of superficial telangiectasias (Fig. 140.5), unwanted hair (electroepilation) and ingrown toenails (electrosurgical matrixectomy). Hemostasis using electrocoagulation can be achieved by either monopolar or bipolar means. Because the electrosurgical energy may be transmitted for several millimeters along the vessel wall, it is important to use the minimum effective exposure time and power setting in order to prevent delayed bleeding from damaged vessels. We often use monopolar electrocoagulation, in which the electrode is touched directly to the bleeding vessel. Coagulation can also be achieved by touching the electrode to a hemostat that has been clamped on the severed vessel. In bipolar electrocoagulation (Fig. 140.6), a bipolar forceps is used to provide more directed pinpoint hemostasis. Electrocoagulation current delivered in this manner causes less adjacent tissue damage but requires a dry operative field to be effective.

Electrosection (cutting)

Electrosection involves the biterminal application of a slightly damped current. The current, of low voltage and high amperage, causes minimal lateral heat spread and tissue damage, and has the additional advantage

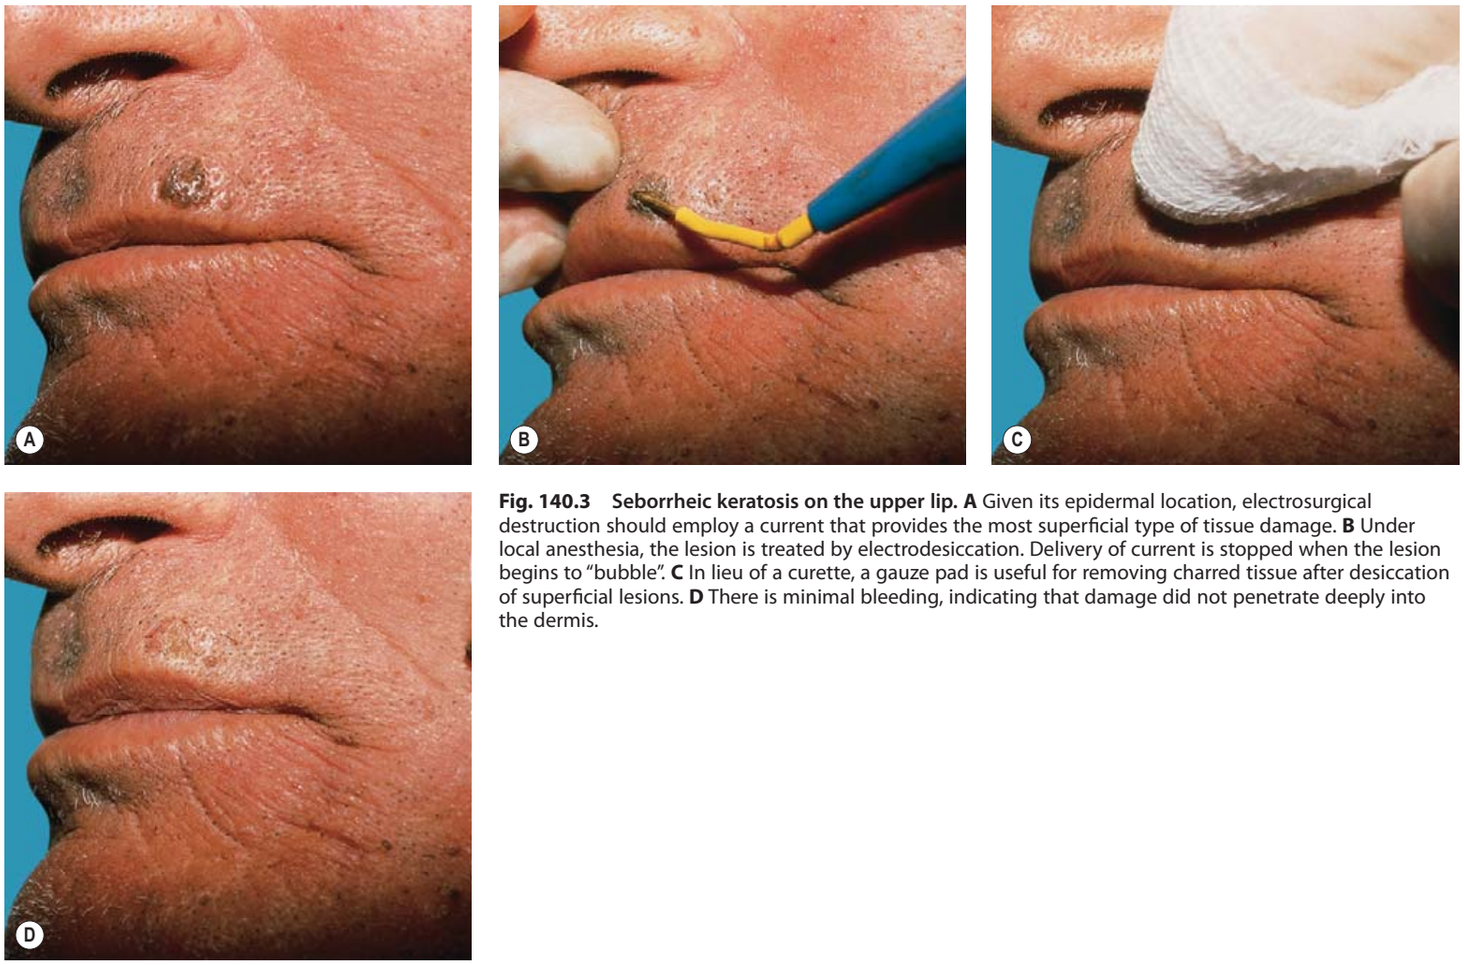

Fig. 140.3 Seborrheic keratosis on the upper lip. A Given its epidermal location, electrosurgical destruction should employ a current that provides the most superficial type of tissue damage. **B** Under local anesthesia, the lesion is treated by electrodesiccation. Delivery of current is stopped when the lesion begins to "bubble". **C** In lieu of a curette, a gauze pad is useful for removing charred tissue after desiccation of superficial lesions. **D** There is minimal bleeding, indicating that damage did not penetrate deeply into the dermis.

Fig. 140.4 Basal cell carcinoma on the right deltoid area, treated by curettage and electrosurgery. A Nodular basal cell carcinoma preoperatively after injection of local anesthesia. **B** The tumor is curetted to debulk all friable tissue. **C** Further curettage, often with a smaller-diameter curette, should proceed in all directions to remove small extensions of tumor. **D** Following thorough curettage, the surface and periphery of the wound are treated by electrocoagulation current to stop bleeding and potentially remove further tumor. **E** Final wound – curettage and electrosurgery have been repeated twice more, until all friable tissue has been removed. Healing occurs over 4–6 weeks, depending upon the site.

Fig. 140.5 Telangiectasias on nose and upper lip being treated by fine-needle electrocoagulation. A Preoperative photograph shows linear telangiectasias on the nose and upper lip. **B** The electrode consists of a hub adapter with a 30-gauge metal-hubbed needle attached. The machine is energized at a low power setting and the electrode momentarily touches the skin surface, along the length of the vessel being treated, at 3 to 4 mm intervals. The patient experiences some discomfort during the procedure, but this is usually tolerable. **C** The same patient immediately after treatment. This technique is usually performed quickly without anesthesia.

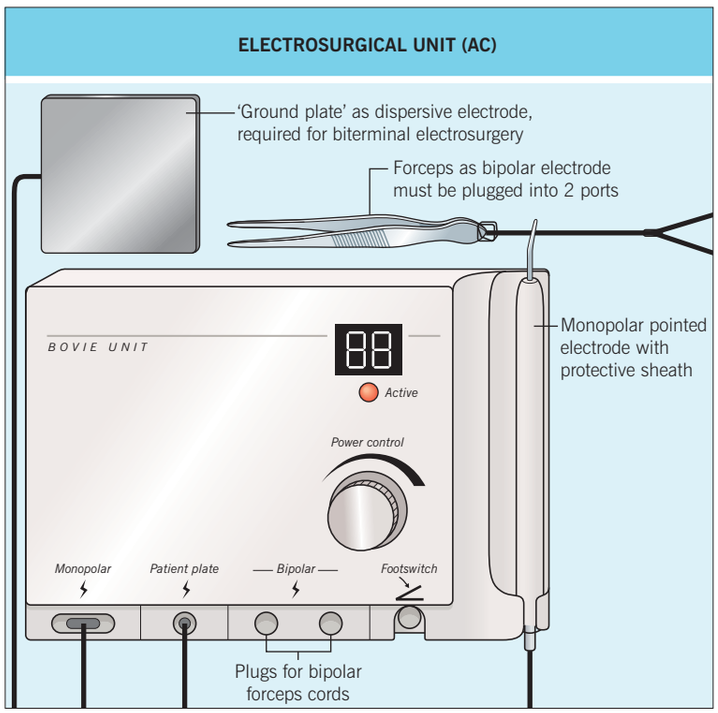

Fig. 140.6 Electrosurgical unit (AC) with attached electrosurgery pencil. The monopolar pencil is used for electrodesiccation and electrofulguration. When used with the grounding plate, it is utilized in a biterminal mode for electrocoagulation. Alternatively, the unit can be used with the bipolar forceps to provide pinpoint electrocoagulation for hemostasis. Bipolar electrocoagulation is also recommended for use in patients with cardiac pacemakers.

of simultaneously achieving hemostasis and cutting. "Pure" cutting can be obtained using a true undamped tube current, which provides the least amount of lateral heat spread and causes vaporization of tissue without hemostasis. Such current has been suggested by Chiarello[15] to be useful in debulking large skin cancers, contouring surrounding skin following shave excisions, scar revision following skin flaps and grafts, and rhinophyma repair. When electrosection is performed using a filtered, fully rectified current, subsequent spot electrocoagulation can be achieved by changing to the electrocoagulation current.

Electrosection can be used to perform rapid and effortless excisions or incisions. Virtually no manual pressure by the operator is required. Electrodes configured as loops, triangles or diamonds can be used for quick removal of skin tags, papillomas, intradermal nevi and other exophytic skin lesions. A straight, narrow electrode is most often used to incise the skin and is applied to the tissue in brisk, continuous paintbrush-like strokes. The difference between electrosection and scalpel excision is immediately apparent to the first-time user of electrosection. At the appropriate power setting, the electrode passes smoothly through the tissue like a "hot knife through butter". If perceptible sparking occurs during incision, the power setting is too high; if the electrode "drags", the power setting is too low.

Slightly damped currents cause some charring at the margins of the excised tissue. Therefore, when a specimen suitable for histopathologic analysis is required, the filtered current (see Fig. 140.2) should be used because it does not create significant electrosurgical artifact. It is recommended that the new initiate to electrosection develop technical skills and concepts by practicing on beefsteak before utilizing these techniques in the clinical arena.

The major advantage of electrosection over scalpel surgery is that when a blended cutting and coagulating current is utilized, hemostasis is achieved immediately as the incision is made. However, larger blood vessels (>2 mm) require additional spot electrocoagulation at the completion of the excision. Another drawback is that vaporization of the tissue generates a smoke plume, which can be unpleasant for both the patient and the operator and may contain potentially infectious viral particles (see below). Consequently, effective smoke evacuation equipment should be available during such procedures.

Electrosection is extremely useful for achieving relatively bloodless excision of large, bulky lesions, such as acne keloidalis nuchae and rhinophyma (Fig. 140.7), in which the surgical defect is allowed to heal by second intention. Electrosurgical excision followed by primary closure can also be undertaken with no impairment of wound healing, as compared with conventional scalpel surgery. This modality has been used, without complication, to create skin flaps and perform cosmetic facial surgery, including blepharoplasty and rhytidectomy, with excellent outcomes.

VARIATIONS/UNUSUAL SITUATIONS

Cardiac Pacemakers and ICDs

The use of electrosurgery in patients with cardiac pacemakers or ICDs raises the question of whether the flow of electrical energy during electrosurgery might interfere with the function of these devices[16]. Although modern pacemakers and ICDs have improved shielding technology to guard them from the influence of external electromagnetic currents, prudence requires that a modicum of precaution be taken. If used indiscriminately in these patients, electrosurgery can occasionally

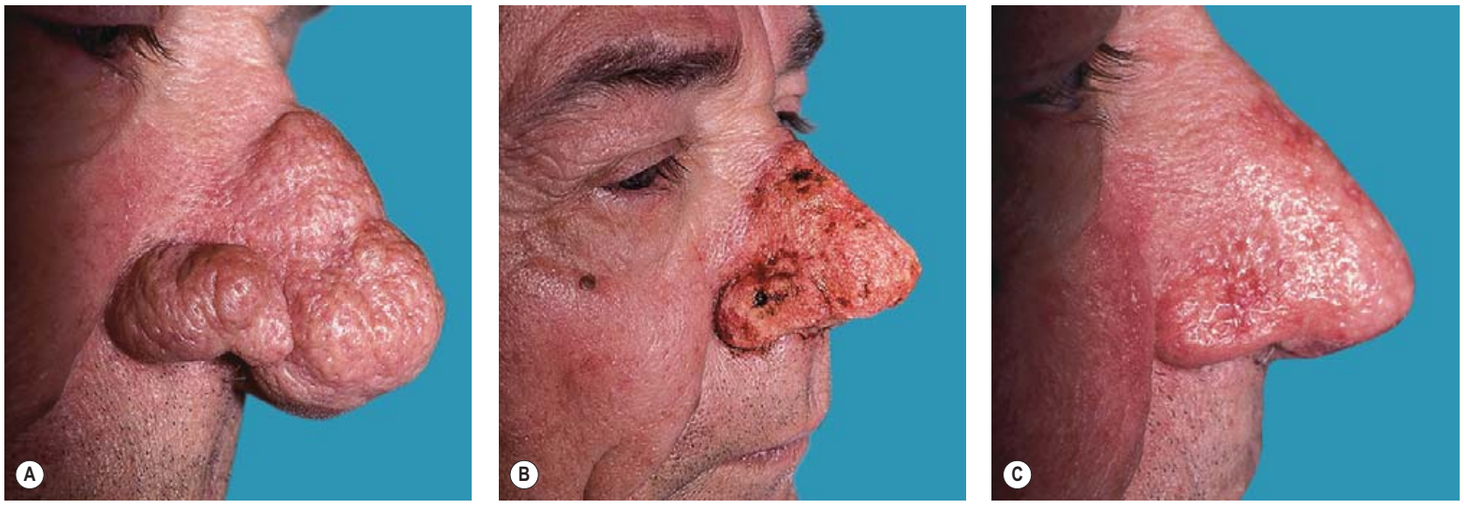

Fig. 140.7 Rhinophyma. A Moderately severe rhinophyma in a middle-aged man. **B** Immediately after electrosurgical planing of excess sebaceous glands. Care is taken to perform subtotal removal as very aggressive therapy can result in significant scarring and possible deformity caused by scar contracture. **C** Four weeks later, healing with good cosmetic outcome is noted. During healing, the wound is kept moist with an antibiotic ointment and semi-occlusive dressings.

trigger skipped beats, reprogramming of a pacemaker, firing of an ICD, asystole or bradycardia.

Routine precautions recommended when using electrosurgery in patients with pacemakers and ICDs include: (1) utilize short bursts of energy that are less than 5 seconds in duration; (2) keep power settings as low as possible; (3) avoid the use of cutting current; and (4) avoid use on the skin around the pacemaker or ICD. Although recommended in the literature, most dermatologists do not follow specific precautions such as intraoperative monitoring, preoperative cardiology consultation, or postoperative evaluation of the cardiac device by a cardiologist. This may be due to the fact that to date there have been no reported cases of interference with a pacemaker or ICD in a dermatologic setting. Also, at least one article suggests that practical experience of complications due to electrosurgical interference is rare among dermatologic surgeons[17].

There is less risk of potential side effects when the electrosurgical current is confined to a very small area, as is the case when bipolar forceps are used as electrodes. A way to virtually eliminate such risk in very unstable cardiac patients or those with ICDs is to use true electrocautery, rather than other forms of electrosurgery[18]. Although the use of this modality may cause more of a burn injury than does true electrosurgery, there is no flow of current to cause electrical interference. In a survey of Mohs surgeons, 34% used electrocautery and 19% used bipolar forceps in patients with pacemakers or ICDs. Among this group, there was only one reported case of interference in one of the electrocautery patients. However, since there is no current flow in true electrocautery, this was likely an error in reporting.

It is the author's belief that the use of either electrocautery or bipolar forceps as electrodes in pacemaker and ICD patients will eliminate the need for intraoperative monitoring, preoperative cardiology consultation or postoperative evaluation by a cardiologist in the majority of patients.

POSTOPERATIVE CARE

Standard postoperative wound management, incorporating antibiotic ointments and/or semi-occlusive dressings, is followed. For superficial skin ablations, such as those following electrodesiccation or electrofulguration, twice-daily application of an antibiotic ointment or petrolatum is generally all that is required. An adhesive plaster may be used if the area is prone to rubbing. An eschar forms within a few days and separates in about 10 days. For deeper wounds, in which healing can take 2–4 weeks (or longer on the lower extremities), once- or twice-daily application of an antibiotic ointment followed by an adhesive plaster is recommended. For larger wounds, such as those following rhinophyma repair, Telfa™ sheets are cut to size to cover the defect and kept in place with semi-occlusive paper tape (e.g. Micropore®, 3M Corporation, MN).

COMPLICATIONS

Patients should be warned of the possibility of delayed bleeding and should be reassured that it can, in the vast majority of cases, be controlled by 20–30 minutes of constant direct pressure over the wound. Trips to the local emergency room to stop postoperative bleeding are unusual but can occur. Patients should also be advised that for ablative procedures, scarring, in the form of a hypopigmented area, may occur.

Other potential hazards of electrosurgery are briefly discussed below.

Fire

There is a risk of fire or explosion if electrosurgical procedures are conducted in the presence of alcohol, oxygen or bowel gases (methane). Care should be taken to be certain that the operative site is free of alcohol residue. Oxygen is usually not a problem except in the operating room setting. Bowel gases are highly flammable! Use care in the perianal region.

Thermoelectric Burns

Although modern generators are isolated from earth, and are often equipped with sophisticated monitoring systems, current can still be diverted away from the return electrode and cause an accidental burn at the point at which it leaves the patient's body. Alternative pathways occur when the current is diverted from the return electrode and finds an alternative path to return to the generator. When the point of contact between the patient and the grounded object is small, even a relatively low-power current can generate sufficient current density to cause a burn. Grounded objects may include metal parts of the operating table, table accessories, or ECG electrodes. This problem is reduced, but not eliminated, by the use of isolated electrosurgical units, which have little or no connection to the ground.

Microorganism Transmission

The potential exists for transmission of microorganisms either via the electrode[19,20] or via smoke plume inhalation. Neither possibility has been investigated in sufficient depth to yield conclusive results. Practitioners should minimize the risk of possible electrode transmission by using disposable or sterilized electrodes. Adapters are available that allow disposable metal hypodermic needles to be used as electrodes.

Surgical Smoke

During surgical procedures using a laser or electrosurgical unit, the thermal destruction of tissue creates a smoke by-product. Research studies have confirmed that this smoke plume can contain toxic gases and vapors such as benzene, hydrogen cyanide and formaldehyde, bioaerosols, dead and live cellular material (including blood fragments)[21],

and viruses[22]. At high concentrations, the smoke causes ocular and upper respiratory tract irritation in healthcare personnel and creates visual problems for the surgeon. The smoke has unpleasant odors and has been shown to have mutagenic potential[23].

Research by the National Institute for Occupational Safety and Health (NIOSH) has shown that airborne contaminants generated by these surgical devices can be effectively controlled by appropriate ventilation using a portable smoke evacuation system. Smoke evacuators contain a suction unit (vacuum pump), filter, hose, and an inlet nozzle. The smoke evacuator should have high efficiency in airborne particle reduction and should be used in accordance with the manufacturer's recommendations to achieve maximum efficiency. A capture velocity of approximately 100–150 feet per minute at the inlet nozzle is generally recommended. It is also important to choose a filter that is effective in collecting the contaminants. A high-efficiency particulate air (HEPA) filter or equivalent is recommended for trapping particulates. Various filtering and cleaning processes also exist which remove or inactivate airborne gases and vapors. The different filters and absorbers used in smoke evacuators require monitoring and replacement on a regular basis and are considered a possible biohazard requiring proper disposal.

The smoke evacuator hose inlet nozzle must be kept within 2 inches of the surgical site to effectively capture airborne contaminants generated by these surgical devices. The smoke evacuator should be activated at all times when airborne particles are produced during an electrosurgical procedure that generates a significant smoke plume. After each procedure, all tubing distal to the filter must be considered infectious waste and be disposed of appropriately. The filters themselves may be used for the cumulative time specified by the manufacturer, before replacement.

ELECTROEPILATION

Electroepilation is the use of electricity for the permanent removal of hair[24]. It predated the development of laser hair removal and is still used, in a variety of forms, by aestheticians and electrologists. The word *electrolysis,* which is used by most people as a generic term to mean the electrical destruction of hair, is technically the use of direct (galvanic) current for hair removal. Hair destruction with an alternating current occurs as a result of the accumulation of heat in the vicinity of the hair bulb and is designated *thermolysis*.

Electrolysis vs Thermolysis

Electrolysis uses direct current to create a destructive chemical reaction at the hair root. The negative electrode (anode) is inserted into the hair follicle (see Fig. 140.1). The positive electrode (cathode) is a moistened pad held in the patient's hand. When direct current is applied, a chemical reaction at the tip of the anode causes the production of sodium hydroxide. The latter acts as a caustic and destroys the hair root. This process may take from 30 to 60 seconds to occur, so pure "galvanic electrolysis" is a tedious procedure to perform. Of note, electrolysis can also be used to treat small telangiectasis (see Fig. 140.1).

Thermolysis relies on heat to cause hair destruction. A high-frequency (13.56 MHz) alternating current is used. As the current passes through tissue, it encounters resistance, causing the current to stall and convert to heat. Current can be applied by the "slow" (manual) technique or the "flash" technique. Lower heat is used over 3–10 seconds in the slow technique. Gentle traction of the hair allows the operator to determine when destruction is complete. The flash technique uses higher heat, delivered by a preset mechanical timer (<1 second). Several such pulses may be required to cause hair root destruction. Theoretically, the flash technique is less painful.

The technique for needle insertion is the same as for electrolysis. A patient hand-held electrode is not required since the patient is not included in the electrical circuit. The speed of thermolysis allows for treatment of much larger areas over a shorter time period. For this reason, it has replaced galvanic electrolysis as the preferred manner of electroepilation. The *blend* is a form of electroepilation that takes advantage of attributes of both electrolysis and thermolysis, by blending the two types of current in one machine. The blend is slower than thermolysis, but may offer some advantages in rate of hair root destruction, particularly for coarser hairs.

Side Effects

Thermolysis and the blend are more painful than classic galvanic electrolysis and the risk of scarring and hair regrowth may be higher. However, highly motivated patients generally tolerate the pain and are treated with 30–60-minute sessions once or twice weekly. The use of topical anesthetics under occlusion for 1–2 hours pretreatment decreases the pain in some patients. Scarring is a real risk and is operator-dependent. Generally, when this occurs, it presents as punctate or ice-pick-like depressed lesions. In some patients, small hypertrophic papules may be present.

Hair regrowth has been reported in the range of 15% to 50%, and this is also technique-dependent. Regrowth may be related, in part, to the hair cycle. Hairs treated while in telogen phase may not experience root destruction. Some electrologists recommend shaving 2 days prior to treatment so that only actively growing hairs will be apparent.

Varying degrees of erythema and edema may be present shortly after the procedure. Postinflammatory hypo- and hyperpigmentation have been reported. The theoretical risk of infections, both local and systemic, exists, but proper skin cleansing helps prevent this problem. Some patients have a higher propensity for developing post-treatment folliculitis and it is recommended that they cleanse with an antibacterial cleanser (e.g. chlorhexidine), before and after treatment. Disposable needles are the norm in the practice of permanent hair removal.

IONTOPHORESIS

In some patients, tap or deionized water iontophoresis can be used successfully to treat localized hyperhidrosis of the palms, soles or axillae. In this technique, direct electrical current is passed through the treatment site while the patient is in contact with an aqueous ionic solution. The electric current introduces ions from the solution into the patient's skin and appears to inhibit sweating by occluding the eccrine ducts at the level of the stratum corneum[25].

A battery-powered unit for home use (Drionic®) is available. It is more effective for treatment of palmoplantar hyperhidrosis than for axillary hyperhidrosis. Cessation of sweating usually requires treatment of each palm or sole with 20 mA of current for 30 minutes daily. The recent use of botulinum toxin type A injections for hyperhidrosis has provided many hyperhidrosis sufferers with a more efficient and lasting treatment modality, albeit at greater expense.

FUTURE TRENDS

Interest and innovation in electrosurgery have actually increased over the past two decades, since continuous wave CO_2 laser systems were introduced. Practitioners came to realize that superficial ablation, deep ablation, and tissue incision with immediate hemostasis were available through electrosurgery without the need for expensive laser systems. As examples, specially adapted electrosurgery equipment that utilizes electricity to remove the epidermis and upper dermis for facial skin resurfacing has been introduced[26] as has the use of electrosurgical cutting current (Ellman Surgitron®) to resurface surgical scars. The latest electrosurgical development is use of a standard radiosurgery device (Surgitron® Dual Frequency RF) for non-ablative tightening of skin laxity[27]. Radiofrequency current produces heat because of resistance in the dermis and subcutaneous tissue. When heated, collagen fibrils will denature and contract, presumably leading to the observed tissue tightening.

Key features

- Wound healing is a complex and dynamic biologic process, consisting of three consecutive phases: inflammation, tissue formation and tissue remodeling
- Effective wound healing requires synchronization of cell–cell and cell–matrix interactions as well as an interplay of cytokines
- Extracellular matrix proteins are multifunctional molecules that bind directly to cell surface receptors (e.g. integrins) and influence the effects of growth factors on cells (e.g. TGF-β)
- In children and adults, the cutaneous wound healing response represents a *reparative* process that can lead to fibrosis (scar), whereas injured fetal tissue can heal completely without fibrosis, in a process resembling *regeneration*
- A number of systemic diseases (e.g. diabetes mellitus, atherosclerosis) as well as more local factors (e.g. pressure, infection) are associated with chronic non-healing wounds

INTRODUCTION

Restoration of skin integrity and homeostasis following injury is a fundamental process that ensures survival. The primary goal of the wound healing response is to re-establish a functional skin barrier as quickly as possible. Ideally, the wound healing response would lead to complete regeneration of skin tissue and its adnexal structures, with complete restoration of original skin function and morphology. Unfortunately, this is often not the final result of wound repair and the quality of newly formed skin tissue varies considerably.

Regeneration Versus Repair

In children and adults, the wound healing response characteristically leads to fibrosis, i.e. scar formation. In addition, adnexal structures (e.g. hair follicles, sweat and sebaceous glands) as well as components of the dermal extracellular matrix may fail to regenerate, resulting in a loss of normal skin function and impaired morphology. Because it is less than ideal, this type of wound healing is sometimes referred to as a *reparative process*.

In contrast, during embryogenesis, injured fetal skin can heal completely without fibrosis. Thus, the process resembles *regeneration*. Fibromodulin (FMOD), a small leucine-rich proteoglycan, is thought to mediate scarless fetal skin wound repair, at least in part, via transforming growth factor-β (TGF-β) modulation[1]. Compared to wild-type mice, *fmod*$^{-/-}$ mice were found to have delayed wound closure and a significant increase in scar size, and this was partially rescued by exogenous FMOD administration[1].

Of note, there are vertebrates such as amphibians and fish that retain the capability to regenerate tissues throughout adult life (see below). Obviously, insights gained into this process, as well as from fetal skin wound repair, could provide methods for transforming repair into regeneration and novel therapies for wound healing.

Effect of Immune Response on Wound Healing

The immune system, including neutrophils and macrophages, plays a critical role in wound healing (see Fig. 141.3). By influencing the repair process, inflammation has an impact on the quality of the wound and the extent of scarring[2]. In a number of models, there appears to be an inverse correlation between the strength of the inflammatory immune response and the ability to undergo regeneration, with inappropriate immune reactions leading to tissue damage and impairment of tissue repair (Fig. 141.1). On the other hand, there is evidence that appropriate immune responses may actually promote repair and protect local tissues.

WOUND REPAIR AND REGENERATION IN DIFFERENT SPECIES

Amphibians

Among the vertebrates, amphibians and fish are exceptional in their capacity to regenerate anatomically complete and fully functional tissues and organs during adulthood. In particular, urodele amphibians (newts and salamanders) can regenerate a range of organs and tissues[3], with cellular and molecular studies focusing on limb regeneration. Regeneration in urodele amphibians involves dedifferentiation of cells at the site of amputation injury, followed by their proliferation to produce a blastema that finally reforms the missing tissue. The excellent capacity for regeneration in these species may be related to the fact that the regenerative response induces only minimal inflammation, but further investigations are required.

Zebrafish

Zebrafish also represent a valuable model for the study of regeneration because even as adults, they are able to regenerate their entire caudal fin following its amputation[5]; this includes the original pigment and color structures. Early on, there is an infiltration of myeloid inflammatory cells, with complete regeneration occurring in the presence of this inflammation. Of note, loss of the gene responsible for myeloid cell lineage development (PU.1) can fully abrogate the inflammatory response, but this has no effect on fin regeneration[6]. In other words, fin regeneration in zebrafish is independent of the inflammatory response.

Mammals

The effects of inflammation on regeneration and repair have also been studied in mammals, primarily in mice, but also in humans. Postnatally, the repair response leads to scar formation whereas injured fetal

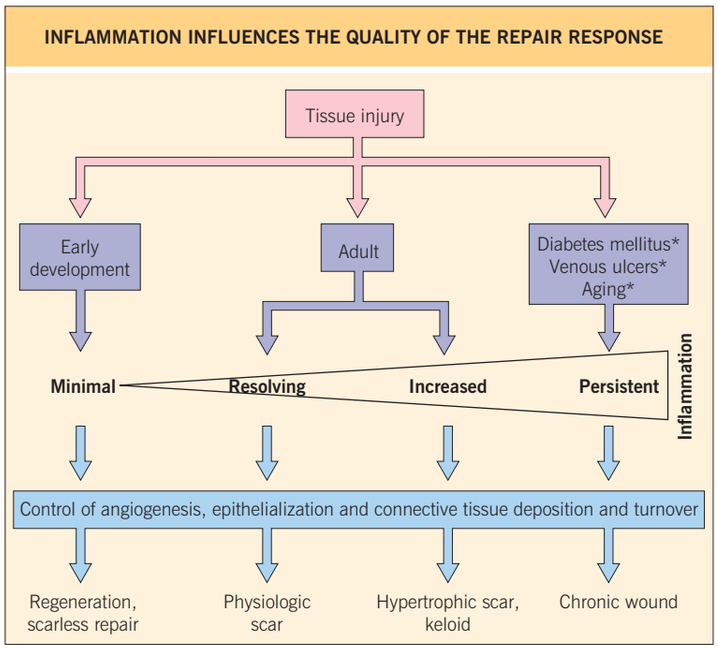

Fig. 141.1 Inflammation influences the quality of the repair response. Modulation of the local immune response at the site of injury can influence repair mechanisms and the quality of tissue restoration. *The underlying etiology of chronic, non-healing ulcers is multifactorial and it includes hypoxia due to vascular disease or sustained pressure and infection, as well as persistent inflammation (see Ch. 105).

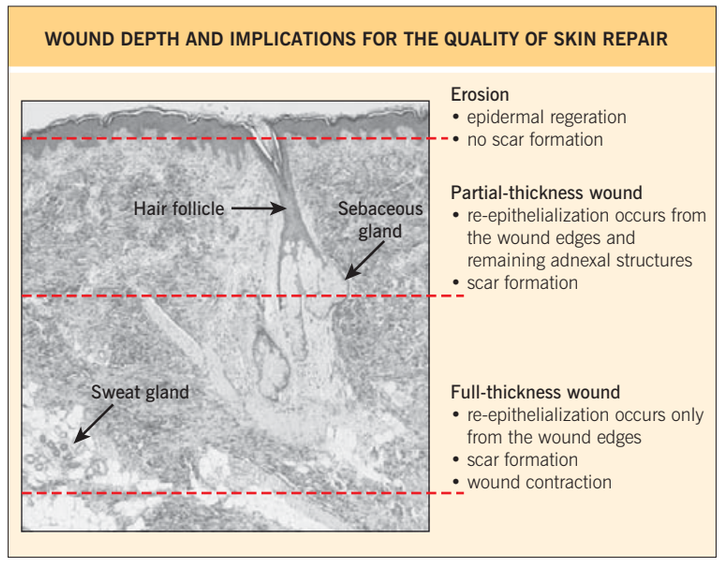

Fig. 141.2 Wound depth and implications for the quality of skin repair. The depth of skin injury determines the ability of the skin to repair versus regenerate. The red dashed lines indicate the levels of injury: injury limited to the epidermis has the capability for regeneration, while injuries to the dermis heal with scar formation. If adnexal structures are present, they contribute to re-epithelialization and wound closure is faster (see Fig. 141.3). If these structures are lost, epithelia can only migrate from the wound edges and complete restoration of the epidermis will require a longer time period.

skin can completely regenerate in a scarless manner (see above)[7]. One major difference between these two clinical settings is the lack of significant inflammation in fetal skin post injury. Other factors that may possibly play a role include differences in the extracellular matrix, cellular mediators, gene expression profiles, and as revealed by transplantation experiments, yet unknown factors intrinsic to fetal skin[7a].

One remarkable example of tissue regeneration in the presence of a functional immune system is the phenomenon of post-amputation fingertip regeneration in higher vertebrates, including rodents and humans. In neonate and adult rodents, regeneration of the digital tip can occur, including the terminal phalangeal bone[8], via the formation of a blastema-like structure containing proliferating undifferentiated cells (similar to limb regeneration in amphibians). These cells express bone morphogenetic protein-4 (BMP-4), the protein product of a gene known to be expressed during the embryonic development of digits[9]. Even in children, but not adult humans, conservatively managed amputation injuries can be followed by restoration of the contour, fingerprints, and normal sensation and function of the digit, with minimal scarring[10]. In humans, the molecular mechanisms underlying this phenomenon are not known.

More recently, transgenic mouse models have provided insights into wound healing[11]. For example, *delayed* wound healing has been observed in mice lacking nidogen 1 (a basement membrane component) or TGF-β, in mice with a fibroblast-specific deletion of integrin β1 (which binds extracellular matrix proteins), in mice that lack superoxide dismutase (an important antioxidative enzyme) or interleukin (IL)-6, and in mice that lack Toll-like receptor 3 and have defective recruitment of neutrophils and macrophages. In contrast, *accelerated* wound healing has been observed in mice that lack matrix metalloproteinases (MMPs) (e.g. ADAM-9) which degrade extracellular matrix proteins and in mice deficient in NK/T cells. Obviously, wound healing is a very complex process and over the next decade, a more precise understanding should emerge.

Clinical Implications

The underlying etiology of chronic, non-healing ulcers is multifactorial (see Ch. 105). It includes hypoxia due to vascular disease or sustained pressure, infection and persistent inflammation[12]. How the latter impairs the healing response is still not well understood, but increased protease activity (e.g. MMPs) and generation of reactive oxygen species are thought to play a role. Additional studies to unravel the underlying molecular pathophysiology of chronic wounds in humans are required, as the search for novel therapies continues.

IMPACT OF WOUND DEPTH ON WOUND HEALING

Skin wounds are often categorized according to their depth (Fig. 141.2). Defects that affect only the epidermis (or a portion of the epidermis) are referred to as *erosions*. When the wound extends into the dermis, it is termed an *ulceration*. In "partial-thickness" wounds, the epidermis and a portion of the dermis are missing, with the ulcer extending into the mid dermis, but the adnexal structures remain. Full-thickness wounds, on the other hand, involve the entire dermis and extend into the subcutaneous fat. As a result, adnexal structures are lost as a source of keratinocytes for re-epithelialization.

The depth of a skin injury clearly affects the capacity of the skin to repair or regenerate. When erosions heal, there is regeneration of the entire epidermis, without scarring (see Fig. 141.2). Ulcerations, however, heal via a reparative process and are associated with scar formation. In partial-thickness wounds, the preserved adnexal structures serve as a source of epithelial cells to repopulate the epidermis (Fig. 141.3). Epithelia from these structures, as well as from the wound edge, migrate across the wound surface to provide coverage. In contrast, because adnexal structures are lost in full-thickness wounds (see above), re-epithelialization can only occur from the wound edges.

Healing of full-thickness wounds includes, to some extent, contraction. While there is minimal contraction in partial-thickness wounds, the reason for this difference is not clear. Contraction may be mediated by mechanical or biologic factors, e.g. the differentiation of fibroblasts into myofibroblasts. During contraction, the wound area decreases via centripetal movement of *pre-existing* tissue, not the formation of new tissue. Unfortunately, contraction of wounds may result in cosmetically disfiguring contractures. However, the contraction of wounds occurs in predictable directions (in relation to "skin tension lines"; see Fig. 142.7) and surgical incisions should be placed, if possible, parallel to these

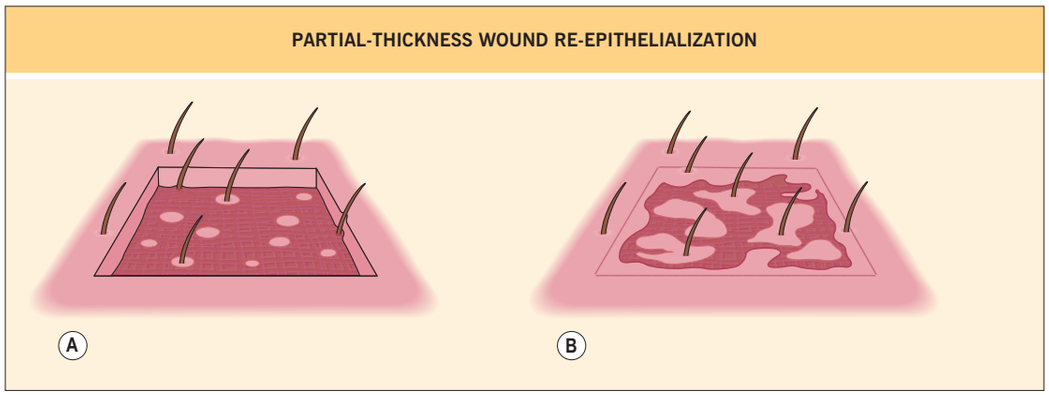

Fig. 141.3 Partial-thickness wound re-epithelialization. A The red area is the wound bed and the pink areas within the wound bed represent remaining adnexal structures; the latter serve as a source of keratinocytes. **B** Over a period of several days after wounding, cells migrate from both the wound edges and the adnexal structures, eventually leading to re-epithelialization. *Courtesy, Robert S Kirsner, MD.*

skin tension lines in order to direct the contracture. Also, an argument in favor of the use of full-thickness skin grafts is to prevent wound contraction and subsequent contracture (see Ch. 148).

Primary versus Second Intention Healing

When an acute wound, such as one resulting from a surgical excision, is allowed to heal on its own, this is termed second (secondary) intention healing (see Ch. 146). In primary intention healing, closure of the wound is accomplished by approximating the wound edges; the latter includes side-to-side closures, flaps and grafts. Both primary and second intention forms of wound healing proceed through the three phases of healing.

In secondary intention healing, the time interval until complete re-epithelialization depends upon several factors. These include wound depth, anatomic location (e.g. facial wounds heal faster than acral wounds), any secondary infection, vascular supply, and geometric shape (for a given area, a more narrow diameter will heal faster). For smaller wounds, especially those that are partial-thickness, primary and second intention healing can produce similar cosmetic results. Once wounds have a diameter >8 mm, primary intention healing leads to better cosmetic results. Tertiary intention healing refers to wounds that are closed with the goal of primary intention healing, but dehiscence occurs and the wound is then allowed to heal by second intention (Fig. 141.4).

The decision to choose primary versus second intention wound healing depends on a number of variables, including a patient's overall medical status and cosmetic concerns, as well as the anatomic location, depth and size of the wound and whether it is located on a convex or concave surface. In addition to comorbidities such as atherosclerosis, venous hypertension and diabetes mellitus, the risk of infection (which may be increased in open wounds) and the patient's preference also influence the decision.

SKIN REPAIR – CELLULAR AND MOLECULAR ASPECTS

In most mammalian organ systems, the repair response involves a complex and dynamic interplay of numerous cell types, including cells that reside within the tissue (e.g. keratinocytes, endothelial cells, fibroblasts) and hematopoietic cells recruited to the site of tissue damage. Three sequential phases of wound repair have been delineated – inflammatory, proliferative and remodeling (maturation)[13] and this section discusses the associated cellular and molecular events.

Three Phases of Wound Healing

Tissue injury causes leakage of blood constituents into the wound site and release of vasoactive factors (Table 141.1), resulting in the activation of the clotting cascade. Clotted blood provides a matrix that allows for cell adhesion and migration. Not only do platelets trapped within the clot play an important role in hemostasis, but they also represent a rich source of growth factors (e.g. PDGF) and proinflammatory cytokines that mediate the recruitment of inflammatory cells and fibroblasts into the wound site (Fig. 141.5). The early *inflammatory phase* of repair is characterized by local activation of innate immune

CHEMICAL MEDIATORS OF INFLAMMATION THAT PLAY A ROLE IN WOUND HEALING

Chemical mediator	Action
Histamine	Increased vascular permeability
Serotonin	Stimulation of fibroblast proliferation Cross-linking of collagen molecules
Kinins	Increased vascular permeability
Prostaglandins	Increased vascular permeability Sensitize pain receptors Increased synthesis of GAGs
Complement	Increased vascular permeability Increased phagocytosis Enhanced bacterial lysis Mast cell and basophil activation

Table 141.1 Chemical mediators of inflammation that play a role in wound healing. GAGs, glycosaminoglycans.

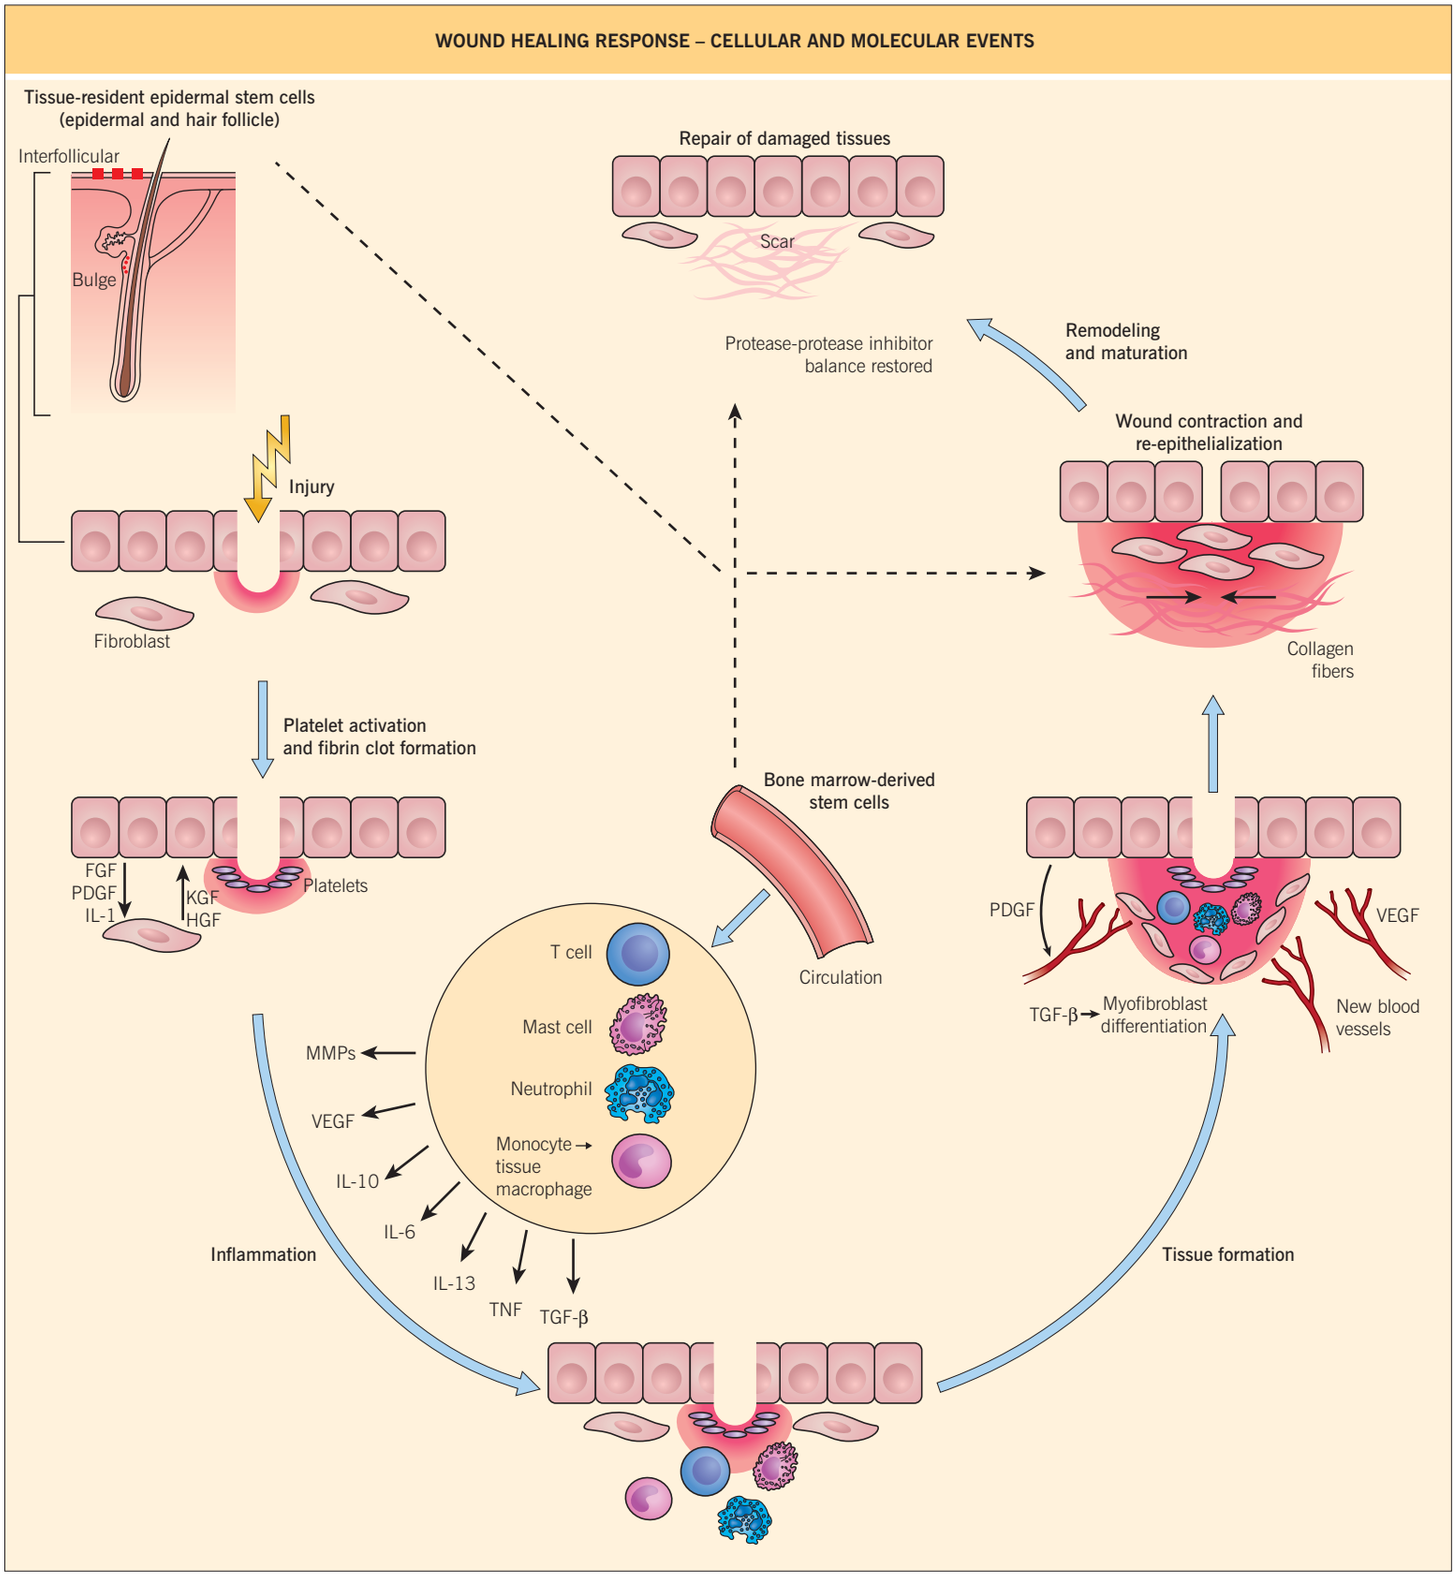

Fig. 141.5 Wound healing response – cellular and molecular events. Leakage of blood constituents and vasoactive factors into the wound site leads to hemostasis. The fibrin clot consists of platelets as well as extracellular matrix molecules (e.g. fibronectin, vitronectin) which facilitate the infiltration and migration of cells. Influx of different subsets of leukocytes characterizes the *inflammatory phase* of repair. These cells release angiogenic growth factors and proinflammatory cytokines, which then induce the recruitment of additional inflammatory cells, fibroblasts and endothelial cells into the wound site. During the *proliferative phase* in which there is formation of granulation tissue, activated macrophages, endothelial cells and fibroblasts form a functional unit essential for efficient blood vessel growth. Transformation of granulation tissue and provisional wound matrix into scar tissue occurs during the *remodeling phase* and this is characterized by a decrease in inflammation and regression of vascular structures. Lastly, stem cells that are intrinsic to the skin (e.g. epidermal stem cells) as well as circulating stem cells contribute to the repair response. FGF, fibroblast growth factor; HGF, hepatocyte growth factor; IL, interleukin; KGF, keratinocyte growth factor; MMPs, matrix metalloproteinases; PDGF, platelet-derived growth factor; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

GROWTH FACTORS INVOLVED IN WOUND HEALING			
Growth factor	**Abbreviation**	**Source**	**Functions**
Platelet-derived growth factor	PDGF	Platelets, keratinocytes, fibroblasts, endothelial cells, perivascular cells	Fibroblast proliferation, chemotaxis & collagen metabolism; angiogenesis
Transforming growth factor-β	TGF-β	Platelets, keratinocytes, fibroblasts, endothelial cells, macrophages	Fibroblast proliferation, chemotaxis & collagen metabolism; angiogenesis; immunomodulation
Transforming growth factor-α	TGF-α	Platelets, keratinocytes	Keratinocyte proliferation & migration
Epidermal growth factor	EGF	Platelets	Keratinocyte proliferation & migration
Interleukins	IL-1, IL-10	Leukocytes, keratinocytes	Fibroblast proliferation; promotes inflammation
Tumor necrosis factor-α	TNF-α	Leukocytes, keratinocytes	Promotes inflammation
Connective tissue growth factor	CTGF	Fibroblasts, endothelial cells	Fibroblast proliferation, chemotaxis & collagen metabolism
Fibroblast growth factor	FGF	Keratinocytes, macrophages	Fibroblast and epithelial cell proliferation; matrix deposition, wound contraction; angiogenesis
Keratinocyte growth factor	KGF	Fibroblasts	Keratinocyte proliferation
Insulin-like growth factor 1	IGF-1	Fibroblasts	Keratinocyte proliferation & differentiation
Hepatocyte growth factor	HGF	Fibroblasts, macrophages	Keratinocyte proliferation
Vascular endothelial growth factor	VEGF	Platelets, keratinocytes, macrophages, neutrophils	Angiogenesis; vascular permeability; macrophage chemotaxis

Table 141.2 Growth factors involved in wound healing.

functions and chemoattraction, both of which lead to an early influx of polymorphonuclear leukocytes (PMNs; neutrophils). This is followed by invasion of blood monocytes, which differentiate into tissue macrophages[14].

While one function of the inflammatory infiltrate is to combat invading microbes, another equally important function is the release of cytokines and growth factors (e.g. IL-1, IL-6, vascular endothelial growth factor [VEGF] tumor necrosis factor [TNF], TGF-β; Table 141.2), which are critical for the initiation of the second *proliferative phase* of skin repair (see Fig. 141.5). During this phase of tissue formation, newly formed granulation tissue, consisting primarily of invading macrophages and fibroblasts as well as endothelial cells (as vessel precursors), covers and fills the wound area. Fibrin, fibronectin, vitronectin, collagen III and tenascin are components of the provisional extracellular wound matrix which facilitate cell adhesion, migration and proliferation. At the wound edge, epidermal–mesenchymal interactions stimulate keratinocyte proliferation and migration, leading to re-epithelialization[15].

Upon completion of epithelialization, cell proliferation and neovascularization cease, scar tissue forms and the wound enters the *remodeling* (*maturation*) *phase,* which lasts for several months. This last phase is characterized by a balance between the synthesis of new components of the scar matrix and their degradation by proteases. This balance determines whether there is normal versus abnormal scar formation (e.g. atrophic scars, hypertrophic scars, keloids). The mechanisms underlying granulation tissue regression and its transformation into scar tissue during this phase are largely unknown. Typically, there is also regression of vascular structures, transformation of fibroblasts into myofibroblasts, substitution of provisional extracellular matrix (ECM) with a permanent collagenous matrix (see Fig. 141.10), and a final resolution of the inflammatory response. Potential explanations for the latter are increased production of anti-inflammatory mediators, active suppression of proinflammatory factors, normalization of microvascular permeability, and induction of apoptosis of inflammatory cells and their efflux from the tissue.

Cellular Components

Keratinocytes

Within hours after injury, keratinocytes at the wound edge are activated and undergo marked phenotypic and functional alterations, a fundamental change required for re-epithelialization of the wound bed (Fig. 141.6). In order to initiate migration, keratinocytes need to undergo significant alteration of their junctions and adhesion molecules; this includes detachment of hemidesmosomes and replacement of their collagen-binding receptors with new integrins that allow the keratinocytes to adhere to the newly formed provisional wound matrix. In addition, these keratinocytes begin to proliferate as they reduce the production of proteins normally expressed by differentiated stratified epidermis, in particular specific keratins (see Ch. 56). During wound healing, one classic marker of activated keratinocytes is the expression of keratins associated with proliferation, keratins 6 (K6) and K16.

It has been proposed that the cytoskeletal changes associated with activation, including the expression of these particular keratin filaments, provide plasticity and flexibility, while still maintaining resilience of the intracellular scaffold that is important for migration[16]. Many of the growth factors active during wound healing, such as keratinocyte growth factor (KGF) and hepatocyte growth factor (HGF), are potential regulators of these processes. These growth factors can be synthesized either by activated keratinocytes (and act in an autocrine loop) or by cells present in the dermis, in particular fibroblasts, and then act in an paracrine fashion[16a].

As the stratified epithelium consists of keratinocytes committed to multiple stages of differentiation, it is important to know which keratinocytes can be activated for regeneration. Experimental data from mice expressing a transgene within defined keratinocyte subpopulations revealed that interfollicular epidermal stem cells, transient amplifying cells and early differentiated cells have the ability to form a fully differentiated epidermis[17]. These data suggest that primarily skin stem cells and transient amplifying cells contribute to wound healing and that keratinocytes become irreversibly committed to the differentiation process fairly rapidly and then respond poorly to activating signals. Once keratinocytes process profilaggrin into filaggrin, they undergo specific changes that mark late terminal differentiation, which seemingly demarcates the final "line of regenerative potency" within the differentiating keratinocyte population (see Fig. 141.6)[17a].

Although epidermal regeneration via cell division within the basal layer of the interfollicular epidermis is well characterized, there appears to be a second type of resident epidermal stem cell that has attracted intensive research in recent years – the stem cells in the bulge region of the outer follicular root sheath (see Fig. 141.5). These cells, the hair follicle stem cells (HFSCs), are multipotent stem cells[18]. Originally, HFSCs were thought to be responsible for just the regeneration of hair follicles and sebaceous glands. Later studies suggested that they are also responsible for long-term replenishment of the interfollicular epidermis, and, more recently, repopulation of the epidermis following injury[19]. Based upon studies in mice, it appears that for re-epithelialization following mechanical injury, both interfollicular stem cells and stem cells in the bulge region contribute to the newly

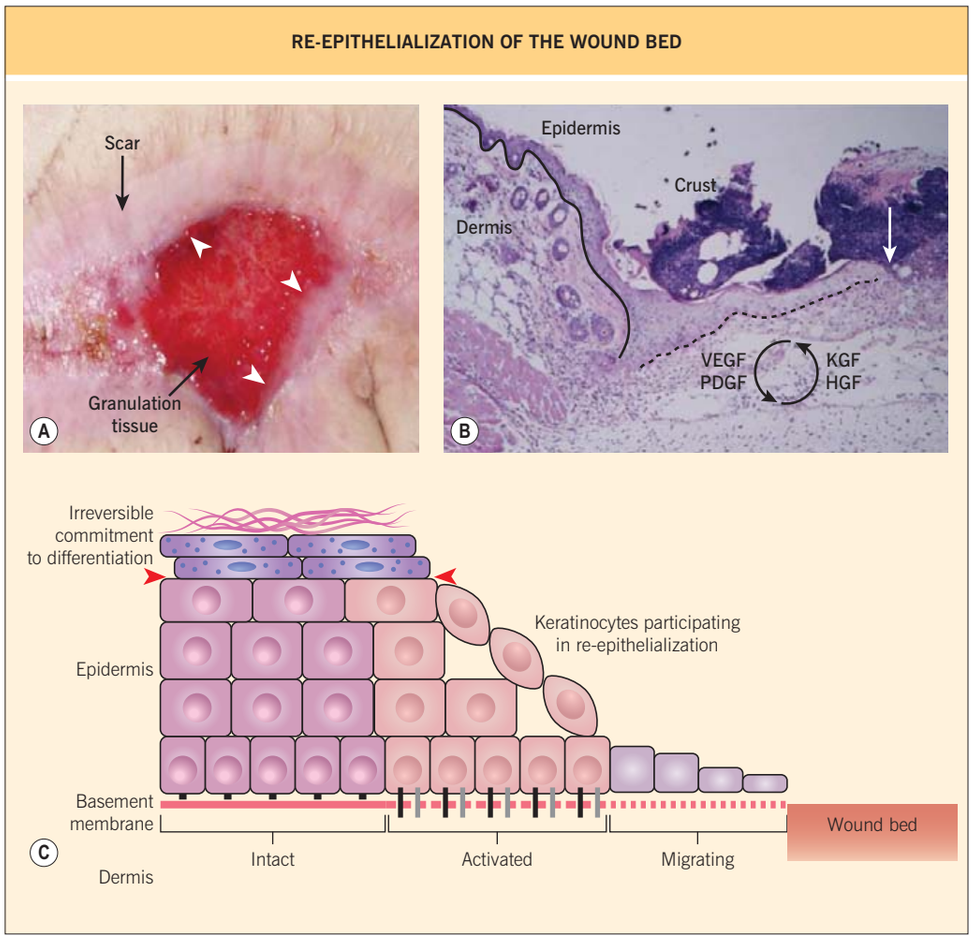

Fig. 141.6 Re-epithelialization of the wound bed. **A** Clinical appearance of a re-epithelializing wound; arrowheads indicate the epithelial wound edge. **B** Photomicrograph of the wound edge demonstrating the migration of keratinocytes over the wound bed; this process is in part regulated by growth factors synthesized by fibroblasts such as keratinocyte growth factor (KGF) and hepatocyte growth factor (HGF). The white arrow indicates the tip of the epithelial tongue, the black dashed line indicates activated and migrating epithelium, and the black solid line indicates intact epithelium. **C** Epithelial cells present at the wound edge undergo marked morphologic and functional alterations. They lose their contacts with neighboring cells and the underlying extracellular matrix, then proliferate and migrate toward the center of the wound. The red arrowheads demarcate the terminally differentiated cells that are irreversibly committed.

generated epidermis. These findings help to explain how depth of injury affects the capability of a wound to repair and to re-epithelialize.

Endothelial cells

Activated and proliferating endothelial cells that form blood vessels normally express the $\alpha_v\beta_3$ integrin and make a significant contribution to angiogenesis, which is a vital component of normal wound healing (Fig. 141.7)[20]. New blood vessels ensure delivery of nutrients to meet the increased metabolic requirements of wound tissue and they help to reverse the hypoxic and acidotic milieu. Several features characterize neoangiogenesis within wounds: firstly, there is increasing evidence that this process occurs via both *angiogenesis* (sprouting of capillaries from existing blood vessels) and *vasculogenesis* (mobilization of bone marrow-derived endothelial progenitor cells; see Ch. 102). Secondly, the process is highly complex and requires a dynamic, temporally and spatially regulated, interaction amongst endothelial cells, soluble angiogenic growth factors and ECM molecules. Thirdly, wound angiogenesis is induced, at least in part, by the activation of the innate immune response. Immediately after injury, different subsets of leukocytes are attracted to the wound site and they release multiple pro-angiogenic mediators (e.g. IL-6, IL-8, TNF) that trigger and sustain the angiogenic response. Importantly, as shown for TNF, the time of action and the concentration of a given cytokine determine whether it activates, terminates or inhibits angiogenesis.

Several additional mediators have been identified that are crucial for vessel formation and play a role in controlling vascular remodeling and angiogenesis. Genetically engineered mice, in particular, have provided substantial evidence that wound angiogenesis requires a dynamic interaction amongst endothelial cells, pro- and anti-angiogenic growth factors, and the ECM environment. Of the cytokines involved in angiogenesis (and there is significant functional redundancy), basic fibroblast growth factor (bFGF) and platelet-derived growth factor (PDGF) are two with key functions. In addition to these more classic cytokines, the family of VEGF proteins and their receptors has emerged as key mediators in embryonic vascular development, as well as physiologic and pathologic angiogenesis in adults[21].

As with many physiologic and pathologic processes of tissue remodeling, ECM molecules play a pivotal role in the repair response and wound angiogenesis. For example, basement membrane proteins provide essential information for the organization and orientation of endothelial cells; the latter are anchored to this dense polymeric sheet that is crucial for the proper function of blood vessels. The essential nature of the basement membrane has been demonstrated in that removal of its major components leads to leakiness of blood vessels. Such major constituents of this polymer structure include laminins, nidogens, collagens III and IV, and heparin sulfate proteoglycans (e.g. perlecan). A vital role for these components is reflected in genetic disorders such as the vascular form of Ehlers–Danlos syndrome in which reduced or abnormal type III collagen fibers are associated with marked vascular fragility.

During neoangiogenesis, new vessels sprout from existing vessels and grow along a growth factor gradient, determined primarily by VEGF. Degradation of the surrounding ECM also has to occur via MMPs (see below) as well as serine and cysteine proteases[22]. Both the ECM (often via integrins) and growth factor concentrations provide signals that lead to a balance between the formation of new blood vessels and the prevention of aberrant angiogenesis.

There is a growing appreciation of how interactions between endothelial cells and vascular mural cells (pericytes) play a role in the regulation of vascular formation, stabilization, remodeling and function. For example, pericytes have been shown to play a role in large, well-vascularized tumors, and in such tumors, pharmacologic anti-angiogenic targeting of only the endothelial cells (and not the pericytes) often proves ineffective. A role for pericytes in dermal wound healing was predicted several decades ago, but so far their precise functional relevance is largely unknown.

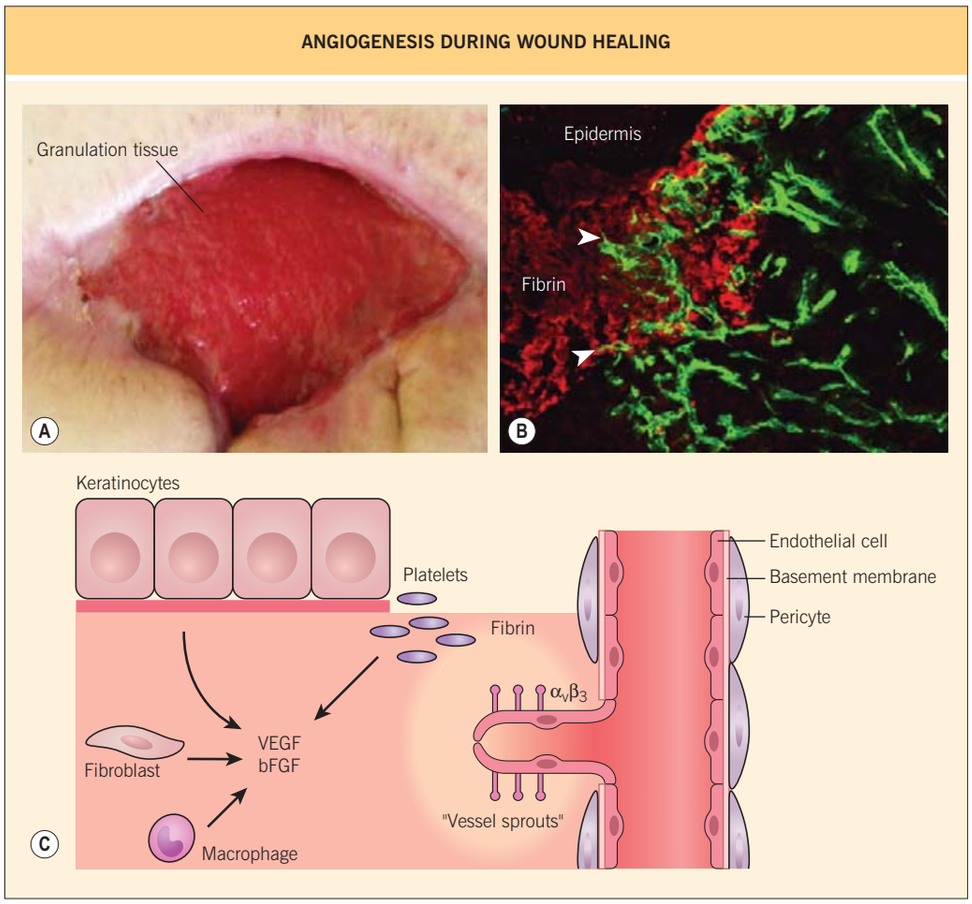

Fig. 141.7 Angiogenesis during wound healing. **A** Clinical appearance of a highly vascularized wound bed. **B** Immunohistochemical staining demonstrating endothelial invasion ($CD31^+$ [green]) into a fibrin matrix (red); white arrowheads indicate sprouting capillaries. **C** Capillary sprouts invade the fibrin/fibronectin-rich provisional wound matrix and within a few days they organize into a microvascular network throughout the granulation tissue. The process is regulated by a dynamic interaction among endothelial cells, growth factors (e.g. VEGF, bFGF) and the extracellular matrix. In particular, the $\alpha_v\beta_3$ integrin appears to be required for endothelial cell attachment and wound angiogenesis. bFGF, basic fibroblast growth factor; VEGF, vascular endothelial growth factor.

Leukocytes and platelets

The inflammatory response in normal wound healing is characterized by spatially and temporally changing patterns of various leukocyte subsets. The well-defined chronology of these events seems essential for optimal repair.

Polymorphonuclear leukocytes and platelets

Immediately after injury, extravasated blood constituents form a hemostatic blood clot (Fig. 141.8). Platelets then aggregate within the clot and release a wide spectrum of factors that amplify the aggregation response, trigger the coagulation cascade, or act as chemoattractants for cells involved in the inflammatory phase. Within a few hours following the injury, polymorphonuclear leukocytes (PMNs; neutrophils) transmigrate across the endothelial cell wall of capillaries. Upon activation, the neutrophils produce and release proinflammatory cytokines including IL-8 and TNF, in addition to growth-related oncogene-α (GRO-α) and monocyte chemoattractant protein-1 (MCP-1)[23]. This leads to expression of various classes of adhesion molecules (selectins, ICAM, VCAM) essential for leukocyte adhesion and diapedesis (see Fig. 141.8 and Ch. 102)[24]. Neutrophils can further amplify their own recruitment via IL-8 and GRO-α.

Recruited neutrophils play a major role in the debridement of devitalized tissue and in controlling infectious agents. To perform this task, they release a large variety of highly active antimicrobial substances (reactive oxygen species [ROS], cationic peptides, eicosanoids) and proteases (elastase, cathepsin G, proteinase 3 [PR-3], urokinase-type plasminogen activator [uPA]). Uncontrolled release of these factors can cause severe damage to the tissues of the host[25]. Of note, bacterial products such as lipopolysaccharides and formyl-methionyl peptides, which accumulate within infected wounds, can accelerate directed neutrophil locomotion. The important role of neutrophils in phagocytosis and debridement is underlined by the observation that patients with defined deficiencies in PMN function, such as the leukocyte-adhesion deficiency syndrome 1 (LAD1)[26] or attenuated PMN actin polymerization[27], in which neutrophil locomotion is impaired, also display impaired wound healing.

Blood monocytes and tissue macrophages

Attraction of monocytes to the wound site occurs via chemotactic factors, including growth factors, proinflammatory cytokines, and chemokines. The latter include macrophage inflammatory protein 1α (MIP-1α), MCP-1, RANTES and fraktalkine. Within the wound, major sources of these chemoattractants include platelets trapped in the fibrin clot, hyperproliferative keratinocytes at the wound edges, fibroblasts and various subsets of leukocytes, including macrophages. As monocytes extravasate from the blood vessel, they become activated and differentiate into mature tissue macrophages.

Macrophages display a variety of functions during wound healing[14]. While their role as antigen-presenting cells may be less important in this setting (e.g. RAG 1 knockout mice which lack mature T cells have normal wound healing)[27a], they are important phagocytes. Macrophages are also a major source of growth factors, such as TGF-β, TNF, PDGF, bFGF and VEGF. These factors critically regulate angiogenesis, keratinocyte motility, the recruitment and activation of immune cells, and the synthesis of ECM molecules.

Over 30 years ago, a crucial role for macrophages in wound repair was established. Macrophage depletion in rats, using antisera, resulted in a significant delay of wound healing[28]. More recent studies have supported and extended these observations[12]. For example, in transgenic mice in which the accumulation of macrophages (but not monocytes or neutrophils) within wounds has been ablated, there is delayed re-epithelialization, reduced collagen deposition and impaired angiogenesis[29]. In addition, P- and E-selectin-double-deficient mice, mice deficient in β-1,4-galactosyltransferase (which glycosylates P- and E-selectins), and ICAM-1-deficient mice all have a profound delay in wound closure (see Fig. 141.8); this delay is associated with a significantly reduced infiltration of macrophages. These studies demonstrate the importance of cell adhesion molecules in the regulation of blood monocyte recruitment and infiltration into the wound site.

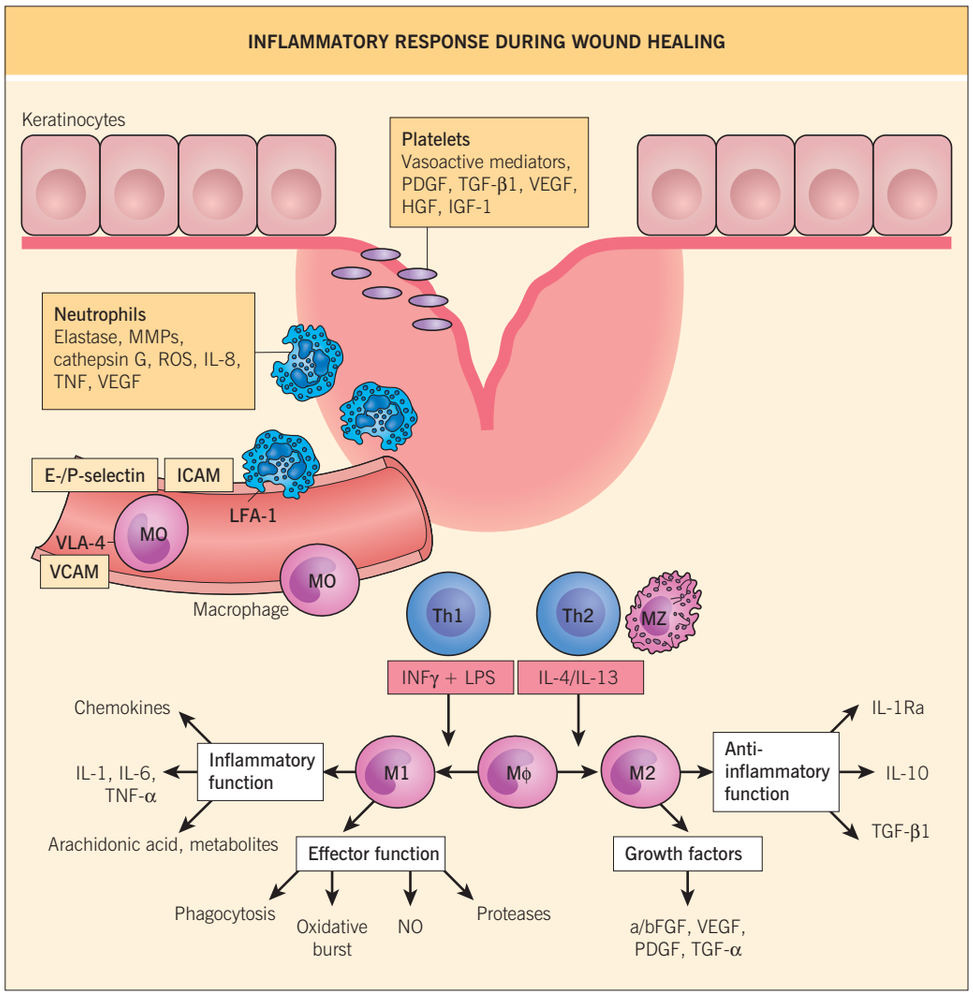

Fig. 141.8 Inflammatory response during wound healing. During normal wound healing, the inflammatory response is characterized by spatially and temporally changing patterns of leukocyte subsets. A well-defined chronology and interplay is essential for optimal repair. Within a few hours after injury, neutrophils transmigrate across the endothelial cell wall of blood capillaries; recruited neutrophils begin to debride devitalized tissue and attack infectious agents by releasing a number of antimicrobial molecules, proteases and cytokines. Shortly after the neutrophils appear, monocytes migrate from the blood vessels into the dermis, become activated within the wound environment and transform into tissue macrophages. In addition to functioning as antigen-presenting cells and phagocytes, macrophages are thought to play an integral role in wound healing due to their release of numerous growth factors. Their morphologic and functional heterogeneity is a reflection of factors released by other cells, e.g. T cells or mast cells, present in the wound environment. FGF, fibroblast growth factor; ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; IL-1Ra, interleukin-1 receptor antagonist; LFA-1, lymphocyte function-associated antigen 1; LPS, lipopolysaccharide; M1, classically activated macrophages; M2, alternatively activated macrophages; MMPs, matrix metalloproteinases; MO, monocyte; Mϕ, macrophage; MZ, mast cell; NO, nitric oxide; PDGF, platelet-derived growth factor; ROS, reactive oxygen species; TGF, transforming growth factor; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor; VLA-4, very late antigen-4.

Activation and differentiation of monocytes into mature tissue macrophages involves changes in gene expression and cellular function. This activation is directed by mediators present in the microenvironment, and it is thought to be crucial for the proper adaptation of macrophage functions to the specific requirements of the wound site[30]. Macrophages sense their microenvironment via numerous cell surface receptors, including Toll-like receptors, complement receptors, Fc receptors and cytokine receptors[31].

One current model of tissue macrophage activation is based on the observation that macrophages may acquire distinct activation states, in particular macrophages that are "classically activated" (also called M1) versus "alternatively activated" macrophages (also called M2; see Fig. 141.8). M1 macrophages exhibit proinflammatory activities, including production of IL-1 and nitric oxide (NO), eradication of invading microorganisms and promotion of type I immune responses. On the other hand, M2 macrophages produce IL-10 (but minimal NO), are hyporesponsive to proinflammatory stimuli and are involved in debris scavenging, angiogenesis and tissue remodeling[30]. These latter cells play a role in the resolution of inflammation and are thought to promote repair.

Classical macrophage activation is mediated by priming of macrophages by cytokines, in particular interferon-γ (IFN-γ), followed by Toll-like receptor (TLR)-mediated triggers such as lipopolysaccharide signaling via TLR4. Key mediators of *alternative macrophage activation* are IL-4 and IL-13, acting through a common receptor chain IL-4Rα. Manipulation of macrophage polarization might represent a potential avenue for future therapeutic approaches to wound healing.

T cells

During the phase of tissue remodeling (maturation), when wound closure is complete and local infections have been overcome, cells of the *adaptive* immune response, in particular T cells, are the most frequent leukocyte subset in human skin wounds[32]. Definitive understanding of T-cell functions during repair requires further investigation in that wound healing appears to be unaffected in T-cell-deficient mice (e.g. RAG-1 knockout mice). Similar to macrophages, $CD4^+$ T cells can differentiate into different subsets, e.g. Th1 and Th2 cells (see Ch. 4), and thereby influence the wound microenvironment by secreting distinct cytokine profiles (see Fig. 141.8)[33]. Th1 cells are a primary source of IFN-γ while Th2 cells are the major source of IL-4 and IL-13. As noted previously, these cytokines have a major effect on the state of macrophage differentiation. Thus, even though they are not mandatory for wound healing, $CD4^+$ T-cell cytokines critically influence two important components of wound healing: macrophage function and angiogenesis.

Mast cells

Mast cells are a hematopoietic cell population that normally resides in skin and mucous membranes. They are an important source of a number of mediators such as prostaglandins and biogenic amines as well as pro- and anti-inflammatory cytokines (e.g. TNF, IL-8) that strongly influence inflammation, tissue modulation and vascular modeling. Even though they influence both innate and adaptive tissue inflammation and can affect angiogenesis and the risk of wound infection, an essential role for mast cells in normal wound healing has not been determined. It is most likely that mast cells represent redundant "players" in wound healing, i.e., they are not required for normal wound healing but can modify its course[34].

Fibroblasts

Connective tissues, including the dermis, typically have large amounts of ECM in which a small number of relatively quiescent fibroblasts are

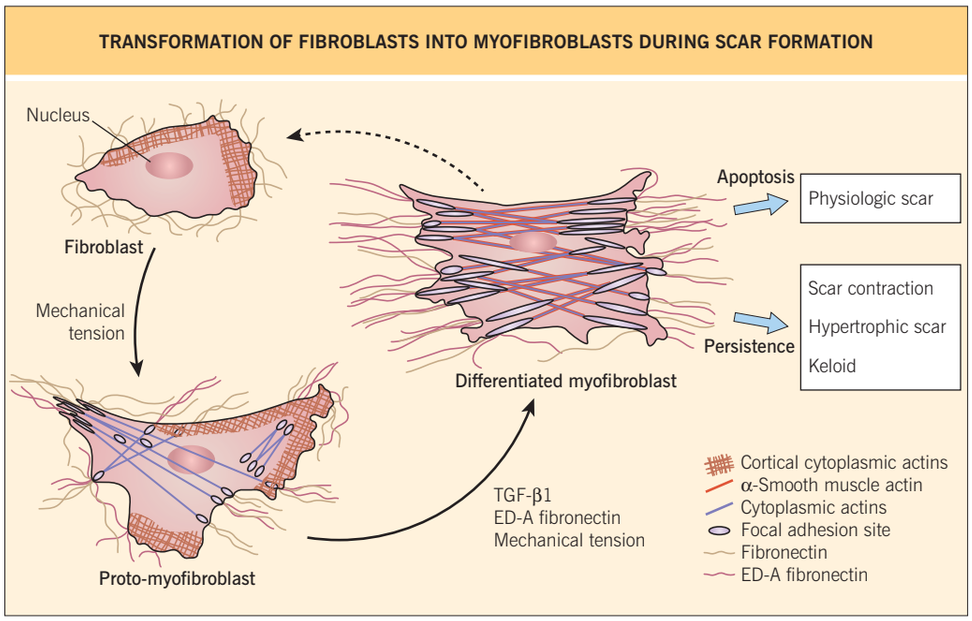

Fig. 141.9 Transformation of fibroblasts into myofibroblasts during scar formation. Fibroblasts undergo a series of phenotypic and functional changes during granulation tissue formation and then scar formation. Under mechanical stress, fibroblasts differentiate into proto-myofibroblasts which are characterized by the expression of a fibronectin variant ED-A; the latter, in combination with TGF-β1, promotes the differentiation of proto-myofibroblasts into myofibroblasts. Typically, myofibroblasts express α-smooth muscle actin (SMA) and can generate potent contractile forces. The persistence of myofibroblasts within the scar may lead to disabling scar contraction. *From Tomasek JJ, Gabbiani G, Hinz B, et al. Myofibroblasts and mechano-regulation of connective tissue remodelling. Nat Rev Mol Cell Biol. 2002;3:349–63.*

embedded. During development, fibroblasts establish a "resting" tension by actively synthesizing and cross-linking fibrillar ECM proteins such as collagen and elastin (see Ch. 95), thereby establishing the shape of the skin and ensuring that the skin retains its shape in response to mechanical stress[35].

During tissue repair, fibroblasts next to the site of injury become activated and reconstitute new ECM and restore proper matrix tension. To achieve these goals, fibroblasts acquire smooth muscle cell-like features, including contractile stress fibers and *de novo* expression of α-smooth muscle actin (α-SMA), thus differentiating into myofibroblasts (Fig. 141.9)[36]. The transition of a fibroblast into a myofibroblast depends on the concerted action of cytokines, in particular TGF-β1, and specific ECM proteins, especially the cellular fibronectin splice variant ED-A. Acquisition and maintenance of the myofibroblast phenotype also depends on mechanical tension, which is regulated by the continuous interaction between the rigidity of the ECM and the contractile activity of its cells.

Following closure of the wound, apoptosis of myofibroblasts or their reverse differentiation into fibroblasts normally occurs. However, abnormal persistence of myofibroblasts has been observed in hypertrophic scars and keloids (see Fig. 141.9). Determining how perception of mechanical signals translates into myofibroblast differentiation may lead to therapeutic strategies for exaggerated scarring[37].

Stem cells

Stem cells are defined as cells that have clonogenic and self-renewing capabilities and can differentiate into multiple cell lineages (see Ch. 2). Whereas *embryonic stem cells* are derived from mammalian embryos in the blastocyst stage and have the ability to generate any terminally differentiated cell in the body, *adult stem cells* are postnatal tissue-specific cells that are primarily committed to differentiate into the cells of the tissue in which they reside. During cutaneous wound healing, tissue-resident stem cells (e.g. epidermal stem cells, hair follicle stem cells, mesenchymal stem cells)[18,19,38] and/or stem cells recruited from the bloodstream into the wound can participate in the repair process (see Fig. 141.5)[39].

Currently, the best-studied model of adult stem cells is the hematopoietic system, in which long-term self-renewal is achieved only by specific and rare hematopoietic stem cells (HSC). These cells reside within the bone marrow niche and retain their ability to both self-renew and give rise to all blood cell lineages. In addition to hematopoietic progenitors, other cells with stem cell-like qualities such as mesenchymal stem cells (MSC) and multipotent adult progenitor cells (MAPC) have been cultured from human and murine bone marrow[40].

MSC were first isolated from bone marrow and later from different tissues, including adipose, pancreas, skeletal muscle, nervous tissue, and skin. Upon appropriate stimulation *in vitro*, these cells differentiate into mature, committed cells. In animal studies, they migrated from their bone marrow niche to sites of injury and differentiated appropriately, e.g. into endothelial, nervous or cardiac tissues. Differentiation into fibroblasts, endothelial cells and keratinocytes has been observed in injured murine skin[41].

Based on studies in mice, the percentage of MSCs recruited into small cutaneous wounds appears to be low[42]. Nonetheless, there is significant therapeutic interest in the delivery of stem or progenitor cells to skin wounds to promote repair or to optimize the quality of the repair response (see below)[40].

Cytokines and their Receptors

In addition to cell–matrix interactions (see below), all stages of the repair process are influenced by a complex network of soluble peptide growth factors, chemokines and hormones as well as their receptors (see Figs 141.5, 141.7 & 141.8)[43]. Major growth factor families have been identified that contribute significantly to the wound healing process, such as PDGF, FGF, VEGF and TGF-β (see Table 141.2).

Growth factors were initially discovered by their ability to stimulate continuous mitosis of quiescent cells in a complete culture medium that lacked serum. This is in contrast to essential elements, cofactors and nutrients, which are required for metabolic processes but are not sufficient to initiate cell division. Growth factors are synthesized and secreted by various cell types involved in the wound healing process, including keratinocytes, fibroblasts, vascular endothelial cells, platelets and inflammatory cells. Growth factors may act on the producer cell (autocrine stimulation), an adjacent cell (paracrine stimulation), or distant cells (endocrine stimulation)[43]. Following binding of growth factors to their respective receptors, complex signaling cascades (e.g. β-catenin) result in cellular functions crucial for wound healing, including cellular proliferation and migration[44].

Extracellular Matrix

Although the ECM was long viewed as an inert scaffold upon which cells were arranged, it has been redefined as a dynamic, mobile and flexible entity that plays a key role in regulating cellular behavior. Genetically modified mice have greatly accelerated the understanding of the multifunctionality of the ECM in developmental and regenerative processes[45].

Within the wound site, the components of the ECM vary continuously as the healing process evolves, and they support fundamental, wound phase-specific repair mechanisms. During the inflammatory phase, the initial wound matrix (consisting primarily of blood constituents such as fibrin and fibronectin) provides a substrate for the

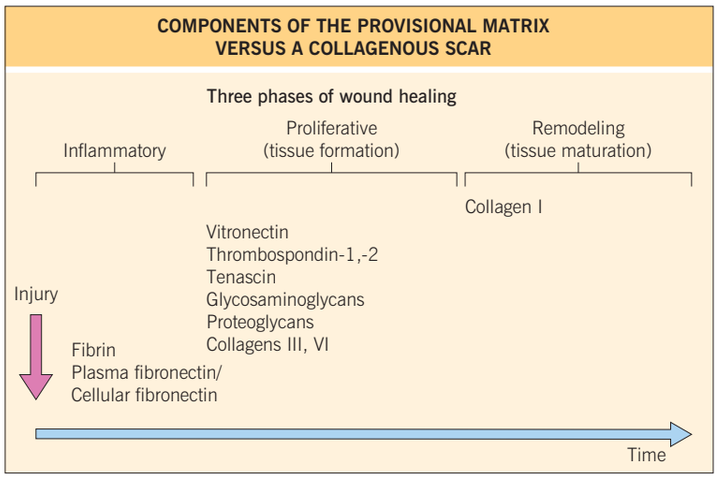

Fig. 141.10 Components of the provisional matrix versus a collagenous scar. The first extracellular matrix to be deposited within the wound space and surrounding tissue is the fibrin clot. Leukocytes, fibroblasts and endothelial cells invade the fibrin clot, which is then lysed. These cells begin to deposit a network of ECM components, including fibronectin, vitronectin, tenascin and type III collagen. Following complete re-epithelialization, fibroblasts start to deposit a stable matrix composed of type I collagen. Thus the wound evolves from an initial plasma-derived provisional matrix to an *in situ* cell-derived provisional matrix and finally to a mechanically stable collagen matrix. Examples of glycosaminoglycans are hyaluronic acid, chondroitin-4-sulfate and dermatan sulfate, while examples of proteoglycans are decorin, biglycan, versican and syndecan (see Ch. 95).

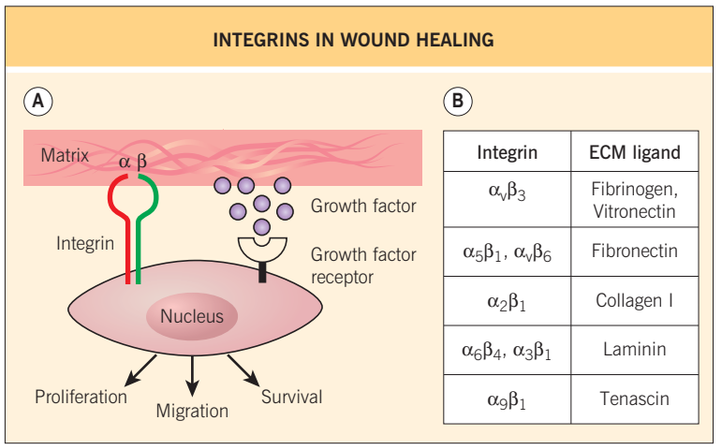

Fig. 141.11 Integrins that play a role in wound healing. A Integrins are transmembrane receptors that recognize and bind to extracellular matrix (ECM) proteins. They are heterodimers composed of one α-subunit and one β-subunit. Integrins allow cells to attach to the ECM and they interact with growth factor receptors, ultimately controlling cellular functions essential for wound healing. **B** The composition of integrins expressed by a cell determines the ECM components to which that cell can bind. Examples of the integrins and their ECM ligands that are important for wound healing are listed.

migration and in-growth of various cell types, including macrophages and fibroblasts (Fig. 141.10). During the formation of granulation tissue (the proliferative phase of wound healing), components of the provisional matrix, such as vitronectin and tenascin, facilitate cell adhesion, migration and proliferation (see Fig. 141.5). As the provisional matrix matures over the ensuing weeks, it is replaced by type I collagen during the remodeling phase, thus increasing wound tensile strength.

Matrix molecules can regulate cellular functions via interaction with specific cell surface transmembrane receptors (integrins) that transduce signals into the nucleus (see below). In addition, they can bind growth factors, e.g. TGF-β, and act as a reservoir (see Fig. 95.7).

Integrins

Integrins are cell surface transmembrane receptors that can recognize and bind to ECM proteins. They are heterodimers composed of α-subunits and β-subunits. Eighteen α-subunits and eight β-subunits can assemble in 24 different combinations, with overlapping substrate specificity and cell type-specific expression patterns[46]. For example, integrins containing β1 or β3 chains are ECM receptors, whereas those containing β2 chains are leukocyte cell–cell receptors. The composition of integrins expressed by a particular cell determines to which ECM components that cell can bind. For example, $\alpha_9\beta_1$ binds to tenascin and $\alpha_v\beta_6$ binds to fibronectin (Fig. 141.11).

Upon binding of an integrin to its ligand, the integrin may change its configuration and transform into an activated state[47]. This can trigger a signaling cascade within the cell that leads to an alteration in gene expression, as well as a change in the integrin's binding characteristics. Integrin-mediated signaling is also influenced by the binding of growth factors and cytokines to their respective receptors, along with various levels of cross-talk (see Fig. 141.11). For example, $\alpha_v\beta_3$ binding in conjunction with VEGF-A binding to its receptor leads to synergistic downstream effects regulating endothelial cell function. Thus, today it is very clear that integrins are more than just simple receptors mediating physical attachment of cells to their environment.

Proteases (Proteinases)

Proteases are enzymes that cleave peptide bonds at specific sites along polypeptides, and they can be classified into distinct groups based upon the biochemical mechanisms responsible for their catalytic activities[48].

Proteases are crucial for tissue remodeling, which is a fundamental process during all stages of wound repair, including inflammation, angiogenesis and re-epithelialization. Those most crucial for skin repair are serine proteases and metalloproteinases. In addition to matrix degradation, these proteases are crucial for growth factor activation, and they exert antimicrobial activities. To protect tissues from excessive and uncontrolled proteolytic degradation, protease activity has to be tightly regulated by protease inhibitors. An imbalance, with high levels of proteases and low levels of protease inhibitors, is considered a major contributor to chronic, non-healing skin ulcers[12,49,50].

Serine proteases have a catalytically essential serine residue in their active site. Neutrophils and macrophages are an important source of this group of proteases which includes neutrophil elastase, cathepsin G and proteinase 3. Furthermore, plasmin and its activators, tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA), are serine proteases that are fundamental for wound repair. In addition to dissolving the fibrin clot, the plasmin-related proteases are involved in the activation of matrix metalloproteinases (MMPs) and numerous growth factors.

The major *ser*ine *p*rotease *in*hibitors (SERPINs; e.g. α_1-antichymotrypsin) as well as α_2-macroglobulins are synthesized by hepatocytes and are released into the plasma. In contrast, *s*ecretory *l*eukocyte *p*rotease *i*nhibitor (SLPI) and elafin are synthesized locally by keratinocytes. Plasminogen activator inhibitors (PAIs) are the major inhibitors of uPA and are produced by endothelial cells.

The family of MMPs shares a common domain structure, and collectively they are capable of degrading all the components of the ECM. To date, at least 28 members of the human MMP family have been identified and they are differentially expressed by diverse cell types[51]. MMPs can be subdivided into several groups based upon substrate specificity (Table 141.3). Tissue inhibitors of metalloproteinases (TIMPs), which are synthesized by connective tissue cells and leukocytes, specifically inhibit MMPs.

ABNORMAL WOUND HEALING

The complex network of cell–cell and cell–matrix interactions leading to wound healing can be disturbed. This may result in either a delayed healing response and ultimately a chronic wound, or excessive scarring as in hypertrophic scars or keloids. Dysfunctional wound healing represents a major clinical and socioeconomic problem and the development of effective therapies is essential.

Impaired healing can be classified according to whether it results from systemic factors or from the local microenvironment (see Ch. 105)[12]. A chronic wound is a symptom of an underlying disease, rather

DIFFERENT TYPES OF MATRIX METALLOPROTEINASES INVOLVED IN WOUND REPAIR	
Enzyme	**MMP number**
Collagenase-1	MMP-1
Collagenase-2	MMP-8
Collagenase-3	MMP-13
Collagenase-4	MMP-18
Stromelysin-1	MMP-3
Stromelysin-2	MMP-10
Stromelysin-3	MMP-11
Gelatinase-A	MMP-2
Gelatinase-B	MMP-9
Matrilysin	MMP-7
Macrophage metalloproteinase (elastase)	MMP-12
MT1-MMP	MMP-14

Table 141.3 Different types of matrix metalloproteinases (MMPs) involved in wound repair. MT1, membrane-type 1.

than a disease entity. The most common systemic factors influencing wound repair are venous insufficiency, advanced age, ischemia and diabetes mellitus-associated microangiopathy (see Fig. 105.1), and, less often, vasculitis, hypercoagulability, malnutrition, and concomitant therapies (e.g. hydroxyurea, immunosuppressives). Local factors include inadequate blood supply, necrotic tissue, increased proteolytic activity, mechanical irritation, pressure, bacterial components, local toxins, and growth factor deficiency. Each of these factors has to be critically considered when assessing factors responsible for impaired healing and when outlining a treatment regimen for a non-healing wound.

Wound Healing and Aging

The prevalence of chronic wounds in the population increases with age[52,53], as does the prevalence of venous hypertension, peripheral artery disease and diabetes mellitus. Aging can be regarded as an accumulation of molecular changes that leads to functional failure in different tissues, including impaired wound healing.

Human aging may be triggered by two principal mechanisms: telomere shortening (see Fig. 67.21) and DNA damage. Telomere shortening or dysfunction leads to instability of chromosomes, and a functional link between age-dependent telomere shortening and impaired wound healing has been demonstrated in telomerase-deficient mice (telomerase is an enzyme that prevents telomere shortening)[54]. How telomere shortening translates into impaired cell function during the healing response is not understood. Furthermore, mice with increased activation of the transcription factor p53 within the epidermis develop an early aging phenotype of their skin with impaired wound healing[54a].

THERAPEUTIC OPTIONS FOR CHRONIC WOUNDS

Wound Dressings

A large variety of wound dressings is currently available, with recommendations for particular dressings based upon characteristics of the wound (see Ch. 145). Clinical experience, rather than controlled trials, forms the basis of many of these recommendations. There is still no consensus on the mechanisms of action, but most dressings are thought to support wound healing by acting as a barrier between the wound and the environment, by preventing drying of the tissue[55–57], or by allowing autolytic debridement. Only a few dressings appear capable of interfering with cellular and molecular mechanisms of the wound microenvironment or to counteract mechanisms that are considered hostile for repair. Of note, controlled trials have shown the benefit of compression therapy in the case of venous ulcers.

Growth Factors

As outlined previously, growth factors are essential regulators of cell function during repair. Experimental studies have shown that the topical application of certain growth factors can modify and probably even accelerate wound repair[43,44]. Based on these observations, clinical studies to determine whether tissues with inherently poor or pathologically altered healing potential could profit from therapeutic growth factor interventions have been conducted. PDGF-BB was the first, and to date the only, recombinant growth factor to be approved for the topical treatment of diabetic foot ulcers (see Ch. 105). The efficacy of perilesional injections of granulocyte–macrophage colony-stimulating factor (GM-CSF) awaits further studies, but in transgenic mice where an antagonist of GM-CSF was overexpressed in the epidermis, delayed wound healing was observed, suggesting a role for this growth factor.

The limited success of clinical trials with peptide growth factors underscores an important aspect of the growth factor/tissue repair paradigm: the effective delivery of these polypeptides to the wound site. The latter is biologically and biochemically complex, and in situations such as a chronic or infected wound, the environment is hostile to repair. Current drug delivery strategies suffer from the inherent loss of drug activity due to the combined effects of physical inhibition and proteolytic degradation. While this may account for some of the limited success of clinical studies, a key factor is a poor blood supply. A combined molecular and genetic approach, where genetically modified cells synthesize and deliver the desired growth factor in a time-regulated and locally restricted manner to the wound site, may overcome some of the limitations inherent to the local application of recombinant growth factors.

Cell-Based Therapies

When skin defects are too large to heal by second intention, skin grafts and cell-based treatments may be used to cover the wound and to replace the defect. Split-thickness skin grafts are most commonly used for the treatment of acute surgical or chronic wounds (see Ch. 148), as are "pinch" grafts. The latter are 2–5 mm superficial skin biopsies, often obtained from the anterolateral thigh, that are placed dermis-down in a clean wound bed.

Numerous efforts have been directed toward the development of skin substitutes with qualities similar to native skin in order to aid in the healing of acute surgical or chronic wounds as well as extensive thermal burns[58]. Both autologous and allogeneic components have been incorporated into bioengineered human skin equivalents (see Ch. 145), and several clinical studies have demonstrated a beneficial effect on chronic wounds refractory to conventional therapy. However, these skin substitutes tend to be expensive and grafted cells are eventually lost.

FUTURE DIRECTIONS

Current limitations in the treatment of chronic wounds are due to the incomplete understanding of the molecular mechanisms hindering repair. Therefore, the success of novel therapies depends upon a comprehensive knowledge of the underlying pathomechanisms and correction of pathogenic factors. Advances in molecular and cellular biology, as well as in material sciences, have broadened research and it is expected that those findings, together with a better understanding of the molecular aspects of tissue repair, will lead to the development of enhanced therapeutic modalities.

Gene Therapy

Effective local treatment of chronic wounds requires an adequate delivery of drugs or proteins that promote healing of the injured tissue. A critical issue is optimizing this delivery. A molecular genetic approach in which genetically modified cells synthesize and deliver the desired peptide factor (e.g. growth factor) in a time-regulated manner may overcome the limitations associated with simple topical application.

In various animal models, different gene delivery technologies (*ex vivo* and *in vivo*) have been investigated and successfully applied to tissue repair[59]. Despite the fact that *ex vivo* techniques (i.e. *in vitro* gene transfer and subsequent cell transplantation; see Ch. 3) have been shown to be safe and successful in various experimental models of

tissue repair, to date only direct *in vivo* gene transfer approaches have been tested for wound repair in humans.

Recently, a phase I/II clinical trial evaluating the safety and potential clinical utility of topical applications of a gene that encodes PDGF-B and is contained within an adenoviral vector formulated in a bovine collagen matrix (gene-activated matrix) was published[60]. This treatment regimen did not appear to have any toxicity at doses that showed biologic activity and is promising as treatment for non-healing diabetic foot ulcers. Furthermore, there is a phase II clinical trial investigating the overall safety and clinical outcome of a gene therapy approach for peripheral artery disease based on a hepatocyte growth factor (HGF) plasmid vector. Evaluation includes reduction of amputation and mortality rates, speed of wound healing, rest-pain reduction, and improvement in subject's ability to function without adverse consequences on quality of life (www.clinicaltrials.gov).

Stem Cells

Recent advances in stem cell biology may provide novel treatment strategies for acute and chronic wounds (Fig. 141.12)[40]. There is great interest in the delivery of stem or progenitor cells (see above), either applied topically or via stimulation of their recruitment from the circulation into the wound site. Preliminary work suggests that topically applied autologous bone marrow-derived cells promote the healing of treatment-resistant chronic wounds[61]. Furthermore, recruitment of $CD34^+$ cells from the circulation has shown promise in ischemic limbs[61a]. However, stem cell therapy still poses many questions regarding timing of stem cell application, stem cell survival and differentiation within the hostile "chronic wound" environment, and potential side effects.

Molecular Modeling of Growth Factors

Advances in the field of biomaterial science and protein engineering are expected to contribute to the development of novel therapies for tissue repair. For example, the development of protease-resistant growth factors might circumvent the imbalance in proteolytic activity that is characteristic of chronic wounds[62]. Moreover, growth factors engineered for enhanced binding to ECM molecules had an augmentation of their biologic properties with regard to tissue repair[63]. This approach not only utilizes the ECM as a carrier, but it also mimics the natural interactions between growth factors and the ECM, which appears to be crucial for the physiologic actions of growth factors.

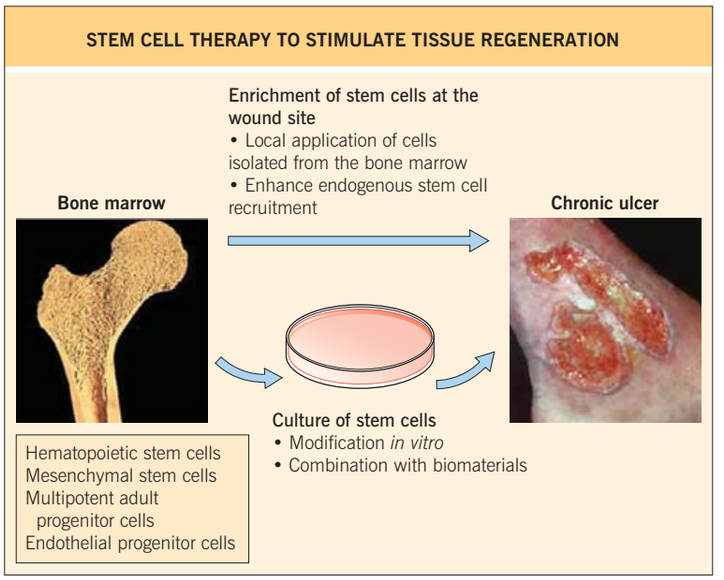

Fig. 141.12 Stem cell therapy to stimulate tissue regeneration. Wounding stimulates the engraftment of bone marrow-derived stem/progenitor cells to the skin and induces bone marrow-derived cells to incorporate into skin structures. Therefore, bone marrow might provide a valuable source of stem cells for skin repair.

Muscles of facial expression 2334
Vascular anatomy 2335
The facial nerve 2336
Sensory innervation of the head and neck 2338
Lymphatic drainage of the head and neck 2340

Key features

- The muscles of facial expression all arise from the second branchial arch, are concentrated in the central facial region, and receive their motor innervation from the facial (7th cranial) nerve
- The superficial musculoaponeurotic system (SMAS) is a fibromuscular layer that ensheathes and connects the facial muscles and plays an intricate role in coordinating facial expressions
- The SMAS can be utilized as a guide to dissection, tissue mobilization and closure, minimizing trauma to neurovascular tissues
- The three branches of the trigeminal (5th cranial) nerve provide sensory innervation to the face, while various branches of the cervical plexus provide sensory innervation to the neck, parts of the ear, and posterior scalp
- Familiarity with the muscular and neurovascular structures of the head and neck region allows the surgeon to properly approach the "danger zones", e.g. Erb's point in the neck, the temporal nerve as it crosses the zygomatic arch, and the marginal mandibular nerve at the jawline just anterior to the masseter muscle
- The rich and anastomosing vascular supply of the face and scalp, derived from both the external and internal carotid arteries, explains the excellent healing potential and viability of local flaps and grafts in this region
- Cosmetic subunits and the junction lines separating them should be considered when planning excisions, repairs and cosmetic procedures of the head and neck

The dermatologic surgeon must have a comprehensive knowledge of regional anatomy in order to obtain acceptable operative results. Tissue movement on the face and neck must be considered in order to obtain closure under minimal tension without cosmetic distortion or functional loss of vital structures. Preservation of tissue viability, sensory and motor innervation, and prevention of postoperative morbidity can be achieved with a fundamental appreciation for the macromechanics of the head and neck[1,2]. The fascial planes, vascular supply, innervation, and aesthetic subunits of the face must be considered when planning a surgical or cosmetic procedure. In order to accurately and thoroughly counsel patients regarding procedural risks and benefits, the surgeon must have a thorough appreciation of head and neck anatomy.

TOPOGRAPHIC ANATOMY OF THE HEAD AND NECK

It is possible to pinpoint underlying anatomic structures of the head and neck by observing surface anatomy. The bony structure of the face serves as a simple anatomic framework (Fig. 142.1). The supraorbital ridges are formed by the frontal bone and are more prominent in men. The supraorbital foramen transmits the sensory supraorbital nerve (from the ophthalmic division of the trigeminal nerve), artery and vein. It is palpable on the bony supraorbital ridge at the vertical midpupillary line. This line lies approximately one finger-breadth lateral to the lateral nasal root or 2.5 cm lateral of the midline on the face (Fig. 142.2). Other important foramina lie in this midpupillary line and transmit important neurovascular bundles. The infraorbital foramen is located 1 cm below the infraorbital rim in the midpupillary line. It transmits the sensory infraorbital nerve (from the maxillary division of the trigeminal nerve) and its associated artery and vein. The mental foramen lies in the same vertical line in the midportion of the mandible. The mental neurovascular bundle emerges here as a terminal sensory branch of the mandibular division of the trigeminal nerve.

The anterior border of the temporalis muscle can be palpated in the temporal fossa above the zygomatic bone. The latter bone forms the malar eminence of the cheek. The buccal fat pad provides fullness to the cheek; elderly or cachectic patients often have very prominent zygomatic arches. These arches form the widest points on the face and serve as the point of attachment for several muscles of facial expression and for a muscle of mastication called the masseter. The masseter muscle spans the zygomatic arch and mandibular ramus, serving as a muscle of mastication innervated by a motor branch of the trigeminal nerve (see below). This muscle is easily palpated by clenching the jaw.

The parotid gland lies beneath the subcutaneous fat of the lateral cheek and is invested by parotid fascia. The superficial lobe of the parotid covers the posterior half of the masseter muscle and extends from the preauricular sulcus to the angle of the mandible. The deep lobe lies on the medial side of the ramus of the mandible and is connected to the superficial lobe by an isthmus. The superficial temporal artery and vein, as well as branches of the facial nerve (which provides motor innervation to the muscles of facial expression), course through the parotid gland in channels between glandular tissue[3]. The duct of the parotid gland (Stensen's duct) travels across the anterior surface of the masseter muscle (Fig. 142.3). After crossing the muscle surface, the duct penetrates deeper to pierce the buccinator muscle and eventually drains into the mouth at the level of the second upper molar. It can be palpated as a "cord" crossing a clenched masseter muscle. If the duct is transected, a chronic draining fistula will form, requiring corrective surgical intervention. Stensen's duct can be identified topographically by drawing a line between the tragus and the midportion of the cutaneous upper lip. The duct traverses the masseter muscle at the middle one-third of this line (see Fig. 142.3).

Several structures of importance can be located by observing the surface anatomy of the neck. The sternocleidomastoid muscle comprises two heads originating from the sternum and the medial one-third of the clavicle. It inserts onto the outer surface of the mastoid process and nuchal ridge, dividing the neck into anterior and posterior triangles. A dermatologic surgeon should be familiar with the anatomic structures that lie within each of these topographic triangles (Fig. 142.4). Although the sternocleidomastoid muscle covers and protects most of the major anatomic structures in the neck, the external jugular vein traverses its surface with many cutaneous sensory nerves of the cervical plexus. In addition, the posterior triangle of the neck contains trunks of the brachial and cervical plexus as well as the spinal accessory nerve

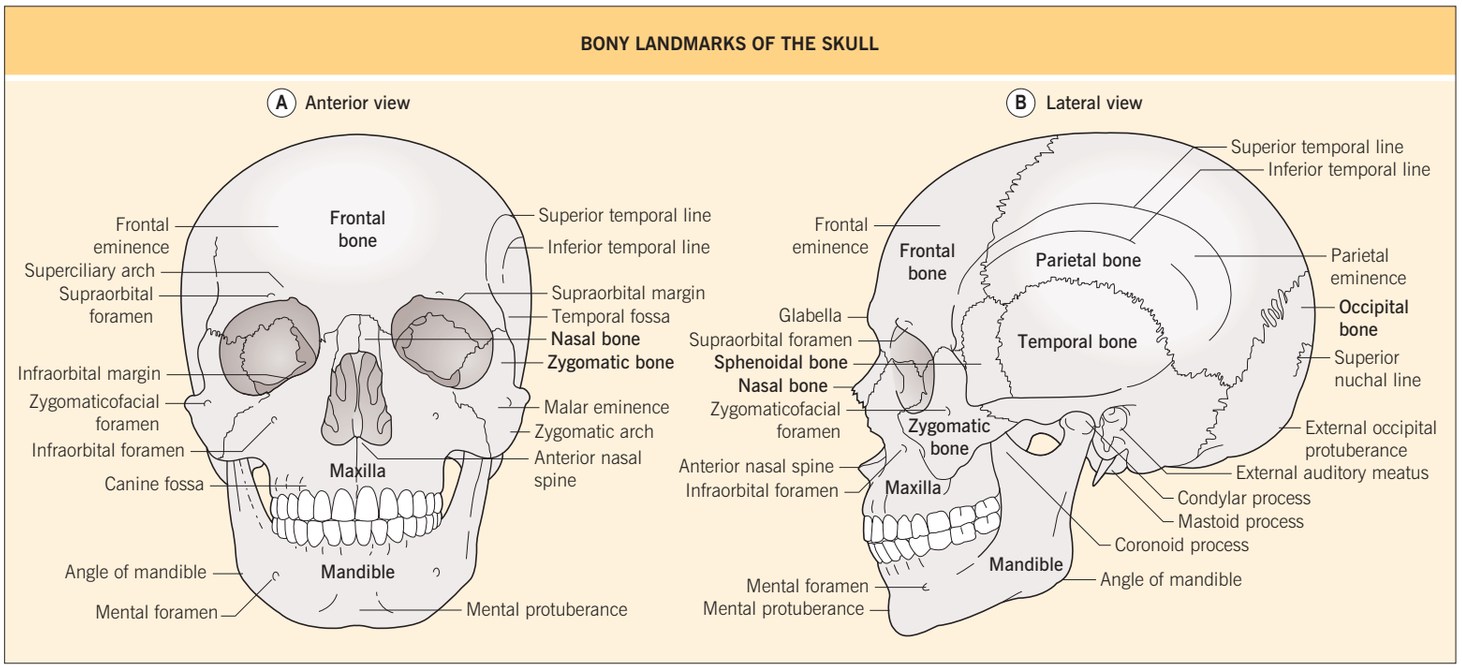

Fig. 142.1 Bony landmarks of the skull. A Anterior view. **B** Lateral view.

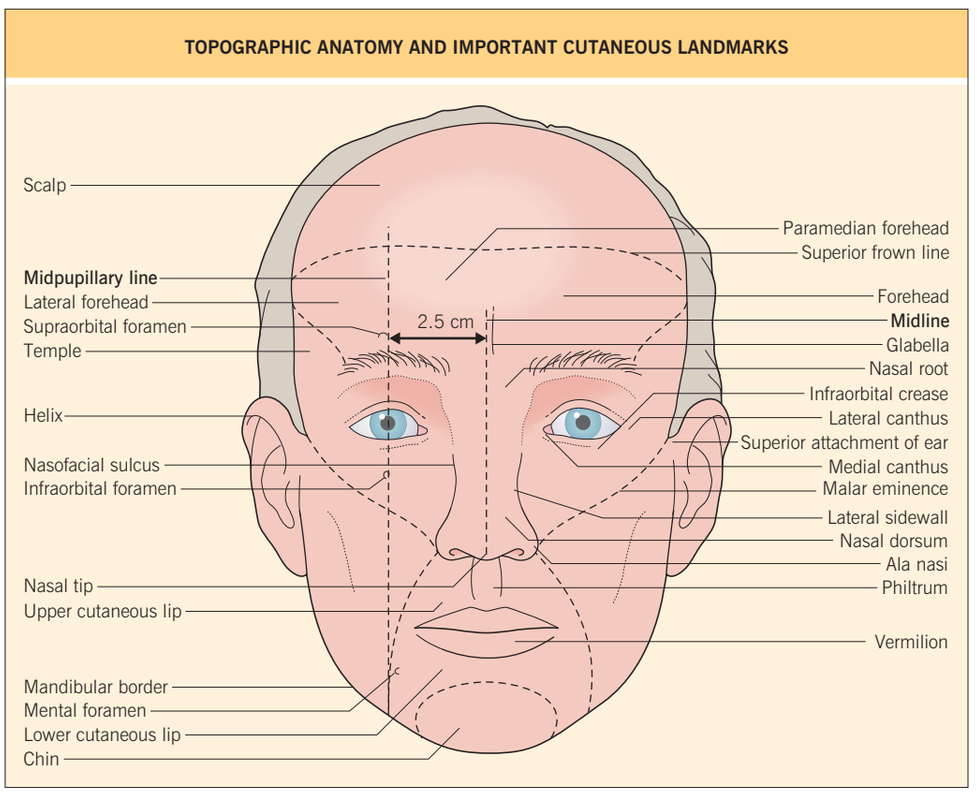

Fig. 142.2 Topographic anatomy and important cutaneous landmarks.

(cranial nerve XI). Cranial nerve XI innervates the trapezius muscle of the back. It may be damaged when operating in this posterior triangle. This may result in chronic shoulder and neck pain, shoulder drop and trapezius atrophy, arm paresthesias, and the inability to abduct the arm greater than 80°.

Erb's point designates the area where the cervical plexus emerges from the posterior margin of the sternocleidomastoid muscle (see Figs 142.4 & 151.6). The spinal accessory nerve courses through this area on its way to the trapezius muscle. This surgical danger zone can be visualized by drawing a line connecting the angle of the jaw to the mastoid process. In an adult, a perpendicular line dropped 6 cm from the midpoint of this connector will intersect the posterior border of the sternocleidomastoid where the spinal accessory nerve and cervical plexus emerge[4]. Extreme caution is warranted when dissecting around these anatomic structures, in order to avoid loss of innervation to the trapezius muscle.

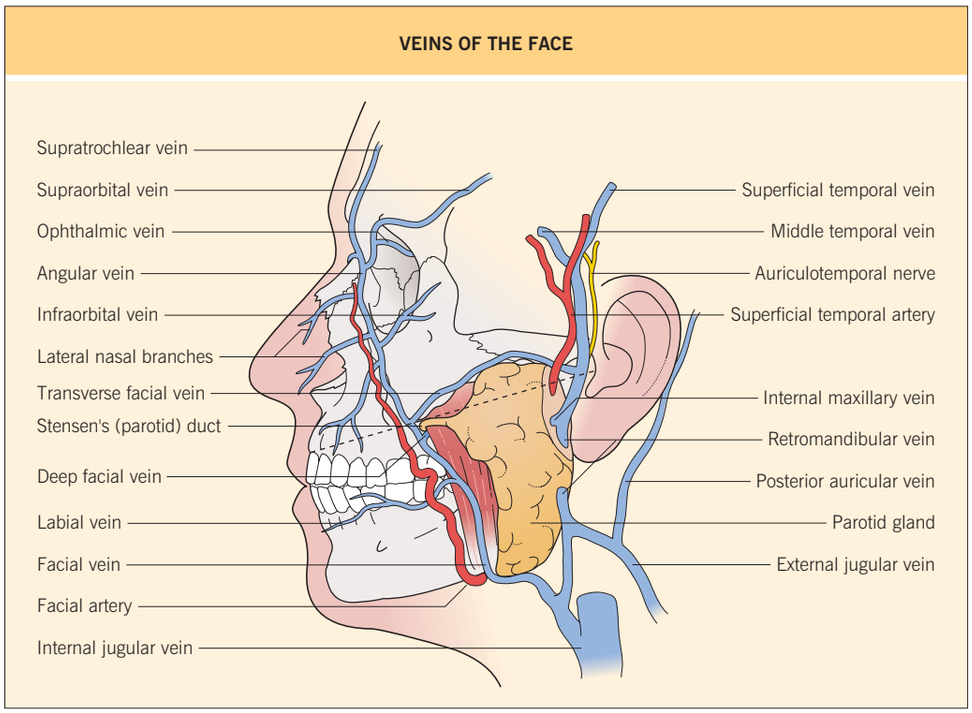

Fig. 142.3 Veins of the face. Stensen's duct can be identified topographically by drawing a line between the tragus and mid portion of the cutaneous upper lip (dotted line). It can be palpated as a cord at the middle third of this line.

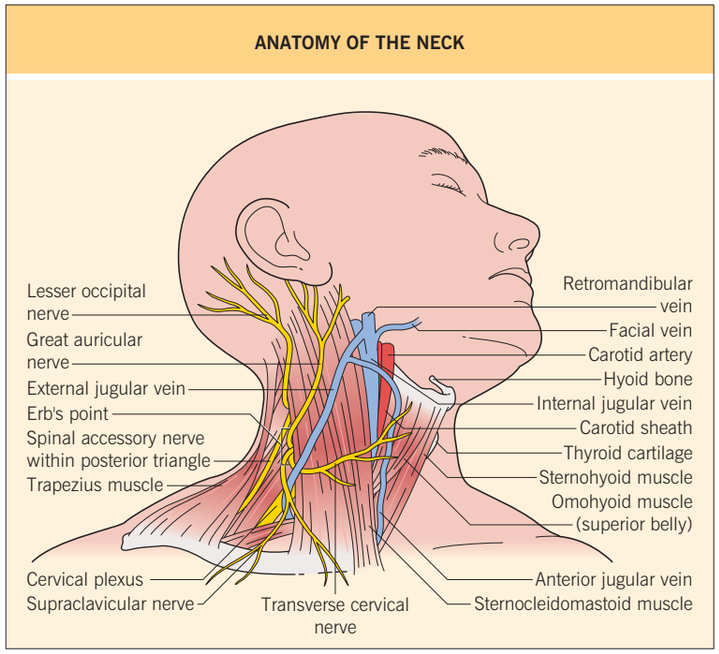

Fig. 142.4 Anatomy of the neck.

THE SUPERFICIAL MUSCULOAPONEUROTIC SYSTEM

The superficial musculoaponeurotic system (SMAS) or superficial fascia of the head and neck region plays an intricate role in coordinating and exaggerating facial expressions. It is a fibromuscular layer that ensheathes and connects the facial muscles. When the regional muscles contract, their impulse is distributed by the SMAS via fibrous connections to the skin and other muscle groups. This contributes to organized movements, symmetry in facial expression, and the appearance of skin tension lines. In certain areas where facial musculature is absent, the SMAS layers form a thick, inelastic membrane. These regions are clinically identifiable as the galea aponeurotica of the scalp and the superficial temporalis fascia. Major anatomic structures predictably course in and around the superficial fascia. The dermatologic surgeon can maximize this relatively avascular dissection plane and minimize trauma to important neurovascular structures by using the SMAS as a guide to dissection, tissue mobilization, and closure. Rejuvenation procedures such as facelifts rely on the redistribution and manipulation or plication of the head and neck SMAS.

The deep fascia of the face covers bone, cartilage, muscles of mastication, and visceral structures. It is a continuous sheath, forming periosteum, perichondrium, temporalis muscle fascia, and the parotid-masseteric fascia[1]. This fascia is resistant to stretch and particularly impedes tissue movement on the scalp. Plication or suspension sutures are often used to "tack" overlying structures to the deeper fascia in order to secure tissue and redirect tension vectors.

The SMAS of the cheek is located between the skin and the deeper muscles of mastication. By mobilizing the preauricular SMAS plane, the anterolateral neck and lower cheek below the zygomatic arch can be repositioned as a whole. The SMAS of the cheek is continuous with the orbicularis oculi muscle of the lower eyelid and has several bony attachments in the periocular region[5]. Note that the SMAS of the upper face is discontinuous with the SMAS below the zygoma. Different embryologic development patterns of the upper and lower facial muscle groups account for this separation. The galea aponeurotica of the scalp and the fascia of the superficial temporalis muscle split to envelop the frontalis muscle of the forehead and the occipitalis muscle of the posterior scalp. This superior SMAS terminates 1 cm below the zygomatic arch.

The parotid gland, Stensen's duct, and emerging branches of the facial nerve lie on the deep masseteric fascia. They are covered by thin fibrotic platysma remnants called the parotid fascia, which is covered by the SMAS. The aponeurotic investiture of the central face is thin and often indistinct. The intrinsic nasal muscles and lip elevators and depressors are essentially devoid of superficial fascial interconnections. This makes dissection in this area challenging, because the planes are often difficult to establish and many important anatomic structures are under threat of compromise.

Large sensory nerves and axial blood vessels that supply the face ascend to lie within the SMAS or between the SMAS and subcutaneous fat (Fig. 142.5). Motor nerves run deep to the SMAS and penetrate the muscles of facial expression from their undersurface. Knowledge of these anatomic relationships assists the surgeon in establishing a relatively avascular and safe plane of dissection. Blunt dissection of the scalp SMAS separates the galea aponeurotica from the skull periosteum, the superficial temporalis fascia from the deep temporalis fascia, and the subfrontalis SMAS from the forehead periosteum. This is called

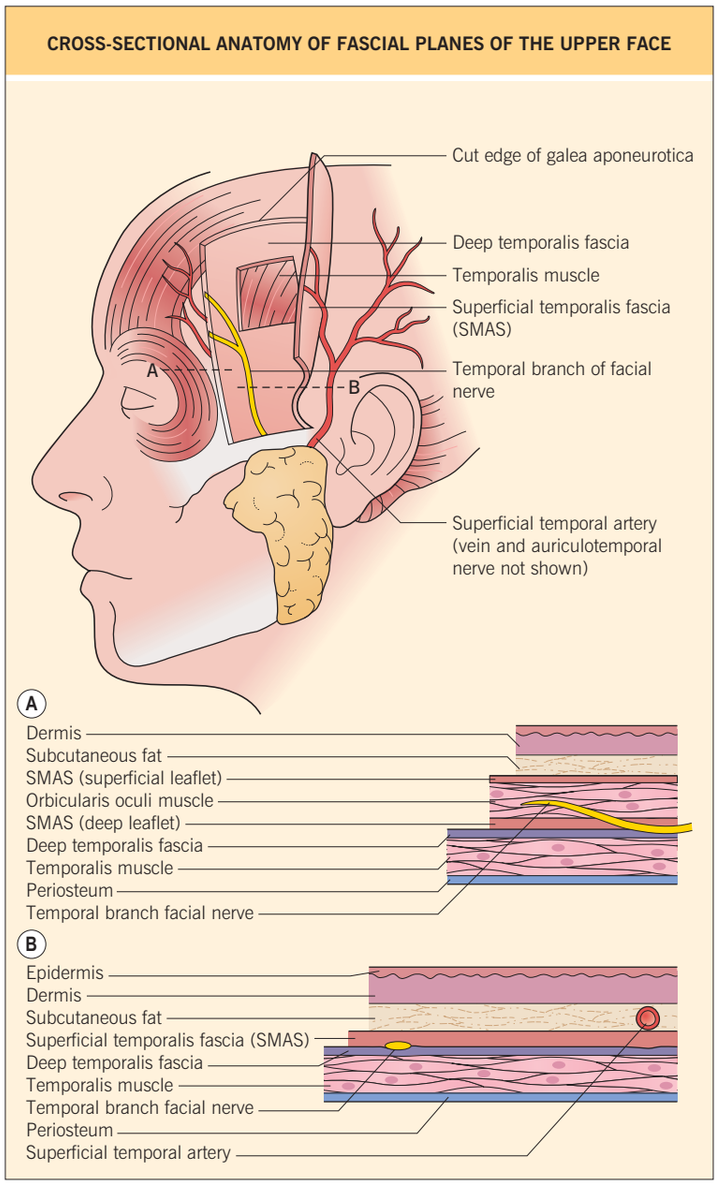

Fig. 142.5 Cross-sectional anatomy of fascial planes of the upper face. SMAS, superficial musculoaponeurotic system.

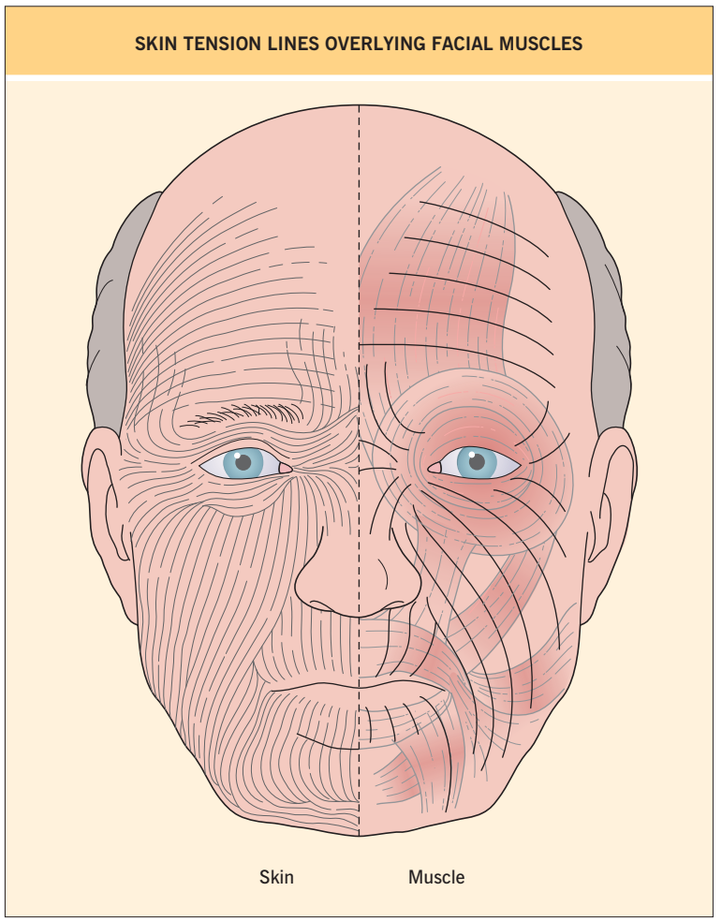

Fig. 142.6 Skin tension lines overlying facial muscles. Note that wrinkles are often directed perpendicularly to the underlying muscle fibers of facial expression.

the subgaleal plane, and it is the ideal avascular dissection plane for scalp surgery. Beware of the supraorbital/supratrochlear neurovascular bundles above the eyebrows when dissecting to the deep galea, as these can be damaged as they exit the inferior frontalis muscle origin. In the SMAS-parotid fascial plane of the cheek, the buccal and zygomatic branches of the facial nerve are endangered due to thin protective aponeurotic tissue in this area. The superficial temporal vessels and auriculotemporal nerve course within the superficial temporalis fascia above the zygomatic arch, then assume a superficial plane in the subcutaneous fat.

Surgical undermining and dissection should maximize the horizontal planes provided by the superficial fascial network of the head and neck. Undermining in the subcutaneous fat of the face below the subdermal plexus minimizes the risk to motor nerves, but remember that sensory branches and blood vessels do course through this area. There is sparse subcutaneous fat on the dorsal nose, forehead, upper lip, and eyelid. The ideal dissection plane in these regions lies just superficial to the thin investing fascia (SMAS) covering the regional muscles of facial expression[6].

In short, the SMAS acts as a unifying infrastructure to the head and neck that creates an anatomic plane for identification and protection of key structures. Knowledge of neurovascular anatomy with respect to the superficial investing fascia will promote effective surgical dissection and closures that minimize functional compromise and maximize cosmesis.

SKIN TENSION LINES

Collagen and elastin afford flexibility and extensibility to the skin, and derangements of their architecture or abundance contribute to the aging process. Wrinkles (rhytides) develop over time in predictable areas on the face. The fine wrinkles seen on an aged face may be referred to as the skin tension lines (Fig. 142.6); on the body, skin tension lines (Fig. 142.7) are an important consideration when designing surgical excisions (see Ch. 146). Many environmental and intrinsic factors, such as ultraviolet exposure, smoking, underlying facial muscles, etc., contribute to the appearance of the expressive human face. A thorough understanding of the derivation and implications of skin tension lines is essential to successful dermatologic surgery.

Continuous tension is exerted on the skin of the head and neck by the muscles of facial expression. A complicated network composed of muscles, fibrous septae of collagen, elastin and fascial planes contributes to this stress, which eventually results in sagging, wrinkling and redundant skin. Collagen is flexible but much less extensible than elastic fibers. The resistance to tensile forces by collagen promotes a "youthful" appearance. Over time, the prolonged tension exerted on the skin from many factors forces collagen fibrils to accommodate by way of elongation. Eventually, aged skin manifests the consequences of persistent skin tension. The collagenous tissue becomes increasingly intertwined, diminished in volume, and permanently elongated. This causes the accentuation of skin tension lines[4].

Elastic fibers promote extensibility (i.e. the ability of skin to stretch) and elasticity (i.e. the skin's capacity to restore its original shape after physical stress). They contribute to the skin tension lines by promoting vector distribution of tension along fascial planes. The elastic properties

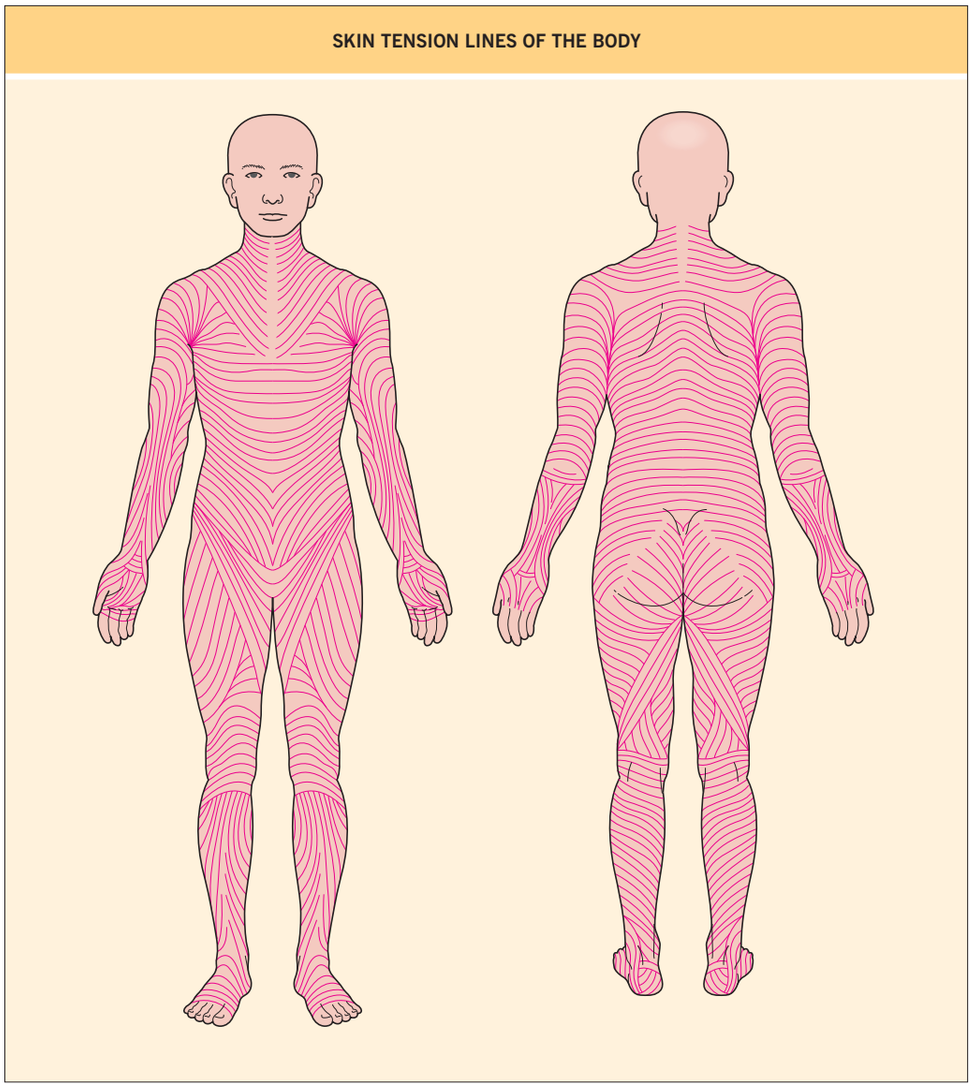

Fig. 142.7 Skin tension lines of the body.

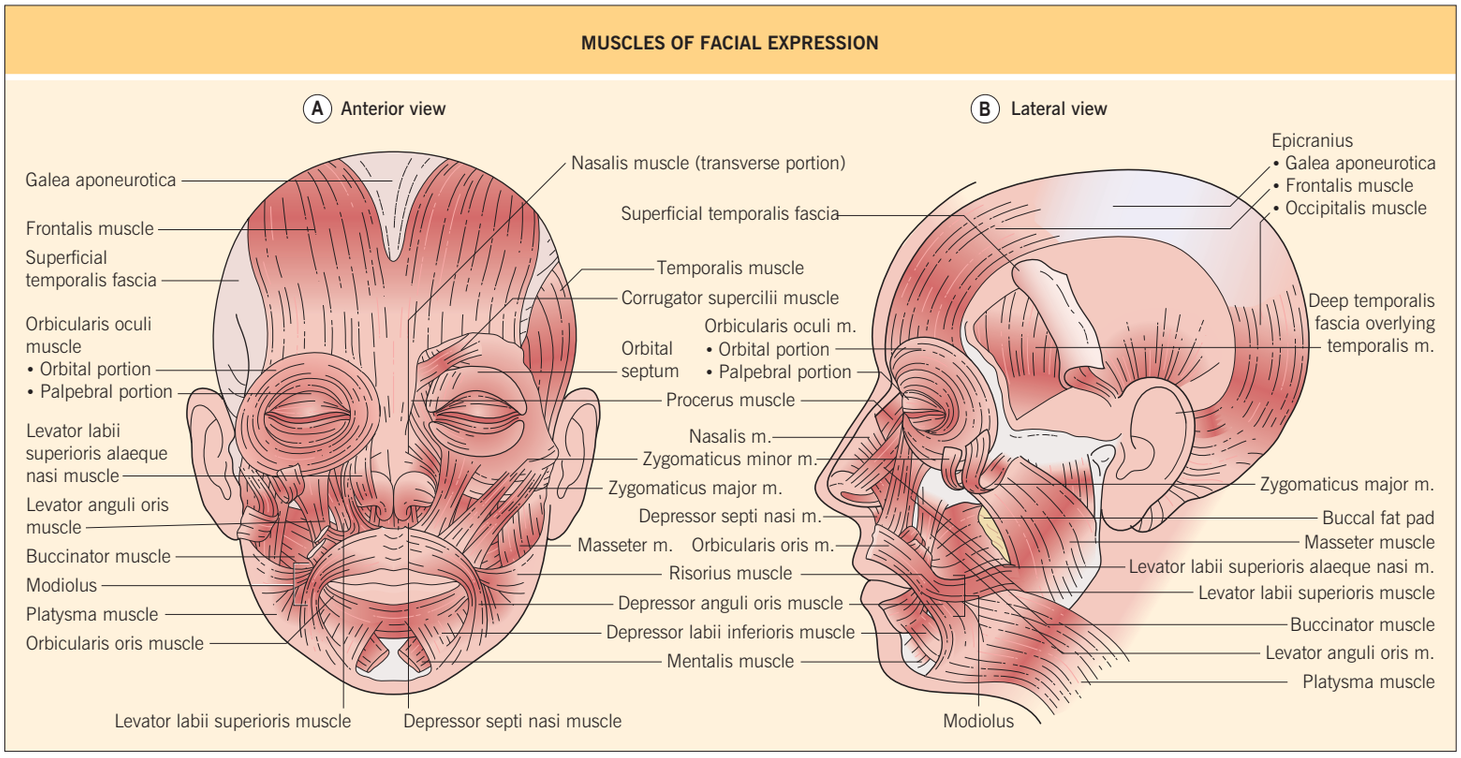

Fig. 142.8 Muscles of facial expression. A Anterior view. **B** Lateral view. The transverse portion of the nasalis muscle is identified. m, muscle.

of the skin explain the phenomenon whereby round surgical wounds relax into an axis parallel to the patient's wrinkles. Tension vectors are increased parallel to the skin tension lines and are diminished perpendicular to them; therefore, the linear appearance of wrinkles is often directed perpendicularly to the underlying muscle fibers of facial expression (see Fig. 142.6). The continuous tension exerted on the overlying skin by these muscles challenges the competency of elastic tissue and collagen. They induce this geometric linearity via fibrous connections to the dermis via the SMAS. For example, the forehead undergoes transverse wrinkling due to contractions of the frontalis muscle, whose fibers run in a cephalocaudad direction. Periocular rhytides are often radially oriented due to underlying contraction of the orbicularis oculi. Similarly, perioral wrinkling occurs under the influence of the concentric orbicularis oris muscle, which induces a radial arrangement of skin tension lines as well. The procerus muscle causes transverse nasal root lines, and vertical glabellar lines are determined by the corrugator supercilii muscles (Fig. 142.8).

Knowledge of these functional anatomic principles is necessary in surgical and cosmetic dermatology. For example, the successful use of botulinum toxin for the diminution of rhytides requires an understanding of the anatomic relationships between various muscle groups and their influence on the skin tension lines. Proper surgical technique entails placement of incision lines parallel to the skin tension lines in order to achieve excellent cosmesis. It is helpful to determine and even sketch the patient's skin tension lines with a gentian violet pen. This will help orient the axis of incision and guide the closure parallel to and preferably "buried" within individual lines of tension.

There is often a significant amount of recruitable or "redundant" skin within the skin tension lines. In addition, "extra" skin may also be found in the preauricular folds, glabella, nasolabial folds, and the "jowls" or lower cheeks[7]. These tissue reservoirs can be used as donor sites for flaps (see Ch. 147) and grafts (see Ch. 148) in order to achieve surgical closure under minimal tension.

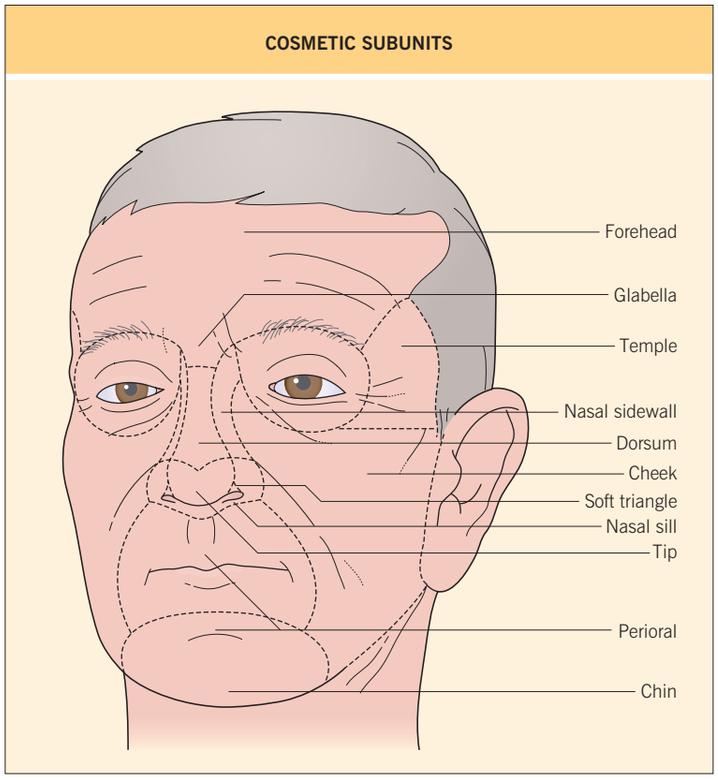

Fig. 142.9 Cosmetic subunits.

COSMETIC SUBUNITS

Cosmetic units (i.e. aesthetic, topographic or regional units) represent the major structural areas of the face that are separated by contour or junctional lines or boundaries (Fig. 142.9). Units are designated based upon their similarity in topographic anatomy, texture and color, solar exposure, hair density, and sebaceous features. The forehead, temples, eyelids, nose, cheeks, upper and lower lips, chin, and ears represent the major cosmetic subunits of the face. Within each division, smaller units are designated that further guide surgical closures. The junctional or contour lines between cosmetic units serve as excellent locations to place incisions and hide surgical scars. They include the hairline, alar and nasolabial creases, eyebrows, the philtrum, the labiomental crease,

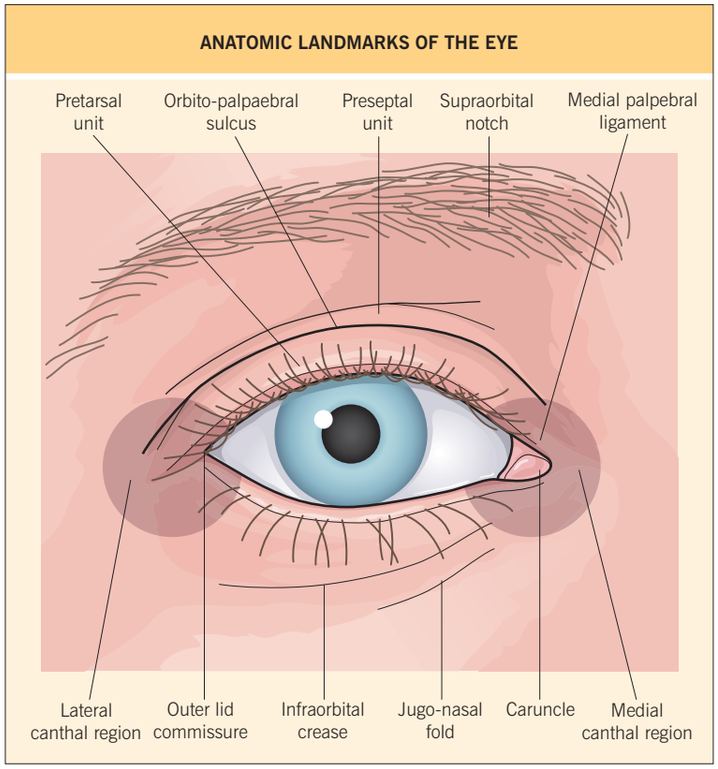

Fig. 142.10 Anatomic landmarks of the eye.

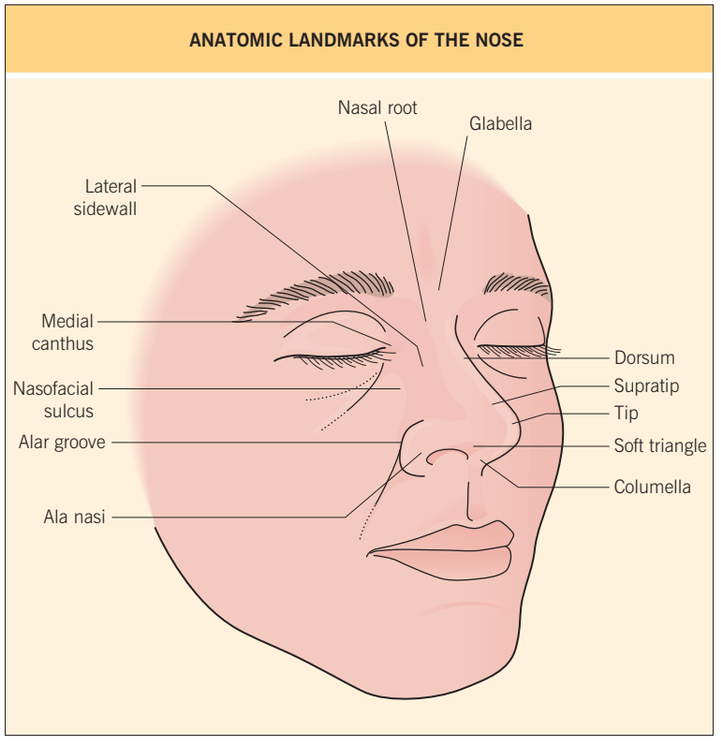

Fig. 142.11 Anatomic landmarks of the nose.

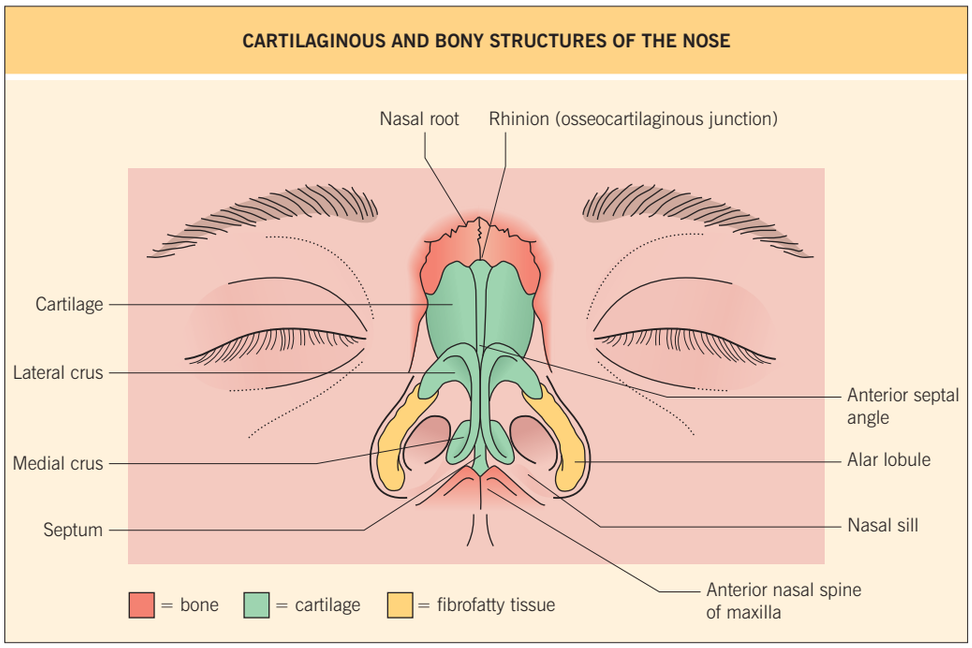

Fig. 142.12 Cartilaginous and bony structures of the nose.

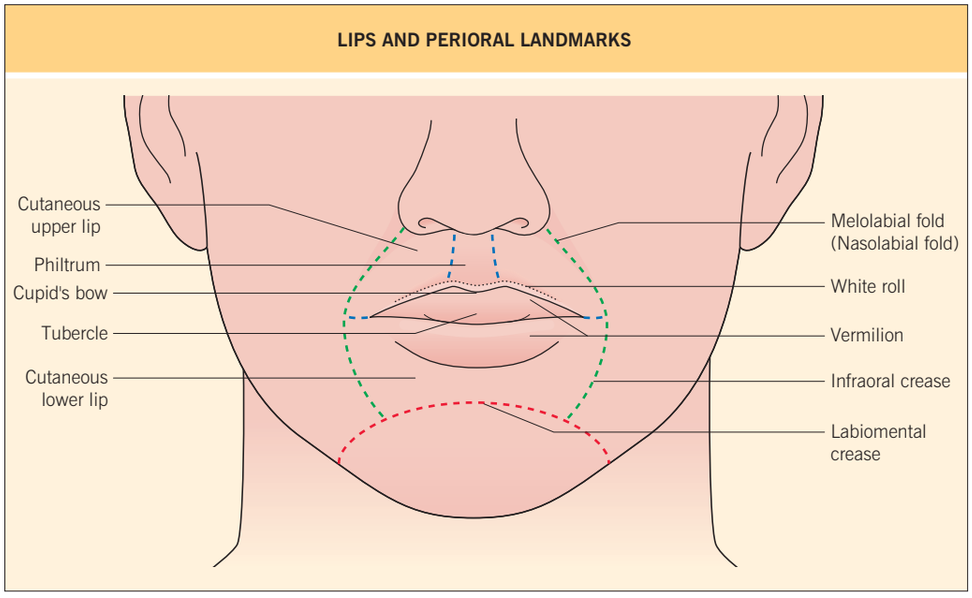

Fig. 142.13 Lips and perioral landmarks.

and the upper and lower vermilion–cutaneous interfaces (see Figs 142.2 & 142.13).

In general, defects should be repaired with tissue from within the same cosmetic unit in order to preserve topographic consistency and to match skin color and texture. If this cannot be achieved, it is reasonable to utilize tissue from an adjacent aesthetic unit, which will most closely match the skin of the recipient cosmetic unit. The goal is to optimize the match in skin texture, color, actinic damage and thickness. Scars that cross aesthetic units and boundary lines are obvious and often cosmetically unacceptable. A primary goal of cutaneous surgery is to "respect" the cosmetic subunits.

An appreciation for cosmetic units and contour lines also helps the surgeon determine areas of "recruitable" tissue for closures. Redundant or freely mobile skin can be mobilized from the preauricular folds, neck, nasolabial folds, temple, glabella, the lower and lateral cheeks, and the "jowls". The potential for such tissue recruitment depends on the patient's age, degree of actinic damage and skin elasticity, which varies from patient to patient. Areas of redundancy or high elasticity may serve as excellent donor sites within or adjacent to the cosmetic subunit which contains a given surgical defect. For example, cheek advancement flaps and temple to lateral forehead advancement and rotation flaps are frequently used for defect repairs.

The forehead unit can be divided into the glabella, temple and supraeyebrow aesthetic subunits. The transverse creases of this region serve as excellent sites to place cosmetically acceptable incisional scars. The eyelids represent a major cosmetic subunit of the face whose subdivisions correspond to portions of the orbicularis oculi muscles[8] (Fig. 142.10). The inferior pretarsal portion of the upper eyelid is relatively fixed, while the preseptal unit becomes increasingly redundant with age. Over time, progressive laxity of the preseptal unit can cause functional visual impairment in some patients. It is the preseptal unit of the palpebral portion of the lid that is reduced in blepharoplasties. The infraorbital crease lies between the lower eyelid and the upper cheek.

Nasal cosmetic subunits include the alar groove (which defines the ala nasi) and the columella, which extends from the nasal tip to the junction with the upper cutaneous lip. The dorsum, lateral sidewalls, soft triangles, root and nasal tip are important landmarks that pose a significant challenge in dermatologic surgery (Fig. 142.11). The nasal tip unit forms the shape of a chevron or heart due to the anatomy of the nasal cartilage (Fig. 142.12). When possible, surgical defects should

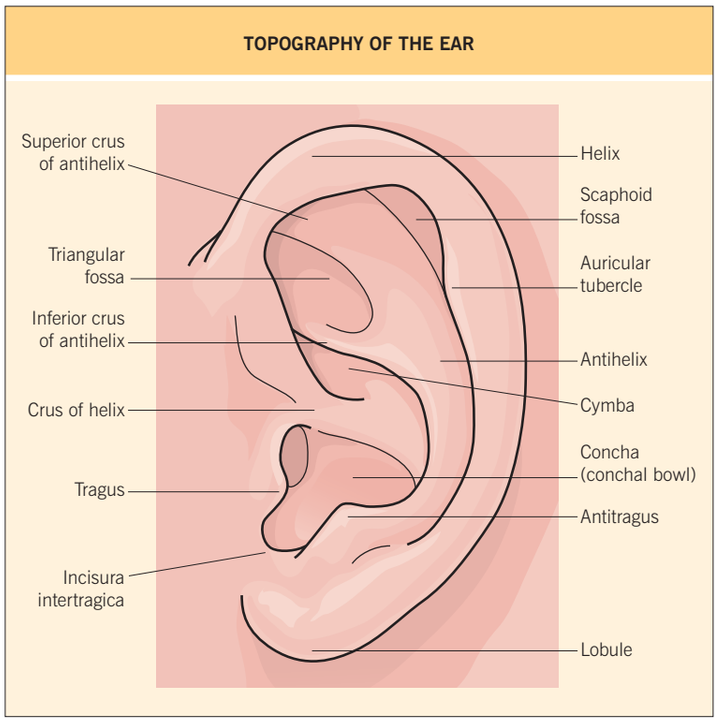

Fig. 142.14 Topography of the ear.

be contained within the boundaries of a given nasal subunit in order to effect acceptable cosmesis[9].

The philtrum is located above the upper vermilion lip and extends superiorly to the columella of the nose (Fig. 142.13). Because it is a midline structure, even minimal anatomic distortion results in a poor cosmetic outcome. The vermilion lip extends from the vermilion lip–cutaneous junction to the mucous membrane junction. It is a modified epithelium that usually does not contain adnexal structures or salivary glands. Approximation of the vermilion borders is crucial to maintaining facial symmetry. The melolabial or nasolabial crease serves as a useful landmark that separates the cheek from the mouth and chin aesthetic units. It is an ideal place to hide suture lines and often serves as a generous donor site for repairs.

The external ear (auricle or pinna) consists of a single cartilaginous plate that results in the complex curves and folds of the ear (Fig. 142.14). The skin is loose on the posterior portion but tightly adherent on the anterior surface.

FREE MARGINS

Free margins of the face are anatomic structures that are in some way discontinuous with adjacent skin. They include the lips, helices, eyelids and nostrils. These areas deserve special attention from the dermatologic surgeon because they do not have evenly distributed tension vectors. This characteristic makes the free margins especially vulnerable to any iatrogenic directional pull. Surgical closures, wound healing and scar contraction can cause these free margins to lose their cosmetic or functional integrity. Ectropion (eyelid eversion) or eclabium (lip eversion) may ensue. Primary elliptical closures that are strictly parallel to a free margin and second intention healing are not frequently used in these areas.

The opposing force inflicted upon a free margin depends on closure axis orientation, flap or graft design, and the tensile strength and elasticity of the skin. Aged skin is often less able to resist directional vectors. The lower eyelid often becomes especially lax with cumulative actinic damage and age. The "pinch" or "snap" test can be used in free margin evaluation by gently pulling the lower lid away from the eye. Upon release, a competent lower lid should assume its original shape against the globe, while a lax lid will regain its configuration slowly[4]. Instruct the patient to open his or her mouth and gaze upwards while simulating closure options under the eye. This generates the maximum intraoperative tension on the lower eyelid and can help to estimate the risk for distortion of this free margin. No more than 2 mm of inferior pull or "drag" on the lower eyelid can generally be tolerated during cutaneous surgical repairs. Any additional inferior tension puts the patient at high risk for ectropion[10].

Maintenance of cosmesis and function of the lip vermilion is of utmost importance. Elliptical closures often create drag on these free margins, but careful redirection of tension vectors may allow simple closures here as well. Flaps that can be performed in this area are reviewed in Chapter 147. Although the helical rims are free margins, they are far more "forgiving" than the aforementioned sites. Second intention healing and axial elliptical closures can achieve excellent results on the ear. The tissue is easily dissected and the posterior auricular skin provides excellent mobility. Most patients have some ear asymmetry at baseline, thus making this free margin less cosmetically sensitive.

The nasal tip, alae and adjacent lateral sidewall require special consideration due to their classification as "free margins" and the underlying cartilage framework that prevents significant tissue mobility. Elevation and distortion of the nasal rim may occur if second intention healing or simple primary closure is attempted. Full-thickness skin grafts and transposition or rotation flaps from adjacent areas are particularly appealing repairs in this cosmetically sensitive area[11].

MUSCLES OF FACIAL EXPRESSION

The muscles of facial expression arise from the second branchial arch, are innervated by the facial nerve (cranial nerve VII), and are concentrated in the central facial region. They insert into overlying skin and other local muscle groups and contribute to the relaxed skin tension lines of this region. Fluidity of facial movements is orchestrated by their interaction with the SMAS. A surgeon must have detailed knowledge of these muscles and the potential consequences of disrupting their innervation.

The epicranius or occipitofrontalis muscle of the scalp has an anterior and posterior region connected by the galea aponeurotica (see Fig. 142.8). Contraction of these muscles allows the skin to slide over the scalp. Humans no longer have voluntary control of the posterior muscle group, which is innervated by the posterior auricular branch of the facial nerve. The frontalis muscle is a member of the epicranius complex that begins at the anterior hairline and inserts into the forehead and eyebrow skin. It also connects with the procerus, orbicularis oculi and corrugator supercilii muscles. Midline vertical forehead skin tension lines occur due to variation in distance between the left and right frontalis bellies. Horizontal skin tension lines occur perpendicular to the frontalis contractile orientation (see Fig. 142.6). Loss of frontalis function results in flattening of forehead skin tension lines and a drooping eyebrow. This occurs when the temporal branch of the facial nerve is disrupted. Patients with compromised frontalis function may be unable to open their eyes widely, due to the synergistic effect this muscle has with the orbicularis oculi muscle.

The small periauricular muscles or the temporoparietalis group arise from the superficial temporalis SMAS and the lateral galea. They help draw back the temporal skin and are innervated by the posterior ramus of the temporal branch of the facial nerve. The orbicularis oculi muscle complex is the major group that acts on the eyelid and periorbital skin. It inserts into the medial and lateral canthal tendons and encircles the eye region. Its palpebral portion has a preseptal component overlying the orbital septum and a pretarsal portion overlying the tarsal plate of the eyelid. The palpebral orbicularis oculi muscle aids in tear excretion. Upper pretarsal and preseptal muscles depress the upper lid. The orbital component of this muscle group allows voluntary tight closure of the eye. The palpebral portion allows gentle eye closure and blinking. The orbicularis oculi is intertwined with the procerus, corrugator supercilii, and frontalis muscles and attaches to the superficial temporal fascia at its lateral border.

The corrugator supercilii muscle is located over the medial upper orbital rim. It contributes to a "scowling" facial expression by drawing the eyebrows medially and downward. It interdigitates with and is covered by the frontalis and orbicularis oculi muscles. The vertical and oblique skin tension lines of the glabella are caused by contraction of

Table 142.1 Innervation of the muscles of facial expression via cranial nerve VII (the facial nerve)[4,12].

this muscle, which is innervated by the temporal branch of the facial nerve (Table 142.1).

The procerus muscle overlies the nasal bone and attaches to the nasal root skin. It causes foreshortening of the nose and "bunny lines" (i.e. skin tension lines exaggerated by wrinkling up the nose). The nasalis muscle courses across the nasal dorsum and facilitates alar "flaring" and compression. These muscles are innervated by the zygomatic and buccal branches of the facial nerve. The depressor septi nasi muscle lies deep to the orbicularis oris and can form a transverse skin tension line across the philtrum. It plays a minor role in facial expression by pulling the columella down toward the lip.

An intricate network of interdigitating agonist and antagonist muscle groups contributes to lip movements and oral expression. Lip elevators, depressors and retractors assist the sphincteric orbicularis oris muscle in lip movement. The orbicularis oris muscle allows pursing and puckering of the lips, apposition of the corners of the mouth, and pulling of the lips up against the teeth and gingivae. It has no bony or cartilaginous attachment and is innervated by the buccal or marginal mandibular branches of the facial nerve. This circumferential muscle is necessary for correct speech and allows enunciation of the letters M, V, F, P and O[4].

The facial arteries and veins are covered and protected from damage by the lip elevator muscles. The quadratus labii superioris muscle group comprises several lip elevators. The levator anguli oris and risorius muscles are mouth angle retractors and elevators. The zygomaticus major muscle travels from the zygoma downward and diagonally to the upper corner of the mouth, where it contributes to the nasolabial fold. Zygomaticus major and minor muscles are the main contributors to smile formation. The risorius muscle also contributes to a smiling facial expression by drawing back the corners of the mouth. The modiolus platform is formed by the convergence of fibers from the orbicularis oris and lip elevators and depressors. It is located 1 cm lateral to the mouth angle and accounts for cheek "dimples" in some patients. It works in synergy with the perioral muscles to facilitate speech enunciation.

The buccinator muscle constitutes a large area of the cheek as it courses from the posterior maxillary area to the upper medial surface of the mandible, where it interdigitates with the orbicularis oris. The facial vascular bundle crosses its surface. The parotid duct and transverse facial artery run parallel to each other as the duct pierces the buccinator to enter the mouth at the second maxillary molar. The buccinator is innervated by the buccal branch of the facial nerve and contracts synergistically with the orbicularis oris muscle. Together, these muscles allow pursing of the lips as in whistling. The buccinator also keeps the cheek flat against the teeth, which prevents food accumulation during chewing. It also prevents overextension of the cheek when high intraoral pressures are generated.

The depressor anguli oris (triangularis), depressor labii inferioris (quadratus) and the mentalis muscles are lip depressors and retractors that antagonize the superior perioral muscle groups. They are innervated by the marginal mandibular branch of the facial nerve. The deep mentalis muscle permits chin elevation and depression and protrusion of the lower lip. The bellies of the mentalis muscles have variable proximities to each other. A patient with a chin "dimple" or "cleft chin" has a larger distance between mentalis muscles. This is a normal anatomic variant.

The platysma muscle runs from the superficial fascia of the chest across the anterior and lateral neck over the mandible to intercalate with the lower lip depressors and retractors. It is innervated by the cervical branch of the facial nerve and is continuous with the superficial fascia or SMAS of the lower face. It provides only a thin protective cover to the anterior facial vascular bundle and mandibular branch of the trigeminal nerve.

VASCULAR ANATOMY

The internal carotid artery supplies the eyelids, upper nose and nasal dorsum, forehead and scalp via sub-branches of its ophthalmic branch. The ophthalmic artery arises behind the eye and branches into the orbital and ocular group. The orbital group includes the supraorbital, dorsal nasal and the anterior ethmoidal artery (Fig. 142.15). The supraorbital artery exits the orbit through the supraorbital foramen alongside the supraorbital nerve and perforates the frontalis muscle to ultimately course in the subcutaneous tissue of the forehead and scalp. The supratrochlear artery exits the medial orbit and courses medial to the supraorbital artery to supply the nasal root and the low midline forehead. This artery serves as the axial blood supply for the midline forehead flap often used to repair nasal defects. The success of this flap depends upon isolation and preservation of the supratrochlear artery. The anterior ethmoidal artery exits the nasal passage at the interface of the nasal bone and nasal cartilage to provide arterial supply to the nasal dorsum. The dorsal nasal artery crosses the midline over the nasal root and anastomoses with the angular artery, which originates from the external carotid artery.

While the internal carotid artery contributes to some areas of the scalp and upper face, the external carotid artery supplies most of the face. The facial artery branches off from the external carotid artery and courses deep to the mandible up through or behind the submandibular salivary gland. It passes over the mandibular ridge onto the face anterior to the masseter muscle, where it can be palpated. Its tortuous course maintains a diagonal and superior direction passing alongside the nose and terminating at the medial canthus. The platysma and risorius muscles protect the facial artery near the mandible. As the vessel traverses up the face, it becomes covered by the zygomaticus muscles of the midface and the orbicularis oculi as it nears the medial canthus.

The facial artery gives rise to the inferior and superior labial arteries that course horizontally below and above the lips, respectively. These arteries are found deep to the lip mucosa, but can course more superficially into the submucosa of the lip in elderly patients. After forming the superior labial branch, it becomes known as the angular artery. At its endpoint near the medial canthus tendon, the angular (or facial) artery anastomoses with the dorsal nasal branch of the ophthalmic

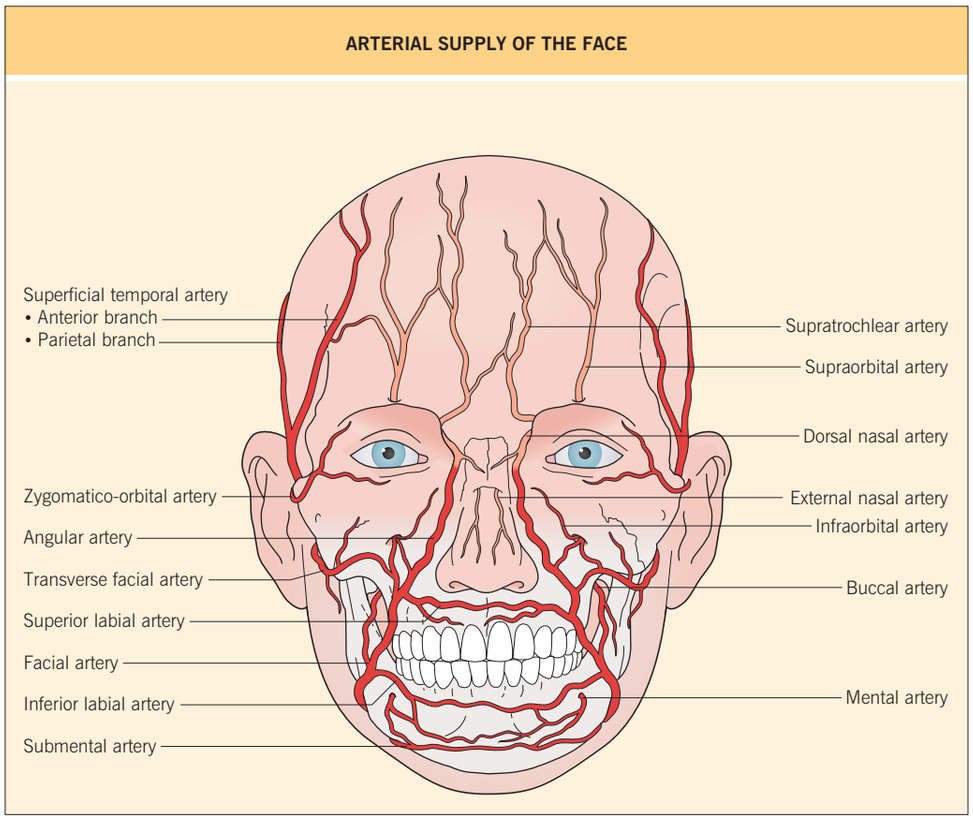

Fig. 142.15 Arterial supply of the face. Light pink designates arteries derived from the internal carotid artery; dark pink, from the external carotid artery.

artery. Since the ophthalmic artery is a branch of the internal carotid system, this anastomosis joins the internal and external carotid arterial systems. During most of their course, the facial artery and vein are covered by the superficial muscles of facial expression. The facial artery also anastomoses with branches of the internal maxillary (the infraorbital branch) and superficial temporal (transverse facial) arterial tree. This allows excellent blood supply to the facial skin even if distal arterial branches are cut or tied during surgery. The high density of arterial supply to the head and neck accounts for its excellent healing potential and viability of local flaps and grafts.

The lateral face, scalp and forehead are primarily supplied by the superficial temporal artery and its branches. This artery arises in the superficial lobe of the parotid gland as the terminal branch of the external carotid artery. It courses superficially to the main facial nerve trunks, then gives off the transverse facial artery before exiting the parotid gland superficially. The latter transverse artery runs parallel to and 2 cm below the zygomatic arch[4]. The superficial temporal artery exits the parotid and enters the subcutaneous fat in the preauricular crease, where it assumes an ascending vertical course over the zygomatic arch. It can be easily palpated just medial to the upper tragus of the ear. It runs alongside and superficial to the auriculotemporal nerve within, then above the SMAS layer of the temple and lateral forehead. The most superficial portion of the superficial temporal artery is often visible in aged patients within the subdermal fat above the galea aponeurotica as it courses cephalad above and anterior to the ear. Here it forms the parietal and frontal (anterior) arterial branches that originate just above the uppermost attached portion of the ear. The forehead, eyebrows and lateral scalp receive their arterial supply from these branches of the superficial temporal artery. There are many anastomoses on the scalp between the bilateral superficial temporal arteries. Because of this rich supply chain, the entire scalp tissue remains viable even if one of these arteries is occluded. This rich anastomotic network also explains why scalp surgery can be a very bloody process. Surgical dissection at the level of the galea aponeurotica may serve to avoid transection of the copious subdermal vascular supply.

Most of the arteries of the face run anterior to and parallel with their corresponding veins (see Fig. 142.3). The veins lack valves and therefore permit two-way flow of venous blood. The facial vein connects to the deep facial vein as it drains the cheek. The latter vein parallels the internal maxillary artery and anastomoses with the pterygoid venous plexus medial to the upper mandibular ramus. The facial vein crosses over the submandibular glands, while its corresponding artery passes beneath them. It then drains into the internal jugular vein, which connects with the external jugular vein via the retromandibular vein. The facial vein can communicate with the cavernous sinus of the brain via the ophthalmic vein or the pterygoid plexus. The paranasal area and upper lip are the regions drained by this network. This interface may permit skin or wound infections to gain access to the cavernous sinus of the brain from the draining facial or ophthalmic veins, with potentially devastating consequences.

Arterial blood supply to the face is delivered by a rich subdermal plexus that is fed by larger perforating arteries. Wound healing and flap success depend on maximal blood supply to the area. Axial flaps, such as the paramedian forehead flap, incorporate a known subcutaneous artery (e.g. the supratrochlear artery) into their design. Random pattern flaps are maintained by the subdermal arterial plexus and do not rely on a single feeder artery to maintain blood flow. The anastomotic vascular network permits facial arteries to be clamped or tied off during surgery without compromising tissue viability. Nearby ipsilateral or contralateral anastomotic arterial branches can often compensate for any loss in local blood supply.

THE FACIAL NERVE

The muscles of facial expression are innervated by the facial nerve, or cranial nerve VII. The facial nerve courses between the SMAS and the deep fascia before its branches penetrate the lateral underside of the facial muscles. There is significant variability in the course and arborization of this nerve from patient to patient. Cranial nerve VII has two major roots, the smaller of which, via the chorda tympani branch, provides taste sensation to the anterior two-thirds of the tongue; the chorda tympani nerve travels with the lingual nerve (cranial nerve V_3) to the tongue. Sensory innervation to a portion of the external auditory meatus, soft palate, and pharynx is also derived from this small facial nerve root. The submaxillary, submandibular and lacrimal glands contain parasympathetic fibers of the facial nerve that have secretory effects. In addition to the muscles of facial expression (see Table 142.1), the buccinator, stapedius, posterior belly of the digastric, stylohyoid and platysma muscles are all innervated by branches of the facial nerve.

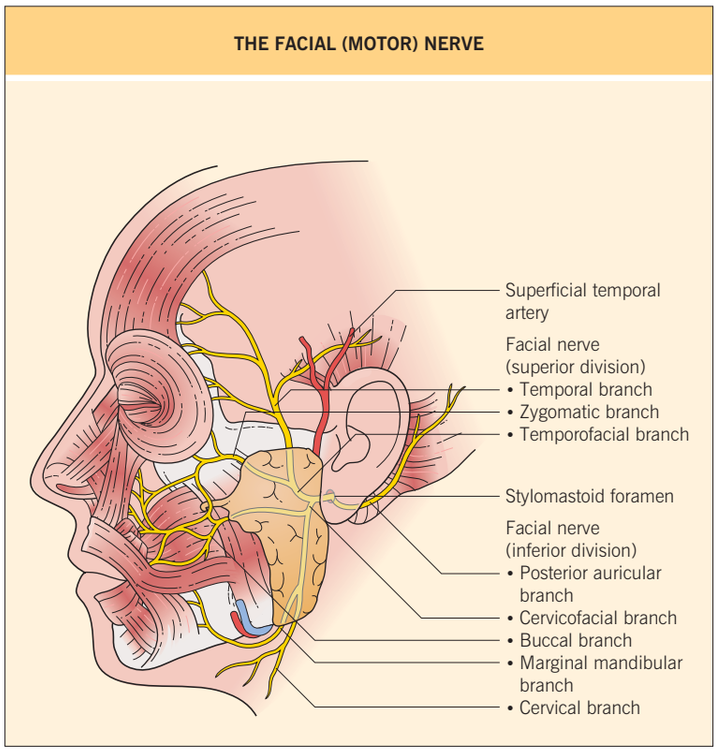

Fig. 142.16 The facial (motor) nerve.

Upon exiting the skull at the stylomastoid foramen near the level of the earlobe, the facial nerve immediately gives off the posterior auricular branch, which provides motor innervation to the occipitalis and posterior auricular muscles (Fig. 142.16). The remainder of the nerve trunk enters the parotid gland and bifurcates into the horizontally oriented temporofacial branch and lower cervicofacial branch. If a line is drawn from the superior border of the tragus to the angle of the mandible, the entrance site of the facial nerve trunk into the parotid gland lies at the midpoint. The temporal, zygomatic, buccal, marginal mandibular, and cervical branches arise from the two major rami of the facial nerve. It courses in between the glandular parotid tissue and becomes more superficial as it follows an upward curvilinear pathway on its way to the ventral surfaces of the muscles of facial expression.

While the facial nerve trunk is well protected in adults at its exit from the skull by the mastoid process, the surgeon must beware when performing procedures in this anatomic region in children. Because the mastoid process is not fully developed until age five, the main facial nerve trunk lies in a superficial subcutaneous plane behind the earlobe and may be damaged in superficial cutaneous procedures. The major facial nerve branches on the cheek are protected only by a small amount of parotid tissue, parotid fascia and subcutaneous fat. If a surgical procedure requires violation of the parotid fascia, meticulous dissection is necessary to avoid major facial nerve damage and subsequent functional disability. The motor nerves of the face course deeper than the sensory nerves or axial vasculature.

The temporal branch of the facial nerve provides motor innervation to the frontalis, upper orbicularis oculi, and corrugator supercilii muscles. It usually has four rami that originate over the middle third of the zygomatic arch for a combined approximately 2.5 cm "danger" zone in this area (see Fig 151.6). The most posterior ramus of the temporal branch can be topographically located on the temple 1 cm anterior to a vertical line drawn from the anterior insertion of the ear to the scalp. This posterior ramus runs anterior to the superficial temporal artery and vein. The most significant "danger zone" for the temporal branch of the facial nerve lies between a line drawn from the earlobe to the lateral edge of the eyebrow and a line drawn from the tragus to just above and lateral to the highest forehead crease. Within this zone, the temporal branch is at highest risk as it crosses the midzygomatic arch, where it lies most superficially over this bony prominence.

The temporal branch of the facial nerve courses between the superficial and deep temporalis fascia, penetrating the underside of the frontalis muscle from its lateral edges. The superficial temporal artery and vein as well as the auriculotemporal sensory nerve run posterior to but more superficial than the temporal nerve branch (compare Fig. 142.3 with Fig. 142.16). This neurovascular bundle lies in the subcutaneous fat overlying the SMAS of the temple and lateral forehead region. Remember that once the temporal nerve reaches the lateral underbelly of its ipsilateral target muscles, it is most protected. In order to avoid damaging this facial nerve branch, the surgeon should either remain superficial to the SMAS (i.e. the superficial temporalis fascia) or dissect in the subgaleal plane from the medial to lateral forehead. Similar to the other facial nerve divisions, the greatest potential for nerve damage lies in the lateral regions of the face. The central face has many nerve arborizations and protective muscles that usually afford a minimal risk for facial motor nerve damage.

Damage to a ramus of the temporal branch of the facial nerve can result in notable cosmetic and functional loss. The temporal branch consists of long, usually singular and often superficially coursing rami that have few arborizations or cross-innervations. These characteristics make nerve damage and permanent sequelae more likely when cutaneous procedures are performed in the lateral forehead and temporal regions. Even though the upper orbicularis oculi and corrugator supercilii muscles are innervated by the temporal branch, minimal functional or cosmetic compromise occurs, due to cross-innervation by other motor nerves. However, only 15% of patients will have any cross-innervation to the frontalis muscle by the more inferior zygomatic branch of the facial nerve. Such arborization permits retention of some functional mobility of the frontalis should the temporal branch be sacrificed. For the other 85% of patients, violation of the temporal nerve results in motor denervation and the inability to raise a now lowered or "droopy" eyebrow[4] (see Fig 151.7). Flattening of the forehead with diminished visibility of wrinkles and skin tension lines on the ipsilateral side is easily noted. The functional loss of the frontalis muscle significantly hampers a patient's ability to communicate non-verbally via facial expression and may have devastating psychosocial consequences. Over time, the inability to raise one's eyebrow can lead to eyebrow and eyelid ptosis and upper visual field compromise as muscular disuse atrophy progresses. Brow lifts and blepharoplasty may be necessary if the temporal nerve branch is permanently damaged.

The zygomatic branch of the facial nerve provides motor innervation to the lower orbicularis oculi, procerus, mouth elevators and nasal muscles. Its fibers overlie the parotid (Stensen's) duct and course horizontally and upwards after emerging from the parotid gland as the second division of the facial nerve. There is marked variability in the innervation it provides to these muscles; thereby, damage to this nerve branch can have unpredictable outcomes. Generally, injury to the zygomatic branch results in decreased orbicularis oculi function and a diminished ability to close the ipsilateral eyelid tightly. The orbicularis oculi is also innervated in its supraorbital aspect by the temporal branch of the facial nerve. Therefore, complete loss of circumferential periocular motor function is highly unlikely. Other effects may include dysfunction of nasal muscles and lip elevators.

The buccal branch is the third division of the facial nerve, and it courses inferiorly to the zygomatic branch in a downward direction on the cheek. It innervates the orbicularis oris muscle, the zygomaticus muscles, the lip elevators, the buccinator muscle and nasal muscles to a variable extent. Damage to this nerve causes buccinator dysfunction that results in accumulation of food between the teeth and the buccal mucosa with chewing. Approximately 80% of patients have anastomoses between the fibers of the zygomatic and buccal branches[13]. Each branch has two points of arborization, with the first occurring 2 cm anterior to the anterior edge of the parotid gland and the second usually occurring under the modiolus 1 cm lateral to the oral commissure at the anterior aspect of the buccal fat pad. Here the nerves may be damaged due to their superficial anatomy, protected only by the thin fascia of the SMAS, an often underdeveloped risorius muscle, and the subcutaneous fat. At the first branching site near the parotid, the zygomatic and buccal nerves lie between the masseter muscle and the posterior side of the buccal fat pad.

Although damage to the zygomatic or buccal branches of the facial nerve may occur during surgical procedures, subsequent motor dysfunction is often temporary and far less debilitating than a similar injury to the temporal nerve. The high degree of anastomoses between the zygomatic and buccal branches minimizes functional damage and promotes nerve recovery after trauma. Partial paralysis of the perioral muscles may occur, causing variable symptomatic defects in facial

expression, including a diminished ability or unilateral defect in forming a smile or pucker, lip pursing and lip seal formation. Drooling, food accumulation between the cheeks and gingivae, and muffled speech may occur secondary to buccal or zygomatic nerve damage. Orbicularis oculi defects have already been discussed and include lower eyelid droop, which can lead to chronic conjunctivitis, sicca symptoms, and ectropion. Difficulty wrinkling up the nose and inability to flare the nostrils may also occur with zygomatic or buccal branch trauma. Fortunately, most of these symptoms resolve within 6 months due to the extensive ramification and cross-innervation of these branches of the facial nerve.

The orbicularis oris, mentalis, and lip depressor muscles are innervated by the marginal mandibular branch of the facial nerve. The nerve courses along the angle of the mandible below the parotid gland and continues up over the mandibular body anterior to the facial artery, which can be palpated easily as it courses over the medial mandible. The nerve is very susceptible to damage, due to its superficial location over the bony edge of the jaw (i.e. just inferior and lateral to the lateral oral commissure), where it is covered only by fascia and an often unpredictably thin or poorly developed platysma muscle. This facial nerve branch is often composed of only one ramus. The marginal mandibular nerve "communicates" with the buccal branch of the facial nerve in only 10% of patients; therefore, damage to the former branch can lead to permanent disfiguring and functional defects in facial expression[4]. Normal symmetric facial expression and function of the mouth depends upon the equal and opposite effects exerted by the lip depressors and elevators in conjunction with the orbicularis oris muscle. Characteristically, a patient with marginal mandibular nerve damage cannot form a symmetric smile. There is inability to pull the ipsilateral lower lip downward and laterally or evert the corresponding vermilion border. The end result is a "crooked" smile. The defect is appreciated upon smiling, but is not as apparent when the patient is at rest.

The cervical branch of the facial nerve innervates the platysma muscle. This muscle receives nerve fibers from the marginal mandibular nerve as well. Damage incurred to the cervical branch rarely causes functional or cosmetic defects.

SENSORY INNERVATION OF THE HEAD AND NECK

The trigeminal nerve, or cranial nerve V, provides the primary sensory innervation to the face, while the upper cervical nerves (C2, C3) provide sensory supply to the neck, part of the ear, and posterior scalp (Fig. 142.17; Table 142.2). The facial, glossopharyngeal and vagus nerves provide a small portion of sensory innervation to the ear[14] (Fig. 142.18). The trigeminal nerve is the largest cranial nerve. It has motor (to the muscles of mastication), sensory and parasympathetic functions, supplying secretory fibers (originating from the facial and glossopharyngeal nerves) to the lacrimal and parotid glands. The sensory branches of the trigeminal nerve course more superficially than the trunk of the facial nerve, and are thereby readily subject to damage during surgical procedures. Fortunately, most resulting sensory dysfunction is not debilitating or permanent. Transmedian re-innervation after unilateral trigeminal root transection has been demonstrated. This is due to collateral sprouting of sensory nerves from the contralateral trigeminal nerve root[15]. The sensory nerves exist in the superficial plane between the subcutaneous fat and the SMAS and often run together with arteries and veins in neurovascular bundles. Knowledge of the sites where the major branches of sensory nerves emerge from the skull assists the surgeon in performing regional nerve blocks that facilitate facial surgery and improve patient comfort.

The trigeminal nerve is divided into three main branches: the ophthalmic (V_1), maxillary (V_2) and mandibular (V_3) (see Fig. 142.17). The smallest, uppermost sensory branch is the ophthalmic division, which gives off three branches (nasociliary, frontal and lacrimal nerves) before exiting the orbit (Fig. 142.19). Sensory fibers to the sinuses and upper nasal septal mucosa, as well as secretory parasympathetic fibers (that originate from the facial nerve) to the lacrimal gland, are also provided by the ophthalmic branch of the trigeminal nerve. The nasociliary branch gives rise to the infratrochlear nerve and the external branch of the anterior ethmoidal nerve. Sensory innervation to the root of the nose and part of the medial canthus is supplied by the infratrochlear nerve. The nasal dorsum, tip, supratip and columella derive cutaneous innervation from the external nasal branch of the anterior ethmoidal nerve, which emerges between the upper nasal cartilage and nasal bones. Nerve blocks for the nose rely on knowledge of these anatomic relationships among the sensory nerves. The nasociliary branch also supplies the corneal surface via

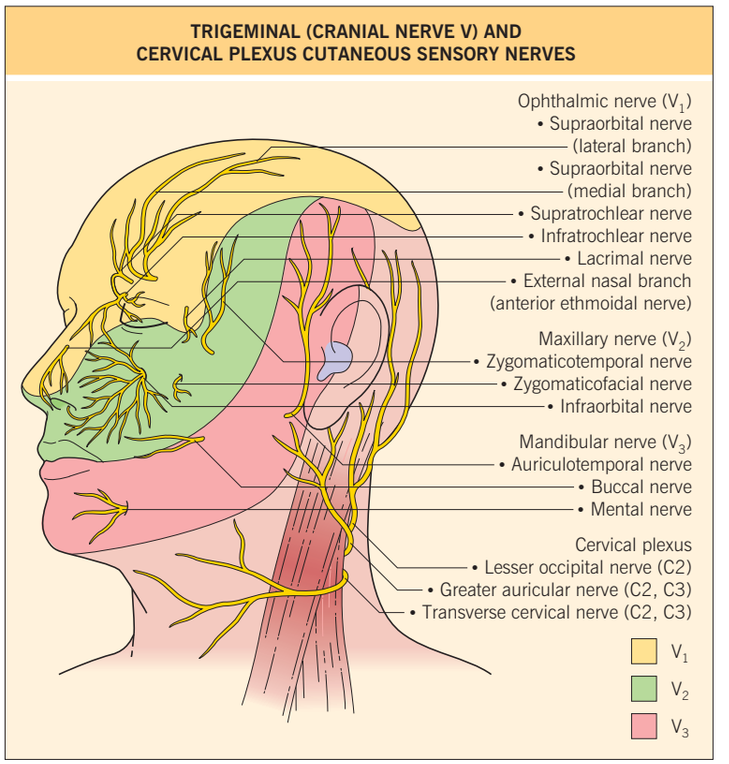

Fig. 142.17 Trigeminal (cranial nerve V) and cervical plexus cutaneous sensory nerves. The concha and external auditory canal are variably innervated by branches of the vagus, glossopharyngeal and facial nerves (see Fig. 142.18).

SENSORY INNERVATION OF THE HEAD AND NECK

- **Trigeminal nerve**
  - Ophthalmic branch (V_1)
    - Nasociliary
      - Infratrochlear – root of nose, medial canthus
      - Anterior ethmoidal (external nasal branch) – nasal dorsum, tip, supratip, columella
      - Ciliary – corneal surface
    - Frontal
      - Supratrochlear – medial upper eyelid, medial forehead, frontal scalp
      - Supraorbital – forehead, scalp, upper eyelid
    - Lacrimal – lateral eyelid
  - Maxillary branch (V_2)
    - Infraorbital – medial cheek, upper lip, nasal sidewall and ala, lower eyelid
    - Zygomaticofacial – malar eminence
    - Zygomaticotemporal – temple, supratemporal scalp
    - Superior alveolar and palatine – upper teeth, palate, nasal mucosa, gingiva
  - Mandibular branch (V_3)
    - Auriculotemporal – external anterior ear and auditory canal, temple, temporoparietal scalp, temporomandibular joint, tympanic membrane
    - Buccal – cheek, buccal mucosa, gingiva
    - Inferior alveolar – mandibular teeth; chin and lower lip (mental nerve)
    - Lingual – anterior two-thirds of tongue, floor of mouth, lower gingivae
- **Greater auricular nerve** (C2, C3) – lateral neck, angle of the jaw, posterior and inferior ear, portions of the helical rim, postauricular scalp
- **Lesser occipital nerve** (C2) – neck, postauricular scalp
- **Transverse cervical nerve** (C2, C3) – anterior neck
- **Supraclavicular nerve** (C3, C4) – anterior chest, shoulder

Table 142.2 Sensory innervation of the head and neck.

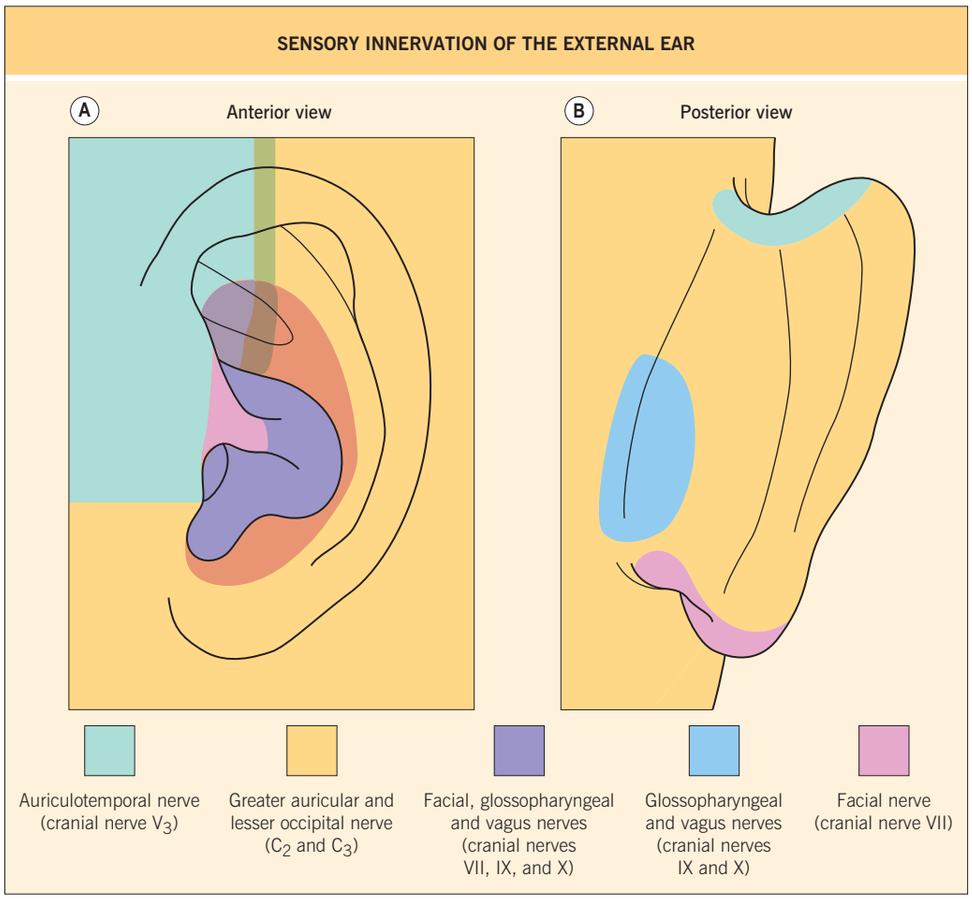

Fig. 142.18 Sensory innervation of the external ear. A Anterolateral view. **B** Posterior view.

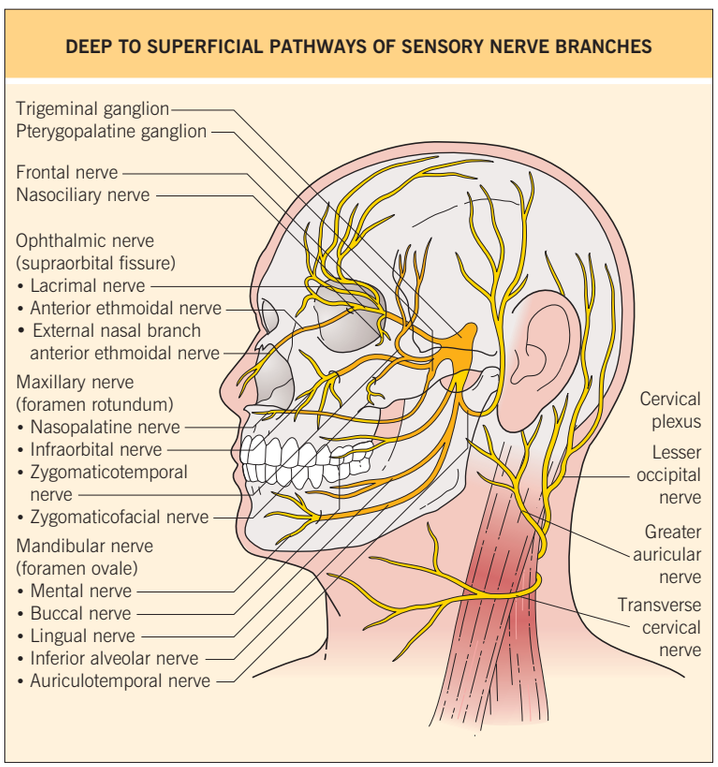

Fig. 142.19 Deep to superficial pathways of sensory nerve branches.

the ciliary nerve. If an episode of zoster (varicella zoster virus) involves the nasal tip, then close ophthalmologic follow-up is warranted due to presumed corneal involvement.

The frontal nerve branch of the ophthalmic division forms the supratrochlear and supraorbital nerves. The exit route (supratrochlear ridge) of the supratrochlear nerve lies 1 cm lateral to the midline on the supraorbital ridge. This branch of the frontal nerve provides sensory innervation to the medial upper eyelid, medial forehead, and frontal scalp. The supraorbital foramen (through which emerges the supraorbital neurovascular bundle) lies 2.5 cm lateral to the midline on the supraorbital ridge (see Fig. 142.2). After penetrating the frontalis muscle to emerge above the frontalis SMAS, the supraorbital nerve provides cutaneous sensation to the forehead, scalp and upper eyelid. A small lacrimal nerve branch of the ophthalmic division of cranial nerve V innervates the lateral eyelid skin and lies near the upper lateral orbital rim. Frontal nerve blocks, and specifically the supratrochlear and supraorbital block, offer quick and effective anesthesia for surgical procedures of the forehead.

The maxillary branch (V_2) of the trigeminal nerve forms the infraorbital, zygomaticofacial and zygomaticotemporal cutaneous sensory branches (see Fig. 142.17). The infraorbital foramen lies 2.5 cm lateral to midline and 1 cm inferior to the infraorbital rim, in the same vertical line as the supraorbital and mental foramina. The infraorbital neurovascular bundle emerges here to provide significant sensory innervation to the medial cheek, upper lip, nasal sidewall and ala, and the lower eyelid. Infraorbital nerve blocks offer simple and effective anesthesia for much of the cheek, lower eyelid, and nose. Lateral to the infraorbital foramen, the zygomaticofacial nerve emerges to innervate the skin of the malar eminence. Cutaneous innervation of the temple and supratemporal scalp region is provided by a third branch of the maxillary division, the zygomaticotemporal nerve. It emerges from the lateral orbital margin at the zygomatic bone. The superior alveolar and palatine nerves are deeper branches of V_2 that provide sensory innervation to the upper teeth, palate, nasal mucosa, and gingiva.

The mandibular branch (V_3) is the largest division of the trigeminal nerve and the only one to carry both cutaneous sensory and motor fibers. It supplies cutaneous sensory innervation to the face as well as motor innervation to the muscles of mastication. The auriculotemporal, buccal and inferior alveolar nerves represent the three main cutaneous branches of V_3 (see Fig. 142.19). The auriculotemporal nerve emerges from behind the neck of the mandible to course just deep to the superficial temporal artery from the superior margin of the parotid gland in the

preauricular sulcus up towards the lateral scalp. It provides sensory innervation to the external ear and auditory canal, temple, temporoparietal scalp, temporomandibular joint and tympanic membrane. It also carries parasympathetic secretory fibers to the parotid gland.

The buccal nerve supplies sensory innervation to the cheek, buccal mucosa, and gingiva. It runs deep to the parotid over the pterygoid muscle to the upper surface of the buccinator, which it pierces to reach the overlying skin. Because the terminal branches of the buccal nerve are small and numerous, regional buccal nerve block techniques are not feasible anesthetic options. The inferior alveolar branch of V_3 innervates the mandibular teeth as it courses through the mandibular sulcus. Its terminal branch forms the mental nerve, which emerges from the mental foramen in the same topographic line as the supraorbital and infraorbital neurovascular bundles (i.e. 2.5 cm lateral to the midline). The mental vein, artery and nerve emerge from the mental foramen below the lower second premolar. The lingual nerve supplies sensory innervation to the anterior two-thirds of the tongue, the floor of the mouth, and the lower gingivae. It arises from V_3 and courses parallel and superior to the inferior alveolar nerve.

The cervical plexus is a network of arborizing and anastomosing nerve branches of the ventral rami of the four most superior cervical nerves. It emerges from the mid-posterior margin of the sternocleidomastoid (SCM) muscle at Erb's point to give off three branches, designated as C2, C3 and C4. C2 and C3 compose the greater auricular nerve, which runs from the posterior edge of the SCM towards the earlobe in the same plane and path as the external jugular vein (see Fig. 142.17). It innervates the skin of the lateral neck, angle of the jaw, and part of the auricular and postauricular skin (see Fig. 142.18).

The lesser occipital nerve (C2) emerges from the same point at the SCM and assumes a course parallel to the SCM upward to innervate the skin of the neck and postauricular scalp. The transverse cervical nerve (C2 and C3) likewise emerges from behind the SCM and arcs anteriorly around and across the SCM in a transverse direction. Its many terminal branches supply the skin of the anterior neck. The supraclavicular nerve (C3 and C4) emerges from the same point at the SCM posterior margin, then courses inferiorly until it reaches the supraclavicular region, where it terminates, and provides sensory innervation to the anterior chest and shoulder skin (see Fig. 142.4).

Perineural invasion of cutaneous tumors such as basal cell carcinomas, neurotropic melanomas and squamous cell carcinomas may be encountered by the clinician. Patients are often asymptomatic from dermal nerve twig infiltration by tumor cells, with the diagnosis made only by histopathologic tissue examination. Some patients may experience sensory abnormalities and, rarely, motor dysfunction. Most of these scenarios occur in the setting of squamous malignancies (incidence rates range from 3% to 14%), with less than 1% of basal cell carcinomas showing any histologic evidence of perineural spread[13]. Knowledge of the neuroanatomy of the head and neck assists the surgeon in planning adjuvant therapy, such as radiation, for patients with nerve involvement.

LYMPHATIC DRAINAGE OF THE HEAD AND NECK

Squamous cell carcinomas, melanomas, Merkel cell carcinomas and other cutaneous neoplasms may spread via lymphatics to regional lymph nodes and subsequently metastasize to other organs. It is important for the clinician to have a thorough understanding of the lymphatic drainage of the head and neck (Fig. 142.20), as well as the remainder of the body, in order to appropriately stage and manage patients. Before any surgical endeavor is undertaken for a malignancy, palpation of regional lymph nodes and basins should be performed. Head and neck cancers usually spread to adjacent lymph nodes in a diagonal direction from cephalad to caudad (see Fig. 142.20). There is a large degree of variability in drainage pathways, but the anatomic location of individual lymph nodes is more consistent from patient to patient. Cutaneous neoplasms that breach the papillary dermis may spread from small lymph capillaries to progressively larger and deeper lymphatic trunks in the area. Lymph channels often course along the same directional pathway as the head and neck veins. They are more numerous and often more superficial than the corresponding veins and lie predominantly between the superficial and deep fascial layers.

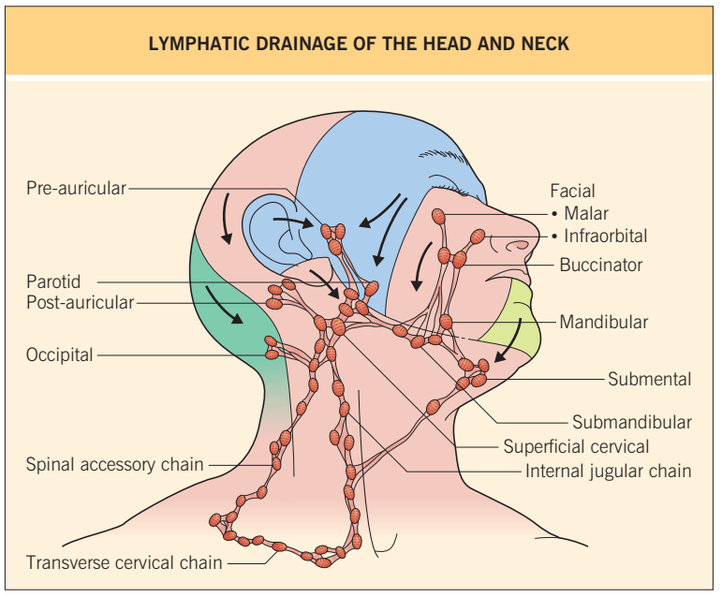

Fig. 142.20 Lymphatic drainage of the head and neck.

Important primary lymphatic drainage patterns of the head and neck region include the following: parotid nodes often collect from the forehead and eyelids (upper lateral face); submandibular nodes from the lower and medial face or from the submental nodes; and submental nodes from the central lower lip and chin. Lateral cervical nodes are the common subsequent lymph collection site from these areas. Parotid nodes may be extraglandular or intraglandular. The extraglandular channels are invested within the parotid sheath. Two-thirds of all people will also have one to three pretragal and infra-auricular lymph nodes that are considered part of the parotid node basin[4]. These pre- and infra-auricular nodes drain the ear, the lateral lower cheek, the frontolateral scalp and the forehead, as well as the nasal root. Drainage of the parotid unit may then follow the external or internal jugular vein in the jugular lymph node chain; therefore, palpation for nodes from the site of the cutaneous lesion to the supraclavicular and even axillary nodal basins is recommended.

Submandibular nodes should be examined as the patient relaxes the neck muscles and tilts the chin down. This nodal group drains the gingival and mucous membranes, lower eyelids, anterior two-thirds of the tongue, lips, nose and medial cheeks. The submental nodes (up to eight) of the neck lie beneath the platysma and drain the anterior third of the tongue and floor of the mouth, in addition to the lower middle lip, chin and medial lower cheeks. They are best examined by elevating the chin and asking the patient to engage the platysma. Submental nodes frequently drain bilaterally or contralaterally and empty into the submandibular basin or directly into the internal jugular lymphatic chain. Note that up to one-quarter of healthy people have small (less than 1 cm) non-fixed palpable submental nodes[4].

The superficial lateral cervical nodes are adjacent to the infra-auricular parotid nodes and lie near the high external jugular vein. Use the sternocleidomastoid muscle as a landmark to palpate these nodes (up to four) over its cephalad portion. Deeper lateral cervical nodes include the spinal accessory, internal jugular and transverse cervical chains, which form a triangle on the neck. The internal jugular chain is the main lymphatic collection trunk of the head and neck and may contain up to 25 lymph nodes in each patient. The internal jugular chain on the right often drains into the subclavian vein, whereas the left-sided lymphatic chain empties into the thoracic duct. These nodes can be palpated by rolling two fingers over the area of the carotid triangle.

Acute or chronic lymphedema may ensue after transection of larger lymphatic channels or nodes, or even after disruption of smaller channels in areas (e.g. infraorbital) with limited or vulnerable lymphatic drainage. Adequate drainage can be achieved by orienting flaps in the same direction as lymphatic patterns. The surgeon must be mindful of the variability in drainage patterns and sites and the fact that malignancies do not respect the midline. Since cross-communication between lymphatics may result in contralateral drainage, bilateral examination for lymphadenopathy should be undertaken before a neoplasm is excised.

143 Anesthesia

George J Hruza

Key features

- Local anesthetics are classified into two groups – amides and esters, depending upon the linkage in their intermediate chain
- "Anesthetic allergies" vary from palpitations secondary to epinephrine and vasovagal reactions, to urticaria and anaphylaxis from preservatives or the local anesthetic (especially esters)
- Additives to the local anesthetic include epinephrine, sodium bicarbonate and hyaluronidase
- Nerve blocks are particularly helpful when performing procedures on the face, digits and palmoplantar surfaces

INTRODUCTION

Effective anesthesia is an essential component of dermatologic surgery. Almost all dermatologic surgical procedures can be performed under local anesthesia. Local anesthetics have been in use since the 1880s with the introduction of cocaine hydrochloride, which was extracted from the leaves of the South American bush *Erythroxylon coca*[1]. This was followed by procaine in 1904, tetracaine in 1930, and the first amide local anesthetic, lidocaine, was introduced in 1943[1]. The introduction of lidocaine was a major breakthrough because lidocaine is far less likely to cause an allergic reaction than the ester-type anesthetics that preceded it.

Local anesthesia has several advantages over general anesthesia, including reduced morbidity (especially in patients who are poor anesthesia risks), reduced cost, reduced procedure time and faster recovery. The main disadvantages are some limitation on the extent of a procedure and the possibility of greater patient discomfort from the injections. Knowledge of the physiology, dosage, side effects, and proper "painless" local anesthesia technique are essential for performing dermatologic surgery and to keep patients safe and satisfied.

DISCUSSION

Physiology and Structure

Local anesthetics act by blocking sodium channels in the axon cell membrane, and this prevents sodium from entering the nerve cell. The nerve cell is not depolarized and consequently the action potential is blocked. The cationic form of the anesthetic appears to bind to the inner pore of voltage-gated sodium channels, possibly leading to both narrowing of the pore lumen (steric block) and creation of an electrostatic barrier to permeation[2]. Smaller unmyelinated C-type nerve fibers that conduct pain sensation are blocked more quickly and easily than intermediate fibers that carry sensations of heat and cold. The myelinated A-type fibers that carry pressure sensation and motor fibers are blocked last. Clinically, this is evident when an area seems fully anesthetized for scalpel surgery, but the patient still feels the pressure of the surgeon's fingers at the surgical site.

All local anesthetics consist of three parts (Fig. 143.1):

- a secondary or tertiary amine end
- an aromatic end
- an intermediate connecting chain that contains an ester or amide.

The aromatic portion is hydrophobic and lipophilic. This is essential to allow the anesthetic to diffuse through nerve cell membranes. The amine portion is hydrophilic and is responsible for the anesthetic's water solubility, which is important for preparing, storing and administering the anesthetic[2].

Local anesthetics are weak organic bases, which, to be water-soluble and injectable, require the addition of a hydrochloride salt. In aqueous solution, the salt equilibrates between the ionized and non-ionized form. The ionized form is water-soluble, allowing injection into and diffusion through tissue. However, it is the non-ionized, lipid-soluble base that can diffuse into the nerve cell membrane. Within the sodium channel's inner pore, it is the ionized cation that is responsible for blocking nerve conduction (see above)[2].

The dissociation constant (pKa) of each anesthetic determines the proportion of the anesthetic base and its cation at a given pH. The pKa of all local anesthetics is higher than physiologic pH. For most local anesthetics at a pH of 7.4, 80% or more is in the cationic ionized form. Alkalinization of the anesthetic solution, as is done with the addition of sodium bicarbonate, will speed its onset of action as more of the anesthetic will be in the non-ionized form. However, if the pH is raised too much, the anesthetic may precipitate out of solution. Anesthetic sensitivity to pH also helps explain why infected tissue is difficult to effectively anesthetize[3]. The inflammatory response surrounding the infection acidifies the site (reduces the pH), which reduces the proportion of the anesthetic in the non-ionized, lipid-soluble form.

Pharmacology

Local anesthetics are classified into two groups, depending on the linkage in the intermediate chain (Table 143.1). Amide anesthetics have an amide linkage and ester anesthetics have an ester linkage (see Fig. 143.1). They differ in how they are metabolized and in the risk of sensitization. Ester anesthetics are hydrolyzed by plasma pseudocholinesterase, and the metabolites are excreted by the kidneys. Patients with a deficiency of functional pseudocholinesterase, who are often diagnosed after prolonged paralysis following administration of standard doses of succinylcholine, are at an increased risk of ester anesthetic toxicity. The metabolite para-aminobenzoic acid (PABA) is responsible for the allergic reactions seen with ester anesthetics. Amide anesthetics are metabolized by the hepatic microsomal cytochrome P450 enzyme system, and the metabolites are excreted by the kidneys. Patients with severe liver disease may be at increased risk of amide anesthetic toxicity.

Local anesthetics differ in the speed of onset, duration of action, and potency, depending on each compound's intrinsic chemical characteristics (Table 143.1). A low pKa leads to rapid onset of anesthesia, as more of the anesthetic will be in the non-ionized form. Greater lipid solubility is associated with higher anesthetic potency, as the compound penetrates the nerve cell membrane more easily. Duration of action is determined by the strength of anesthetic binding to the sodium channel pore.

Occasionally, pregnant women need to undergo skin surgery. The local anesthetic of choice in pregnancy is lidocaine. It is classified as pregnancy category B, which means that, in animal studies, no teratogenic effects have been documented. Studies in pregnant women who received lidocaine during the first trimester of pregnancy have shown no increase in anatomic abnormalities in the newborns. However, it is recommended that lidocaine, as with all other pharmacologic agents, be used cautiously during the first 4 months of pregnancy, when maximum organogenesis takes place. Lidocaine crosses the placenta into the fetus. Lidocaine can be safely used in nursing mothers with the realization that some of the anesthetic may be excreted in the mother's milk.

Lidocaine can be safely used in children, but the maximum recommended dosage should be adjusted downward based on the child's

LOCAL ANESTHETICS FOR INFILTRATIVE AND NERVE BLOCK ANESTHESIA					
Generic name	**Trade name®**	**Onset (min)**	**Duration plain (h)**	**Maximum dose plain (mg for 70 kg man)**	**Maximum dose with epinephrine (mg for 70 kg man)**
AMIDES					
Articaine	Septocaine	2–4	0.5–2	350	500
Bupivacaine hydrochloride	Marcaine	5–8	2–4	175	225
Etidocaine	Duranest	3–5	3–5	300	400
Levobupivacaine hydrochloride	Chirocaine	2–10	2–4	150	Not available
Lidocaine	Xylocaine	Rapid	0.5–2	350	500 (3500 dilute)
Mepivacaine	Carbocaine	3–20	0.5–2	300	500
Prilocaine hydrochloride	Citanest	5–6	0.5–2	400	600
Ropivacaine*	Naropin	1–15	2–6	200	Not available
ESTERS					
Chloroprocaine hydrochloride	Nesacaine	5–6	0.5–2	800	1000
Procaine	Novocaine	5	1–1.5	500	600
Tetracaine	Pontocaine	7	2–3	100	Not available

*Addition of epinephrine has no effect on onset or duration of action of ropivacaine.

Table 143.1 Local anesthetics for infiltrative and nerve block anesthesia. In clinical practice, the duration of anesthesia appears to be less than stated, especially for head and neck areas. Addition of epinephrine prolongs anesthesia by a factor of two.

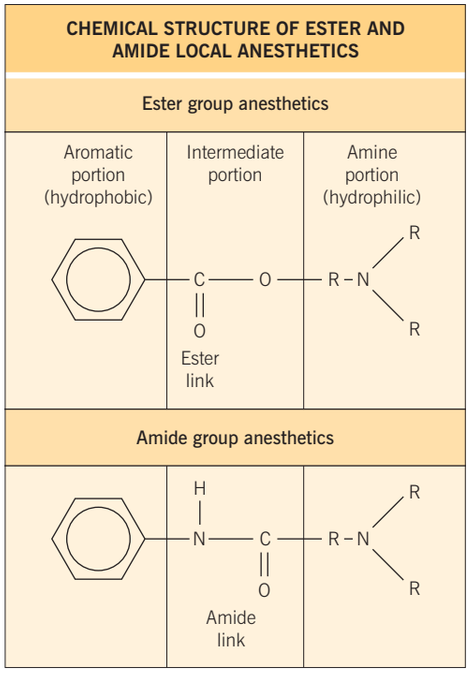

Fig. 143.1 Chemical structure of the ester and amide group local anesthetics. The aromatic (hydrophobic and lipophilic) end is joined to the amine (hydrophilic) end with an ester or amide linkage.

weight and age. Care must be taken in premature infants due to cardiovascular effects. Parabens, used as preservatives, are bound to albumin. In a jaundiced newborn, they could displace bilirubin from the albumin, worsening the hyperbilirubinemia[4]. For this reason, only paraben-free anesthetics should be used in newborns.

Additions to Local Anesthetics

Epinephrine

All local anesthetics, except for cocaine hydrochloride, relax vascular smooth muscle, which results in vasodilation. This causes increased bleeding at the operative site and reduced duration of anesthetic action as the anesthetic is rapidly removed from the surgical site via the dilated blood vessels. The addition of epinephrine (adrenaline) has the beneficial effect of constricting blood vessels, which prolongs the duration of anesthesia 100% to 200% by slowing removal of the anesthetic from the surgical site. Also, there is reduced intraoperative bleeding due to the vasoconstriction. The addition of epinephrine provides more effective anesthesia by decreasing the volume of anesthetic needed. The reduced absorption rate decreases anesthetic toxicity and allows larger doses to be used safely. The vasoconstrictive effect of epinephrine, manifested by skin blanching, takes about 15 minutes to fully develop. While they usually coincide, blanching does not always denote the anesthetized area.

Epinephrine is premixed with local anesthetics at a concentration of 1:100 000 or 1:200 000. However, concentrations as low as 1:1 000 000 achieve effective vasoconstriction, while concentrations greater than 1:100 000 are associated with greater risk of side effects. The concentration used in a given patient should be individualized. Patients who have relative contraindications to epinephrine should receive lower concentrations, while highly vascular areas such as the scalp should receive higher concentrations. The maximum dosage used at a concentration of 1:100 000 is determined by the anesthetic with which the epinephrine is premixed (Table 143.1).

Epinephrine is a strong β- and α-agonist and, as such, it must be used cautiously in patients with altered β- and α-receptors. Absolute contraindications to the use of epinephrine include hyperthyroidism and pheochromocytoma. Patients taking β-blockers, monoamine oxidase inhibitors, tricyclic antidepressants, and phenothiazines are more sensitive to epinephrine. Therefore, epinephrine should be used with caution, with the dose and concentration reduced accordingly. Severe hypertension developing after epinephrine-containing anesthetic injection in patients taking β-blockers has been reported[5]. This is probably due to unopposed α-adrenergic activity with its associated vasoconstriction. Fortunately, this reaction seems to be quite rare[6], and mainly occurs when higher doses are used. Patients with severe hypertension or with severe cardiovascular disease (especially coronary artery disease) may have their underlying disease exacerbated if large amounts of epinephrine are administered with the local anesthetic. High doses of epinephrine can induce labor. However, the low doses of epinephrine used in cutaneous surgery can be safely used during pregnancy. Epinephrine use in the periorbital area in patients with narrow angle glaucoma should be avoided, as it may aggravate the patient's glaucoma.

DIFFERENTIAL DIAGNOSIS OF LOCAL ANESTHETIC SYSTEMIC REACTIONS				
Diagnosis	**Pulse rate**	**Blood pressure**	**Signs and symptoms**	**Emergency management**
Vasovagal reaction	Low	Low	Excess parasympathetic tone; diaphoresis, hyperventilation, nausea	Trendelenburg, cold compress, reassurance
Epinephrine reaction	High	High	Excess α- and β-adrenergic receptor stimulation; palpitations	Reassurance (usually resolves within minutes), phentolamine, propranolol
Anaphylactic reaction	High	Low	Peripheral vasodilation with reactive tachycardia; stridor, bronchospasm, urticaria, angioedema	Epinephrine 1:1000 0.3 ml subcutaneous, antihistamines, corticosteroids, fluids, oxygen, airway maintenance
Lidocaine overdose				
1–6 mcg/ml	Normal	Normal	Circumoral and digital paresthesias, restlessness, drowsiness, euphoria, lightheadedness	Observation
6–9 mcg/ml	Normal	Normal	Nausea, vomiting, muscle twitching, tremors, blurred vision, tinnitus, confusion, excitement, psychosis	Diazepam, airway maintenance
9–12 mcg/ml	Low	Low	Seizures, cardiopulmonary depression	Respiratory support
>12 mcg/ml	None	None	Coma, cardiopulmonary arrest	Cardiopulmonary resuscitation and life support

Table 143.2 Differential diagnosis of local anesthetic systemic reactions. In case of systemic reactions during or after local anesthetic injections, hemodynamic signs are helpful in determining the cause of the reaction.

The use of epinephrine on digits has been controversial. Historically, epinephrine was not used on digits for fear of causing vasoconstriction that might result in digital necrosis. More recent studies have not demonstrated any increased risk from epinephrine in digital anesthesia. It appears that most cases of digital necrosis occurred due to vessel compression from too much anesthetic volume being injected (tamponade), constricting circumferential dressings, tourniquets, postoperative hot soaks, infection, use of vasoconstrictive anesthetics such as cocaine hydrochloride, or non-standard mixing of lidocaine with epinephrine[7]. There is no evidence of digital necrosis due solely to commercially available lidocaine with epinephrine[7]. However, epinephrine is clearly contraindicated for digital anesthesia in patients with peripheral vascular disease. I have found that combining lidocaine with dilute epinephrine (1:500 000) and small volumes provides safe digital anesthesia. Ring blocks of the digit should be avoided.

Self-limited systemic side effects of epinephrine include palpitations, anxiety, fear, diaphoresis, headache, tremor, weakness, tachycardia and elevated blood pressure. These signs and symptoms can be seen on occasion even with normal doses used for skin surgery, but they usually resolve within a few minutes (Table 143.2). They are more commonly seen when injecting highly vascular areas, especially the face and scalp. Skin necrosis from vasoconstriction is an extremely rare complication of epinephrine injection and would be an issue only in patients with severe vascular compromise at the injection site.

Serious side effects of epinephrine injection include arrhythmias, ventricular tachycardia, ventricular fibrillation, cardiac arrest and cerebral hemorrhage. None of these should be expected to occur at the doses used for skin surgery. However, it is prudent to limit the total dose injected in patients with severe cardiac disease.

Epinephrine is stable only in an acidic environment. Therefore, when epinephrine is premixed with local anesthetics, the pH is lowered into the 3.5 to 5.5 range with the addition of acidic preservatives such as sodium metabisulfite to stabilize the epinephrine. This acidic solution not only is more painful at the time of injection[8], but also slows the onset of anesthetic action, as less anesthetic is in the non-ionized form. By preparing the mixture fresh daily and using it by the end of the day, the mixture has a higher pH, which is less painful. Adding 0.5 ml epinephrine (1:1000) to 50 ml plain lidocaine will give a final concentration of 1:100 000 epinephrine. Alternatively, the lidocaine with epinephrine can be neutralized with sodium bicarbonate (see below).

Sodium bicarbonate

Injecting the standard lidocaine with epinephrine mixture at a pH of 3.5 to 5.5 is quite painful, with significant stinging due to the acidic pH. The pH can be neutralized with the addition of sodium bicarbonate. Adding one part of 8.4% sodium bicarbonate to ten parts lidocaine with epinephrine will bring the pH into a more physiologic 7 to 8 range. This mixture significantly reduces the pain of anesthetic injection[8,9]. Both components can be drawn up into the syringe, immediately before injection. Alternatively, 5 ml sodium bicarbonate (8.4%) can be added to a 50 ml bottle of lidocaine with epinephrine. As the epinephrine activity is lost at a rate of 25% per week in an alkaline or neutral environment, the mixture should be labeled with the date prepared, kept refrigerated, and used within about 1 week.

Hyaluronidase

Hyaluronidase (derived from bovine testicular hyaluronidase) depolymerizes hyaluronic acid, which breaks up ground substance, allowing anesthetics to diffuse further away from the injection point. In addition, there is less distortion of the injected structures[10]. The greater diffusion of anesthetic may decrease its duration of action. Hyaluronidase is most useful for periorbital surgery and to increase the rate of successful nerve blocks. It is prepared by adding 150 units to 30 ml of local anesthetic. Allergic reactions to hyaluronidase are rare, but they can occur. Some surgeons recommend an intradermal skin test before using hyaluronidase. In addition, the preparation may contain thimerosal preservative, which can cause contact dermatitis.

Anesthetic Mixtures

In an attempt to take advantage of different anesthetic properties, some surgeons combine two local anesthetics in one syringe. For example, a combination of lidocaine, for its rapid onset of action, with bupivacaine hydrochloride, for its longer duration of action, is often used. However, a study looking at such combinations has found that these mixtures do not live up to their promise. The mixture seems to take on the properties of one of the components to the exclusion of the other[11]. Therefore, most surgeons will inject the rapid-onset anesthetic first and the longer-acting anesthetic later, to minimize the pain of injection and maximize the duration of action.

Side Effects

Vasovagal reactions

By far the most common side effect of local anesthetic injection is a vasovagal reaction, in which the vagus nerve discharges due to patient anxiety, resulting in an increase in parasympathetic tone (Table 143.2). Vasovagal reactions are manifested by dizziness, diaphoresis, syncope, bradycardia and hypotension. Placing the patient in the Trendelenburg position will rapidly relieve the patient's symptoms. A cold towel on the forehead can also be helpful. Oxygen, fluids or epinephrine are usually not necessary. To avoid significant vasovagal reactions, all patients should have local anesthetic infiltrated in the recumbent position.

Allergic reactions

The most important side effect of local anesthetics is the development of allergic reactions. The allergy is usually a type I IgE-mediated reaction manifested by urticaria, angioedema, bronchospasm, and, on rare occasions, anaphylaxis with associated hypotension and tachycardia (Table 143.2). Most true local anesthetic allergies have been reported with ester anesthetics; amide anesthetics are implicated only very rarely. Preservatives added to multidose vials, especially methylparaben and sodium metabisulfite, have frequently been shown to be the cause of "local anesthetic" allergy[12].

There is some allergy cross-reactivity within the various ester anesthetics and within the amide anesthetics, but there is no cross-reactivity between the ester and amide anesthetic classes. It is PABA (the metabolite of ester anesthetics) that is thought to be responsible for the ester anesthetic allergic reactions. Ester anesthetics can also cause type IV delayed hypersensitivity reactions and cross-react with several contact sensitizers, including PABA, para-amino salicylic acid and para-phenylenediamine.

Patients who present with a history of "local anesthetic" allergy need to be questioned in detail about the "allergy" with a review of relevant medical records whenever possible. Often, the "allergy" is a result of a vasovagal reaction or epinephrine sensitivity. If the reaction seems to represent a true allergic reaction and the offending anesthetic is known (usually an ester), using an anesthetic from the other class (usually an amide) in a preservative-free solution is a reasonable option. Skin testing, by an allergist, may be warranted if the offending agent is not certain[13]. The testing should include pinprick followed by intradermal tests of an ester anesthetic, an amide anesthetic, methylparaben and sodium metabisulfite. Alternatively, for small procedures, adequate anesthesia can be obtained with intradermal injection of 1% diphenhydramine solution. Epinephrine may be added to counteract vasodilation caused by diphenhydramine, to enhance the anesthetic effect, and to reduce systemic antihistamine symptoms[14]. Intradermal normal saline with benzyl alcohol preservative will achieve very brief anesthesia through pressure effects on cutaneous nerve endings and the anesthetic properties of the benzyl alcohol preservative. It can be used for very short procedures such as a shave biopsy[15].

Limited allergic reactions can be managed with oral antihistamines and prednisone. However, patients developing bronchospasm, angioedema, or hemodynamic compromise require immediate emergency management including epinephrine, bronchodilators, parenteral antihistamines, corticosteroids, intravenous fluids, and oxygen (Table 143.2).

Local side effects

Bruising and edema are frequently seen after local anesthetic infiltration, especially in the periorbital area. Periorbital edema will often develop after surgery on the forehead and frontal scalp. Transient motor nerve paralysis is sometimes seen. This may be delayed for some time after the sensory nerves have become anesthetized, because of the large myelinated nerve fibers involved. The paralysis may persist for several hours after the sensory nerves have returned to normal. Informing the patient when a motor nerve has been affected by the anesthetic will eliminate distressed patient telephone calls later in the day. Prolonged sensory nerve paresthesia may develop if a sensory nerve is injured through intraneural injection. This is most commonly seen after nerve blocks. It can be minimized by avoiding intraneural injection and by using small gauge needles for injection.

Overdosage

If the local anesthetic dosage administered is kept within the recommended maxima, clinical symptoms of local anesthetic overdose are unlikely to be encountered. Maximum recommended dosages of *lidocaine* are 5 mg/kg plain (i.e. with no epinephrine), 7 mg/kg if with epinephrine and at standard (1–2%) concentrations, and 35–50 mg/kg for tumescent lidocaine anesthesia with dilute lidocaine (0.05–0.1%) as well as epinephrine concentrations (Table 143.1)[16–18].

The symptoms of local anesthetic overdose are directly related to the serum blood level, and include increasing CNS and cardiovascular signs and symptoms (Table 143.2). CNS symptoms start with circumoral and digital numbness and tingling, followed by lightheadedness, tinnitus, visual disturbances, slurred speech, muscle twitching, and, finally, seizures and coma. Cardiovascular and pulmonary symptoms develop at significantly higher doses than do early CNS symptoms and include hypotension, arrhythmias, respiratory arrest and cardiac arrest.

When lidocaine is administered, there are over 150 potential drug–drug interactions. Most are minor or only relevant when large doses of lidocaine are used. Patients receiving medications that inhibit the liver's cytochrome P450 system (e.g. erythromycin, ketoconazole, itraconazole; see Ch. 131), and therefore inhibit lidocaine metabolism, can exhibit signs of lidocaine overdose at lower doses. With large doses of lidocaine, patients taking class I and III antiarrhythmic drugs are at increased risk of cardiac arrhythmias and those taking CNS depressants (e.g. opiates) are at increased risk of CNS toxicity.

Bupivacaine hydrochloride has a greater risk of cardiac toxicity than lidocaine. *Prilocaine hydrochloride* metabolizes to ortho-toluidine, which is an oxidizing agent capable of converting hemoglobin to methemoglobin. This can become significant with large doses of more than 500 mg. *Benzocaine* has also been implicated in causing methemoglobinemia when used on mucosal surfaces[19]. The treatment of methemoglobinemia is methylene blue infusion.

Topical Anesthetics

Skin

Historically, the only anesthetic used for topical anesthesia of keratinized skin was benzocaine, which is an ester anesthetic. Anesthesia was generally effective only when applied to traumatized skin. Little, if any, anesthesia was achieved in intact normal skin. Of greater concern was the high rate of allergic contact dermatitis seen with benzocaine.

More recently, there have been several topical anesthetics introduced that seem to achieve moderate topical anesthesia of intact skin (Table 143.3). EMLA® cream is a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine hydrochloride. It is able to achieve superficial anesthesia, with the degree of anesthesia related to the amount and duration of application before surgery. EMLA® is applied as a thick layer under occlusion at least 1 hour before the procedure. It is especially useful for reducing the pain of non-ablative laser procedures and to reduce the pain of local anesthetic or other injections. There are reports of more extensive procedures, such as split-thickness skin graft harvesting, being done with EMLA® alone. However, I have found the degree of anesthesia to be too unpredictable to rely on EMLA® alone for most surgical procedures. Some dermatologists who perform CO_2 laser ablative resurfacing solely under EMLA® anesthesia prepare the skin with vigorous degreasing followed by two applications of EMLA® 1 hour apart under occlusion. Additional EMLA® is applied to the skin after the first pass with the laser has removed the epidermis.

EMLA® appears to be safe, but some caution is advised when using large amounts on skin with a damaged skin barrier and in infants who might be susceptible to methemoglobinemia from too much prilocaine hydrochloride absorption. For recommended applications in children, see Table 143.4. EMLA® often blanches the skin after application, followed by vasodilation 30–60 minutes after its removal. Even though this initial blanching has no effect on treatment efficacy, when treating vascular lesions, relatively light-colored lesions may become difficult to identify. I have patients mark out the outline of the vascular lesion before applying EMLA®. The vasodilation is usually of no clinical significance, but a few case reports of purpura developing at the site of EMLA® application have been reported in children.

Other preparations that have been optimized for epidermal penetration and have been shown to achieve moderate superficial skin anesthesia include: Betacaine-LA®, consisting of a proprietary mixture of lidocaine and prilocaine hydrochloride; LMX®, containing 4% or 5% lidocaine (Table 143.5); Topicaine®, containing 4% lidocaine; 4% tetracaine gel; 30–40% lidocaine in acid mantle cream; and various other compounded mixtures of lidocaine, benzocaine and tetracaine (Table 143.3). In a comparison study, EMLA® and LMX® 4% were found to achieve superior anesthesia to tetracaine 4% gel, which was superior to Betacaine-LA®, which was superior to control[20]. According to the manufacturers, Betacaine-LA® and LMX® do not require occlusion to be effective. A comparison of EMLA® under occlusion and LMX® unoccluded found that LMX® achieved equivalent anesthesia to EMLA® after less than one-third of application time[21]. None of the topical anesthetics have any significant effectiveness for palmar or plantar surfaces.

TOPICAL ANESTHETICS FOR MUCOUS MEMBRANE AND INTACT SKIN ANESTHESIA				
Generic name	**Trade name®**	**Concentration (%)**	**Type**	**Primary use**
Benzocaine	Americaine otic	20	Ester	Tympanic membrane
Benzocaine	Hurricaine	20	Ester	Mucous membranes
Benzocaine/tetracaine/butamben (butyl aminobenzoate)	Cetacaine, Exactacain		Ester	Mucous membranes
Benzocaine/lidocaine/ tetracaine	compounded	Various	Ester/amide	Intact skin
Cocaine hydrochloride		2–10	Ester	Nasal mucosa
Dibucaine (cinchocaine)	Nupercaine	1	Amide	Mucous membranes
Lidocaine	LMX	4–5	Amide	Intact skin (4%); anorectal (5%)
Lidocaine	Topicaine	4	Amide	Intact skin
Lidocaine	Xylocaine	2–5	Amide	Mucous membranes
Lidocaine in acid mantle cream	compounded	30–40	Amide	Intact skin
Prilocaine/lidocaine	EMLA	2.5/2.5	Amide	Intact skin
Proparacaine (proxymetacaine)	Alcaine	0.5	Ester	Conjunctiva
Prilocaine/lidocaine mix	Betacaine LA	Proprietary	Amide	Intact skin
Tetracaine gel	Tetracaine gel	4	Ester	Intact skin
Tetracaine	Pontocaine	0.5	Ester	Conjunctiva

Table 143.3 Topical anesthetics for mucous membrane and intact skin anesthesia. Anesthetics for topical skin anesthesia require application 0.5–2 hours prior to surgery under occlusion for maximal effect.

MAXIMUM RECOMMENDED EMLA® APPLICATION IN CHILDREN				
Age	**Weight**	**Maximum total dose of cream**	**Maximum area**	**Maximum time**
<3 months	<5 kg	1 g	10 cm^2	1 hour
3–12 months	5–10 kg	2 g	20 cm^2	4 hours
1–6 years	10–20 kg	10 g	100 cm^2	4 hours
7–12 years	>20 kg	20 g	200 cm^2	4 hours

Table 143.4 Maximum recommended EMLA® application in children.

MAXIMUM RECOMMENDED LIDOCAINE 4% LIPOSOMAL CREAM (LMX4®) APPLICATION IN CHILDREN			
Age	**Weight**	**Maximum area**	**Maximum time**
<12 months	<10 kg	100 cm^2 (4 × 4 in)	1 hour
1–6 years	10–20 kg	200 cm^2 (5.5 × 5.5 in)	2 hours
7–12 years	>20 kg	600 cm^2 (9 × 9 in)	2 hours*
*0.072 mg 4% lido absorption/cm^2/h × 600 cm^2 × 2 h = 86 mg (≤4 mg/kg).			

Table 143.5 Maximum recommended lidocaine 4% liposomal cream (LMX4®) application in children. Cream should be applied to intact skin, with or without occlusion. Currently not approved for children less than 2 years of age so its application in that age group represents an off-label use. *Courtesy, Julie V Schaffer, MD.*

Iontophoresis of 1–4% lidocaine with epinephrine can enhance the depth and effectiveness of topical anesthesia. It is practical only for rather small areas, but anesthesia can be achieved within a few minutes with a 1 mA current. The main drawback is the additional equipment and supplies needed. Ultrasound or warm steaming of the skin also enhances the effect of topical anesthetics, probably by enhancing anesthetic penetration.

Topical skin anesthetics are useful primarily for non-invasive laser and intense pulsed light treatments, including laser hair removal, laser acne treatment, tattoo fading, pigmented lesion destruction, vascular lesion photocoagulation and non-ablative photorejuvenation. They are very useful in reducing the pain of needle insertion as well as some of the pain of injection when injecting local anesthetics, botulinum toxin or filler materials such as the various hyaluronic acid-based filler materials that, due to their acidity, sting on injection. Anesthesia is too unpredictable to be able to use topical skin anesthetics even for minor surgical procedures such as skin biopsies, curettage or electrodesiccation.

The various preparations have different recommendations regarding times of application and whether or not occlusion is necessary. However, for maximal effectiveness, the anesthetic should be applied as a thick layer under occlusion to the proposed treatment area for at least 1 hour. Caution should be exercised when large areas are to be anesthetized, especially when using compounded mixtures with high lidocaine concentrations, as several deaths have been reported in patients applying compounded topical anesthetics under occlusion to their entire legs and thighs.

Mucous membranes

Topical anesthetics for mucous membranes are far more effective than skin anesthetics, as the stratum corneum barrier is absent (Table 143.3). One to two drops of 0.5% tetracaine into each eye achieves complete conjunctival anesthesia after a few seconds of stinging. This allows for insertion of eye shields or painless injection through the conjunctiva. Proparacaine (proxymetacaine) hydrochloride is an equally effective alternative conjunctival anesthetic.

A 2–10% solution of cocaine hydrochloride is the topical anesthetic of choice for intranasal anesthesia because of its excellent vasoconstrictive and hemostatic properties. However, onerous record-keeping requirements make it relatively impractical for in-office use. Due to its significant cardiac stimulatory effects, cocaine hydrochloride should be used with caution in patients with significant heart disease.

Oral and anal mucosa can be effectively anesthetized within a couple of minutes with 2–4% lidocaine jelly or viscous lidocaine as well as various benzocaine-containing preparations. Topical intraoral anesthesia is especially helpful in reducing the pain of nerve block injections done through the intraoral route.

Cryoanesthesia

Rapid cooling of the skin surface is used routinely for many non-ablative laser procedures. The anesthesia is achieved with one of the following: a short burst of cryogen sprayed onto the skin surface (Dynamic Cooling Device™); a cold glass window placed directly onto the site being treated (contact cooling); an iced gel placed on the surface being treated (passive cooling); or −5°C refrigerated air blown onto the

skin surface with a coupling gel in place (Cryo 5™). All of these methods cool the skin to reduce pain of laser treatment and to protect the epidermis from laser-induced heat injury.

Cryoanesthesia can also be helpful in skin surgery. Dermabrasion can be done entirely under cryoanesthesia by freezing the skin with a cryogen spray before dermabrading. Unfortunately, the most effective and safe cryogen sprays (Frigiderm®, Fluro-Ethyl®) contain chlorofluorocarbons that are harmful to the ozone layer, and their manufacture has been discontinued. They are still available in limited quantities at ever-escalating prices. Ethyl chloride spray can, through evaporative cooling, achieve brief anesthesia to reduce the pain of needle insertion. An ice cube or –5°C forced air cooling (see above) will likewise numb the skin just long enough to reduce the pain of needle insertion. I have found forced air cooling helpful in reducing the pain of palmar and finger injections of botulinum toxin A for hyperhidrosis. However, if the cold air is directed directly onto the needle, the liquid within the needle may freeze momentarily, making it seem that the needle is clogged. Moving the cold air blower away from the needle for 5 to 10 seconds will permit the contents of the needle to thaw out, allowing injection to continue.

Anesthetic Injection Techniques

Local infiltration

The great majority of dermatologic surgical procedures are done under anesthesia achieved with local infiltration. Every attempt should be made to minimize the pain of injecting the anesthetic. There are several maneuvers that can significantly reduce pain of injection[22]. The pain of needle insertion is reduced by reassurance, verbal distraction, and mechanical distraction such as a pinch at the site of injection. An explanation for how mechanical distraction works is the gate theory of pain. The pinching stimulates cutaneous nerves, making them somewhat refractory to the immediately following pinprick sensation from needle insertion. A very useful adjunct, which also takes advantage of the gate theory of pain, is the use of vibration at or immediately proximal to the injection site. This is very useful when injecting anesthetic in very anxious or young patients and has made it feasible for us to eliminate the need for nerve block anesthesia when injecting botulinum toxin A into the palms and soles in many patients. Care must be taken when applying a vibrator to the injection site, as the needle may move unpredictably across the skin surface due to the vibration before being inserted into the skin. Small 30-gauge needles that are inserted quickly further reduce pain. Slow, timid needle insertion is felt more by the patient than a quick needle insertion. Topical anesthesia, as noted above, can almost completely eliminate the pain of needle insertion.

The actual injection of the anesthetic causes a significant stinging sensation that is usually far more painful than the needle insertion. Buffering the anesthetic to a physiologic pH and using anesthetic that has been warmed to body temperature will reduce the stinging sensation[8,9,23]. Injecting the anesthetic as slowly as practical will reduce the pain from tissue distention by the anesthetic fluid, and this also allows the injection of additional anesthetic to be done through an already numb area. Additional sticks should be through an already numb area, and the injection should start on the side that the sensory innervation is coming from and proceed distally. Using the smallest practical syringe size, usually 1 or 3 ml, will allow for low pressures of injection, which are less painful. Subcutaneous anesthetic injection is less painful than intradermal injection, but the onset of anesthesia is slower and of shorter duration. I usually start by creating a small intradermal wheal, followed by subcutaneous injection, and finish with intradermal injection at the incision line to enhance anesthesia and hemostasis.

Field block anesthesia

Field block anesthesia involves injecting a ring of anesthetic around the proposed surgical site. It is useful for anesthetizing large areas while conserving the amount of anesthetic used and minimizing distortion of the surgical site. Injecting a ring of anesthesia around a cyst will avoid puncturing the cyst. Ring block anesthesia is practical only in areas where innervation arrives horizontally through the skin, such as is seen on the scalp, rather than vertically from deeper tissues, as is seen on the eyelid. A ring block may achieve anesthesia, but there will be no hemostasis at the incision site. Therefore, the addition of intradermal anesthetic with epinephrine at the proposed incision site is recommended. The most frequent use of ring block anesthesia is on the scalp, nose (for rhinophyma repair), ear pinna, and on the trunk and extremities (where the injection is started as a ring block but often finished with infiltration inside the ring block).

TUMESCENT ANESTHESIA FORMULA	
Ingredient	**Quantity (ml)**
Lidocaine 1%	50–100
Epinephrine (1:1000)	1
Sodium bicarbonate 8.4%	10
Hyaluronidase 150 U/ml	6 (optional)
Triamcinolone acetonide 40 mg/ml	0.25 (optional)
Normal saline 0.9%	900–950

Table 143.6 Tumescent anesthesia formula. For tumescent anesthesia, a final concentration of 0.05% to 0.1% lidocaine with 1:1 000 000 epinephrine is prepared. Hyaluronidase may be added to enhance diffusion and corticosteroids may be added to reduce inflammation, edema and possibly fibrosis.

Tumescent anesthesia

Tumescent anesthesia involves the subcutaneous infiltration of large amounts of dilute 0.05–0.1% lidocaine with 1:1 000 000 epinephrine (Table 143.6). It has been used most extensively for liposuction under local anesthesia (see Ch. 156), ambulatory phlebectomy, hair transplantation, and dermabrasion. The anesthetic is infiltrated with the help of a pump, with the injection carried out through long 18–20-gauge 3.5 inch (8.9 cm) spinal needles or specially designed multiport cannulas. The infiltration is started slowly with small needles and then gradually speeded up utilizing spinal needles and finally infiltration cannulas. Infiltration of the deep subcutaneous plane is done first, followed by the superficial fat compartment. The solution is injected until firm tumescence of the tissue has been achieved. Anesthesia and epinephrine-induced hemostasis develop within about 20 minutes and last for several hours, which is significantly longer than the duration of anesthesia achieved with conventional concentrations of lidocaine with epinephrine. In the subcutaneous fat, dilute lidocaine is absorbed at a much slower rate than standard lidocaine concentrations. Doses as high as 35–50 mg/kg lidocaine have been found to be safe when used in tumescent anesthesia[16–18].

Nerve Block Techniques

Nerve blocks are an effective and efficient way to anesthetize large areas using the least amount of anesthetic, minimizing both patient discomfort and distortion of the operative site. When injecting in the region of a nerve, care must be taken not to inject the accompanying blood vessels. Using larger, 25–27-gauge needles allows one to draw back to make sure that the needle is not intravascular. To reduce pain of injection, an intradermal wheal using a 30-gauge needle should be placed first. The aim of nerve block injections is to deposit the anesthetic near, but not into, the nerve, as intraneural injection may cause nerve injury and subsequent dysesthesia. Insertion of the needle into a nerve is usually felt by the patient as a sharp pain radiating along the nerve. If this happens, the needle should be pulled back and repositioned slightly. Intra-foramina injections should also be avoided to minimize the risk of nerve injury. With proper placement, most nerves can be blocked with a 1–2 ml injection. The addition of hyaluronidase will enhance diffusion of the anesthetic and increase the rate of nerve block "take".

For most nerve blocks, 1% lidocaine with epinephrine and sodium bicarbonate is used. If prolonged anesthesia is desired, 0.25% bupivacaine hydrochloride with epinephrine can be added. As the sensory nerves are large and myelinated, anesthetic effect may take 10 to 20 minutes to develop[24]. Using 2% lidocaine may increase success of the nerve block. Articaine 4% with or without epinephrine supplied in dental carpules seems to be especially effective for relatively painless facial nerve blocks, with very small volumes (often less than 0.2 ml/injection site) of anesthetic needed for effective anesthesia. This seems

to be due to its more effective diffusion from the site of injection compared to lidocaine. Some surgeons omit epinephrine from the nerve block anesthetic as it is not needed for vasoconstriction at the site of the nerve. I use it as part of my anesthetic mix to prolong the duration of the nerve block. Once a nerve has been effectively blocked, local infiltration of lidocaine with epinephrine along the proposed incision line to achieve local vasoconstriction may be helpful in reducing bleeding.

Facial nerve blocks

The forehead and frontal scalp above the eyebrows are innervated by the *supraorbital nerve* (Fig. 143.2), which exits the skull through the supraorbital foramen at or immediately above the orbital rim in the midpupillary line (Fig. 143.3). The notch can often be palpated on the patient. Approximately 1 ml of anesthetic is infiltrated through a 0.5 inch (1.3 cm) needle inserted perpendicularly into the skin immediately superficial to the periosteum at the orbital rim in the midpupillary line (Fig. 143.4). The *supratrochlear nerve* innervates the midforehead, glabella and frontal scalp (Fig. 143.2). It exits the skull at the upper medial portion of the orbit (Fig. 143.3). Injecting 1 ml of anesthetic immediately superficial to the periosteum at the superomedial orbital rim at the junction of the glabella and eyebrow will block the supratrochlear nerve (Fig 143.4). To achieve complete forehead and frontal scalp anesthesia requires extending a line of anesthetic injected in the subcutaneous plane laterally from the supraorbital nerve to the region immediately superior and posterior to the attachment of the ear pinna. This will block the auriculotemporal nerve and greater auricular nerve branches that innervate the forehead, temple and frontal scalp.

The *infraorbital nerve* exits the skull through the infraorbital foramen (Fig. 143.3) and innervates the medial cheek, upper lip and nasal ala (Fig. 143.2). With a 1 inch (2.5 cm) needle inserted perpendicularly to the skin, 2 ml of anesthetic is injected approximately 1 cm inferior to the orbital rim in the midpupillary line, immediately superficial to the maxillary bone periosteum (Fig. 143.4). A less painful and more reliable alternative is to block the infraorbital nerve through the intraoral approach. The needle is inserted between the first and second premolars (bicuspids), moving cephalad along the periosteum until bone is reached (Fig. 143.5). The needle is pulled slightly back and the anesthetic is injected. The pain of needle insertion can be lessened by applying a topical anesthetic to the mucosa a couple of minutes prior to injection. The *infratrochlear nerve*, which innervates the lateral and dorsal nose (Fig. 143.2), can be blocked by injecting anesthetic superficial to the periosteum at the inferomedial orbital rim at the superior end of the nose-cheek concavity (Fig. 143.4). The nasal tip receives innervation from the external nasal branch of the *anterior ethmoidal nerve* (Fig. 143.2), which emerges at the nasal cartilage and bone junction slightly lateral from the midline (Fig. 143.3). Perichondrial infiltration of anesthetic at this spot will anesthetize the nasal tip (Fig. 143.4). To complete nasal anesthesia, a few drops of anesthetic at the base of the columella may be needed as well.

The lower lip and portions of the chin are innervated by the *mental nerve* (Fig. 143.2), which exits the mandible through the mental

foramen in the midpupillary line (Fig. 143.3). A 0.5 inch (1.3 cm) needle is inserted perpendicular to the skin to the level of the periosteum in the midpupillary line halfway cephalad along the mandible, and 1 ml of anesthetic is injected to block the mental nerve (Fig. 143.4). The intraoral route is less painful and more reliable. The needle is inserted between the first and second premolars (bicuspids) caudally along the periosteum to a halfway point down the mandible (Fig. 143.6).

Digital nerve blocks

Nerve blocks for the fingers and toes are technically very similar. There are two options to anesthetize a digit. The technique most commonly used by dermatologists blocks the sensory nerves coursing laterally along the digit. A 0.5 inch (1.3 cm) needle is inserted perpendicular to the digit near its base in the horizontal plane until the bone is touched. At this point, the needle is withdrawn slightly, positioned dorsally and anesthetic is injected. Next, the needle is positioned ventrally and additional anesthetic is injected. This process is repeated on the other side of the digit. This block should be done without epinephrine, and small volumes (usually less than 1.5 ml) should be injected to minimize the risk of ischemic injury from mechanical circumferential compression of the blood supply to the digit.

Alternatively, the digit can be blocked at the level of the metacarpal or metatarsal bone. A 1.5 inch (3.8 cm) needle is inserted dorsally between the metacarpal/metatarsal bones, and anesthetic is infiltrated as the needle is advanced ventrally, with most of the anesthetic injected just dorsal to the palmar/plantar skin. This injection will block the metacarpal/ metatarsal nerve, which travels immediately superficial to the flexor retinaculum. The process is repeated on the other side of the metacarpal/metatarsal bone of the digit being anesthetized. The advantage of this block is that there is less risk of compression injury than can occur with the more commonly performed digital block.

Penile nerve block

The dorsal nerve of the penis is a branch of the pudendal nerve. It divides into major anterior (dorsal) and minor posterior (ventral) branches at the base of the penis. By injecting a ring of anesthesia without epinephrine in the subcutaneous plane around the base of the penis, most of the penis will be anesthetized. The only areas that may require additional anesthetic infiltration will be the periurethral region of the glans and, sometimes, the ventral glans and frenulum.

Hand nerve block

With the popularity of botulinum toxin A for palmar and plantar hyperhidrosis, a method to anesthetize the palmar surface is necessary. Topical anesthetics are ineffective on palmoplantar skin, and local anesthetic injections are too painful in the palms or soles. Nerve block of the median nerve will anesthetize the palmar surface of the first three and a half fingers plus two-thirds of the palmar surface (Fig. 143.7). Block of the ulnar nerve will anesthetize the rest of the fingers and palm (Fig. 143.7). The median nerve lies in the carpal tunnel, deep to the palmaris longus tendon and between the flexor digitorum superficialis and flexor carpi radialis tendons. By apposing the thumb and fifth finger with the wrist slightly flexed, the palmaris longus tendon will become apparent. A 0.5–1 inch (1.3–2.5 cm) needle is inserted at the first (proximal) wrist crease, immediately medial (ulnar) to the palmaris longus tendon (Fig. 143.8). It is then advanced deep into the carpal tunnel and a few milliliters of anesthetic are injected. A slight "popping" or reduction in resistance can be felt as the needle enters the carpal tunnel.

The ulnar nerve is most easily blocked at the elbow where it travels between the olecranon process and the epicondyle of the humerus. The

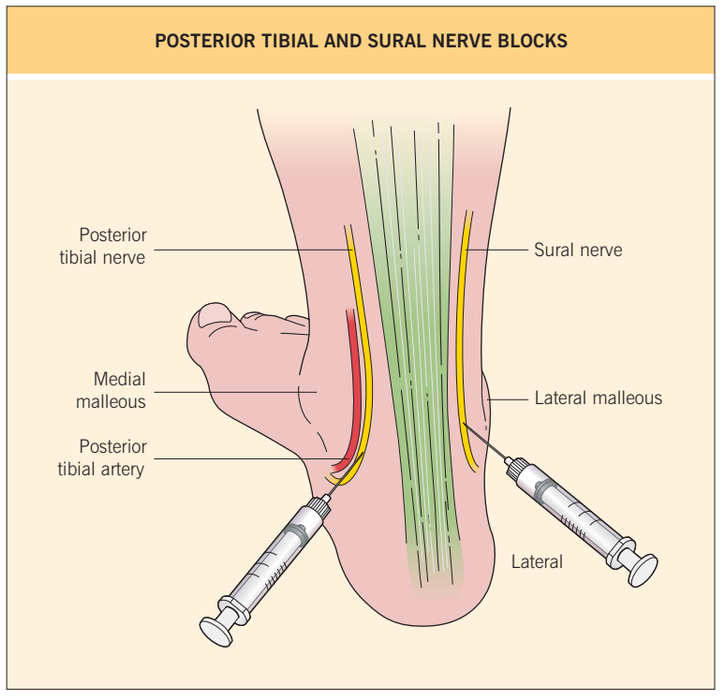

Fig. 143.10 Posterior tibial and sural nerve blocks.

ulnar nerve is the "funny bone". The patient's arm is flexed, and the needle is inserted between the bones with several milliliters of anesthetic injected.

An alternative is to have an anesthesiologist perform a Bier block, in which the blood is pushed out of the arm with a compressive bandage, a tourniquet is applied, and dilute lidocaine is injected intravenously. Anesthesia of the hand will develop in 5 to 10 minutes and last for about 1 hour. Once the procedure is complete, the tourniquet is gradually released and the anesthetic is released into the general circulation. Therefore, the dose administered should be monitored to keep it at a safe level.

Foot nerve block

Anesthesia of the plantar surface requires nerve blocks of the posterior tibial nerve, which innervates the heel and middle of the sole of the foot; the sural nerve, which innervates the fifth toe and the lateral side of the sole of the foot; the superficial peroneal nerve, which innervates the skin of the toes; the saphenous nerve, which innervates the instep; and the deep peroneal nerve, which innervates the skin between the first and second toes (Fig. 143.9). Before starting injections around the ankle, the area should be thoroughly prepared with antiseptic to minimize the risk of infection.

The patient is placed in the prone position. The posterior tibial artery is palpated using a Doppler ultrasound probe if needed, and a 1.5 inch (3.8 cm) needle is directed anteriorly and laterally, immediately lateral to the arterial pulse, until the bone is touched. The needle is pulled back slightly, and several milliliters of anesthetic are injected in the groove between the medial malleolus and the Achilles tendon (Fig. 143.10). The sural nerve is blocked by injecting anesthetic in the groove between the lateral malleolus and Achilles tendon in an identical fashion to the tibial nerve injection (Fig. 143.10).

The patient is placed in the supine position. The saphenous and superficial peroneal nerves are blocked by infiltrating anesthetic subcutaneously from malleolus to malleolus on the dorsal surface of the foot (Fig. 143.11). The deep peroneal nerve is blocked by inserting a 1.5 inch (3.8 cm) needle lateral (toward the middle of the foot) to the extensor hallucis longus tendon down to the bone (Fig. 143.11). Next, the needle is pulled back slightly, and several milliliters of anesthetic are injected. The tendon is identified by having the patient dorsiflex his or her great toe against resistance. Alternatively, local anesthetic infiltration between the first and second toes may be easier and more expeditious.

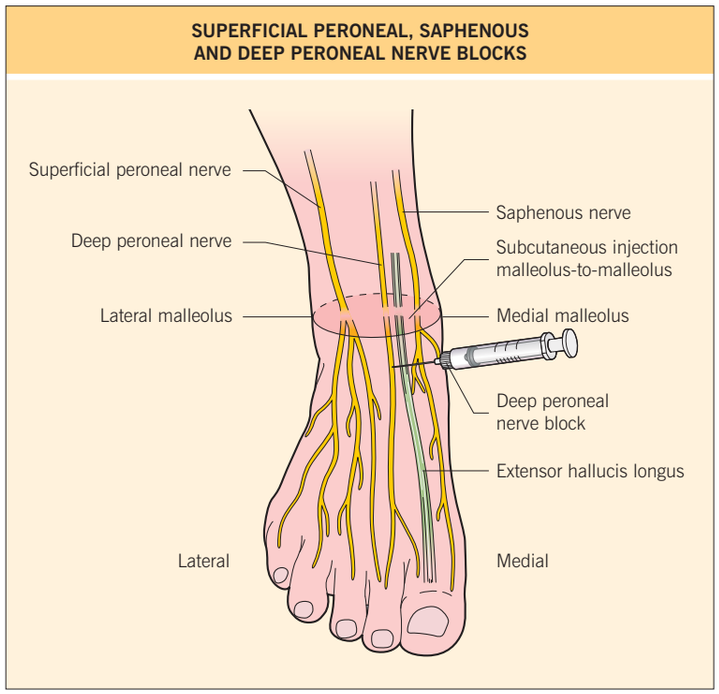

Fig. 143.11 Superficial peroneal, saphenous, and deep peroneal nerve blocks. Great toe dorsiflexion aids in visualizing the extensor hallucis longus tendon.

Higher Levels of Anesthesia

In anxious patients, or when relatively large areas are to be anesthetized, oral or sublingual anxiolytics such as triazolam (Halcion®) 0.25–0.5 mg or zolpidem tartrate (Ambien®) 5–10 mg will reduce anxiety and may even generate a certain degree of amnesia for the procedure. The addition of a narcotic analgesic such as oxycodone (10 mg)/acetaminophen (650 mg) orally (Percocet®) or meperidine hydrochloride (Demerol®) 50 mg intramuscularly, will act synergistically with the anxiolytics to achieve a greater degree of sedation as well as reducing the pain of local

anesthetic infiltration. I find these useful for procedures done under tumescent anesthesia. Of course, patients given any sedating medications should have someone else take them home after the procedure.

Credentialing for higher levels of anesthesia may be regulated by local medical licensure authorities and hospitals, and the physician must be in full compliance with the rules in his or her particular locale. Most of the regulations require procedures done under general anesthesia or with intravenous sedation to be done in an ambulatory surgery center or hospital with a supervising anesthesiologist. Higher levels of anesthesia involving the use of intravenous medications such as midazolam hydrochloride (Versed®) and fentanyl should be done in a monitored environment with appropriate resuscitative equipment readily available. Nitrous oxide administration is a useful form of moderate analgesia, with the degree depending on the concentration administered. At a 20% concentration, the analgesia is equivalent to giving a narcotic analgesic. At an 80% concentration, most patients will become unconscious. The advantage of nitrous oxide is the rapid reversal of anesthetic effect as soon as the gas is turned off. With proper training, nitrous oxide can be safely administered in the office, as it has been done for many years in many dental offices. General inhalation anesthesia or deep intravenous sedation with propofol should generally be performed by anesthesiologists.

Wound Closure Materials and Instruments

144

Christie Travelute Ammirati and Glenn Goldman

Key features

- The characteristics ascribed to a suture include:
  - capillarity
  - physical configurations
  - USP size
  - elasticity
  - coefficient of friction
  - memory
  - plasticity
  - pliability
  - tensile strength
  - tissue reactivity
- Sutures used to approximate the dermis and deeper tissue layers are generally absorbable, while cutaneous sutures are usually non-absorbable and require removal
- The most commonly employed needle in dermatologic surgery is a 3/8 circle that is triangular in shape, with a reverse cutting surface
- Needle holders with small smooth jaws accommodate finer needles and those with large serrated jaws are best for larger needles
- The major types of scissors used in dermatologic surgery are Gradle, tissue, undermining, suture-cutting, and bandage-cutting

INTRODUCTION

As dermatologic surgery continues to expand as a specialty, so does the variety of materials and instruments that are available to facilitate the greater complexity of tissue excisions and repairs. A thorough working knowledge of these tools is essential and allows the physician to optimize the cosmetic and functional outcome of a given procedure. For example, the suture material and surgical instruments chosen for a melanoma excision on the back will vary greatly from those for a blepharoplasty. This chapter will carefully review the wound closure materials and surgical instruments of greatest value to the dermatologic surgeon. Helpful hints and model surgical tray setups are included to assist in the preparation for surgery in specific anatomic locations.

DISCUSSION

Sutures

Although it has been thought that humans have been using various materials to sew skin wounds since prehistoric times, the first known reference appears in the Edwin Smith Papyrus (c. 1600 BC)[1]. The precise suture material was not described, but based upon artifacts from that time period, it was most likely linen. Hippocrates (400 BC) has been credited with being the first to use the term "suture" in reference to sewing human tissue.

In the history of medicine, there are many accounts of the quest by surgeons for the ideal suture material. Their ingenuity is reflected in the vast array of materials that have been tried over time, including cotton, leather, flax, insect mandibles, horse hair and even human hair[2–8]. Ancient Roman physicians would braid the hair of gladiators tightly when closing their scalp wounds, having realized that "sutures" can provide immediate hemostasis as well as wound edge approximation.

The ideal suture would handle easily, hold a secure knot, and have high tensile strength. It would neither cause inflammation nor promote infection, and it would gradually dissolve, thereby obviating the need for suture removal. Unfortunately, the perfect suture material does not exist. However, the ever-widening array of choices available to the dermatologic surgeon and a knowledge of each suture's individual characteristics increases the likelihood of choosing the best possible materials for each surgical situation.

Suture materials are subdivided into absorbable and non-absorbable. Studies of wound healing have shown that during the first 1–2 weeks following surgery, the intrinsic tensile strength of the wound is approximately 7–10% of native bursting pressure[9]. At 5 weeks, the intrinsic tensile strength is approximately 60%, and dehiscence is unlikely with normal activity. During this time period, absorbable buried dermal sutures are utilized to alleviate tension and maintain wound edge approximation. Epidermal, non-absorbable sutures are non-tension-bearing, but allow for fine adjustments of the epidermal edges and thus provide for an improved cosmetic result.

The characteristic attributes ascribed to a suture are defined and standardized by the United States Pharmacopeia (USP) as follows:

- **Capillarity** is defined as the ability of a suture to absorb and transfer fluid. Multifilament (braided or twisted) sutures have greater capillarity than monofilament (single-stranded) sutures.
- Two **physical configurations** exist: monofilament and multifilament. Multifilament suture may be spun, twisted or braided. Braiding serves to increase pliability, strength, knot security and handling[10], but it can lead to abrading or shearing of tissue. In addition, braiding potentially increases the risk of infection by allowing bacteria to become entrapped between filament strands[11]. Therefore, rather than a braided suture, a monofilament suture may be more appropriate for closing a contaminated wound[10,12–15]. Monofilament sutures have a low coefficient of friction and, as such, slide easily through tissue (see below)[15]. Their drawback is that they are traditionally stiffer than braided sutures and may have decreased knot security, requiring additional throws to ensure that the knot is secure. Until recently, monofilament sutures were used primarily for exterior suturing, and most buried sutures were braided. With the introduction of poliglecaprone 25 (Monocryl®), monofilament absorbable suture is now regularly employed for deep sutures.
- The **USP size** of a suture is determined by the diameter of the suture material needed to achieve a given tensile strength and is expressed in multiples of zeros; the smaller the cross-sectional diameter of the suture, the more zeros. For example, 7–0 polyglactin 910 (Vicryl®) is a much finer suture than 3–0 Vicryl®. The actual diameter of a given USP size varies depending upon the composition of the suture; for example, 4–0 surgical gut is a larger-diameter suture than 4–0 polypropylene (Prolene®) because polypropylene is innately stronger for a given diameter. In general, the smallest suture that will provide adequate tensile strength for the indicated repair should be utilized.
- **Elasticity** refers to the ability of a suture to regain its original length after being stretched. An elastic suture, such as polybutester (Novafil®), allows for tissue swelling, and then maintains tension on the wound edges after the edema has resolved.
- The **coefficient of friction** determines the ease with which a suture will pull through tissue. A suture with a low friction coefficient, such as polypropylene (Prolene®), slides easily through tissue (Fig. 144.1). For this reason, polypropylene is the material most commonly used for the running subcuticular suture (see Ch. 146). Knot strength is directly proportional to the friction coefficient of the suture material. The more slippery the suture material, the more likely it is that the resulting knot will unravel. Hence, when suturing with polypropylene, it may be useful to place several additional throws for each knot.

- **Memory** is defined as a suture's tendency to retain its natural configuration and is determined by the elasticity and plasticity of the suture material. Memory is a useful property for maintaining closure during the postoperative period, and high-memory sutures such as nylon are widely used for surface approximation. Drawbacks of high-memory sutures are that they do not handle very easily and they have a relatively low knot strength. As with sutures that have a low coefficient of friction, the surgeon may find that it is helpful to place a few extra throws in order to ensure a secure knot. Suture material with low memory, such as silk, is easy to handle and rarely becomes untied.
- **Plasticity** is the ability of the suture to be molded or to retain its new length and form as well as tensile strength after it has been stretched. This is an important characteristic for a suture material that is to be used in situations with tissue edema. Sutures with plasticity, such as polypropylene, will stretch to accommodate edema and not cut into tissue[16].
- **Pliability** refers to how easily the suture can be bent. Braided suture materials, such as silk, are the most pliable, and they are capable of readily being tied into a knot. Polyglactin (Vicryl®) is a buried, absorbable braided suture that is also easily tied.
- The **tensile strength** of a suture is determined by the force (in pounds) required to snap it divided by the cross-sectional diameter of the suture. In general, synthetic materials are stronger than natural materials. A suture that has been knotted has approximately one-third of the tensile strength of the same material unknotted[17].
- **Tissue reactivity** is the degree of foreign body inflammatory response evoked by a suture when placed into a wound. In general, natural materials (e.g. surgical gut, silk) cause much more of an inflammatory response than synthetic materials (e.g. nylon, polypropylene, polyester)[13,18].

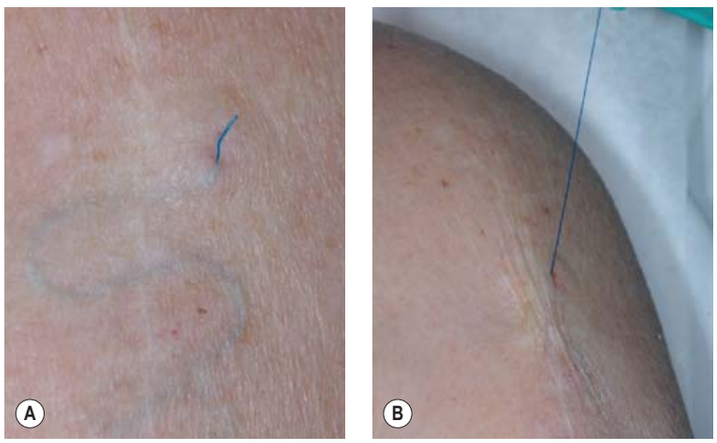

Fig. 144.1 Polypropylene suture – demonstration of its low coefficient of friction. A The blue color of the polypropylene suture is visible under the skin 1 year after its placement as a running subcuticular closure; the patient had neglected to return for suture removal. **B** The ease of removal, despite having been in the skin for 1 year, demonstrates its very low coefficient of friction and minimal tissue adherence.

Types of Suture Material

Sutures are characterized as absorbable or non-absorbable, based upon their ability to be enzymatically digested or hydrolyzed. Most *absorbable* sutures lose the majority of their tensile strength long before they are fully absorbed. In general, absorbable sutures are used to close the dermis and deeper subcutaneous layers and are not removed. *Non-absorbable* sutures are resistant to hydrolysis and enzymatic degradation. Non-absorbable sutures such as nylon and polypropylene are usually used as surface sutures, and they are routinely removed 5–10 days after surgery (earlier on the face and later on the trunk and extremities).

Absorbable Sutures

The most commonly employed absorbable sutures are outlined in Table 144.1[19].

Surgical gut

Surgical gut (catgut), one of the first sutures ever mass-produced, is derived from bovine or sheep intestine. It is a natural tan fiber that is packaged wet in alcohol and dries quickly when exposed to air. Plain

COMMONLY USED ABSORBABLE SUTURES

Suture	Configuration	Tensile strength	Ease of handling	Knot security*	Tissue reactivity	Uses
Surgical gut (plain)	Virtually monofilament	Poor at 7–10 days	Fair	Poor	Moderate	Rarely used today in skin
Surgical gut (chromic)	Virtually monofilament	Poor at 21–28 days	Poor	Poor	Less than plain	Skin grafts; surface sutures for mucosae
Surgical gut (fast-absorbing)	Virtually monofilament	50% at 3–5 days	Fair	Poor	Low	Skin grafts, surface sutures
Polyglycolic acid (Dexon®)	Braided†	20% at 21 days	Good	Good	Low	Subcutaneous closure, vessel ligature
Polyglactin 910 (Vicryl®, Polysorb®)	Braided†	75% at 14 days; 50% at 21 days	Good	Fair	Low	Subcutaneous closure, vessel ligature
Polydioxanone (PDS II®)	Monofilament	70% at 14 days; 50% at 30 days; 25% at 42 days	Poor	Poor	Low	Subcutaneous closure (high-tension areas)
Polyglyconate, a copolymer of glycolic acid and trimethylene carbonate (Maxon®)	Monofilament	81% at 14 days; 59% at 28 days	Fair	Good	Low	Subcutaneous closure (high-tension areas)
Poliglecaprone 25, a copolymer of glycolide and ε-caprolactone (Monocryl®)	Monofilament	50–60% at 7 days	Good	Good	Minimal	Subcutaneous closure when minimal tissue reactivity is essential
Glycomer 631 (Biosyn®)	Monofilament	75% at 14 days; 40% at 21 days	Good	Poor	Minimal	Subcutaneous closure (high-tension areas)

*Directly proportional to the friction coefficient and indirectly proportional to memory.
†Multifilament.

Table 144.1 Commonly used absorbable sutures. Adapted from ref. 19.

surgical gut is rarely used today because of its poor tensile strength and high tissue reactivity. When used as a buried suture, plain gut loses its tensile strength in 7 to 10 days and is completely digested in 60 to 70 days[20].

Chromic gut is plain gut that has been processed with chromium salts to increase its resistance to enzymatic degradation and to decrease its tissue reactivity. The tensile strength of chromic gut typically lasts for 10 to 14 days. Chromic gut is still widely used for surface suturing of mucosal surfaces, where it lasts long enough to maintain wound edge apposition but breaks down reasonably fast.

Fast-absorbing gut is plain gut that has been heated to begin breakdown of the collagen within the suture prior to use. This suture maintains its tensile strength for 3 to 5 days[21]. Fast-absorbing gut has experienced renewed popularity over the past 10 years for suturing skin grafts and for placing surface sutures in wounds that are well approximated by buried sutures. No increase in wound infections has been reported and it is convenient for both the surgeon and patient because suture removal is not necessary[21,22]. However, wound edge dehiscence is a possible risk due to the short duration of tensile strength.

Polyglycolic acid

Polyglycolic acid (Dexon®), introduced in 1970, was the first synthetic absorbable suture and its low tissue reactivity and predictable absorption profile represented a vast improvement over surgical gut[23]. It is a braided glycolic acid polymer with easy handling qualities, and it maintains 20% of its tensile strength at 3 weeks. Dexon® produces minimal inflammation, because it is absorbed primarily by hydrolysis, unlike surgical gut, which is degraded by proteolytic enzymes[23,24]. Poloxamer 188-coated and uncoated Dexon® are available. The lubricant coating makes the suture easier to tie and allows it to pass more easily through tissue.

Polyglactin 910

Polyglactin 910 (Vicryl®, Polysorb®), a synthetic, braided copolymer of glycolide and L-lactide, was first introduced in 1974 and supplanted Dexon® as the most popular buried suture in cutaneous surgery[25]. Similar to Dexon®, the absorption of Vicryl® occurs primarily via hydrolysis. The water-repelling properties of lactide delay penetration of water, and thus delay the loss of tensile strength. Polyglactin 910 (Vicryl®) maintains 75% of its tensile strength at 2 weeks and 50% at 3 weeks. Although stronger than polyglycolic acid, polyglactin 910 absorption is usually complete by 90 days, whereas polyglycolic acid is usually still being absorbed at 120 days[24].

Vicryl® is available either undyed or dyed violet. The violet form may be visible when embedded in the skin, and for cutaneous surgery, it should be avoided[26]. Vicryl® is available with a lubricant coating of polyglactin 370 and calcium stearate that allows for easier suture passage through tissue. Vicryl® is immensely popular due to its easy handling characteristics. It also holds knots well and does not tear tissue.

Although polyglactin 910 is traditionally used as an absorbable dermal suture, it may safely be used for wound edge approximation as a running suture and then removed at 5–14 days[27]. This method still requires suture removal, but the use of a single suture for both the dermal and epidermal wound closure results in a 50% saving of suture cost per reconstruction. Based upon the authors' experience, it is also an excellent choice for the vermilion lip as it causes much less inflammation than silk and still does not irritate the opposing mucosal surface.

Polyglactin 910 is also available in a partially hydrolyzed form (Vicryl Rapide®), which is particularly useful as a percutaneous suture that does not need to be removed because it spontaneously dislodges within 7–14 days. Similar to fast-absorbing gut, it is indicated for wound edge approximation where only 1–2 weeks of support will be needed and suture removal may be painful or is not convenient.

Polydioxanone

Polydioxanone (PDS II®) is a monofilament polymer made from the polyester poly (*p*-dioxanone). Introduced in 1980, the primary advantage of PDS® over polyglycolic acid (Dexon®) and polyglactin 910 (Vicryl®) is prolonged tensile strength[28]. It maintains approximately 70% of its tensile strength at 2 weeks and 50% at 4 weeks. Traces of buried polydioxanone are present in 6-month histologic preparations[15]. PDS® is employed in high-tension areas, such as the proximal extremities and trunk.

Similar to Dexon® and Vicryl®, PDS® has minimal tissue reactivity[28]. As a monofilament suture, it retains packaging memory[15], and can be relatively stiff and difficult to tie[29]. However, polydioxanone demonstrates an optimal capacity to glide through tissue[15], and the monofilament configuration allows it to be used safely in contaminated wounds. When compared with polypropylene, nylon and polyglycolic acid as a subcuticular closure, polydiaxanone was associated with a lower incidence of hypertrophic scar formation[30].

Polyglyconate

Polyglyconate, a copolymer of glycolic acid and trimethylene carbonate, is used to create a monofilament suture (Maxon®). It combines the prolonged tensile strength of PDS® with supple handling and smooth knot formation[29]. This suture maintains 81% of its tensile strength at 2 weeks and 59% at 4 weeks[31], with complete absorption occurring via hydrolysis within ~180 days. Despite this prolonged absorption, there is minimal tissue reactivity. Maxon® may be most useful for large surgical procedures on the trunk or extremities that are under substantial tension and which require prolonged, suture-based approximation during healing.

Poliglecaprone 25

Poliglecaprone 25 (Monocryl®) is an absorbable monofilament suture consisting of a copolymer of glycolide and ε-caprolactone. At 7 days, it maintains approximately 50–60% of its tensile strength, and complete absorption by hydrolysis occurs at ~90 days[15]. Similar to Maxon®, Monocryl® offers supple handling and minimal tissue reactivity, which led to a lower incidence of hypertrophic scarring in a breast reduction scar model[32]. Furthermore, poliglecaprone 25 demonstrates better knot tying and security than other commonly used absorbable monofilament suture materials[15]. Because poliglecaprone 25 leads to less inflammation than polyglactin 910 and glides easily through tissue, it has become the absorbable suture-of-choice for many dermatologic surgeons when performing closures in the head and neck region.

Glycomer 631

Glycomer 631 (Biosyn®) is an absorbable monofilament suture material with physical characteristics similar to poliglecaprone 25 (Monocryl®). Complete absorption occurs at approximately 6 months, with low tissue reactivity[15]. Because of its relative permanence, Biosyn® (like Maxon®) is used to suture large truncal wounds.

Non-absorbable Sutures

The most commonly employed non-absorbable sutures are outlined in Table 144.2[19].

Silk

Silk is a braided, natural suture. It represents the gold standard with regard to ease of handling, knot formation and knot stability, by which newer synthetic sutures are measured. Also, braided silk is very soft and pliable, and, therefore, it is commonly used on mucosal surfaces and in intertriginous regions. Despite these advantages, there are major drawbacks to its use in cutaneous surgery. Silk has a low tensile strength, its braided configuration produces a high coefficient of friction, and the high capillarity increases the risk of infection. In one study, for example, the presence of one braided silk suture increased the risk for a staphylococcal infection by 10 000-fold[33]. As an organic, foreign protein (fibroin) made by the silkworm, silk has greater tissue reactivity than any other suture except surgical gut.

Nylon

Nylon (Ethilon®, Dermalon®), a monofilament, polymerized polyamide introduced in 1940, was the first synthetic non-absorbable suture to become commercially available. Nylon quickly became very popular, and because it has high tensile strength and low tissue reactivity and is inexpensive, it is the most commonly used non-absorbable suture in dermatologic surgery[34,35]. Monofilament nylon is available in clear, black or green colors, and the green suture can be particularly helpful

COMMONLY USED NON-ABSORBABLE SUTURES						
Suture	**Configuration**	**Tensile strength**	**Ease of handling**	**Knot security***	**Tissue reactivity**	**Uses**
Silk	Braided†	None in 365 days	Gold standard	Good	Moderate	Mucosal surfaces
Nylon:						
Ethilon®	Monofilament	Decreases 20% per year	Good to fair	Poor	Low	Skin surface closure
Dermalon®	Monofilament	Good	Good to fair	Poor		
Surgilon®	Braided†	Good	Good	Fair		
Nurolon®	Braided†	Good	Good	Fair		
Polypropylene (Prolene®, Surgilene®, Surgipro®)	Monofilament	Extended	Good to fair	Poor	Minimal	Skin surface closure, running subcuticular suture
Polyester (Dacron®, Mersilene®, Ethibond®)	Braided†	Indefinitely	Very good	Good (coating decreases)	Minimal	Mucosal surfaces
Polybutester (Novafil®)	Monofilament	Extended	Good to fair	Poor	Low	Skin closure when significant edema is anticipated (elastic suture)

*Directly proportional to the friction coefficient and indirectly proportional to memory.
†Multifilament.

Table 144.2 Commonly used non-absorbable sutures. Adapted from ref. 19.

when performing closures in dark hair-bearing areas. Nylon is also available as a braided suture (Surgilon®, Nurolon®), which handles more easily but is more expensive.

Nylon's elasticity allows it to expand and contract with transient wound edema but its stiffness and memory lead to decreased knot security[35]. In practice, this can be easily counteracted by firmly setting knots and increasing the number of knot throws. Traditionally, nylon is placed as a cutaneous suture but clear nylon may be used as a permanent, tension-bearing, dermal suture that is not removed. This can be very useful when approximating the orbicularis oris muscle in a lip wedge repair or when tacking tissue to the periosteum, i.e. situations where prolonged wound strength is desired. In addition, when compared to polyglycolic acid, subcuticular nylon sutures were found to decrease the risk for scar spread[36].

Polypropylene

Polypropylene (Prolene®, Surgilene®, Surgipro®) is a monofilament polymer of propylene[37]. An inert plastic, it has minimal tissue reactivity. The major advantage of this suture is its low coefficient of friction, which allows for a gentle, smooth pull through tissue[37]. Even after extended periods of time, it can be withdrawn easily without disrupting the wound (see Fig. 144.1). This characteristic makes it the suture of choice for the running subcuticular suture. Polypropylene also has high plasticity and stretches with tissue swelling, thus reducing the likelihood of postoperative track marks[16,35] (see Ch. 151). Disadvantages of this suture are its memory (which compromises knot security) and increased cost compared to nylon. It is available in clear and blue colors. Similar to nylon, clear polypropylene may be used as a dermal suture in areas of high tension in order to provide prolonged support.

Polyester

Polyester sutures (Dacron®, Mersilene®, Ethibond®) are braided, multifilament sutures with high tensile strength, very good handling, and low tissue reactivity. These sutures last indefinitely in the body. Ethibond® comes coated with polybutilate, which decreases its drag through tissue (decreased friction coefficient). Similar to Vicryl®, polyester sutures are of great assistance for approximation of mucosal tissues, particularly the vermilion lip. They combine the soft feel of silk with a lack of tissue reactivity.

Polybutester

Polybutester (Novafil®) is a monofilament suture of polyglycol terephthalate and polybutylene terephthalates. Its major advantages are excellent handling, low coefficient of friction, high elasticity, and low tissue reactivity[38].

COMMONLY UTILIZED SUTURES BY SITE			
Site	**Deep suture**	**Surface suture**	**Other suture**
Face	4–0 or 5–0 polyglactin 910 or poliglecaprone 25	5–0 or 6–0 nylon or polypropylene	
Neck and distal extremities	4–0 polyglactin 910 or poliglecaprone 25	4–0 or 5–0 nylon or polypropylene	
Trunk and proximal extremities	3–0 or 4–0 polyglactin 910 or polyglyconate	3–0 or 4–0 nylon or polypropylene	
Mucosa	None	5–0 silk or polyester	
Vascular ligature			4–0 or 5–0 polyglactin 910

Table 144.3 Commonly utilized sutures by site. Note that there is considerable variation, depending upon the preference of the surgeon.

Suture Selection

In general, a surgeon should select the smallest suture that will provide adequate strength for a given closure (Table 144.3). For facial repairs, 4–0 or 5–0 polyglactin 910 (Vicryl®) are common absorbable sutures, and 5–0 or 6–0 nylon or polypropylene are typical surface sutures. Poliglecaprone 25 (Monocryl®) is popular as a dermal suture due to its relatively fast absorption and lack of tissue reactivity; it is useful in areas where minimal tissue reactivity is essential. Prolene® is the suture of choice for the running subcuticular suture given its low coefficient of friction.

For larger truncal defects, 3–0 or 4–0 Vicryl® or Monocryl® for buried sutures and 3–0 or 4–0 nylon for epidermal closure are good choices. PDS® is used mainly for dermal and subcutaneous suturing of large truncal defects, because it assures prolonged support. Maxon® can also be used when very-long-term wound support is essential. Skin staples offer a quick, strong alternative for epidermal closure of large scalp and truncal defects[39].

Fast-absorbing gut (6–0 or 5–0) is a convenient suture for small full-thickness skin grafts and for linear repairs that are well approximated with buried sutures. Recent studies have confirmed the safety, convenience and economy of using absorbable sutures (e.g. Vicryl®, Monocryl®, surgical gut) for epidermal skin closures in certain clinical situations, but they still require removal, similar to a non-absorbable suture[22,27,40].

Octylcyanoacrylate tissue adhesive (Dermabond®) is a practical, but expensive, alternative method of epidermal closure in wounds with minimal to no tension[41,42]. Wound closure tapes offer a non-traumatic alternative to epidermal sutures, and they are useful when applied to healing wounds following suture or staple removal. Additionally, they can be used over a running subcuticular suture at the time of surgery, relieving tension from the wound edges and providing a cosmetic, convenient alternative to a daily dressing change[43]. The optimal application of wound closure tapes is in a parallel, non-overlapping pattern (perpendicular to wound tension), following complete coating of the skin surface with Mastisol® adhesive[44].

Complications

Suture-related complications are generally due to placement technique, i.e. the sutures are tied too tightly and strangulate tissue or they are tied too loosely and not do not adequately approximate the wound edges. However, suture materials can also create complications due to their inherent properties. For example, sutures such as surgical gut and silk frequently induce inflammatory tissue reactions. Absorbable sutures (e.g. Vicryl®, Monocryl®) generally lead to little or no tissue reaction, but occasionally they may cause a granulomatous foreign body reaction (see Fig. 151.18). The latter can be seen with both braided and monofilament sutures.

Patients can develop a sterile pustule or suture abscess with associated inflammation ranging from mild to marked (Fig. 144.2A,B). These reactions can be distressing, especially if the patient has not been warned of the possibility they may occur. In patients receiving anticoagulants, the reaction may be hemorrhagic rather than purulent (Fig. 144.2C,D). Rarely, they may become secondarily infected (Fig. 144.2E). Sutures may also extrude or "spit" and create a sinus track within the skin (Fig. 144.2F).

Removal of the offending suture is the basic treatment for both a suture abscess and an extruding or "spitting" suture. If it is readily accessible, the suture should be grasped with a smooth forceps and snipped. A comedone extractor may help to express a suture that is slightly embedded; otherwise, the intact skin overlying the suture may need to be nicked with a #11 blade. Unless there is a secondary infection, antibiotics are not necessary. Removing the foreign suture material is usually sufficient to resolve the reaction.

Needles

The ideal needle is sharp and strong, and closely matches the suture diameter. The needle should be strong enough to hold its shape and retain its sharpness, pass after pass. In addition, the size and shape of the needle should be selected to correspond to the thickness and toughness of the tissue to be sutured.

There are several major brands of suture materials and each manufacturer uses a different needle nomenclature (Fig. 144.3). Most manufacturers, however, provide needle comparison reference guides. In general, the needle is the most expensive component of the needle/suture unit.

A needle is composed of three parts: the shank, the body and the point (Fig. 144.4)[45]. In dermatologic surgery, most needles have a swaged (eyeless) shank with a hollow proximal end into which the suture is inserted and then crimped. The suture track is determined by

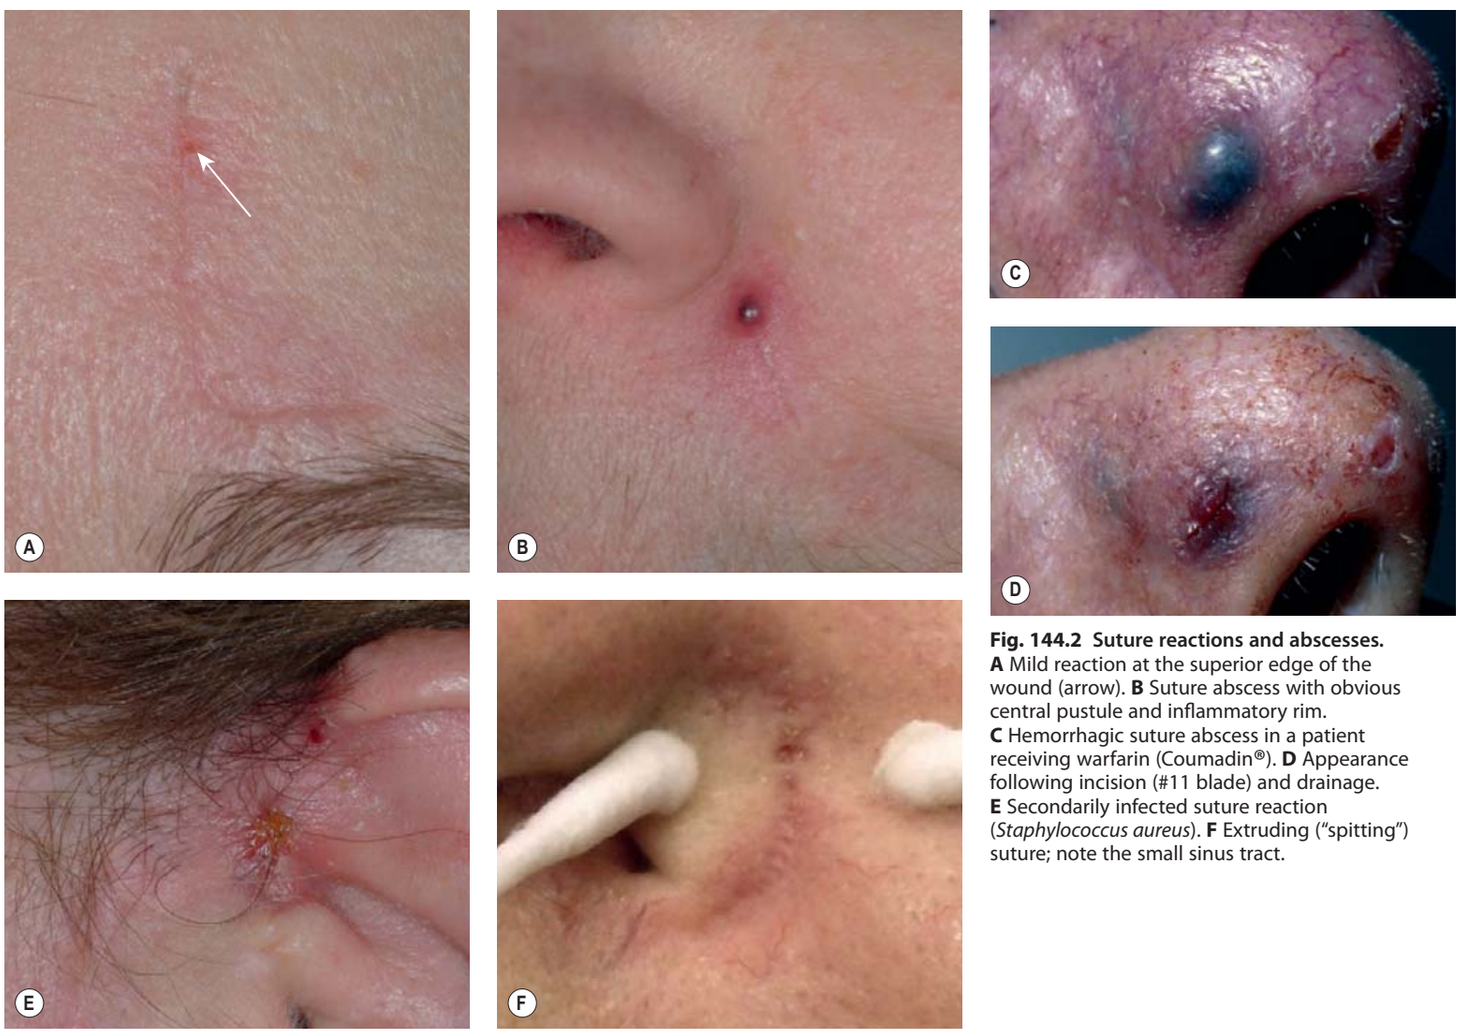

Fig. 144.2 Suture reactions and abscesses. **A** Mild reaction at the superior edge of the wound (arrow). **B** Suture abscess with obvious central pustule and inflammatory rim. **C** Hemorrhagic suture abscess in a patient receiving warfarin (Coumadin®). **D** Appearance following incision (#11 blade) and drainage. **E** Secondarily infected suture reaction (*Staphylococcus aureus*). **F** Extruding ("spitting") suture; note the small sinus tract.

the size of the needle shank, not the suture size. The body of the needle can be straight, 1/4 circle, 3/8 circle, 1/2 circle, or 5/8 circle (Fig. 144.5). The most common shape used in skin surgery is the 3/8 circle. Flattened needle bodies allow for firm grasping with needle holders to limit "twisting" during suture placement.

The most common needle-point used in cutaneous surgery is triangular in shape (see Fig. 144.4). Triangular-shaped "cutting" needles are preferred because they are easier to pass through tissues than are round needles. The conventional cutting needle has a triangular tip and is flat along the outer arc, with a sharp edge on the inside arc of the needle.

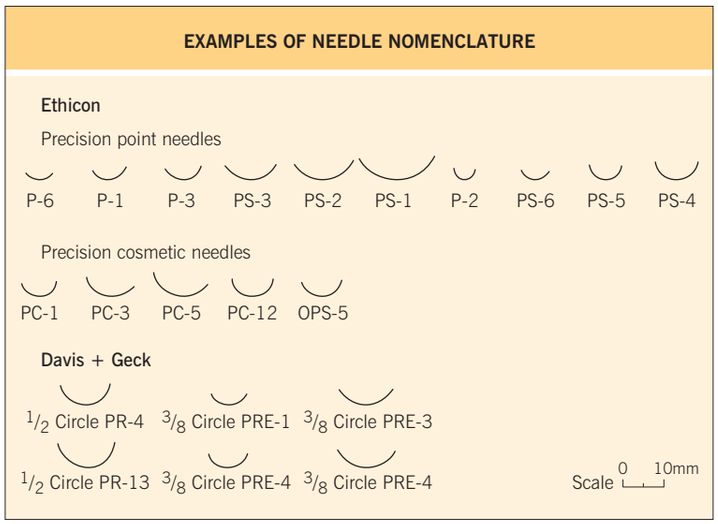

Fig. 144.3 Needle nomenclature by two representative manufacturers.

The reverse cutting tip has a flat edge facing the inside arc of the needle, and a sharp edge facing the outer arc. Reverse cutting needles have the advantage of minimizing the risk of tearing through the wound edge during suture placement. The more the needle-point is honed, the sharper the needle is and the greater the cost of the suture unit.

For the majority of wound closures on the face, the Ethicon P ("plastic") and PS ("plastic skin") or an equivalent series are adequate and economical. The P-3 and PS-3 needles are particularly suited to dermatologic surgery. They are hand-honed and reverse cutting. The PC ("precision cosmetic") series represents Ethicon's superior skin surgery needle, and it can be used for fine, delicate work. These are the sharpest, most expensive needles, and they have flattened bodies for better grasping and conventional cutting points. The PC-1 needle is a very fine sharp needle ideal for repair of delicate facial areas such as the eyelid.

The FS ("for skin") and equivalent series of needles are not finely honed, and they are less sharp and less expensive. These needles are certainly adequate for skin surgery on the trunk or extremities, although some dermatologic surgeons usually use PS needles even for these sites.

The number after the series designation denotes the needle size. Most needles are drawn to size on the package (Fig. 144.6). The smallest needle/suture unit that will provide adequate tensile strength for a given repair should be utilized. In areas with thick dermis (e.g. the back), larger needles are much easier to pass through the tissue and do not bend. A PS-2 reverse cutting needle is very useful for this indication.

Instruments

Proper instruments are essential for effective execution of cutaneous surgery. Instruments should be selected to allow the greatest precision and speed for a given procedure. There is a wide variation in the cost and quality of surgical instruments, and it is clear that "you get what you pay for". A high-quality instrument will more than make up for

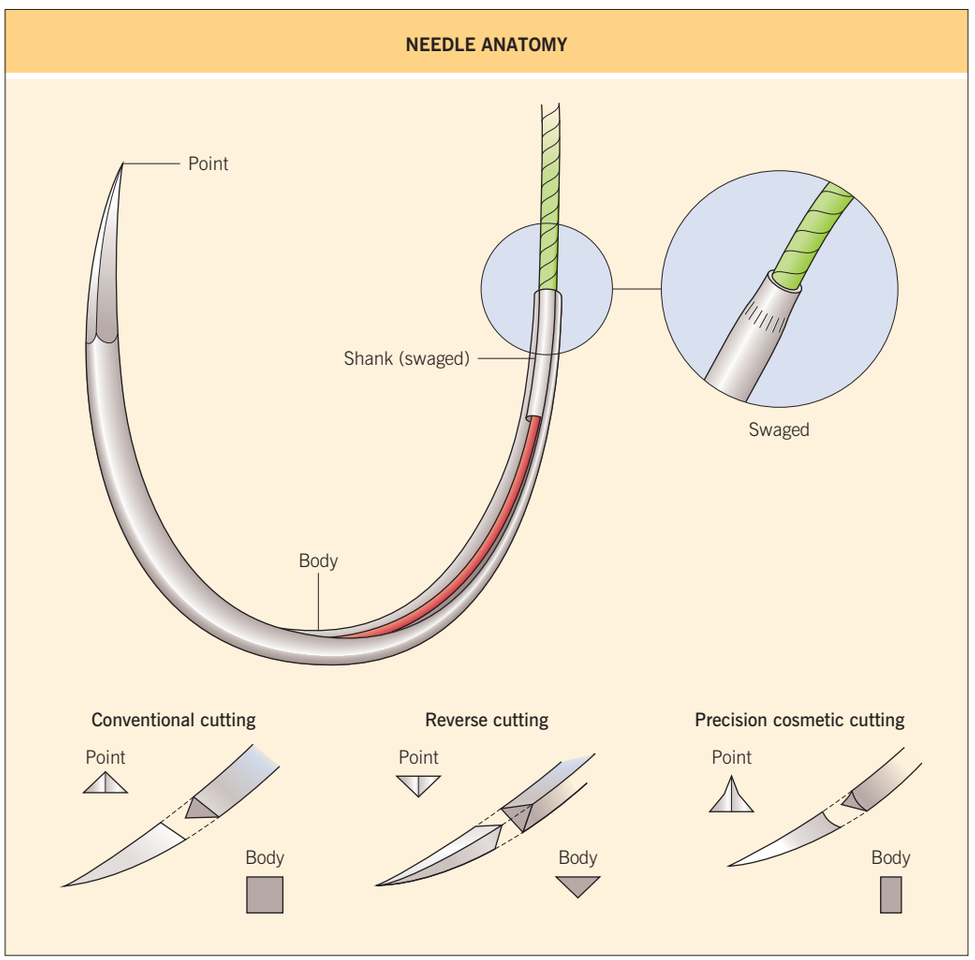

Fig. 144.4 Needle anatomy. The shank body and point are shown, and specific needle points for different types of cutting.

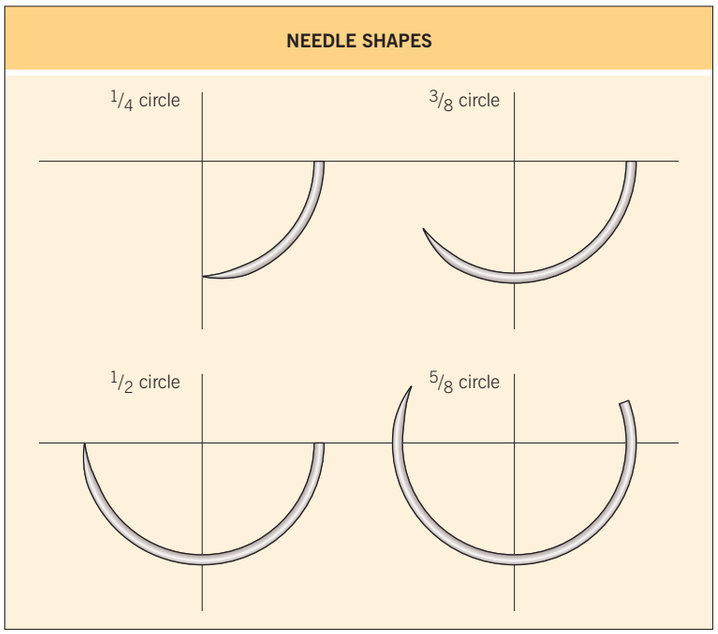

Fig. 144.5 Needle shapes. The most common shape used in skin surgery is the 3/8 circle.

its cost by performing well day after day in countless procedures. Modern instruments are a blend of surgical stainless steel with carbon alloy, chromium, nickel and tungsten carbide. Tungsten carbide is a very hard alloy that enhances function and durability of blades of scissors and jaws of needle holders. Quality instruments are usually covered by a warranty which will range from 1 to 5 years, depending on the instrument type and cost. The surgeon should work closely with a reputable dealer to collect a set of instruments that best fulfills his or her special needs. It is important to keep instruments in good condition by caring for them properly and keeping them sharp.

Some of the authors' instruments and trays of choice for given procedures are listed and shown in Figures 144.7–144.9.

Biopsy blades

Shave biopsies can be performed using a #15 blade on a disposable handle. However, an economical alternative that allows great precision is a Gillette® blade. The disadvantage of this blade is that two back-to-back blades must be separated and sterilized by office staff. In addition, the blades may snap and present a sharp hazard. A similar, more convenient (but more expensive) alternative is the DermaBlade®, which comes prepackaged and sterilized. The DermaBlade® offers a plastic holder that adds a margin of safety for the operator.

Curettes

The first dermatologic instruments were curettes. Developed in the late 1800s, the dermal curette has been used to treat a wide variety of cutaneous neoplasms, both benign and malignant, and they have changed relatively little over the years. Common curettes have a round head (Fox) or an oval head (Cannon), and they are labeled by size (much like sutures), depending upon the aperture of the head of the curette. For standard curettage and electrodesiccation, a set of curettes ranging from 4.0 or 5.0 down to 1.0 or 2.0 is employed. Curettes must be sharpened periodically. They are used for tumor removal and debulking, and they may allow a surgeon to better define tumor margins prior to excision[46]. Disposable curettes tend to be very sharp and may cut into tissue, and the surgeon must be aware of this potential drawback.

Fig. 144.9 Eyelid tray. Tray setup for eyelid surgery includes (from right to left) topical anesthetic, Teflon® eye shield, Beaver blade setup, Westcott (or Castroviejo) scissors, Bishop–Harmon forceps, and ophthalmic ointment. *Instruments courtesy of George Tiemann & Company, Hauppauge, NY, USA.*

Fig. 144.10 Standard scalpel handles. From top to bottom: Beaver blade handle, #7 handle, and #3 handle. *Instruments courtesy of George Tiemann & Company, Hauppauge, NY, USA.*

Scalpels

The choice of scalpel handle and blade is based on the surgical site and personal preference of the surgeon (Fig. 144.10). Available blade handles are flat, round, or long and thin in shape. The flat, standard #3 handle is the most frequently used handle in dermatologic surgery, and it comes with or without an imprinted ruler. This is a durable, inexpensive handle that is adequate for most cutaneous procedures. Many plastic surgeons prefer the rounded, textured #7 handle and feel that it gives better control and comfort because the cutting angle of the blade may be changed by rolling the handle with the fingers rather than having to use the wrist to accomplish the same task with a flat #3 handle. For small procedures, such as those on the eyelid and/or ear, some surgeons prefer small hexagonal or round knurled blade handles.

The most commonly used blades in dermatologic surgery are #15, #10 and #11. The #15 blade is the most popular blade. It is gently curved and is appropriate for the majority of skin surgery. The #10 blade is a wide blade, similar in shape to the #15 blade, and it is used primarily for larger excisional procedures on sites such as the back. Of note, the sharpest area of a curved blade is the belly, not the tip. The #11 blade is tapered to a sharp point; it is used for stab incisions in incision and drainage procedures, removal of milia, and for "through and through" excision. For small specialty procedures, disposable mini-blades are available for use in conjunction with small hexagonal or round knurled blade handles. Scalpel blades are made of either stainless steel or the sharper, more expensive carbon steel. Disposable scalpels are available, but they are not weighted and are usually less sharp. For operator protection, blade extractors are available.

Fig. 144.11 Standard delicate Webster and Halsey needle holders. *Instruments courtesy of George Tiemann & Company, Hauppauge, NY, USA.*

Needle holders

Needle holders for facial and hand surgery are small and light with narrow, fine jaws, while larger needle holders with wide sturdy jaws are designed for work on the trunk and proximal extremities. The jaws of needle holders are either smooth or serrated. As a general rule, smaller, smooth jaws can accommodate finer needles and suture materials, and larger, serrated jaws accommodate larger needles and sutures. Serrations prevent "twisting" of larger needles (e.g. Ethicon PS-2 and FS-2) during suturing. Smooth jaws are less damaging to fine-caliber needles (e.g. Ethicon P-3) and will not tear smaller sutures (6–0), but suture needles may slip if not grasped carefully. There are now some small needle holders that have delicate serrated jaws. These allow for a good grip on fine needles without damaging the needle. Large needles should not be used with fine needle holders as this may lead to damage to the inserts of these delicate instruments, i.e. a fine needle driver used a single time to suture a large wound on the back may never again function properly.

Because of constant metal-to-metal contact, needle holders must be strong and durable. Alloy inserts of tungsten carbide are used to increase the strength and hardness of the jaws and prolong the life of the needle holder. Carbide inserts are more expensive, but they are typically guaranteed for 5 years. Instruments with tungsten carbide have gold finger handles.

Popular models such as the Webster and Halsey needle holders (Fig. 144.11), which have smooth or delicately serrated jaws and tapered tips, are ideal for small needles and fine suture materials. Use of these instruments for procedures on the trunk will lead to their demise. The Crile–Wood needle holder has a gently tapered blunt tip and is designed to hold larger needles. Baumgartner and Mayo–Hegar holders are durable, strong drivers with serrated jaws, which will stand up to repeated use on the back. The Olsen–Hegar needle holder has suture-cutting scissors behind the jaws and is convenient to use when working alone.

Scissors

Surgical scissors are used for cutting skin, undermining, cutting sutures, and removing wound dressings (Fig. 144.12). Scissors may have long or short handles, and the blades are straight or curved and serrated or smooth. The tips may be sharp or blunt. Scissors used in cutaneous surgery can be either completely stainless steel (most popular, least expensive) or have tungsten carbide inserts to strengthen the blades.

Gradle scissors are small, delicate, sharp-tipped, and tapered to a very fine point with a gentle curve[47]. Due to their sharpness and precision, Supercut® Gradle scissors are ideal for removing thin stages during Mohs surgery and for removing skin tags. Gradle scissors must be used with care, and they should never be used to cut sutures. With improper use, they are quickly dulled and the tips are easily malpositioned.

Tissue scissors have relatively short handles and sharp tips. They are available in straight or curved models, with or without the serrations that prevent tissue motion during cutting. Of the various models available, the authors prefer curved Supercut® iris scissors to cut tissue and for sharp dissection. Supercut® iris scissors have the sharpest edge and are easily recognized by their black handles. They are available with smooth edges or one serrated edge. The "razor-like" edge of these scissors makes it possible to cut tissue with a smooth, easy cutting motion.

Westcott and Castroviejo scissors are delicate, spring-loaded tissue scissors with very sharp tips (see Fig. 144.9). The configuration of their handle and spring-loaded action make them ideal for manipulation in small delicate sites, specifically the eyelid. For this reason, they are popular with oculoplastic surgeons. They should only be used for eyelid surgery or they will quickly dull.

Large, less expensive scissors are sufficient for cutting sutures. Tissue scissors should never be used to cut suture material. Specially designed suture-removal scissors with a half-moon hook on the lower blade are available and the small hooked tip easily grasps the loop and prevents accidental sticks (Fig. 144.13). The O'Brien scissors have a short-angled blade that allows for suture cutting with the very tip of the blade so as to avoid digging into the skin.

Undermining scissors are usually blunt-tipped (for safety) and have longer handles (for comfort). They are available in different sizes to accommodate the various anatomic regions in which skin surgery is performed. Baby Metzenbaum scissors have a high handle-to-blade length ratio (see Fig. 144.12), and, with the resultant small blade arc, they have become the most widely used scissor for sharp or blunt undermining. Larger Metzenbaum scissors are ideal for undermining in fascial planes on the scalp, trunk and extremities. Steven's tenotomy scissors and Supercut® Shea undermining scissors are ideal for more superficial, delicate undermining. The tips of these scissors allow for sharp, less traumatic undermining.

The most popular bandage cutting scissors are the 5.5-inch Lister scissors, which have angled blades and large blunt tips that easily slide under a dressing without damaging the underlying skin. The Universal scissor is another popular choice. The serrated edges and larger rings provide greater cutting power.

Forceps

Proper forceps are essential for delicate, safe handling of tissue and suture needles during skin surgery. The most useful forceps in skin surgery are lightweight and have fine tips. The tips may be either toothed (tissue forceps) or serrated (thumb forceps). Serrated forceps can exert excessive pressure on tissues, resulting in crush injury. Toothed forceps have opposing teeth and allow for gentle handling of tissue. The most popular tissue forceps have 1×2 teeth; however, 2×3 and multi-toothed patterns are available. Some forceps have both distal teeth for handling of tissue and a more proximal raised platform for firmly grasping suture needles, allowing the surgeon to avoid manual handling of sharp needles.

Forceps are available with delicate (≤0.6 mm), regular (1–1.5 mm) or heavy (≥1.6 mm) tips. Adson forceps are the standard large forceps used for excisional surgery on the trunk and proximal extremities (see Fig. 144.8). Both the Bishop–Harmon and Foerster forceps are very lightweight, fine-tipped, and ideal for delicate work on the face and hand, where they are our forceps of choice (see Figs 144.7 & 144.9). Because Bishop–Harmon forceps are easily bent and "offset", they must be handled with care, and they should not be used for manipulating the thicker skin of the trunk or proximal extremities.

Both epilating and jewelers' forceps have a fine, sharp point and are useful for suture removal. Splinter forceps have fine, extra-fine or super-fine delicate pointed tips; they are used in hair transplants, for splinter removal, for removing embedded sutures, and for grasping bleeding vessels prior to cautery or electrodesiccation.

Hemostats

Hemostats are used to grasp bleeding vessels prior to ligation. The most popular hemostat is the Halstead Mosquito model, which is available in 3.5-inch and 5-inch lengths, either curved or straight, and either delicate- or regular-tipped.

Skin hooks

Skin hooks enable the surgeon to handle tissue with minimal trauma, and they are particularly useful for elevating flaps and reflecting skin edges during undermining[48]. Many surgeons also use skin hooks to visualize bleeding vessels for hemostasis and for placement of dermal sutures. Since the rise in HIV and hepatitis C viral infections, some

STERILIZATION METHODS		
Method	**Advantages**	**Disadvantages**
Steam autoclave	Most popular in office; easiest; safest	Must use 20–30 min at 2 atm pressure and 121°C; corrosive; may dull sharp instruments
Chemiclave	Lower humidity than steam; less dulling of sharp instruments; instruments are drier	Special chemical needed (mixture of formaldehyde, methyl ethyl ketone, acetone and alcohols)
Dry heat (oven)	Inexpensive; no corrosion or dulling	High temperature, longer time (1 h at 171°C; 6 h at 121°C); cannot use cloth, paper or plastic
Gas sterilization	Good for large volumes (mostly used in hospitals)	Expensive equipment; prolonged times (1 day for paper, 7 days for polyvinyl chloride); toxic and mutagenic gas
Cold sterilization (alcohol, detergent, quaternary ammonium, or more effective glutaraldehyde solutions)	Simple; inexpensive	Irritating to skin; not recommended as only method; not always effective against bacterial spores or hepatitis B virus

Table 144.4 Sterilization methods.

surgeons have abandoned the use of the skin hook in exchange for a fine forceps, hoping to decrease the risk of an accidental stick. With caution, however, skin hooks can be valuable when elevating flaps.

Skin hooks are available in single-, double- or multiple-pronged patterns. The multiple-pronged instruments are referred to as skin rakes; they are used mainly for rhytidectomies and larger truncal procedures in which large flaps or margins of tissue are being elevated and/or undermined. Single-pronged hooks are used most frequently in cutaneous surgery for flap elevation and undermining delicate skin (see Fig. 144.7). The single shepherd hook – which has a more circular shape – holds tissue better than does the single standard hook, but it does not release as easily.

Special Instruments

For delicate work near the eye, the dermatologic surgeon needs fine instruments that allow for precise cutting and carefully controlled tissue manipulation. The Beaver handle (see Fig. 144.10), which comes in a variety of sizes, can be rolled with one's fingertips, providing greater precision and control. Beaver handles are fitted with specialized smaller, sharper blades. The #64 blade has a rounded shape with a blunt tip that one may prefer for work around the eye. The #67 blade is smaller but similar in shape to the standard #15 blade, and the #65 blade is a miniature version of the #11 blade for stab incisions. Beaver blades dull more rapidly than do the standard #15 blades. Angled Beaver blades are useful for taking Mohs stages or biopsies in the external ear canal.

The Castroviejo needle holder is ideal for suturing the delicate skin near the eye or for use by a surgeon with small hands and for whom the rings in the standard needle driver prove cumbersome. This needle holder has spring handles and an optional self-locking device. Castroviejo and Westcott scissors provide precise meticulous control when cutting eyelid skin. Lightweight forceps, such as Bishop–Harmon or Foerster forceps, aid in achieving the delicate handling of tissues necessary in this region. Plastic, Teflon® and metal eye shields can be used when the lid margin will be breached and when cautery will be performed near the eye. Metal eye shields conduct heat and electricity while smooth ones reflect laser beams, which may be a disadvantage. Chalazion clamps are commonly used for immobilizing earlobes, lips, eyelids and tongues during procedures on these areas.

Nail nippers, splitters and elevators are necessary for nail surgery (see Ch. 149). The double-action nail nipper is extremely strong, and it will cut the thickest nails. Nail splitters have a perpendicular, flat second blade that will not damage the nail bed.

Sterilization

A summary of sterilization methods is presented in Table 144.4[49].

Key features

- Dressings should provide the optimum environment for rapid healing by protecting the wound from further trauma or bacterial invasion
- Dressings that provide a moist environment and prevent eschar formation allow wounds to re-epithelialize and heal faster than if left uncovered
- Semipermeable or occlusive dressings provide a moist environment, retain wound fluid that contains growth factors conducive to healing, and promote a low tissue oxygen tension that stimulates angiogenesis and deposition of collagen
- A traditional layered dressing consists of a non-adherent contact layer, an absorbent contouring layer and a securing layer
- Advanced technology dressings include the following types: hydrogels, alginates, foams, films and hydrocolloids
- More recently, tissue-engineered composite skin equivalents have been developed, combining living keratinocytes and fibroblasts from human foreskins with bovine collagen

INTRODUCTION

The variety of cutaneous surgical procedures performed by dermatologists, as well as the types of wounds they manage clinically, require dressing materials and techniques that address the specific needs of the injury. In addition to the care of surgical incision sites such as those created by any surgeon, the dermatologist's armamentarium often extends into the care of poorly healing and chronic wounds. The choice of treatment modalities is indeed substantial and ever-expanding, giving dermatologists flexibility in wound care strategy.

THE HISTORY OF DRESSINGS

The practice of using dressings dates back thousands of years. The use of fabrics such as linen on wounds continued for at least 4000 years until woven absorbent cotton gauze was introduced in 1871. The Edwin Smith Surgical Papyrus, which is one of the earliest medical treatises (dating back to 1615 BC), describes the use of linen strips and plaster to dress wounds, stating that closed wounds would heal more quickly than open wounds[1]. Ancient documents disclose how lint was used to pack and fill open wounds and how bandages were used to re-approximate wounds in order to facilitate healing. Linen strips were sometimes coated with grease or oil to prevent adherence to wounds or with honey to create a semi-occlusive and adherent dressing[2].

Lister connected the presence of pus with infections. However, this association became linked such that it was held that one is always indicative of the other, which is not always true. It is this link that interfered with the acceptance of occlusive dressings, as well as with progress in the study of their value. Although the work of Pasteur, Koch and Lister in the late 1800s on the cause of bacterial infections spurred the investigation of specific therapies for wound management, it was not until the mid-1900s that the understanding of wound healing completely changed. Until that time, it was firmly believed that wounds healed more quickly if they were kept dry and uncovered.

In 1948, Oscar Gilje described a "moist chamber effect" for healing ulcers[3]. Two years later, Schilling and colleagues published a study in which the treatment of common minor wounds with highly occlusive or semi-occlusive nylon films was evaluated. They found semi-occlusive dressings to be more effective for healing than open treatment. The fact that the semi-occlusive dressing proved to be more effective than the highly occlusive dressing is said to have set back this area of study. In 1962, George Winter conducted what is considered to be the landmark study on moist wound healing, demonstrating a 30% greater benefit of occlusive dressings versus air drying of wounds[4]. Many studies conducted since Winter's work have contributed to the concept of the benefits of moist wound healing by occlusive dressings.

THE FUNCTIONS OF A WOUND DRESSING

A wound dressing is a substitute for native epithelium lost as a result of injury. The process of wound repair occurs in stages (see Ch. 141), each of which may require different dressings. An ideal wound dressing would have many features (Table 145.1). However, the main function of a dressing is to provide the optimal environment for rapid healing by protecting the wound from further trauma, bacterial invasion or exposure to caustic substances, which is especially important during the early acute, inflammatory stage. The composition of the dressing is also an important consideration. It should be composed of inert material that does not shed fibers or compounds into the wound that could lead to a foreign body reaction or an irritant or allergic reaction[5]. The "ideal" dressing that meets all these requirements for every wound type does not yet exist (Table 145.2). However, in the vast array of dressings available, it is quite possible to select or fashion one for achieving one's goal.

MOIST HEALING ENVIRONMENT

A wound dressing's capacity to maintain a moist environment is of prime importance in healing (Fig. 145.1). There are several mechanisms by which moisture assists the reparative process, the most basic of which is the suppression of tissue desiccation and crust formation. A "scab" or eschar forms as a result of the drying of a wound, particularly of the superficial dermis which itself becomes integrated into the scab. The studies of Winter and Scales illustrated that uncovered, air-dried wounds developed thicker scabs and re-epithelialized at a slower rate. This slower rate has been attributed to the requirement of the regenerating epidermis to migrate deeper below the dry fibrous tissue to a region of moisture where live cells survive. It is only in such an

environment that epidermal cells can move toward bridging the defect of the wound; therefore, the thicker the scab, the deeper the migration. This, along with the continuing loss of dermis and collagen and a reduction in adnexal structures, contributes to the depth of the scars and a worse cosmetic outcome[1].

Many endogenous factors that are critical to wound healing (e.g. fibrin degradation products, platelet-derived growth factor) are found in fluid from occluded (or dressed) acute cutaneous wounds and may be more available in a moist environment (see Ch. 141). Another possible value of a moist wound environment may be its ability to confer an electrical gradient between the wound and normal skin. That is, upon injury of skin, an internal battery and a current flow are created until drying of the wound occurs. It is thought that in maintaining moisture, this electrical gradient may promote epidermal cell migration between the wound and surrounding skin[6].

THE ROLE OF OXYGEN

For many years, it was believed that oxygen availability was of primary importance in the rate of healing. However, subsequent studies have shown that the oxygen requirement is initially low during the early wound repair stages. After acute injury, wounds experience a temporary but extreme hypoxia due to disruption of blood flow from clotting that prevents exsanguination. This distress is the signal for migration of keratinocytes and fibroblasts as well as the initiation of angiogenesis. Hypoxia has been shown to upregulate proliferation and production of transforming growth factor (TGF)-β by dermal fibroblasts; TGF-β is known to stimulate production of extracellular matrix molecules. Under hypoxic conditions, keratinocytes migrate better along collagen and fibronectin, and low oxygen levels also promote angiogenesis in the acute wound[7]. The use of a semipermeable dressing can provide the appropriate oxygen tension for wound repair to proceed quickly.

In summary, *acute* wounds that heal under occlusion have demonstrated accelerated healing, greater resistance to breaking open, and better cosmetic outcomes than those that heal open to the air. Also, as a result of occlusion, *chronic* wounds are often less painful (particularly upon wound debridement) and they have better formation of granulation tissue.

TRADITIONAL WOUND DRESSINGS

Wound dressings can be categorized either by the composition and structure of the dressing or by the dressing technique and how the dressing is utilized relative to the wound. Traditional or conventional dressings have commonly been made of natural, synthetic or partially synthetic materials[1]. Readily available and inexpensive traditional wound dressings include Band-Aids® and Telfa® pads, while multilayered Exu-dry® dressings are more costly.

Naturally occurring materials such as cotton, silk, linen or cellulose-based substances have a long history of use and have been produced in various combinations for maximal clinical usefulness. Bleached cotton is processed into balls or fibers which are woven into gauze pads, packing strips, wrapping strips, knitted tubes and compressed felt.

The basic cotton gauze dressing in use today is frequently composed of cotton plus cellulose acetate (added for increased absorbency) and is

FEATURES OF AN IDEAL WOUND DRESSING
Protects the wound from further trauma
Protects the wound from bacterial invasion or exposure to caustic substances
Conforms to the shape of the wound
Absorbs wound fluid without increasing bacterial proliferation or causing excessive desiccation
Provides pressure for hemostasis
Prevents leakage from the bandage
Supports the wound and surrounding tissues
Eliminates pain
Promotes re-epithelialization during the reparative phase
Can be easily applied and removed with minimal injury to the wound
Composed of an inert material

Table 145.1 Features of an ideal wound dressing.

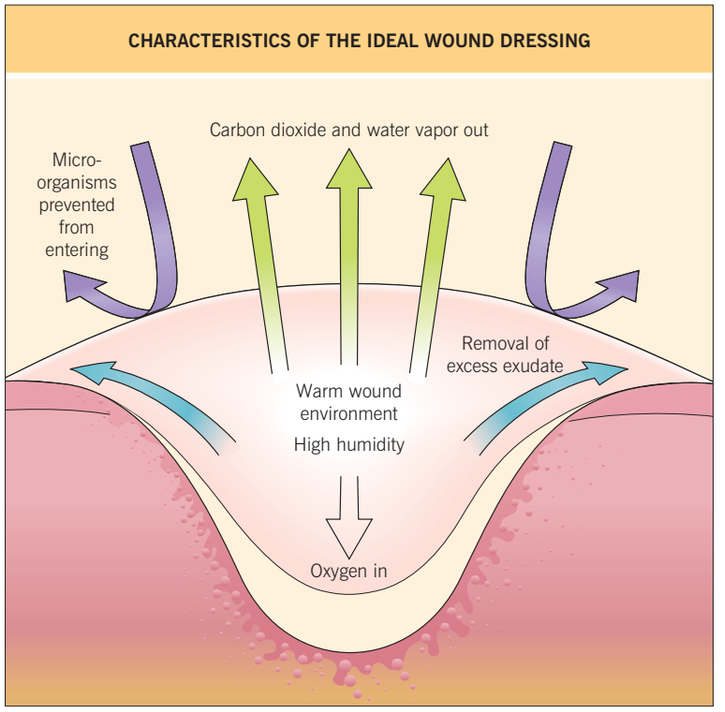

Fig. 145.1 Characteristics of the ideal wound dressing.

COMPARISON OF THE IDEAL DRESSING VERSUS OCCLUSIVE DRESSINGS AND SKIN SUBSTITUTES										
	Characteristics of an ideal dressing									
	Conforms	Absorbs wound fluid	Decreases bacterial proliferation	Provides pressure	Supports surrounding tissue	Eliminates pain	Promotes re-epithelialization	Easily reapplied	Inert material	Does not shed fibers or compounds into the wound
Films						+	+		+	+
Foams	+	++		+		+	+	+	+	
Hydrogels	++	+				++	+	+	+	+
Alginates	++	++	+				+	+		
Hydrocolloids	+	++		+		+	+	+	+	
Epidermal grafts						+	++			+
Dermal grafts					+	+	++	+		+
Composite grafts					+	+	++			+

Table 145.2 Comparison of the ideal dressing versus occlusive dressings and skin substitutes (i.e. ideal dressing versus reality).

manufactured with or without various substances incorporated into the fabric. White petrolatum and other ointments such as soft paraffin wax (e.g. Vaseline™ gauze, Aquaphor® gauze, Adaptic®), with or without antibacterials such as povidone-iodine (Betadine®), sulfadiazine, bismuth tribromophenate (Xeroform®), framycetin and chlorhexidine, are examples of impregnated substances. Balsam of Peru is found in the tulle gras used predominantly in Western Europe. These medicated dressings are often composites of rayon, nylon or gauze, and are used for malodorous wounds such as chronic ulcers. Activated charcoal cloth (with or without antibacterial silver salt) is also used for exudate absorption plus odor control.

These types of dressings are placed directly against the wound bed and have the advantage of having less chance of adhering to the wound as well as the ability to mold into the depression of deeper wounds for the purpose of filling dead space and providing absorption. The disadvantage of this type of dressing is the potential for maceration of the wound and surrounding skin should the dressing remain in place for an extended period of time. Other pros and cons of traditional dressings are that although relatively inexpensive and readily available, they do require frequent replacement, which is time-consuming for the medical staff and the patient and is potentially costly in healthcare personnel time[8].

The technique used for most conventional dressings is that of the "layered dressing" and it is either a "pressure" or "non-pressure" dressing. A layered dressing is usually constructed in three parts (Fig. 145.2): (1) the contact or interface layer, which is usually a non-adherent, fluid-permeable material that makes direct contact with the wound; (2) the absorbent layer, usually a cotton pad, gauze or other such material, which is placed on top of the contact layer to "wick in" and retain wound exudate and help the dressing mold to the shape of the wound; and (3) the outer layer or wrap, often tape or other banding material for retention of the underlying layers. Of note, each layer should be placed in close approximation to the one before it, with no gaps or air pockets, and should increase in size and degree of overlap, from wound bed to outermost layer.

A "pressure" dressing has more bulk added to the absorbent layer and is arranged so as to create hemostasis at the wound site. Usually applied immediately after surgery and changed to a lighter dressing within 24 hours, the body sites for this type of dressing are most often digits, extremities and the scalp. In addition to limiting bleeding, the pressure dressing also minimizes edema and lends support to the surrounding tissue. It is important to be aware of the amount of pressure exerted upon the wound bed so as not to create localized ischemia, potentially resulting in tissue necrosis[9].

FIRST AND SECOND INTENTION HEALING

Postsurgical skin wound defects healing by first intention are those that are clean, free of debris and sutured by aseptic technique. Placing sutures postsurgically provides hemostasis, reduces the possibility of wound infection (which may potentiate a delay in healing and chance of dehiscence), and usually improves the ultimate cosmetic result (see Fig 145.2A). After suture removal, the use of external splinting tape (such as Steri-Strips™) supports the tissues, enabling favorable collagen remodeling that may limit scar formation and hypertrophy.

Second intention healing is often employed following many cutaneous surgical techniques such as punch biopsy, cryosurgery, laser surgery, excision (Fig. 145.3) and curettage. In such cases, moisture at the wound bed is the key to optimal spontaneous healing. A semi-occlusive dressing is the treatment of choice, with the topical application of ointment directly on the wound. Monitoring of the wound, as it progresses

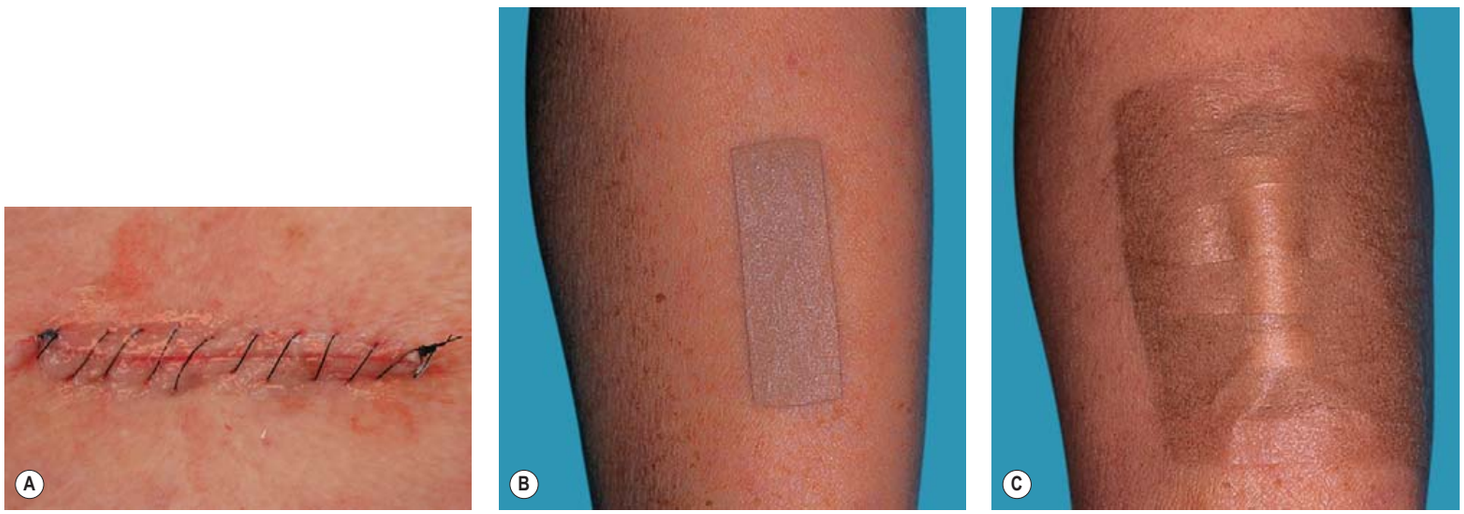

Fig. 145.2 Pressure dressing. A Antibiotic ointment applied over sutures helps to prevent infection and prevents the contact layer from adhering directly to the wound. **B** Three layers of paper tape comprise the contact layer. **C** Rolled gauze or a cotton dental roll can be used to: (i) provide pressure for hemostasis; (ii) aid in conforming the dressing to the wound; and (iii) absorb excess exudate. The entire dressing is secured with additional layers of tape.

Fig. 145.3 Second intention healing. A Surgical wound immediately following Mohs micrographic surgery; a semi-occlusive dressing will be used. **B** Wound healing by second intention 3 weeks following surgery. Note abundance of pink granulation tissue. **C** Fully re-epithelialized wound 6 weeks following surgery.

through stages of healing, for signs of infection and prevention of drying of the wound bed until re-epithelialization has occurred is usually sufficient in the management of this type of surgical wound[10].

DRESSINGS THAT CONTAIN ANTIMICROBIAL AGENTS

The usefulness of topical antimicrobial agents for cutaneous wounds is a matter of debate. It is thought by some that a clean wound created with good aseptic technique does not require a topical antimicrobial, as long as the wound is well cared for in the postsurgical period. Also, while it is well known that infection prolongs wound healing, a distinction must be made between bacterial colonization of the wound and true infection that leads to tissue compromise. Lastly, chronic wounds treated with the most commonly used topical antibiotic preparations often require repeated, sometimes painful, dressing changes.

There are, however, more sophisticated methods of providing bacterial control of wounds. For example, a number of dressings include compounds such as silver and iodine that attempt to control infection (Table 145.3). Silver is an ion that has been used for decades for treating wound infections owing to its strong antimicrobial activity. Silver ions kill microorganisms by inhibiting bacterial-specific enzymes important in bacterial cell wall synthesis and gene transcription. Studies have shown that silver-containing dressings can significantly reduce burn wound-associated sepsis and bacteremia as well as shorten hospitalization time. In addition, silver ions appear to decrease the levels of matrix metalloproteinases that are upregulated in non-healing, chronic wounds.

In older silver-containing dressings, the silver ions were present in the form of silver nitrate ($AgNO_3$) and silver sulfadiazine. However, newer formulations consist of high-density polyethylene mesh impregnated with nanocrystalline silver. Examples of nanocrystalline silver dressings include Acticoat™, Actisorb® Silver (Fig. 145.4), Contreet® Foam, Contreet® Hydrocolloid and Silverlon®. They offer broad-spectrum antibiotic activity against both Gram-positive (including methicillin-resistant *Staphylococcus aureus* [MRSA]) and Gram-negative pathogens[11]. These dressings can release antibacterial levels of silver for 3 to 7 days. A recent meta-analysis found that silver-impregnated dressings may improve the short-term healing of wounds and ulcers, but how these agents affect long-term wound care is still unclear[12].

For over 150 years, iodines have been used to aid wound healing[13]. However, povidone-iodine, a commonly used antiseptic, can actually inhibit wound healing. In contrast, newer formulations – such as cadexomer-iodine polymer, which slowly releases iodine from dextran beads – have not demonstrated toxic effects on keratinocytes. The level of iodine that is slowly released from the beads is sufficiently low so as to confer antimicrobial activity, but with little or no cytotoxic effects; the gel that results from the process then works to absorb exudate. Bacteria and cellular debris become trapped in the spaces between the beads and are removed with irrigation at the time of dressing changes. Recommended for exudative wounds such as leg ulcers, a layer of beads is applied to the wound and covered with a pad or other suitable secondary dressing. The frequency of dressing changes is determined by the nature of the wound, perhaps requiring daily changes (if the beads are saturated) reducing to three times per week as the healing progresses[7]. Studies have shown a significant decrease in ulcer size with cadexomer-iodine when compared to hydrocolloid and paraffin gauze dressings[14].

Cadexomer-iodine is also found in multiple types of occlusive dressings (see next section), including hydrogels (e.g. Iodoflex®). Because the iodine is absorbed, caution must be taken when using these dressings in patients with a history of thyroid disease. They should not be used in young children, pregnant or lactating women, or patients with a known or suspected iodine sensitivity.

Fig. 145.4 Activated charcoal cloth impregnated with silver (Actisorb® Silver 220). The envelope is spun bonded nylon.

ABSORPTIVE AND PASTE DRESSINGS

Medicated paste bandages can be used alone or underneath graduated compression dressings, especially on the lower extremities. In addition, they are used to treat the chronic dermatitis associated with leg ulcers, by creating an absorptive, protective, contact layer against the wound surface and surrounding skin. These open-weave, cotton bandages are impregnated with zinc paste, calamine or ichthammol, all of which have a soothing action on irritated skin; coal tar, which has an

DRESSINGS THAT CONTAIN ANTIMICROBIAL AGENTS

Antimicrobial agent	Examples of dressings	Coverage spectrum	Advantages	Disadvantages
Silver	Acticoat™ (A or N), Actisorb® Silver 220, Algicell® (alginate), Aquacel® Ag, Contreet® Foam, Contreet® Hydrocolloid, Silvercel®, SilvaSorb®, Silverlon®	Broad-spectrum antibacterial, including MRSA and VRE	Release antibacterial levels of silver for 3–7 days Appear to decrease the levels of matrix metalloproteinases that are up-regulated in non-healing, chronic wounds Microbial resistance is rare Variety of products available for different wound situations Infrequent application required	Levels of silver absorption are not well-defined Silver may stain tissues Relatively expensive
Iodine				
• Povidone-iodine	Inadine®; Betadine® cream applied to gauze	Broad-spectrum antimicrobial – bacteria, fungi, viruses	Less irritating to skin than iodine alone	May cause stinging and local irritation May inhibit wound healing
• Cadexomer-iodine	Iodosorb®, Iodoflex®	Broad-spectrum (see above)	Less irritating to skin than iodine alone	May cause stinging and local irritation

*Not to be used in young children, pregnant or lactating women, or individuals with a known iodine sensitivity; to be used cautiously in patients with thyroid disorders.

Table 145.3 Dressings that contain antimicrobial agents. MRSA, methicillin-resistant *Staphylococcus aureus*; VRE, vancomycin-resistant enterococci.

anti-inflammatory effect; or clioquinol, which has deodorizing and antibacterial actions (plus some type of preservative). There are also commercially available preservative-free zinc oxide formulas as well as combinations of zinc oxide with each of the above components and calamine–clioquinol combinations.

Examples

Calaband® (ZnO, calamine); Ichthaband® (zinc paste, ichthammol); Quinaband® (ZnO, clioquinol, calamine); Steripaste® (ZnO; preservative-free); Tarband® (ZnO, coal tar); Viscopaste™ PB7 (ZnO); and Zincaband® (ZnO).

OCCLUSIVE DRESSINGS

Occlusive dressings are a separate category of dressings, commonly divided into five major groups: films, foams, hydrogels, alginates and hydrocolloids (Table 145.4 & Fig. 145.5).

Polymer Films

Polymer films are thin, elastic, transparent sheets of polyurethane or other synthetic semipermeable, self-adhesive, polymer dressing (Fig. 145.6). This dressing is gas-permeable, allowing for the exchange of oxygen, carbon dioxide and water vapor, but impermeable to larger molecule efflux, due to its pore size. Therefore, bacteria and the proteins and water of wound fluids are prevented from moving across the dressing. Its permeability to water vapor allows for the release of insensible water and for sweat from the skin to vaporize. This provides the potential advantage of preventing maceration of the wound and its surrounding skin. The semi-occlusive nature of this dressing allows for passage of oxygen to the wound, which had been considered to be an important feature when these dressings were initially introduced. There has been evidence since then, however, that low pO_2 levels (similar to those that actually exist under the dressings) facilitate healing.

Uses

Although polymer film dressings may theoretically be used on any uncontaminated wound, they are most commonly used to cover intravenous catheter sites and sites of partial-thickness wounds such as skin tears, superficial decubitus ulcers, split-thickness graft donor sites, burns, laser wounds, dermabrasion, and Mohs surgery defects[15]. They are also useful for holding pinch grafts in place for venous ulcer treatment. As the dressing allows for the visual monitoring of the wound, it may be used to keep a graft in place until engraftment. A film dressing can also be used as a "splint" to hold a thin split-thickness graft stiff as it is being harvested from the donor site. The harvested skin graft is prevented from folding or wrinkling by the attached film as it is sutured into place at the recipient site. An additional piece of film may be used to secure the graft instead of using sutures[16].

Examples

Bioclusive™ (Johnson & Johnson); Mefilm® (Mölnlycke); Opsite™ (Smith & Nephew); Polyskin® II (Kendall); ProCyte Transparent Film Dressing (Bard Medical); Silon-TSR® (Bio Med Sciences); and Tegaderm™ Transparent Film Dressing (3M).

Advantages/disadvantages

The advantages of this type of dressing are: its translucency, thereby allowing direct visualization of the wound without removal of the

OCCLUSIVE DRESSINGS

Dressing type	Composition	Permeability	Indicated uses	Advantages	Disadvantages
Films	Thin polyurethane sheet	Semipermeable	Intravenous sites Skin tears Split-thickness graft donor sites Laser resurfacing Mohs surgery defects	Translucent Permeable to water vapor Tends to reduce postoperative pain Creates bacterial barrier	Difficult to position properly May adhere to wound as it dries Possible exudate accumulation Non-absorbent
Foams	Bilaminate polyurethane or silicone	Semipermeable	Chronic wounds Dermabrasion Burns Mohs surgery defects Laser resurfacing	Absorbent Permeable to water vapor Conforms to wound shape Thermally insulates Comfortable	Opaque Cannot be used on dry wounds Possible undesirable drying effect on inadequately exudative wounds
Hydrogels	Hydrophilic polymer sheets, gel and impregnated dressings	Semipermeable with outer membrane in place	Ulcers Dermabrasion Laser resurfacing Superficial thermal burns Chemical peels Graft donor sites	Semitransparent Donates fluid to necrotic tissue Soothing, cushioning and cooling effect, reduction of postoperative pain Available in sheets, powdered or pre-mixed amorphous gels Low trauma at dressing changes Reportedly helpful for pruritus	No spontaneous sucking ability Absorption is slow Requires secondary dressing Caution in infected wounds
Alginates	Seaweed-based complex polysaccharide	Semipermeable	Chronic highly exudative wounds Full-thickness burns Surgical wounds Split-thickness graft donor sites Mohs surgery defects	Highly absorbent with spontaneous sucking ability Hemostatic properties Non-adherent Conforms to wound shape Soluble for low trauma dressing changes with normal saline No reports of toxicity Useful in infected wounds	Requires a secondary dressing to prevent desiccation Gel has unpleasant appearance and odor Mild burning sometimes reported upon application
Hydrocolloids	Starch or plastic woven polymer, dextran, polyethylene glycol, water	Semipermeable	Chronic ulcers Burns Trauma wounds Surgery wounds Dermabrasion Bullous disorders Inflammatory disorders (e.g. lichen simplex chronicus)	Capillary action facilitates debris removal Conforms to wound shape Directly adheres to wound site and is easy to use Increased patient comfort Thermal insulation	Risk of maceration of surrounding skin Possible wound trauma with dressing change Gel has unpleasant appearance and odor Opaque Caution in infected wounds

Table 145.4 Occlusive dressings.

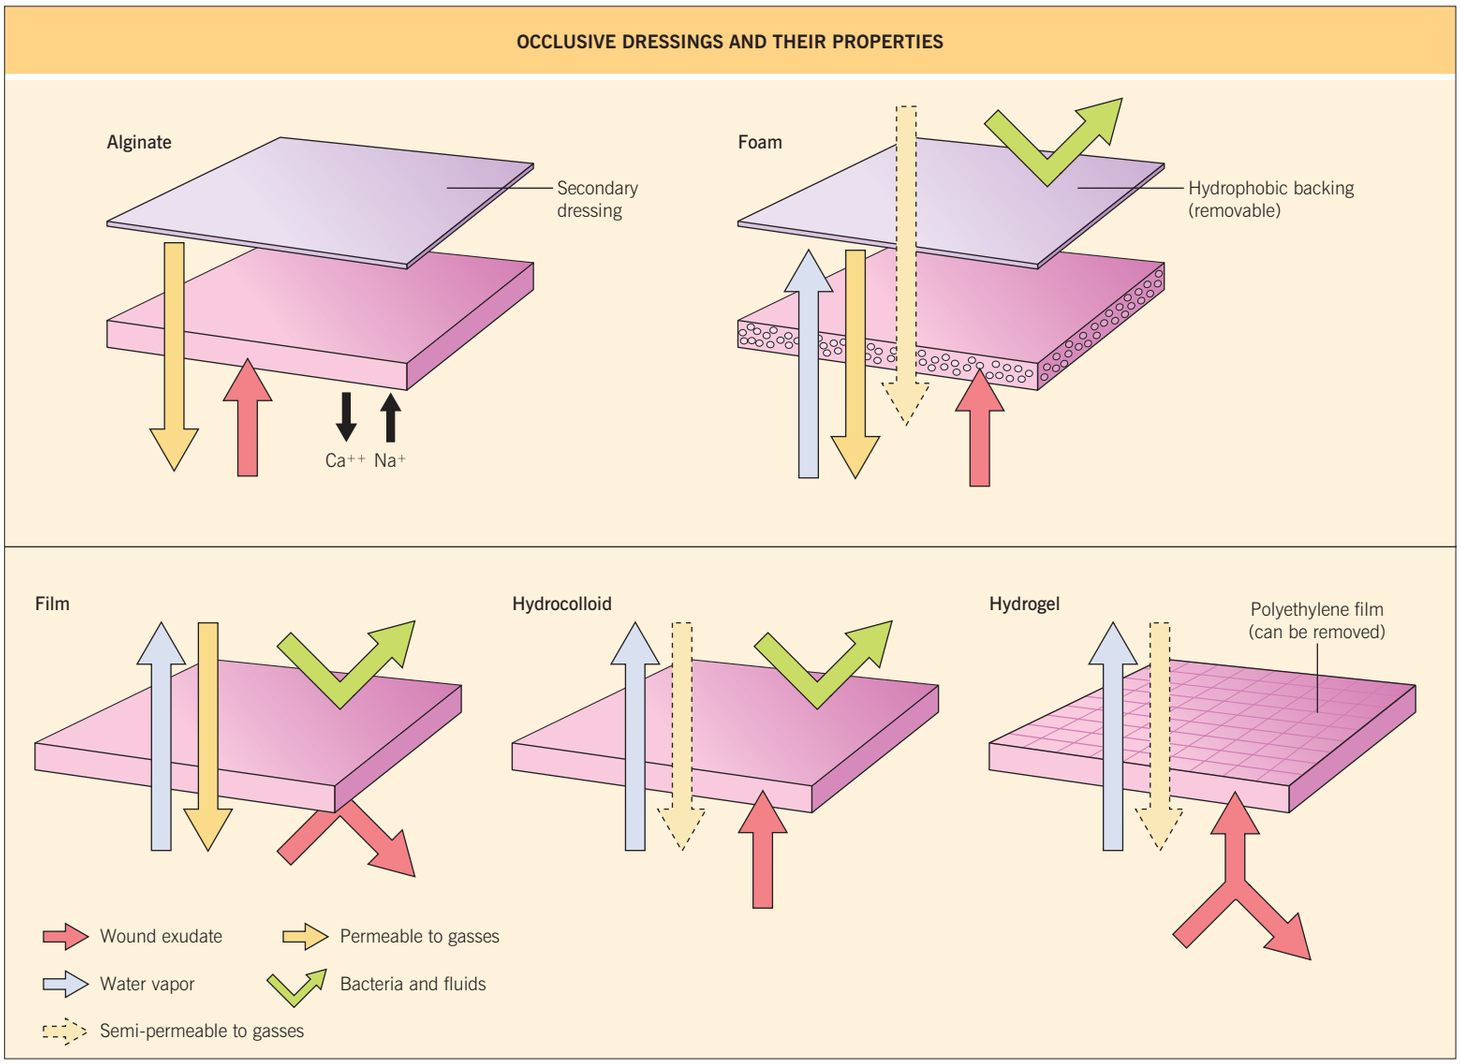

Fig. 145.5 Occlusive dressings and their properties. The five major dressings are polymer films, polymer foams, hydrogels, alginates and hydrocolloids.

Fig. 145.6 A polymer film is used to occlude a wound that has been covered by cotton gauze.

dressing; its permeability to water vapor; and its tendency to reduce postoperative pain. It is also thought to enhance re-epithelialization of graft donor sites, with a reported increase in healing rates of 25–45%[17]. One disadvantage of film dressings is that they are difficult to place properly, requiring uniform tension on the film to prevent wrinkling and its adhering to itself. As the film usually only adheres to intact skin, a 1–2 cm application margin is recommended. Films may also adhere to the wound as drying progresses, thereby risking disruption or stripping of the newly formed epithelium which is not yet tightly bound to the underlying dermal layer. It is possible also to traumatize newly grafted skin tissue during dressing changes. For these reasons, it is advised to allow the film dressing to remain in place until it spontaneously falls off, which can occur after 1–2 weeks.

There are several film dressings, however, that have no adhesive at all or have an adhesive-free zone. Examples of such dressings are Blister Film® (which is composed of polyester rather than polyurethane) and Omniderm®. A dressing with no adhesive maintains contact with the wound via the surface tension created by the fluid layer of the wound. This type of product has been reported to promote wound healing without toxic effects to the underlying tissue[18]. However, any wrinkling of the film during placement can create a conduit for bacterial penetration and for leakage of wound exudative fluid. It is therefore recommended that the film be placed over the wound with a complete 2–3 cm adhesion margin to prevent this leakage.

Another disadvantage of film dressings is that they are non-absorbent; therefore, wound fluid can accumulate under the dressing layer, especially with highly exudative wounds. This is often the case during the first 7–10 days after the creation of a wound. Exudate accumulation does not adversely affect wound healing; in fact, in a study by Buchan et al.[19] it was shown to have significant bactericidal activity. This aside, fluid can leak out, necessitating frequent changing of the dressing for comfort and appearance sake. Because the adherent characteristic of film dressings makes frequent changing undesirable (especially for

certain types of wounds), a 27- or 30-gauge needle can be used to puncture the film for the purpose of aspirating the exudate. This is followed by placement of another piece of the same film to reseal the wound site. Another method employs the placement of butterfly tubing as a drain under the film dressing, with the needle inserted into a Vacutainer® for aspiration.

Numerous studies regarding the proliferation of bacteria under occlusive dressings have documented significant increases in bacterial growth. In such studies, significant increases in bacterial populations, with a shift toward Gram-negative organisms, have been noted and documented[20]. The elevated bacterial counts, however, have not correlated with an increased rate of infection.

Polymer Foams

Polymer foam dressings are semi-occlusive, bilaminate, and polyurethane- or silicone-based. They consist of a hydrophilic foam with a hydrophobic backing, which can prevent leakage, provide a barrier against bacterial penetration, and provide the moist environment afforded by films but with the addition of some absorbency (Fig. 145.7). The inner layer is composed of an absorbent, gas-permeable polyurethane foam mesh, which lies adjacent to the wound. The outer layer is a semipermeable, non-absorbent membrane composed of polyurethane, polyester, silicone or Gore-Tex®, surrounded by a polyoxyethylene glycol foam. This layer protects against outside bacterial contamination to some extent and against the drying out of the underlying layers.

Foam dressings are typically non-adherent, thereby requiring secondary dressing layers to ensure secure placement with a good seal. The quality of the seal is important to prevent leakage, desiccation and problems with adherence. There are, however, some foams available with an adhesive surface, usually surrounding a central absorptive core. Ideally, once a foam dressing has absorbed some amount of exudate, it should be able to retain that fluid, even if exposed to pressure. Some brands are described as having that quality.

Uses

They have been used for: wounds from Mohs surgery, surgical incisions, dermabrasion and burns; chronic wounds such as diabetic ulcers, venous ulcers and pressure ulcers (stages I, II and III); and deep cavity wounds refractory to other methods[21]. They have also gained popularity for use after laser resurfacing, as they greatly reduce postprocedure discomfort and simplify wound care.

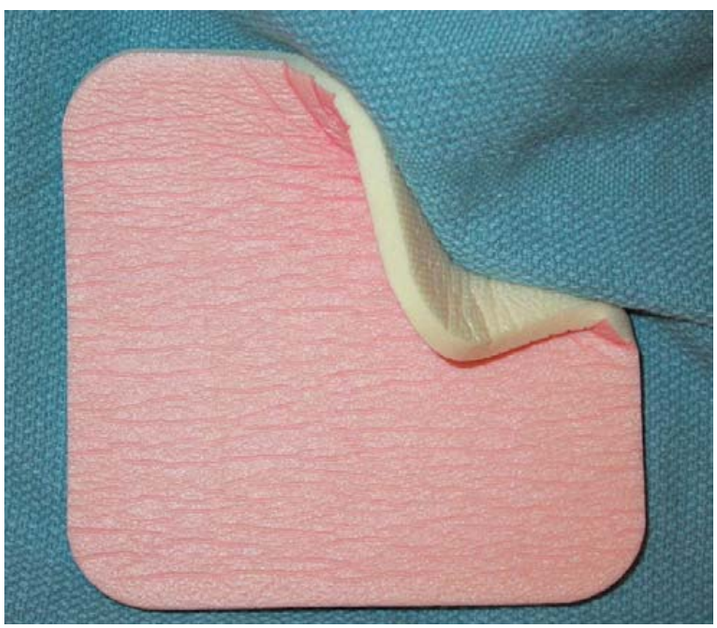

Fig. 145.7 Example of a polymer foam. It consists of a hydrophilic foam with a hydrophobic backing.

Examples

Adherent and non-adherent: Allevyn™ (Smith & Nephew); Biatain™ (Coloplast); Curafoam™ and Hydrosorb® (Kendall); Flexzan® (Bertek); Lyofoam® (Convatec); Mepilex® (Mölnlycke); Optifoam® (Medline); Reston™ (3M); and Sof-Foam™ (Johnson & Johnson).

Advantages/disadvantages

Although very absorbent, there is a limit to the amount of wound exudate this type of dressing can absorb. Therefore, it should be changed every 1–3 days. The permeability of foams to both gas and water vapor makes them suitable for mild to moderately exudative wounds, although there are brands designed for heavily exudative wounds.

Silicone-based rubber foams, known as silastic foams, are composed of a silicone mixture to which a stannous octoate catalyst has been added. This type molds and contours to the shape of the wound and therefore can be used for packing cavities or deep ulcers such as pilonidal sinuses. The additional advantages are absorbency, non-adherence, increased comfort for the patient, a tendency to be less expensive, and dressing changes that do not generally require skilled nursing care[22].

The disadvantages of foam dressings are the inability to use them with dry wounds, their opacity, which prevents visual monitoring of the wound, and the need for frequent changing, perhaps as often as every day. Infrequent changing could risk incorporation of the dressing material into the wound itself. There is also the possibility of an undesirable drying effect of the wound if drainage is insufficient to maintain a moist environment.

Hydrogels

As their name implies, hydrogels are composed primarily of water – up to 96% of the content. This dressing type consists of a cross-linked hydrophilic polymer network composed of polyvinyl alcohol, polyacrylamides, polyethylene oxide or polyvinyl pyrrolidone; it is produced as sheets (Fig. 145.8), amorphous gels (pre-mixed or dry), or as impregnated dressings. Hydrogels are semitransparent (allowing visual inspection of the wound), have a high absorptive capacity (between 100% and 200% of their volume), and are able to maintain a moist wound environment. However, this absorptive action is delayed in its onset and increases slowly as it provides for continuous, long-term absorption. Hydrogels are described as semi-adherent or completely non-adherent, depending upon the subtype, and therefore require a secondary dressing to hold them in place[23]. The latter is necessary as hydrogels are poor bacterial barriers and selectively permit Gram-negative organisms to proliferate. For this reason, antibiotic ointment is often applied prior to the application of the dressing[24]. Hydrogels are soothing and actually lower the temperature of cutaneous wounds, a cooling effect that can be augmented by refrigerating the dressing prior to application.

In general, the sheet form of a hydrogel dressing is constructed by sandwiching the hydrophilic polymer between two removable thin sheets of polyethylene film, with some types containing a supportive inner gel mesh. For application to the wound, the film on the contact side is removed, leaving the outer film in place. With this mode of application, the dressing is semipermeable to gases (including oxygen) and water vapor. If the outer film is also removed, then the dressing

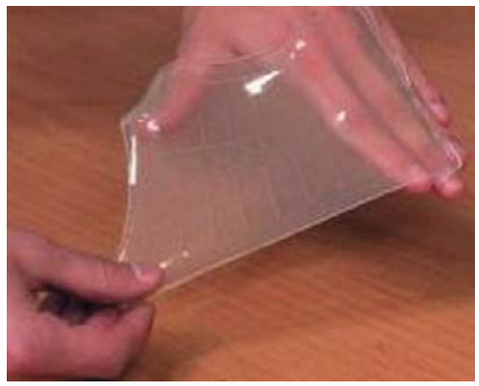

Fig. 145.8 Example of a hydrogel sheet.

becomes permeable to fluid as well; as a result, exudate can pass to a secondary gauze dressing. The polymer sheets can be removed easily without trauma to the wound bed. The amorphous type of hydrogel is composed of a cornstarch-derived, polymerized compound that forms a gel upon hydration at the time of its use. It is available commercially in a powdered or pre-mixed form, is applied wet to the wound defect, requires a secondary outer dressing and requires water application to the surface for removal.

Uses

Hydrogels are particularly useful with dermabrasion, laser resurfacing, chemical peels, superficial thermal burns, ulcers, surgical wounds such as graft donor sites, and partial-thickness wounds in which an interval of light-to-moderate exudate production is likely. They are also quite helpful in the prevention of pressure ulcers.

Examples

Hydrogel sheets: Aquaflo™ (Kendall); Aquasite™ Hydrogel Sheet (Derma); CarraDres™ Clear Hydrogel Sheet, CarraSorb™ M Freeze Dried Gel (Carrington Labs); Lamin-2™ (Procyte Corporation); Nu-Gel™ (Johnson & Johnson); and Vigilon® (Bard Medical).

Amorphous gels: Biolex® Wound Gel (Bard); CarraSyn™ Hydrogel, CarraSorb™ M Freeze Dried Gel (Carrington); GRX® Wound Gel (Geritrex Corp.); Intrasite™ Gel (Smith & Nephew); and Tegagel™ Hydrogel Wound Filler (3M).

Impregnated dressings: Aquagauze™ (Deroyal); DermaGauze™ (DermaRite); and Tegagel™ Hydrogel Wound Filler with gauze (3M).

Advantages/disadvantages

One significant advantage to hydrogel dressings is a reduction in postoperative pain and inflammation. Another is that hydrogels have been shown to accelerate the rate of wound healing when compared to traditional Telfa® and gauze dressings. For example, Geronemus and Robins[25] found, on average, a 25–45% faster rate of re-epithelialization of split-thickness wounds in pig skin. They reported that 100% of hydrogel-treated wounds were healed by postoperative day 4 compared with 32% of open-air (control) wounds. Hydrogels have also been credited with faster healing rates in studies of dermabrasion and hair transplant donor and recipient sites, when compared to standard Telfa® and Adaptic™ dressings[26].

One potential disadvantage is that hydrogels allow bacterial growth at the wound site. However, as with other types of occlusive dressings, studies have not shown an increase in infection rate. The semi- or non-adherent nature of hydrogels often results in more frequent dressing changes than is seen with other occlusive dressings.

Alginates

Alginate dressings are made from a natural, complex polysaccharide derived from various types of algae or kelp (seaweed). An extraction process produces a sodium salt form of alginic acid, and, during a second step, sodium ions are exchanged for calcium, zinc and magnesium. The end result is an alginate fiber, and non-woven mats or twists of this fiber are then made into a dressing (Fig. 145.9). Upon application of the dressing, a reverse ion exchange occurs between the calcium within the alginate fibers and the sodium from blood or the wound exudate. This results in the formation of a soluble sodium alginate gel that fills and completely covers the wound in a non-adherent manner, providing a moist wound healing environment. The extent and rate of gel formation depends on the amount of wound exudate. Alginate dressing materials have hemostatic properties, believed to be the result of the release of free calcium by the fibers during the ion exchange. This release of calcium augments the clotting cascade, producing the hemostatic advantage.

Alginate gel dressings are highly absorbent, which allows them to remain in place at the wound site for several days at a time, thereby minimizing dressing changes. To secure an alginate dressing, a secondary dressing is required. A dressing change is indicated when the dressing has been in place for several days or when exudate soaks through to the secondary dressing[27]. Removal of the dressing in a dried state can re-injure the wound.

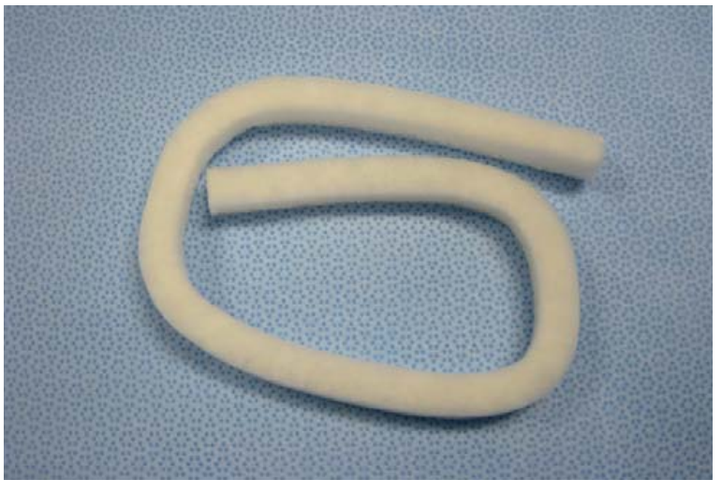

Fig. 145.9 Example of a collagen–alginate complex dressing. The rope form can be used to pack deep wounds.

Uses

As alginates are transformed into a gel matrix by wound fluid, they are best employed for highly exudative wounds. Full-thickness burns and surgical wounds, split-thickness graft donor sites, Mohs surgery defects, and refractory decubitus and chronic ulcers may benefit from alginate dressing application. Alginates can reportedly be used on dry wounds as well, but moistening with saline pre-application is necessary, and the dressing should be changed on a daily basis to limit desiccation.

Examples

Algicell® (Derma Sciences); Algiderm® (Bard Medical); AlgiSite™, Algosteril® (Smith & Nephew); Fibracol® Plus, a collagen–alginate complex dressing (Johnson & Johnson); Kalginate® (DeRoyal); Kaltostat® (ConvaTec); Maxorb® (Medline); and Sorbsan® (Bertek).

Advantages/disadvantages

Alginate dressings are soluble and can be removed by saline irrigation, which allows for less painful dressing changes. They have been shown to encourage wound healing and are metabolized by the body, should residual material remain at the wound. Despite concerns about the potential toxicity of alginates, they have been used for over 50 years without any commonly reported complications. One disadvantage of alginates is that the gel has a yellow–brown appearance, which can be confused with purulent discharge. Therefore, careful wound monitoring for signs of infection is indicated. Similar to hydrocolloids, alginate gel may have an unpleasant odor associated with its normal use, so patients should be made aware of this feature. Additionally, removal of the secondary outer dressing is necessary to visually inspect the wound and to monitor for desiccation.

Hydrocolloids

Colloid is a Greek term for a two-phase system comprised of a uniform dispersion of one phase of matter (unfilterable small particles) into another phase of matter or matrix. Mutually attractive charges exist between the particles, which contributes to the diffusible properties of colloids. Colloids are characterized by the strength of attraction of the particles to the continuous medium and to the proportion of water within that medium. This property accounts for the absorptive and expansive capacity of colloid gels, which function as a semipermeable membrane. Gel swelling occurs because the particle concentration of the gel is usually higher than that of the surrounding medium, thereby drawing water from the surroundings into the gel.

Since cells and tissues throughout the body are comprised of colloids, it seems reasonable that the creation of an environment similar to that found on cell surfaces would aid in the healing process. Colloid dressings are available in more than one usable form, and they were first used as ostomy products. Chronic ulcers and fissures around ostomy

sites were found to heal rapidly when they were bandaged with hydrocolloid products, so these materials were quickly adapted for use as wound dressings.

The most commonly used hydrocolloid dressings (e.g. DuoDERM®) are available as sheets with an inner adhesive layer consisting of a hydrophilic colloid base that is a mixture of pectin, karaya, guar or carboxymethyl cellulose and an adhesive containing polyisobutylene, styrene isoprene or ethylene vinyl acetate (Fig. 145.10). The outer layer is composed of a thin semipermeable material such as polyurethane. A gel is formed in the presence of wound exudate, and as a unit, the dressing is semipermeable to water vapor and gases[28].

Another type of hydrocolloid dressing is a synthetic, non-adherent, high-density plastic woven polymer (e.g. N-Terface®). Fluid is able to flow through this matrix to be absorbed by an overlying dressing without adherence to the new epithelial surface.

Uses

Hydrocolloids are used for the treatment of burns, partial-thickness and dermabrasion wounds, traumatic wounds such as lacerations and abrasions, surgical wounds such as donor graft sites and excisions, chronic ulcers, bullous disorders such as epidermolysis bullosa, and refractory inflammatory diseases such as lichen simplex chronicus and psoriasis.

Examples

Allevyn™ (formerly Cutinova™; Smith and Nephew), RepliCare™ (Smith and Nephew); DuoDERM® (Convatec); Exuderm® (Medline); N-Terface® (Winfield Labs); Primacol® (Derma Sciences); Tielle™ (Johnson &Johnson); Sorbex® (Bard); and Tegasorb™ (3M).

Advantages/disadvantages

When in sheet form, these dressings can be cut and conformed to the shape of the wound. They are waterproof and adhere directly; as a result, they do not require a secondary dressing. In addition, these dressings have a cushioning or pressure-relieving effect (especially at bony sites), which increases as the dressing absorbs exudate. The resulting colloidal gel that forms prevents the dressing from adhering to the wound base. Accumulation of the exudate itself in a moist, semipermeable environment becomes a source of phagocytic cells and endogenous enzymes. This feature, along with the gel, results in autolytic debridement that can be washed away with saline irrigation of the wound bed[29].

Due to their semipermeable outer barrier, hydrocolloids have also been shown to stimulate angiogenesis and increase the rate of healing by as much as 40% when compared to open-air controls. A comparison of hydrocolloids versus wet-to-dry saline gauze dressings in the treatment of decubitus ulcers found that hydrocolloids do not require as many dressing changes as traditional wound dressings. Although the cost of individual hydrocolloid dressings is greater than gauze dressings and the healing rates were the same, the savings were in the cost of nursing time. In addition, the dressing changes tend to be simple and painless for the patient[30].

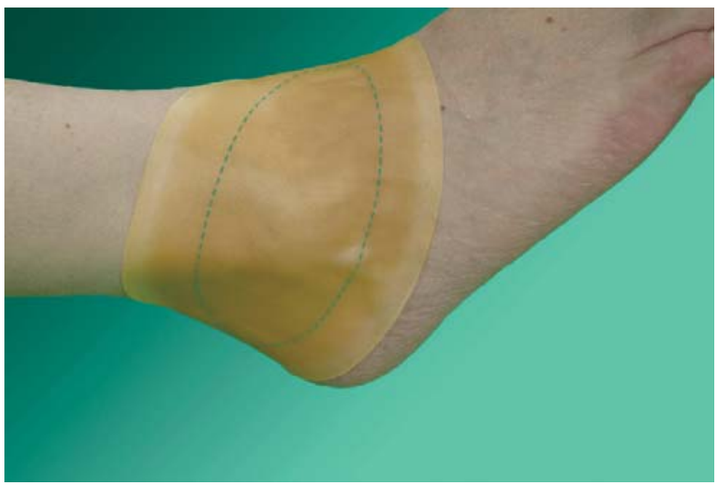

Fig. 145.10 Hydrocolloid wound dressing (DuoDERM®) placed over a healing wound on the ankle. *Courtesy of ConvaTec, Skillman, NJ.*

One disadvantage of hydrocolloids is that as an occlusive dressing, maceration of the skin surrounding the wound is possible. Leakage of excessive tissue exudate can also occur, resulting in soiling of outer garments and bedding. In addition, there is the possibility of the growth of excessive granulation tissue, the extension of which into a woven matrix (as is found in N-Terface®) could result in trauma to the wound upon attempted removal of the dressing. Similar to alginate dressings, the end product of hydrocolloids is a yellow–brown, thick, foul-smelling gel resembling purulent discharge. As with other occlusive dressings, hydrocolloids are subject to similar bacterial proliferation and colonization within the moist environment underneath the dressing, but they have not shown increased rates of infection as a result. Some investigators, in fact, have reported a decrease in the growth of *Pseudomonas* spp.[20].

Composites

The designs of occlusive dressings are constantly changing, with the goal of improved and simplified care for a greater range of wounds. Several new types of composite dressings, which combine two or more types of semi-occlusive dressings into one product, are commercially available. They have three components: (1) a semi- or non-adherent layer that contacts the wound (like a hydrogel, hydrocolloid, foam or alginate); (2) an absorptive layer; and (3) an outer layer (like a film with an adhesive border). This maximizes the efficiency and comfort of the dressing by expanding absorbency as well as lessening the chance of maceration[31]. Other features include the lack of need for secondary retention dressings and better waterproof coverings, which enable the patient to shower or bathe.

Examples

Alldress® (Mölnlycke); Covaderm Plus® (DeRoyal); Stratasorb® (Medline); Telfa XTRA® (Kendall); and Tegaderm™ +Pad (3M).

WOUND THERAPY – SUPPLEMENTAL TREATMENTS

Debridement

With the possible exception of ulcers due to pyoderma gangrenosum, the practice of wound debridement is commonly accepted as the standard of care for leg ulcers. Although there is no solid scientific evidence for the benefit of this procedure, it is thought to permit the adequate development of granulation tissue and epithelialization. Debridement can be accomplished by the following mechanisms: surgically; mechanically via irrigation, wet-to-dry dressings or the use of dextranomers; autolytically via compression bandaging and the use of occlusive dressings such as hydrocolloids and alginates (see above); chemically via proteolytic enzymes; and biosurgically via leeches and maggots[32].

A moist wound environment promotes the lytic activity of enzymes that clear residual debris during early wound healing. Topical application of the commercially available enzymatic agents – collagenase, papain and trypsin, can be used to supplement this autolytic activity. Collagenase (Santyl® ointment) is reported to be effective in the removal of devitalized tissue and to contribute to the formation of granulation tissue and ulcer epithelialization, without attacking healthy or new granulation tissue. Papain (e.g. Accuzyme® ointment, Panafil® ointment or spray) is harmless to viable tissue, while functioning as a potent digestive agent to non-viable tissue. Its action, however, requires the presence of an activator such as urea with which it is processed (usually at a concentration of 10%), since papain alone is relatively ineffective; some formulations also contain chlorophyllin copper complex sodium, which adds to the healing action. Trypsin (e.g. Granulex®, Balsa-Derm®) is processed with balsam of Peru, an effective capillary bed stimulant and mild bactericide, and castor oil, which is used to reduce premature epithelial desiccation and cornification as well as pain.

Fly larvae (order Diptera) have been used for centuries to biosurgically debride chronic ulcers. Today, the most commonly used maggots are

those of the green bottle fly *Lucilia sericata*. These maggots digest necrotic tissue, leaving healthy tissue exposed. This digestion is accomplished though collagenases and trypsin-like enzymes. They also have antimicrobial effects via secretion of antibacterial compounds (e.g. phenylacetic acid, phenylacetaldehyde) and the ingestion and subsequent killing of Gram-positive bacteria (including MRSA) and, to a lesser extent, Gram-negative bacteria. In a small clinical trial, larval therapy was superior to hydrogel therapy with regard to cost-effectiveness and superior wound healing ability[33].

Topical Growth Factors

It is known that exudate from acute cutaneous wounds contains many endogenous factors that are critical to the wound healing process, including growth factors such as platelet-derived growth factor (PDGF) and epidermal growth factor (EGF). As a result, retaining this fluid over wounds, as is accomplished by the use of occlusive dressings, has been shown to augment wound healing. The potential therapeutic use of exogenous growth factors to enhance healing is reviewed in Chapter 141.

Examples

Regranex® 0.01% gel (recombinant human PDGF [rPDGF-BB]; Ortho-McNeil); Procuren® (Cytomedix).

Topical Emulsions

A water-based, trolamine-containing topical emulsion (Biafine®) has been approved for the treatment of minor abrasions, superficial and full-thickness wounds, dermal ulcers (including pressure-induced), donor graft sites, first- and second-degree burns, and radiation dermatitis. This emulsion is thought to promote wound healing by recruiting macrophages to the wound site, with an associated increase in the IL-1/IL-6 ratio enhancing granulation tissue formation. In addition, its occlusive properties impart protection from external contaminants and hydration of the wound aids in healing[34]. However, in a porcine partial-thickness burn model, similar rates of re-epithelialization were observed when silver sulfadiazine 1% cream, Biafine® topical emulsion, and saline-soaked gauze were compared[35].

Heat

The use of infrared energy[36] and radiant heat[37] bandages has been effective in the laboratory and in small trials involving healing leg ulcers that were refractory to other methods as well as ulcers of different etiologies. The practical value of these therapies has yet to be determined.

TISSUE-ENGINEERED SKIN EQUIVALENTS

Advances in tissue culture techniques for keratinocytes and fibroblasts, as well as new methods that allow the generation of large quantities of these cells, are rapidly being incorporated into a new group of wound dressings that blur the distinction between wound dressing and tissue-engineered skin (Table 145.5). For chronic ulcers that are resistant to healing, skin equivalents can be used. One advantage is that painful, often slow-to-heal donor sites do not have to be created. These previously unresponsive wounds undergo an "edge effect", where the skin equivalents promote epithelialization from the edge of the ulcer toward its center, likely due to a release of cytokines by the donor cells that stimulates healing[38]. There are three types of skin substitutes: epidermal grafts, dermal replacements, and composite grafts (with both an epidermal and dermal component).

Epidermal Grafts

The first epidermal autografts were successfully cultivated in 1975 by Rheinwald and Green. They have been used successfully in a variety of clinical situations, including burns, chronic ulcers, vitiligo and post-surgical wounds. Only one product is currently commercially available in the US: Epicel® (Genzyme Biosurgery). A skin biopsy is first obtained from the patient and then the autologous keratinocytes are co-cultured with irradiated murine fibroblasts that serve as a feeder layer. A sheet of keratinocytes two to eight cells thick forms and is attached to petroleum gauze. The graft must be sutured into place and the gauze backing is removed after 1 week, when the keratinocytes have attached to the wound. Biopsies of skin obtained 6 months to 1 year post-grafting show anchoring fibrils and neovascularization. This epidermal autograft is approved for use in partial- and full-thickness burns.

There are several studies demonstrating the efficacy of cultured epidermal autografts. For example, in a review of 30 patients with burns averaging 78% of the body surface area, 69% of the grafts had permanently adhered to the patients[39]. The advantages of this type of graft are the use of autologous keratinocytes and the ability to minimize the amount of tissue harvesting. Epidermal grafts must be placed onto clean wound beds, and the primary disadvantages are the short shelf-life, the expense, and the 3-week interval required for the culture of the keratinocytes.

There are additional epidermal grafts available outside of the US, such as Laserskin® and Celaderm™. Laserskin® (Anika Therapeutics) is another cultured autologous keratinocyte sheet requiring an initial small skin biopsy, but the sheet is attached onto a hyaluronic membrane with laser-drilled microperforations to allow keratinocytes to migrate onto the wound bed[40]. This hyaluronic membrane is a biodegradable biopolymer of esterified hyaluronic acid (referred to as HYAFF™) and is also available without keratinocytes (Hyalofill®, Hyalomatrix®) for use as a primary dressing for wounds such as ulcers[41].

Celaderm™ (Advanced BioHealing) is composed of allogenic keratinocytes cultured from neonatal foreskins. It has a much longer shelf-life, but, as an allogenic rather than autologous graft, it is not permanent. The graft is placed on the wound every other week until it heals; pain relief occurs and stimulation of epithelialization is observed. Although clinical trials of both Laserskin® and Celaderm™ are limited, improved healing of diabetic foot ulcers and venous stasis ulcers was noted when compared to saline gauze[42]. They are also used for partial- and full-thickness burns.

Dermal Replacements

There are two types of dermal replacements: allogenic and xenogenic (see Table 145.5). Neither of these is permanent: DNA analysis of wounds after the application of non-autologous skin substitutes shows complete disappearance of grafted cells after 2 months[43]. The goal of these dermal grafts is to provide a temporary biologic dressing in order to stimulate the healing process. They are placed over the wound, extending slightly onto normal skin, and then bolstered into place. Secondary dressings must be applied. The major component of dermal replacements is collagen, and occasionally there are additions such as extracellular matrix (including glycosaminoglycans), fibroblasts, and basement membrane material.

Xenogenic

Details of the xenogenic dermal replacements are outlined in Table 145.6. The advantages of these products are their ability to effect hemostasis and to provide immediate closure as well as cosmetically acceptable scars with second intention healing, safety from potential human pathogen transmission due to their animal origin, and an adequate shelf-life, facilitating off-the-shelf access. Biobrane® has significant elasticity, enabling a full range of motion to the covered body part, and it has no requirement for dressing changes once it has adhered to the wound bed.

The drawbacks are that these dressings need to remain dry and a pressure dressing is often needed to keep the graft in place. They are all ineffective over exposed bone, and because healing time is slower compared to sutured repairs, there is the potential for infection if not cared for adequately. Bovine allergy is also a possibility. Biobrane® may adhere to the wound so tightly that it could damage newly developed epithelium and inhibit wound contraction[49]. Because Integra™ has a complicated application procedure, the Food and Drug Administration (FDA) requires that all physicians complete a company-sponsored training program.

Allogenic

Details of the allogenic dermal replacements are outlined in Table 145.6. The advantages of these products are their ability to provide immediate closure, cosmetically acceptable scars with second intention healing, and adequate shelf-life, facilitating off-the-shelf access.

TISSUE-ENGINEERED SKIN EQUIVALENTS			
Name and description	**Possible uses**	**Advantages**	**Disadvantages**
EPIDERMAL–AUTOLOGOUS			
Epicel® – sheet of cultured keratinocytes (derived from a skin biopsy) attached to petrolatum gauze Laserskin® – esterified hyaluronic acid (laser-perforated) and seeded with keratinocytes	Partial- and full-thickness burns Congenital melanocytic nevus excision sites Pyoderma gangrenosum (non-inflammatory; see Ch. 26) Epidermolysis bullosa Chronic ulcers	Capable of self-repair Single application is often sufficient Permanent and cosmetically acceptable Good adherence Covers a large surface area from a small skin biopsy	Very expensive Minimal shelf-life; must be used soon after delivery from manufacturer Needs biopsy of normal skin Available 3 weeks after biopsy Technically difficult to apply Susceptible to infection
DERMAL			
Xenogenic (see Table 145.6)			
Biobrane®, E-Z Derm™ – acellular porcine collagen type I Oasis® – porcine intestinal collagen type I and extracellular matrix (Fig. 145.11) Integra™ – bovine tendon collagen and shark chondroitin	Burns Split-thickness graft donor sites Post-laser resurfacing Chronic ulcers	Translucent Elastic Minimal exudate accumulation Reduces pain of some wounds Long shelf-life Non-human origin avoids human pathogen transmission Immediately available	May adhere to wound strongly enough to damage new epithelium May have higher infection rate Expensive Possible bovine allergy Usually needs multiple applications
Allogenic (see Table 145.6)			
Alloderm® – cadaveric decellularized dermis Transcyte™ – neonatal foreskin fibroblasts grown on Biobrane® (see above)§ Dermagraft™ – neonatal foreskin fibroblasts grown on a biodegradable mesh	Burns and split-thickness skin graft sites Chronic ulcers Epidermolysis bullosa, in particular recessive dystrophic	Decreased pain Immediate availability Immunologically inert Easy to remove	Theoretical risk of transmission of human pathogens Usually needs multiple applications
COMPOSITE			
Xenogenic & allogenic			
Apligraf®, OrCel™ – neonatal foreskin keratinocytes and fibroblasts plus bovine collagen type I; bilayered§	Chronic ulcers, e.g. venous, diabetic Wounds resistant to healing Burns Epidermolysis bullosa, in particular recessive dystrophic	Capable of self-repair Single application is often sufficient Immediately available	Very expensive Minimal shelf-life (Apligraft®); must be used soon after delivery from manufacturer
Allogeneic			
StrataGraft® – NIKS cells form a fully stratified squamous epithelium in organotypic culture plus a dermal equivalent	Deep partial- and full-thickness burns Chronic, non-healing ulcers	Promotes self-repair Single application may be sufficient Immediately available Long shelf-life (can be cryopreserved) Pathogen-free human cell source	Expensive Currently in clinical trials as a regulated biologic (not a device)

*NIKS cells, spontaneously immortalized human keratinocyte cell line.
§At the time of writing, Transcyte™ and OrCel™ are not commercially available.

Table 145.5 Tissue-engineered skin equivalents.

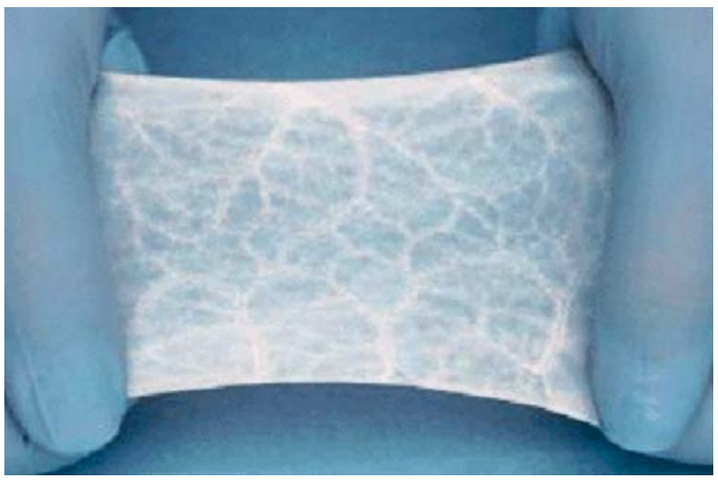

Fig. 145.11 Example of a xenogenic wound matrix derived from porcine small intestine submucosa (Oasis®).

Composite Grafts

Apligraf® (Organogenesis) is a bilayered human skin equivalent derived from human neonatal foreskins (Fig. 145.12). It contains living human keratinocytes within an epidermal layer and a dermal layer equivalent consisting of bovine collagen type I gel seeded with fibroblasts. This composite graft produces its own matrix proteins and growth factors, and, if wounded, it can repair itself. Apligraf® has been used to treat both acute and chronic wounds that fail to heal by standard means. Whereas several applications of the material may be required to completely heal chronic wounds, a single application may be sufficient to initiate a satisfactory healing response. Chronic venous ulcers that were randomized to receive compression plus Apligraf® healed in a shorter time period compared to compression alone, especially in the case of larger defects[50]. It is currently approved by the FDA for venous and diabetic ulcers, but has also been shown to be useful in epidermolysis bullosa, pyoderma gangrenosum, burns and surgical excisions.

OrCel™ (Forticell Bioscience) is a similar bilayered skin equivalent. It is composed of neonatal foreskin-derived keratinocytes grown on the non-porous side of a cross-linked bovine collagen I sponge. On the other, porous side of this sponge are human dermal fibroblasts that

DERMAL REPLACEMENT GRAFTS		
	Description	**Comments**
	XENOGENIC	
Biobrane® (Dow Hickam/Bertek)	Bilayer dressing: inner nylon mesh fabric coated with porcine type I collagen ("dermis") bonded to a semipermeable silicone film membrane ("epidermis")	Tissue ingrowth into the nylon fabric following binding of collagen to fibrin[44] Two versions: (1) trilaminar nylon (better for clean, partial-thickness burn wounds or donor sites); and (2) monofilament nylon (better for meshed autografts) Approved for burns
E-Z Derm™ (Brennen Medical)	Porcine-derived type I collagen attached to a gauze liner	Gauze liner is discarded upon placement[45] Approved for partial-thickness skin loss injuries
Oasis® (Healthpoint)	Derived from porcine small intestine submucosa (mucosa and muscle removed) Porcine type I collagen, extracellular matrix (e.g. hyaluronic acid, fibronectin) and growth factors (FGF, TGF-β)	In study of 120 patients with venous leg ulcers, after 12 weeks of treatment, 55% of Oasis® + compression group healed vs 34% in compression alone group; at 6 months, 100% and 70% remained healed, respectively[46] Approved for venous, diabetic and pressure ulcers, second-degree burns, graft donor sites, and full-thickness skin injuries
Integra™ (Integra LifeSciences)	Bilayer dressing: bovine tendon collagen admixed with shark-derived, modified GAGs ("dermis") plus an outer silicone membrane	Debridement required prior to graft placement with sutures or staples Outer silicone cover removed after several weeks; in large wounds, replaced by ultrathin autograft (two-step process) In a controlled trial of matched-pair thermal injuries, as efficacious as other xenografts and synthetic skin substitutes[47] Approved for life-threatening third-degree burns
	ALLOGENIC	
Alloderm® (LifeCell)	Human cadaveric skin, chemically treated and purified to remove epidermis, all cellular components and pathogens Cryopreserved (shelf-life of 6 months)	Repopulation of host fibroblasts and endothelial cells seen within 10 days of grafting Approved for repair or replacement of damaged or inadequate integumental tissue, e.g. breast reconstruction
Transcyte™ (Advanced BioHealing; Smith & Nephew)	Biobrane® (see above) plus neonatal foreskin fibroblasts	Approx. 2 weeks for graft take Fibroblasts initially secrete extracellular matrix (including collagen) and growth factors that stimulate granulation tissue and epithelialization but then die In a controlled trial of excised burns, easier to use and similar outcomes when compared to human cadaveric skin Approved for partial- and full-thickness burns
Dermagraft™ (Advanced BioHealing)	Neonatal foreskin fibroblasts are seeded onto a 3-D scaffold of biodegradable polyglactin mesh	Similar time to graft take and similar fibroblast function as Transcyte™ (see above) In 235 patients with diabetic ulcers, improved but not a significant difference in healing time compared to conventional therapy Approved for full-thickness diabetic foot ulcers and chronic ulcers that are deep but do not involve tendons, muscle or bone; previously HDE for ulcers in epidermolysis bullosa[48]

*At the time of writing, not commercially available.

Table 145.6 Dermal replacement grafts. 3-D, three-dimensional; FGF, fibroblast growth factor; GAGs, glycosaminoglycans; HDE, Humanitarian Device Exemption; TGF-β, transforming growth factor-β.

Fig. 145.12 Example of a composite (xenogenic and allogenic) graft sutured into place (Apligraf®).

also produce multiple matrix proteins and growth factors. As with all of the allogenic and xenogenic grafts, this is not a permanent skin replacement, and DNA from the cultured cells is not detectable 2 weeks post-grafting. It is FDA-approved for the treatment of full- and partial-thickness donor sites as well as burns[43].

Each of these products is extremely expensive, at approximately US $1000 per graft. However, they have the advantage of mimicking the structure and function of normal human skin. Apligraf® has great safety data based upon its use in over 200 000 patients. OrCel™ has the advantage of a 9-month shelf-life because it is cryopreserved, whereas Apligraf® has a shelf-life of only 5 days. Another disadvantage is the potential for disease transmission. Nevertheless, these composite grafts may be justified in certain situations when adequate skin grafts cannot be obtained from the patient. Of note, at the time of writing, OrCel™ is not commercially available.

SPECIAL CONSIDERATIONS

Leg Ulcers

The predominant types of skin ulcers that affect the lower extremity are venous, arterial and neuropathic; less commonly, they are due to inflammation, infection, trauma or malignancy (see Ch. 105). Venous disease is by far the most common etiology, causing up to 80% of leg ulcers. Moisture retention at the ulcer site is often best accomplished

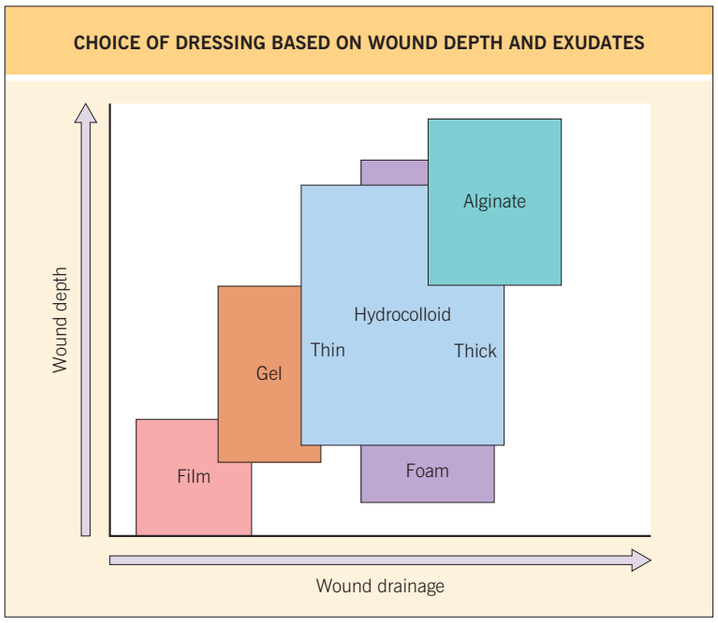

Fig. 145.13 Choice of dressing based on wound depth and exudates.

Fig 145.14 Unna boot. It confers semi-rigid compression and should be changed once-weekly unless heavy drainage from the wound necessitates more frequent replacement.

with occlusive dressings (see Fig. 145.5), and choice of a particular dressing type is influenced by ulcer depth and drainage (Fig. 145.13). However, only a few comparative studies of dressings have been conducted, and no particular category has been proven conclusively to enhance rates of healing of acute surgical wounds or chronic ulcers[22,51]. Therefore, the choice of a moisture-retaining dressing is often determined by the preference of the physician and patient.

Compression is considered to be of utmost importance in the care of venous ulcers. It alleviates edema by increasing hydrostatic pressure and decreasing the pressure of surface veins, thereby decreasing macromolecule and fluid extravasation. Compression is also said to promote fibrinolysis and ultimately improve cutaneous blood flow once edema has been mechanically reduced. Studies by Fletcher et al.[52] concluded not only that compression increased healing rates, but that high compression was better than low, and that compression without a moist dressing yielded better results than did a moist dressing without compression.

Types of compression

Compression can be accomplished by dressings that range from adhesive, relatively non-absorbent types to those which are moderately compressive and absorbent. Traditionally, compression or "pressure dressings" are composed of a non-adherent contact layer, followed by an absorbent layer, and then an outer layer. The efficacy and benefit of the dressing depends upon the role of each of these layers. Although the definitive optimal pressure required to prevent the capillary leakage that occurs with venous hypertension has not been delineated, the general recommendation for leg ulcers is to achieve an ankle pressure of 30–40 mmHg (see Ch. 105)[53].

Compression stockings

With graduated compression stockings, the patient is afforded some independence in the application of the device, if he or she is physically capable. However, for arthritic and/or elderly patients, application can be difficult. Some stockings are fashioned with silk inner linings or zippers for easier use.

Examples

Relief, Vairox, UlcerCARE (Jobst); Futuro™ Energizing, Futuro™ Restoring (3M); Varin Dynamic, Silver Soft (Juzo); Assure, Forte (Mediven); Support Therapy, EverSheer (Sigvaris).

Compression bandages

The Unna boot has existed for over 100 years. Created by Paul Gerson Unna during the 1880s for the treatment of venous stasis ulcers and selected eczematous dermatoses, it was originally a cotton bandage impregnated with zinc oxide, gelatin and glycerin paste. It is frequently the preferred dressing for this type of wound[54]. Applied in a semi-rigid state, the Unna boot confers (semi-rigid) compression, along with the advantages of a moisture-retaining occlusive dressing (Fig. 145.14). It should be applied by a qualified medical professional and changed once a week unless heavy drainage from the wound necessitates more frequent replacement. Correct application of the Unna boot prevents excessive or abnormal pressure to the limb, compromised circulation, skin breakdown, additional ulcer formation or further limb deterioration[55]. In one study, healing time for ulcers treated with Unna boots alone was less than half the time required to heal ulcers treated with only support stockings[56]. Combining compression with occlusive dressings also increased the healing rate of venous ulcers[57].

The use of a flexible compression bandage has the advantage of increased absorbency and compression maintenance as compared to the rigidity of the Unna boot. There is a wide selection of elasticity gradations and brands, and they are categorized as elastic or inelastic, single- or multilayer, long- or short-stretch compression, and cohesive wrap. The greatest difficulty in using elastic compression is determining the proper amount of tension needed to safely and effectively achieve the desired goal. One manufacturer's attempt to help resolve this problem involved marking the bandage with a drawing that changed as the bandage was stretched to the proper tension during application. In general, it is thought that multilayered compression bandaging is superior to single-layered techniques.

Multilayer compression bandages

The components of this system often include four distinct layers, the first of which is an orthopedic wool layer applied loosely in a spiral fashion. It absorbs exudate as well as redistributes pressure around the ankle. The second layer is a crepe bandage, used to smooth the wool layer and to increase absorbency. The third layer is a light elastic compression bandage, followed by the fourth and last layer, which is the outer, elastic, cohesive bandage used to secure all the layers in place. The four-layered system can remain in place for up to 1 week and has the advantage of providing absorption as well as evenly distributed pressure throughout the leg. Multilayered compression systems are available commercially in complete kits[58].

Examples

Unna boot: Gelocast® Unna's Boot (Beiersdorf-Jobst); Primer Modified Unna Boot (Glenwood); Tenderwrap Unna Boot Bandage (Kendall); and UNNA-FLEX® Elastic Unna Boot (ConvaTec).

Single layer: CircAid Ready-Fit™ 2000 (CircAid Medical); SurePress® High Compression Bandage (ConvaTec).

Multilayer: DYNA-FLEX™ Multi-Layer Compression System (Johnson & Johnson Medical); Profore™ (Smith & Nephew).

Cohesive wrap: FLEX-WRAP™ Self Adherent Wrap (Kendall); 3M™ Coban™ Self Adherent Wrap (3M Health Care).

Laser Resurfacing

Laser skin resurfacing has emerged as a useful modality for conditions such as actinic skin damage, acne scarring and rhytides (see Ch. 137), although it does require a prolonged and often painful recovery period for the patient. The primary goal after laser resurfacing is total and uniform re-epithelialization. In the absence of infection and with the use of occlusive dressings, this is possible within 5–7 days. Delay of re-epithelialization has been attributed to crust formation, to which the wound is most prone during the first 2–3 postoperative days.

Occlusive dressings may be classified as open or closed. An open dressing is defined as the application of an ointment or cream directly to the skin wound without an overlying textile dressing. The choice of this more labor-intensive method requires the commitment of the patient to maintain adequate coverage of the wound by frequent, scheduled ointment reapplications and to be able to tolerate the soiling of bedding and garments during the healing period. However, an open dressing does result in less bacterial colonization than closed dressings and it allows for easy wound monitoring; an open dressing is also less expensive than the closed wound care technique. Examples of products used for open dressings are: petrolatum, Aquaphor® (Beiersdorf-Jobst), Neova® Complex CU_3™ lotion (Procyte), and Elta® Crème (Swiss-America Products). Antibiotic ointment applied to facial wounds less than 48 hours old has been reported to significantly increase the rate of contact dermatitis and is therefore not recommended.

Closed dressings representing four of the major occlusive dressing categories (all but alginates) have been specifically designed for post-laser skin resurfacing care. Weinstein et al.[59] examined the most commonly used post-laser resurfacing dressings in order to compare their clinical advantages and disadvantages. Samples from each of the following categories were evaluated: composite foams (Flexzan®), hydrogels (2nd Skin®), polymer films (Silon-TSR®), and hydrocolloids (N-Terface®, Mepitel®).

Among their conclusions were that when compared with open dressing techniques, closed dressings overall resulted in faster re-epithelialization with improved patient comfort. In following their postoperative care protocol, they found that regular wound inspection within the first postoperative week was necessary in order to monitor for signs of infection, healing progress, and patient adherence to care instructions, regardless of the choice of occlusive dressing. The immediate placement of a closed dressing after surgery was followed by return of the patient on postoperative days 1 and 2, at which point the wound was cleaned and the entire dressing was changed. There was no perceptible delay or interference in re-epithelialization by changing the dressing at this point. The replacement dressing remained in place until postoperative day 5, at which time the closed dressing was removed and the patient was converted to only an open dressing[59].

Desirable characteristics of a closed dressing for laser resurfacing include absorbency without saturation, placement stability, ease of use, patient comfort, and minimal adherence to the newly developing epithelium. Flexzan® is an open cell (porous) polyurethane foam with an adhesive coating that is applied in strips and does not need an absorptive secondary dressing. Patients appreciated the light maintenance it required. Because this foam is opaque, careful removal with sufficient moistening is necessary for inspection of the wound.

The hydrogel 2nd Skin® was reported to decrease pain and pruritus, but maintaining the dressing in place was challenging. There was a preference for the use of this dressing in areas of prolonged re-epithelialization. Silon-TSR® and N-Terface® are thin, transparent polymer films that have slits or are meshed in order to allow passage of exudate into an overlying absorptive secondary dressing. They conform well to facial contours and do not adhere to new epithelium, but they do have the problem of slippage. Mepitel® is a silicone polymer, with large pores to allow escape of exudate, that is self-adhesive only to dry areas. It has several benefits, including passage of exudate into a secondary dressing without crust formation, stability without slipping from the original placement site, and easy removal from the moist wound. This dressing is reported to leave behind an imprint of its mesh pattern on the healing skin, a side effect that fades within a few weeks of converting to an open dressing[59].

Oxygen mist therapy following CO_2 laser resurfacing has also been examined. In one study, a semipermeable polyurethane foam dressing was applied as the postoperative dressing on one half of the face and oxygen mist therapy was applied to the other half. Mist therapy consists of oxygen (93% at 15 liters/minute) and a nutrient mist (Aminoplex®) consisting of sterile water, sodium, chloride, potassium, lactate, acetate, glucose, urea, choline, amino acids, and nucleic acid derivatives. The two methods demonstrated comparable healing rates, with no significant differences in the occurrence of erythema, scarring and acne. Patients did, however, express a preference for the oxygen mist therapy over the foam dressing because of decreased pain and less of a sense of confinement. The additional benefit of oxygen mist therapy was that as an "open" dressing, it allowed for wound monitoring. Therefore, oxygen mist therapy may represent another option following laser resurfacing[60].

FUTURE DIRECTIONS

The past 100 years have brought great advances in wound dressing technology. Research into the mechanisms of wound healing has led to our ability to heal wounds in nearly half the time using occlusive dressings. With recent advances in both polymer and tissue-engineering technology, it is likely that the field will continue to change at an even faster pace. While topical synthetic growth factors will likely speed the healing of all types of wounds, their cost is still a concern. Complex bioengineered skin replacements will likely continue to proliferate (e.g. skin grafts that express angiogenesis growth factors or antimicrobials such as cathelicidins [ExpressGraft™]), as will mechanical skin equivalents; for example, an electronic skin that can sense touch was recently described in which a matrix of nanowires and nano-scale transistors on a polyimide film was overlaid with flexible, pressure-sensitive rubber.

Key features

- Choice of a particular biopsy technique is based upon the anatomic site, type of skin lesion, desired histologic information and patient preference
- Wound closure is accomplished via suturing (primary intention) or second intention
- Choice of a specific suturing technique depends upon the needs of the wound, e.g. eversion of the edges, with the goal being an optimal functional and aesthetic result
- Excision *in toto* with repair is a common surgical procedure for dermatologists and it is accomplished through a series of well-defined steps
- Postoperative care and instructions minimize the risk of complications

INTRODUCTION

The cornerstone of dermatologic diagnosis is the correlation of clinical and histologic findings. A biopsy procedure is required in order to obtain tissue for pathologic examination, and fortunately the skin is more accessible than most other tissues. Modern instruments and techniques allow cutaneous biopsies to be performed efficiently with minimal tissue distortion. In some situations, a biopsy procedure is also curative, either coincidentally or intentionally. Knowledge of basic excisional surgical techniques can minimize cosmetic and functional impairment. Performance of a timely skin biopsy may also circumvent the need for more invasive procedures, and even critically ill patients can undergo a skin biopsy with minimal risk.

KEY CONCEPTS

Site Selection

Performance of a biopsy that will yield accurate and relevant histologic information depends upon the selection of an appropriate lesion or site within a lesion (Table 146.1).

The anticipated depth of the lesion to be biopsied must also be considered. In the case of a superficial lesion, e.g. an actinic keratosis versus Bowen's disease, it can be assessed via a more "superficial" biopsy that extends to the papillary dermis. On the other hand, accurate diagnosis of a subcutaneous nodule, e.g. panniculitis versus polyarteritis nodosa, requires a biopsy that includes subcutaneous tissue. Occasionally, fascia must be obtained, e.g. morphea profunda versus eosinophilic fasciitis. Disorders that primarily affect the collagen and elastic fibers within the dermis may have subtle histologic findings (e.g. atrophoderma of Pasini and Pierini) and longitudinally sectioned wedge biopsies that include both the affected area as well as adjacent normal-appearing skin prove most helpful.

Biopsy Technique Selection

Seven major methods are employed to biopsy skin: curettage, snip or scissors biopsy, shave biopsy, saucerization biopsy, punch biopsy, incisional biopsy, and excision *in toto* (Table 146.2). Depending upon the type of lesion and its size, several of these procedures are also curative, especially excision *in toto*. However, these methods do differ with regard to the quality and quantity of skin obtained. Lesional characteristics and operator experience are factors that influence the choice of a particular procedure.

Although *curettage* is frequently used to remove clinically benign epidermal lesions (e.g. verrucae, seborrheic keratoses) as well as actinic keratoses (e.g. in patients with vascular rosacea in whom hypopigmentation from liquid nitrogen application can be problematic), there are situations where histologic confirmation of the presumed diagnosis is desirable. For example, curettings are used to confirm the clinical diagnosis of basal cell carcinoma (BCC) just prior to definitive treatment by curettage and electrodesiccation. However, because the tissue specimen is often fragmented, pathologic orientation is difficult, and this may hinder histologic interpretation. *Snip or scissors biopsy* is an efficient technique for assessing pedunculated lesions as well as removing benign growths (e.g. acrochordons, filiform warts).

The *shave biopsy* usually provides a specimen consisting of epidermis, papillary dermis and, sometimes, reticular dermis (particularly in elevated lesions). It is a popular biopsy technique for "planing" papular, clinically benign lesions (e.g. irritated or unwanted compound and dermal melanocytic nevi, fibrous papules of the nose) where histologic confirmation is desired. Shave biopsy is also a useful procedure for diagnosing superficial carcinomas, e.g. nodular and superficial BCCs, squamous cell carcinoma (SCC) *in situ*, lentigo maligna.

Some authors distinguish a shave biopsy from a *saucerization procedure* in which the depth of the biopsy specimen is intentionally deeper due to the angulation of the blade. This latter technique is often used to biopsy melanocytic nevi with atypical features, especially on the trunk, as well as minimally invasive SCCs or keratoacanthomas. Its advantage is that it allows histologic examination of the entire lesion, which increases diagnostic accuracy, especially in the case of larger lesions (as compared to partial punch biopsy).

BIOPSY SITE SELECTION

Lesion/disorder	Appropriate site
Tumor	Thickest portion; avoid necrotic tissue
Blister	Edge of lesion, including perilesional skin (see Fig. 0.11)
Ulcerated/necrotic lesion	Edge of ulcer or necrosis plus adjacent skin
Generalized polymorphous eruption	Characteristic lesion of recent onset (± more developed lesion)
Small vessel vasculitis	Characteristic lesion of recent onset

Table 146.1 Biopsy site selection.

SELECTION OF TYPE OF BIOPSY TECHNIQUE				
Method	**Indication**	**Type of specimen obtained**	**Anesthetic technique (see Fig. 146.1)**	**Closure**
Curettage	• Lesions involving the epidermis (e.g. SKs, AKs, verrucae) • Confirm clinical diagnosis of BCC prior to definitive treatment	Epidermal sheet or fragmented	Wheal	Secondary
Scissors biopsy	• Pedunculated lesion	Tissue above connection to the epidermis	None or wheal	Secondary
Shave biopsy	• Lesions involving the epidermis ± superficial dermis • Elevated lesion	Epidermis, papillary dermis and, occasionally, reticular dermis (elevated lesions)	Wheal	Secondary
Saucerization biopsy	• Lesions involving the epidermis and dermis	Similar to a shave biopsy, but specimen is thicker (i.e. contains reticular dermis)	Wheal	Secondary
Punch biopsy	• Process (e.g. tumor, inflammation) involves the dermis • Depressed lesion	Epidermis, dermis and, sometimes, subcutaneous fat	Wheal or deep	Primary; simple suture
Incisional biopsy	• Process (e.g. tumor, inflammation) involves the subcutaneous fat or fascia • Large-sized tumors • Subtle disorders of dermal connective tissue	Epidermis, dermis and subcutaneous fat	Deep	Primary; layered closure
Excision *in toto*	• Biopsy intended to be definitive treatment • Strong clinical suspicion of cutaneous malignancy (e.g. invasive melanoma)	Epidermis, dermis and subcutaneous fat	Deep	Primary; layered closure

Table 146.2 Selection of type of biopsy technique. AKs, actinic keratoses; BCC, basal cell carcinoma; SKs, seborrheic keratoses.

SPECIMEN HANDLING		
Proposed laboratory test	**Carrier medium**	**Comments**
Routine microscopy, immunohistochemistry, PCR	10% neutral buffered formalin	Fixation process begins immediately
Direct immunofluorescence	Michel's medium or fresh*	Depends on laboratory preference or availability
Flow cytometry	Fresh*	Lymphoma cutis
Culture for bacteria, mycobacteria or fungi	Fresh* or minced in sterile culture/carrier medium appropriate for organism (usually performed by laboratory)	
Culture for viruses	Viral transport medium (e.g. M4RT)	
Electron microscopy	Glutaraldehyde	

*Laboratory must be in close proximity and specimen placed on saline-moistened gauze, but need to avoid bacteriostatic saline solution when culturing for microbes.

Table 146.3 Specimen handling. PCR, polymerase chain reaction.

The *punch biopsy* supplies a cylindrical to conically shaped specimen consisting of epidermis, dermis and, sometimes, subcutaneous fat. The volume of tissue sampled correlates with the size of the punch biopsy instrument. In general, the diameter of the metal "barrel" varies from 2 to 6 mm, and the wider the diameter, the greater the likelihood of obtaining subcutaneous fat. However, the thickness of the dermis and the amount of subcutaneous fat required to establish the diagnosis must be kept in mind. Punch biopsies are particularly helpful for examining processes within the dermis, e.g. tumors, inflammation (see Table 146.2). In the case of tumors, sampling a majority of the lesion is desirable, but for large-sized tumors, multiple punch biopsies may be required.

The *incisional* biopsy removes a wedge of tissue from the center or edge of a lesion (see Site selection) and is the best option for obtaining deep subcutaneous fat or fascia for histologic examination. It is also used to sample a significant portion of large-sized tumors. Excision *in toto* removes the entire lesion and includes epidermis, dermis and subcutaneous fat. For these reasons, it is often the biopsy of choice for a presumed invasive cutaneous melanoma[1].

Specimen Handling

Transportation of the biopsy specimen to the laboratory differs according to the processing and type of examination required. Most specimens are placed in formalin, but, occasionally, special carrier media are necessary (Table 146.3). Fresh tissue specimens are sent on saline-moistened gauze and either promptly delivered to the laboratory or packed in ice; the laboratory must be in reasonable proximity and have the capability of processing the tissue immediately. When handling small or thin biopsy specimens, it is important to confirm that they are clearly within the formalin solution and not adhering to the upper portions of the container or lid; this prevents desiccation artifact.

A protocol must be established within the clinician's practice to ensure that specimens and results are appropriately tracked and assigned to the correct patient. Immediately after the biopsy specimen has been obtained, it should be placed in a container previously labeled with the patient's name and other identifying information. If multiple biopsies are to be performed, prelabeling the containers alphabetically and with the respective sites avoids confusion. The specimen and its accompanying requisition form are then taken to a designated site, where the appropriate information is first logged into a pathology specimen book (paper or electronic), and then the specimen is set aside for delivery to the pathology laboratory.

When the report is received, a notation is made in the pathology book, cross-checking the patient-identifying information. It is also useful to have the pathology book identify the plan for the patient and whether the plan has been accomplished. For instance, the book may document that the patient already has an appointment for suture removal. When the suture removal has taken place and the patient has been informed of the results of the biopsy, this information is also logged into the book. Some patients prefer a call regarding any anxiety-provoking biopsy results such as skin cancer, but most patients appreciate a written letter detailing the diagnosis and recommended treatment plan. Regardless, if a biopsy has been performed, it is the physician's responsibility to track the specimen and follow through to notification of the results to the patient and disposition of recommended care.

Patient Preparation

A discussion of the reason(s) to do the biopsy, the site to be biopsied and the technique to be used can be brief and to the point. Informed consent requires a discussion of the major risks, which include bleeding, discomfort, infection and scarring (see Ch. 151). Bleeding can often be controlled by firm pressure at the site of the wound, but may require more aggressive forms of hemostasis. Discomfort is usually minimal, although some sites such as the forehead, fingers and feet may throb.

Infection is unusual. Except when the area to be biopsied is already infected or the site is mucosal, the skin can be prepared by application of an antiseptic agent and the procedure is then considered to be a *clean* procedure. For clean procedures of non-mucosal sites, preoperative prophylactic antibiotics are currently not recommended, even in patients with artificial valves or joints (with the possible exception of sites at high risk of infection, e.g. groin, during the first 2 years after joint placement)[2–4]. Tables 151.2 and 151.3 review the guidelines for antibiotic prophylaxis as well as regimens for both oral and non-oral sites. Preoperative antibiotics are administered within a 2-hour window before the incision; there is debate as to whether or not a second dose is administered 6 hours later and under which circumstances antibiotics should be continued for 48–72 hours[5]. When pretreated with a 5-day regimen of intranasal mupirocin ointment (twice daily) and a total body wash with chlorhexidine soap (daily), nasal carriers of *Staphylococcus aureus* were observed to have fewer postoperative infections[6].

Most patients are primarily interested in discussing whether or not there will be visible scarring. This is best predicted by the type of biopsy to be performed and the anatomic site. Generally, patients can be reassured that small biopsies may be done without grossly noticeable permanent "marks".

Many patients are anxious about the needle sticks required for administration of the local anesthesia and the pain of the procedure. The patient's cooperation is easily obtained in an organized and peaceful environment with a calm and reassuring staff. A well-informed, comfortable patient in a supine position will tolerate the procedure without difficulty.

Site Preparation and Anesthesia

Effective site preparation is most efficient if a standard clinical protocol has been established (Table 146.4). Marking and photographing the site[7], cleansing the skin (Table 146.5)[8], and draping are important procedures prior to the instillation of local anesthesia. Local anesthesia is adequate for all skin biopsies and is reviewed in detail in Chapter 143.

When the local anesthetic agent is instilled in a deep compartment (i.e. subcutaneous fat; Fig 146.1A), 5 to 10 minutes is required for anesthesia to develop on the surface of the skin. Gentle massage of the site may assist in spreading the agent subepidermally and achieving

SITE PREPARATION PROTOCOL

Sequential steps	Comments
Mark site with surgical pen or ink	Local anesthesia may obscure site, especially when the erythematous color is due to vasodilation or when there is a minimally elevated dermal tumor
Time out for patient and site identification	JCAHO universal protocol for patient safety
Photograph site or record landmarks	Up to ~15% of biopsy sites may be later incorrectly identified by the patient and ~5% by the surgeon[7]
Clip hair as needed	Shaving hair increases incidence of infection
Cleanse skin surface	Antiseptic agents listed in Table 146.5
Drape	Gauze (small biopsies) or sterile cloths
Anesthetize	Local instillation of anesthetic agent

Table 146.4 Site preparation protocol. JCAHO, Joint Commission on Accreditation of Healthcare Organizations.

ANTISEPTIC AGENTS

Agent	Advantages	Disadvantages
Povidone-iodine (Betadine®)	Broad antimicrobial spectrum, including fungi	Skin irritant; contact dermatitis; residual color; may cross-react with radiopaque iodine and iodides in medications
Chlorhexidine (Hibiclens®)	Broad antimicrobial coverage; no absorption; non-toxic; prolonged suppression of bacterial growth	Irritating to eyes (keratitis) and middle ear (otitis)
Isopropyl alcohol	Inexpensive; denatures protein, including bacterial cell walls; immediate (but not prolonged) effect	Weak antimicrobial activity; flammable in the setting of cautery; skin irritant; skin must remain wet for 2 minutes for maximum effect
Chlorhexidine–isopropyl alcohol combination (ChloraPrep®)	Combination provides both short-term and long-term effects; evidence it is more effective than povidone-iodine[8]	Those of either agent alone (see above)
Hexachlorophene (pHisoHex®)	Strong effect against Gram-positive cocci	Little effect on Gram-negative organisms or fungi; teratogen; absorbed through skin with potential neurotoxicity in infants
Soap and water	Traditional preoperative handwashing regimen; disinfects hands as well as alcohol-based rubs[9]; better against *Clostridium difficile* and Norwalk virus	At operative site, cumbersome and messy; no prolonged antisepsis
Hydrogen peroxide		No significant antiseptic properties; cytotoxic to keratinocytes in culture

Table 146.5 Antiseptic agents.

LOCAL ANESTHESIA INJECTION

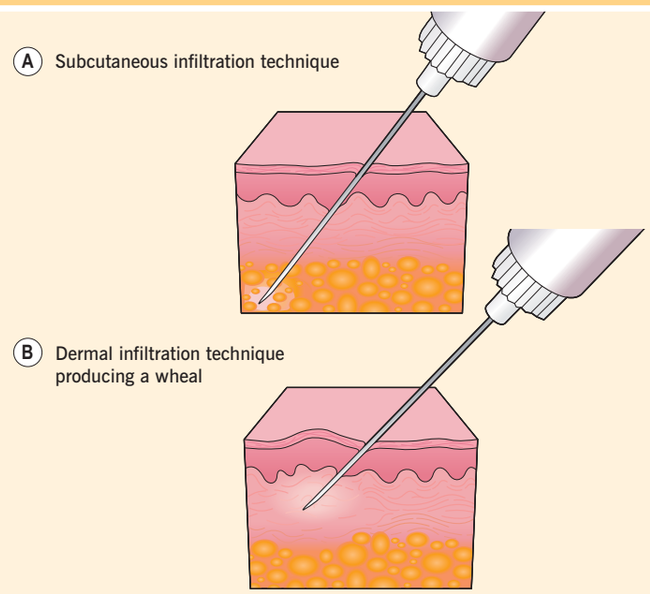

Fig. 146.1 Local anesthesia injection. A Deep infiltration. **B** Superficial infiltration.

METHODS OF HEMOSTASIS	
Method	**Comments**
Compression	• Appropriate for small-diameter, superficial wounds • Folded dry sponge with tightly applied bandage
Styptics: aluminum chloride hexahydrate (Drysol™, Xerac AC™) or ferric subsulfate (Monsel's solution)*	• Apply pressure to diminish active bleeding • Then apply styptic with cotton-tipped swab and pressure to wound bed for 30 sec - 2 min
Absorbable hemostatic sponge: Gelfoam®, Instat®	• Apply pressure to diminish active bleeding • Then place sponge in wound and bandage in place with pressure • Warn patient of presence of "foreign body"
Electrocoagulation and heat cautery	• Reviewed in Chapter 140
Sutures	• When used for wound closure, generally creates sufficient hemostasis in the sidewalls of the wound • Figure-of-eight stitch, utilizing an absorbable suture (see Fig. 146.2), may be required for a large-caliber vessel
*Ferric subsulfate (Monsel's solution) can result in a tattoo.	

Table 146.6 Methods of hemostasis.

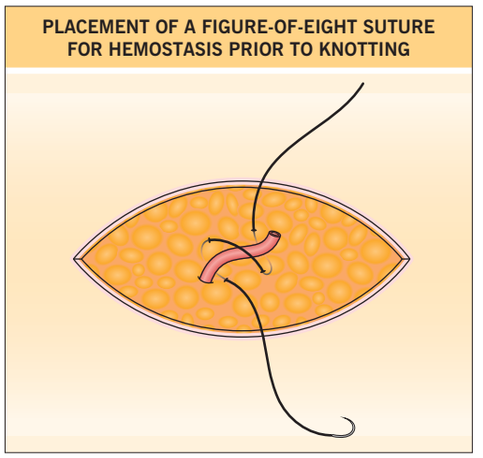

Fig. 146.2 Placement of a figure-of-eight suture for hemostasis prior to knotting.

SECOND INTENTION HEALING – INDICATIONS, DISADVANTAGES AND CONTRAINDICATIONS
INDICATIONS
• Shallow wounds • In combination with a primary closure in which the deepest portion is closed primarily • Concave sites (e.g. medial canthus, conchal bowl, alar crease, temple) • Mucosal sites (e.g. conjunctivae, lip, genitalia) • Infected, necrotic or easily infected sites • Sites under significant tension because of physical exercise or size of the wound • Preferred by patient (simple, no sutures, normal activities)
DISADVANTAGES
• Sometimes prolonged healing time • Scarring which may be depressed and angulated or circular (especially if not in concave site)
CONTRAINDICATIONS
• Relative: wound into muscle or fascia • Absolute: inability to stop bleeding without a suture

Table 146.7 Second intention healing – indications, disadvantages and contraindications.

good anesthesia. Injection of the agent superficially, creating an edematous wheal, has immediate efficacy but is more painful (Fig. 146.1B). Since a punch or shave biopsy requires very little agent and therefore a very short injection time, superficial instillation is the technique often used. In addition, a wheal is helpful prior to a shave biopsy as the lesion is further elevated from the plane of the surrounding skin. Of note, since epinephrine (adrenaline) requires up to 15 minutes to produce maximal vasoconstriction and thereby minimize bleeding[10], lidocaine without epinephrine is sufficient for an immediate biopsy. Regardless of other considerations, it is critical to have the local anesthesia in the compartment that is to be biopsied, i.e. a superficial wheal may be entirely adequate as anesthesia for a shave biopsy but will not suffice for an incisional wedge biopsy that extends into the subcutaneous fat.

Hemostasis

All biopsy procedures require attention to hemostasis of the wound bed (Table 146.6; see Table 151.4). While styptics and absorbable hemostatic sponges are used for those wounds healing by second intention, punch biopsy sites are usually closed primarily, with the suturing itself providing sufficient hemostasis. Wounds created during incisional biopsy or excision *in toto* may require electrocoagulation for hemostasis before closure (see Ch. 140). The endpoint is no active bleeding in the wound bed. Bleeding within the dermis in the sides of the wound can be controlled by suturing and does not need cautery. At times, to produce hemostasis, a large actively bleeding vessel may need to be identified, grasped with a hemostat, and tied off with an absorbable suture and a figure-of-eight stitch (Fig. 146.2).

Wound Closure

Closure of wounds created by a biopsy procedure may occur by either secondary or primary intention healing. Second intention healing repairs wounds by the processes of granulation tissue formation, epidermal cell migration, and contraction (see Ch. 141). These processes occur simultaneously, beginning within the first few days after surgery and continuing until the wound has completely re-epithelialized. For the remainder of the patient's life, maturation of the scar occurs, with gradual improvement in color, texture and contour. Indications, disadvantages and contraindications for second intention healing are outlined in Table 146.7.

Closure of the wound via suturing is regarded as primary intention healing. The same processes of granulation tissue formation, epithelial migration, and contraction occur; however, they are significantly reduced, because the sides of the wound are already opposed. Processes related to fibroblast activity and collagen deposition play a more important role in primary intention healing, allowing adequate tensile strength to develop in order to keep the wound closed[11]. These scars also undergo maturation throughout the remainder of the patient's life. Both secondary and primary intention healing are promoted by appropriate wound care and dressings.

For primary intention healing, wounds may be closed either by placement of a simple full-thickness suture or by a layered closure. In a layered closure, subepidermal buried sutures oppose subcutaneous and dermal tissue, provide alignment of the wound edges, set up the wound edges for eversion, and assist with hemostasis by occluding any vessels bleeding within the edge of the wound. In addition, the subepidermal sutures supply strength to handle tension within the closure. Although subepidermal sutures are generally absorbable, they remain intact within the tissue for 8 to 12 weeks, the period during which the scar is slowly acquiring tensile strength. As a result, they prevent dehiscence and spread of the scar. Epidermal or skin sutures oppose the epidermal edges and complete eversion. They can also correct minor degrees of misalignment in the closure. Satisfying these objectives via conscious placement of sutures improves the function and appearance of the scar[12].

Knotting is the means for stabilizing the placement of the suture, usually produced with an instrument tie (Fig. 146.3). The first throw of the knot is started by pulling the long end of the suture tight with the fingers of the non-dominant hand and looping it around the needle holder once or twice. The needle holder then grasps the short end and pulls it through the loops. The loops are pulled across the wound so that they lie flat. These steps are then repeated to produce the second throw of the knot, but this time with the loop in the opposite direction around the needle holder. When this second loop is pulled across the wound, a square knot is created. Depending on the memory and thickness of the suture material (see Ch. 144), three to six throws may be required to properly secure the knot. Care is taken to ensure that the knot lies flat without significant tension or tightness[13]. Sometimes, a loose loop is left in the second throw, to allow the suture to adjust to any wound swelling that may develop.

Sutures commonly used for subepidermal placement are composed of synthetic absorbable materials, e.g. braided polyglactin (Vicryl®) and monofilament polydioxanone (PDS®). The *interrupted buried dermal stitch* (Fig. 146.4A) is designed such that the stitch is in the dermis and fat and the knot is inverted (buried). The needle enters the undermined deep surface of the wound (not the sidewall) and passes up into the dermis. After crossing the wound, it enters the opposite side of the wound at the same level in the dermis and then exits the deep surface. The knot is then tied and the ends of the suture cut. When the suture material is released, the knot settles within the deep portion of the wound, minimizing tissue reaction to the suture and extrusion through the wound. Enough buried dermal sutures are placed such that tension is eliminated and the deep tissues are completely opposed. In order to facilitate eversion, this basic stitch may be modified, creating a *buried vertical mattress stitch*[14]. In this stitch, the suture is nearest to the skin surface (within the superficial dermis) at a point 3–4 mm lateral to the wound edge, and then it exits the wound deeper in the dermis (Fig. 146.4B). A very subtle dimple may be appreciated above the suture where it lies superficially in the dermis.

On occasion, a *running dermal stitch* is used to close the deep component. This stitch is begun similarly to the interrupted buried dermal stitch, but, after tying, only the short end of the suture is cut. The needle then draws the suture through the subcutaneous fat and dermis on one side, passing to the other side, and then continuing along the length of the wound. At each step, the suture is pulled tightly to oppose the edges. At the end of the wound, the knot is achieved by tying the loose end to the last loop. This stitch is only used when there is little tension in the wound, as rupture of the suture material anywhere along the suture line would release the suture for the entire length of the wound, allowing dehiscence or spread of the scar.

Monofilament nylon (Ethilon®) or polypropylene (Prolene®) are commonly used epidermal sutures. The *simple interrupted epidermal stitch* is placed by passing the needle through the epidermis into the superficial dermis in a plane just superior to the buried suture, across the wound, into the dermis on the opposite side and then up through the epidermis (Fig. 146.4C). Eversion is assisted by placing the suture closer to the wound edge but relatively deeper in the wound so the epidermal surface does not roll. Using the curve of the needle to create the path for the suture also facilitates eversion. If there are no buried sutures, the stitch opposes the edges for the full depth of the wound (e.g. for closure of punch biopsies).

The *vertical mattress stitch* (Fig. 146.4D) is sometimes used for wounds in thicker skin where eversion may be difficult and when a single suture opposing the deep and superficial edges is desired. This stitch has four points of entry into the skin. It is started by passing the needle through the epidermis 5–8 mm lateral to the wound edge, exiting from the deep portion of the wound. It re-enters the opposite side of the wound in the same deep position, and exits from the epidermis equidistant from the wound edge as the entry point. The needle is reversed and the epidermis is re-entered *closer* to the wound edge; it is then drawn through the upper dermis before crossing the wound, entering the dermis and finally exiting close to the wound edge. Once tied, the knot is positioned on one side of the wound, not over the line of closure.

A *horizontal mattress stitch* can be used in thinner skin such as the neck or the dorsum of the hand, and it also has four points of entry into the skin. The first two points of entry are the same as in the vertical mattress stitch (Fig. 146.4E), but closer to the wound edge (i.e. 3–5 mm). However, after the needle is reversed, the third point of entry into the epidermis is *lateral* to the exit point (i.e. on the same side of the wound edge) and at the same distance from the wound edge. The suture is then drawn through the deep portion of the wound again, crosses the wound, enters the opposite sidewall in the same deep position and finally exits at the same distance from the wound edge, lateral to the first entry point. This knot, when tied, is also positioned on one side of the wound, not over the line of closure.

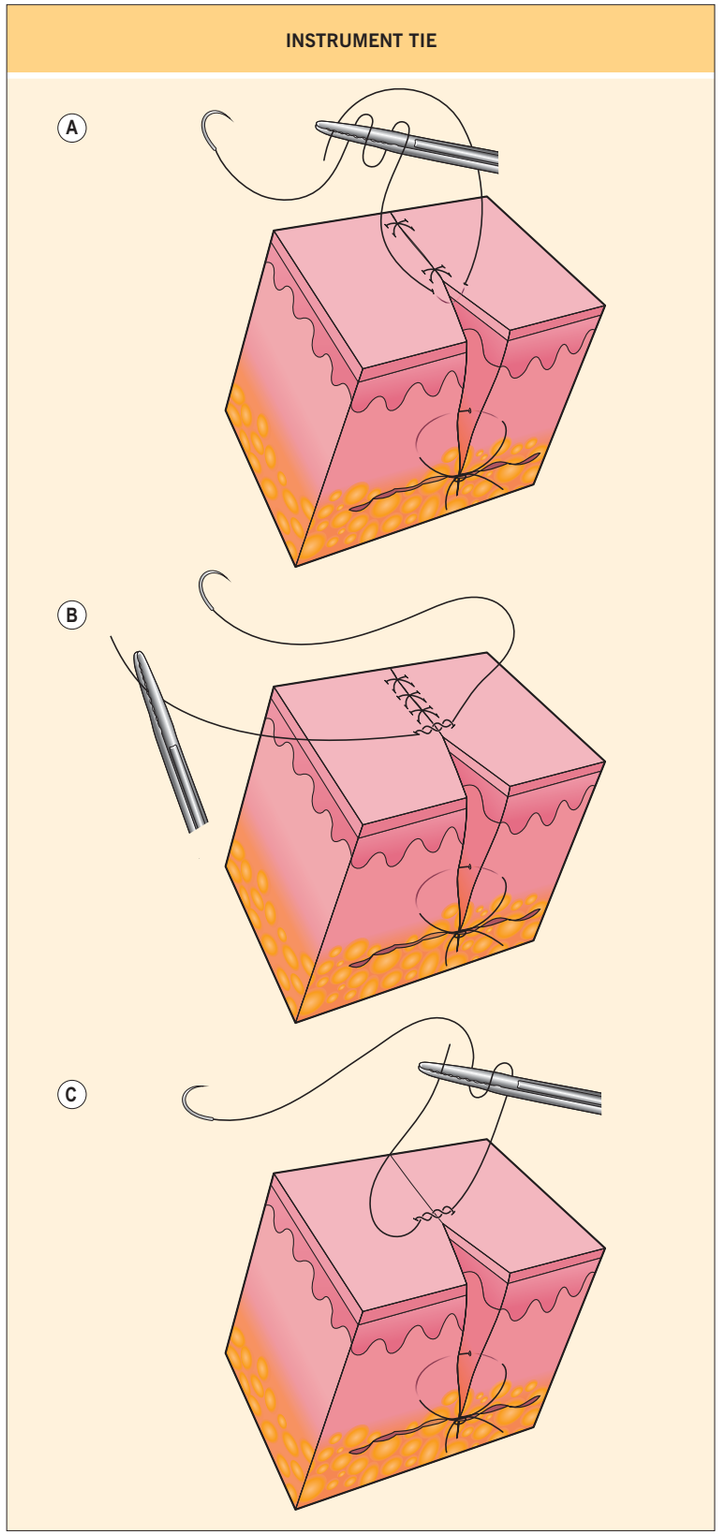

Fig. 146.3 Instrument tie. A The suture is looped around the needle holder, then the needle holder grasps the short end and pulls it through the loops to create a knot. **B** The suture is drawn over the wound so that the knot lies flat across the wound. **C** A loop is made around the needle holder in the opposite direction. The needle holder then grabs the short end and pulls it through so that the knot lies flat on the skin surface.

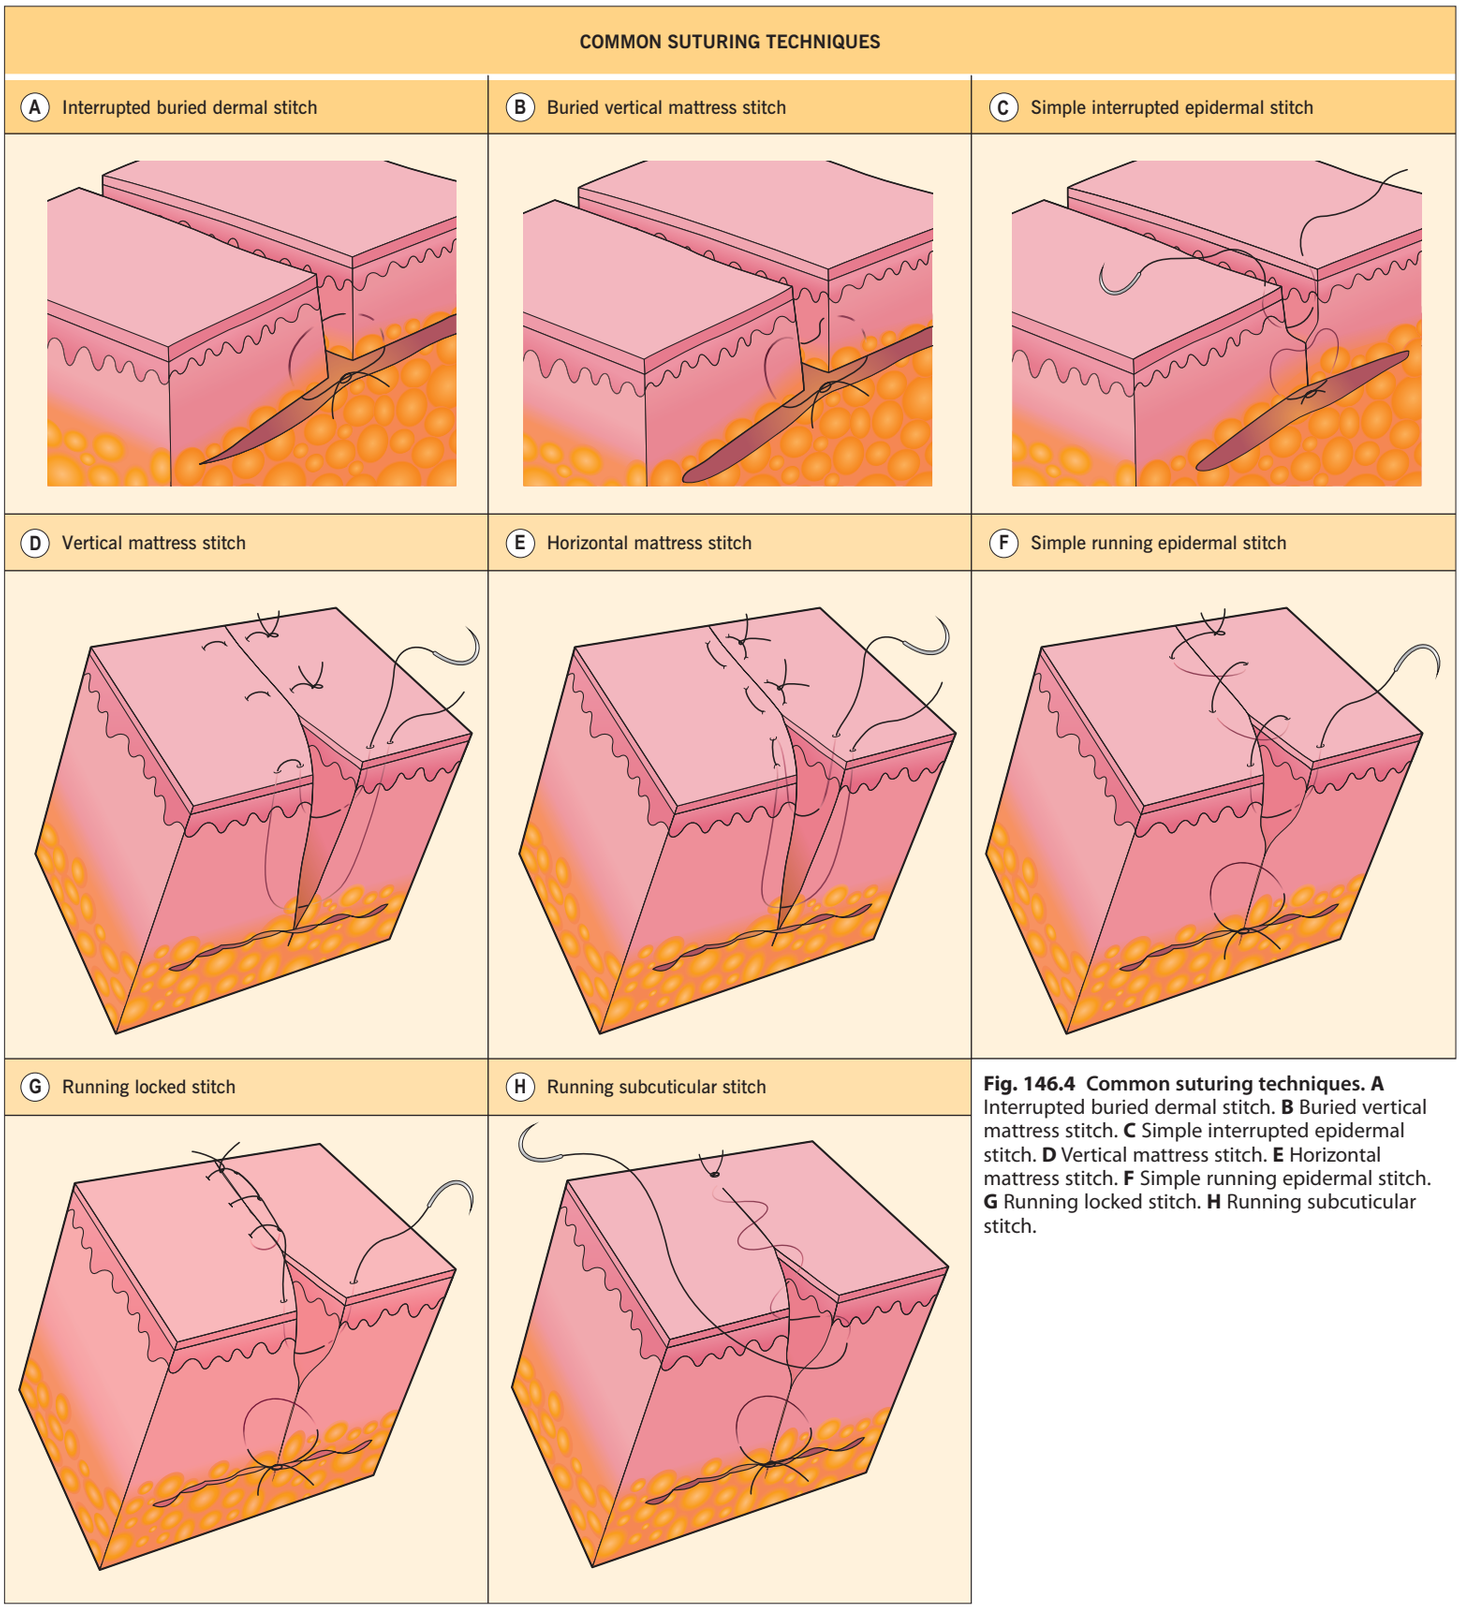

Fig. 146.4 Common suturing techniques. A Interrupted buried dermal stitch. **B** Buried vertical mattress stitch. **C** Simple interrupted epidermal stitch. **D** Vertical mattress stitch. **E** Horizontal mattress stitch. **F** Simple running epidermal stitch. **G** Running locked stitch. **H** Running subcuticular stitch.

Since sutures of both the vertical mattress and horizontal mattress stitches must be removed within 1–2 weeks (depending upon the site), they are not good stitches to use as the sole means of closure in a wound with tension. Of note, a variant, the running combined simple and vertical mattress stitch, also everts well and saves surgical time[15].

In the presence of buried sutures, a *simple running epidermal stitch* may be placed for opposition of the epidermal edges. This running stitch may be passed via the dermis and the epidermis in a fashion similar to the simple interrupted epidermal stitch (Fig. 146.4F). In addition, the needle may be passed under the superficial loop of the previous stitch, thus creating the *running locked stitch* (Fig. 146.4G). This stitch can assist with hemostasis and will not completely unravel if the suture breaks under wound tension. Alternatively, the stitch may be placed within the upper dermis, referred to as a *running subcuticular*

WOUND CLOSURE – ALTERNATIVES TO SUTURING	
Adhesive tapes (Steri-Strips™)	• For perfectly opposed lacerations or wound edges under little tension • Often used with a liquid adhesive, e.g. Mastisol®
Staples*	• Highest tensile strength • Good for wounds under tension
Tissue glues (e.g. 2-octyl cyanoacrylate [Dermabond™], fibrinogen [Tisseel™], hydrogel [Duraseal™])	• Can be considered for epidermal closure of wounds under little tension • Less effective than suturing for minimizing dehiscence
Laser welding (Nd:YAG, CO_2, argon lasers)	• Experimental and used infrequently in the clinical setting
Photochemical welding (Rose Bengal plus green light)	• Experimental
*Also requires skin stapler and staple remover.	

Table 146.8 Wound closure – alternatives to suturing.

stitch (Fig. 146.4H). This stitch is placed with the needle passing in and out of the upper dermis in a plane horizontal to the surface. Two knots are tied, one on each end of the wound, and they are the only visible portion of the suture. Running stitches are frequently used to save time, but they can accentuate minor misalignments of the wound edges[16]. They also do not necessarily prevent track marks, which occur because of tension, inadequate undermining, ineffective buried dermal sutures, and poor placement of the epidermal suture.

Non-absorbable sutures that pass through to the surface of the skin are removed. If they remain in place, they cause tissue inflammation and create a less than optimal functional and cosmetic result. To remove a suture, the thread is severed near the knot with either fine-tipped scissors or a #11 blade. The knot is then pulled over the line of closure so that the wound edges are not pulled apart. Sutures on the face are generally removed after 5–7 days, and sutures elsewhere, at 10–14 days. If buried dermal sutures are used, the epidermal sutures may be removed at the earlier times. Sometimes, absorbable suture material is used for superficial closures, especially in the simple running epidermal stitch, precluding the need for suture removal. Sterile adhesive tapes such as Steri-Strips™ or tissue glue (Dermabond™) are also occasionally used instead of epidermal sutures to avoid the need for suture removal, but they are ineffective in producing eversion and in dealing with tension. They may, however, reduce the amount of scar spreading if they are placed after suture removal and left in position for several weeks[17]. Table 146.8 outlines alternatives to sutures for wound closure[18–20].

INDICATIONS/CONTRAINDICATIONS

A biopsy is indicated at any time in which the clinical diagnosis of a cutaneous disorder is unclear or must be substantiated before a course of treatment is undertaken. Inflammatory disorders are often biopsied to assist in the differentiation of multiple processes that may have a similar clinical appearance. Infectious processes are biopsied so as to observe the causative organism in tissue sections and/or to obtain tissue for culture. Lesions suspicious for malignancy are biopsied in order to develop a surgical plan appropriate for the tumor type. Biopsies of normal skin may also be performed, to obtain tissue for metabolic or genetic studies[21,22]. Nowadays, skin biopsies are even performed prenatally.

Most patients can safely undergo a skin biopsy, so contraindications are not absolute. A skin biopsy may save the patient from a more invasive procedure if the disease process can be determined via histologic examination of the skin. Patients who are immunosuppressed because of medications (e.g. cyclosporine, prednisone, chemotherapy) or underlying diseases (e.g. HIV infection, lymphoma, leukemia) often require biopsies because of the complicated interplay between the underlying disorders and the side effects of therapy (e.g. infections, drug reactions).

In addition, there are no cutaneous or mucosal sites where a biopsy is contraindicated. Diagnostically, it is more useful to biopsy a lesion from the hand or the face that provides accurate information than it is to biopsy a late-stage, nonspecific lesion on the arm. Biopsies can be done on the legs of patients with diabetes mellitus as well as the digits of patients with vascular compromise, although greater attention to postoperative care may be necessary. For patients with coagulation or platelet disorders (due to either underlying diseases or medications), it may be preferable to biopsy a site that can be compressed to produce hemostasis. For example, if an arm or leg were biopsied, postoperative bleeding can be controlled by pressure applied by an elastic circumferential bandage.

In certain anatomic sites, it may be necessary to exercise caution to avoid injuring a vital structure (see Chs 142 & 151). The temporal nerve lies in a superficial location, just beneath thin dermis and subcutaneous fat, midway between the eyebrow and the temporal hairline. The spinal accessory nerve also courses superficially at the posterior edge of the sternocleidomastoid muscle at a point one-third of the distance between the mastoid process and the inferior attachments of the muscle. Severing these nerves leads to motor dysfunction; thus, these sites are best biopsied in a superficial manner. The temporal and thyroid arteries are also relatively superficial. Cutting them leads to temporary difficulty with hemostasis but has no long-term adverse effect.

Some lesions require special consideration before performing a biopsy. A mass that is pulsatile may indicate large arterial vessel involvement, a situation requiring additional clinical evaluation prior to biopsy and special surgical arrangements in case of bleeding. A post-traumatic cephalic mass or cystic midline lesion may need preoperative radiologic examination to determine any possible connection to the intracranial or intraspinal space[23]. Biopsy of a lesion on the upper trunk or shoulders of a patient who tends to form keloids must be carefully discussed, weighing the possibility of keloid formation against the utility of the information that will be obtained. Hypertrophic scars, on the other hand, are common and resolve with time and/or pressure as well as corticosteroid injections, and need not interfere with the performance of a biopsy.

PREOPERATIVE HISTORY AND CONSIDERATIONS

While there are no absolute contraindications to performing a biopsy, a clinician will want to be aware of certain features of a patient's medical and surgical history in order to formulate an adequate surgical plan and to predict the need to manage possible complications. Table 146.9 summarizes information pertinent to the issues previously discussed. In particular, patients who are taking medications or have underlying disorders that lead to abnormalities in coagulation or platelet function should be identified in advance. Almost all procedures can be done despite a patient receiving warfarin, heparin, clopidogrel or aspirin if the site of the biopsy is planned carefully and the options for hemostasis are readily available. The bleeding time may also be affected by alcohol ingestion, oral vitamin E, and nonsteroidal anti-inflammatory drugs, in addition to a number of alternative therapies,

PREOPERATIVE HISTORY
Allergies
Medications, including nutritional supplements and over-the-counter preparations (see Ch. 133)
Past reactions to local anesthesia
Difficulties with hemostasis during previous procedures
Past problems with wound healing, including infection, keloid formation
Pacemaker or implantable cardioverter-defibrillator (ICD)
Disease or past replacement of the cardiac valves
Past orthopedic surgery with joint replacement
Hypertension
Diabetes mellitus
Immunosuppression
Infection or vascular compromise at the biopsy site
Possible pregnancy

Table 146.9 Preoperative history.

including garlic, gingko, ginger, ginseng, feverfew, fish oil and green tea[24] (see Table 133.3). While biopsies may be done safely during pregnancy[25], the emotional turmoil surrounding a coincidental miscarriage or pregnancy mishap is great enough to defer elective procedures (e.g. shave biopsy of an unwanted intradermal nevus) to the postpartum period, whereas biopsies of atypical pigmented lesions in which the differential diagnosis includes cutaneous melanoma are not deferred. As long as they can cooperate, biopsies and excisions can also be done safely in children under local anesthesia.

TECHNIQUES

Curettage

Local anesthesia is achieved by wheal formation (see Fig. 146.1). Depending upon the size and thickness of the lesion, a curette 3–5 mm in diameter is held like a pencil and drawn with pressure under the lesion (if epidermal) or through the lesion (e.g. presumed BCC). With one smooth movement and moderate pressure (as well as traction by the non-dominant hand), an epidermal sheet or ball of tissue may be obtained (Fig. 146.5). In the case of incomplete removal, further fragments may be obtained by repeated curettage. This type of biopsy assumes that healing will be by second intention. Hemostasis may be obtained by a styptic, electrodesiccation, absorbable hemostatic sponge, or pressure. The resulting scar is usually minimal in the case of epidermal lesions or of no significant concern in the case of a BCC, as it is definitive treatment of the latter that produces the final scar.

Snip or Scissors Biopsy

Pedunculated lesions can be biopsied via a snip or scissors biopsy (Fig. 146.6). Local anesthesia is obtained by wheal formation in the upper dermis just under the narrow attachment of the lesion to the skin surface. For tumors with a very narrow neck, this type of biopsy can be done quickly without anesthesia. Scissors, usually fine iris scissors or sharp Gradle scissors, are used to separate the lesion from its base at the level of the skin surface. A toothed forceps is often used to handle the tissue. Healing is by second intention, and a styptic, electrodesiccation, absorbable hemostatic sponge, or pressure may be required for hemostasis. Scarring produced by this type of biopsy procedure is a small, often hypopigmented macule and may be very difficult to see.

Shave Biopsy and Saucerization Biopsy

Shave biopsy is the most commonly used technique for obtaining a skin specimen for histologic examination (Fig. 146.7). A local anesthetic is used to produce a wheal under the lesion so that it is elevated above the plane of the surrounding skin. A #15 blade on a blade handle is used (almost parallel to the skin surface) to cut the specimen from its bed. Alternatively, only the blade without the blade handle is used. Cutaneous surgeons generally hold the blade or the blade handle like a pencil, to facilitate control of small movements. It is helpful to begin on one edge by holding the blade vertically and incising only through the epidermis. The blade is then turned to a horizontal position and a smooth sawing motion is used to complete the removal of the specimen. A good specimen may also be obtained by a single-edged razor blade held in a semi-curved shape[26].

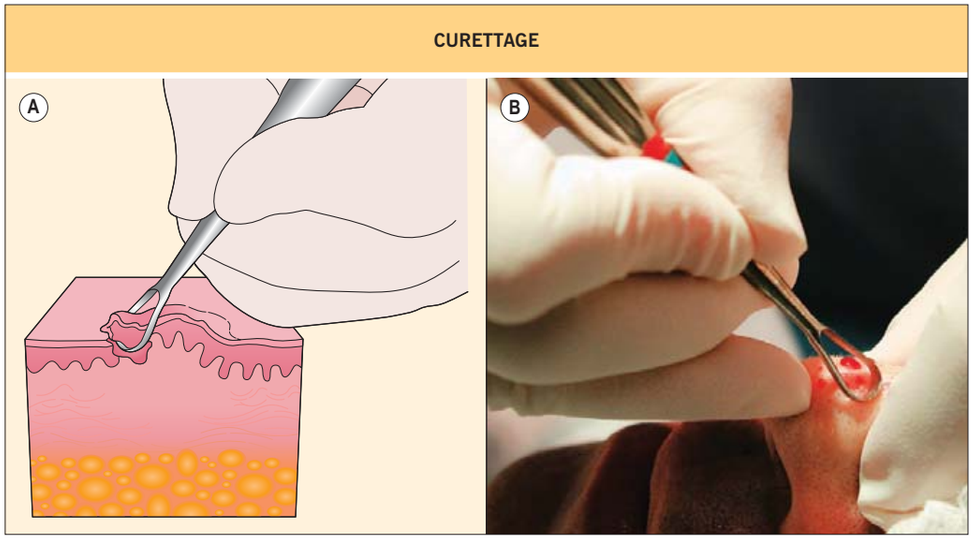

Fig. 146.5 Curettage. A Diagram. **B** Demonstration of technique.

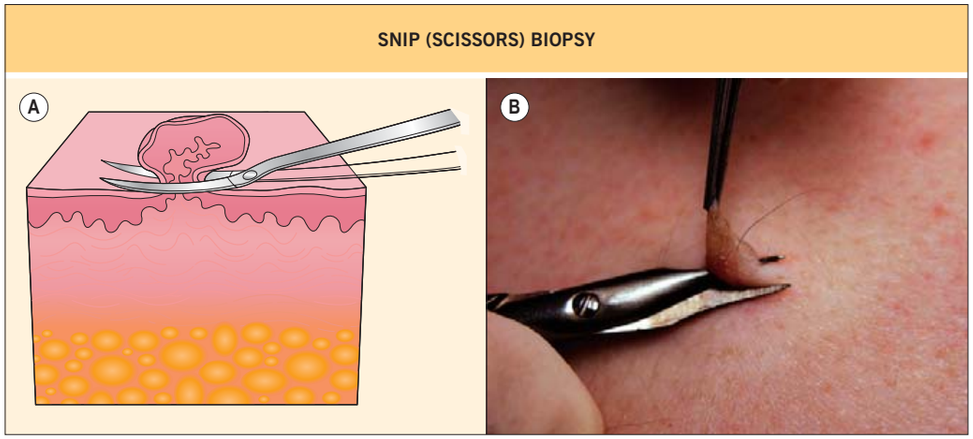

Fig. 146.6 Snip (scissors) biopsy. A Diagram. **B** Demonstration of technique.

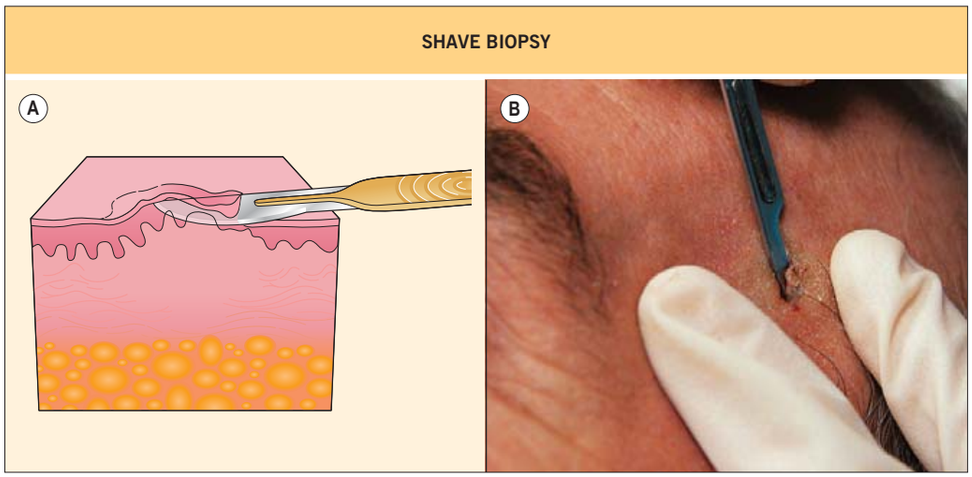

Fig. 146.7 Shave biopsy. A Diagram. **B** Demonstration of technique.

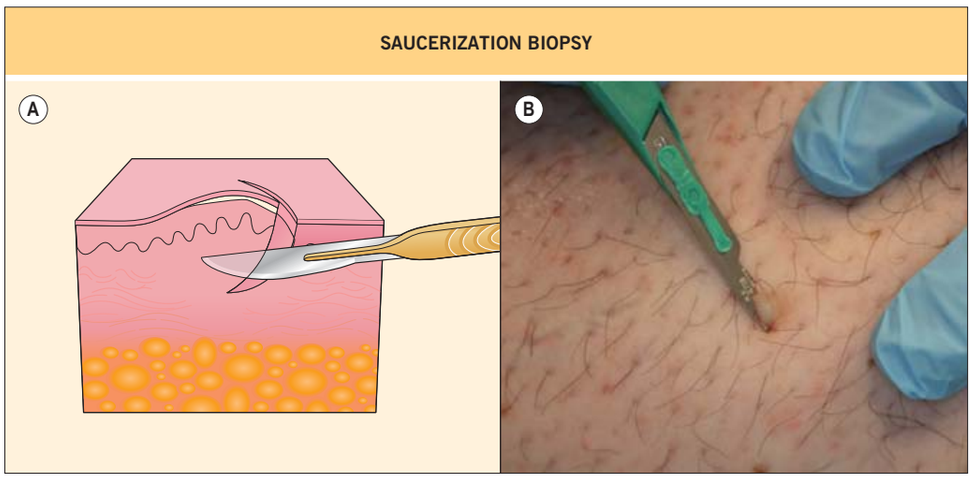

Fig. 146.8 Saucerization biopsy. A Diagram. **B** Demonstration of technique.

The goal is a shallow, saucer-shaped defect and a single piece of unfragmented tissue; edges should be smooth. Forceps may be used to hold the specimen while *in situ* in order to supply traction against the movement of the blade and then to remove the entire specimen and place it in the appropriate container. However, the tissue must be handled gently so that crush artifact does not confuse the microscopic appearance. Toothed, as opposed to smooth or ridged, forceps minimize crushing of the tissue. The specimen should include full-thickness epidermis and superficial dermis. The most common error when first performing shave biopsies is to remove only keratotic debris or the upper portion of the epidermis. The latter is especially true in areas with thick stratum corneum (e.g. palms, soles). Therefore, the dermatologist needs to appreciate the angulation of the blade that is required in order to obtain the full thickness of the epidermis for histologic examination. Observation of the wound bed and review of the tissue sections will help refine the skills needed to perform this procedure.

In a saucerization procedure, the depth of the biopsy specimen is intentionally deeper due to the angulation of the blade (Fig. 146.8). Both saucerization and shave biopsy sites heal by second intention. As with curettage and snip biopsy, hemostasis is easily obtained with a styptic, electrodesiccation, absorbable hemostatic sponge, and/or pressure. With practice and skill, as well as choosing the appropriate lesion to biopsy in this manner, the resulting mature scar is flat or slightly depressed with slight hypopigmentation.

Punch Biopsy

Punch biopsy is used to sample processes within the dermis or the occasional depressed lesion. As discussed above, the volume of tissue obtained varies depending upon the diameter of the metal "barrel". For example, the specimen obtained with a 2 mm punch biopsy is very small and may not yield sufficient pathologic findings for an accurate diagnosis. In one study, however, where 2 mm punch biopsy specimens (examined by a dermatopathologist) were compared to excisional specimens, an accurate diagnosis was made in 79 of 84 cases[27]. For most punch biopsies, an instrument with a 3 to 4 mm diameter is adequate. Occasionally, a 6 mm punch biopsy is performed to increase the likelihood of obtaining subcutaneous fat. However, as stated previously, the thickness of the dermis and the amount of subcutaneous fat required to establish the diagnosis must be kept in mind.

Disposable punch biopsy instruments are generally used. Reusable stainless steel instruments are available but must be sterilized following each procedure and sharpened frequently. Toothed forceps, scissors, needle holder, and suture material are also required. Local anesthesia is achieved with either superficial or deep instillation of the agent.

An optimal aesthetic result is obtained when the round punch biopsy instrument is used to produce an oval-shaped defect that can be closed without standing cone (dog-ear) formation when sutured into a straight line parallel to the other skin lines in the region. While traction is applied by stretching or spreading the skin with the index finger and thumb of one hand in the direction perpendicular to the relaxed skin tension lines (see Figs 142.6 & 142.7), the instrument is pushed into the skin and rotated in one direction with the other hand (Fig. 146.9). Back-and-forth twisting is not recommended as epidermis may be sheared off. Generally, the instrument is pushed and rotated until the subcutaneous plane is reached, as indicated by loss of the resistance encountered while cutting through the dermis. At times, the punch biopsy is utilized to just incise the skin superficially as when the skin is very thin (e.g. on the ear). The punch biopsy instrument is then

SPECIAL CONSIDERATIONS FOR A PUNCH BIOPSY ON THE FACE

- Position patient in a supine position with draping or gauze to protect the eyes from light or inadvertent damage by suture or instrument
- Use a 3 mm punch biopsy instrument (if possible); a 4 mm punch biopsy wound can produce standing cones when closed
- Choose a site with low visibility (if possible), e.g. in the shadows of the face, at cosmetic unit boundaries, or off/beyond the center of the face
- Protect underlying tissue with an anesthetic wheal
- Tailor depth of excision to depth of pathology rather than rotating and pushing the punch biopsy instrument to its hub
- Control bleeding with suture(s) – simple interrupted stitches of monofilament 5–0 or 6–0 nylon or polypropylene
- Protect with bandage and remove sutures at 5–7 days

Table 146.10 Special considerations for a punch biopsy on the face.

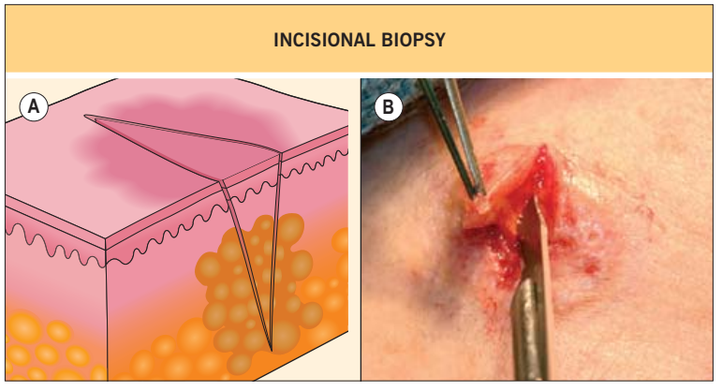

Fig. 146.10 Incisional biopsy. A Diagram. **B** Demonstration of the procedure.

removed and forceps are used (peripherally at one superficial edge) to gently extricate the specimen from the wound. Scissors may be needed to detach the base of the specimen, which can then be transferred to the appropriate container. In the case of fibrotic tumors or disorders, pressure may need to be applied to the surrounding skin to elevate the biopsy specimen.

Although a punch biopsy wound can be left to heal by second intention after achieving hemostasis, the resulting scar is often depressed and takes several weeks to heal. Usually this wound is closed primarily, and the resulting scar is generally white or hypopigmented and has a linear or cruciate configuration. On the trunk or extremities, one or two simple interrupted epidermal stitches of 4–0 nylon or polypropylene monofilament suture achieve closure and hemostasis. On the face, neck or hands, the resulting scar may be less apparent if 5–0 or 6–0 simple interrupted sutures are utilized. Some physicians use fast-absorbing gut for patients who are unable to return for suture removal. However, it is also reasonable to have the patient return for a face-to-face discussion of the biopsy results, since the biopsy is being done to establish a diagnosis and determine a treatment plan. Sutures on the face are removed at 5–7 days, and on the trunk or extremities, at 10–14 days. A pathology report is usually available within 7 days.

Table 146.10 highlights special considerations when performing a punch biopsy on the face.

Incisional Biopsy

Large lesions in which the characteristic pathology is within the dermis or subcutis are often biopsied via an incisional or wedge biopsy (Fig. 146.10). The specimen may be entirely lesional or may contain an edge of clinically normal skin, which allows comparison of involved versus uninvolved skin as well as examination for any microscopically apparent early changes at the edge of the lesion. The goal is to obtain a wedge of tissue 3–4 mm wide and as deep as necessary. The tissue should be in one piece for accurate orientation of the specimen during preparation; depending upon the possible diagnoses, longitudinal sectioning may be requested. The length of the wedge varies, but should be long enough to avoid cutaneous cone formation in the final closure.

Local anesthesia is obtained by deep and slow infiltration of the agent. It is advisable to wait 10 to 15 minutes after instillation to allow for complete anesthesia and to obtain the maximal vasoconstrictive effect of epinephrine. With a #15 blade (mounted on a blade handle) held perpendicular to the skin surface, a superficial incision into the epidermis scores one long side of the wedge using a light touch and one long motion, facilitated by traction by the non-dominant hand or an assistant. The second long side is then scored similarly. These lines are then redrawn with the blade held in the same manner but with firm pressure, incising into deep tissue, first one side, then the other. The incision is continued until the desired depth has been reached, usually in one or two more cutting movements. The incision is angled toward the center axis so that deep within the tissue, the two incisions meet and complete the separation of the tissue. A forceps is used to lift the tissue out of the wound. If the tissue is still connected at its base, the blade or tissue scissors may be used to complete the detachment.

Hemostasis is best achieved by point electrocoagulation. Large arterioles may require tying off with absorbable suture. An incisional biopsy wound is generally closed with suturing. In some circumstances, such as a site compromised by necrosis or infection, second intention healing may be the best option, even if it is slow and prolonged (see Table 146.7). Deep interrupted stitches of absorbable suture material, 4–0 or 5–0 in caliber, with the knot inverted are utilized to close the subcutis and the dermis (see Fig. 146.4). The epidermis is then closed with

EXCISION OF COMMON BENIGN CUTANEOUS LESIONS	
Lesion	**Comments**
Epidermoid inclusion cyst	Dissection facilitated by injection of liberal amount of local anesthesia into surrounding tissue; allows surgeon to work in plane between resulting edema and cyst wall[29] Fusiform excision should include any poral opening or scarring attaching the cyst to the surface Fusiform excision may be smaller than the area deformed by the cyst, but enough of the redundant expanded tissue should be excised so that the scar lies flat
Pilar cyst	See epidermoid inclusion cyst; dissection usually easier
Lipoma	The extent can be appreciated by palpation, then marked with surgical marking pen. A linear incision is made in the middle of the skin covering the lipoma. The tumor is more firm and dense than the surrounding normal subcutaneous fat
Dermatofibroma	Patient needs to be warned that scar may be more noticeable than original lesion, especially on the lower extremities
Melanocytic nevi	See text

Table 146.11 Excision of common benign cutaneous lesions.

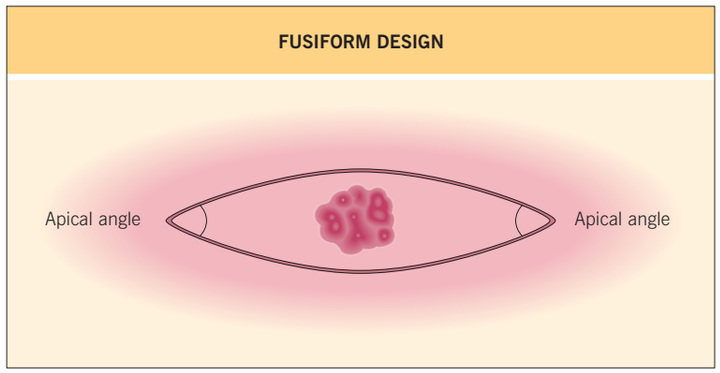

Fig. 146.11 Fusiform design.

simple interrupted sutures of nylon or polypropylene monofilament. The size of the epidermal suture varies depending upon the site; the face is generally closed with 6–0 suture and other sites by 4–0 or 5–0 suture.

Excisional Biopsy (Excision *in toto*)

Excision represents the workhorse of dermatologic surgery[28]. The procedure is designed to remove entire lesions for histopathologic examination as well as for surgical cure. Lesions such as a clinically typical BCC or an unsightly or troublesome subepidermal lesion presumed to be benign are commonly biopsied (or excised) in this fashion (Table 146.11). Atypical pigmented lesions highly suspicious for invasive melanoma are typically excised *in toto* as a biopsy procedure because the degree of atypia and depth of invasion may not be uniform; the excision allows the pathologist to examine the entire lesion and decreases the likelihood of sampling error. In addition, excision is frequently the treatment of choice after the diagnosis of a cutaneous malignancy has been established by a previous biopsy. The excision specimen is again submitted for histologic examination in order to confirm the diagnosis and for comment as to whether the margins of the specimen are clear of tumor. Although the basic concepts discussed above with regard to an incisional biopsy also pertain to this procedure, an excision *in toto* is more complicated because it is intended to be the final definitive procedure. Therefore, margins required for cure, as well as cosmetic and functional challenges with respect to the final scar, must be carefully considered in advance.

Recommended margins for removal of an entire lesion depend on the clinical diagnosis. Most benign lesions can be removed completely by including a 1–2 mm margin of normal-appearing skin around the circumference of the tumor. A clinically well-demarcated, small BCC or SCC is generally, though not always, cured with 4–5 mm margins[30,31]. Atypical nevi are frequently excised with 3–4 mm margins. While 4 mm may not be required for complete removal of the lesion, it may save some patients from a second procedure, since it is standard practice to re-excise a nevus with severe atypia that is still present at the margins microscopically. The suggested margin for melanoma *in situ* (with the possible exception of lentigo maligna, where wider margins may be required) is 5 mm. For invasive melanoma, the recommended margin depends on the Breslow depth, e.g. 1 cm margins for tumors ≤1.0 mm in depth (see Ch. 113). The depth of the defect to be created must also be planned in advance[32]. Primary closure is facilitated when the base of the surgical wound lies within subcutaneous fat. In the case of melanomas, the excision should include full-thickness skin and subcutis, with fascia at the base of the wound.

Although an excision is often referred to as an ellipse, the actual shape is fusiform (Fig. 146.11). The optimal geometry of the wound varies depending on the contour of the site and the elasticity and thickness of the skin[33]. The angle at each end of the excision varies from 30 to 75 degrees[34]. In order to minimize standing cone formation, each side of the fusiform shape is three to four times as long as it is wide. The central axis becomes the line of closure and dictates where the surface scar will be visible. The mature scar should appear as a thin line, although some spreading may be seen on the upper trunk and shoulders. From a cosmetic standpoint, an optimal scar results when the line of closure is placed within major skin folds, skin lines with minimal tension, wrinkles, or boundaries between distinct cosmetic units (see Ch. 142). Movement of underlying muscles may distort the line of closure, but this can be predicted in advance and the excision plan adjusted. For hair-bearing areas, the line of closure should follow the normal patterns of hair growth.

The process of excision and repair can be divided into a series of steps (Fig. 146.12). Local anesthesia is best obtained by injection into the subcutaneous tissue. The planned excision, which can be delineated with surgical marking dye *prior* to injection, is ringed by the anesthetic agent, with the needle pointed outward to include the area needed for undermining. After ensuring that anesthesia has developed, the site is cleansed and draped with sterile cloths. The excision is begun by stabilizing the site either with the non-dominant hand or by an assistant. As with an incisional biopsy (see above), the epidermis is scored on both sides by drawing lightly with a #15 blade (mounted on a blade handle) along the lines chosen to create the fusiform shape. With continued traction, the incision is completed to the base of the wound by drawing the blade with increased pressure. Unlike with the incisional biopsy, the blade is held vertically throughout the procedure so that the edges of the wound are perpendicular to the skin surface, not angled inward to create a wedge. Completing the incision in one to two strokes after scoring minimizes ragged edges. Care is taken at both apical angles to completely incise to the same depth as that reached at the center of the wound. When the fusiform incision is complete, to either the level of the subcutaneous fat or the fascial plane, the specimen sits up from its base like an island. The specimen is then dissected from the base of the wound using scissors or a blade and the specimen is transferred to the appropriate container. The end result of the excision is a fusiform-shaped wound with vertical sides and a flat even base consisting of subcutaneous fat or fascia. Hemostasis is achieved by electrocoagulation.

The remainder of the procedure deals with the creation of a cosmetically acceptable and functional closure. In order to free tissue for movement into the wound, undermining is performed at the edges of the wound with either scissors or a scalpel. A favorite technique is to use scissors with rounded tips for insertion and then spreading of the tissue to produce blunt dissection in the plane of undermining, a procedure advocated because of the belief that it is less likely to cut arteries or nerves. Using the same scissors, but with a snipping or cutting motion to sharply dissect, is also safe and more effective in generating a smooth, less ragged unit of skin[35]. Sometimes, the two techniques are combined, with spreading followed by snipping of the intervening tethering strands. Undermining is done in a controlled fashion, and

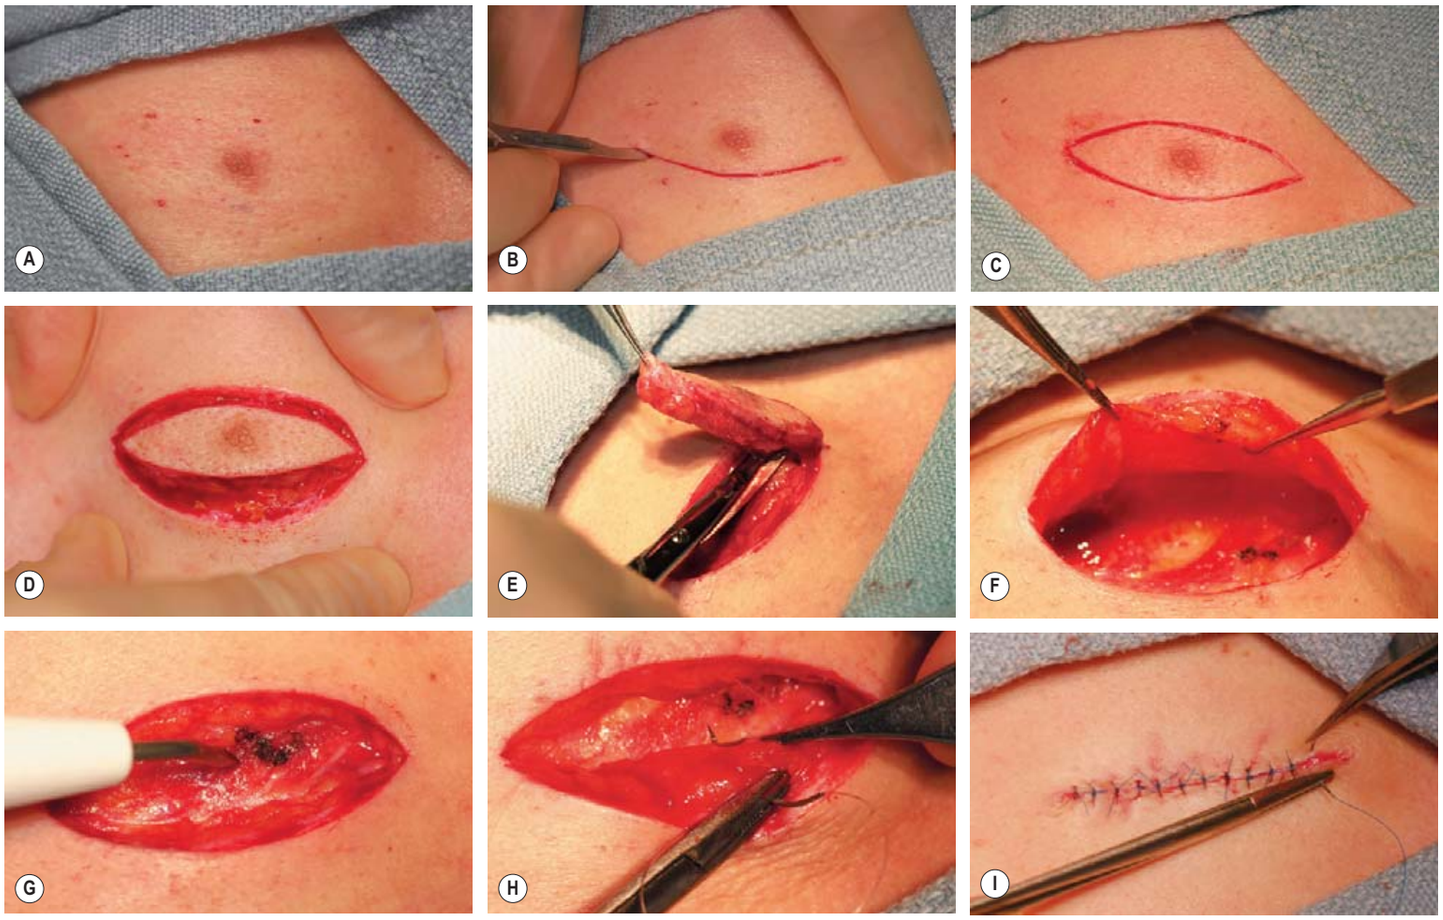

Fig. 146.12 Fusiform excision of an atypical melanocytic nevus. A After the margins are marked, the site is anesthetized, prepared with an antiseptic agent, and draped with sterile cloths. **B** Stabilizing the site with traction, the epidermis on one side of the fusiform design is scored using a #15 blade. **C** The epidermis on the opposite side is then scored. **D** The incision is completed into the appropriate plane in the subcutaneous tissue and the specimen then sits up in the middle of the wound like an island. **E** The base of the specimen is dissected with scissors or a blade. **F** The wound edges are then undermined in the same plane as the base of the wound. **G** Electrodesiccation or electrocoagulation is used to address small actively bleeding vessels to achieve hemostasis. **H** The subepidermal space is closed with buried stitches. **I** The epidermal edges are opposed by simple interrupted stitches.

good exposure and visualization is achieved by maintaining adequate hemostasis as the dissection proceeds. Tactile confirmation of the position of the tips of the scissors is also helpful.

In order to fill the defect with skin that matches with regard to thickness, the level of undermining is almost always at the same depth as the base of the wound, i.e. within the subcutaneous fat or at the fascial plane. Rarely, when there are superficially located arteries and nerves to be avoided, the plane of undermining is more superficial than the base of the wound. The use of curved scissors with the tips pointed upwards may facilitate staying in the appropriate plane.

The goals of undermining are to mobilize a unit of skin to be moved into the defect[36] in order to reduce wound closure tension[37], to allow proper wound edge eversion[38], and to provide a wide area for distribution of redundant tissue over the base of the wound. Undermining around the entire wound to a distance that is at least the diameter of the wound may be required to meet these goals. When little undermining is done, opposed wound edges are pulled inward and redundant tissue bunches up in the wound bed. This redundant tissue has a force and mass that may apply pressure to the healing wound, producing a situation that allows for maturing scars to spread out (Fig. 146.13). During closure, wide undermining disperses the redundant tissue over a large area of wound bed. It may also serve to create a plate-like horizontal scar that distributes the forces of contraction and stabilizes the final result. Undermining must include the apical angles, where it facilitates the rotation that occurs as the two sides of the fusiform shape are brought together. The adequacy of the width of undermining can be tested either by picking up both wound edges with toothed forceps or skin hooks and opposing them or by placing a large temporary suture. The temporary suture may also supply some intraoperative tissue expansion that will facilitate closure. Braided polyester (e.g. Ethibond®) suture is commonly used for this purpose since it is soft and will not cut through tissue. If, with these tests, the wound edges cannot be draped easily for closure, undermining can be extended.

Once undermining is adequate and after again ensuring that the wound is dry, subcutaneous and epidermal sutures are placed to complete the closure. As with the incisional biopsy, deep interrupted stitches of absorbable suture material (4–0 or 5–0 in caliber, with the knot inverted) close the subcutis and the dermis. If the wound is thick or under tension, optimal closure may entail two layers of subcutaneous stitches (i.e. a complex layered closure). The epidermis is then closed with simple interrupted or running sutures with a smaller caliber. For a fusiform excision *in toto*, the end result of the procedure is a straight or curved line of closure that has the wound edges completely opposed and everted. The line of closure sits above the surrounding skin, sometimes described as having the appearance of the ridge line of a tent or a mountain range. The healing of a tensionless everted wound edge results in a flat, hairline scar.

Cutaneous cone (dog-ear) Repair

Closure of a fusiform excision may create cutaneous cones, i.e. tissue redundancies that distort the normal contour of the skin at the apical angles[39]. These cutaneous cones are also referred to as dog-ears and may consist of standing cones, lying cones, inverted cones or protruding cones. Inverted cones can be the most difficult to diagnose, as the appearance is that of a subtle dimple rather than a protrusion.

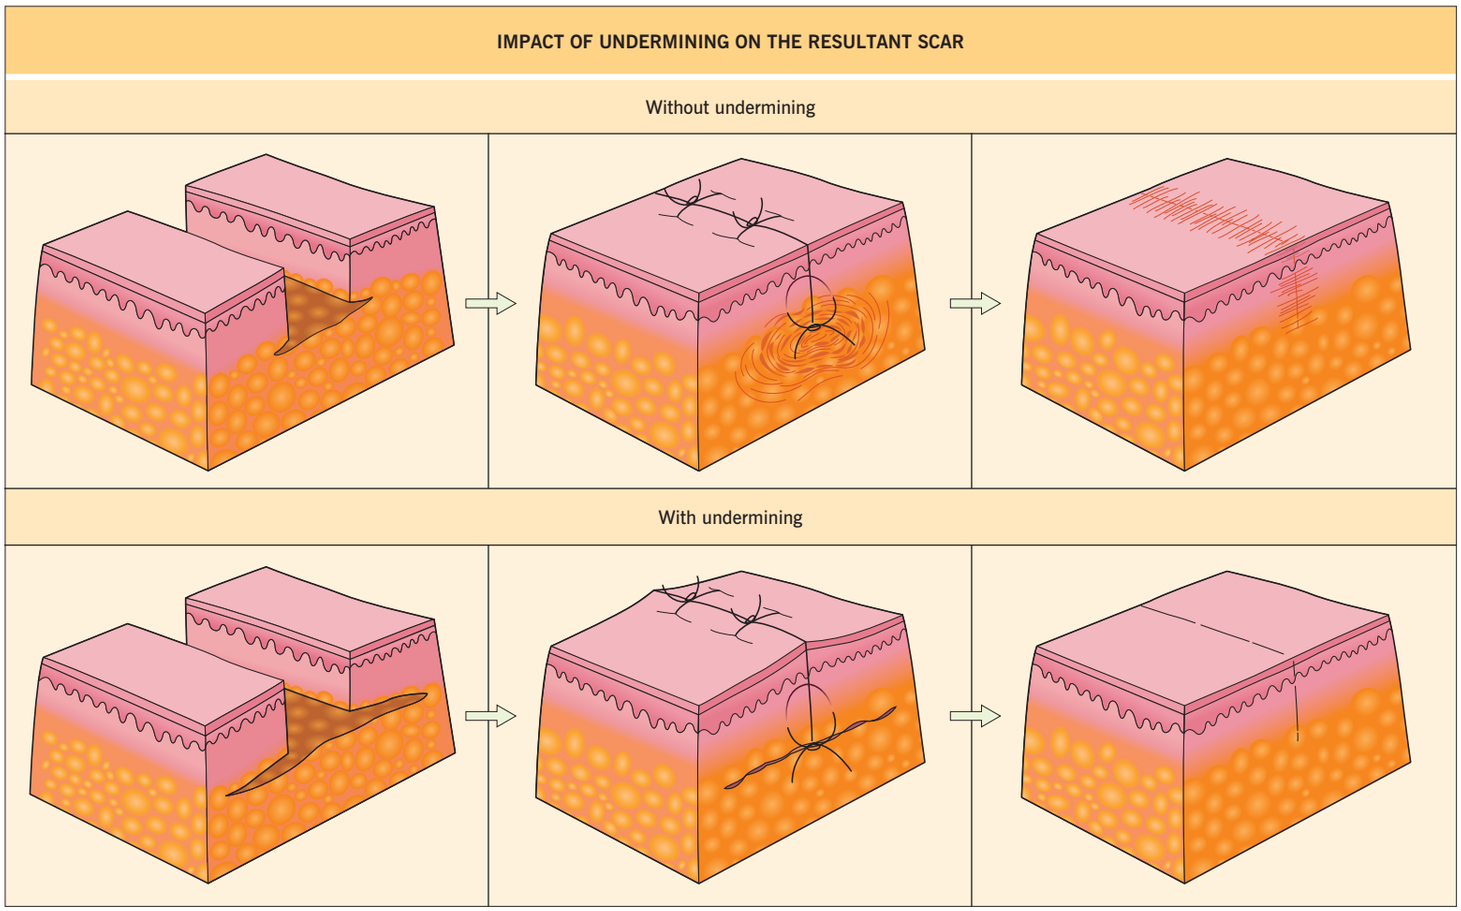

Fig. 146.13 Impact of undermining on the resultant scar. Without undermining, there is tension on the wound and eversion of the wound edges does not occur. Another consequence is spreading of the scar.

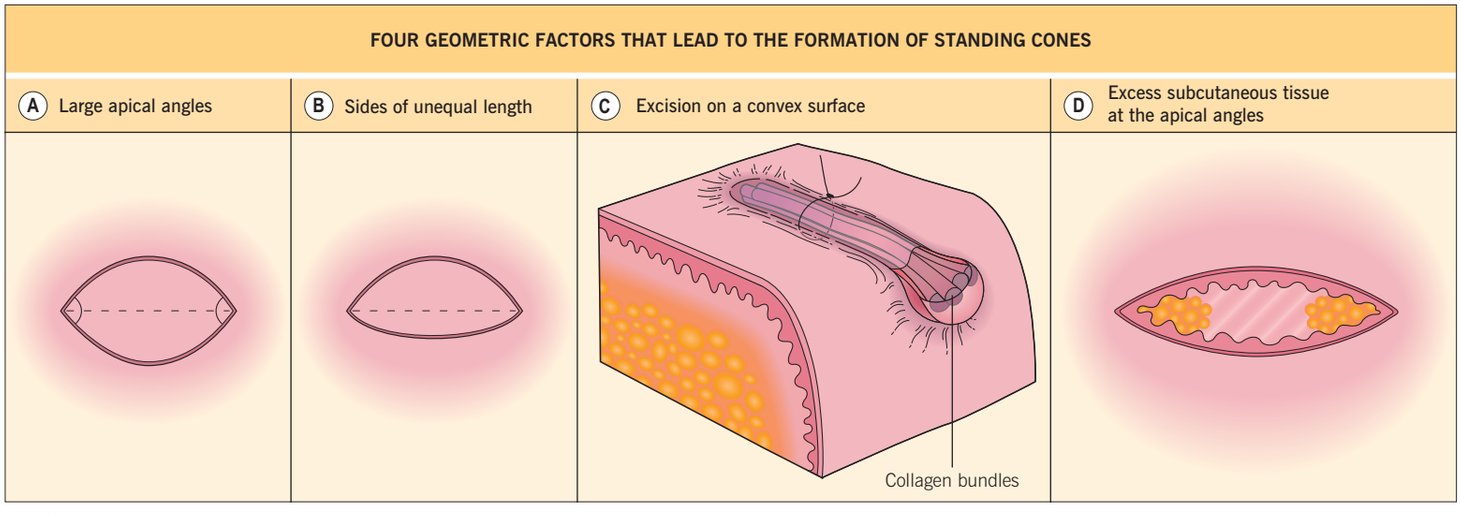

Fig. 146.14 Four geometric factors that lead to the formation of standing cones.

Regardless of their subtle nature, these redundancies will distort the final scar unless they are repaired. Cutaneous cones are also produced by tissue movement during flap closures.

Standing cones primarily result from geometric factors (Fig. 146.14). They may appear in closures of fusiform excisions (with sides of equal length) when the sides are of insufficient length compared to the width of the excision. The resulting apical angles are too wide to rotate in and maintain a flat contour to the skin surface. For this reason, linear closure of a circle, an oval or an ellipse will always create standing cones. Also, cutaneous cones always form during closure of fusiform shapes that have sides of unequal length; redundant tissue becomes apparent on the longer side. Notably, when an excision is performed on a convex surface, standing cones may occur despite seemingly small apical angles. With suture placement, collagen bundles are pulled together and act as rigid rods that will not lie flat on a curved surface.

In addition to geometric forces, protrusions are produced when there is excessive subcutaneous tissue in the base of the wound at the apices (as compared to the center of the wound). A lack of adequate undermining at the apices will then magnify these protrusions. This process is usually called "boating" or "pseudo dog-ear" formation. It is

important to distinguish boating from true standing cone formation because repair of the former requires removal of the excess subcutaneous tissue and appropriate undermining as opposed to the techniques described below.

Many standing cones are small and can be repaired via a closure that employs the rule of halves (Fig. 146.15). The midpoint of each side is opposed with a suture, bisecting the wound. Each unclosed half is then bisected again and the closure is continued until all tissue has been opposed. For a fusiform shape with unequal sides, repair of standing cones in this manner produces a curved line of closure. The curvature is directly proportional to the size of the dog-ear. If the wound is in a site such as the forehead, which lacks loose tissue to free up and mobilize, the line of closure may remain straight; however, there will be noticeable gathering on one side of the line and a depressed contour on the opposite side of the line where the skin thinned as it was stretched to fit.

Simple straight, curvilinear or angled excisions of standing cones will also restore the desired contour of the site, even though they lengthen the scar (Fig. 146.16). The first step is to close the center portion of the wound with subcutaneous sutures. It is helpful to continue to oppose subcutaneous tissue from the center of the wound outward until the standing cones become visible. Epidermal sutures may also need to be placed since any gaping at the center of the wound will underestimate the size of the dog-ears. After undermining, one limb of the standing cone is cut through to the base of the wound along the line that is desired for final closure. Undermining is repeated until the excess tissue can be draped over the cut edge. The new apical angle will lie flat if the limb has been adequately cut and if undermining has been sufficient. The second limb of the standing cone is then addressed by cutting from the wound to the new apical angle. The excess tissue that is removed will be in the shape of a triangle that is referred to as a Burow's triangle[40]. An alternative method, helpful for novices wanting to create a straight closure, is bisection of the standing cone, laying each half out along the skin surface and then cutting the two triangles of excess tissue. Closure is then completed with subcutaneous and epidermal sutures.

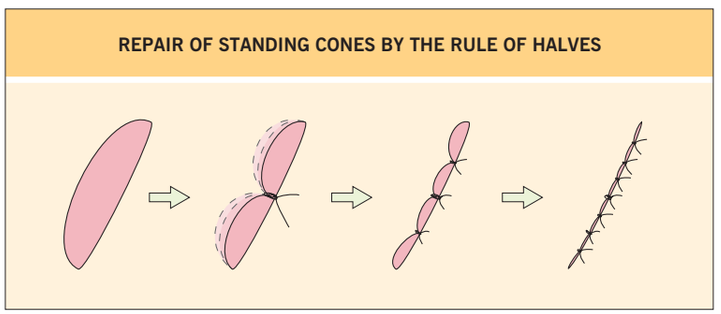

Fig. 146.15 Repair of standing cones by the rule of halves.

An M-plasty is a dog-ear repair that shortens the total scar length (Fig. 146.17). Depending upon the site, M-plasty scars may also fit within prominent lines and folds more accurately. This procedure is particularly helpful in sites that are not flat. The first step, as above, is to close the center portion of the wound and adequately undermine the apical angle. *Both* lateral limbs are cut at an obtuse angle from the end of the wound to about halfway toward the apex of the redundancy. The excess tissue is then draped over the cut edge and an M is now apparent. Cutting from the central tip to the two new apical angles removes two pieces of tissue that are also triangular in shape. The area of these two triangles is equal to the area of the single triangle that would have been removed had a simple excision of the standing cone been performed. If the central tip lies in a good position, then a standard closure is performed. If the tip needs to be advanced to approximate the wound edges and fill the defect, a *half-buried horizontal mattress stitch* (also called a *tip stitch* or *three-corner stitch*) is used (see Fig. 146.17E). Care must be taken with the three-corner stitch, as necrosis of the tip can occur with too much tension.

A dog-ear may also be displaced to a distant site. After closure of the central portion of the wound, an incision is made perpendicular to the dog-ear to an appropriate site where there is enough redundant tissue such that it can be removed as a triangle (Fig. 146.18). Undermining is required over a wide area so that tissue can be moved without tension. This procedure is also referred to as a Burow's advancement flap (see Ch. 147). It is commonly used to avoid dog-ear repair in a free margin or in a cosmetically or functionally sensitive area.

Finessing closure of fusiform excisions may require changing the axis of the line of closure so that the scar blends better with the prominent lines and folds of the site. Changing the axis will produce dog-ears that can be repaired by any of these methods.

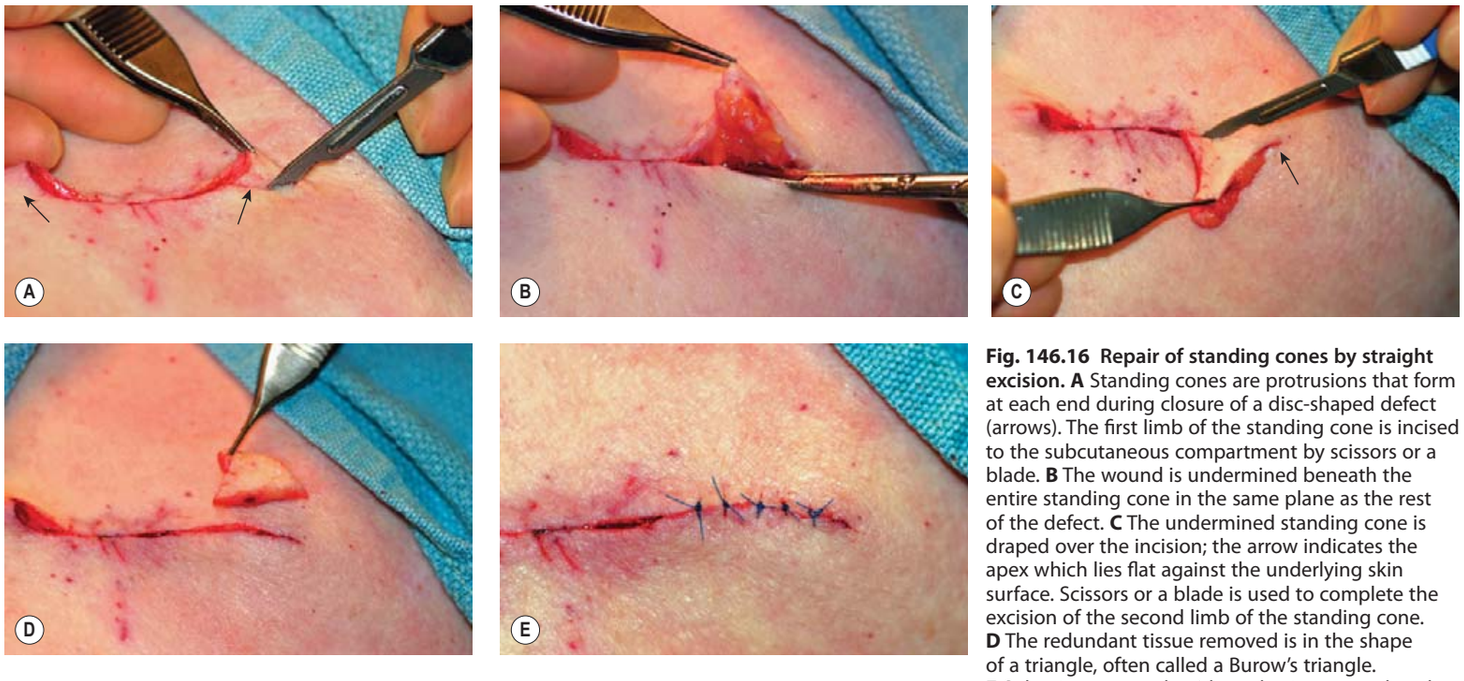

Fig. 146.16 Repair of standing cones by straight excision. A Standing cones are protrusions that form at each end during closure of a disc-shaped defect (arrows). The first limb of the standing cone is incised to the subcutaneous compartment by scissors or a blade. **B** The wound is undermined beneath the entire standing cone in the same plane as the rest of the defect. **C** The undermined standing cone is draped over the incision; the arrow indicates the apex which lies flat against the underlying skin surface. Scissors or a blade is used to complete the excision of the second limb of the standing cone. **D** The redundant tissue removed is in the shape of a triangle, often called a Burow's triangle. **E** Subcutaneous and epidermal sutures are placed to complete the closure.

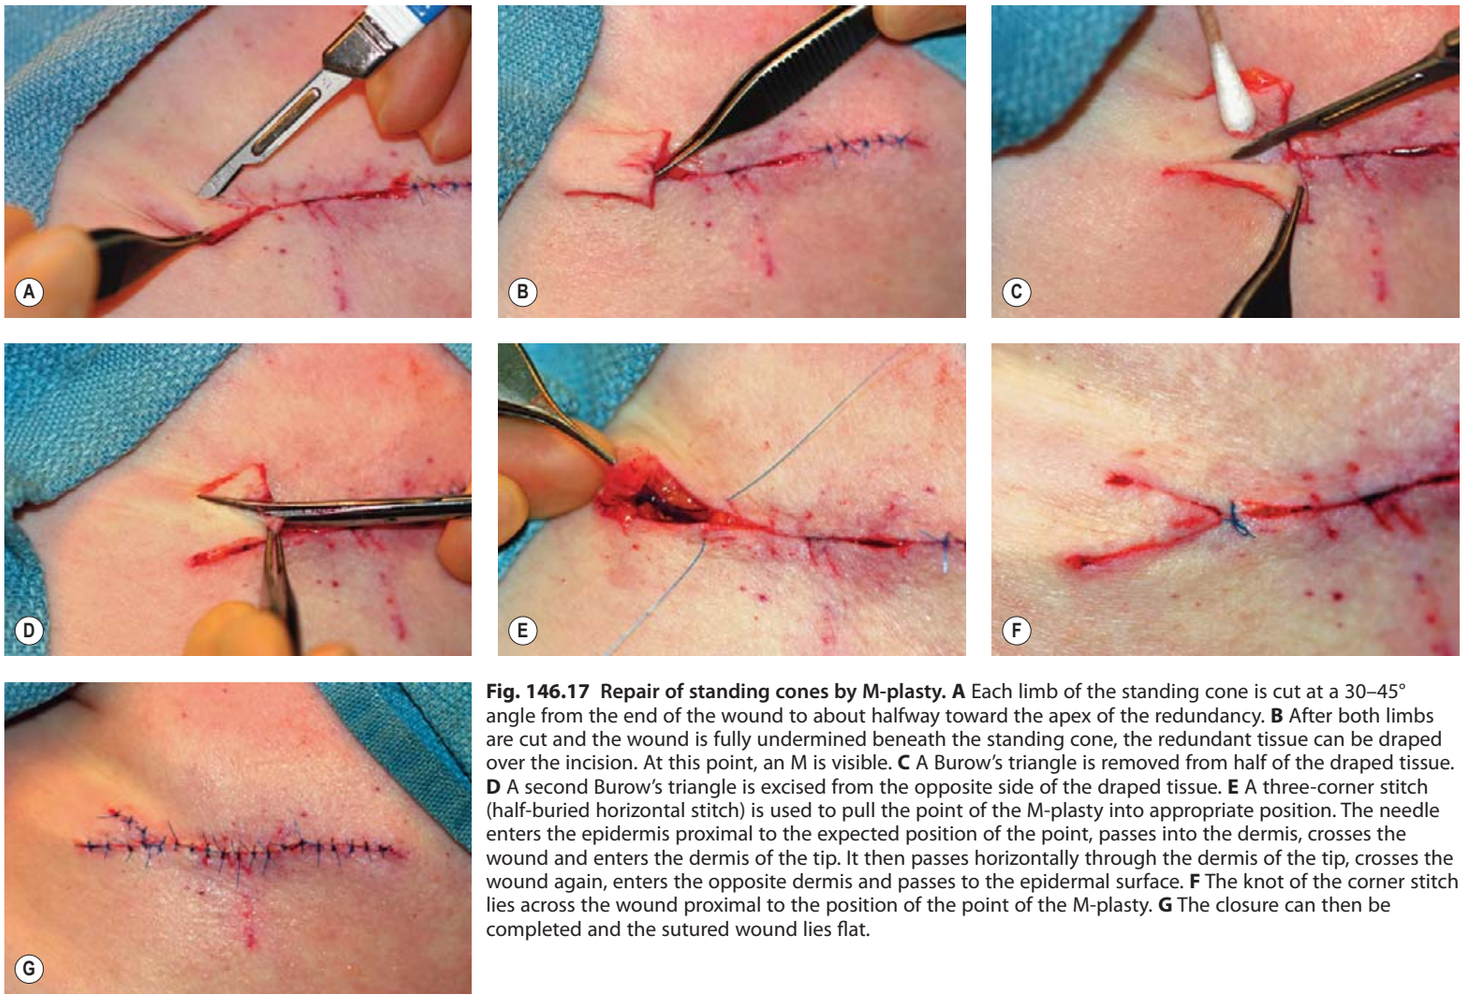

Fig. 146.17 Repair of standing cones by M-plasty. A Each limb of the standing cone is cut at a 30–45° angle from the end of the wound to about halfway toward the apex of the redundancy. **B** After both limbs are cut and the wound is fully undermined beneath the standing cone, the redundant tissue can be draped over the incision. At this point, an M is visible. **C** A Burow's triangle is removed from half of the draped tissue. **D** A second Burow's triangle is excised from the opposite side of the draped tissue. **E** A three-corner stitch (half-buried horizontal stitch) is used to pull the point of the M-plasty into appropriate position. The needle enters the epidermis proximal to the expected position of the point, passes into the dermis, crosses the wound and enters the dermis of the tip. It then passes horizontally through the dermis of the tip, crosses the wound again, enters the opposite dermis and passes to the epidermal surface. **F** The knot of the corner stitch lies across the wound proximal to the position of the point of the M-plasty. **G** The closure can then be completed and the sutured wound lies flat.

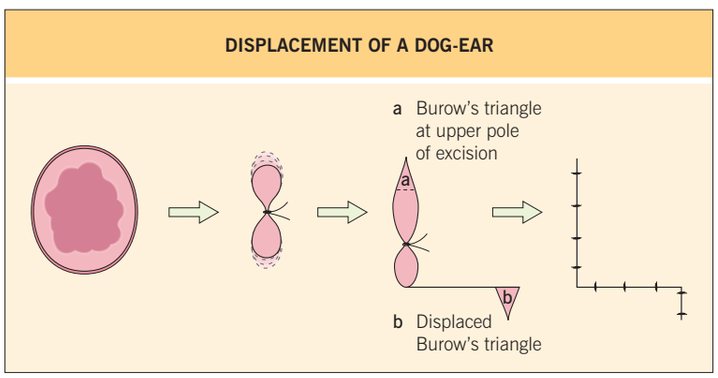

Fig. 146.18 Displacement of a dog-ear.

VARIATIONS/UNUSUAL SITUATIONS

A disc excision (with straight or angled edges) may be performed either for biopsy purposes or for biopsy and definitive treatment. This option is chosen when healing by second intention is preferred[41] or when it is desirable to remove the tumor first and then repair the dog-ears during the closure. Second intention healing may be advantageous when the risk of adverse reactions with primary closure is high. For example, excisions of even small tumors on the anterior lower leg that are closed primarily can produce wounds with tension and wounds that are more likely than those at other sites to dehisce, become infected or be painful. This is especially true if undermining is inadequate and weight-bearing is not minimized for the first 5–7 postoperative days (including, at times, the use of crutches).

Another option for wounds with too much tension on the anterior lower leg is the placement of a skin graft, but postoperative care requires leg elevation and the absolute avoidance of weight-bearing. Alternatively, the wound can be closed, either partially or completely, with a pursestring suture[42,43]. The latter is a running suture that is placed around the entire perimeter of the disc. After its placement, tension is applied to the ends of the suture until maximum constriction is obtained and then the ends are knotted. Advantages of the pursestring suture are speed, distribution of tension circumferentially, and amelioration of the need for the removal of excess normal skin in order to complete a fusiform excision. Since the time for complete re-epithelialization of a wound undergoing second intention healing is related to the diameter of the largest circle that can be drawn within the wound, even closure of a wound by 30% can result in a significant reduction in healing time. This smaller wound can also be grafted if desired.

When wounds heal by second intention, postoperative care is less burdensome, as the patient may resume normal activities almost immediately while dressing and bandaging the wound daily. However, compared to a linear excision, re-epithelialization requires a significantly longer period of time; the latter varies directly with the size of the wound and can range from 2 weeks to at least 2 months on the distal lower extremities. The patient also needs to consider the resultant scar, i.e. a depressed circular scar versus a graft versus a linear scar.

Removal of melanocytic nevi on the upper trunk and shoulders via disc excision or saucerization (angled edges) results in a smaller, often more cosmetically acceptable scar than does a fusiform excision. Also, the excision of tumors in sites such as the ear may be amenable to disc excision followed by second intention healing.

Performing a disc excision and then repairing the dog-ears during the closure allows the surgeon to pay particular attention to the issue of appropriate curative margins without dealing simultaneously with the cosmetic and functional issues of the closure. Once the tumor has been removed and the area widely undermined, the line of closure can be determined, that is, the closure with the least amount of tension that fits into the dominant lines of the site[44,45]. The central portion of the wound is opposed by subcutaneous and epidermal sutures or by a large simple interrupted temporary suture and then the dog-ears are repaired. Since the cosmetic and functional issues are addressed after excision of the tumor and undermining, the resulting scar can be optimized.

The shape of the excision can also be modified via a procedure known as an S-plasty[46]. Most useful on convex surfaces, this variation increases the total length of the scar while keeping the linear distance between the two apices constant. In a simple fusiform excision, the tension is located primarily in the center of the wound and is exerted along a single vector that is perpendicular to the axis of the wound. On the other hand, an S-plasty redirects and redistributes tension into multiple vectors along the wound, thereby minimizing tension in the center of the wound; in addition, the central tension vector is perpendicular to the primary tension vectors at the apices of the wound. Because much of the tension is displaced from the area of maximal convexity, the likelihood of a central depression or dehiscence is reduced.

POSTOPERATIVE CARE

Wound care and bandaging both play an important role in minimizing the risk of complications and in obtaining optimal cosmetic and functional results. Wound care removes surface debris and promotes re-epithelialization. A good bandage supports and stabilizes the wound in the closed position, wicks away excessive blood or tissue fluid, supplies pressure to the wound for hemostasis, and protects the wound from the dryness and bacterial contamination of the external environment.

A small shallow wound that is to heal by second intention is cared for by daily cleansing of the site with mild soap and water, application of petrolatum and coverage with an adhesive bandage such as a Band-Aid® (with a central non-adherent area). A liquid adhesive bandage has also been reported to be effective, and, in a trial on minor cuts and abrasions, proved easy to use[47]. A large shallow wound that is to close by second intention may need a bandage fashioned specifically for that site, usually consisting of layers of petrolatum, Telfa®, gauze or cotton, and tape or other means of adhering the bandage at the site.

A layered bandage is also required for a sutured wound. A liquid adhesive (e.g. Mastisol®) is applied to the skin surface surrounding the sutures. Petrolatum is applied in a thin line onto the wound edge. Sterile tapes such as Steri-Strips™ are placed perpendicular to the line of closure. The final layer is rolled gauze or cotton, which is then taped in place with paper tape or Hy-Tape® ("pink" tape). Elastic dressing (e.g. Coban®) can be used for compression, but should be released and reapplied if it is used circumferentially, so that vascular compromise distally does not occur.

Patients need oral and written instructions regarding the care the wound will require at home. Most simple wounds are cleansed daily with soap and water and redressed until the sutures are removed or the wound has completely re-epithelialized. Patients should understand that they need to remove any crusting or debris from the wound as they cleanse it and they may prefer to use cotton-tipped swabs or gauze. Instructions regarding bandages should likewise be clear. Leaving the wound open to the air or allowing it to become dry retards re-epithelialization and may compromise the final appearance or the scar[48].

Bandages that minimize the need for wound care are preferred by many patients. In addition, the stability and protection afforded by a bandage that stays in place for a week or more may further optimize the results, especially for wounds closed primarily. These bandages may be constructed in layers as discussed above and should be kept dry to prevent maceration of the covered skin. On the trunk and extremities, a bandage can be made of a polyurethane foam dressing (e.g. Cutinova Hydro®) covered by a water repellent film (e.g. Bioclusive®), precluding the need for any care and allowing ease of movement and a normal regimen for bathing.

Once the sutures have been removed and the wound cleaned, the use of liquid adhesive and sterile tapes for another week or two further stabilizes the wound. Many specialized bandaging systems are available for complicated wounds (see Ch. 145).

COMPLICATIONS

Short-term complications of biopsies and excisions are few in number and generally engender limited morbidity (Table 146.12)[49]. In addition, the smaller the procedure, the fewer the complications, which explains why shave biopsies and snip biopsies are quite safe. Hemorrhage may occur, from the time of the procedure to afterwards when the patient has returned home, and it usually occurs within the first 24 hours. Although many patients take aspirin, warfarin or other agents that affect coagulation or platelet function, hemostasis can be achieved during the procedure, resulting in few adverse bleeding events[50].

Infection occurs rarely, in less than 1% of most procedures[51]. Some patients have difficulty with either irritant or allergic reactions to topical antibiotics[52] or to tapes and bandages. These often pruritic eruptions are managed with a change in the wound care regimen but do not usually require topical corticosteroid creams. Biopsies performed on the lower limbs, limbs affected by lymphedema, intertriginous areas, and ears are most susceptible to infections. If an infection develops, oral antibiotics may be required.

Pain is generally minimal. When it occurs 3–5 days after the procedure, infection is the most likely cause, even in the absence of erythema, tenderness and purulence. Very rarely, paresthesias may result and can persist for several months, especially on the forehead. Wounds that are closed primarily may dehisce because of tension, hematoma formation, poor wound healing or infection. These wounds are thereafter managed for second intention healing and a delayed reconstruction can be undertaken, if needed, when the attendant inflammation has resolved.

Long-term complications (see Table 146.12) generally consist of functionally or cosmetically adverse scarring[53]. Depressed scars may occur if not enough subcutaneous tissue is brought into the line of closure. Atrophic and widened scars occur in areas where there is intermittent stretching of the scar as it overlies major muscle groups. Careful surgical technique that includes adequate undermining, minimization of tension at the line of closure and the use of multiple subcutaneous sutures can reduce the likelihood of this complication.

Scars may pursue a prolonged course of healing with erythematous thickening at the line of closure. These hypertrophic scars do resolve with time. To speed their resolution, practitioners often advise massage

SHORT-TERM AND LONG-TERM COMPLICATIONS OF BIOPSY PROCEDURES AND EXCISIONS
SHORT-TERM COMPLICATIONS
• Irritant or allergic reactions to topical antibiotics and/or tapes and bandages • Hemorrhage • Poor wound healing; dehiscence of closed wounds • Pain • Infection • Pruritus, paresthesias
LONG-TERM COMPLICATIONS
• Atrophic scars (thin, depressed, spread) • Hypertrophic scars (red, thickened) • Keloids • Distortion of normal structures (e.g. ectropion, elevated nasal ala, notching of the lip or helix of the ear) • Hypoesthesia, anesthesia • Paralysis (e.g. due to injury to facial nerve branches)

Table 146.12 Short-term and long-term complications of biopsy procedures and excisions.

or inject triamcinolone (10–40 mg/ml) into the scars. Silicone dressings are also recommended, but they are probably no more effective than non-silicone gel dressings[54]. In addition, scars may have a fragile surface (due to reduced dermal–epidermal attachments), pruritus or paresthesias, most of which resolve with time.

A true keloidal scar is one that grows beyond the boundaries of the original surgical injury and appears as a thickened erythematous or hyperpigmented nodule or plaque (see Ch. 98). It occurs in predisposed individuals who may have a history of previous keloid formation. Keloidal scarring is most commonly observed when procedures are performed on the upper trunk and shoulders and may be very difficult to treat.

FUTURE TRENDS

For the foreseeable future, histologic examination of tissue specimens will be the mainstay of dermatologic diagnostic testing. Excisions likewise will be frequently utilized, both to remove a specimen for diagnosis as well as to clear pathologic tissue completely. Future near-term advances will include improved means of anesthesia[55] and improved wound care with the development of agents to speed healing and minimize scarring. It is possible that advances in confocal laser microscopy may visualize *in situ* microscopic tissue architecture and cellular detail, but it is unlikely that this process will replace standard biopsy techniques.

147 Flaps

David G Brodland and David B Pharis

Key features

- A cookbook approach to flap reconstruction is not realistic
- The mnemonic STARTS lists basic reconstruction options: simple side-to-side closures, transposition flaps, advancement flaps, rotation flaps, tissue importation flaps, and skin grafts
- Understanding the dynamics of a flap optimizes its execution
- For reconstruction, the simplest approach that achieves the desired result is often best
- Extensive undermining, everted wound edges, meticulous hemostasis without excessive electrocoagulation, and technical precision are important in achieving an outstanding result

INTRODUCTION

Cutaneous reconstruction has played an important role in the establishment of dermatologic surgery as a vital discipline within dermatology. An in-depth understanding of reconstructive options, combined with a dermatologist's intimate familiarity with skin, enables optimal aesthetic and functional results. Equally important is an intimate understanding of the tissue dynamics of flaps, why they work, what problems each flap type can address, and their limitations. A cookbook approach to flap reconstruction is not realistic because of the many variables relating to the characteristics of the defect, the donor skin, the patient and the surgeon. It is better to attempt to provide a foundation of basic concepts from which the individual can build his or her skills and, hopefully, his or her unique style in reconstruction. Therefore, this chapter will emphasize the fundamentals of the various types of flaps and their execution. Clinical examples will be used to illustrate these key points.

BACKGROUND

At the patient's side, it is always helpful to have an on-demand recall of the flap options that are available. With experience, this is automatic, but those with less experience may find the mnemonic STARTS helpful (Table 147.1). The basic options for reconstruction include: simple side-to-side closures, transposition flaps, advancement flaps, rotation flaps, tissue importation flaps, and skin grafts. It is incumbent upon the surgeon to synthesize the many factors that may affect the choice of the most appropriate flap for a defect. The characteristics of the wound, qualities of the adjacent skin, the functional aspects of the affected anatomic site, the pertinent aesthetic considerations, the anatomic borders in proximity to the defect, and the age and expectations of the patient all contribute to the decision regarding the most appropriate reconstructive approach.

STARTS MNEMONIC
Simple side-to-side closure
Transposition flaps
Advancement flaps
Rotation flaps
Tissue importation flaps
Skin grafts

Table 147.1 STARTS mnemonic.

The most important goal in reconstruction is functional aesthetics. This means that the reconstruction should first and foremost maintain all vital functions and accomplish this with an aesthetic result. It should be remembered that not all aesthetic reconstructions are functional, but all functional reconstructions can be aesthetic.

Fundamentals of Flap Design and Suturing Technique

Technical precision, including suturing technique, may be the most important variable in achieving an outstanding result. The first important step is to prepare the wound edges of both the defect and the flap. All incisions should be made at a 90° angle to the skin surface such that the wall of the defect and the skin edge of the flap are square. Secondly, the wound base should be made a uniform depth. Whether reconstructing with an elliptical side-to-side closure or with any of the more intricate flaps, the contour of the wound base will persist and may affect the long-term appearance of the wound. Likewise, the thickness of the flap should be uniform. While the thickness of the flap relative to the depth of the defect merits some consideration, care should be taken when considering the use of a flap with a thick subcutaneous tissue component, since these flaps are much more prone to postoperative edema and "pincushioning". Nevertheless, all components of the flap should be fashioned with uniformity in mind.

Widespread undermining of the subcutaneous tissue adjacent to both the defect and the donor site defect is important for creating a broad "plate-like scar". This results in the distribution of scar contraction over a greater area and diffuses the effects of contraction such that the latter is not focused on the flap itself or the incision lines of the flap (Fig. 147.1). Undermining should be uniform and complete, including the areas of low tissue tension such as the tips of an ellipse or the pivot points of flaps.

Next, meticulous pinpoint hemostasis with complete visualization of all undermined skin with the help of an assistant is critical. Excessive postoperative bleeding within a sutured wound often results in an inferior outcome. It should be emphasized, however, that extensive tissue injury caused by electrosurgical hemostasis should be avoided as fervently as postoperative bleeding, since this can contribute equally to unwanted results. With a well-prepared wound and flap that are characterized by uniformity in thickness, sharply squared edges, well-loosened tissue margins and excellent hemostasis, the wound is ready for suturing.

Whether it is a side-to-side closure or a flap, eversion of the skin edges (along with undermining) is also essential (Fig. 147.2). Given their longer period of effectiveness, as compared to epidermal sutures, the authors prefer the use of subcutaneous ("buried") vertical mattress sutures to achieve eversion (see Ch. 146).

Flap Movement Characteristics

It is helpful to broadly characterize flap types according to their mechanism of skin rearrangement. By understanding the dynamics of each flap, it is easier to select one that will provide functionally aesthetic results. Upon consideration of the unique characteristics of the defect, the donor skin, and the functional and aesthetic issues of reconstruction in the context of the mechanics of flap tissue movement, a rational decision regarding the method of closure can be made. The components flaps share include the flap body, the pedicle or vascular base, primary and secondary defects, and, as an integral part of flap dynamics, the primary and secondary movements (Table 147.2, Fig. 147.3).

Most tissue movement results in some degree of tension. This tension creates vectors of force that tend to return moving skin to its original position. Therefore, the primary movement of a flap creates a

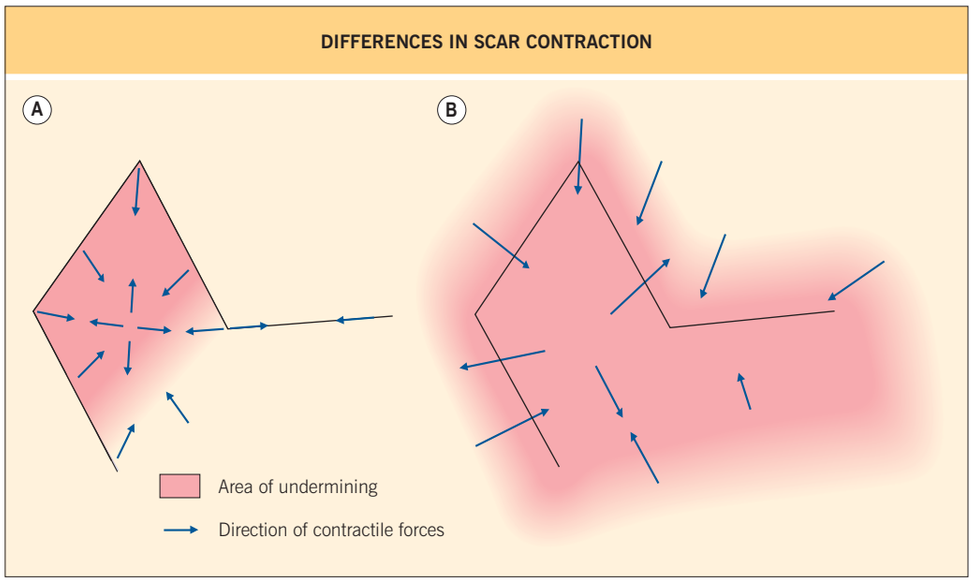

Fig. 147.1 Differences in scar contraction. Depiction of differences between wounds that are undermined and those that are not undermined prior to suture placement. **A** The contraction forces are focused on the margins of the flap in a wound that was not widely undermined. **B** Broad diffusion of contractile forces that are not concentrated at the flap margins, making "pincushioning" less likely in the widely undermined flap.

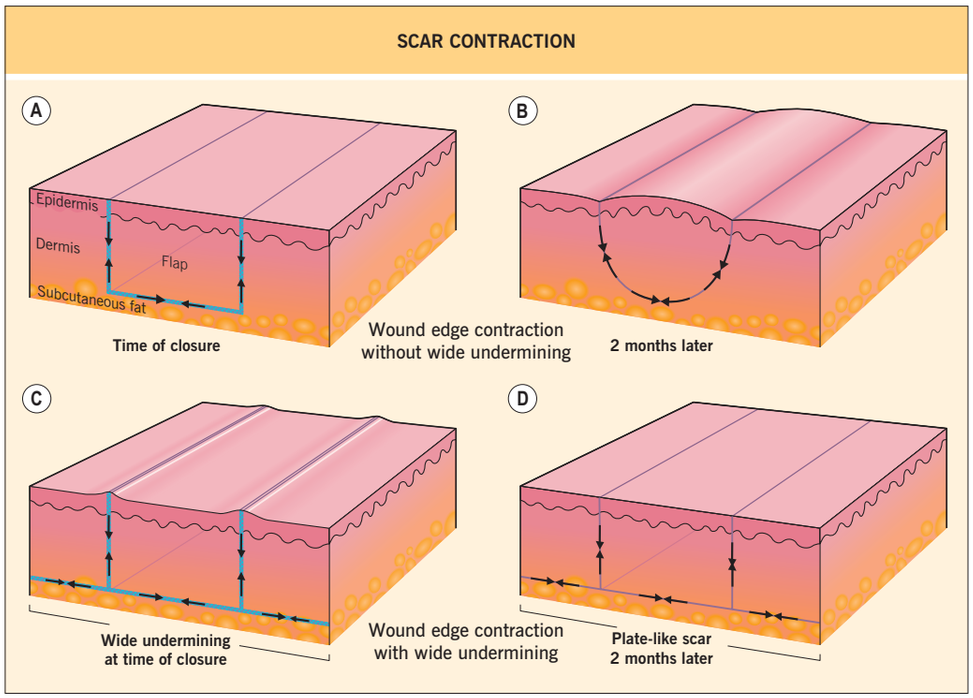

Fig. 147.2 Scar contraction. A Sutured wound without wound edge eversion and without undermining of the surrounding tissue. **B** The results of scar contraction, leading to inversion of the scars and "pincushioning" of the flap. **C** A wound sutured with eversion and wide undermining. **D** The canceling effect of scar contraction and wound eversion as well as the diffusion of scar contraction in the deep, undermined wound plane.

DEFINITIONS OF FLAP COMPONENTS	
Body	The skin being advanced, transposed, rotated, interpolated or imported into the primary defect
Pedicle	Also known as the vascular base of the flap, it is the conduit of the vascular supply that will remain intact and maintain the vascularization of the body of the flap intraoperatively and for the early postoperative period
Primary defect	The area deficient in skin that will be reconstructed by the movement of the body of the flap
Secondary defect (donor site defect)	The area devoid of skin created by the movement of the body of the flap
Primary flap movement	The movement of the flap body into the defect
Secondary flap movement	The tissue movement necessary to close the void or donor site defect created by the movement of the body of the flap
Primary tension vector	The direction of the force tending to counteract the movement of the body of the flap
Secondary tension vector	The direction of the force created by the closure of the donor site defect

Table 147.2 Definitions of flap components.

primary tension vector, while the secondary movement (during closure of the donor site defect) creates a secondary tension vector. Consideration of these forces and the effects of these forces on adjacent tissue and even the blood supply of the flap is the primary factor in selecting one flap over another. The most perfectly executed flap that via tension vectors results in the distortion of a free margin (e.g. a lip or eyelid) is of little value to the patient or the goal of aesthetic restoration. Therefore, the initial and most important skill required for the proper execution of flaps is the ability to anticipate the direction and amount of tension created by particular flaps and to predict what effects this tension will have on adjacent structures.

There are four broad categories of flaps based upon how the tissue is rearranged in order to achieve closure (Table 147.3). The first category of flaps essentially displaces one or both Burow's triangles that would be removed if the wound were closed by a simple side-to-side closure. The second category includes the flaps that reconfigure defects, while the third includes flaps that reorient tissue from adjacent pools of laxity into the defect. Finally, there is a category of flaps that enables defect closure by tissue importation.

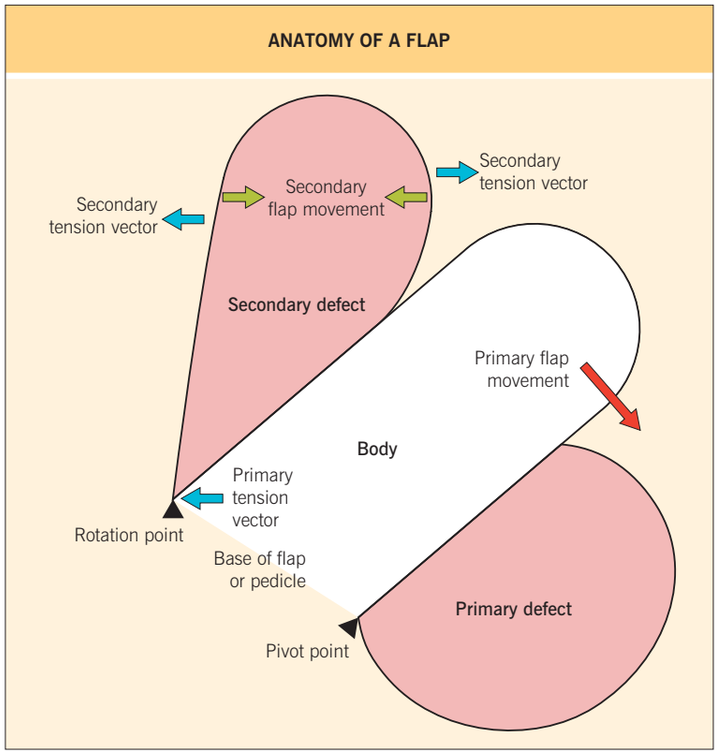

Fig. 147.3 Anatomy of a flap. Definitions of the components of a flap are outlined in Table 147.2.

Burow's triangle displacement flaps

Flaps that displace Burow's triangles to a convenient location distant from the defect include the single tangent advancement flap (Burow's flap), the bilateral single tangent advancement flap (A-to-T flap), the double tangent advancement flap (U-flap), the bilateral double tangent advancement flap (H-flap), and rotation flaps (including the glabellar or Rigor flap, Mustarde flap and the helical advancement flap) (Fig. 147.4). For the most part, these flaps displace Burow's triangles along straight or curved incision(s) tangential to the wound.

The key features of these flaps are: (1) they displace Burow's triangles to a distant site; (2) there is limited reorientation of tissue; and (3) their movement is dependent upon the intrinsic elasticity of the skin. Just as a simple side-to-side closure performed in stiff, inelastic skin would result in a tense closure, so would a Burow's triangle displacement-type flap. When the surrounding skin is elastic and "loose", the wound edges can be closed under minimal tension in both a side-to-side closure and with these flaps. Thus, the only advantage that these flaps confer over a side-to-side closure in tight skin is that a larger area of skin is typically undermined, which releases the latter from the tethering effect of the subcutaneous tissue. This allows for a modest decrease in wound closure tension. The most obvious utility of these flaps is in defects where, for functional or aesthetic reasons, it is inconvenient to remove a Burow's triangle immediately adjacent to the defect. An example of

CLASSIFICATION OF FLAPS BASED ON DESIGN CHARACTERISTICS

Flap category	Flap variations	Synonyms	Mechanism of tissue movement	Advantages	Disadvantages
Burow's triangle displacement flaps	Single tangent adv flap Bilateral single tangent adv flap Double tangent adv flap Bilateral double tangent adv flap Curvilinear tangent adv flap	Burow's flap A-to-T flap, O-to-T flap U-flap H-flap Rotation flap, Karpandzic flap, Mustarde flap	Tissue advancement: dependent upon intrinsic tissue elasticity	• Enables closures adjacent to vital structures through displacement of Burow's triangles • Single tangent flaps have excellent blood supply	• Depends on intrinsic skin laxity of the flap skin • Requires extensive undermining • Double tangent flaps have a more limited blood supply
Defect reconfiguration flaps	Island pedicle flap	Kite flap, myocutaneous pedicle flap	Tissue advancement: dependent upon intrinsic elasticity of subcutaneous pedicle Tissue movement results in reconfiguration of the defect	• Tissue-conservative due to reconfiguration of the defect without removal of Burow's triangle	• Blood supply is limited to the subcutaneous pedicle • Use limited to locations with spongy, elastic subcutaneous tissue
Tissue reorientation flaps	Rhombic transposition flap Bilobed transposition flap Nasolabial transposition flap Nasolabial flap with a twist (Spear's flap)	Limberg flap, Dufourmentel flap, Webster's 30° flap Melolabial fold flap	Reorientation of adjacent tissue laxity	• Effective for tight closures • Directional tissue gain can be achieved in direction of tissue deficit	• Depends on laxity adjacent to the defect • Multidirectional incisions; difficult to place all in RSTL
Tissue importation flaps	Paramedian forehead flap Nasolabial interpolation flap Retroauricular pedicled flap Modified Hughes flap Abbe cross-lip flap	Indian flap Pin back flap	Importation of tissue from a distant site	• Coverage of large wounds • Can provide vascularity for coverage of avascular grafts such as cartilage grafts	• Two-stage flap • Vascular supply limited to narrow pedicle

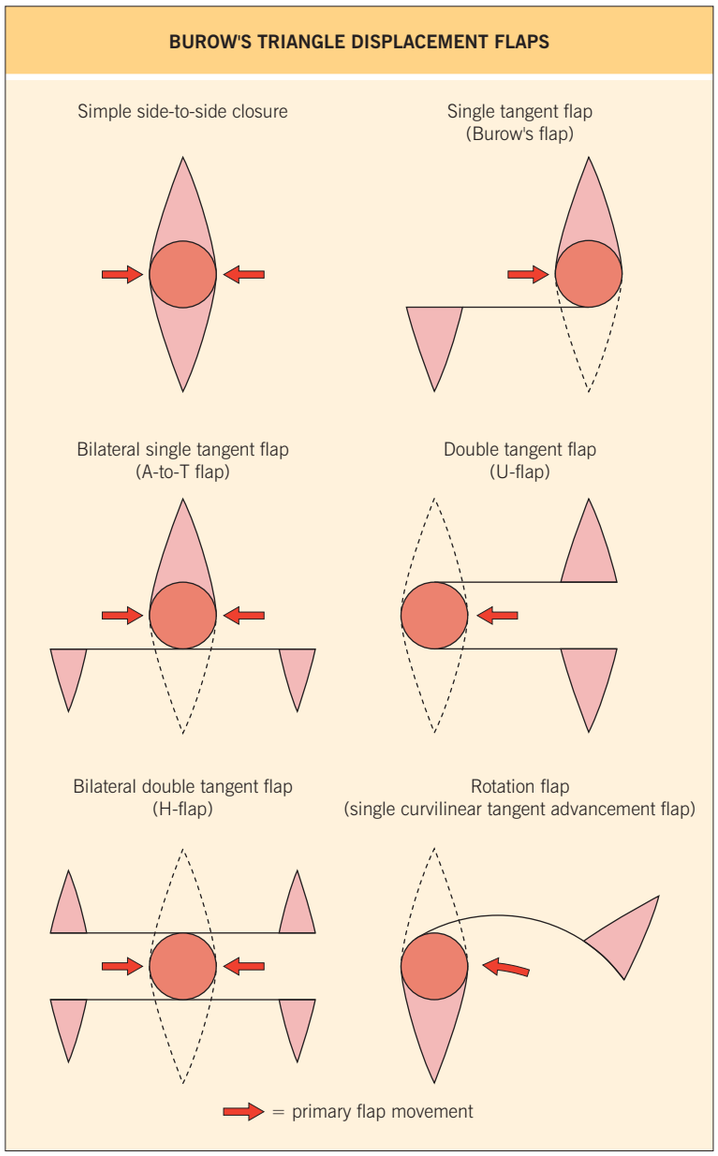

Fig. 147.4 Burow's triangle displacement flaps.

this is a defect above or below the eye in which displacement of the Burow's triangle is useful in order to avoid removing a triangle from the eyebrow or eyelid skin (Fig. 147.5).

Defect reconfiguration flaps

The island pedicle advancement flap is unique in that it is an advancement of tissue oriented in a plane perpendicular to the skin and at 90° to the more traditional advancement or rotation flaps. In this case, the tissue redundancy created at the pivot point of the flap is buried in the subcutaneous plane at the advancing edge of the flap (see below).

Tissue reorientation flaps

The tissue reorientation flaps are characterized by the lifting of skin from an adjacent donor site and reorienting it through the transposition of the flap over a peninsula of skin between the donor site and the defect. There is a pivot point at the base of this flap (see Fig. 147.3). The tissue movement depends on the presence of laxity in adjacent tissue. Although intrinsic elasticity of the flap skin may facilitate the ease of execution, without ample laxity in the flap donor site, the transposition can not be performed. Some of the flaps that fall into this category include the rhombic transposition flap, the bilobed transposition flap, and the nasolabial transposition flap (see Table 147.3).

To better understand the reorientation of tissue that occurs in these flaps, a review of the most basic tissue reorientation flap, the Z-plasty, is helpful. Z-plasties transpose two angular flaps, placing them in a complementary fashion into the defects of the other flap (Fig. 147.6). This reorientation of tissue ultimately results in the lengthening of the skin in the direction of the middle arm of the Z-plasty (Fig. 147.7). There is a complementary decrease in the length of skin perpendicular to this same arm. The amount of lengthening is proportional to the angles of the flap(s). Put another way, tissue gain in the direction of the middle arm is directly proportional to the width of the base of the flaps. This is effectively the mechanism of tissue reorientation in transposition flaps. Upon careful examination, Z-plasties can be found within the design of transposition flaps (Fig. 147.8). Therefore, just as with Z-plasties, transposition flaps work because the reorientation of the tissue results in lengthening of tissue in the direction of the skin deficit at the expense of the laxity in the donor site.

It is helpful to understand the utility of these principles of reorientation. An example of the utilization of these principles is in the case of a defect on the nasal tip (Fig. 147.9). The skin is typically very tight in this area, making simple side-to-side closure in the vertical direction difficult. Side-to-side closure in the horizontal direction is impractical because of the distortion that would occur to the free margin of the ala. When one looks for donor sites, there is typically a substantial amount of laxity on the mid nasal dorsum and nasal sidewall. A bilobed flap allows utilization of this laxity through tissue reorientation using two lobes. The underlying mechanism of tissue reorientation is a series of Z-plasties inherent in this flap. Since tissue gain in Z-plasties is in the direction of the middle arm of the Z-plasty, a substantial reorientation and lengthening of tissue in the desirable direction for repair of the defect occurs without distortion. In contrast to the Burow's triangle displacement flap, this flap does not rely upon intrinsic elasticity of the flap skin. This is key to avoiding distortion of the alar rim.

Tissue importation flaps

Large defects, or defects in areas where tissue laxity is lacking, may be reconstructed by importing vascularized tissue from a site that is not adjacent to the defect (see Table 147.3). Tissue importation flaps are typically derived from a distant donor site with ample tissue laxity and, most importantly, an excellent blood supply. This blood supply may be based on a particular artery (e.g. paramedian forehead flap based on the supratrochlear artery) or by a rich, random-patterned blood supply (e.g. the retroauricular pedicled flap).

These flaps are typically two-staged flaps requiring a period of vascular ingrowth from the wound bed of the defect. This time period ranges from 2 to 6 weeks, with 3 weeks being the most commonly reported time point for transection of the pedicle. In the head and neck region, defect sites where tissue importation flaps are commonly employed include the nose, ear, eyelid and lip. The appropriate selection and execution of these four broad flap categories are discussed in more detail below.

DESCRIPTION OF TECHNIQUE

Burow's Triangle Displacement Flaps

The group of flaps that comprise the Burow's triangle displacement flaps has the common feature of the displacement of Burow's triangle(s) along an incision made tangential to the defect (see Fig. 147.4). In each case, the basic method of closure is side-to-side advancement of tissue with the removal of Burow's triangles in the direction perpendicular to the side-to-side tissue movement. The greatest utility of these flaps is in situations where the normal adjacent location of one or both of the Burow's triangles would impinge upon a vital functional or cosmetic structure (see Fig. 147.5). These flaps allow for displacement or relocation of the triangle(s) to a more convenient location. As discussed earlier, one drawback is that the area of the flap is relatively large and the resulting tissue undermining is increased dramatically with only a modest increase in lax tissue recruitment.

Single tangent advancement flaps (STAF) and rotation flaps

There are several variants of Burow's triangle displacement flaps that are differentiated by the number of Burow's triangle displacements, or the configuration of the tangential line extending to the displaced

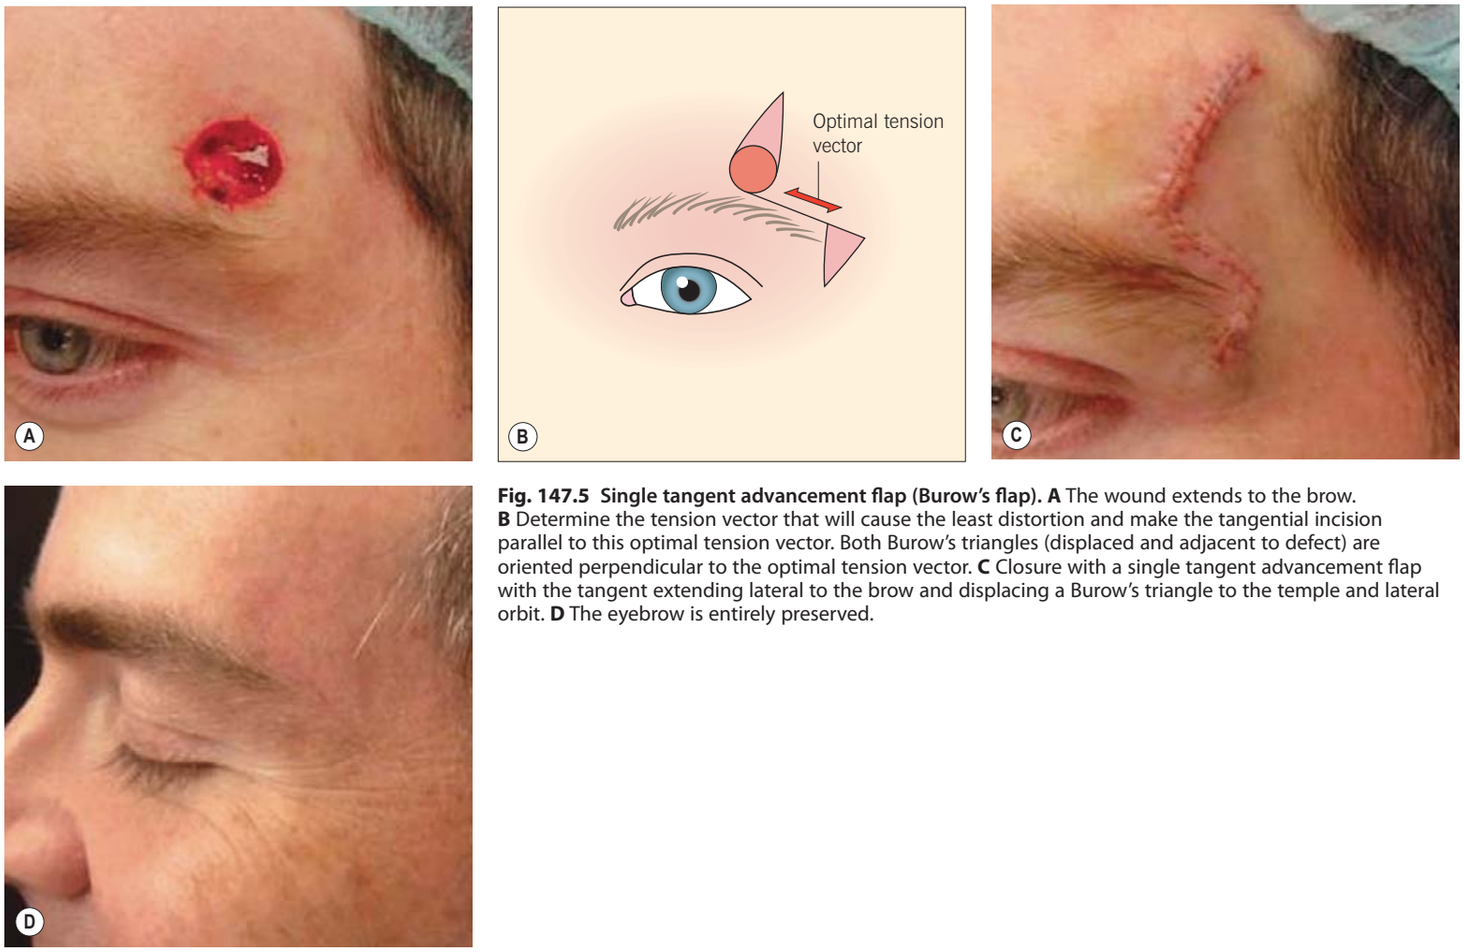

Fig. 147.5 Single tangent advancement flap (Burow's flap). A The wound extends to the brow. **B** Determine the tension vector that will cause the least distortion and make the tangential incision parallel to this optimal tension vector. Both Burow's triangles (displaced and adjacent to defect) are oriented perpendicular to the optimal tension vector. **C** Closure with a single tangent advancement flap with the tangent extending lateral to the brow and displacing a Burow's triangle to the temple and lateral orbit. **D** The eyebrow is entirely preserved.

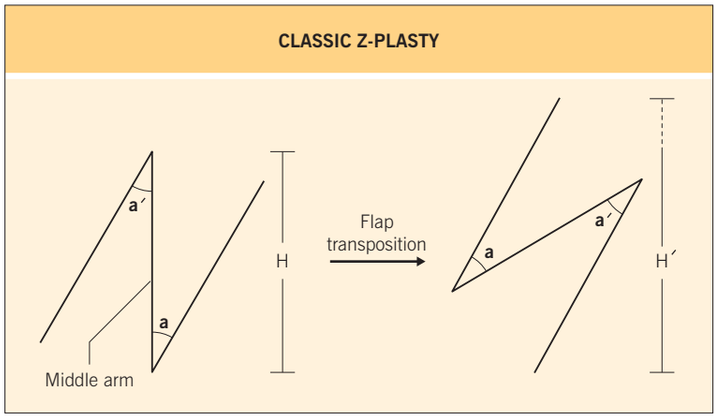

Fig. 147.6 Classic Z-plasty. The directional tissue gain (dotted line) is depicted (H to H') after flap transposition in the direction of the middle arm of the Z-plasty.

triangle (see Fig. 147.4). Ideally, the design of these flaps should, when possible, incorporate the concept of placing surgical scars at cosmetic subunit borders and within relaxed skin tension lines. Therefore, when a defect is located near an arcing junction of a cosmetic subunit or if the relaxed skin tension lines are curved, the Burow's triangle displacement flap, classically known as the rotation flap, may be an excellent option. An example of this would be the cheek rotation flap for a defect on the mid to medial upper cheek (Fig. 147.10). On the other hand, when the cosmetic subunit junctions or relaxed skin tension lines are relatively straight, the single tangent advancement flap, traditionally known as the Burow's advancement flap, may be optimal. A variation, the crescentic advancement flap, can be employed when the anatomic structures are naturally curved (Fig. 147.11).

Once the need to displace a Burow's triangle in order to avoid a vital structure is established, the incision lines should be planned in the optimal location. The incision, whether straight or arced, should be made perpendicular to the skin and should extend to the point of preferred displacement of the triangle. The triangle should then be excised to a depth commensurate with the depth of the defect being repaired and the thickness of the flap. The flap should be elevated by dissection in the subcutaneous plane and all other wound edges should be widely undermined at a similar depth. The optimal thickness of a flap will depend upon the location of the flap. Creating a flap that is too thin with dissection at the dermal–subcutaneous junction may compromise the flap's blood supply and may lead to a less natural-looking flap. Conversely, if the flap is in a site with very thick subcutaneous tissue and an excessively thick flap is created, flap mobility may be decreased, the flap edges may be more difficult to evert, and the underlying neurovascular structures or facial muscles can be unintentionally damaged. Therefore, the optimal plane of dissection of a flap is normally somewhere between the upper mid subcutaneous tissue and the deep subcutaneous tissue. Flaps involving the movement of hair-bearing skin, cartilage or other special anatomic structures may specifically dictate the thickness of the flap.

Once the flap has been raised and the surrounding skin undermined, the flap is ready to be sutured into place. If the flap is large and heavy and would result in distortion of adjacent structures (e.g. eyelids), it may be necessary to use a flap suspension suture. This is typically achieved by placing a suture in a fixed or rigid structure that underlies the flap. Periosteal placement is often the most effective way of anchoring a suspension suture. The suture is then placed into the flap's undersurface through the subcutaneous tissue, into the deep dermis. Placement within the flap should correspond topographically to its

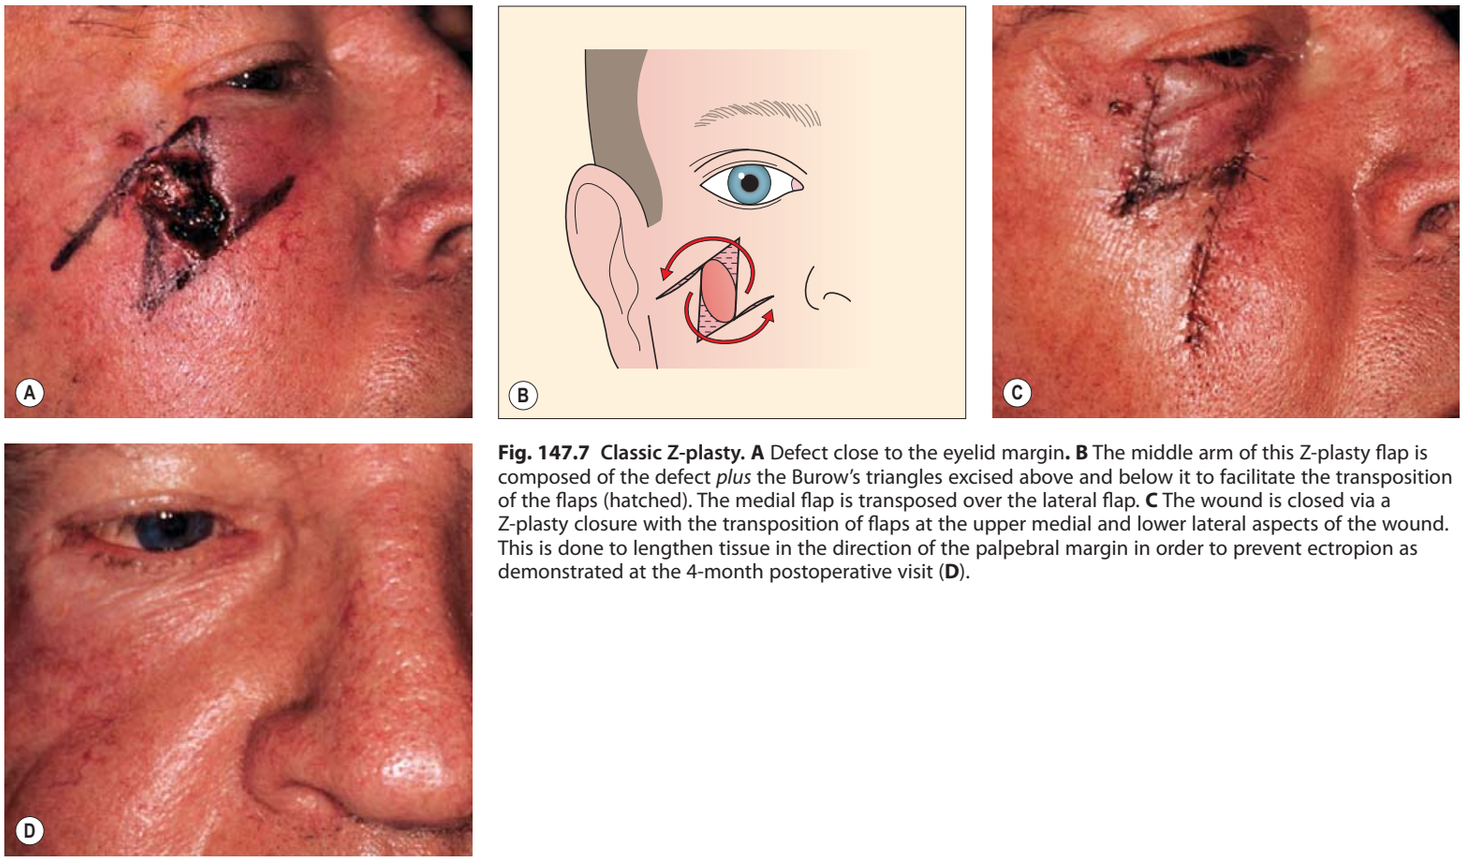

Fig. 147.7 Classic Z-plasty. A Defect close to the eyelid margin**. B** The middle arm of this Z-plasty flap is composed of the defect *plus* the Burow's triangles excised above and below it to facilitate the transposition of the flaps (hatched). The medial flap is transposed over the lateral flap. **C** The wound is closed via a Z-plasty closure with the transposition of flaps at the upper medial and lower lateral aspects of the wound. This is done to lengthen tissue in the direction of the palpebral margin in order to prevent ectropion as demonstrated at the 4-month postoperative visit (**D**).

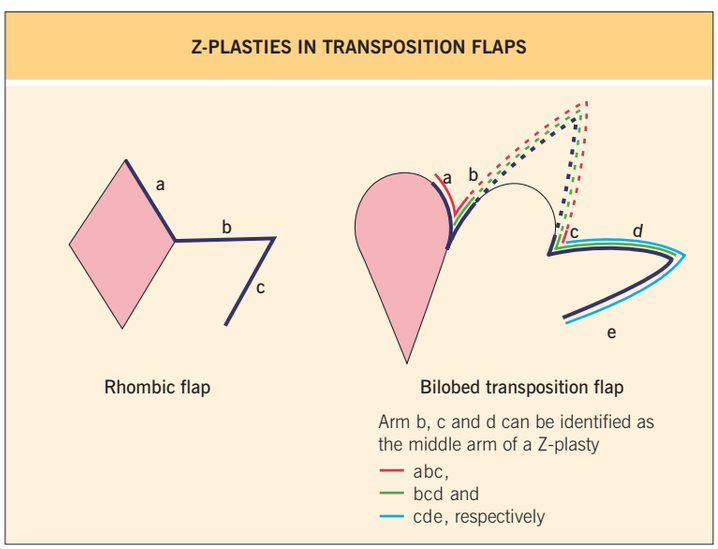

Fig. 147.8 Z-plasties in transposition flaps. Z-plasties are highlighted within the designs of both the rhombic and the bilobed transposition flap. Note in the rhombic flap the middle arm of the Z-plasty is line B and is the direction of anticipated tissue lengthening. In the bilobed transposition flap diagram, there is a series of three Z-plasties all contributing to tissue gain in the desired direction of the defect.

desired location relative to the periosteal suture. This can be repeated as necessary, with care to avoid interruption of vascular supply.

The next step of the closure is to suture the skin edges of the two Burow's triangles, evenly distributing them. The remainder of the flap can now be completely sutured into the defect with even distribution of the wound edges of the flap and opposing skin.

Double tangent advancement flaps (DTAF)

Double tangent advancement flaps displace both Burow's triangles along parallel tangents (see Fig. 147.4). Therefore, these flaps are typically peninsular in configuration with an isolated vascular base at the distal ends of the tangents. The execution of this flap is very similar to that of single tangent advancement flaps, except that one must be mindful of the more limited vascular supply (Fig. 147.12). This isolated vascular supply necessitates limiting the length of the flap to three to four times the width. The thickness of the flap should be commensurate with the thickness of the defect, with the typical plane of dissection between the upper mid subcutaneous tissue and the deep subcutaneous tissue. When suspension sutures are necessary, extreme caution is necessary in order to avoid compromise of the vascular supply to the leading edge of the flap. Again, the first closure points are at the site of the displaced Burow's triangles. Suturing the advancing flap with even distribution of the flap along the recipient tissue margins completes the execution of this flap.

Site-Specific Variations of Burow's Triangle Displacement Flaps

Helical advancement flaps

Helical advancement flaps are often discussed as a unique entity, but they are merely variants of Burow's triangle displacement flaps. As the name indicates, they are specific for the helix of the ear. The characteristics of the helix are unique owing to its highly distortable free margin that is curved in nearly every dimension and its limited pool of adjacent tissue laxity. The most typical form of the helical advancement flap is directly analogous to the double tangent advancement flap in that parallel tangents are incised from the helical defect along the anterior rim of the helix and the posterior helix. A less commonly described variant of the helical advancement flap is the single tangent advancement flap in which a single incision is made along the anterior helical rim while a non-displaced Burow's triangle is excised directly posterior to the defect on the posterior ear. Both the double tangent advancement flap and the single tangent advancement flap variant can

Fig. 147.10 Rotation flap. Large defect (**A**) on the medial cheek and lower eyelid reconstructed with a rotation flap (Mustarde flap) with displacement of the superior Burow's triangle laterally along the curvilinear tangent which follows the relaxed skin tension lines (**B**). **C** Final results with no distortion of the eyelid and incision lines nicely camouflaged along cosmetic subunit borders and relaxed skin tension lines.

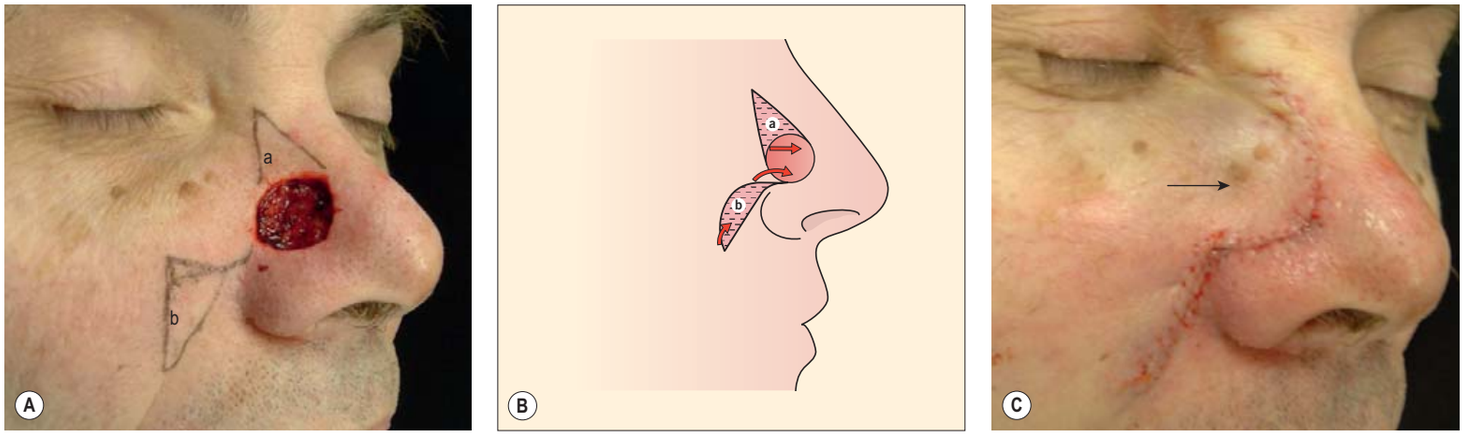

Fig. 147.11 Crescentic advancement flap. A Medium-sized defect on the right inferior nasal sidewall. A single tangent advancement flap (Burow's flap) is planned with a crescent-shaped Burow's triangle on the medial cheek. **B** The crescent (b) fits nicely with the naturally curved anatomic configuration of the alar crease and creates a "wound edges of unequal length" situation which further contributes to the advancement of skin onto the nose. **C** Flap sutured in place; note the subtle indentation (arrow) that corresponds to a periosteal suture placed at the nasofacial sulcus in order to prevent tenting and to recreate the sulcus. **D** Four-month postoperative appearance.

Fig. 147.12 Double tangent advancement flap. This technique was used to reconstruct and preserve the continuity of the eyebrow in this patient.

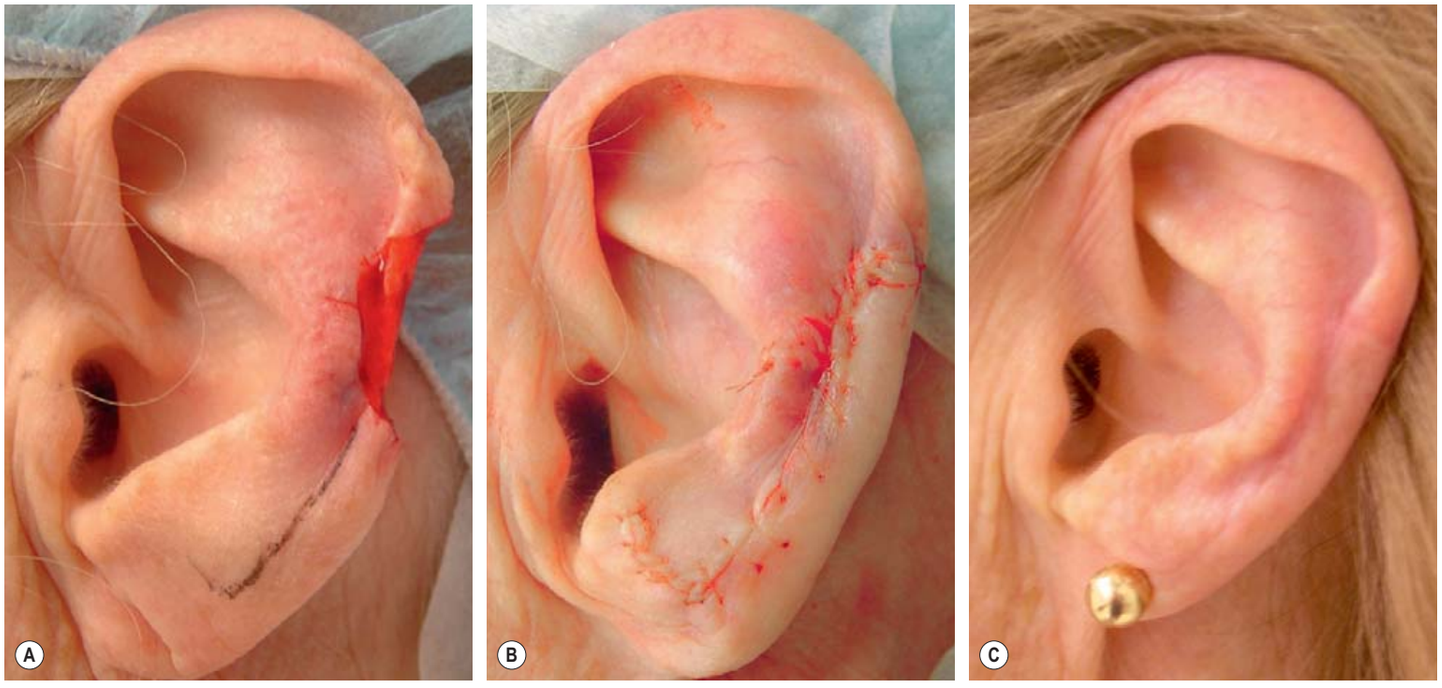

Fig. 147.13 Helical advancement flap. A Defect of the mid helix involving a small amount of cartilage. A single tangential incision is planned inferiorly within the helical groove to the earlobe. A Burow's triangle excision is planned directly behind the defect on the posterior ear. The flap will be raised by dissection of the skin from the posterior ear above the perichondrium. The displaced Burow's triangle will be removed from the earlobe and the skin of the flap will be redraped through upward advancement into the defect. **B** The flap is sutured after a very small wedge of cartilage has been removed to reconstitute the helical rim of cartilage. **C** Three-month postoperative appearance.

be either a single flap (derived superior or inferior to the defect) or two flaps (derived both above and below the defect). As with all Burow's triangle displacement flaps, the helical advancement flap is a technique devised to displace the Burow's triangle to a more convenient location distant from the defect. The majority of the defects on the helix derive donor pool skin from the inferior direction. The donor pool from the superior helix is typically less abundant but is very beneficial in large mid-helical defects (when two flaps are used) and in defects of the superior helix.

A common use of the helical advancement flap is for a small- to medium-sized defect on the mid helix not involving the cartilage (Fig. 147.13). While a wedge closure of the ear could be considered, displacing the anterior triangle by utilizing the lax skin of the lower helix and earlobe obviates the need to do a wedge resection of the auricular cartilage. Burow's triangles can easily be displaced to the earlobe, which facilitates the advancement of the helical skin into the defect. Despite the resultant decrease in the size of the earlobe, the aesthetic impact tends to be minimal as long as the anterior profile of the ear is maintained. Since the earlobe is most visible on the lateral view and because the opposite earlobe is not simultaneously visible, subtle changes in size often go unnoticed.

With a more superiorly located defect, the donor pool is at the anterior aspect of the helical rim. Although the extent of tissue movement from the anterior helix is often less than can be expected on the inferior helix, this varies greatly and must be determined for each case.

In the "classic" helical advancement flap, which is a double tangent flap or "U-flap", the parallel lines are well hidden in the helical groove or on the helical rim and posteriorly on the ear. A possible disadvantage is the very narrow flap base through which all blood flow must pass. However, the helical rim has a rich vascular supply and is more forgiving even when tension on the wound edges is considerable. Nevertheless, there is a risk of distal necrosis of a "classic" helical advancement flap that is under tension.

The lesser known variant (see above), which is analogous to a Burow's flap, does not have the same narrow base. Rather than a parallel incision being made on the posterior surface of the ear, a Burow's triangle is excised directly posterior to the defect. The same anterior incision is made along the helical rim (see Fig. 147.13), but the base of the flap now becomes the entire posterior ear. The flap can be dissected from the cartilage on the posterior ear and redraped with advancement over the defect. Equally excellent cosmetic results can be obtained with this variant, with very little downside.

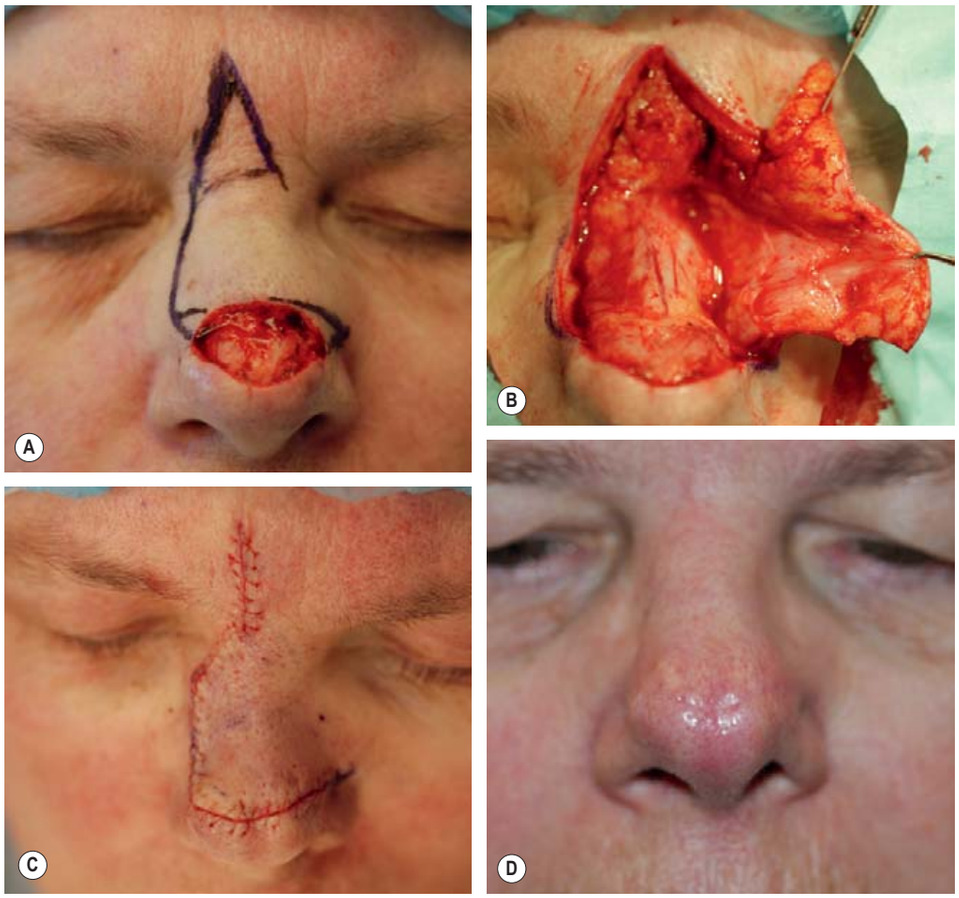

Fig. 147.14 Dorsal nasal flap. A Moderate-sized defect of the nasal tip. **B** The flap is incised and reflected demonstrating the deep plane of dissection just above the nasal periosteum. The flap will be redraped over the tip of the nose with primary closure of the displaced Burow's triangle on the glabella. **C** Flap sutured into place. **D** Result four months postoperatively.

Dorsal nasal flap

The dorsal nasal flap is a specialized, site-specific variant of the Burow's triangle displacement flap that is useful for reconstructing moderately sized distal nasal defects. The basic design of this flap is predicated upon the fact that it is often inconvenient or unfeasible to remove a Burow's triangle on the nasal tip. Therefore, the design of this flap displaces a Burow's triangle from the nasal tip to the glabella along an incisional arc that extends from the more inferior aspect of the defect (above the alar crease) to along the nasofacial sulcus and finally onto the glabella (Fig. 147.14). However, this flap involves a large area of skin in order to accomplish the closure of a relatively small defect.

The dorsal nasal flap relies on the rich blood supply of the medial canthal plexus that is largely supplied by the angular artery. Classically, in a dorsal nasal flap, there is a back cut in the glabellar skin; this skin is then trimmed after rotation of the flap and is equivalent to the removal of the displaced Burow's triangle. The back-cut technique narrows the base of the rotation flap, thereby reducing the overall pivotal restraint on the flap. Because of its excellent vascular supply, the dorsal nasal flap is ideally suited for this technique. The reduction in the pivotal restraint decreases the secondary tension on the nasal tip defect, which helps to avoid distortion of its free margins.

The most important aspect in the execution of the dorsal nasal flap is creation of a broad-enough arc by extending to the nasofacial sulcus, but skirting the medial canthal skin en route to the glabella. The second key element is the plane of dissection when elevating the flap. While the portions of the flap that will be covering the nasal defect can be trimmed and thinned to match the native skin and defect, the body of the flap must be dissected at the level of the perichondrium and periosteum. This assures incorporation of the perforator arteries from the canthal plexus and subsequent survival of the flap. When these principles are observed, this flap is robust and can reconstruct moderately large-sized nasal tip defects without distortion and with an excellent tissue match.

While the surgeon must be aware of important variables that can substantially affect the successful use of any flap, this is especially true in the case of the dorsal nasal flap. The ideal situation is a patient with very non-sebaceous and elastic or "loose" skin of the nasal dorsum. Characteristics that raise concern about whether this flap can be successfully executed include thick, inflexible and highly sebaceous skin. Also, prior surgeries on the nose or the medial canthus should be viewed as a potential source of compromised vascular supply. Distortion of the distal nose structures may occur if there is severe structural compromise of the free margin or the cartilage of the nasal tip and consideration should be given to other reconstructive options (e.g. a tissue importation flap). The dorsal nasal flap should be reserved for defects that are too large to be reconstructed with a small local flap such as the bilobed flap yet smaller than a defect for which a tissue importation flap would be more ideally suited. The most difficult aspect of successfully executing a dorsal nasal flap is anticipating and dealing with the secondary motion inherent in this flap.

Wedge closure of the lip

Wedge closure of the lip is a special form of the simple elliptical closure that deserves mention here. It is used in small- to moderate-sized defects of the lip that involve the vermilion or the vermilion border. It is traditionally taught as a full-thickness excision of skin, mucosa, submucosa and musculature. However, when tissue-conserving excisions (e.g. Mohs micrographic surgery) are employed and much of the orbicularis oris muscle is preserved, a subtotal wedge excision of the muscle is preferred due to its simplicity, the decreased chance of lip dysfunction and the smaller chance of complications.

For an excellent cosmetic result, careful realignment of the vermilion border is essential. Prior to excision of the tumor, hash marks are made with a scalpel along the vermilion border as reference points. This is done because after injection of anesthesia and excision, the precise location of the vermilion border can often become indistinct. The hash marks ensure precise realignment of the vermilion border (Fig. 147.15).

In assessing how much muscle needs to be removed in a subtotal wedge excision, the surgeon surveys the amount of redundant soft tissue that forms when the wound edges are approximated. Usually,

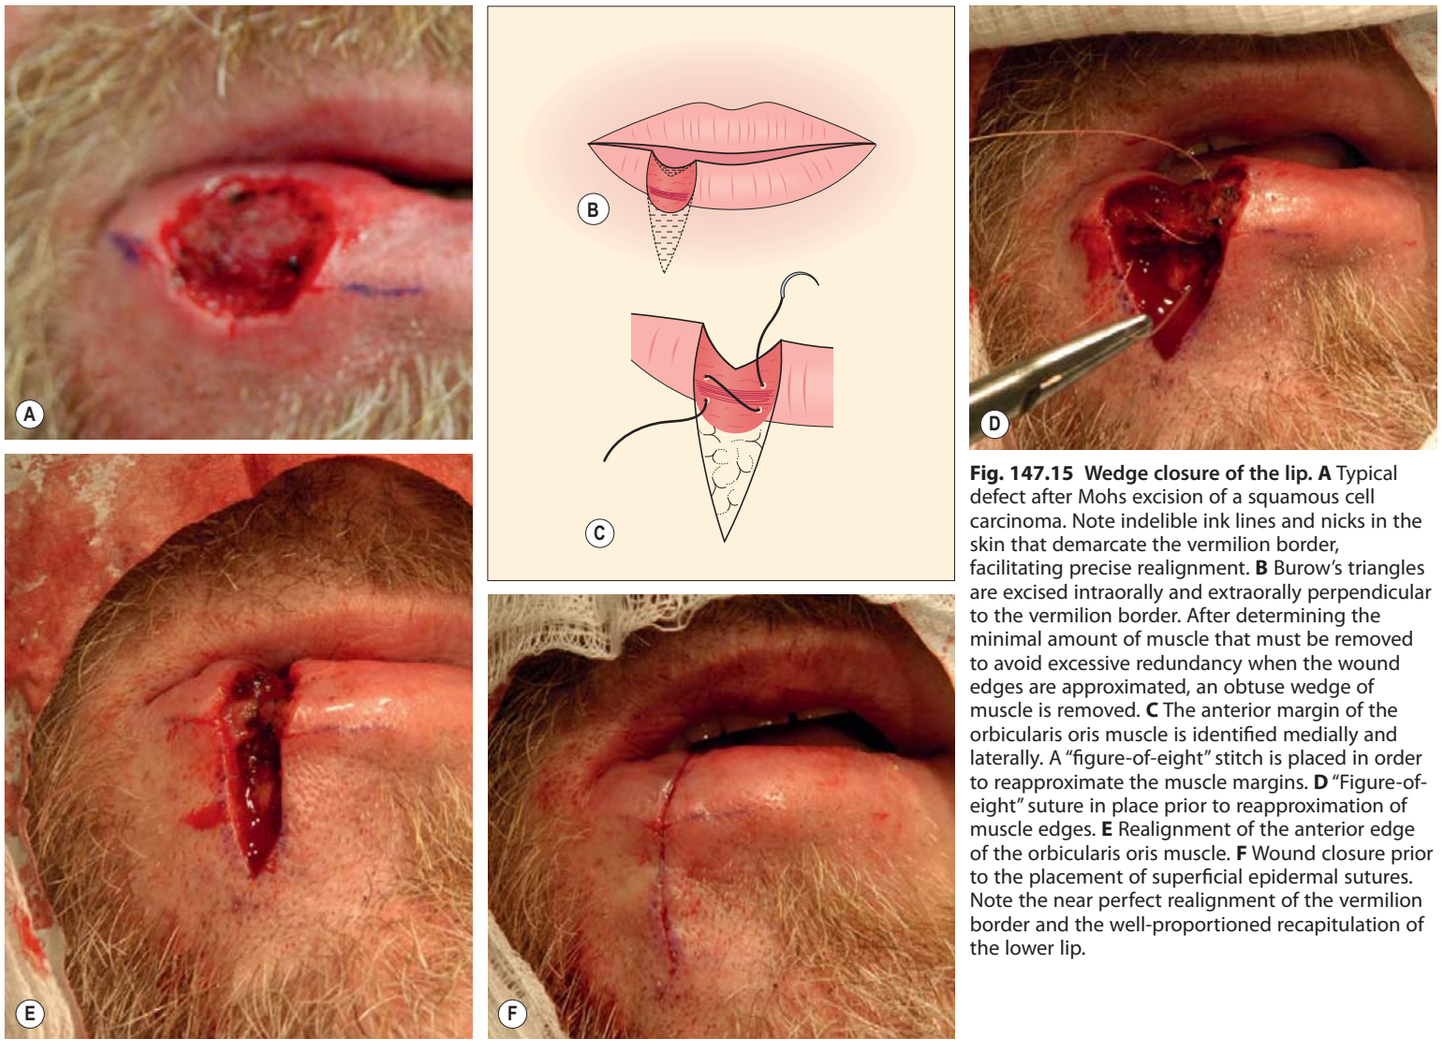

Fig. 147.15 Wedge closure of the lip. A Typical defect after Mohs excision of a squamous cell carcinoma. Note indelible ink lines and nicks in the skin that demarcate the vermilion border, facilitating precise realignment. **B** Burow's triangles are excised intraorally and extraorally perpendicular to the vermilion border. After determining the minimal amount of muscle that must be removed to avoid excessive redundancy when the wound edges are approximated, an obtuse wedge of muscle is removed. **C** The anterior margin of the orbicularis oris muscle is identified medially and laterally. A "figure-of-eight" stitch is placed in order to reapproximate the muscle margins. **D** "Figure-of-eight" suture in place prior to reapproximation of muscle edges. **E** Realignment of the anterior edge of the orbicularis oris muscle. **F** Wound closure prior to the placement of superficial epidermal sutures. Note the near perfect realignment of the vermilion border and the well-proportioned recapitulation of the lower lip.

the apex of the wedge (after removal of redundant muscle) is obtuse, creating a very slight trough in the lip in an anterior-to-posterior direction. In our experience, the less muscle that is removed, the less likely a noticeable notch or dip in the vermilion lip will form and the function of the lip is beautifully maintained. After excision of Burow's triangles on the external lip and the internal lip (see Fig. 147.15B), and after undermining the cutaneous portion of the defect, the key suture is the one that reapproximates the medial and lateral muscle edges. This is best done by the placement of a "figure-of-eight" suture, which is similar to a horizontal mattress suture and snares the bellies of the anterior edge of the orbicularis oris muscle and precisely approximates them (see Fig. 147.15C–E). Upon healing, the ridge created by this approximation becomes a functional and aesthetic component of the lip and recreates the appropriate muscular bulge at the vermilion border.

Adjustment of the wound edges to perfectly realign the previously placed hash marks with epidermal sutures will ensure a perfectly realigned vermilion border.

Defect Reconfiguration (Island Pedicle) Flaps

The island pedicle flap is a unique advancement flap in that the creation of an island of epidermis and dermis eliminates any blood supply from the rich vascular plexus within the deep dermis and superficial subcutaneous skin. In effect, the vascular supply is isolated to the subcutaneous tissue. The two variations in pedicle design hinge upon whether the pedicle is created immediately beneath the island or from the subcutaneous tissue lateral to the island (Fig. 147.16). The variant with the vascular pedicle immediately beneath the island of skin is created by dissecting away surrounding superficial subcutaneous tissue and eliminating the tethering effects of the tissue adjacent to the pedicle. The island pedicle flap with laterally based pedicles is created by tunneling immediately beneath the island while carefully maintaining vascularized sheets of subcutaneous tissue, either bilaterally or unilaterally to the side of the island (Fig. 147.17). The authors' preference has been to develop a pedicle immediately under the island because of the more durable and reliable vascular supply. However, there are clearly some anatomic sites where the lateral pedicles provide adequate blood supply and better flap mobility.

In general, it is appropriate to think of the island pedicle flap as an advancement of what would be one of the Burow's triangles in a simple side-to-side closure. It must be located in areas with very elastic and spongy subcutaneous tissue with a rich blood supply. The island pedicle flap is an extremely tissue-efficient flap in which little or no tissue is discarded and yet it often provides outstanding clinical results. The mechanism for tissue conservation involves a reconfiguration of the defect into an angular shape via the use of what would be a Burow's triangle (Fig. 147.18). The original shape of the defect is reconfigured behind the advancing island to a defect of equal area but very angular in shape that can be closed without tissue redundancy, obviating removal of a Burow's triangle.

It is useful from the standpoint of flap execution to recognize conceptually that an island pedicle flap (especially those with the pedicle based immediately beneath the island) is essentially a rotation flap turned perpendicular to the surface of the skin (Fig. 147.19). Whereas, in a rotation flap, the vascular source lies parallel with the skin, the analogous vascular supply of the island pedicle flap runs perpendicular to the skin. While the plane of tissue movement in the traditional rotation flap is parallel with the skin, it is perpendicular to the skin in an island pedicle flap. Once this analogy between a rotation flap and

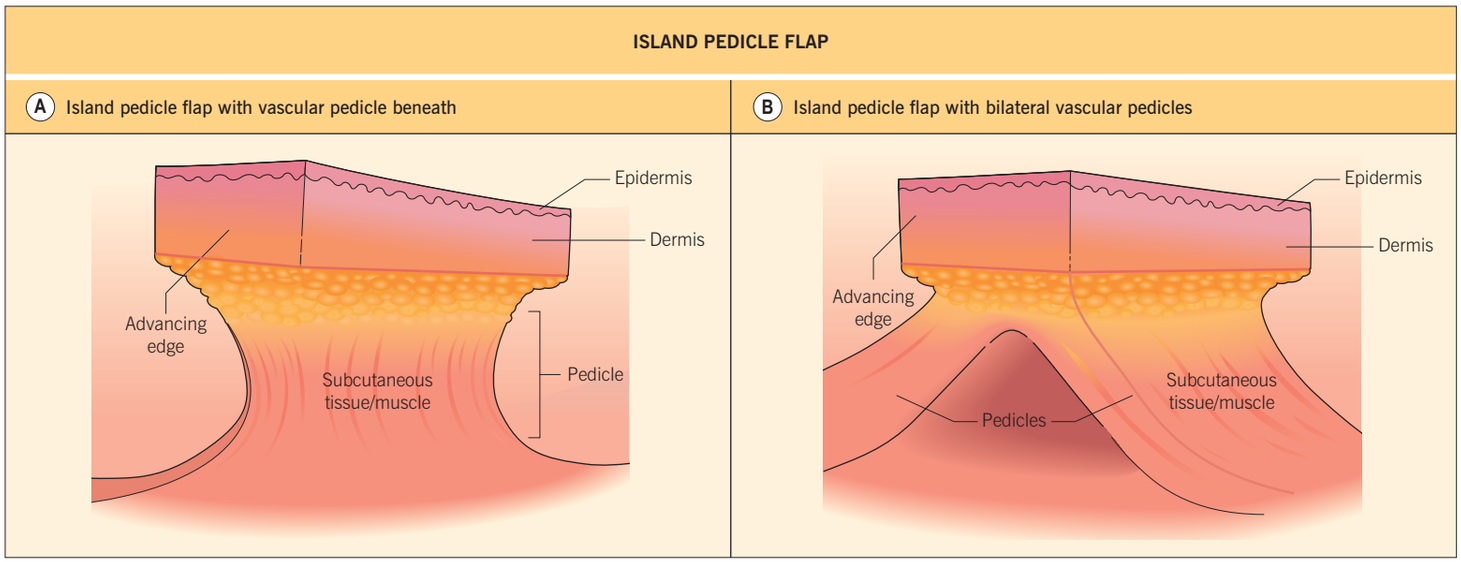

Fig. 147.16 Island pedicle flap. A Vascular pedicle derived immediately beneath the island of skin. **B** Vascular pedicles derived from tissue lateral to the island flap.

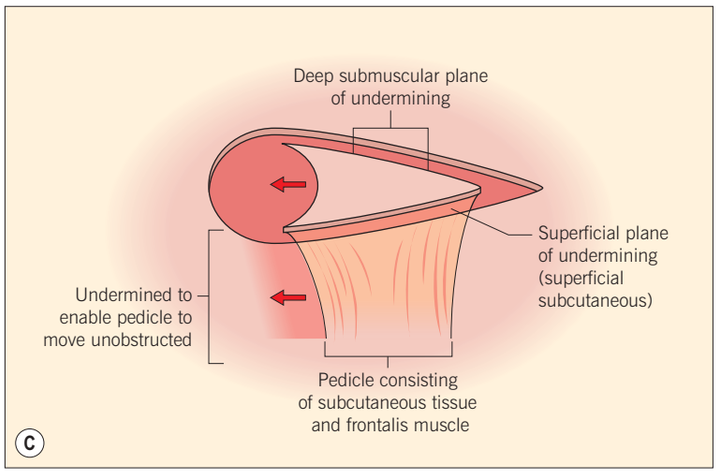

Fig. 147.17 Island pedicle flap. A Large mid-upper forehead defect. **B** Intraoperatively, an island pedicle flap is designed with a single inferior muscular pedicle based on the rich blood supply of the supratrochlear and supraorbital arteries. **C** The frontalis muscle serves as the inferiorly based pedicle for the flap. This muscular pedicle is constructed via undermining in the subcutis beginning at the lower edge of the flap (superficial plane) and undermining in the submuscular plane which is begun at the superior edge of the flap (deep plane). The skin medial to the pedicle must also be undermined to facilitate its advancement in the direction of the defect. **D** The defect is now comprised of acute angles which are more easily closed primarily.

an island pedicle flap is understood, it is easy to see that movement of the island pedicle flap is facilitated by the same factors that facilitate movement of a rotation flap. For example, excision of the Burow's triangle facilitates the rotation and advancement of the rotation flap. Likewise, the advancement of an island pedicle flap is facilitated by the removal of the tissue analogous to the Burow's triangle, i.e. any subcutaneous tissue at the base of the defect (see Fig. 147.19B). Without its removal, the subcutaneous tissue left in the base of the wound serves as a physical impedance to the advancing island pedicle flap.

Another technique for enhancing rotation flap mobility, the back cut, is also applicable to the island pedicle flap. A back cut for a rotation flap releases some of the restraining tension of the flap and is helpful in its mobilization. The equivalent of a back cut can also improve the mobility of an island pedicle flap. This is done by incising the subcutaneous pedicle at the trailing edge of the flap in a direction beveled slightly into the pedicle (see Fig 147.19B).

In order to enable eversion of the skin edges of the island pedicle flap, the island is very slightly undermined at the dermal–subcutaneous junction to facilitate its eversion. Extreme care must be taken to avoid compromise of the vascular supply. The skin surrounding the island pedicle flap is widely undermined in the superficial subcutaneous tissue. Once adequate mobility of the flap is obtained, it is advanced into the defect, with closure of the donor site behind the flap and closure of all skin edges.

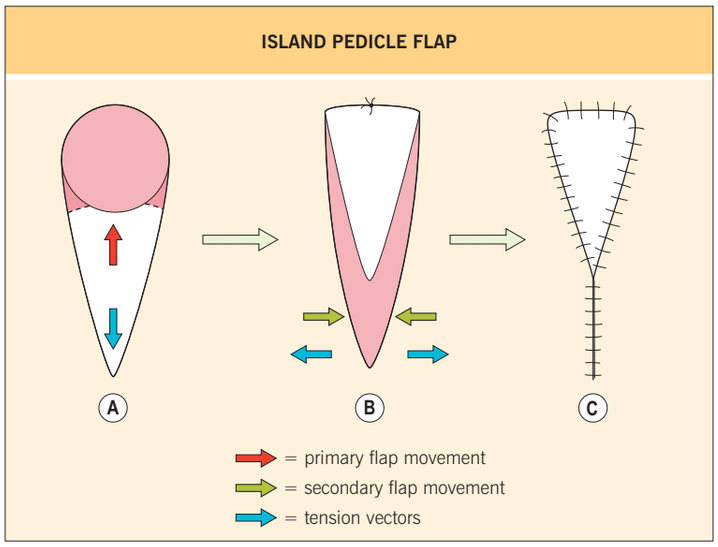

Fig. 147.18 Island pedicle flap. Reconfiguration of the defect (shaded area) in **A** to the defect in **B.** The shaded secondary defect in **B** is comprised entirely of acute angles which are easily closed primarily (**C**).

Subcutaneous tunneling island pedicle flap

The subcutaneous tunneling island pedicle flap is not a traditional island pedicle flap and technically is not a defect reconfiguration flap. Rather, it is a type of tissue importation flap. However, this flap is based upon a pedicle that, like the traditional island pedicle flap but unlike other tissue importation flaps, is composed entirely of subcutaneous and muscular tissues. The flap skin and its pedicle are then passed through a tunnel beneath intervening skin to the defect (Fig. 147.20). As a result, it is a higher-risk flap than most island pedicle flaps and tissue importation flaps. Finding suitably vascular locations for these flaps is the initial key step.

First, the donor skin is identified in an area with a suitably vascular pedicle (see Fig. 147.20A). Careful measurements of both the defect and the length of the subcutaneous pedicle are necessary so that the latter reaches the defect under minimal tension. Next, the island is incised and a pedicle deep to the island is developed (see Fig. 147.20B). It is helpful to elevate the skin overlying the prospective pedicle in order to visualize its construction. Once an adequate pedicle is developed, the skin between the base of the pedicle and the defect is undermined, creating a tunnel. The tunnel must be large enough for the tissue to pass and not be compressed; cautious defatting of the tunnel walls is often helpful to ensure ample room. This defatting also decreases the degree of fullness of the intervening skin created by the bulk of the pedicle. We recommend limiting the length of the pedicle to three to four times its diameter unless it is an axial flap based directly on and incorporating a known axial vessel.

The best locations for these types of flaps are the melolabial and paranasal areas as well as the glabellar region. Of note, it prudent to anticipate a 10–20% "shortening" of the pedicle as it is rotated and stretched through the tunnel into the defect. Careful preoperative planning improves the success of this flap.

Tissue Reorientation Flaps

Transposition flaps as a whole are some of the most useful flaps because of their ability to tap into adjacent tissue reservoirs in order to repair defects in anatomic locations with minimal inherent laxity. These flaps allow for repair of even large defects with minimal or no skin tension and without distortion of important surrounding anatomic structures. The classic transposition flap is the rhombic flap, with other useful transposition flap variants being the bilobed flap and the single-staged nasolabial transposition flap.

Rhombic transposition flap

The classic rhombic flap, originally described by Limberg in 1963, was based on the concept of placing the tension vector of the secondary defect nearly perpendicular to that of the primary defect (Fig. 147.21A). After closure of the donor site, the Limberg flap allowed for repair of the primary defect with essentially no wound edge tension. Dufourmentel added important modifications that made the closure of the donor site easier by placing the secondary defect at an acute angle (60°) to the primary defect. Thus, the flap must pass through a shorter arc in order to be positioned within the primary defect (Fig. 147.21B). Webster modified the rhombic flap further by making the angle of the secondary defect even more acute (30°) to further facilitate closure of the secondary defect (Fig. 147.21C). The smaller flap size of the Webster variant allows the surgeon to position the flap in almost any position relative to the primary defect in order to tap into the most lax skin available. However, as the angle of the secondary defect becomes more acute, more of the wound tension is transferred from the donor site to the primary defect. Care must be taken to ensure that the tension on the flap does not compromise vascular supply and flap viability. Another important concept to bear in mind is that as more tension is transferred to the primary defect, important nearby anatomic structures will be more prone to distortion.

Careful planning is required prior to incising the rhombic transposition flap in order to ensure that the donor site comes from the area

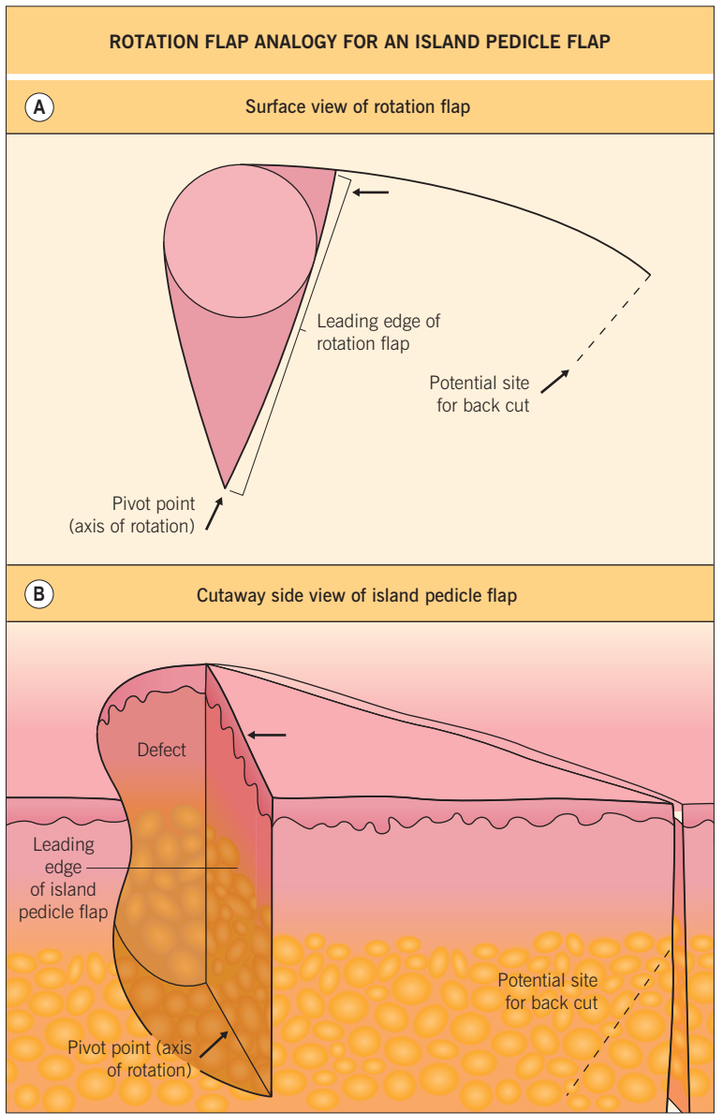

Fig. 147.19 Rotation flap analogy for an island pedicle flap. A A rotation flap with standard removal of a Burow's triangle adjacent to the defect and the site of a potential back cut which would facilitate flap movement. **B** Side view of a defect and an island pedicle flap. The plane of rotation is perpendicular to the skin surface. The shaded area is where the equivalent of a Burow's triangle has been removed to facilitate flap movement. The dotted line is analogous to the back cut of a rotation flap. Note the similarities between a rotation flap and an island pedicle flap.

adjacent to the defect with the most abundant tissue laxity. This donor site, most commonly, parallels the relaxed skin tension lines. We prefer to remove the Burow's triangle at the pivot point prior to insetting of the flap. This ensures more accurate incision lines and allows more precise suture placement in order to distribute the flap tension evenly. The flap and the skin surrounding the defect and the donor site are undermined to ensure all are of the same thickness. Following careful hemostasis, the secondary defect is closed in a layered fashion. Next, the flap is inset into the defect, trimmed to fit and sutured in place.

Although extremely versatile, there are specific areas where the rhombic transposition flap provides reliable and reproducible results. The lateral, upper two-thirds of the nose and the lateral forehead are ideally suited for the rhombic flap because of the frequent difficulty in closing defects in these areas primarily (Fig. 147.22). The adjacent tissue laxity available on the nasal sidewall and the lateral cheek provide ample reservoirs of donor tissue. Large defects of the central cheek may occasionally be closed by the rhombic flap when simpler options are not possible because of the size of the defect. In other anatomic sites on the face, the rhombic flap may be a second or third option for repair, but other options are usually chosen first because of the difficulty in concealing the geometric shape of the incision lines of the rhombic flap.

Bilobed transposition flap

The bilobed flap is essentially two transposition flaps in series, and it is one of the most useful flaps for repair of defects of the lower one-third of the nose. The bilobed flap was first described by Esser in 1918 and important modifications to the flap were described by Zitelli in 1989. Zitelli modified the classic flap to decrease the pivot angle of the flap from 180° to close to 90–100° (Fig. 147.23). This simple modification helps to minimize two of the most common problems associated with the bilobed flap – the problem of pincushioning of the primary lobe and the tendency for standing cones to form at the pivot point of the flap.

Careful planning is required for the bilobed flap in order to ensure minimal distortion of surrounding structures. Figure 147.23B depicts

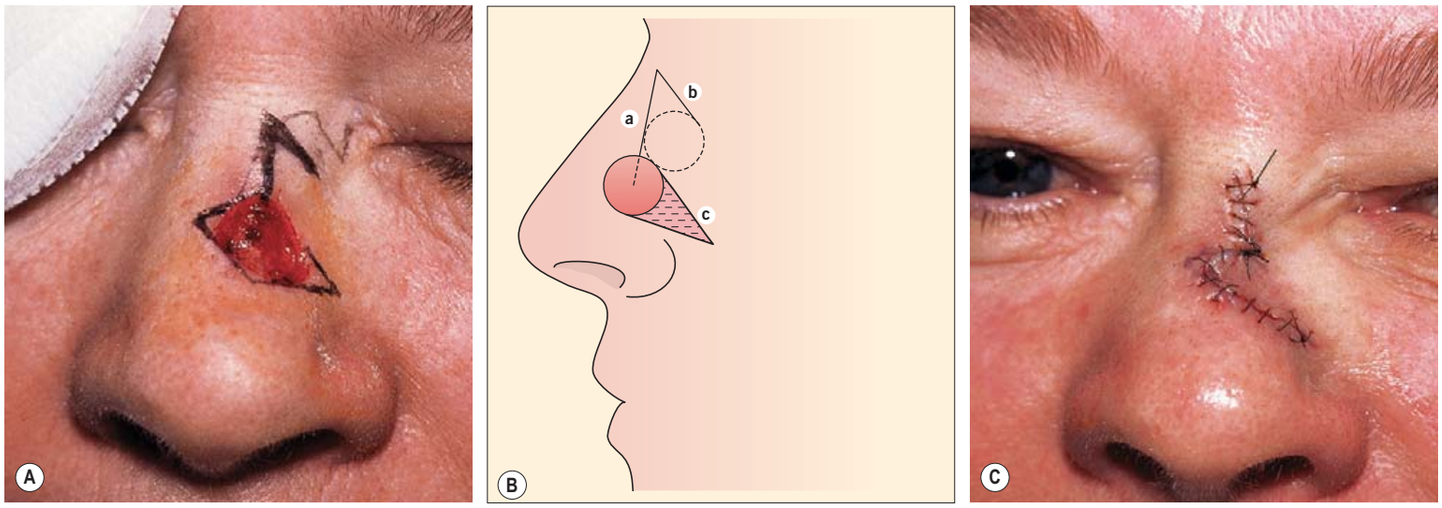

Fig. 147.22 Rhombic transposition flap on the upper lateral nose. A,B Key to the correct design of this flap is identification of the center point of the defect. The first incision for the flap is made in a line (**a**) along a vector radiating from the central point into the donor skin. The second incision (**b**) is made at an angle between 45° and 60° to this radiating incision, keeping in mind that the width of the flap must equal the width of the defect. Next, a 30° Burow's triangle is excised such that the flap side of the incision (**c**) is parallel to the lateral edge of the rhombic flap (**b**). **C** The tip of the flap is trimmed to fit the defect and the wound edges are sutured.

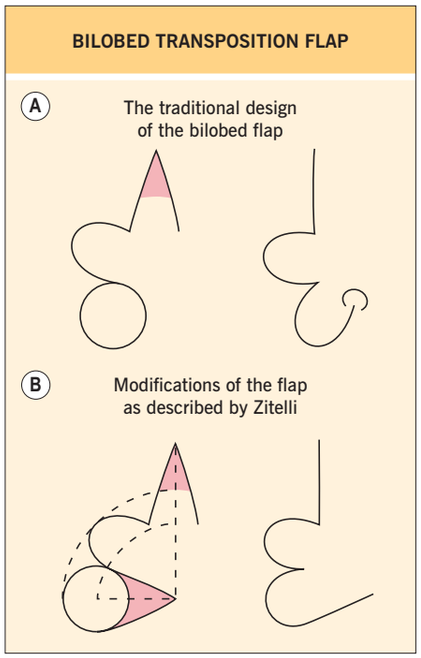

Fig. 147.23 Bilobed transposition flap. A The traditional design of the bilobed flap results in tissue protrusion at the pivot point. **B** Modifications of the bilobed flap as described by Zitelli.

a reliable method for planning the incisions of the bilobed flap. Drawing with a sterile marker on the patient (prior to incising the flap) ensures that the incision lines are placed in such a way as to maximize both functional and aesthetic results. For nasal defects, the flap should be designed so that the tertiary defect is closed in a fashion that is perpendicular to the line of the alar rim. This ensures that the contralateral ala is not lifted during closure of the tertiary defect. We remove the Burow's triangle when incising the bilobed flap, in order to provide the most accurate placement. Wide undermining of both the donor and recipient sites in a submuscular plane allows for good tissue mobility while providing excellent blood supply. On the side of the flap where the pivot point is located, we carry the plane of undermining to the nasofacial groove in order to facilitate proper placement of the flap, with no distortion of surrounding anatomic structures. Careful hemostasis is followed by closure of the tertiary site, followed by careful insetting and suturing of the flap into the primary defect. The secondary flap is then trimmed to match the circular secondary defect and sutured in place (Fig. 147.24).

Defects of the lower one-third of the nose measuring between 0.5 and 1.5 cm are the ideal size for the use of the bilobed flap. Smaller defects can often be closed in a primary fashion and larger defects may need either a skin graft or a two-staged tissue importation flap. Although the bilobed flap is the most common flap chosen for the distal third of the nose, it is rarely used in other anatomic sites because simpler options are usually available for those locations.

Nasolabial transposition flap

The single-staged nasolabial (melolabial) flap is a variation of a transposition flap that can be used to reconstruct defects of the nasal sidewall or large alar defects. Traditional designs of the nasolabial flap resulted in significant blunting of the nasofacial groove and frequent flap pincushioning, often requiring one or more postoperative revisions. This is perhaps why this flap has been underutilized in reconstruction of the nose. In 1990, Zitelli described several modifications of the traditional design that helped to minimize the need for surgical revisions. These modifications are outlined below.

The flap should be designed to include the preplanned excision of the Burow's triangle along the lateral nasal sidewall (Fig. 147.25). The donor site should parallel the nasolabial fold and, once incised and elevated, should be widely undermined in a subcutaneous plane across the cheek. The recipient site should be undermined in a submuscular plane on the nose and then the surgeon should transition to the more superficial subcutaneous plane at the nasofacial sulcus. After careful hemostasis has been obtained, a periosteal suture is placed in the undersurface of the flap corresponding to the new location of the nasofacial groove. This is secured to the periosteum of the nasal sidewall and, once tied, recreates this important cosmetic structure while at the same time essentially eliminates any tension on the flap. The periosteal sutures also minimize secondary flap movement that might pull the ala laterally postoperatively. The flap should then be thinned of subcutaneous fat and sutured in place. We frequently utilize tacking sutures on the undersurface of the flap in an attempt to recreate the alar crease and to prevent collapse of the internal nasal valve. The tip of the flap is finally trimmed to match the distal aspect of the defect and sutured in place with minimal tension in order to limit flap ischemia.

Tissue Importation Flaps

Tissue importation flaps are a loosely associated group of flaps that employ the concept of transferring tissue from a distant reservoir into a defect when other adjacent repair options are unsatisfactory. The flap itself is supported by either: (1) a single vessel as in the paramedian forehead flap (an axial flap); or (2) a rich collection of subcutaneous perforating vessels that enter the flap pedicle through underlying muscle

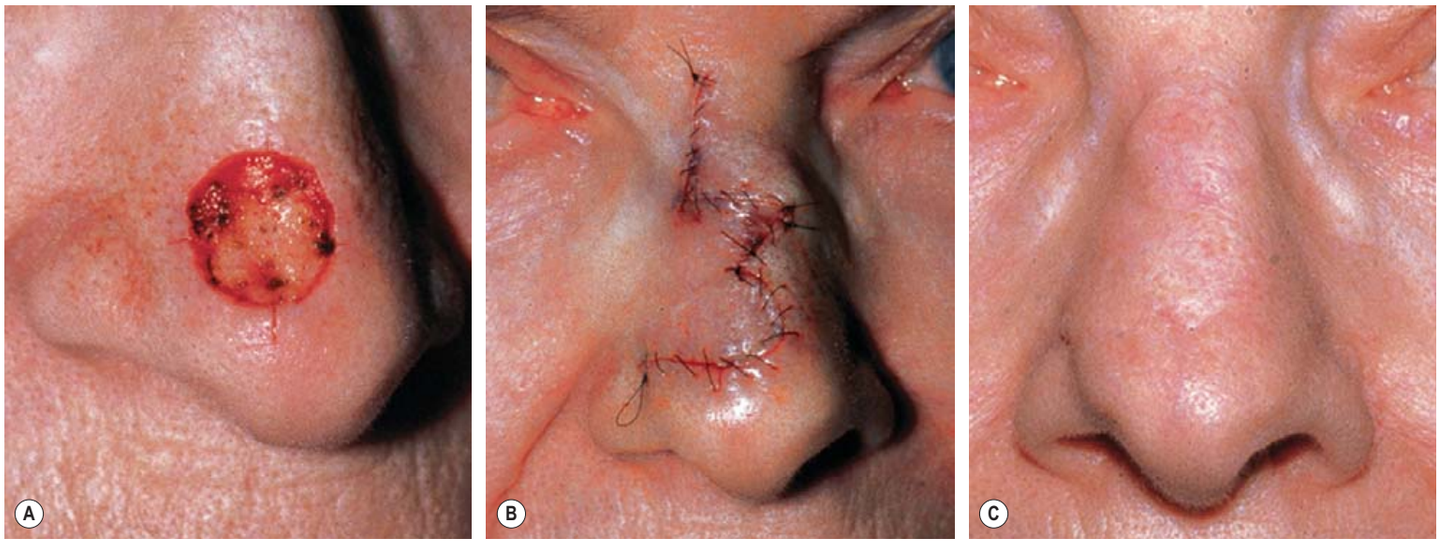

Fig. 147.24 Bilobed flap. A Distal nose defect. **B** Defect reconstructed with a modified bilobed transposition flap. **C** Cosmetic result at 1 year postoperatively.

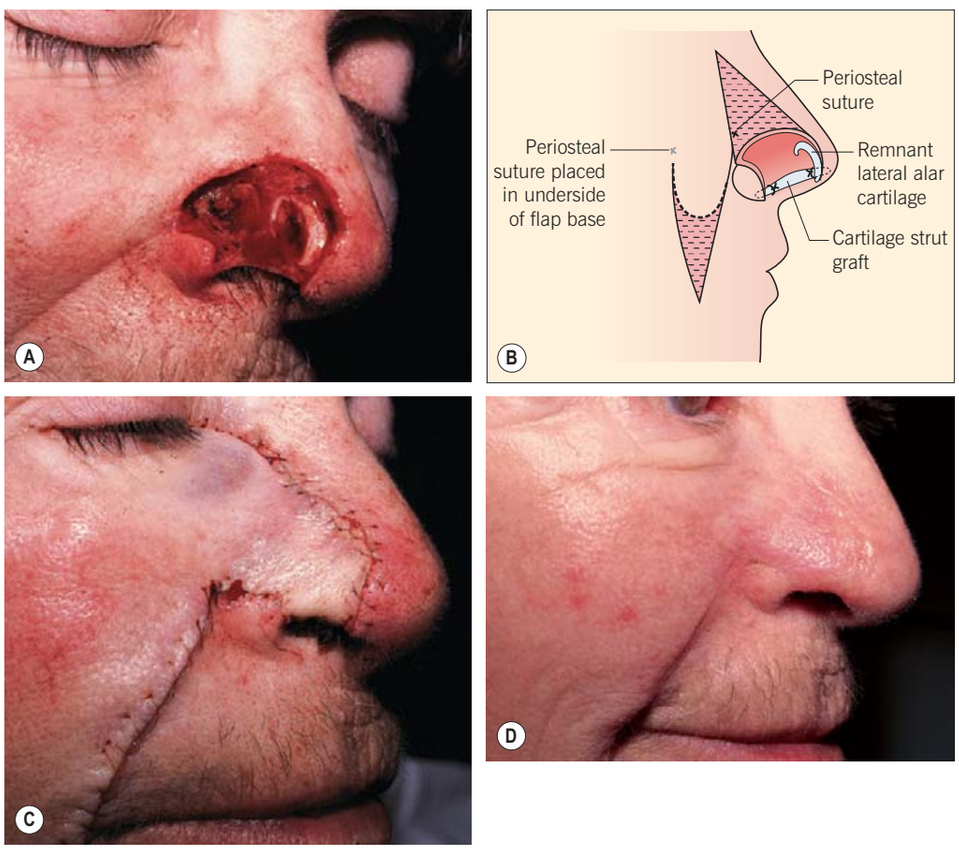

Fig. 147.25 Nasolabial transposition flap. A Large nasal defect involving loss of cartilage and extending to the intranasal skin. **B** Excision of a Burow's triangle on the nasal sidewall is oriented towards the medial canthal tendon. The lateral incision of the flap should extend no higher than the apex of alar skin over which the flap is to be transposed. In this case, an auricular cartilage strut graft is placed along the alar rim and inserted into medial and lateral dermal pockets and anchored with deep sutures into the wound base. The points of placement of the periosteal sutures into the undersurface of the advancing flap are indicated with an X. The distal flap is aggressively defatted. **C** The flap is trimmed to fit the defect, wrapped around the alar rim and folded onto itself, reforming the rim. **D** Cosmetic result at 6 months postoperatively.

(random pattern flap). Tissue importation flaps are ordinarily two-stage procedures. The first stage includes the initial planning and implementation of the flap. The vascular pedicle is left in place after the first stage in order to ensure adequate blood supply. The second stage involves the separation of the pedicle and the insetting of the proximal flap. Tissue importation flaps are most useful for reconstruction of large defects and are especially valuable when cartilage grafting is required to rebuild normal anatomic substructure and preserve proper function. The most common tissue importation flaps used in dermatologic surgery include the paramedian forehead flap, the nasolabial interpolation flap, the retroauricular flap, and the turnover nasolabial or Spear's flap.

Paramedian forehead flap

The paramedian forehead flap, an axial flap based on the supratrochlear artery, is the most useful flap for reconstruction of subtotal and total nasal defects. The excellent vascular supply supports both the flap as well as any cartilage grafts that are used to rebuild the cartilage framework of the nose. The paramedian forehead flap also provides the best color and texture match of any of the tissue importation flaps used to reconstruct large defects of the nose and far exceeds the cosmetic results of a skin graft (Fig. 147.26).

An important concept in flap design includes the enlargement of the nasal defect to encompass the entire cosmetic unit when possible. This makes the junction of the flap and the remaining nasal skin less

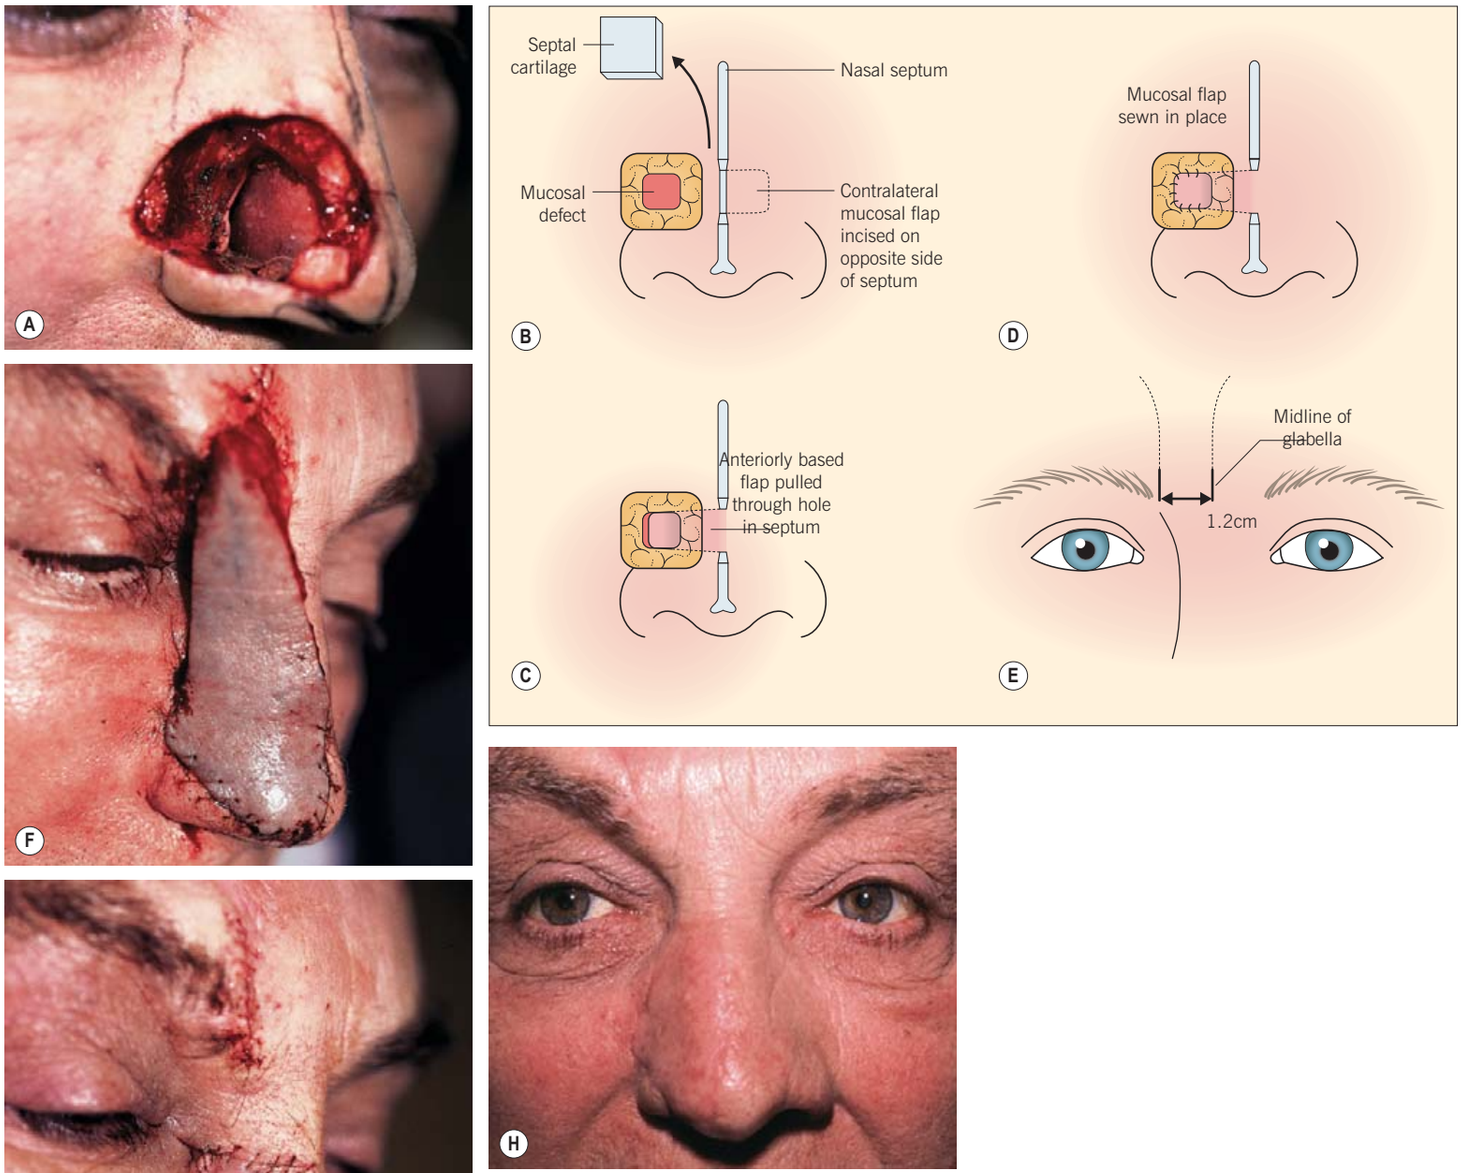

Fig. 147.26 Paramedian forehead flap. A Large full-thickness defect of the right half of the distal nose. **B** The mucosal defect is reconstructed with a contralateral septal mucosal pull-through flap. A U-shaped incision is made in the contralateral septal mucosa, based anteriorly and correctly sized to cover the defect. In addition, a 15 mm^2 cartilage graft is harvested from the nasal septum and used to reconstitute the structural integrity of the nasal sidewall. (Note that the remainder of the nasal sidewall cosmetic subunit and the right nasal tip subunit will be excised prior to reconstruction with the forehead flap.) **C** The mucosal flap is delivered through the septal defect into the right nasal vestibule. **D** The mucosal flap is sutured into place. **E** The design of the pedicle uses the midline of the glabella as the medial incision point; the lateral incision is made 1.2 cm lateral to the midline. Using a template, the forehead flap is then incised and raised on this 1.2 cm-wide pedicle. **F** Immediately postoperatively. **G** Immediately after takedown of flap 3 weeks later. **H** Early cosmetic results with no revision 2 months postoperatively.

conspicuous and is more likely to result in an excellent cosmetic outcome. If necessary, proper mucosal lining is ensured by using a nasal mucosal flap or split-thickness skin graft. If cartilage support is required, conchal or nasal septal cartilage is used to rebuild the normal subcutaneous cartilage framework. Next, a foil template of the defect is constructed and then transferred to the forehead. Using a length of 4-inch × 4-inch gauze to simulate the length of the pedicle, the surgeon ensures that the flap is long enough to be inset without tension on the tip. The base of the pedicle, fed by the supratrochlear artery, can be located with the use of a Doppler device, but this artery is consistently located 10 mm lateral to the midline of the glabella. When planning the forehead flap, keep in mind that the base of the flap must be thin enough to allow adequate twisting of the base in order to reach the defect. However, too small a pedicle base may risk vascular compromise that would result in disastrous consequences. We find a pedicle width between 8 and 15 mm to be adequate for both flap mobility and vascular supply.

Flap procurement is begun by incising the distal flap (on the upper forehead) in the subcutaneous plane and, as work progresses proximally (toward the inferior forehead), dissecting to a gradually deeper plane. The distal one-third of the flap should be dissected in the superficial subcutaneous plane, the middle one-third in the deep subcutaneous plane, and the proximal one-third (just above the brow) in the sub-muscular plane. The surgeon must carefully dissect the remaining pedicle above the periosteum, being sure to not sever the supraorbital artery as it exits the supraorbital foramen. Bilaterally,

the forehead is undermined in a subgaleal plane and then closed in a layered fashion. The widest part of the forehead defect may not close, but heals well by secondary intention. Finally, the distal end of the flap is thinned to match the thickness of the remaining nasal skin before it is inset.

The second stage of the forehead flap is performed 3 weeks later. The pedicle is severed near the brow and the edges of both the brow and the pedicle stump are freshened so that an upside-down V is formed by both the pedicle stump and the brow defect. The stump is then trimmed of all fat and inset in a layered fashion, being sure to reposition the medial brow to match the contralateral side. After carefully trimming and thinning of the proximal edge of the remaining flap, it is inset into the remaining nasal defect.

Nasolabial interpolation flap

The nasolabial (melolabial) interpolation flap, a random pattern pedicle flap, has traditionally been utilized primarily for defects of the nasal ala. This flap is especially useful for large defects and complex defects involving the alar rim. In certain circumstances, the nasolabial interpolation flap may be utilized for the repair of nasal tip defects when the latter are moderate in size and a paramedian forehead flap is less optimal.

When utilizing the nasolabial interpolation flap for the repair of alar defects, we recommend excising the remainder of the cosmetic unit of the ala in order to ensure a better aesthetic and functional result (Fig. 147.27). After providing any necessary cartilage support, a foil template is made of the contralateral ala and then it is turned over and placed on the ipsilateral nasolabial skin. A length of 4-inch × 4-inch gauze can be utilized to ensure proper flap length prior to outlining the flap on the cheek skin. The flap on the cheek is incised and dissected to a well-vascularized pedicle deep in the subcutis. The cheek and the defect are widely undermined in the superficial subcutaneous plane; the flap is then turned on its pedicle, trimmed, and sutured into place in a layered fashion. The donor defect is closed up to the base of the pedicle.

Three weeks later, the patient returns for separation of the pedicle. The surgeon amputates, trims and sutures the flap and the cheek in a layered fashion to ensure recreation of the normal complex anatomic features of this aesthetically important area. We find that fusiform excision of the pedicle stump provides for the most aesthetically pleasing repair of the cheek donor site.

Retroauricular flap

The two-staged retroauricular flap is useful for large defects of the helical rim that involve loss of cartilaginous support (Fig. 147.28). The retroauricular flap is a random pattern flap without a single vascular pedicle. Nonetheless, because of the rich blood supply of the scalp skin, this is one of the most well-vascularized random pattern tissue importation flaps.

After providing cartilage support (if needed), a foil template of the defect is fashioned and then placed on the skin of the postauricular scalp. The necessary size of the flap is marked and then the flap is incised from the retroauricular sulcus back to the hairline. The flap is dissected in a subcutaneous plane and the tip judiciously thinned to match the thickness of the skin at the defect. The flap is sutured into place in a layered fashion, being sure to minimize tension as the flap curls around the anterior helical rim. We find the use of bolster sutures to be very helpful in recreating the curve of the antihelix. Three weeks later, the pedicle is severed near the scalp and the posterior aspect of the flap is sutured into place. The donor site can either be closed with a skin graft or left to heal by second intention.

Spear's flap

The reverse nasolabial (melolabial) pedicle flap, described by Spear, is useful for reconstruction of full-thickness defects of the ala that involve the attachment point of the lateral ala to the cheek (Fig. 147.29).

The design of the Spear's flap is planned in a manner similar to that of the single-staged nasolabial interpolation flap, with the use of a foil template made from the contralateral ala. This template is placed upside down on the skin of the cheek lateral to the nasolabial fold and the flap is incised to a point just lateral to the edge of the defect. The flap is then dissected to a well-vascularized pedicle deep in the subcutis adjacent to the defect. Next, the flap is twisted on its pedicle and the edge of the mucosal defect adjacent to the nasal tip is sutured to the under-turned skin of the medial edge of the flap; we use a 5–0 chromic gut suture for this portion of the flap. The lateral portion of the under-turned flap is then sutured to the lateral mucosal defect. By folding the flap on itself, the alar rim and the surface of the ala are recreated, and the tip of the flap is carefully trimmed to match the contralateral ala. The surface of the flap is closed in a layered fashion. As with the other nasolabial flaps, the donor site is closed after widely undermining the

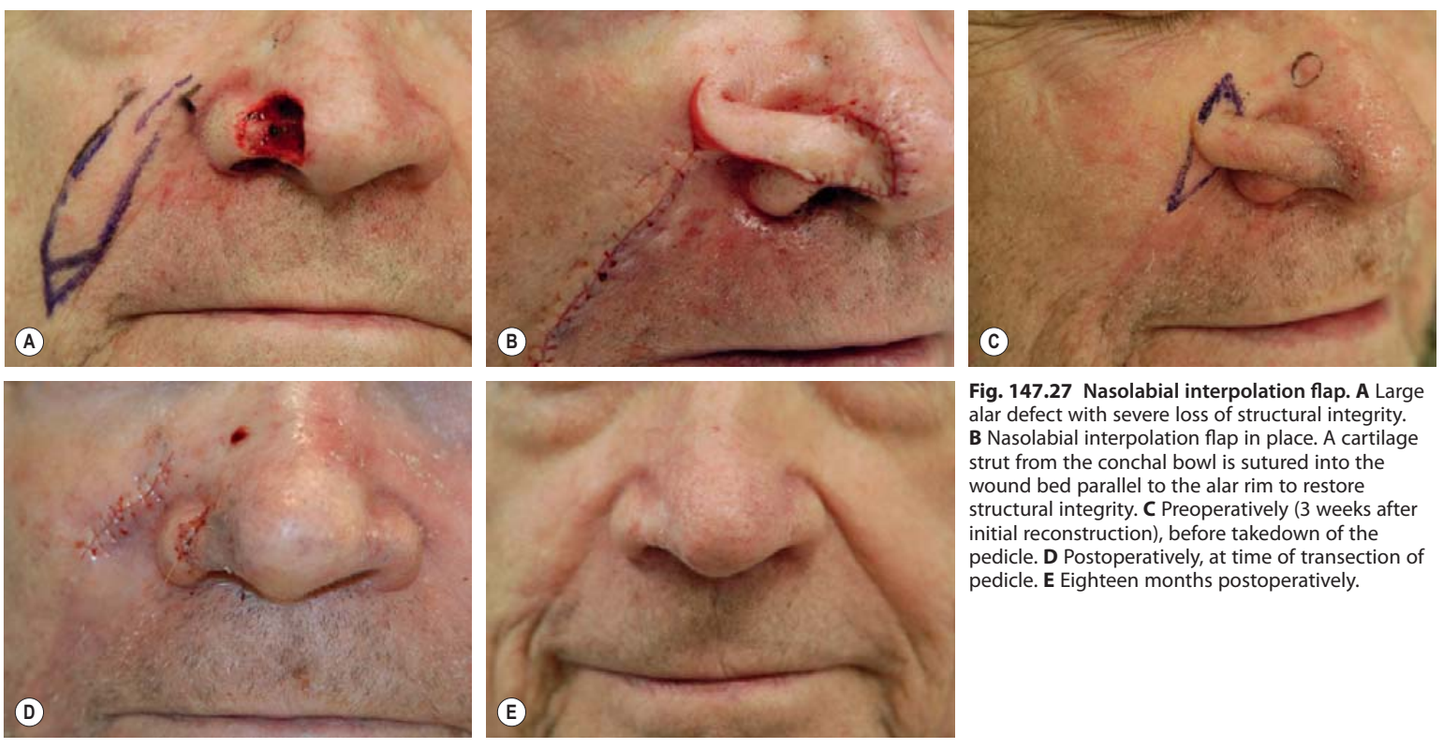

Fig. 147.27 Nasolabial interpolation flap. A Large alar defect with severe loss of structural integrity. **B** Nasolabial interpolation flap in place. A cartilage strut from the conchal bowl is sutured into the wound bed parallel to the alar rim to restore structural integrity. **C** Preoperatively (3 weeks after initial reconstruction), before takedown of the pedicle. **D** Postoperatively, at time of transection of pedicle. **E** Eighteen months postoperatively.

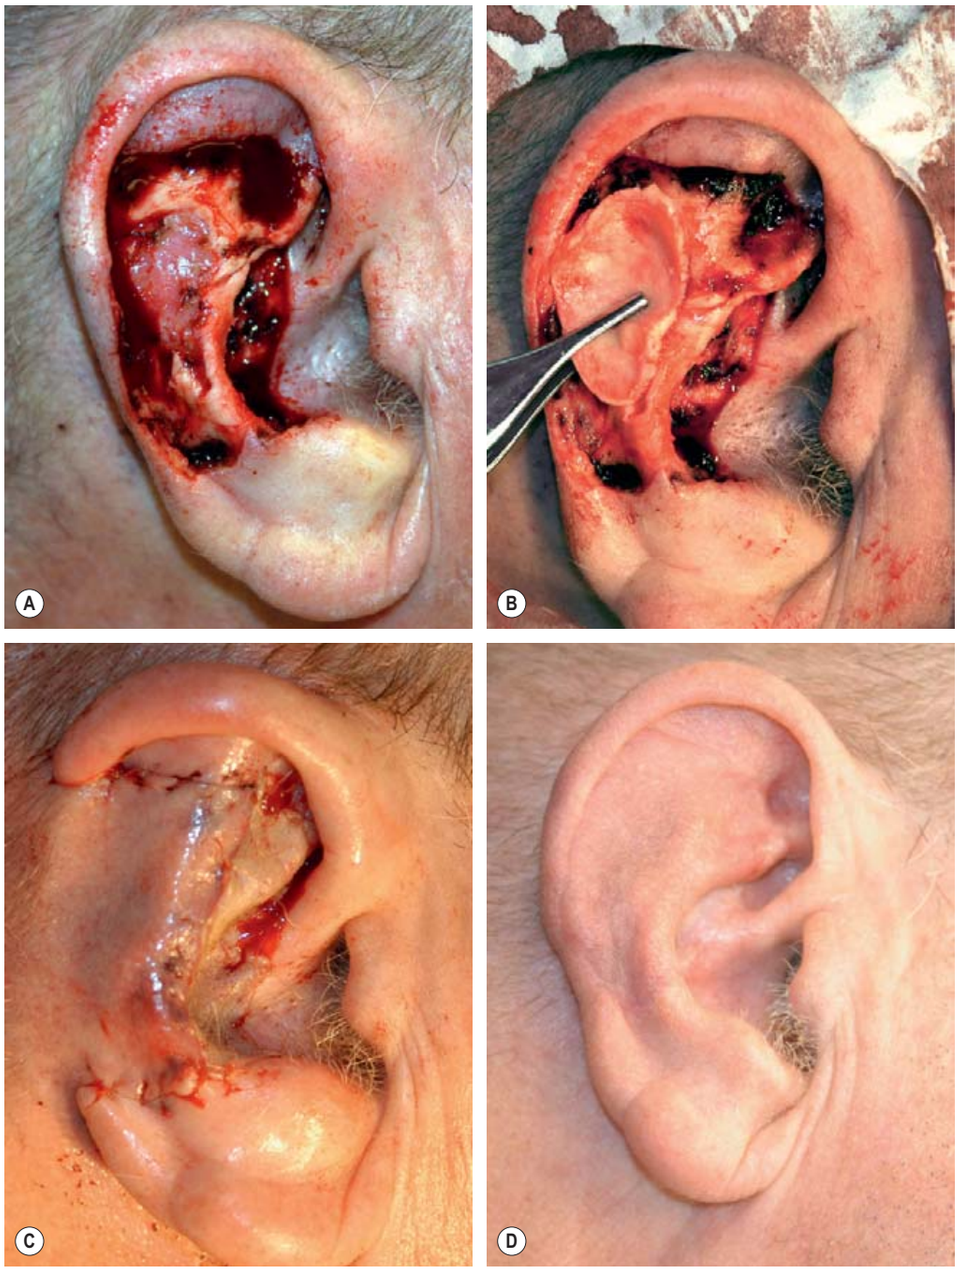

Fig. 147.28 Retroauricular flap. A Large defect of the anterior ear including substantial loss of cartilage of the mid antihelix and helical rim. **B** A cartilage graft harvested from the contralateral conchal bowl is used to restore structural integrity of the infrastructure of the auricle. **C** Closure of the retroauricular flap with resurfacing of the helix and antihelix. A split-thickness skin graft is used to resurface the crus of the antihelix and a portion of the conchal bowl. The pedicle from the retroauricular skin will be divided at 3 weeks. **D** Reconstructive results at 4 months.

skin of the cheek. Occasionally, a standing cone is created superolaterally to the new ala and it needs to be excised and sutured to complete the repair. Usually, a second stage to reposition the new, lateral aspect of the ala is necessary by folding the flap on itself. Typically, the newly formed ala is positioned too far laterally and is shifted up to 1 cm medially to correspond with the position of the contralateral ala.

Combination Flaps

Not all defects can be conveniently closed with a single flap. There are times when a combination of closure techniques is employed, either because the defect is too large or because the defect involves more than one cosmetic subunit. These types of wounds are better closed using a combination of flaps or flaps plus grafts. Combination closures for very large defects are usually employed when a flap is able to close a significant portion, but not all, of the defect. In that situation, a full-thickness graft may be used to supplement a flap and complete the coverage of a defect (Fig. 147.30). Grafts can be harvested from any of the common donor sites, depending on ideal tissue match and the adequacy of donor skin. When reconstructing a wound after Mohs surgery (i.e. a high degree of certainty of cancer-free margins exists), tissue adjacent to the wound can be safely used as "Burow's grafts". The Burow's triangle(s) of a flap can be defatted and trimmed to fit the remaining defect rather than being discarded.

Sometimes, flap and graft combinations are used to reconstruct defects that involve more than one cosmetic subunit. In such a wound, a flap is used to reconstruct one cosmetic subunit while a full-thickness skin graft is used to reconstruct the other, maintaining the "separateness" of each cosmetic subunit. The principle of maintaining the boundaries between cosmetic subunits is very useful in achieving a much less noticeable cosmetic result. If flaps or grafts are applied across the cosmetic subunits, the aesthetic disruption that occurs becomes more visible.

There are also defects that involve multiple cosmetic subunits that are best repaired individually with different flaps (Fig. 147.31). The same principle applies in that maintaining the integrity of individual cosmetic subunits is an important consideration in achieving a more natural and less noticeable result. These types of closures require crea-

Fig. 147.29 Spear's flap. tivity and sometimes ingenious methods in order to accomplish complete closure.

Table 147.4 summarizes the flaps discussed above and lists the areas of the face where the specific flaps are most useful for providing excellent functional and aesthetic results.

POSTOPERATIVE CARE

Postoperative care after flap surgery varies from practice to practice. Some surgeons have the patient change the bandage once or several times a day, cleansing the wound at each bandage change. Others apply a bandage for a day or two and leave the sutured wounds open to air thereafter. Still others apply a single bandage at the time of the surgery and leave it undisturbed for up to a week. Regardless of how the postoperative care is accomplished, there are common goals to achieve during the postoperative period.

One of these common goals is to prevent postoperative bleeding. The first 48 hours is the time period during which bleeding from the wounds and the formation of hematomas most commonly occur. Efforts to reduce these complications include meticulous intraoperative hemostasis and the application of pressure to the wounds. Pressure can be applied by using taping techniques, pressure wraps or specialized pressure garments. Normally, pressure becomes less important after 24 to 48 hours. In the patient at higher risk for bleeding, it may be necessary to maintain pressure for a more prolonged period of time. In some patients with a very high risk of postoperative bleeding, it may be helpful to use a tie-over bolster dressing directly over the wound to ensure constant firm pressure throughout the postoperative period.

Another common goal in the postoperative care of flaps is to reduce the risk of infection. All forms of infection can complicate the postoperative course and affect the cosmetic and functional results. Prevention of postoperative infections is covered elsewhere (Ch. 151). However, good surgical technique and observance of sterile technique during reconstruction is paramount. One novel approach, particularly well suited for cutaneous reconstructions, is the direct infiltration of the unclosed wound preoperatively with local anesthesia containing antibiotics. The benefit of intralesional nafcillin and clindamycin has been studied and this procedure is used routinely in some practices prior to reconstruction.

An additional important goal in the postoperative care of flap reconstructions is protection of the flap tissue from all environmental insults, including contamination, physical injury, temperature extremes, excessive movement and stretching of the sutured skin during the early postoperative period, and UV radiation. This is best accomplished by occlusive bandaging techniques and thorough education of the patient.

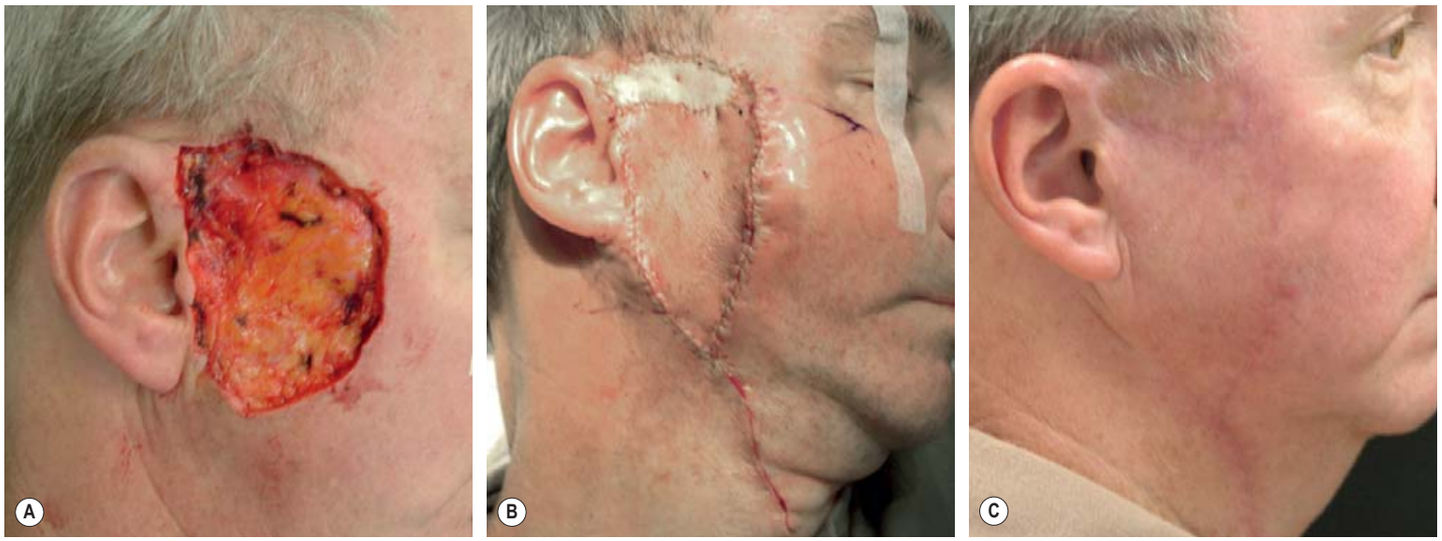

Fig. 147.30 Combination flap and graft. A Large defect of the preauricular cheek. **B** Partial closure of the lower 75% of the defect with an island pedicle flap. The remaining defect is closed with a full-thickness skin graft derived from an extension of the wound inferior to the donor site of the flap on the anterior neck. **C** Reconstructive results 3 months postoperatively.

A Deep defect involving the upper cutaneous lip and the lateral ala, including the alar rim. **B** Combination of an island pedicle flap to reconstruct the cutaneous lip plus a nasolabial interpolation flap to reconstruct the lateral alar rim. **C** Division and debulking of the interpolation flap pedicle at 2.5 months with contouring of the ala and the alar crease. **D** Immediately postoperative. **E** Six months postoperatively.

Presented here are the details of postoperative flap care as routinely implemented in one surgical practice. After the completion of the flap reconstruction, a light bandage is applied over a very thin coat of antibiotic ointment which is placed directly over the incision lines. The light bandage consists of non-stick gauze that is affixed with hypoallergenic paper tape. The tape completely covers the non-stick gauze, resulting in complete occlusion of the sutured skin. A "bulky" secondary bandage is then applied on top of this thin primary bandage. The bulky bandage consists of rolled or fluffed absorbent gauze, which is affixed again with paper tape, using a technique of taping which applies downward pressure to the bulky gauze. This is accomplished by the placement of one end of the tape on the skin of one side of the wound and stretching it over the top of the bulky gauze and then attaching the other end to the opposite side of the flap under tension. This is repeated numerous times with thin, 1-cm-wide strips of tape until the bulky gauze is entirely covered and firmly affixed by the tape. The patient is instructed not to allow the bandage to become wet for 1 week. He or she is instructed to remove the bulky secondary bandage 24 to 48 hours

COMMON LOCATIONS FOR FLAP TYPES
BUROW'S TRIANGLE DISPLACEMENT FLAPS
Burow's flap (single tangent advancement flap) and bilateral single tangent advancement flap (A-to-T flap)
– Distal, lateral nasal sidewall – Upper lateral lip – Infranasal upper lip – Eyebrow and suprabrow forehead – Mid helix
Unilateral or bilateral double tangent advancement flap (U- or H-flap)
– Forehead – Helix – Large defect of upper lip
Rotation flap(s)
– Upper cheek – Medial chin – Nasal dorsum (Rigor flap) – Lower eyelid
DEFECT RECONFIGURATION FLAPS
Island pedicle flap
– Upper lateral and mid upper cutaneous lip – Mucosal lip – Lateral chin and lower lip – Distal nasal sidewall – Preauricular cheek – Eyebrow
TISSUE REORIENTATION FLAPS
Rhombic transposition flap
– Nasal sidewall – Temples and lateral forehead – Lateral canthus and lateral lower lid – Lateral chin and lower lip – Superior and anterior helix
Bilobed transposition flap
– Nasal tip and supratip – Lower lateral lip
Nasolabial transposition flap
– Alar defects, especially those involving the lateral portion of the ala – Lateral alar crease and distal nasal sidewall
TISSUE IMPORTATION FLAPS
Paramedian forehead flap
– Large nasal defects – Moderate-size nasal tip defect – Nasal defects with loss of cartilage and/or nasal lining – Large medial canthus defects
Nasolabial (melolabial) interpolation flap
– Nasal ala and alar rim – Nasal tip – Mid upper lip
Melolabial flap with a twist (Spear's flap)
– Full-thickness alar defects involving the junction of the lateral ala and the cheek/upper lip
Retroauricular flap
– Large defects of the anterior ear or helix – Full-thickness defects requiring cartilage graft reconstruction

Table 147.4 Common locations for flap types.

after the surgery, leaving the thin, primary bandage in place. This bandage is left undisturbed and kept dry for the remainder of the week.

The patient returns to the office after 1 week for bandage removal, suture removal and evaluation of the wound. Any evidence of hematoma, infection or other complication is addressed at that time. The skin is cleansed and another thin bandage with topical antibiotic ointment, non-stick gauze and hypoallergenic paper tape is applied for one more week. The patient is instructed again to keep this bandage dry and to remove it in 1 week (i.e. 2 weeks after the surgery). The patient is encouraged to contact the physician in the postoperative period if there are any problems and to return in 3 months for a final evaluation of the wound healing process. Minor revisions may be made at that time to optimize the aesthetic and functional results.

COMPLICATIONS

In the immediate postoperative period, the potentially serious sequelae are primarily postoperative bleeding and infection. Both adverse events are rare if meticulous surgical technique is used. Nonetheless, failure to recognize either complication and intervene appropriately can lead to disastrous postoperative results. Postoperative bleeding that results in a hematoma requires immediate attention. The most effective intervention is an immediate return to the operating suite to remove the sutures, evacuate the hematoma, locate and ligate the bleeding vessel, and re-suture the wound. Failure to do so likely risks flap necrosis. If a postoperative infection is present, immediate oral antibiotics and drainage of any trapped purulent material are required.

In the mid-postoperative period, the most common complication requiring intervention is the development of a hypertrophic scar or trapdoor deformity. This usually becomes evident about 4 to 8 weeks after surgery and occasionally develops despite wide undermining, appropriate flap thinning, and meticulous suturing technique at the time of surgery. Often, the patient is advised to aggressively massage the site many times per day. Massage and tincture of time often promote adequate remodeling of the healing wound. Occasionally, active intervention is necessary. We use a varying concentration of intralesional triamcinolone acetonide injections (5–40 mg/ml), depending upon the location and thickness of the flap.

Late postoperative complications include persistent pincushioning, surface irregularities, blunting or ablation of the junction between cosmetic units, and surface telangiectasias. Persistent pincushioning and minor surface irregularities can be addressed as early as 6 to 12 weeks postoperatively with the use of a scalpel to plane the surface and dermabrasion or dermasanding to blend the planed surface. In order to redefine the junction between cosmetic units that may have been ablated by the placement of a flap (e.g. the alar crease in a nasolabial transposition flap), incising the area, thinning the subcutis and re-suturing the skin edges to recreate the natural fold is usually all that is required. Laser ablation of telangiectasias that not infrequently develop around the incision lines of large nasal flaps can be done at any time. We find that these tend to develop gradually over time and that ablation may need to be repeated at future visits.

Sometimes, regardless of proper patient selection, flap planning and suturing technique, some amount of postoperative refinements may be necessary. These may vary from simple procedures to correct surface irregularities to more complicated interventions requiring further scalpel surgery. The key to a successful outcome from a postoperative intervention is recognizing the circumstances where an intervention would be helpful and then choosing the appropriate intervention. Understanding the normal sequence of healing after a surgical procedure helps the surgeon to decide when and by what means to intervene in this process.

Wound healing considerations 2421
Full-thickness skin grafts 2422
Split-thickness skin grafts 2427
Composite grafts 2429
Free cartilage grafts 2431

Key features

- Free skin grafts are pieces of skin that have been severed from their local blood supply and transferred to another location
- Grafts for soft tissue reconstruction can be divided into four types: full-thickness skin grafts, split-thickness skin grafts, composite grafts, and free cartilage grafts
- In dermatologic surgery, grafts are most commonly used to repair defects created after removal of skin cancers; grafts also provide coverage and more rapid healing of leg ulcers
- The clinical situation determines the type of graft to be placed
- A working knowledge of the indications, techniques, donor site considerations, postoperative care, and postoperative complications of all types of skin grafting is essential for optimal soft tissue reconstruction

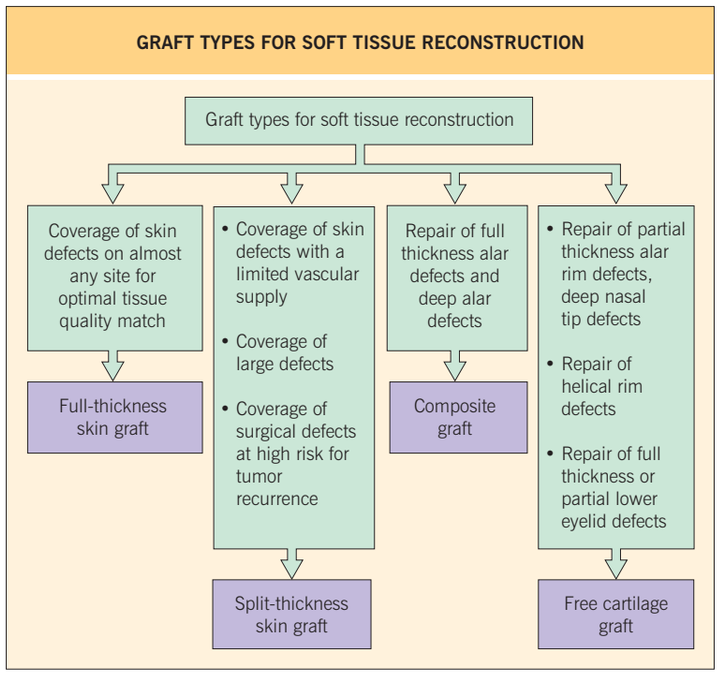

Fig. 148.1 Graft types for soft tissue reconstruction.

INTRODUCTION AND BACKGROUND

Skin grafting procedures originated approximately 2500 to 3000 years ago, when surgeons of the Hindu Tilemaker caste replaced noses amputated as punishment for theft and adultery with skin grafts harvested from the gluteal region[1]. It was not until the nineteenth century, however, that skin grafting was reintroduced. In 1869, Reverdin's account of pinch grafting for leg ulcers was published; in subsequent decades, Ollier and Thiersch's accounts of thin split-thickness skin grafting, and Wolfe and Krause's accounts of full-thickness skin grafting, appeared in the literature. While these and other nineteenth-century surgeons used skin grafts to address only the most difficult problems of surgical management, skin grafting has since evolved into a reconstructive option that is routinely, and sometimes preferentially, used for the surgical repair of skin defects.

Free skin grafts are pieces of skin that have been severed from their blood supply and transferred to another location. They can be divided into four types: full-thickness skin grafts (FTSGs), split-thickness skin grafts (STSGs), composite grafts, and free cartilage grafts (Fig. 148.1; Tables 148.1 & 148.2)[2,3]. FTSGs are composed of the entire epidermis and the full thickness of dermis, including adnexal structures such as hair follicles and sweat glands. STSGs are composed of the full thickness of the epidermis and partial thickness of dermis. These can be subdivided into thin, medium and thick grafts, depending on the amount of dermis included in the graft. Composite grafts are composed of at least two different tissue types, usually skin and cartilage. Free cartilage grafts consist of cartilage with its overlying perichondrium.

WOUND HEALING CONSIDERATIONS

Wound healing after skin grafting proceeds through a unique series of events[2,4]. The first 24-hour period following graft placement is termed the stage of plasmatic imbibition, during which fibrin glue attaches the graft to its recipient bed, allowing it to take up the underlying wound exudate and to become edematous, gaining up to 40% in weight. The graft thereby remains hydrated and obtains a supply of nutrients, which maintains graft vessel patency until revascularization begins. The fibrin beneath the graft is subsequently replaced by granulation tissue, which attaches the graft permanently to its bed.

With proper apposition of the graft to its bed, revascularization may proceed. Anastomoses begin to form within 48–72 hours of grafting, between the recipient bed and pre-existing vessels in the dermis of the graft, a process known as inosculation. Vascular proliferation occurs next, with sprouting and budding of vessels in the graft and its bed. Even relatively avascular tissue may be grafted, as long as the avascular area is small and surrounded by a rich vascular supply. Through a process known as the bridging phenomenon, vascular connections arising from the recipient bed allow blood flow to occur through pre-existing graft vasculature, so that nutrients reach the part of the graft overlying the avascular area. Full circulation is restored to the graft within 4–7 days.

Restoration of the lymphatic circulation parallels restoration of the blood supply over the first week. Epidermal proliferation occurs between the 4th and 8th day post-transplant and persists for several weeks. Degeneration of sebaceous and eccrine glands may occur initially, but subsequent glandular regeneration may allow partial function to be maintained. Graft reinnervation and return of sensory nerve function may begin as early as 2–4 weeks after grafting, although patients do not usually regain full sensation for many months.

COMPARISON OF GRAFT TYPES USED IN SOFT TISSUE RECONSTRUCTION								
Graft type	**Tissue match**	**Nutritional requirements**	**Requirement for recipient bed vascularity**	**Infection risk**	**Graft contraction risk**	**Durability**	**Sensation**	**Adnexal functions**
FTSG	Good to excellent	High	High	Low	Low	Good to excellent	Good	Excellent
STSG	Poor to fair	Low	Low	Low	High	Fair to good	Fair	Poor
Composite	Good	High	Very high	Moderate	Low	Fair	Fair	Good
Free cartilage	NA	Moderate	High	Moderate	Migration or deformation possible, with subsequent resorption	Good	NA	NA

Table 148.1 Comparison of graft types used in soft tissue reconstruction. FTSG, full-thickness skin graft; STSG, split-thickness skin graft.

INDICATIONS, CONTRAINDICATIONS, ADVANTAGES AND DISADVANTAGES OF GRAFT TYPES USED IN SOFT TISSUE RECONSTRUCTION				
Graft type	**Indications**	**Contraindications**	**Advantages**	**Disadvantages**
Full-thickness skin graft (FTSG)	Coverage of skin defects, usually located on the face or scalp, requiring an optimal tissue quality match	Avascular graft bed	Excellent color and texture match Minimal graft contraction	Time consuming Donor site requires closure Requires meticulous technique
Split-thickness skin graft	Coverage of large defects, defects with a limited vascular supply, or at sites at high risk for tumor recurrence	Defects near free margins Facial defects in cosmetically sensitive areas	Increased chance of survival Ease of application Ability to cover large defects Able to act as a "window" to detect recurrence of high-risk tumors	Suboptimal cosmetic appearance Decreased durability Presence of granulating donor site wound Greater graft contraction Special equipment required to harvest larger grafts
Perichondrial cutaneous graft	Repair of deep nasal tip and alar defects, especially those with exposed cartilage	Avascular graft bed	Thicker than FTSG Contract less than FTSG Increased chance of survival under conditions of vascular compromise (compared to FTSG)	
Composite	Repair of full-thickness alar defects or nasal tip defects (<2 cm in diameter) with cartilage loss	Defects >2 cm in diameter	Single-stage procedure May yield good functional and aesthetic results when used to repair appropriately sized defects	Greater risk of graft failure under conditions of vascular compromise Graft size limitations (<2 cm) Limited donor tissue available Donor site may require flap or complex closure Increased risk of infection and graft displacement
Free cartilage	Repair of defects of nasal ala, tip or sidewall, ear or eyelid requiring restoration of structural support or preservation of contour of free margins	None	Provide structural support for selected facial and ear defects	Donor site may be painful Increased risk of postoperative infection Increased risk of graft displacement

Table 148.2 Indications, contraindications, advantages and disadvantages of graft types used in soft tissue reconstruction.

If extension of the ischemic period occurs, decreased graft survival may result (Table 148.3). Hematoma or seroma formation, infection, or mechanical shear forces may disrupt the fragile vascular connections between the graft and its recipient bed. These complications tend to affect FTSGs (which have a greater volume to nourish and revitalize) more than STSGs.

Even after the ischemic period is past, other factors may combine to decrease the vascular supply nourishing the undersurface of the graft[2,3,5]. The most important of these factors is cigarette smoking[5], but diabetes mellitus, protein deprivation, and severe trace element or vitamin deficiencies may also increase the risk of graft failure. Certain systemic medications, such as corticosteroids, chemotherapeutic agents, other immunosuppressive drugs and anticoagulants, may interfere with wound healing as well.

Other causes of graft failure include: insufficient vascularity due to necrotic debris within the recipient bed, hematoma, seroma, an avascular wound bed, previous radiotherapy, infection, excessive graft tension, mechanical shearing forces, and improper postoperative care (see Table 148.3)[2,3]. The most common infectious agents associated with graft failure include coagulase-positive staphylococci, β-hemolytic streptococci and *Pseudomonas* spp. Pseudomonal infections are particularly common in auricular grafts. For all of these reasons, a thorough preoperative evaluation, meticulous intraoperative technique, and good postoperative care are essential to maximize graft survival.

FULL-THICKNESS SKIN GRAFTS

Indications/Contraindications

FTSGs are most commonly used to repair facial defects resulting from the removal of skin cancers. They may be used to repair defects at virtually any site, as long as the recipient bed has both a sufficiently rich vascular supply to promote capillary regrowth and fibroblasts to supply collagen for graft adherence. Small avascular areas may be grafted due to the bridging phenomenon. Larger areas of avascular tissue, including patches of exposed bone, cartilage, tendon or nerve

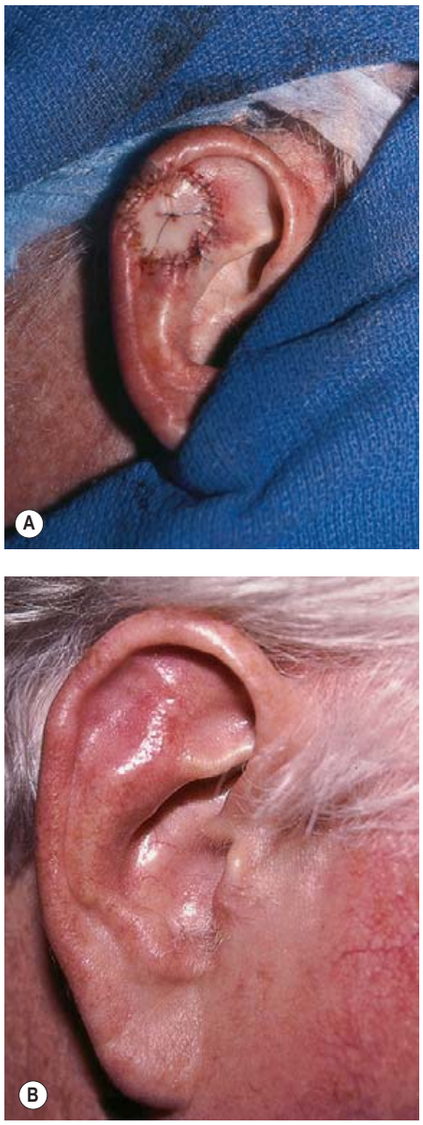

Fig. 148.2 Full-thickness skin graft. A Full-thickness skin graft taken from the preauricular region was used to repair this defect of the right upper anterior ear. **B** Eight-week postoperative result.

devoid of periosteum, perichondrium, peritenon or perineurium, respectively, are unable to support FTSGs. For this reason, FTSGs should not be placed over such avascular tissue.

Under the proper circumstances, FTSGs can provide excellent color, texture and thickness matches for facial defects because they include the full thickness of epidermis and dermis. Wound contraction is minimized since the full thickness of dermis is present, and dermal adnexal structures remain intact[6]. FTSGs may be especially useful for the cosmetically and functionally acceptable repair of defects of the nasal tip, dorsum, ala and lateral sidewall, as well as the lower eyelid and ear (Fig. 148.2)[7].

Preoperative History and Donor Site Considerations

A thorough preoperative evaluation that includes questions regarding bleeding tendencies, alcohol use, use of anticoagulant medications (including aspirin and nonsteroidal anti-inflammatory drugs) and a history of hypertension can help assess the risk of excessive bleeding and clot formation beneath the graft postoperatively[2,3]. Diabetes mellitus, nutritional deficiencies, cigarette smoking or the use of other nicotine-containing products may increase the risk of graft failure, and any history of these should be identified preoperatively.

Selection of a donor site for full-thickness skin grafting depends upon the color, texture, thickness, and sebaceous qualities of the skin surrounding the defect (Tables 148.4 & 148.5). Most FTSGs are taken from sun-exposed areas above the shoulders whose color, vascular pattern, texture, and distribution of adnexal structures best match the skin surrounding facial defects. The thinnest grafts are usually harvested from the upper eyelid or the postauricular sulcus. Medium-thickness grafts are often harvested from the preauricular and cervical regions, while thicker grafts may be taken from the supraclavicular or clavicular region, conchal bowl or nasolabial fold. Donor skin thickness, irrespective of site, will vary from one patient to another. It is

CAUSES OF GRAFT FAILURE	
Poor graft–bed contact	Hematoma Seroma Shearing forces due to excessive postoperative activity Shearing forces due to inadequate immobilization of graft
Poor recipient bed vascularity	Inadequate vascular bed (e.g. previous radiotherapy) Exposed cartilage, bone, tendon Nicotine-induced vasoconstriction
Infection	Coagulase-positive *Staphylococcus* spp. Beta-hemolytic *Streptococcus* spp. *Pseudomonas* spp.
Host factors	Diabetes mellitus Immunosuppression Poor general health Nutritional deficiencies Systemic conditions with vascular compromise
Technique	Rough handling of tissue Excessive devitalized tissue in recipient bed due to cautery Increased tension on graft due to inadequate size Inadequate hemostasis Inadequate trimming of adipose layer Placement of upside-down graft (more common with STSG) Inadequate anchoring (composite and free cartilage grafts)

Table 148.3 Causes of graft failure. STSG, split-thickness skin graft.

DONOR SITE CONSIDERATIONS FOR FULL-THICKNESS SKIN GRAFTS
• Pattern of sun exposure • Color • Vascular pattern • Texture • Sebaceous quality • Skin thickness • Skin consistency • Sufficient tissue available for harvesting • Ability to camouflage donor site scar

Table 148.4 Donor site considerations for full-thickness skin grafts.

SUMMARY OF POSSIBLE FULL-THICKNESS DONOR SITES FOR DEFECTS IN DIFFERENT LOCATIONS	
Defect sites	**Donor sites**
Nasal dorsum, sidewalls, tip	Preauricular region, supraclavicular region or lateral neck (if large)
Nasal tip, ala	Preauricular region, conchal bowl, nasolabial fold
Junction of nasal dorsum/tip	Burow's graft
Ear	Postauricular sulcus, preauricular
Lower eyelid/medial canthus	Upper eyelid, postauricular sulcus
Scalp	Supraclavicular region, lateral neck, inner upper arm
Forehead	Burow's graft, supraclavicular region, lateral neck, inner upper arm (if large)

Table 148.5 Summary of possible full-thickness donor sites for defects in different locations.

therefore important to examine all sites carefully to find the best possible tissue match. This approach will ensure optimal donor site selection for each individual patient and surgical defect.

A regional approach may at times be used to obtain the best possible match for a given defect. Grafts taken from redundant upper eyelid skin may be used to repair lower eyelid defects, providing a good color and texture match in addition to a well-camouflaged donor site scar. Grafts used for lower eyelid defects should be oversized by 100–200% to allow for contraction and to avoid ectropion. Due to its relatively large size and inconspicuous location, postauricular skin may also be useful as a donor site for eyelid and auricular defects. Because postauricular skin is relatively non-sun-exposed, grafts harvested from this region may not provide a good color or texture match for other facial defects.

Preauricular skin is more versatile and can be used to repair most nasal defects, since the thickness and degree of sun exposure of these areas tend to be comparable. Donor site scars in this region can be easily camouflaged, as in facelift surgery, to provide a cosmetically desirable result. Even bearded individuals have a 1–2 cm hairless zone in the preauricular region. Care must be taken not to harvest hair-bearing skin in grafts taken from this area. Accidentally including mature follicular units may produce undesirable hair growth within the graft. Hair-bearing skin from the temporoparietal region may be used to repair eyebrow defects, where survival of the follicular units after transplantation may help to produce a superior cosmetic result. Skin from the nasolabial fold or the conchal bowl can sometimes be used to graft small nasal tip defects[8]. At times, sufficient skin laxity may be present, particularly on the nose or forehead, to allow for partial defect closure by utilizing the adjacent Burow's triangle as a FTSG, providing an excellent tissue match[9–11].

For larger defects requiring FTSGs of sun-damaged skin, such as the forehead and scalp vertex, the supraclavicular region or lateral neck can be used as a donor site. Again, care must be taken not to harvest unwanted hair along with the graft. These donor sites are often more difficult to camouflage, and must be carefully placed, especially in areas that might not always be covered by clothing. Although the color and texture match may be suboptimal, areas below the neck with thin, redundant skin, such as the upper inner arms, forearms and inguinal area, can be used.

Description of Technique

Varying techniques for harvesting and placing FTSGs have been described[2,3,9–11]. To perform a FTSG, a template of the defect is first made, using any flexible material, such as gauze, Telfa™ or aluminum foil, which can be bent to conform to the defect. After marking the periphery of the recipient site with a marking pen, the template material is pressed against the defect, and the resulting outline of the inked margin serves as a guide to cut a perfect template (Fig. 148.3A,B). The template is applied to the donor site, and inking material applied around it (Fig. 148.3C). The graft should be 3–5% larger in size than the true template to allow for the natural contraction and shrinkage of the graft after it has been harvested. Often, just cutting around the outside of the inked margin accounts for this extra "safety" skin. For eyelid defects, grafts should be oversized significantly, to minimize the risk of ectropion. Marking the donor site prior to local anesthesia prevents incorrect sizing due to tissue stretch from lidocaine infiltration. It is important to note that a donor site ellipse with a 3:1 ratio may not always be required, allowing for smaller donor site defects[12].

After the donor site is marked, local anesthesia may be injected into the donor and recipient sites. Epinephrine (adrenaline) may be used without compromising graft survival. If waterproof ink is not available for template marking, the outline of the template may be scored on the donor site with a needle. The donor site and recipient beds are then scrubbed with an antibacterial preparation such as chlorhexidine, rinsed with saline, and draped with sterile towels.

The donor site is excised with a scalpel to the level of the subcutaneous fat. The graft is placed in a sterile bowl or Petri dish containing normal saline, where it may remain for up to 1–2 hours. Grafts may be utilized up to 24 hours after harvesting if refrigerated or kept on ice. Before suturing the graft into place, defatting should occur (Fig. 148.3D). This is an essential step, since direct contact between the graft and its bed allows for connections between existing vessels as well as new vessel growth and nutritional support from the base of the defect. Adipose tissue adherent to the graft is poorly vascularized and is therefore not a good medium for new vessel growth between the graft and its bed.

When defatting is performed, the graft is placed dermal-side-up on the fingers or in the palm. All fat is trimmed from the underside using sharp scissors. Fat is adequately removed when all of the yellow globular material is gone, leaving a white glistening dermal surface. If indicated, part of the dermis can also be trimmed to allow for differences in recipient site depth, although adnexal structures may be removed in the process, potentially altering the cosmetic result. The graft is then placed dermis-down in its bed, and rotated and trimmed if necessary, to achieve a perfect fit (see Fig. 148.3F). While one surgeon is trimming the graft, another may close the donor site, usually in a linear layered fashion with bilateral removal of standing cones (Fig. 148.3E). If the conchal bowl is the donor site, a 2 or 3 mm punch biopsy instrument may be used to remove full-thickness discs of cartilage from its central aspect, thereby facilitating second intention healing from the underlying dermis.

Contouring of donor skin in FTSGs may be challenging, particularly when repairing defects on the nasal tip, ala, lateral nasal sidewall, helical rim of the ear, and eyelid[13]. Graft contouring often requires multiple trial placements within the recipient bed, as well as multiple trimmings, to obtain an optimal result (Fig. 148.3F). Removal of cartilage not needed for structural support may increase the chance of graft survival, particularly for auricular defects, without compromising the aesthetic appearance of the repair[14,15].

Securing the Graft

Perimeter sutures, basting sutures, support dressings, or a combination of any or all of these can be used to anchor the FTSG. Depending upon the graft's size, four to eight interrupted 5-0 or 6-0 absorbable or non-absorbable sutures may be placed at opposite edges of the graft periphery (e.g. at 3, 6, 9 and 12 o'clock) to tack down its four quadrants. A simple running suture, such as 6-0 fast-absorbing chromic gut suture (Fig. 148.3G), may then be placed around the graft's perimeter. Great care is taken to achieve perfect epidermal wound approximation. The running suture is placed in almost epicuticular fashion, passing the needle first through the graft and then through the surrounding skin. Placing the suture slightly higher in the dermis on the graft side and slightly deeper in the dermis of the surrounding skin makes suture placement easier, prevents tenting of the graft edges, and maximizes graft–recipient bed contact.

The use of tissue adhesives in full-thickness skin grafting has been investigated. In an initial pilot study, it was found that using cyanoacrylate tissue adhesive to secure FTSGs to their recipient bed wound edges produced cosmetic results essentially identical to those achieved with suturing[16]. Because these adhesives set virtually instantaneously, the graft must be perfectly trimmed and aligned before adhesive application, since fine adjustments in positioning the edges of the graft are not easily made. Tissue adhesives may represent a useful time-saving alternative for securing the periphery of certain grafts, particularly those in relatively immobile areas such as the temple, forehead and distal nose.

Basting sutures, usually simple interrupted 6-0 fast-absorbing gut sutures, can occasionally be placed to secure the central portion of the graft. They can be useful in securing large grafts to provide extra support against movement, as well as grafts placed on a concave surface where tenting could possibly occur. All sutures should be snug, but not strangulating, so as to not compromise graft survival.

Immobilization of the graft over its bed can be maximized with pressure dressings. Classically, tie-over bolster dressings have been employed to immobilize grafts, using anchoring stents to ensure direct contact between the graft and its bed[2,3]. These stents may consist of various materials such as Xeroform™ gauze (bismuth tribromophenate-petrolatum-impregnated gauze, Kendall), cotton balls, foam rubber, sponges, plastic beads or disks. Although sutures or skin staples are usually employed to anchor the stent, adhesive wound closure tapes or Steri-Strips™ can also be applied to exert even pressure on the bolster[17]. Adherence of the dressing to the graft, which tends to pull the graft from its bed at the time of dressing removal, is minimized by first applying antibiotic ointment, a non-adherent contact dressing, or Xeroform™ gauze to the graft site. Pressure or tie-over dressings help to immobilize the newly placed graft during the critical period

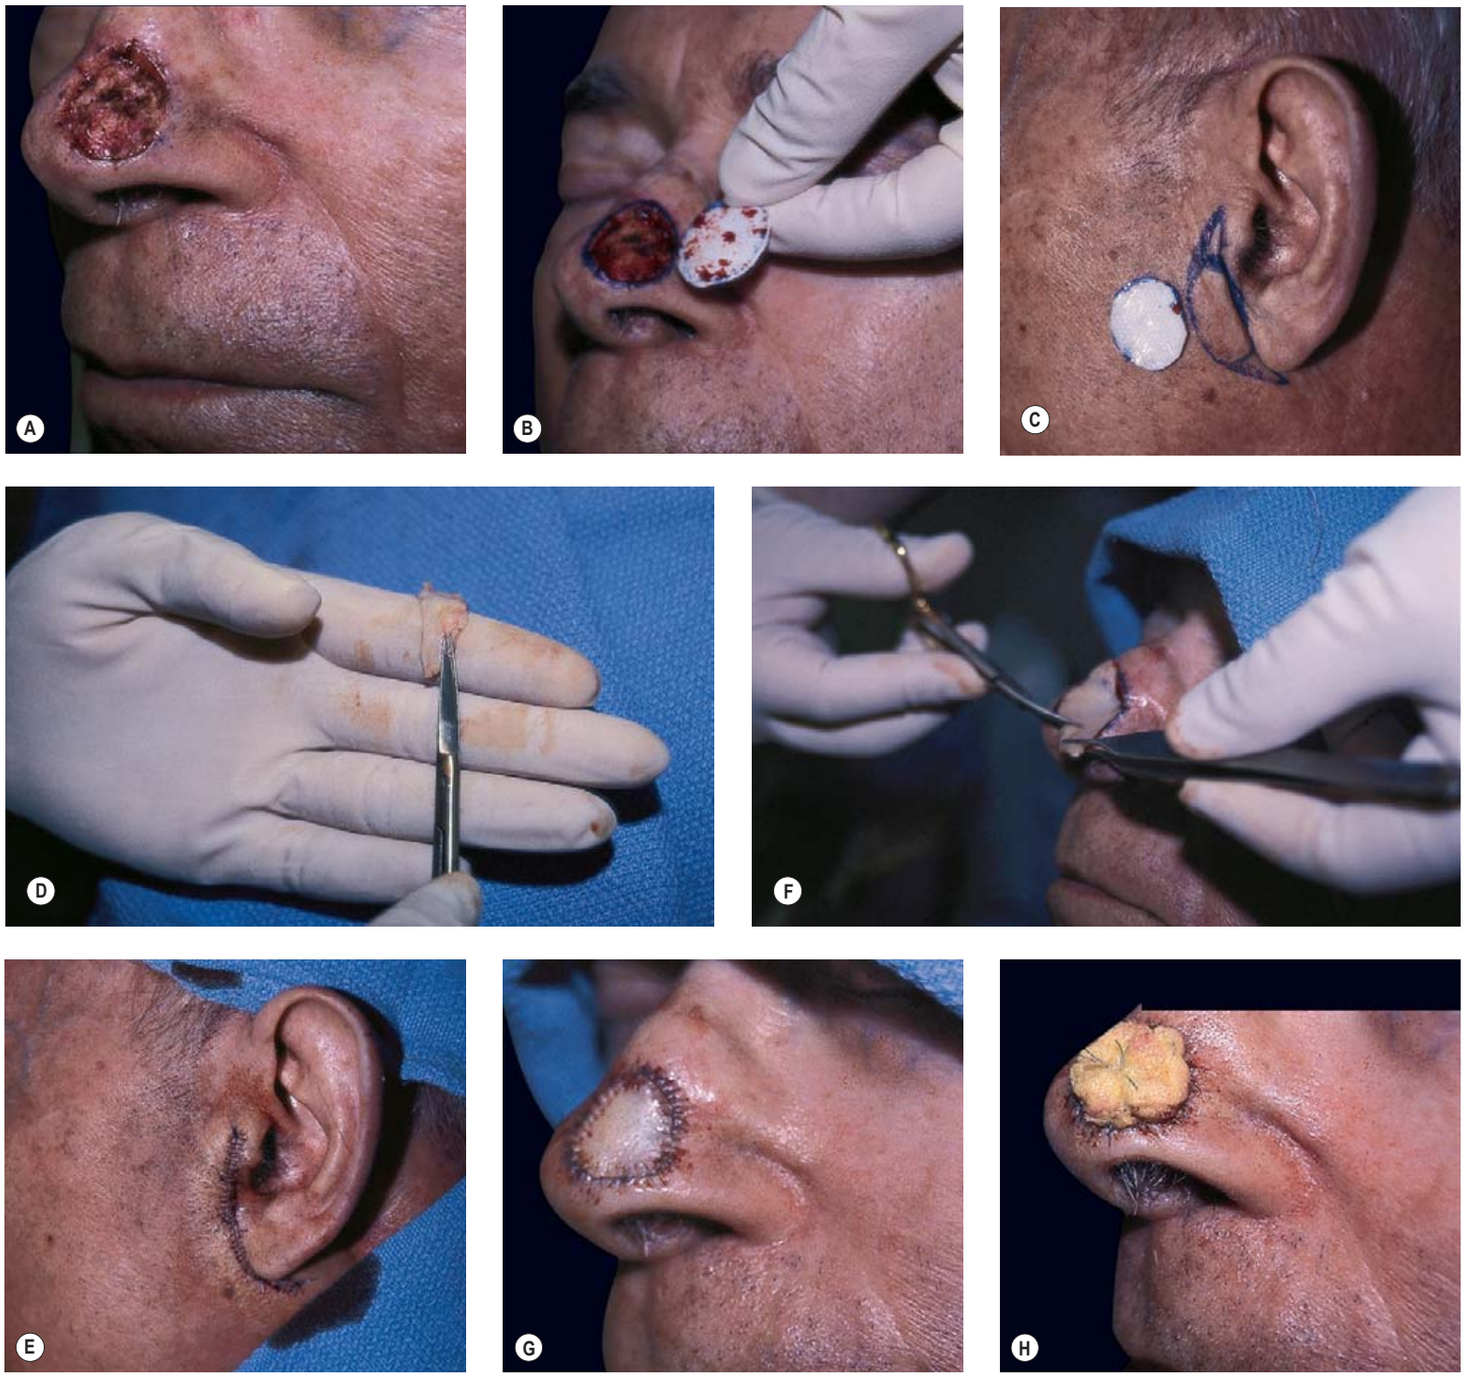

Fig. 148.3 Placement of a full-thickness skin graft. A A 1.7 × 2.0 cm defect of the nasal tip is present after removal of recurrent basal cell carcinoma with Mohs surgery. A preauricular donor site provides the best match in this case for color, sebaceous quality, degree of photodamage, and thickness. **B** After marking the periphery of the recipient site with a marking pen, the template material is pressed against the defect. The resulting outline of the inked margin serves as a guide to cut a perfect template, seen here adjacent to the nasal defect. **C** The template has been applied to the preauricular donor site, and inking material applied around it. Burow's triangles are outlined on either side of the template to close the site primarily. Marking the donor site prior to local anesthesia prevents incorrect sizing due to tissue stretch from lidocaine infiltration. **D** The graft is carefully defatted with curved iris scissors so that only the white, glistening surface of the dermis remains. **E** The preauricular donor site is closed primarily. **F** The full-thickness skin graft is trimmed with curved iris scissors to ensure a perfect fit. **G** Full-thickness skin graft sewn into place with 6-0 fast-absorbing chromic gut sutures. **H** Xeroform™ bolster sewn into place over full-thickness skin graft with 5-0 polypropylene tie-over sutures.

of revascularization, and they help to prevent hematoma or seroma formation. Some authors postulate that such dressings may not be necessary to secure very small FTSGs[18].

The simplest bolster consists of Xeroform™ gauze alone, which is molded and placed to apply pressure to the graft. One end of each of the peripheral non-absorbable sutures is cut long, to a length of approximately 3–6 cm, and its opposing suture is left uncut. The suture ends can then be tied over the dressing two at a time (i.e. 12 o'clock to 6 o'clock and 3 o'clock to 9 o'clock) to secure the bolster (Fig. 148.3H). A running bolster suture has also been described[19]. A light dressing consisting of Telfa™ and Hypafix® (Smith & Nephew) may be placed over the graft. The donor site is dressed with a pressure dressing for 24 hours.

Postoperative Care

After the pressure dressings are removed, careful wound care should be performed once to twice daily. One method is to gently clean the donor site and area immediately surrounding the bolster with hydrogen peroxide to remove all crusts, followed by application of antibiotic or

petrolatum ointment (Vaseline®). The bolster is not disturbed until dressing removal at 1 week, at which point the bolster and all tie-over sutures are removed. Steri-Strips™ may be applied to the donor site as needed after suture removal.

The ideal graft is light pink when the bolster is removed. Its color may range, however, from pink or red to darker blue or purple, depending on the extent of graft revascularization. Patients should be cautioned about these color changes beforehand. A bluish tinge may be a sign of ecchymosis rather than graft failure. At this 1-week time point, a white graft is a sign that the graft has not revascularized and will fail, requiring the underlying wound to heal by second intention. A black graft signals necrosis and is undesirable. It is possible that the entire epidermal surface may become black and necrotic, and then slough without adversely affecting the dermal portion of the graft, as re-epithelialization can occur from adnexal structures and the epithelial edges, with an acceptable cosmetic result. Therefore, eschars should not be debrided, since they can serve as natural dressings under which healing will progress. Patients should be counseled that the vascular supply of the graft remains fragile for weeks. For this reason, trauma, including direct shower water to the area, and excessive activity should be avoided for an additional 1 to 2 weeks.

Variations/Unusual Situations

Purse-string suture

The purse-string suture is a subcuticular stitch placed around the periphery of a circular or oval surgical defect[20]. This type of suture allows partial defect closure by advancing skin from the entire periphery of the wound, and it may help to cover areas of exposed cartilage or bone at the wound edges that could inhibit graft take. In addition, the graft required to cover the remainder of the defect is greatly reduced in size due to an approximately 50% decrease in the defect area. Because of this reduced defect size, the graft needed to complete the repair may be harvested from traditional preauricular, postauricular or supraclavicular donor sites, which provide the best color, texture and thickness match for most sun-exposed areas. Furthermore, FTSG placement decreases the risk of significant wound contraction, resulting in better cosmetic and functional results than would be produced by split-thickness skin grafting or second intention healing.

Large scalp defects extending to bone can present a significant management challenge, which can be handled by placing a purse-string suture followed by a galeal hinge flap[21]. After purse-string placement, the galea aponeurotica adjacent to the scalp defect is scored with a scalpel, and a partial-thickness galeal flap of sufficient size to cover all or a portion of the exposed periosteum or bone may be dissected free and transposed into place, using the same motion as turning a page of a book. This hinged galeal tissue serves to recreate the vascular bed required for successful graft placement, and it permits repair of deep and often difficult scalp defects in a single operative session.

Burow's grafts

Defects of the nasal sidewall and dorsum, and sometimes of the forehead, lateral neck or other areas, may be repaired with Burow's grafts[9–11,22]. Because Burow's grafts utilize skin adjacent to the defect, they tend to provide a cosmetically superior match compared to grafts harvested from distant locations. These grafts are harvested from the skin superior to the defect if on the nose, and medial or lateral to the defect if on the forehead. The Burow's triangle is excised (see Ch. 146) and the resulting donor defect is closed primarily, thereby partially decreasing the original defect size. The triangle is defatted, trimmed, and sutured into the defect. Operating time is decreased because a separate donor site is not required. Burow's grafts tend to be limited in size. When insufficient laxity is present for partial donor site closure, or if the Burow's triangle does not appear to be sufficiently large to cover the remaining defect, alternative donor sites should be sought.

Deep nasal defects

Deep postsurgical defects on the nose may at times pose a challenge for repair. Delaying FTSG placement for 12 to 14 days may increase the likelihood of graft survival over defects of the nasal tip and ala with denuded cartilage[23]. Also, when tissue loss is deep in these areas, delaying skin grafting for 7 to 14 days may allow granulation tissue to fill in the defect such that a better contour may ultimately be achieved[23]. Because the early granulating wound produces an excellent vascular bed, delayed grafting may be considered in patients with reduced wound bed vascularity, e.g. those who smoke or have had previous radiotherapy. At the time of delayed graft placement, the wound bed is debrided by rubbing with dry gauze and the edges are refreshed by scraping the wound edges with a scalpel held perpendicular to the edge. Prophylactic antibiotics are often prescribed when placing delayed grafts.

If a depressed defect is anticipated, but immediate reconstruction is preferred, dermal grafts can be used as a tissue filler prior to FTSG placement[24]. Dermal grafts can effectively fill the defect, with little risk of resorption, and eliminate the need for a more complicated repair choice. The "drumhead" graft repair of deep nasal alar defects involves application of an overlying rigid plastic suspension coupled with an undersized graft, thereby preventing graft depression and nasal valve collapse; a cut portion of the periphery of the sterile plastic packaging from a suture packet can serve as the plastic suspension[25].

Perichondrial cutaneous grafts (PCCGs) are actually composite grafts composed of full-thickness skin and subjacent perichondrium, and may be used as a substitute for FTSGs when reconstructing deep nasal tip and alar defects, particularly those with exposed cartilage[26,27]. PCCGs are harvested from the conchal bowl, utilizing the subperichondrial plane as the plane of dissection. The cartilage is not removed, making this graft more analogous to a FTSG than a cartilage-containing composite graft. The advantages of PCCGs over FTSGs include the following: PCCGs are thicker, have a greater chance of survival under conditions of vascular compromise, contract less than FTSGs, and may achieve better skin texture match on the distal nose due to the sebaceous nature of conchal bowl skin.

Postoperative Complications

The complications of full-thickness grafting can be divided into short-term problems of graft failure and long-term functional and cosmetic problems[2,3]. Short-term problems include infection, hematoma, seroma, and shearing of the graft over its bed. These problems are significant when they occur, but can usually be avoided. Infection after grafting of facial defects, in particular, is not often encountered, and oral antibiotics are not routinely given postoperatively. Nevertheless, it is important to be gentle while handling tissue intraoperatively and to minimize devitalized tissue created by electrocoagulation in order to minimize the risk of infection. Prophylactic oral antibiotics covering *Staphylococcus* and *Streptococcus* spp. may be helpful in selected patients, especially those with diabetes mellitus, immunosuppression, or a prolonged intraoperative time. Grafts on the ears, fingers and legs may benefit from prophylactic antibiotics, as these sites seem more prone to postoperative wound infections.

Hematoma and seroma formation can be avoided by meticulous hemostasis intraoperatively, pressure dressings, and postoperative caution. After consultation with the patient's internist, cardiologist or primary care physician, patients may be instructed to avoid aspirin for 10 days before surgery, nonsteroidal anti-inflammatory drugs for 5 days before surgery, and alcohol for 2 days before and 2 days after surgery. Warfarin can often be discontinued 2 days before surgery and resumed the day after, based on the recommendations of the patient's internist or cardiologist. Patients are also advised not to engage in vigorous activity, heavy lifting or bending for at least 2 weeks postoperatively. The latter measures help to inhibit graft movement and supplement the bolster's effectiveness in minimizing shearing of the graft over its bed.

Long-term complications of FTSGs consist of cosmetic and functional problems. It is imperative to stress to the patient prior to graft placement that FTSGs usually take months to look natural. Preoperative counseling may help to alleviate fears concerning the graft's appearance during the first weeks after bolster removal. Make-up can usually be applied 3–4 weeks after graft placement. It is important to note that FTSGs are often depressed during their first 2–4 weeks. This depression will usually correct itself within 4–6 weeks.

Although careful donor site selection will minimize the color, texture and contour deformities that can occur, patient and physician satisfaction with the cosmetic result may not be complete after healing has finished. Spot dermabrasion or laser resurfacing may be performed after 6 weeks to 6 months to correct differences in elevation between the graft and its surrounding skin, as well as to improve color and texture

mismatch[28]. Resurfacing of the entire cosmetic unit may be helpful in optimizing the cosmetic result. Graft hyperpigmentation can be treated with a brief course of topical hydroquinone and/or tretinoin. The use of tretinoin pre- and postoperatively has not been shown to alter the healing of FTSGs[29].

Functional complications of FTSGs occur primarily as a result of wound contraction. Grafts contract secondary to the centripetal movement of unopposed elastic fibers. A variable amount of shrinkage can therefore be expected, depending upon donor site thickness and elasticity[6,30,31]. In one study, it was found that the area of FTSGs contracted by a mean of 38% by 16 weeks after placement, with grafts applied to the periorbital area and nose contracting more than those on the scalp and temples[30]. Graft contraction usually increases as graft thickness decreases, and is thought to occur in the fibrous layer under the graft, either in the bed itself or in the layer of scar tissue wedged between the graft and its bed[6]. Complications due to graft contraction are usually minimal in FTSGs. If wound contraction does produce functional or cosmetic abnormalities, secondary revisional surgery may be needed.

Future Directions

For patients with an inadequate vascular bed, full-thickness skin grafting may not be possible, necessitating repair with a less cosmetically elegant STSG. High-density porous polyethylene implants have therefore been designed which permit ingrowth of fibroneovascular tissue without changing the size or shape of the implant[32]. When these prefabricated implants were placed in rabbits, it was found that they developed sufficient vascularity to sustain FTSGs. This technology holds promise for patients with deep nasal and ear defects, in whom an anatomically correct structure could be implanted, after which, time could be allowed for fibrovascular tissue ingrowth, and full-thickness skin grafting performed later for a superior cosmetic result. Progress is also being made on incorporating complex blood vessels into bioengineered skin equivalents.

SPLIT-THICKNESS SKIN GRAFTS

Split-thickness skin grafts (STSGs) consist of epidermis and a portion of the dermis. These grafts vary in thickness from approximately 0.005 to 0.030 inches (0.13–0.78 mm), and are classified as thin, medium or thick, depending upon the amount of dermis included in the graft (Table 148.6).

Indications/Contraindications

STSGs have less tissue requiring revascularization than FTSGs, and are therefore more likely to survive when placed on almost any recipient bed, including those with a limited vascular supply. As a result, these grafts may be placed over periosteum, perichondrium, peritenon and perineurium. STSGs are also used to cover large defects, particularly those that cannot be covered by a flap or would heal too slowly by second intention, as well as refractory venous leg ulcers[2,3]. STSGs may be useful for covering surgical defects in sites at high risk for tumor recurrence, since recurrent tumor is usually visible when growing through split-thickness skin. If the tumor has not recurred after 1–2 years, the graft can be removed and a definitive reconstruction performed.

Advantages of STSGs over FTSGs include their improved chance of survival under conditions of vascular compromise, their ease of application, their ability to cover large defects, and their ability to act as a "window" for recurrence of high-risk lesions. The principal disadvantages of STSGs include their suboptimal cosmetic appearance, the presence of a granulating donor site wound requiring postoperative care, greater graft contraction, and the special equipment required to harvest larger grafts. Furthermore, because of their relative thinness, STSGs may be less durable than FTSGs, necessitating regrafting or partial healing by second intention.

While thicker STSGs tend to be cosmetically superior to thinner ones, poor color and texture match with the surrounding skin often occurs after STSG placement. STSGs tend to be pale or white in color, hairless, and smooth in texture, with impaired sweating due to the fact that adnexal structures are not removed in their entirety with the graft and do not survive. The contrast between the STSG and its surrounding skin can therefore produce a "tire-patch" appearance (Fig. 148.4), which is more pronounced than seen with FTSGs.

CLASSIFICATION OF SPLIT-THICKNESS SKIN GRAFTS	
Thin	0.005–0.012 in/0.13–0.31 mm
Medium	0.012–0.018 in/0.31–0.47 mm
Thick	0.018–0.030 in/0.47–0.78 mm

Table 148.6 Classification of split-thickness skin grafts.

Preoperative History and Donor Site Considerations

Cosmesis of the donor site scar should be taken into consideration when selecting a split-thickness donor site. The ease of postoperative donor site care and the type of instrument used to harvest the graft may also help to dictate donor site choice. Ideally, STSGs should be harvested from a site where a broad area of skin can be removed while still being concealed beneath clothing. The most common donor sites include the anterior, medial and lateral portions of the upper thigh, the inner and outer aspects of the upper arm, and the inner aspect of the forearm. Lower back and abdominal skin can also be harvested. The anteromedial thigh is most frequently used as the donor site for STSGs, as harvesting and wound care are convenient, and wounds in this location do not interfere with ambulation. Donor site wounds on the buttocks tend to require assisted postoperative care, although their scars are ideally placed from a cosmetic standpoint. Power-driven dermatomes and large freehand knives require large flat donor surfaces, which may limit donor sites to the thighs, abdomen and buttocks, while smaller grafts can be harvested freehand or with a power-driven dermatome.

Description of Grafting Techniques

A wide variety of techniques for harvesting and placing STSGs have been described[2,3,33]. The instruments used to harvest STSGs can be classified into freehand and electric dermatomes. Freehand dermatomes include scalpel blades, double-edged razor blades, and knives such as the Weck blade. Although acceptable grafts can be obtained using these freehand devices, considerable technical expertise is required to harvest them.

A standard #15, #15c or #10 blade can be an effective tool for harvesting small STSGs of medium thickness. After a template of the

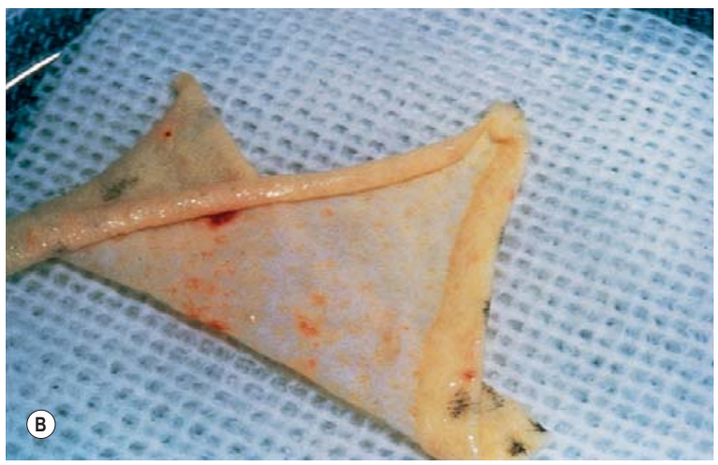
Fig. 148.4 Appearance of a split-thickness skin graft (STSG) on the forehead and scalp placed several years prior, following excision of a cutaneous melanoma. Note the relative hypopigmentation, altered texture and obvious depression of the STSG as compared to the normal surrounding skin. *Courtesy, Jean L Bolognia, MD.*

defect is made, the donor site is marked, anesthetized, and scored lightly with the blade. The graft is then harvested by orienting the blade parallel to the skin and gently sweeping it just below the level of the epidermis, so that the blade is visible beneath the skin (Fig. 148.5). It is helpful to have an assistant apply traction to the donor site while the graft is harvested. Several blades may be required for harvesting, as blade sharpness diminishes quickly with multiple passes. This technique may be especially useful in harvesting small medium-thickness STSGs to repair auricular and postauricular defects.

Fig. 148.5 Freehand harvesting of a small split-thickness skin graft from the upper outer arm. The blade is oriented parallel to the skin, and gently swept just below the level of the epidermis, so that it is just visible through the graft. An assistant applies traction to the donor site to facilitate harvesting.

Power-driven dermatomes became the standard method of harvesting larger STSGs after Brown developed the first such instrument in the 1940s. Electric dermatomes designed to harvest STSGs of varying thicknesses and widths, from several centimeters up to nearly 15 cm, are now commonly employed, and lithium ion battery-powered units are also available. Although STSGs can be obtained easily and reliably with any of these devices when properly used, the quality of the graft is technique-dependent, and substantial irregularity in graft thickness and width may at times occur. The Zimmer dermatome, which was originally powered by compressed water-pumped nitrogen and subsequently modified into an electrically powered version, tends to harvest uniform grafts of predetermined width and thickness such that consistent graft quality tends to be less dependent on the operator's technique. Multipurpose motor systems now exist which include a control box, foot switch and autoclavable motor that can be used not only with dermatomes, but also with diamond fraises for dermabrasion, adjustable skin graft meshers, and other types of surgical handpieces, allowing a wide array of procedures to be performed using a single unit.

After the dermatome is prepared, the donor and recipient sites are anesthetized, prepped and draped in the usual sterile fashion. If chlorhexidine surgical scrub is used, a saline wash is employed to remove any excess scrub. The donor site is lubricated in advance with sterile mineral oil or another lubricant to ease travel of the dermatome over the skin. The handpiece is held on the donor site at an angle of 30–45°. A throttle control is pressed to start the cut, and the unit is guided forward using light downward pressure to ensure that the cutting edge remains in continuous contact with the donor site. An assistant applies tension by pulling the skin away from the donor area to create a flat, even surface. As the dermatome glides over the donor skin, the graft emerges from the pocket area of the dermatome, and is lifted away from the machine with tissue forceps or hemostats (Fig. 148.6A). Once a sufficiently large graft has been harvested, the dermatome is pulled away from the skin and the graft is placed in sterile saline or on sterile saline-soaked gauze (Fig. 148.6B).



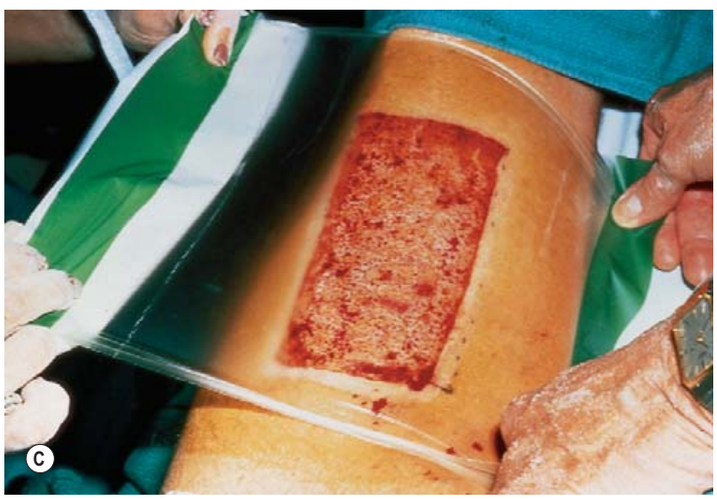


Fig. 148.6 Harvesting of a large split-thickness skin graft with an electric dermatome. A As the Zimmer dermatome glides over the donor skin, the graft emerges from the pocket area of the dermatome, and is lifted away from the machine with sterile hemostats. **B** Split-thickness skin graft placed on sterile saline-soaked gauze. Note that the edges curl inward toward the dermal surface of the graft. **C** An Opsite® dressing is placed over the donor site on the anterior thigh immediately after harvesting.

Securing the Graft

As in the case of FTSGs, STSGs should be secured so that infection, hematoma or seroma formation, and mechanical shearing forces can be prevented. Both the perimeter and the central portion of the graft must be secured for adequate nutritional support and to ensure graft survival. The edges of STSGs need not be as closely approximated to the surrounding wound edge as those of FTSGs, since overlapping skin will slough without affecting the ultimate cosmetic result. After the graft has been placed such that the dermal side is adherent to the recipient bed, the perimeter of the graft may be secured with sutures or staples. Centrally placed basting sutures may also be helpful in ensuring good apposition of the graft to its bed. Once the graft has been secured and its bolster sewn into place, a non-adhesive dressing or pressure dressing may be applied as an additional precaution. Sutures or staples are removed after 7–10 days.

Donor Site Care

Harvesting STSGs creates a second wound, the donor defect, which often causes more postoperative discomfort than the grafted area itself. This partial-thickness wound heals by second intention. While STSG donor sites were once treated with bulky occlusive dressings left in place for 10–14 days, the advent of transparent, vapor-permeable dressings such as Opsite® (Smith & Nephew) has made the postoperative period easier in terms of comfort and ease of care (Fig. 148.6C)[34]. These dressings are advantageous because they allow the serosanguineous drainage that inevitably accumulates at the donor site to collect, keeping the wound moist and thereby shortening healing time. Because these dressings are transparent, the wound can easily be observed for complications during the healing process. In one review, these dressings were found to be associated with the fastest healing rates, a low infection rate, the least amount of pain, and lower cost when compared with other dressings[35].

After the skin around the donor site area is cleaned and dried, a thin coat of an adhesive such as Mastisol® (Ferndale Laboratories) is applied around the wound and allowed to dry. An Opsite® dressing is then placed over the wound. Paper tape is placed around the perimeter of the Opsite®, followed by a gauze dressing and an Ace® wrap (Becton-Dickinson).

Variations/Unusual Situations

Meshing the graft with scalpel slits may be performed to allow drainage of accumulated blood or serosanguineous material that could otherwise inhibit graft–bed contact. This technique may also be used to expand the surface area of STSGs. A graft meshing machine may be utilized to expand the surface area of the graft further by ratios ranging from 3:1 to 9:1. Meshing can help to provide coverage of a large recipient area with smaller donor grafts. Expanded meshed grafts placed experimentally on contaminated recipient beds have been found to exhibit increased take as compared with non-meshed donor skin[36].

Postoperative Care

During the first 24 hours after grafting, a large amount of serosanguineous fluid may accumulate beneath the donor site dressing. Patients need to be forewarned of this so that they do not become alarmed. If this occurs, the fluid can be drained with a needle and syringe, and an Opsite® patch applied. Alternatively, a new Opsite® dressing can be placed. The dressing can then be left in place until healing is complete. Depending on the thickness of the STSG, the donor site should fully re-epithelialize in 7–21 days. The scar usually evolves in color from pink to white over a period of months.

Complications

The complications of split-thickness skin grafting can be divided into early complications, which stem from failure of engraftment, and late complications[2,3]. Failure of engraftment may result from hematoma or seroma formation, infection, or shearing forces. Late complications can be divided into cosmetic and functional problems (Fig. 148.7).

Color and texture mismatch of STSGs with the surrounding skin is predictable and expected. Grafts often remain erythematous for months to years after placement. More importantly, they may exhibit significant postoperative hyperpigmentation or hypopigmentation. Darker-skinned patients are especially prone to graft hyperpigmentation, despite observance of preventive measures. Patients should minimize graft exposure to the sun without sunscreens for 6 months, and wear sunscreens consistently thereafter. The absence of adnexal structures can predispose to xerosis and a build-up of keratinous debris. The resultant scaling, pruritus and dryness can be minimized with liberal use of emollients.

Functional considerations are of paramount concern, since STSGs contract more than FTSGs and can create forces powerful enough to produce joint contraction if placed over or near joints. Contraction of facial grafts, especially near the nasal ala, the eyelid, the helical rim and the free margins of the vermilion border, may produce significant cosmetic deformities, including alar retraction, ectropion, helical rim distortion and vermilion border distortion. Hypertrophic scarring of the graft and donor sites may also occur, and can be treated with corticosteroid-impregnated tape, intralesional corticosteroids, or pulsed dye laser. Graft fragility and breakdown can occur in areas of trauma, particularly in sites such as the lower leg, or in areas with little underlying soft tissue support, such as those directly overlying perichondrium or periosteum. These complications are not always avoidable, but forewarning patients may reduce unnecessary trauma to the area. Lastly, bullae can occur within graft sites, presumably related to decreased anchoring properties of the basement membrane zone (see Ch. 33).

Future Directions

In recent years, biosynthetic and tissue-engineered living skin replacements have been the focus of research in skin transplantation[37–39]. Cultured human keratinocytes have been seeded onto type I collagen membranes to reconstitute the epidermis, enabling transfer of actively proliferating keratinocytes onto partial-thickness wounds. Human epidermal tissues mimicking the biochemical and morphologic properties of human skin have been established *in vitro* by growing human keratinocytes on a dermal fibroblast-containing collagen gel. Such skin-equivalent cultures may hold promise in reconstituting the epidermis in patients with full-thickness burn wounds and chronic ulcers (see Ch. 145).

Artificial dermis is now routinely used prior to full-thickness grafting, and an acellular allograft dermal matrix has been shown to provide a good bed for STSGs in patients with full- and partial-thickness burns. A tissue-engineered human skin equivalent, i.e. a bilayered product containing living human fibroblasts, keratinocytes and bovine collagen, is commercially available for the repair of surgical defects and coverage of lower leg ulcers that would previously have been repaired with STSGs. Dermal–epidermal composites using autologous keratinocytes and human allodermis may in the future be used for grafting full-thickness wounds in patients with burns, leg ulcers or surgical wounds.

COMPOSITE GRAFTS

Indications/Contraindications

Composite grafts are modified FTSGs, consisting of two or more tissue layers. In dermatologic surgery, these grafts are usually composed of skin and cartilage, although they may be composed of skin and fat or skin and perichondrium[3,26,40–47]. Composite grafts are especially useful for repairing full-thickness alar rim defects, as well as nasal tip defects with cartilage loss[45,46]. Full-thickness nasal mucosal defects can be repaired using composite grafts to provide mucosal lining and structural support, with a nasolabial or forehead flap placed thereafter to reconstruct the overlying soft tissue defect. As discussed earlier, conchal bowl composite grafts or PCCGs, consisting of skin and perichondrium, may be used (with or without an underlying cartilage graft) for deeper nasal defects requiring skin coverage, especially defects with exposed cartilage[47].

Preoperative History and Considerations

Composite grafts require rapid revascularization to survive. Early re-establishment of circulation occurs via direct vessel anastomoses between the subdermal plexus of the graft and the subdermal plexus of the wound edge. Since composite grafts are dependent upon this

Fig. 148.7 Late complications of skin grafts. A Hyperpigmentation of an entire STSG placed following excision of an *in situ* ungual melanoma; the sites of suture placement also developed hyperpigmentation. Increased scaling compared to the surrounding skin is commonly observed. **B** Hypertrophic scarring of a STSG placed following partial excision of a large congenital melanocytic nevus on the arm 1 year prior; the skin overlying the elbow was not excised, in an attempt to prevent joint contraction. **C** Mismatch of color, texture and hair density in a skin graft of abdominal skin placed on the face following excision of a congenital melanocytic nevus. **D** Growth of hair within a graft placed on the inner aspect of the foot following excision of a cutaneous melanoma. *Courtesy, Jean L Bolognia, MD.*

bridging phenomenon for their survival, they are of necessity limited in size, with no point being more than 1 cm from a vascular source, as the risk of central necrosis increases significantly at graft diameters greater than 2 cm[3,46]. Composite grafts for nasal alar and ear reconstruction are possible because of the rich vascular supply of the nose and ear, and because of the small surface areas generally involved. Composite grafts, like FTSGs, are threatened by excessive shearing forces on the graft over its bed, which prevent revascularization.

During the healing process, composite grafts pass through four stages[3,46]. After graft placement, the tissue blanches completely. By 6 hours, the graft becomes pale pink, signifying anastomosis of the graft vessels with those of the recipient site. At 12–24 hours, the graft appears dusky blue, reflecting venous congestion, and by 3–7 days, it should be pink, indicating graft survival.

Donor Site Considerations for Composite Grafts

The complexity of nasal alar anatomy makes reconstruction of full-thickness defects involving this area difficult. There may be insufficient nasal skin to develop adequate local flaps, and nasolabial flaps, which provide reasonable defect coverage, generate other cosmetic deformities. The loss of alar tissue support also creates a functional deficit, as the alar skin is liable literally to "blow in the breeze" on inspiration and expiration. Composite grafts provide an excellent cosmetic and functional alternative for repair of full-thickness alar rim defects less than 2 cm in diameter[46]. Grafts taken from the earlobe have been used successfully for this type of repair, although grafts taken from the cartilaginous portion of the ear are more frequently used[41,44,45].

Donor sites for harvesting auricular composite grafts include the helical crus, helical rim and conchal bowl (see Ch. 142)[44–47]. Small alar defects involving loss of cartilage can be elegantly repaired using the helical crus as donor site, while more substantial defects may require repair using the helical rim or conchal bowl, since the crus may not provide sufficient inner lining for the graft. Donor defects involving the helical crus can be repaired with minimal scar formation, while wedge excisions are usually necessary to repair helical rim donor sites. Conchal bowl donor sites heal by second intention.

The advantages of auricular composite grafts in repairing full-thickness alar rim defects relate mainly to the presence of cartilage, which provides structural support and stability, with prevention of alar distortion during inspiration and at rest[45,47]. Disadvantages include a higher risk of graft failure with an increased number of tissue layers, substantial graft size limitations, and limited donor tissue availability. Nevertheless, these grafts, when properly applied, can yield outstanding results.

Composite grafts used for full-thickness nasal mucosal repair are usually obtained from the triangular fossa, scapha, conchal cavum, cymba or helical crus (see Fig. 142.14). The appropriate donor site is that which best matches the contour of the surgical defect. These donor sites are usually allowed to heal by second intention, with good aesthetic outcomes.

Description of Technique

Composite grafts used for alar repair are performed as follows (Fig. 148.8)[40,45,47]. The donor and recipient sites are anesthetized using local anesthesia, and prepped with an antiseptic solution. If the alar tissue is scarred and retracted, the area must be vigorously debrided to assure the best possible blood supply for the graft. The defect is then measured and a template made as described previously. The donor site is marked and anesthetized, and the graft is harvested. The tissue is handled very gently and placed in sterile saline until ready for placement.

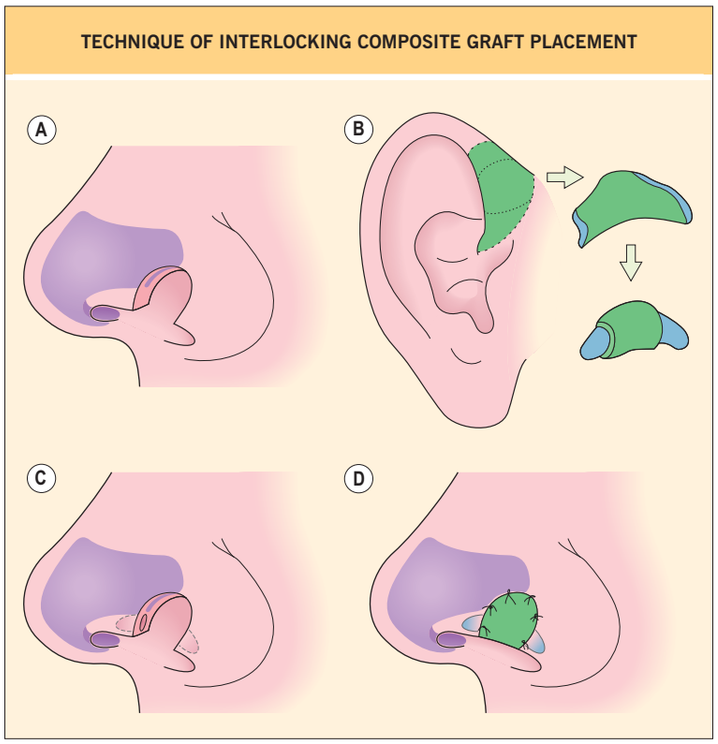

Fig. 148.8 Technique of interlocking composite graft placement. A A full-thickness nasal alar defect extending through both skin and cartilage requires repair. **B** Donor site at the crus of the helix. An area of skin approximately 5–10% greater in area than the actual defect is marked out, with cartilaginous wings marked out on either side. After the graft is harvested, the skin is removed on both sides to expose the cartilaginous portion of the graft, such that two cartilaginous pegs with their overlying perichondrium frame the lateral aspects of the graft. **C** A pocket is undermined on either side of the recipient site, into which the cartilaginous pegs will be placed. **D** The cartilaginous pegs are inserted into the holes prepared within the alar tissue on either side of the defect. The graft is then sutured into place.

Due to the fragility of composite grafts, a tongue-in-groove technique is recommended to maximize graft stability and increase graft survival[45,47]. Two cartilaginous wings are marked out and anesthetized on either side of the donor site prior to graft harvesting. After the graft is harvested, the skin overlying these two cartilaginous wings is removed, leaving the cartilage with its overlying perichondrium (Fig. 148.8B). These wings are then inserted into pockets prepared within the alar tissue of both sides of the defect (Fig. 148.8C) such that the graft interlocks with its recipient bed (Fig. 148.8D). Interlocking the graft with its bed may help to minimize shearing forces and provide a larger surface area for revascularization.

The graft is sutured into place in two layers. The undersurface of the graft, which replaces the inner lining of the nose, can be secured first using a 6-0 absorbable suture. The skin is then closed with a 6-0 nonabsorbable suture, taking very small tissue bites to minimize vessel strangulation and to maximize the number of potential vessels available for reanastomosis. The needle should pass through the mucosal portion of the graft first, then through the outer epithelial edge of the graft, so that the knots are tied externally, and are not buried between the graft and its recipient bed. The cartilage does not need to be sutured, as it will heal on its own. A Vaseline® gauze or Xeroform™ dressing can then be placed in the nasal vestibule for support, and antibiotic ointment applied to the external suture line. A non-stick dressing is then applied to protect the graft from external injury.

Conchal bowl composite grafts used for reconstruction of deep alar defects are harvested in essentially the same way as composite grafts taken from the helical crus[47]. Potential advantages of the conchal bowl technique include increased bulk, which may be superior in filling deep partial-thickness alar defects, and an excellent cosmetic match for the missing sebaceous skin of the nose.

Donor Site Closure[48]

Helical crus defects can often be closed in a side-to-side fashion. A simple advancement, rotation or transposition flap may also be utilized to take advantage of loose preauricular skin. Helical rim defects are usually closed with an ear wedge resection. Auricular grafts obtained from the triangular fossa, scapha, conchal bowl or cymba heal well by second intention. Conchal bowl defects may heal more rapidly if a 2 mm punch biopsy instrument is used to remove small plugs of conchal cartilage, which allows healing by second intention from the soft tissue on the opposite side.

Variations/Unusual Situations

When securing composite grafts onto the nasal ala, delayed intranasal knot tying has been recommended by some authors to facilitate wound closure by improving visualization, allowing gentler manipulation of tissue, and enabling precise suture placement in a confined space[49]. When placing the intranasal sutures, the needle of the 6-0 fast-absorbing chromic gut suture is first passed through the nasal mucosa, and then through the corresponding location on the "mucosal" side of the graft. Sutures are placed at 1–2 mm intervals along the defect and graft, and their free ends are held separately by hemostats to prevent tangling. After all intranasal sutures are placed, the composite graft may be placed into the alar defect and the cartilaginous wings inserted. The most internal intranasal sutures are then tied first, followed by the more accessible external sutures.

Postoperative Care

To minimize graft edema, ice packs should be applied to the grafted area as often as possible for up to several days postoperatively to minimize graft edema. Oral antibiotics are generally advisable because of the high bacterial colonization around the nares and the higher risk of failure with composite grafts. Sutures are removed after 1 week.

Complications

As with other types of grafts, there is a risk of necrosis in the early stages of healing, and contraction, textural changes, atrophy and contour irregularities thereafter. If the graft survives but the cosmetic result is suboptimal, dermabrasion or laser resurfacing may be performed 6 weeks to 6 months postoperatively to correct textural differences between the graft and the surrounding skin, and to improve the color match between them. Resurfacing of the entire cosmetic unit may provide superior cosmetic results. In the event of composite graft failure, a two-stage revision with placement of a cheek interpolation flap may be performed or, alternatively, a second composite grafting procedure may be undertaken.

Conchal bowl donor sites are at somewhat greater risk of postoperative bleeding than other areas if left to heal by second intention. Application of pressure dressings over the front and back of the ear to "sandwich" the conchal cartilage with placement of hemostatic foam over the donor site itself may decrease this risk. Other types of complications at auricular donor sites are rare[48].

The ear is also prone to infection with *Pseudomonas* spp., which reside in the external auditory meatus. Cleaning the ear with a dilute vinegar solution, applying topical gentamicin ointment, and oral quinolone antibiotics are all helpful prophylactic measures which should be considered after harvesting auricular cartilage. If infection is suspected, oral quinolone antibiotics should be started immediately, and therapy guided thereafter by the results of cultures and sensitivities. If the infection does not resolve with appropriate antibiotics, the presence of a fungal infection, most often secondary to *Candida*, should be excluded.

FREE CARTILAGE GRAFTS

Indications/Contraindications

Free cartilage grafts are used most commonly in dermatologic surgery to reconstruct the nasal ala, tip and sidewall, the ear, and the eyelid[40,42,49–51]. These grafts may be used to restore the architecture of an anatomic site that has undergone significant cartilage loss. Free cartilage grafts

are also useful in maintaining the position and contour of free margins against the forces of contraction during wound healing.

Nasal Ala

Partial-thickness alar defects extending into deep soft tissue or approaching the alar rim often lead to alar rim collapse, producing a functional as well as a cosmetic deficit. Placement of free cartilage grafts, consisting of cartilage with its overlying perichondrium, can be used to avert this potential problem[50–53]. The grafted cartilage provides a rigid but flexible cartilaginous framework that braces the alar rim against collapse during inspiration and expiration. Cartilage grafts may be used in conjunction with flaps and FTSGs to maintain airway patency and to minimize the risk of alar retraction during wound healing[42,49–51].

The major usefulness of the free cartilage graft lies in its ability to prevent alar retraction. It is possible that long-term survival of the cartilage itself may not ultimately be important, as the mere presence of the rigid framework of the graft in the initial stages of wound healing seems to be sufficient to inhibit alar retraction.

Nasal Sidewall and Tip

Deep defects of the nasal sidewall may, at times, involve loss of the upper lateral nasal cartilage. Nasal valve obstruction may result, which becomes noticeable with inspiration and resolves on expiration. Delayed nasal valve obstruction can also occur if unresisted scar contracture collapses the remaining cartilaginous structure of the nasal sidewall. Replacement of lost cartilage at the time of reconstruction can avert these potential problems. Similarly, loss of cartilage at the distal nasal tip necessitates replacement of structural support for optimal function and cosmesis.

Ear

Auricular defects involving loss of cartilage are generally repaired for cosmetic, rather than functional, reasons. Cartilage grafts may be used as braces along the helical rim to minimize the risk of contracture, and may also be used in the conchal bowl to assist in hearing-aid placement[40].

Preoperative History and Donor Site Considerations

Potential donor sites for free cartilage grafts include the conchal bowl, the auricular helix, the antihelix, nasal septum, and ribs[40]. The conchal bowl is the donor site most frequently used by dermatologic surgeons[42,46,51]. Conchal cartilage is elastic, has a high degree of memory, and has varied contours that can be matched to the desired alar contour. Although an anterior approach to the conchal bowl may be used, the posterior approach results in better camouflage of the donor site scar and preservation of the shape of the ear. If the antihelix is used as a donor site, it is recommended that subtotal resection of the antihelical cartilage be performed, leaving a complete rim of intact cartilage to prevent distortion.

Description of Technique

Nasal ala

The techniques for alar batten cartilage grafting have been well described[40,42,46,49]. The alar batten provides a rigid but flexible cartilaginous framework to brace the alar rim against collapse. The length of the cartilage graft is determined by measuring the distance between the lateral and medial borders of the defect at the alar rim, and adding to that measurement an extra 4–5 mm. The conchal bowl donor site is incised anteriorly or posteriorly. The skin overlying the cartilage is then undermined with blunt-scissor dissection to expose the perichondrial surface. The desired length of cartilage is incised with a scalpel (Fig. 148.9A), and a second incision is made exactly parallel to the first, creating a cartilaginous strip that may be 3–6 mm in width, depending upon the desired width of the graft. Alternatively, a larger disk or oblong-shaped piece may be harvested to match the base of the defect. The cartilage is easily separated from the anterior skin with sharp-scissor dissection. The graft is placed in sterile saline while the donor site is reapproximated with non-absorbable sutures.

The cartilaginous strip graft is secured by undermining the soft tissue of the recipient bed medially and laterally with a hemostat or blunt-scissor dissection, and the ends of the graft are inserted into the undermined pockets such that the graft interlocks with its bed (Fig. 148.9B). The graft is anchored to its bed with one or two 5-0 absorbable sutures for additional security. A disk- or oblong-shaped cartilage graft also requires suturing for secure placement.

After the graft has been anchored, a nasolabial transposition flap or FTSG is sutured into place to complete the closure (Fig. 148.9C,D). A standard tie-over bolster is placed over the FTSG and secured with 5-0 non-absorbable sutures. Sutures are removed at 1 week.

Nasal sidewall and tip

Free cartilage grafts used for nasal sidewall and tip reconstruction are harvested in much the same way as free cartilage grafts for alar reconstruction[40]. Nasal sidewall grafts tend to be wider and broader than alar grafts, since they must brace a broader surface area against the forces of inspiration. Alternatively, multiple cartilaginous strips can be placed perpendicular to the lateral nasal sidewall, and then secured with absorbable or non-absorbable sutures to brace the side of the nose against collapse. After the cartilaginous structure is in place, a flap or FTSG may be performed to cover the remaining cutaneous defect.

Nasal tip grafts for distal nasal reconstruction are organized to provide both proximal and distal structural support, thus optimizing the aesthetic and functional result[40,49,50]. The proximal grafts consist of bilateral batten grafts secured to the lateral cartilages with 5-0 or 6-0 non-absorbable sutures. On top of these may be sewn a dorsal nasal cartilage graft. A columellar strut of cartilage often provides distal support, on top of which may be sewn an additional tip graft. Alar batten grafts secured to the columellar strut and lateral alar soft tissue provide alar rim support. A paramedian forehead flap or melolabial interpolation flap may be placed thereafter to provide coverage of the cutaneous defect.

Ear

If conchal cartilage is used to repair a large helical defect, the cartilage graft should match the defect as closely as possible in size and shape[40]. Harvesting and placing a narrow strip of cartilage matching the helical defect alone will result in helical rim collapse under the forces of wound contraction. If necessary, a partial wedge closure of the defect may be performed to decrease the portion of the defect requiring replacement of structural support. The cartilage graft is secured by sewing it to the intact cartilaginous framework with 6-0 absorbable or non-absorbable sutures. The graft is then generally covered with a pedicled retroauricular advancement flap.

Eyelid

Partial-thickness lower eyelid defects with loss of the tarsal plate, as well as full-thickness lower eyelid defects, may be repaired with cartilage grafts. Stabilization of the eyelid with free cartilage grafts provides structural support, minimizing the risk of ectropion and preventing corneal desiccation. The technique for performing free cartilage grafts to repair full-thickness and partial-thickness lower eyelid defects is beyond the scope of this chapter, but is well described by Otley and Sherris[40].

Postoperative Care

Regardless of the site of free cartilage grafting, care must be taken postoperatively to minimize movement of the graft. Routine wound care is performed to the flap or graft overlying the free cartilage graft. Trauma to the area should be minimized.

Complications

Postoperative complications following cartilage grafting are rare. There is a risk of postoperative infection at the conchal bowl donor site, particularly with Gram-negative bacilli, which reside within the external auditory meatus. Appropriate bacterial and fungal cultures of any tissue

Fig. 148.9 Harvesting and placement of a free cartilage graft. A The posterior conchal bowl donor site has been incised to the level of the perichondrium. The desired length of cartilage was incised with the scalpel, and a second incision made parallel to the first to isolate a cartilaginous strip with its overlying perichondrium. **B** The ends of the cartilaginous strip with its overlying perichondrium have been inserted into pockets undermined on either side of the recipient bed, such that the graft interlocks with its recipient bed on the left nasal ala. The graft is sutured to the underlying dermis with one 5-0 absorbable suture for additional security. **C** A full-thickness skin graft has been sutured into place over the free cartilage graft. **D.** Eight-week postoperative view of the full-thickness skin graft and underlying free cartilage graft on the left nasal ala. The alar rim remains in perfect alignment.

exudate should be obtained if infection is suspected. Empiric therapy with quinolone antibiotics should be initiated, and modified as sensitivities dictate. When prophylactic antibiotics and appropriate operative technique are used, the risk of suppurative chondritis is extremely low[52].

Postoperative tenderness, swelling and erythema may herald inflammatory chondritis or perichondritis, which should be treated with cool compresses and nonsteroidal anti-inflammatory drugs for several weeks or even months postoperatively.

Later complications may include graft resorption, displacement or deformation after placement, and extrusion. Surgical revision may be required if these complications occur. Auricular and nasal recipient sites are subject to trauma and are therefore at increased risk of graft displacement and resorption. Every effort should therefore be made intraoperatively to utilize grafts of sufficient thickness and stiffness to resist the forces of trauma and wound contracture, and to anchor these grafts so as to maximize their stability.

Future Trends

While autologous cartilage is considered to be the optimal grafting material due to its pliability, accessibility, and ease of harvesting under local anesthesia, its supply may be limited, and harvesting may entail additional morbidity for the patient. Other implantable materials for nasal reconstruction have been investigated, including porous, high-density polyethylene implants[53]. Such implants have shown the ability to heal by second intention and support skin grafts when used to reconstruct auricular cartilage in rabbits[53]. They were also well tolerated as replacements for native cartilage in patients requiring rhinoplasty or nasal reconstruction[54].

Tissue engineering has been used to generate autologous cartilage implants to fill defects of the nose or outer ear[55]. Chondrocytes can be stimulated with growth factors to increase their proliferative rate and extracellular matrix production. Such chondrocytes, when implanted on a resorbable synthetic scaffold, can thereby be induced to produce three-dimensional aggregates of cartilage. In a recent study, collagen lattices containing cultured chondrocytes implanted into rabbit auricular cartilage generated new cartilage within 5 weeks[56]. *In vitro* engineering of human cartilage could be the ideal replacement method, without the risk of infection and with the possibility of reconstructing large defects with different configurations[55]. These and newer implantable materials will, over time, become increasingly available, and will certainly be useful to dermatologic surgeons who perform nasal reconstruction.

CONCLUSIONS

A working knowledge of the indications, techniques, donor site considerations, and postoperative complications of all types of skin grafts is necessary for soft tissue reconstruction. As the incidence of skin cancer continues to rise, increasing numbers of patients are likely to require reconstructive procedures to repair their defects. Furthermore, split-thickness skin grafting for lower extremity ulcers is an effective, reasonable treatment for patients with refractory leg ulcers. With proper defect assessment, reconstructive planning, and attention to detail preoperatively, intraoperatively and postoperatively, optimal cosmetic and functional results using grafting techniques can be achieved. A thorough understanding of skin grafting is invaluable for all physicians performing reconstructive surgery.

Key features

- A thorough understanding of the anatomy and physiology of the nail unit is crucial to performing successful nail surgery
- The nail matrix forms the nail plate; damage to the nail matrix (including from surgical procedures) can cause permanent nail dystrophy
- There is no subcutaneous tissue in the nail unit, so the dermis of the nail bed sits on the periosteum of the distal digit
- Preoperative evaluation prior to nail surgery is essential and should include a radiograph of the digit when a subungual tumor is suspected

INTRODUCTION

Nail surgery allows the dermatologist to diagnose clinically ambiguous nail lesions or dystrophies, remove nail tumors, and alleviate pain caused by ingrown or traumatized nails. The major goal of nail surgery is to achieve the desired diagnosis or outcome by performing the procedure safely with minimal pain and scarring[1]. Because dermatologists are the physicians who understand and manage nail disorders, they are well suited to perform nail surgery. A solid grasp of the anatomy and physiology of the nail unit is a prerequisite for successful nail surgery. Other necessities for an optimal outcome include a well-prepared patient, adequate anesthesia and hemostasis, and proper technique (Table 149.1).

SURGICAL ANATOMY OF THE NAIL UNIT

The structures that comprise the nail unit are the nail matrix, the proximal and lateral nail folds, the hyponychium and the nail bed (Fig. 149.1). The nail matrix is the most vital component of the nail unit, because it is the germinative epithelium from which the nail plate is generated via differentiation of matrix keratinocytes. The distal third of the nail matrix is sometimes visible through the proximal nail plate as the white half-moon-shaped structure called the lunula. Whereas the proximal nail matrix forms the superficial (dorsal) surface of the nail plate, the distal nail matrix forms the inferior (ventral) portion of the nail plate (Fig. 149.2). This observation is key to understanding the clinical presentations of certain pathologic processes and nail tumors and it provides a rationale for basic nail surgery principles and techniques. For example, given that damage to the matrix can cause permanent nail dystrophy, distal matrix surgery is preferable to proximal matrix surgery, since a defect due to the former would be less obvious on the undersurface of the nail plate[2,3].

The nail bed, sometimes referred to as the sterile matrix, extends from the distal lunula to the hyponychium. Its rich vascular supply results in the pink color of the nail bed that is seen through the translucent nail plate. The nail bed is composed of longitudinal ridges and grooves, which explains clinical phenomena such as the longitudinal orientation of splinter hemorrhages. While the bulk of the nail plate is formed by the nail matrix, the nail bed probably contributes a few epithelial cells to the undersurface of the nail plate, which helps to explain the tight adhesion of the nail plate to the nail bed. Surgery of the nail bed rarely leads to permanent dystrophy of the nail apparatus, but it may result in mild onycholysis. An important feature of the nail bed is that there is no subcutaneous tissue beneath it. The dermis of the nail bed sits directly on the periosteum of the distal digit. The lack of subcutaneous tissue in the nail unit explains why nail surgical specimens extend to the level of the periosteum.

The proximal and lateral nail folds support and protect the nail plate. The end product of the proximal nail fold is the cuticle, which adheres tightly to the proximal nail plate and seals and protects the nail unit from environmental pathogens and irritants. The insertion of the extensor tendon of the digit is approximately 12 mm proximal to the cuticle, and is usually proximal to the surgical field in all but the most extensive nail surgery. The proximal and lateral nail folds are collectively called the paronychium. The perionychium consists of the paronychium plus the hyponychium and nail bed[4].

The hyponychium is located under the free edge of the nail plate. It begins at the most distal part of the nail bed (in the region just proximal to the distal groove) and then becomes contiguous with the volar skin of the digit. Like the cuticle, the hyponychium also functions to seal and protect the nail unit from environmental factors. Disruption of the hyponychium by trauma or disease can result in onycholysis with subsequent bacterial and fungal infections.

Sensory Nerves and Anesthesia of the Nail Unit

For patient acceptance of nail surgery, complete anesthesia and a resultant pain-free procedure are mandatory. The sensory nerves to the nail course along the lateral sides of the digit in close approximation to the digital arteries. Anesthesia can be administered as a digital block and/or a wing block. In a digital block, 2–3 ml of 1% or 2% plain lidocaine (without epinephrine [adrenaline]) is injected superficially into the base of the digit on both lateral sides with a 30-gauge needle (Fig. 149.3). To prevent vasospasm and tamponade of the vessels, the volume of local anesthetic should be less than 1.0–1.5 ml on each side of the digit.

An adjunctive or alternative anesthetic approach is a paronychial or wing block in which plain lidocaine is injected into the proximal and lateral nail folds. A small volume of anesthetic is injected, which blanches the skin of the nail fold and may help somewhat with hemostasis. The wing block has several advantages over the digital ring block: (1) the onset of action is more rapid; (2) less volume is required; (3) the injection is more comfortable; and (4) if using epinephrine, there is minimal risk of intra-arterial injection, due to the much smaller diameter of the distal vessels. It is sometimes useful to inject a long-acting anesthetic (e.g. bupivacaine, ropivacaine) around the nail unit at the end of the procedure to provide more prolonged anesthesia, sometimes lasting up to 12 hours.

Although the dogma in nail surgery has been to avoid the use of epinephrine in digital blocks, several recent comprehensive reviews describe the safe use of lidocaine with epinephrine in the digits of

PREREQUISITES FOR SUCCESSFUL NAIL SURGERY OR NAIL BIOPSY
1. Understanding of nail anatomy and physiology
2. Proper patient selection and preparation
3. Adequate anesthesia
4. Hemostasis
5. A nail condition that has eluded diagnosis by routine clinical inspection, history, diagnostic (radiologic) imaging and/or microbiologic evaluation
6. A dermatopathologist who is familiar with the histopathologic idiosyncrasies of the nail unit

Table 149.1 Prerequisites for successful nail surgery or nail biopsy.

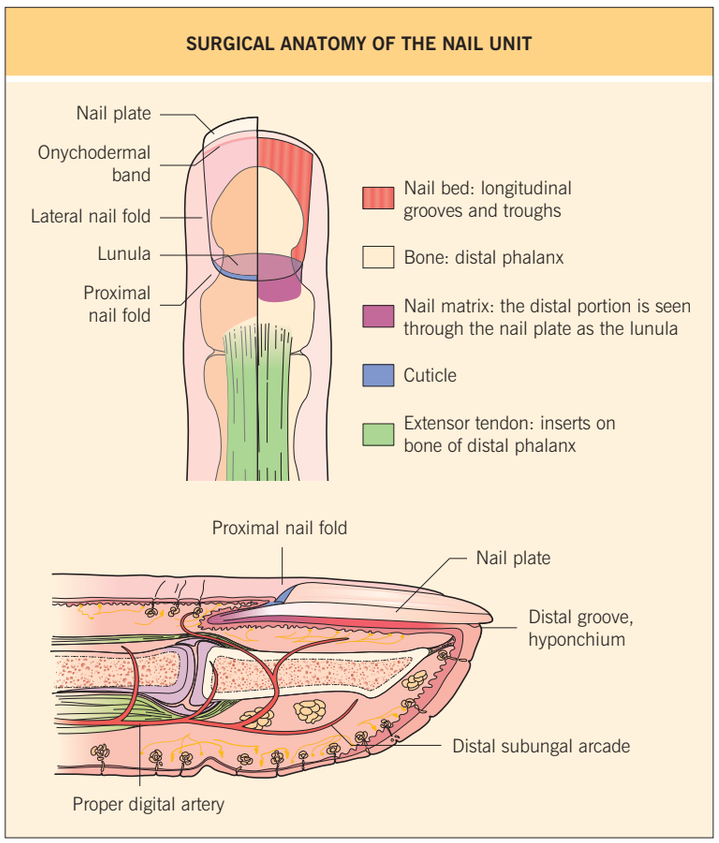

Fig. 149.1 Surgical anatomy of the nail unit.

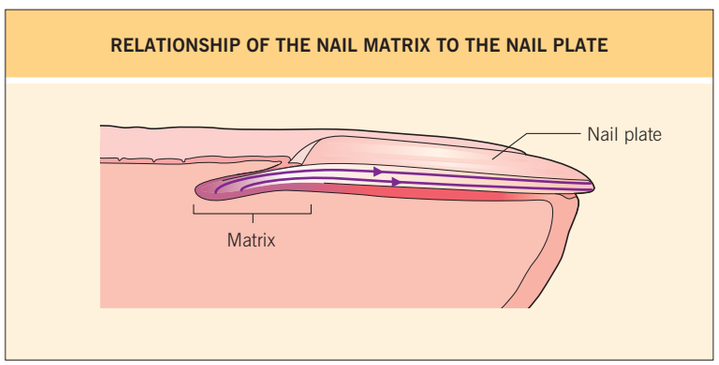

Fig. 149.2 Relationship of the nail matrix to the nail plate. The proximal part of the nail matrix forms the superficial (dorsal) nail surface; the distal portion of the matrix forms the inferior (ventral) portion of the nail plate. Hence, surgery to the distal matrix is preferable to surgery of the proximal matrix, because, if there is scarring, that associated with the former will be on the undersurface of the nail plate and therefore less obvious.

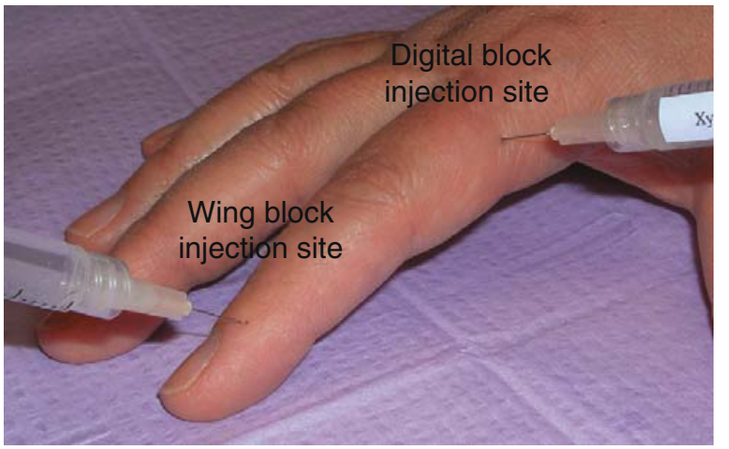

Fig. 149.3 The location of lidocaine injections for a wing block and a digital block.

patients with no history of vascular disease[5]. The author has safely performed over 200 nail procedures using a wing block and a low concentration of epinephrine (1 : 200 000), obtained by mixing lidocaine with 1 : 100 000 epinephrine and lidocaine without epinephrine in a 1 : 1 ratio. Within 15 minutes there is excellent anesthesia and usually no need for a tourniquet for hemostasis. Some nail surgeons use a 1 : 4 ratio (final concentration of epinephrine 1 : 500 000), but then there is less hemostasis and a tourniquet may be required.

Vascular Supply of the Nail Unit and Hemostasis

The proper and lateral digital arteries course along the lateral sides of the digit and represent the main blood supply to the nail unit. The proper digital arteries give rise to branches that form the superficial arcade supplying the nail fold and matrix, as well as a second arcade that feeds the bone, distal nail bed, and hyponychial area (see Fig. 149.1).

Hemostasis is necessary to adequately visualize the surgical field. Although a tourniquet is often not necessary for nail surgery, when one is used, it should be a flat Penrose drain so as not to be too constrictive. Rubber bands should not be used as tourniquets because of the potential for lateral digital nerve damage, and any tourniquet should not be left in place for more than 15 minutes. An assistant applying pressure to the sides of the digit during the procedure usually achieves hemostasis without resorting to a tourniquet. A sterile glove on the patient's hand is sometimes used to impart a sterile field while also providing hemostasis. The tip of the glove finger is removed, and the remainder is rolled back past the affected nail to the base of the finger to act as a gentle tourniquet and to provide a sterile field for the nail surgery (Fig. 149.4).

PATIENT PREPARATION AND PREOPERATIVE EVALUATION

A well-prepared patient facilitates a successful surgical procedure (see Ch. 151). A complete history and appropriate clinical examination of the nail unit are paramount. The history should include prescribed medications (especially anticoagulants and antiplatelet agents) and supplements (see Ch. 133) in addition to a review of systems, with particular attention to the presence or absence of diabetes mellitus, autoimmune connective tissue diseases, peripheral vascular disease, cutaneous conditions with nail manifestations, and prosthetic valves and joints (Table 149.2). Physical examination should include inspection of all 20 nails as well as palpation of peripheral pulses. Appropriate laboratory tests for bacteria, fungi and/or viruses should be obtained when there is a possibility of infection. Radiographic studies to define space-occupying lesions and underlying bony defects are often necessary prior to nail surgery. A full "procedure, alternatives and risks" (PAR) discussion should include the possibility of permanent nail dystrophy, bleeding, pain and infection. While not mandatory, clinical photographs of the preoperative nail are usually worthwhile. The digit is then washed with alcohol or a surgical soap such as chlorhexidine (e.g. Hibiclens®) or

Fig. 149.4 Sterile glove used as a tourniquet and sterile field. The tip of the glove finger is removed, then the remainder is rolled back to the base of the finger.

Fig. 149.5 Instruments used in nail surgery. Freer septum elevator, English nail splitter, and double-action nail clipper (left to right).

PATIENT EVALUATION PRIOR TO NAIL SURGERY
HISTORY

• Medical history
  • Diabetes mellitus
  • Peripheral vascular disease
  • Autoimmune connective tissue disease
  • Raynaud's phenomenon
  • Arthritis
  • Prosthetic joints or heart valves
  • Bleeding diathesis
• Drug history
  • Allergies
  • Use of anticoagulants, antiplatelet agents (salicylates, clopidogrel, NSAIDs)
  • Use of herbal medicine
• Cutaneous history
  • History of the nail condition (duration, progression, exposures, trauma)
  • Psoriasis, lichen planus or other cutaneous disorders with nail manifestations
  • Previous malignancies
  • Previous fungal, bacterial and/or viral cultures or diagnostic tests
  • Occupation and hobbies

EXAMINATION
• All 20 nails, good lighting and magnification • Mucous membranes, hair and scalp • Pertinent cutaneous examination • Peripheral pulses, especially in toenail surgery
LABORATORY TESTS
• Radiography, diagnostic imaging studies (e.g. MRI) • Mycology, microbiology or virology studies
"PROCEDURE, ALTERNATIVES AND RISKS" DISCUSSION (SEE TABLE 149.6)
• Possibility of permanent dystrophy • Possibility of no diagnosis • Length of time for nail to regrow • Bleeding, infection and pain, as with any surgery

Table 149.2 Patient evaluation prior to nail surgery.

povidone-iodine (e.g. Betadine®) and sterilely draped. A sterile glove on the patient's hand can also provide a sterile field (see Fig. 149.4)[6].

INSTRUMENTS FOR NAIL SURGERY

Most of the instruments used in nail surgery are standard instruments used in cutaneous surgery. However, there are several special instruments that can make nail surgery easier (Fig. 149.5). The Freer septum elevator is an instrument with thin curved blades that facilitates atraumatic nail avulsion. An English nail splitter has a cutting blade opposed to a flat anvil-like surface that facilitates partial longitudinal nail avulsion. A double-action nail clipper is an indispensable instrument that easily cuts thickened nail plates.

NAIL AVULSION AND NAIL MATRIX EXPLORATION

Nail avulsion is the most basic procedure in nail surgery and is a prelude to additional surgical procedures that may need to be performed. Avulsion can be partial or total, and it involves removal of the nail by separating the nail plate from its attachments to the nail bed, matrix and nail folds. Avulsion of the nail plate facilitates examination of the nail bed and matrix area for tumors, and thus provides good exposure for subsequent excision or biopsy (Fig. 149.6). Partial

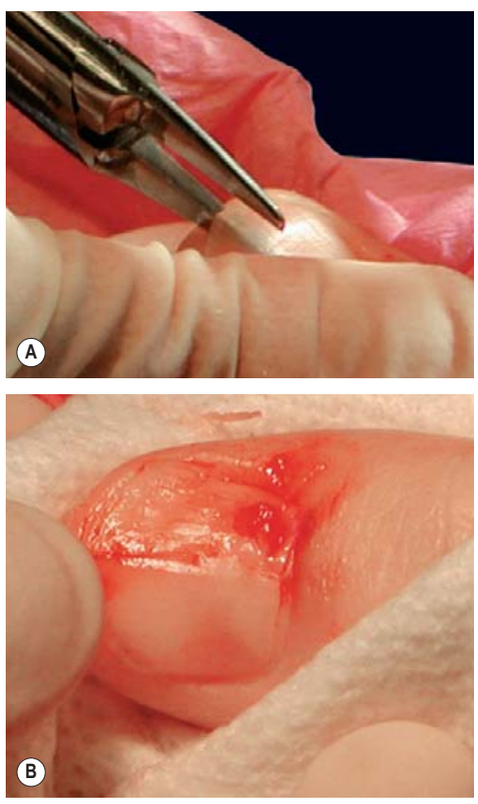

Fig. 149.6 An English nail splitter is used to divide the nail plate prior to partial longitudinal nail avulsion. A Note the flat, anvil-like blade of the English nail splitter that is inserted under the nail plate. **B** After partial nail avulsion, a glomus tumor is identified prior to excision.

Fig. 149.7 Distal nail plate avulsion. A The Freer septum elevator is inserted under the nail plate (from the hyponychium) in several parallel passes. **B** The loosened nail plate is grabbed with a hemostat and removed.

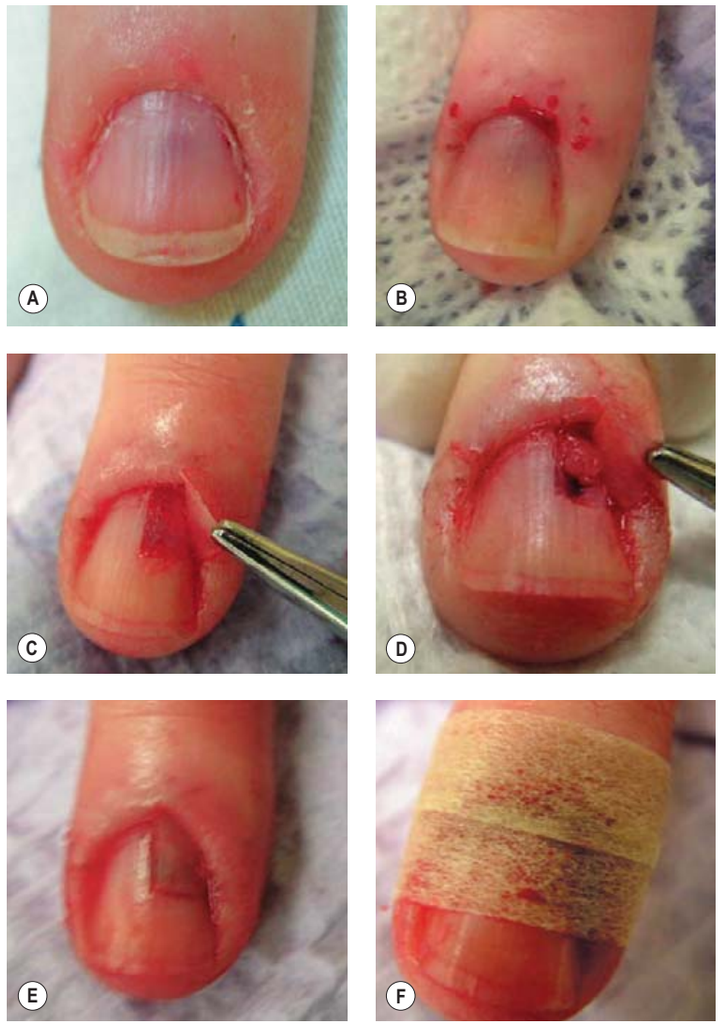

Fig. 149.8 Focal nail surgery with partial removal and then replacement of loosened nail plate. A Preoperatively, a glomus tumor is present beneath the proximal nail plate. **B** The nail unit after wing block anesthesia. **C** A cut in the nail plate allows a flap of nail to be reflected (with a hemostat), thereby exposing the subungual area. **D** The glomus tumor is removed, leaving a small defect. The flap of nail is replaced (**E**) and secured with Steri-Strips™ (**F**).

longitudinal avulsion is useful in the management of ingrown nails when surgical or chemical (phenol) matricectomy is performed (see below). In an acute bacterial infection of the nail unit, distal and/or lateral partial nail avulsion allows drainage of the subungual purulent material.

The basic principle in nail avulsion is to loosen the nail plate from its attachments to the underlying nail bed, matrix, and proximal and lateral nail folds. There are two approaches to nail avulsion: distal and proximal, although the latter is rarely used.

When performing a *distal nail plate avulsion*, after anesthesia, an instrument such as a Freer elevator or dental spatula is inserted under the free edge of the nail plate in a distal to proximal direction (Fig. 149.7A). As the instrument reaches the area of the matrix where the attachment of the nail plate is looser, the decrease in resistance is felt. One must anticipate that change, so that the instrument is not inadvertently jammed into the proximal groove and cul-de-sac with such force as to traumatize that area. It is preferable to insert the instrument from the hyponychium several times rather than to try to slide the instrument back and forth across the nail bed to loosen the nail plate. The attachment of the proximal and lateral nail folds to the nail plate is weak, so those areas are easily separated. Once the attachments to the nail plate are severed, the nail plate can be grasped by a hemostat on one lateral edge and rotated or pulled off the nail bed (Fig. 149.7B).

Partial nail plate avulsion is useful when the precise location of the lesion under the nail is known (see Fig. 149.6). In some cases it is possible to cut a portion of the overlying nail plate and reflect the partially loosened nail plate to expose the lesion so it can be excised (Fig. 149.8)[7]. The nail plate can then be repositioned to cover and protect the wound during the early stages of the healing process. While the piece of replaced nail plate does not reattach and will eventually be shed, it does provide protection and minimizes discomfort for the patient during the immediate postoperative period. The replaced nail plate can be secured with a suture or Steri-Strips™. Partial nail avulsion is also useful in the surgical approach to pigmented lesions within the nail matrix – the distal portion of the nail plate containing the pigmented band is left in place, serving as a marker for the appropriate location for the matrix biopsy (see Fig. 149.17).

The second fundamental nail surgical procedure is *nail matrix exploration*, which allows the clinician to examine the nail matrix and ventral surface of the nail fold for tumors and other pathology. Releasing incisions, about 5 mm in length, are made in the proximal nail fold beginning at the junction of the proximal and lateral nail folds and angling laterally and proximally (Fig. 149.9A). This allows the nail fold to be reflected so that the matrix can be inspected. Skin hooks or sutures, placed through the nail fold and retracted proximally, allow for exposure of the matrix for visual inspection as well as for subsequent biopsy or excision (Fig. 149.9B). At the end of the procedure, the fold is reflected back into place and secured with simple interrupted sutures or Steri-Strips™ (Fig. 149.9C).

NAIL EXCISIONS AND BIOPSIES

The techniques used for nail excision and/or biopsy depend upon the location of the pathology within the nail unit, the type of lesion, and the objective of the procedure. Useful nail surgery techniques are the punch biopsy (with or without prior nail avulsion), the tangential and elliptical excision in the nail bed or matrix, the lateral longitudinal combined biopsy/excision, and the chemical matricectomy. Surgical procedures should be oriented properly so that the nail unit heals in a manner that minimizes scarring and has the best functional and cosmetic outcome. In the nail bed, an excision is usually oriented along the longitudinal axis, whereas in the matrix the orientation of the excision is horizontal (Fig. 149.10). For biopsies of the nail bed, the size of the surgical specimen is determined by the type of lesion; as a general guideline, excisions of 3 mm or less are preferable and defects should be sutured when possible. Nail punch biopsy, elliptical excision and matricectomy will be discussed separately, based on location within the nail unit.

Fig. 149.9 Nail matrix exploration. A After nail plate avulsion, releasing incisions in the proximal nail fold (PNF) are made. **B** The PNF is retracted with skin hooks or sutures to allow visualization of the nail matrix. **C** The PNF is replaced and sutured or approximated with Steri-Strips™.

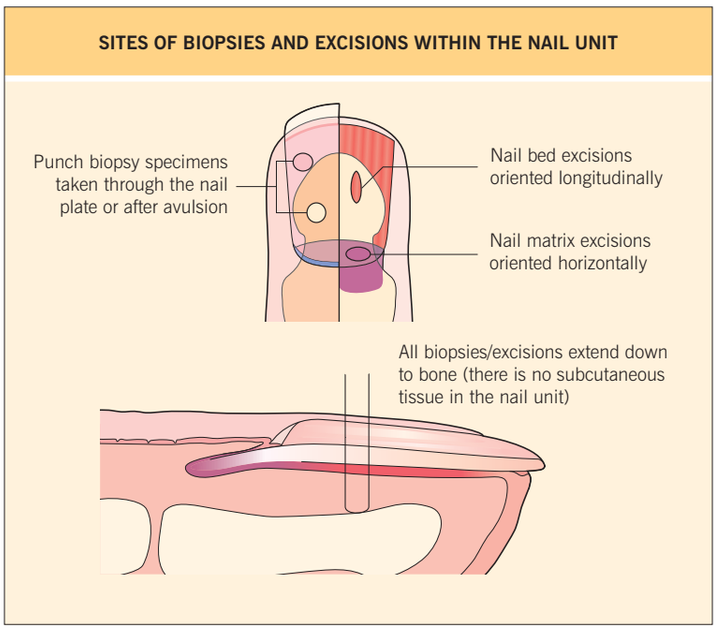

Fig. 149.10 Sites and orientations of biopsies and excisions within the nail unit.

Fig. 149.11 Nail fold biopsy of a space-occupying lesion. A Freer elevator is inserted beneath the proximal nail fold and a crescent of nail fold is removed.

Surgery of the Proximal Nail Fold

The epidermis of the nail folds is similar to that of other cutaneous sites, with two exceptions: the nail matrix lies beneath the proximal nail fold and should be protected, and the nail fold produces the cuticle that attaches to the nail plate. A space-occupying lesion in the proximal nail fold, such as a fibroma or cutaneous myxoid cyst, often presses on the underlying nail matrix and causes a characteristic longitudinal depressed defect in the nail plate immediately distal to its site (see Ch. 71). Lesions of the nail fold can be biopsied via shave, punch or incisional techniques or excised *en bloc*[8]. It is useful to insert a Freer elevator beneath the proximal nail fold in order to shield the matrix from inadvertent damage from the scalpel (Fig. 149.11). The majority of the time, the nail is not avulsed prior to nail fold surgery. A punch or shave biopsy of the nail fold is performed as for other cutaneous sites. Also, a crescent of nail fold can be removed and allowed to heal by second intention; this provides an aesthetically acceptable cosmetic result, with more of the nail plate and lunula visible. For best results with this latter technique (e.g. when excising a myxoid cyst), it is better to remove the entire width of the proximal fold in a symmetric manner to prevent distorted healing.

In the surgical approach to digital mucous cysts (cutaneous myxoid cysts), two more recently described techniques may be of value. Methylene blue can be injected into the cyst to help identify its communication with the joint space. In addition, a rotation flap elevation between the joint and the mucous cyst can disrupt the connection between the cyst and the joint space via the creation of a plate of subdermal scar tissue. Both appear to achieve long-term cure rates of approximately 90%.

Biopsy or Surgery of the Nail Bed

In pathologic conditions, the nail bed has a limited number of responses, including hyperkeratosis, onycholysis, erosion, dyschromia or a space-occupying mass. The similarity of clinical findings due to dissimilar nail conditions makes nail biopsy a useful diagnostic tool. Nail bed biopsy is a simple and safe technique that facilitates the diagnosis and even treatment of a variety of nail bed disorders (Table 149.3). The nail plate is usually avulsed prior to the nail bed biopsy; however, occasionally the biopsy is performed through the nail plate. When a punch biopsy is performed through the nail plate, a "double punch" technique is employed, with a trephine of a greater diameter used to make a larger hole in the nail plate, then a trephine with a smaller diameter used to remove the specimen. This facilitates non-traumatic retrieval of the specimen. When an elliptical excision of a nail bed lesion such as a glomus tumor is performed, the nail bed excision is oriented longitudinally (see Fig. 149.10). The area can be undermined at the level of the periosteum and absorbable polyglactin (e.g. Vicryl®) sutures placed to approximate the nail bed wound edges (Fig. 149.12). The nail bed usually heals with minimal scarring, although occasionally there may be onycholysis.

Nail Matrix Biopsy

Nail matrix biopsy has multiple indications, the most important of which is to exclude the diagnosis of subungual melanoma in a patient

CLINICAL FEATURES OF NAIL BED DISORDERS IN WHICH A BIOPSY MAY FACILITATE DIAGNOSIS AND SUBSEQUENT TREATMENT	
Diagnosis	**Clinical features**
MALIGNANT TUMORS OF THE NAIL BED	
Squamous cell carcinoma, Bowen's disease	Hyperkeratosis, dyschromia, onycholysis, destruction of the nail plate
Keratoacanthoma	Multiple or solitary, nail plate destruction, mass, erosion, granulation tissue, ± pain
Melanoma	Pigmentation of the nail bed, erosion, destruction of the nail plate; 25% are amelanotic
Metastatic carcinomas	Mass, pseudo-clubbing, nail dystrophy, dusky red color, ± pain
Kaposi sarcoma	Pigmentation, elevation, destruction of the nail plate
Basal cell carcinoma	Rare, variable clinical appearance
BENIGN TUMORS OF THE NAIL BED	
Pyogenic granuloma	Exuberant friable mass, needs to be distinguished from amelanotic melanoma
Glomus tumor	Spontaneous pain, blue–red mass
Epidermoid cyst	Mass, nail plate deformity
Fibroma	Mass, elevation, distortion of the nail (if presses on matrix, distal groove; if underneath nail plate, elevation of plate)
Exostosis	Mass, elevation of the nail plate, tenderness, secondary infection can occur
Osteochondroma	Enlargement of digit, elevation or destruction of the nail plate
Enchondroma	Mass, alteration of the nail plate, pain
INFECTIOUS CONDITIONS OF THE NAIL BED	
Onychomycosis	Hyperkeratosis, dyschromia, nail dystrophy, onycholysis
Warts	Verrucous mass, sometimes painful, nail plate deformity or destruction, must distinguish from verrucous or squamous cell carcinoma
Subungual scabies	Hyperkeratosis of hyponychium
INFLAMMATORY DERMATOSES INVOLVING THE NAIL BED	
Psoriasis	Onycholysis, hyperkeratosis, splinter hemorrhages, oil drop discoloration
Lichen planus	Violaceous discoloration, atrophy of nail bed; if nail matrix is involved, trachyonychia, hapalonychia (soft nails), dorsal pterygium
OTHER NAIL BED CONDITIONS	
Hemorrhage, trauma	Red–violet to black discoloration under nail plate; persistent or non-migrating discoloration needs to be distinguished from melanoma

Table 149.3 Clinical features of nail bed disorders in which a biopsy may facilitate diagnosis and subsequent treatment. *Adapted from Rich P. Nail biopsy: indications and methods. J Dermatol Surg Oncol. 1992;18:673–82.*

Fig. 149.12 Nail bed excision of a glomus tumor. A Elliptical excision is oriented longitudinally. **B** Absorbable sutures approximate the wound edges.

with abnormal pigmentation of the nail plate (see Ch. 71). A biopsy of a pigmented band (longitudinal melanonychia) must be taken from the nail matrix where the pigment is generated (see below). Of all the locations within the nail unit where a biopsy can be performed, it is the nail matrix that carries the greatest risk in terms of scarring. However, a nail matrix biopsy is a relatively safe and simple procedure when the principles of nail surgery are followed. With regard to nail anatomy and physiology, it is important to remember that the distal matrix forms the inferior (ventral) surface of the nail plate, and the proximal matrix forms its superficial (dorsal) surface (see Fig. 149.2). When there is a choice, the distal matrix is the preferred site for a matrix biopsy because any resultant split or defect will be hidden in the undersurface (ventral aspect) of the nail plate. Split nails that involve the dorsal surface are unsightly and easily traumatized as they catch on items such as clothing.

Prior to nail matrix biopsy, the nail plate is usually avulsed and the matrix exploration facilitated by releasing incisions that allow the proximal nail fold to be retracted (see Fig. 149.9). The nail plate avulsion can be total or partial. When an elliptical excision is performed within the nail matrix, the preferred orientation is horizontal (Fig. 149.13), and after undermining at the periosteal level, absorbable polyglactin (e.g. Vicryl®) interrupted sutures should be used to approximate the wound edges for the best cosmetic result. Of note, a punch biopsy that is 3 mm or smaller in the mid or distal matrix does not need to be sutured. Nail matrix excision and repair does result in a thinner nail plate because the thickness of the nail plate is to a large extent related to the length of the matrix.

For superficial lesions within the nail matrix, including the origin of broad pigmented bands, a tangential excision can be employed (Fig. 149.14)[9]. This technique, which is analogous to saucerization of a junctional melanocytic nevus elsewhere, allows a conservative margin yet minimizes the risk of scarring and subsequent permanent nail dystrophy. If an invasive process is suspected clinically, then an elliptical excision which extends to the level of the periosteum is more appropriate.

Great care must be exercised when handling the small fragile tissue specimen that is obtained from the nail biopsy. The tissue must be oriented and marked so that it is received by the pathologist in a state that allows for appropriate histologic evaluation. It is best to use surgical markers for the biopsy specimen so as to allow the examining pathologist to orient the epidermal surface properly. Undercutting the specimen avoids the crush artifact often caused by forceps[10].

Fig. 149.13 Nail dystrophy following biopsy of the nail matrix. The excision is oriented in a horizontal axis within the matrix and then sutured.

Fig. 149.14 Tangential excision (saucerization) of nail matrix for assessment of longitudinal melanonychia. This is performed when the pathologic process is thought to be superficial, as elsewhere on the body.

Lateral Longitudinal Nail Biopsy and Excision

Lateral longitudinal nail biopsy is a useful procedure where a length of the lateral nail unit is removed, including the nail matrix, nail fold, nail bed, nail plate and hyponychium. This procedure allows all these parts of the nail unit to be histologically examined simultaneously. It is useful for longitudinal pigmented bands of the lateral one-third of the nail and for inflammatory conditions in which the nail bed, nail matrix, nail plate, nail folds and hyponychium are involved concurrently. In this technique, the lateral one-third of the nail plate with its surrounding and supporting structures is removed *en bloc*. This is performed by incising through the nail plate and the matrix into the proximal nail fold and then laterally through the lateral nail fold up to and including the hyponychium (Fig. 149.15). The scalpel cuts through the nail unit down to the periosteum and the specimen is removed intact by loosening it from the underlying bone. The resultant defect is undermined and sutured or allowed to heal by second intention. The lateral groove heals with a narrower but cosmetically acceptable nail. However, retention of the lateral horn of the nail matrix can lead to a nail spicule which may become tender (Fig. 149.16).

Fig. 149.15 Lateral longitudinal nail biopsy and excision. The lateral portions of the nail unit are excised *en bloc* including the hyponychium, nail plate, nail bed, nail matrix and proximal nail fold.

Fig. 149.16 Complication of a lateral longitudinal biopsy and excision. This nail spicule (arrow) is due to incomplete lateral nail matrix resection. It can become tender. *Courtesy, Jean L Bolognia, MD.*

DRESSINGS AND POSTOPERATIVE CARE FOLLOWING NAIL SURGERY

Proper dressings can reduce postoperative pain and throbbing and minimize postoperative complications. A layer of antibiotic ointment is applied to the surgical site and covered with a non-stick dressing such as Vaseline™ gauze or Telfa®. A bulky gauze dressing is used for its absorptive and protective functions. Tube gauze such as Xspan® secures the dressing, and tape anchors the dressing to the skin. Given the likelihood of postoperative edema, the dressing should not be too tight and the tape should be non-constrictive. Patients should be instructed to keep the dressing dry. Preoperative nonsteroidal anti-inflammatory drugs (NSAIDs) are helpful in controlling mild discomfort and inflammation; narcotic analgesics are sometimes prescribed. Keeping the digit elevated higher than the heart will minimize painful throbbing. Bleeding into the dressing can result in the bandage sticking to the surgical site, in which case discomfort can be minimized by soaking the bandage to loosen it prior to removal.

SPECIAL SITUATIONS IN NAIL SURGERY

Nail Tumors

There are several nail unit tumors that are difficult to diagnose by clinical appearance alone (e.g. pyogenic granuloma, squamous cell carcinoma) and there are others where a preoperative radiograph points to the correct diagnosis (e.g. osteochondroma). These tumors are discussed in Chapter 71 and their treatment is outlined in Table 149.4.

Management of Malignant Neoplasms of the Nail Unit

Melanoma

Approximately 1–3% of all melanomas in Caucasians and 20% of melanomas in African-Americans occur within the nail unit[18]. Due to delays in diagnosis, subungual melanoma often has a poor prognosis.

NAIL UNIT TUMORS: RADIOGRAPHIC FINDINGS AND SURGICAL TREATMENTS

Tumor	Radiographic findings	Surgical treatment
Subungual exostosis	Radiopaque bone growth that is well circumscribed	Nail plate avulsion followed by surgical removal (can use bone rongeur)[11]
Keratoacanthoma	Cup-shaped radiolucent defect (early)	Surgical excision[12]
Enchondroma	Central round radiolucent defect	Surgical excision*
Squamous cell carcinoma	Radiolucent defect (late)	Microscopically controlled (Mohs) surgery[13–15]
Glomus tumor	Occasional radiolucent defect	Surgical excision (nail bed – longitudinal axis; nail matrix – horizontal axis)[16]
Myxoid cyst	Osteoarthritis	Cryosurgery, surgical excision (can use Freer elevator to protect matrix)[17]

*Performed primarily by other surgical subspecialists.

Table 149.4 Nail unit tumors: radiographic findings and surgical treatments.
Adapted from Rich P. Curr Prob Dermatol. 1999;11:161–208.

In many patients, melanoma of the nail unit is treated as a chronic paronychia, verruca, onychomycosis or an ingrown nail prior to biopsy and the correct diagnosis being established. A study by Glat et al.[19] reported a delay of nearly 2 years in the diagnosis of 22 subungual melanomas, resulting in 10- and 5-year survival rates of 13% and 30%, respectively[20].

The most reliable way to diagnose ungual melanoma is by histologic examination of the appropriate part of the nail matrix (or, rarely, the nail bed)[21]. Certain clinical features should raise one's suspicion of the possibility of melanoma. These clinical features are outlined in the mnemonic ABCDEF: *age* of the patient (older); *brown*/black and *breadth* greater than 3 mm; *change* in the band; *digit* involved (thumb, great toe); *extension* of pigment onto the nail fold(s) (Hutchinson's sign); and *family* history of melanoma[22]. Algorithms based on patient age, single or multiple bands, presence of Hutchinson's sign (see below), and ethnic background suggest a logical approach for diagnosis, but the bottom line is that in a Caucasian, a new, unexplained pigmented band in the nail should usually be biopsied, and the biopsy specimen should be taken from the nail matrix at the origin of the pigmented band (Fig. 149.17).

Dermoscopy may be helpful in evaluating pigmented lesions in the nail plate in two ways: (1) end-on dermoscopy of the distal nail plate to determine whether the pigment is dorsal versus ventral as a means of predicting the location of the pigment-producing cells (proximal and/or distal matrix; see Fig. 149.2); and (2) dermoscopic evaluation of the pigmented band itself. While dermoscopic features of pigmentation within the nail plate are not diagnostic[23], they may aid in guiding the decision to biopsy the nail matrix. Some authors believe that the most useful dermatoscopic feature is variability in the color, width and thickness of the lines that compose the pigmented band[24,25].

The clinical diagnosis of nail apparatus melanoma is difficult because there are many benign causes of longitudinal melanonychia (melanonychia striata), including trauma and drugs (see Ch. 71). Inactive

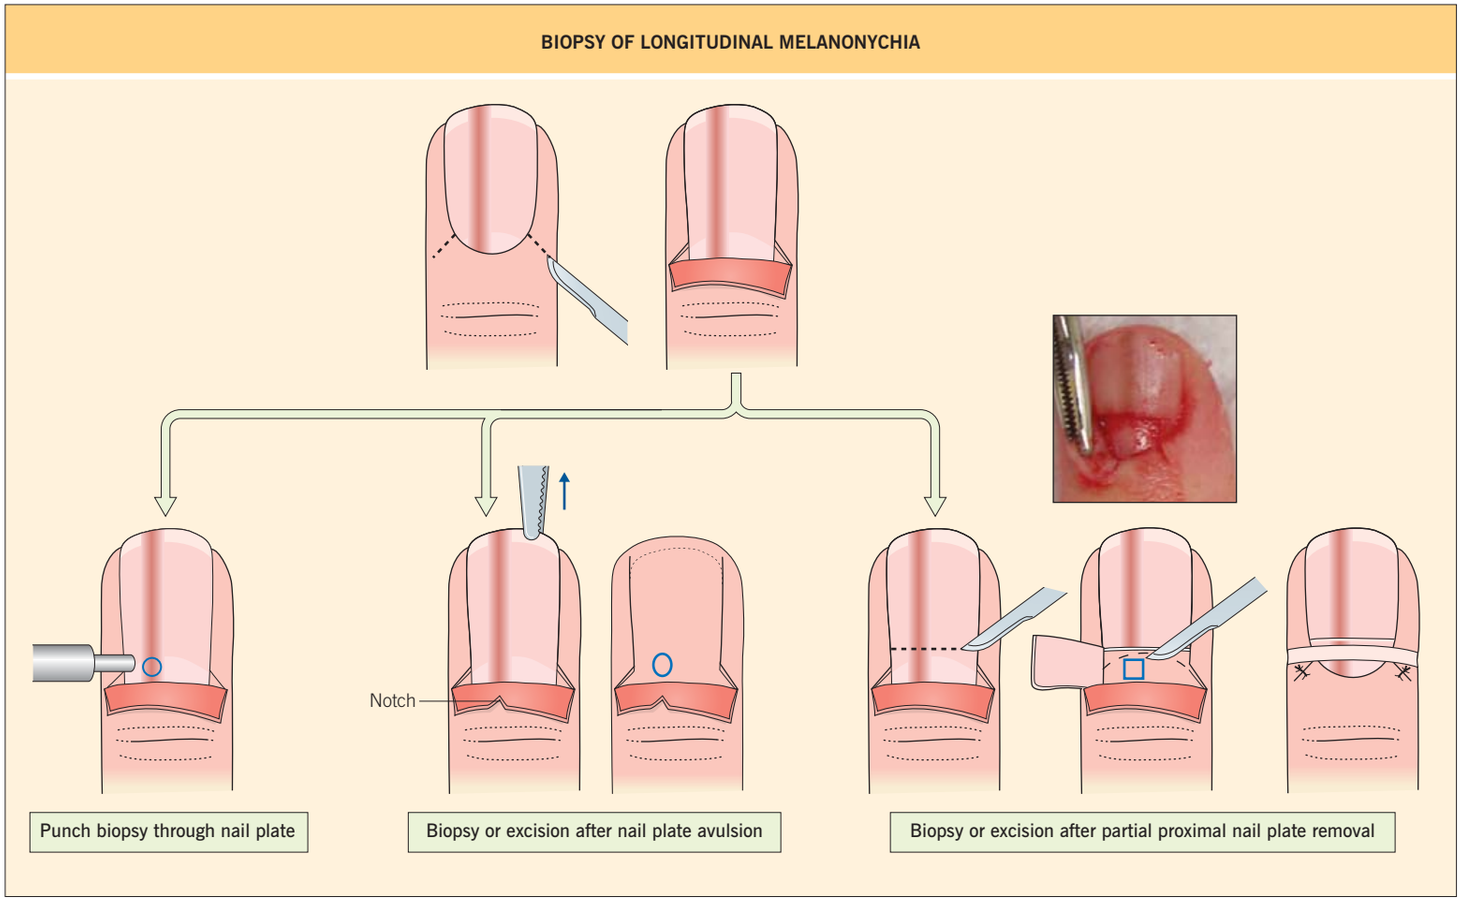

Fig. 149.17 Biopsy of longitudinal melanonychia. Histologic examination of the nail matrix can be achieved via three different initial approaches. A biopsy can be performed without removing the nail plate, following a complete nail plate avulsion or after removal of the proximal nail plate. Depending upon the lesion, a punch biopsy, an excision to the periosteum or a tangential excision (saucerization; see Fig. 149.14) can be performed.

melanocytes are present in the nail matrix and nail bed of Caucasians. When they are stimulated to proliferate or produce melanin, the pigment is incorporated into the nail plate and appears as a longitudinal brown or black band. Histologically, melanocyte activation is seen much more commonly than nevi; additional causes are listed in Table 71.2.

An additional consideration is that darkly pigmented individuals frequently have benign pigmented bands of the nail. In fact, over 90% of African-Americans have one or more longitudinal pigmented bands by the age of 50 years. Longitudinal melanonychia occurs in over 10–20% of Asians and the incidence is much higher in Hispanics and Middle Eastern populations[18]. Because the precise etiology of longitudinal melanonychia often cannot be ascertained from clinical inspection and history alone, subungual melanoma should always be included in the differential diagnosis and a biopsy of any suspicious lesion is mandatory[21].

The management of longitudinal melanonychia in children (<12 years of age) presents a particularly challenging problem. This is because nail unit melanomas are very rare in children, with reported cases primarily *in situ* and in children with more darkly pigmented skin[26]. As a result, there is controversy regarding whether all pigmented bands in children need to be biopsied, with some authors suggesting that it may be safe to observe some of these lesions[27]. Hopefully, additional studies examining the impact of color, width, change and dermoscopic features will provide guidance in the future.

Much discussion has centered around the presence or absence of Hutchinson's sign, which is the leaching of pigment into the perionychium in association with a melanoma. While at times helpful in confirming the clinical diagnosis of melanoma of the nail unit, it is an inconsistent feature and sometimes not particularly helpful. Melanoma can occur without Hutchinson's sign, and pseudo-Hutchinson's sign can occur in the absence of melanoma. Pseudo-Hutchinson's sign represents the presence or illusion of pigment in the perionychium and can be associated with a variety of disorders (Table 149.5).

ETIOLOGIES OF A PSEUDO-HUTCHINSON'S SIGN
PIGMENT PRESENT IN PARONYCHIUM
• Normal variant for Fitzpatrick skin phototypes IV, V and VI
• Laugier–Hunziker syndrome, Peutz–Jeghers syndrome
• Radiation exposure
• Malnutrition
• Minocycline, zidovudine (AZT)
• Postinflammatory
• Benign melanocytic nevi
• Regressing nevoid melanosis in childhood
• Subungual hematoma
PIGMENT VISIBLE THROUGH PARONYCHIUM
• Neoplasms (benign nevi, squamous cell carcinoma, basal cell carcinoma)
• Subungual hematoma

Table 149.5 Etiologies of a pseudo-Hutchinson's sign. *Adapted from Baran R. Hutchinson's sign: a reappraisal. J Am Acad Dermatol. 1996;34:87–90.*

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is the most common malignancy of the nail unit. However, the associated clinical features can be nonspecific and tumors may mimic verrucae as well as dermatitis of the paronychium, or appear as onycholysis, painful erosions or nail dystrophy. The clinical presentation depends in part on the location, duration and extent of the SCC. Because nail unit SCC can imitate a variety of other nail disorders, a high index of suspicion is required. In a review of 35 histologically proven nail SCCs, the most common clinical diagnoses were verrucae, onychomycosis and longitudinal melanonychia, with only 25% of the tumors correctly diagnosed as SCC prior to biopsy[28]. Undiagnosed nail lesions or those that remain unresponsive to therapy for an extended period of time, including hyperkeratosis of the lateral groove or onycholysis with oozing, deserve a biopsy to exclude SCC. Predisposing factors are radiation exposure and infection with high-risk human papillomavirus (HPV) types 16 and 18[29]. While Mohs surgery is the treatment of choice for SCC of the nail apparatus[14,15], well-circumscribed SCC *in situ* of the nail bed can be treated via wide excision. Bony involvement, however, requires amputation. Lastly, even though SCC is the most common malignant tumor of the nail unit and there is often a long delay in diagnosis, it rarely metastasizes.

Management of Ingrown Toenails

An ingrown toenail occurs when a portion of the nail plate grows into the skin of the lateral nail groove. This sharp nail spicule acts as a foreign body, and secondary infection and formation of granulation tissue often ensue. Heredity, poorly fitting shoes and improper nail grooming can contribute to the development of ingrown toenails. Any associated infection should be treated and conservative measures tried first, such as placing lamb's wool between the nail plate and the lateral nail groove and growing longer toenails. Surgical management involves partial or total nail plate avulsion followed by chemical or surgical destruction of the lateral portion of the nail matrix.

Phenol matricectomy is used more commonly than surgical matricectomy, because it is easier to perform and causes less postoperative discomfort. The principle of phenol matricectomy is chemical destruction of the portion of the nail matrix associated with the ingrowing part of the nail. After anesthetizing the digit, the nail is partially or completely avulsed. Full-strength phenol (88%) is applied to the lateral part of the nail matrix with a small cotton swab fashioned from small wisps of cotton wound around a small wooden stick or toothpick. The swab is dipped into the phenol and the excess is drained off, and it is then carefully inserted under the nail fold in the desired area (Fig. 149.18). The swab is rotated over the surface of the matrix for 30 seconds and this is then repeated. A bloodless field is important for this part of the procedure.

Phenol is caustic and causes a chemical destruction of the matrix cells by denaturing proteins and preventing further nail growth in the treated area. The nail folds and nail bed should be protected from the phenol by applying a thin layer of petrolatum, and the phenol is neutralized with isopropyl alcohol or saline following the second pass. The digit is dressed with a bulky dressing which is changed the next day and the nail is soaked daily during the healing phase. There is generally

Fig. 149.18 Phenol matricectomy for ingrown toenails. A portion or all of the nail plate is avulsed (**A, B**) and full-strength phenol on a small cotton wisp on a small wooden stick is inserted under the nail fold and applied to the nail matrix (**C**).

Fig. 149.19 Long-term clinical appearance following total phenol matricectomy. Successful complete destruction of the toenail matrix. *Courtesy, Jean L Bolognia, MD.*

POSSIBLE COMPLICATIONS OF NAIL SURGERY
SHORT-TERM (WITHIN 14 DAYS OF SURGERY)
• Bleeding, pain, infection (including septic arthritis, osteomyelitis), pyogenic granuloma*
LONG-TERM (3 MONTHS OR LONGER AFTER SURGERY)
• Neurologic: paresthesias, reflex sympathetic dystrophy (very rare) • Scarring of the: matrix – nail plate dystrophy (splits, ridges, grooves, thinning†) proximal matrix – pterygium nail bed – permanent onycholysis nail fold – notch in the cuticle • Failure to remove the lesion of concern: recurrence of tumor (e.g. glomus, fibroma, onychomatricoma), confusing clinical picture (e.g. recurrent longitudinal melanonychia) • Retention of matrix (usually lateral horns): spicules of nail plate (inset) • Postinflammatory hyperpigmentation: more common in darkly pigmented individuals
*More common with toenails. †May lead to erythronychia.

Table 149.6 Possible complications of nail surgery. These are in addition to false-negative biopsies, i.e. the pathologic findings are not found within the biopsy specimen.

minimal postoperative pain with this simple, yet effective treatment. The recurrence rate is low, but occasionally nail spicules can be seen in an incomplete phenol matricectomy. Pincer nails, which are characterized by hypercurvature of both sides of the nail, can be managed with bilateral phenol matricectomy[30,31]. Onychogryphosis is sometimes treated with total phenol matricectomy (Fig. 149.19).

Surgical excision of the lateral nail matrix is sometimes performed for the treatment of ingrown toenails and pincer nails. This procedure involves reflecting the proximal nail fold and scalpel excision of the lateral portion of the nail matrix, including the lateral horn[32]. This technique is more complicated and has greater postoperative discomfort than phenol matricectomy and therefore is less frequently performed for simple ingrown nails.

COMPLICATIONS OF NAIL SURGERY

Nail surgery is safe and effective. However, as with all cutaneous surgical procedures, there are occasionally complications. A number of the complications are similar to those associated with other surgical procedures, e.g. bleeding, infection, pain and deformity. In addition, nail surgery can lead to pyogenic granuloma formation, reflex sympathetic dystrophy, and deep infections such as osteomyelitis and septic arthritis (Table 149.6). The most characteristic complication of nail surgery is nail plate deformity, which results from nail matrix damage. When care is taken and the principles of nail surgery are strictly followed, significant complications are rare.

Synonyms: ■ Mohs micrographic surgery ■ Chemosurgery ■ Mohs chemosurgery (fresh tissue technique and fixed tissue technique)

Key features

- 100% microscopic tissue margin examination
- Highest evidence-based cure rate for cutaneous malignancies
- Precise excision of cancerous tissue
- Preservation of the maximum amount of non-cancerous tissue
- Total tissue control and precise mapping
- Same physician serves as both surgeon and pathologist
- Immediate re-excision of residual cancerous tissue as indicated
- Least complicated reconstruction possible, due to preservation of non-cancerous tissue

INTRODUCTION

Mohs micrographic surgery is a specialized method for the removal of skin cancer that combines surgery with pathology. It has an evidenced-based, 5-year cure rate of 99% for basal cell carcinoma (BCC)[1,2] and 94% for cutaneous squamous cell carcinoma (SCC)[3,4]. There are four major components: surgical excision, histopathologic examination, precise mapping and wound management.

The *surgical* component consists of removing a disc of tissue with a beveled surgical margin (see Fig. 150.6). The disc of tissue, or "layer", ensures that the entire 360° of tumor margin is circumferentially removed and examined. A beveled plane of excision allows the tissue specimen sides and bottom to be flattened completely into a single plane. The *histopathologic* component involves removing several thin sections from the bottom of the flattened cryopreserved tissue specimen and mounting them onto glass slides, followed by staining and microscopic examination for residual tumor. Precise *mapping* entails marking any residual tumor on the map or "graph" of the excision with the remaining positive area of tumor re-excised as indicated. This three-step process is then repeated until there is no residual tumor identified microscopically. During this procedure, the Mohs surgeon has complete control of the excised tissue, including laboratory processing and interpretation of the tissue sections, as well as precise mapping. In the fourth step, *wound management*, the tumor-free defect is surgically closed or allowed to heal by second intention.

Cost-effective Care and Indications

In addition to offering the highest cure rates for BCCs and SCCs, only cancerous tissue is removed during Mohs surgery, thereby preserving the maximum amount of normal tissue from a functional, aesthetic and reconstructive perspective. This is of particular importance for skin cancers near the orbit, nose, lips and ears. Mohs surgery is the preferred method of treatment for skin cancers that are clinically poorly defined, recurrent and/or have a higher risk of recurrence because of histologic features or anatomic location (e.g. ear, lips) (Table 150.1). In addition to the face, preservation of tissue also plays an important role in the anogenital region and digits.

The escalating cost of medical care has led to a paradigm shift away from evidence-based treatment (e.g. Mohs surgery) to cost-effective care (e.g. surgical excision). However, typically, the excised specimen is submitted to a pathology service for tissue processing and professional interpretation of histologic sections obtained via "bread-loafing" (Fig. 150.1). When the advantage of a higher cure rate and the costs of pathologic interpretation are considered, the cost differential becomes minimal. Concern has been raised regarding the overutilization of Mohs surgery, e.g. for small primary nodular BCCs or Bowen's disease of the trunk, but adherence to the indications listed in Table 150.1 should lead to its appropriate use.

HISTORY

Mohs surgery was developed by Dr Frederic E Mohs, whose pioneering work was performed at the University of Wisconsin-Madison in the 1930s and first published in 1941[5]. Dr. Mohs described his technique as chemosurgery. In his initial experiments, he observed that intralesional injection of 20% zinc chloride solution produced tumor necrosis with preservation of histology. His original clinical technique involved the application of a zinc chloride paste to cancerous tissue 24 hours prior to surgical removal of the tumor. The paste essentially fixed and isolated the tumor *in vivo*. Subsequently, the tumor was excised, sectioned into multiple pieces, and marked with colored dyes for orientation. A precise and detailed map of the excised tumor was created, including orientation relative to remaining tissue and anatomic landmarks. The specimen was flattened with physical pressure so that the histologic sections would encompass all lateral and deep margins. Serial tissue sections were cut on a freezing microtome, arranged on glass slides, and then stained. The precise location of any residual tumor seen on histologic examination was noted on the map. In cases with residual tumor at the margins, zinc chloride paste was re-applied to cancerous margins for 24 hours; then further tissue resection, processing and analysis were performed until complete tumor clearance was obtained.

With the original fixed tissue technique, the zinc chloride caused tissue necrosis, rendering wounds unacceptable for surgical reconstruction. From this limitation, Dr Mohs' second major innovation emerged – an objective analysis of second intention wound healing. Until that time, surgical dogma held that allowing wounds to heal by second intention (without closure) produced inferior cosmetic results compared to reconstruction, the surgeon's "first intention for healing". The acceptable, and, at times, superior, cosmetic outcome associated with second intention healing, particularly on concave surfaces, was documented by Dr Mohs, affording second intention healing its rightful place among valid reconstructive techniques.

INDICATIONS FOR MOHS SURGERY FOR NON-MELANOMA SKIN CANCER
TUMOR CHARACTERISTICS
• Recurrent • High-risk* anatomic location (periorbital, perinasal, periauricular, perioral, hair-bearing scalp) • Other anatomic sites where tissue preservation is imperative (digits, genitals) • Aggressive histologic subtype: – Morpheaform (sclerosing), micronodular or infiltrating BCC – High-grade, poorly differentiated and/or deeply penetrating SCC – Infiltrating, spindle cell SCC • Perineural invasion • Large size (>2 cm diameter) • Poorly defined clinical borders (lateral and/or deep) • Rapid growth
CHARACTERISTICS OF BACKGROUND SKIN
• Prior exposure to ionizing radiation • Chronic scar (Marjolin's ulcer) • Site of positive margins on prior excision
PATIENT CHARACTERISTICS
• Immunocompromised • Underlying genetic syndrome, e.g. xeroderma pigmentosum, nevoid BCC (Gorlin) syndrome, or Bazex–Dupré–Christol syndrome
*High risk for recurrence.

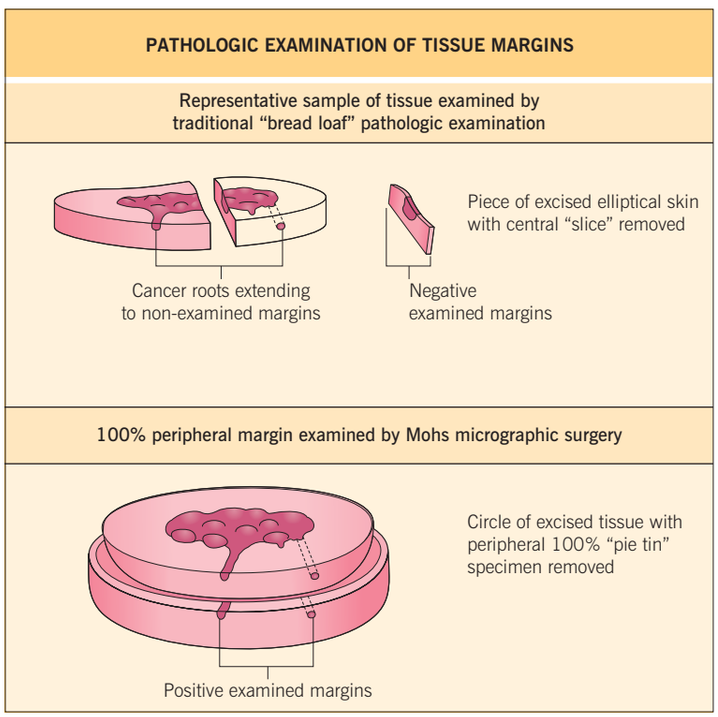

Fig. 150.1 Pathologic examination of tissue margins. Comparison of traditional "bread loaf" sections (0.01% of total margin examined) versus Mohs micrographic surgery (100% of total margins examined). *Courtesy, Clark C Otley, MD.*

Over 30 years ago, the tissue-processing procedure for Mohs surgery evolved from a zinc chloride-based, fixed tissue technique to a fresh-frozen tissue technique, an innovation initially performed by Dr Mohs in 1953 for eyelid cancers. In 1974, the fresh-frozen tissue technique was described in detail and popularized by Tromovitch and Stegman[6]. The fresh-frozen section technique eliminated the need for the escharotic zinc chloride paste, and it allowed complete tumor clearance with multiple resections in 1 day. Furthermore, without a zinc chloride-induced necrotic base, immediate surgical reconstruction could be performed when appropriate. The fresh tissue technique has become the standard of care for modern Mohs surgery.

TRAINING IN MOHS SURGERY

Training in Mohs surgery involves all aspects of tumor resection, tissue preparation and histologic interpretation. Additionally, the surgeon must have an excellent grasp of cutaneous and soft tissue anatomy, particularly of the face, both for excision of tumor and subsequent reconstruction. Knowledge of vascular, muscular and neural anatomy is essential, especially in "danger zones" of the face (see Ch. 142). The substantial clinical, surgical and pathologic training received in a dermatology residency provides the background for specialized training in Mohs surgery. Therefore, the technique has been primarily performed by dermatologists rather than surgeons who lack a background in pathology and other aspects of cutaneous oncology. In addition to the Mohs surgeon's involvement in all aspects of tissue handling, one of the unique advantages of Mohs surgical training is the degree of expertise in clinicopathologic correlation, which derives from dual training in both clinical and pathologic tumor assessment. After the tumor has been excised, the dermatologic surgeon must also have a mastery of soft tissue and cutaneous reconstruction, with an emphasis on both function and aesthetic restoration. While international training programs are of varying lengths, those in the US are one year in duration.

INDICATIONS

Most skin cancers are locally invasive, growing in a relentless and unpredictable manner. On the face, they can invade vital structures such as the eye, nose, lips and ears, leading to significant destruction. With time and neglect, metastasis (SCC and melanoma) may develop. That said, the majority of non-melanoma skin cancers are treated with superficial ablative techniques (e.g. electrodesiccation and curettage) because they are low-risk tumors and these techniques produce reasonable cure rates and are cost-efficient. In contrast, Mohs surgery is ideally suited for skin cancers at high risk of recurrence.

The definition of "high risk" for skin cancer depends on multiple factors, including the clinical and histologic characteristics of the tumor (see Ch. 108), the anatomic site, and history of prior treatments (see Table 150.1). Although these indications are not considered absolute, Mohs surgery is often preferred because of its high cure rate. A thorough review of indications for Mohs surgery can be found in *Guidelines of care for Mohs micrographic surgery*, issued by the American Academy of Dermatology[7].

Because of the diligent and complete histologic examination of the surgical margins, Mohs surgery can be utilized to track unpredictable superficial or deep projections of tumor. In addition, Mohs surgery is extremely useful for tracking tumors that involve embryonic fusion planes, the periorbital region, nerves and bone. These deep and irregular tumor extensions are responsible for the higher recurrence rates with other techniques. We will review the use of Mohs surgery for each of the more commonly managed tumors (Table 150.2).

Basal Cell Carcinoma

For primary BCCs, cure rates of 87% to 95% can be obtained with superficial ablative therapies and excision, especially on the trunk and extremities. Theoretically, the optimal cure rates associated with Mohs surgery could be applied to all BCCs, but from a practical perspective, the majority of BCCs are well managed with the former modalities. Therefore, Mohs surgery is usually limited to BCCs that meet the indications listed in Table 150.1.

For high-risk BCCs (Fig. 150.2), Mohs surgery provides superior cure rates. In the meta-analysis by Rowe et al.[1], the 5-year cure rate for *primary* BCC treated with Mohs surgery was 99%, as compared to 90% to 92% using standard treatments (Table 150.3). The 5-year cure rate for *recurrent* BCC treated with Mohs surgery was 94.4%, as compared to 80% for standard treatments (surgical excision, radiotherapy, cryotherapy, curettage and electrodesiccation)[2].

Mohs surgery is also well suited for the treatment of large BCCs (>2 cm), as size has been directly related to recurrence rate. In general,

CUTANEOUS TUMORS TREATED WITH MOHS SURGERY AND REPORTED CURE RATES	
Cutaneous tumors	**Cure rates (5-year)**
Basal cell carcinoma	99% (primary tumors)[1] 90–93% (recurrent tumors)[2]
Squamous cell carcinoma	92–99% (primary tumors)[3] 90% (locally recurrent tumors)[4]
Erythroplasia of Queyrat	90%[8]
Keratoacanthoma	97.5%[9,*]
Cutaneous melanoma *in situ*, including lentigo maligna	98%[10]
Atypical fibroxanthoma	93–100%[11]
Dermatofibrosarcoma protuberans	98–100%[12–14]
Merkel cell carcinoma	84%[15]
Microcystic adnexal carcinoma	90%[16–18]
Sebaceous carcinoma	89%[19]
Extramammary Paget's disease	92%[20]
Leiomyosarcoma (superficial)	87%[21]
*Only 2-year cure rate.	

Table 150.2 Cutaneous tumors treated with Mohs surgery and reported cure rates. For eccrine porocarcinoma, angiosarcoma and lymphoepithelioma-like carcinoma, efficacy based only upon case reports. For mucinous eccrine carcinoma, increased efficacy relative to wide excision not established. Some surgeons also use Mohs surgery for invasive cutaneous melanoma.

FIVE-YEAR CURE RATES FOR PRIMARY BCC AND SCC		
Treatment modality	**5-year cure rate**	
	BCC (%)	**SCC (%)**
Surgical excision	90	92
Electrodesiccation & curettage	92	96
Radiation	91	90
Cryotherapy	92	N/A
All non-Mohs modalities	91	92
Mohs surgery	99	97

Table 150.3 Five-year cure rates for primary basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) by treatment modality. Based upon refs 1 and 4. There is some inherent bias in these data as the studies quoted in this table did not all use the same patient selection criteria. For example, techniques such as electrodesiccation and curettage appear to have higher cure rates for SCC than excision to adipose, but it is likely that patients who had curettage selected as a definitive treatment had superficial tumors. N/A, not available.

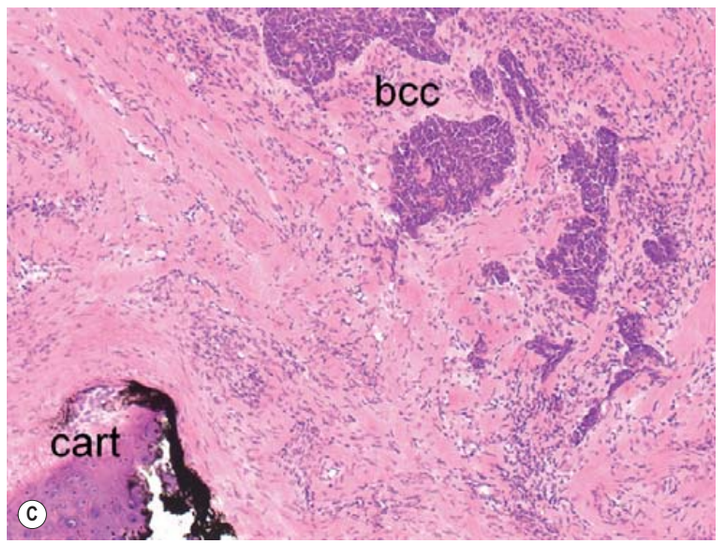

Fig. 150.2 Recurrent biopsy-proven basal cell carcinoma (BCC) of the cymba of the left ear. A Prior to Mohs surgery. **B** Tumor extirpation required 8 Mohs stages as there was unpredictable extension of the BCC. **C** In a frozen section, BCC (infiltrative subtype) invading the dermis (bcc) and adjacent to auricular cartilage (cart). *Reproduced with permission from Stephen Snow, Atlas of Mohs Surgery Wound Management: Flaps, Grafts and Wound Care, Scope Publishing: Madison, WI, 2010.*

tumors >2 cm that have been present for a prolonged period of time have a greater likelihood of recurring if treated by standard methods. When large lesions are present in cosmetically important areas, the sparing of normal tissue is also a critical advantage of Mohs surgery. In addition to aggressive histologic subtypes (see Table 150.1), perineural invasion is an indication for Mohs surgery (Fig. 150.3). Lastly, baso-squamous cell carcinoma, a hybrid between basal and squamous cell carcinoma, has a high risk of local recurrence and is also well managed with Mohs surgery[22].

Squamous Cell Carcinoma

When compared with other treatments, Mohs surgery offers the highest cure rates for patients with high-risk primary or recurrent SCCs. The local recurrence rates, based on a retrospective review of Mohs surgery versus non-Mohs surgery modalities for primary SCC, are outlined in Table 150.3[4].

As with BCC, Mohs surgery is indicated for management of SCCs with one or more risk factors for recurrence or metastasis (see Table 150.1). These indications include large SCCs (>2 cm), recurrent tumors, incompletely excised SCCs, and tumors with ill-defined clinical margins, rapid growth, an aggressive histologic subtype or perineural

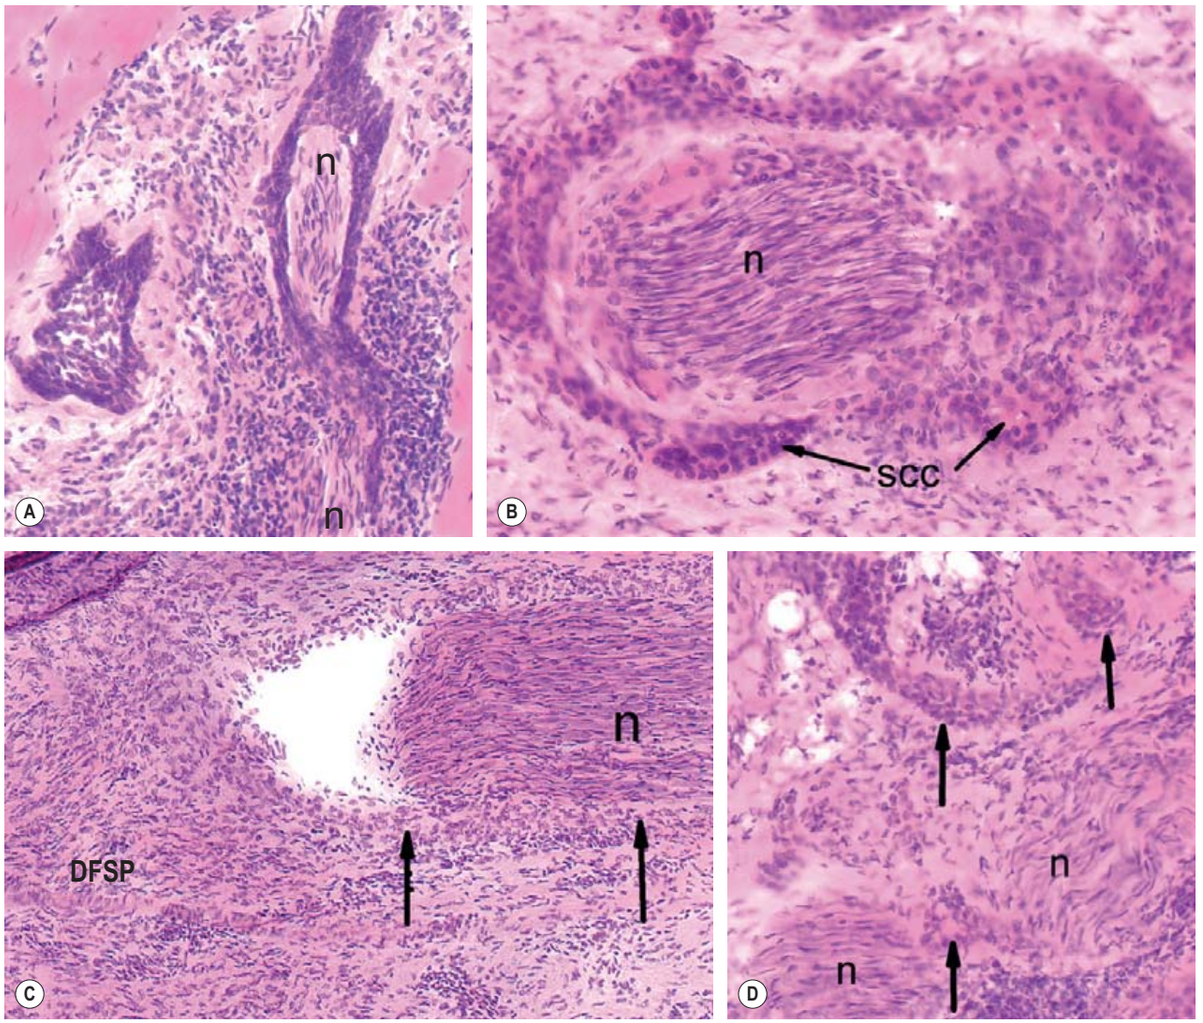

Fig. 150.3 Perineural involvement by various cutaneous tumors (frozen sections). invasion (see Fig. 150.3), as well as SCCs arising in chronic scar tissue[23]. The latter, termed Marjolin's ulcers, can behave aggressively, and a multidisciplinary approach to regional node assessment and reconstruction may be necessary in these patients. Numerous, rapidly arising SCCs may affect immunosuppressed solid organ transplant recipients or individuals with chronic lymphocytic leukemia receiving fludarabine, and Mohs surgery is well suited for the management of these neoplasms.

SCC arising in high-risk anatomic sites may also be managed with Mohs surgery. For example, tumors of the lip have a high propensity for recurrence and metastasis, and cure rates as high as 92% have been obtained with Mohs surgery[24]. Mohs surgery is also well suited for SCCs occurring in anogenital areas and on the digits, where tissue conservation is important. When compared with conventional methods, Mohs surgery for the treatment of penile SCC offers comparable survival rates. Prior to Mohs surgery, most cases of SCCs involving the nail unit were treated with amputation, electrocoagulation or radiation. Mohs surgery provides an excellent choice for treatment of periungual and subungual SCC without osseous involvement, with cure rates of up to 96%[25].

Erythroplasia of Queyrat

Erythroplasia of Queyrat (EQ) is a term for SCC *in situ* confined to mucosal epithelium. In men, an erythematous thin plaque is typically seen on the inner surface of the foreskin, glans penis and/or coronal sulcus (see Chs 73 & 108). Of note, EQ is seen primarily in uncircumcised men. In women, mucosal SCC *in situ* favors the labia minora and the vestibule. Oncogenic human papillomaviruses often play an etiologic role and immunosuppressed individuals (e.g. HIV-infected) are at greater risk for developing anogenital SCC *in situ*.

Mohs surgery is an effective treatment for EQ, with a 5-year cure rate of 90%[8]. When excising EQ of the glans penis, Mohs layers should be very thin in order to minimize entry into and resection of the corpus spongiosum and cavernosum. If either is entered, achieving hemostasis can be challenging. EQ can often extend into the urethra and here differentiation of SCC *in situ* from transitional epithelium is often difficult on frozen sections. With deep extension along the urethra, collaboration with a urologist and completion of the surgery under general anesthesia are recommended.

Keratoacanthoma

Keratoacanthoma (KA) may be considered a well-differentiated SCC with specific histologic features. KAs classically grow quickly and then spontaneously involute; however, there are exceptions and metastasis has been reported, implying that the tumor was actually an SCC. Also, microscopically, some KAs may be difficult to distinguish from an SCC. As a result, nowadays, most KAs are considered to be well-differentiated SCCs and are managed with excisional or Mohs surgery. Mohs surgery may be particularly beneficial for large lesions, as well as those occurring in anatomically sensitive areas. In 1987, Larson[9] reported a 97.5% 2-year cure rate for KAs treated via Mohs surgery (see Table 150.2).

SPECIAL AND IMMUNOHISTOCHEMICAL STAINS USED IN MOHS SURGERY						
	Squamous cell carcinoma (perineural & spindle cell/ infiltrating)	**Basal cell carcinoma**	**Dermato-fibrosarcoma protuberans**	**Extramammary Paget's disease**	**Sebaceous carcinoma**	**Melanoma *in situ* (lentigo maligna)**
Special stains	–	Toluidine blue	–	PAS	Oil red O	–
Immunohistochemical stains	Pancytokeratin (AE1/AE3)	–	CD34	Cytokeratin 7	–	Melan-A/MART-1 (Fig. 150.5), MITF, Mel-5

Table 150.4. Special and immunohistochemical stains used in Mohs surgery. Additional special stains and immunohistochemical stains are reviewed in Table 0.11. MITF, microphthalmic transcription factor; PAS, periodic acid-Schiff.

Verrucous Carcinoma

Verrucous carcinoma is considered a variant of SCC, and it can be triggered by the human papillomavirus. It occurs most commonly in the oral cavity, on the plantar surface of the foot, or on the penis (see Ch. 108). While generally considered a low-grade carcinoma, there are reports of metastasis. Because the tumors are usually localized, Mohs surgery is an excellent treatment option. Sometimes, the histopathologic interpretation of frozen sections can be challenging because the tumor cells are very well differentiated and lack nuclear atypia, making distinction from epithelial hyperplasia, verruca vulgaris or condyloma acuminatum difficult.

Lentigo Maligna

Since lentigo maligna (melanoma *in situ* of sun-damaged skin) may be a clinically and histologically ill-defined tumor, it has a high local recurrence rate with standard wide-excisional surgery. Although frozen section histology of lentigo maligna can be challenging, Mohs surgery offers the possibility of complete margin examination and tissue sparing. Lentigo maligna that is at risk of recurrence or in an anatomically sensitive site may be managed with wide excision Mohs surgery (see below) followed by tangential permanent histologic confirmation, with immunostains as needed[26,27]. This dual method ("slow" Mohs technique) employs the advantages of both Mohs surgery and permanent histology, albeit with the disadvantage of delayed closure for complex cases. Another approach is the geometric staged excision (see Variations). Some groups also use frozen section immunostains to enhance diagnostic accuracy (see below)[26].

Melanoma Other Than Lentigo Maligna

The role of Mohs surgery for the treatment of cutaneous melanoma in which only frozen sections are utilized continues to be controversial. As with lentigo maligna, this is due to disagreements regarding the reliability of detecting atypical melanocytes in frozen sections. The use of special stains, such as HMB45, Mel-5, Melan-A/MART-1 and S100, may increase histologic sensitivity during Mohs surgery for melanocytic lesions (Table 150.4)[26]. Even so, some dermatologic surgeons advocate the examination of formalin-fixed tissue margins to confirm that the final Mohs surgery margin is negative[27].

Another controversial aspect of Mohs surgery for melanoma involves the advisability of margins that are narrower than published guidelines for a tumor that has a higher capacity to metastasize than BCC or SCC. Although uncontrolled, the extensive experience of Zitelli and colleagues in the management of melanoma with Mohs surgery provides reassurance that outcomes are equivalent to standard margins[28,29]. While many clinicians do not find significant benefits to Mohs surgery for routine management of melanoma (e.g. most tumors, with the exception of lentigo maligna, are well defined), specific clinical scenarios appear especially appropriate. These include: locally recurrent melanoma; tumors with a large diameter; ill-defined or amelanotic melanoma; and melanoma near critical anatomic structures such as the genitals, digits, eyelids, nose and ears. Of note, many dermatologic surgeons remove a clinically tumor-free margin of at least 5 mm when managing melanoma, a technique termed "wide excision Mohs surgery" (see below). Mapped serial sections and the "square method" (also referred to as geometric staged excision; see below) are modifications based upon similar histologic principles that attempt to achieve complete margin control with paraffin-embedded pathology only[30,31].

Atypical Fibroxanthoma

Atypical fibroxanthoma (AFX) typically presents as an ulcerated nodule in the head and neck region of an elderly person with sun-damaged skin. In general, it grows in a contiguous fashion. Histologically, AFX is composed of spindle cells mixed with bizarre, multinucleated giant cells, making the tumor relatively easy to identify on Mohs surgery frozen sections. Mohs surgery has demonstrated utility in the management of AFX, especially in areas of cosmetic importance[11]. By immunohistochemistry, the tumor is positive for CD10 and CD68.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is an uncommon, slow-growing, locally aggressive soft tissue sarcoma that most often arises on the trunk of young to middle-aged adults. DFSP typically invades beyond the clinically visible tumor margins with unpredictable and irregular extensions. Recurrence rates after standard excision range from 11% to 53%. Mohs surgery is ideally suited to track the irregular tumor extensions of DFSP and offers cure rates from 98% to 100%[12–14]. Removal of DFSP with Mohs surgery can be quite time consuming due to the frequently large size of these tumors. Some physicians have proposed a modified "slow" Mohs technique in which paraffin-embedded sections ("rush" permanent sections) are utilized for tumors such as DFSP that may be difficult to interpret on frozen sections. Alternatively, CD34 staining can be employed to better define the tumor cells.

Merkel Cell Carcinoma

Merkel cell carcinoma (MCC) is an uncommon, but very aggressive, skin cancer, usually arising in elderly patients (see Ch. 115)[32]. There is usually a history of significant cumulative sun exposure or immunosuppression. Clinically, the tumor presents as a pearly to red–blue papulonodule and is often in the head and neck region. Microscopically, the tumor cells are uniformly deep blue, polygonal in shape and aggregate in large sheets, allowing them to be easily identified in frozen sections. By immunohistochemistry, MCC is positive for CK20 and synaptophysin. Treatment consists of complete surgical removal of the primary tumor via either Mohs surgery or wide excision, followed by radiotherapy to the primary site and regional lymph nodes (unless the lesion is low risk; see Fig. 115.20).

Microcystic Adnexal Carcinoma

Microcystic adnexal carcinoma (MAC) is an uncommon, locally aggressive tumor that typically involves the face of older adults (Fig. 150.4). Histologically, the cells demonstrate eccrine and pilar differentiation and often have an infiltrative growth pattern with frequent perineural invasion (see Fig. 150.3). In the literature, the overall recurrence rate for MAC approaches 40%. To date, Mohs surgery appears to offer the highest cure rate while permitting tissue sparing (see Table 150.2)[17]. A study by Chiller et al.[18] demonstrated that defects following Mohs surgery were four times larger than clinical estimates. They concluded that preoperative estimation of margins is generally unreliable, and complete histologic verification of clear margins is advisable.

Sebaceous Carcinoma

The use of Mohs surgery for management of sebaceous carcinoma has also been debated, primarily due to reports of discontiguous growth.

Fig. 150.4 Basal cell carcinoma (BCC) with microcystic adnexal carcinoma (MAC). A An elderly man who was referred for a biopsy-proven BCC of the left lateral cheek (small circle, upper); the tumor was treated three times as a BCC over the previous 15 years. Six months ago he developed a lump in the cheek (large circle, lower). **B** Defect after 4 Mohs stages confirmed a tumor-free margin; the buccal branch of the facial nerve was transected during tumor removal. Review of the frozen sections showed cells that were suspicious for MAC, so the specimen was thawed and submitted for routine histopathologic examination. **C** Because paraffin-embedded sections also suggested MAC, immunohistochemical stains were performed, demonstrating ductal structures that were CEA-positive (arrows), supporting the diagnosis of MAC. *Reproduced with permission from Stephen Snow, Atlas of Mohs Surgery Wound Management: Flaps, Grafts and Wound Care, Scope Publishing: Madison, WI, 2010.*

However, discontiguous growth will thwart any method of histologic margin evaluation. The desire for tissue conservation on the eyelid (the most common site of sebaceous carcinoma) makes Mohs surgery a logical approach. The removal of an extra safety margin of tissue for permanent sections may be a reasonable strategy with this type of tumor. The advantages of Mohs surgery for sebaceous cell carcinoma of the eyelid have been documented in a study showing an 11% recurrence rate with Mohs surgery, as compared to 30% with standard excision[19].

Other Adnexal Carcinomas

This group consists of the uncommon tumors that have sweat gland (eccrine, apocrine), sebaceous gland, or follicular differentiation. In addition to microcystic adnexal carcinoma (MAC) and sebaceous carcinoma, it includes mucinous eccrine carcinoma, eccrine porocarcinoma, adenoid cystic carcinoma, papillary eccrine carcinoma, and extramammary Paget's disease (EMPD). Except for EMPD of the groin or sebaceous carcinoma of the eyelid, the clinical features are rarely diagnostic[20]. As a group, the tumors are locally destructive with extensive unpredictable local tissue invasion, have a high rate of local recurrence when treated by wide excision, and metastasize late in the course of the disease.

Routine histology of paraffin-embedded sections plus immunohistochemistry are often necessary to confirm the initial diagnosis of these tumors. In addition, perineural spread (e.g. MAC) and epidermotropism (e.g. EMPD, sebaceous carcinoma) can be seen. Because their microscopic features are readily recognizable in frozen sections, they are amenable to treatment by Mohs surgery. EMPD may sometimes be the exception and PAS staining can help delineate the tumor cells within the epidermis.

Other Tumors and Applications

Mohs surgery has been used to treat a number of other malignant neoplasms, including angiosarcoma, lymphoepithelioma-like carcinoma, and leiomyosarcoma[21,33], as well as benign tumors that tend to recur, such as infantile digital fibroma and granular cell tumor. Experience with these rare neoplasms is limited, but the complete margin examination of Mohs surgery may provide enhanced tumor clearance. Mohs surgery has also been used to extirpate difficult-to-treat cutaneous fungal infections.

CONTRAINDICATIONS

Discontiguous tumors can create problems with false-negative margins, but this problem also occurs with all other methods of evaluating surgical margins histologically. Therefore, it is not an absolute contraindication. If a tumor cannot reliably be identified histologically, especially on frozen sections, this can also be a relative contraindication. For example, some cases of lentigo maligna can be difficult to identify as compared to the proliferation of atypical melanocytes found in adjacent

sun-damaged skin uninvolved by malignancy (Fig. 150.5). Also, spindle cell neoplasms can be difficult to distinguish from fibrosis. If patients are unwilling or unable to undergo surgery, then a non-surgical approach such as radiotherapy may be a better option. However, for some patients with serious medical problems, Mohs surgery done under local anesthesia may be safer than more extensive anesthesia and surgery in a hospital operating room facility.

PREOPERATIVE HISTORY AND CONSIDERATIONS

A history and focused skin examination should be performed at the time of consultation. The pathology report should be reviewed and if the diagnosis appears problematic, the histologic sections should be re-examined. Indications for antibiotic prophylaxis should be evaluated and then reviewed with the patient's primary physician if necessary[34]. Similarly, the management of any implanted cardiac pacemakers and defibrillators should be considered, with cardiology consultation if needed. Finally, the management of "blood thinners", including warfarin, aspirin, clopidogrel and nonsteroidal anti-inflammatory drugs (NSAIDs), should be discussed (see Ch. 151).

Upon completion of the medical evaluation, the Mohs surgeon should explain the nature of the tumor and the therapeutic options, and then obtain informed consent. The repair options should be briefly described. The patient should be encouraged to continue regular medications and eat a light meal on the morning of surgery, unless conscious sedation is planned. It is recommended that patients bring a friend or relative on the day of surgery.

Patients with extremely large or deeply invasive tumors may require preoperative evaluation with a CT scan, MRI or PET scan. Very complex cases requiring a multidisciplinary approach should be evaluated preoperatively by other subspecialties (e.g. neurosurgery) as needed. Following removal of the tumor by or with the assistance of the Mohs surgeon, the repair is performed by the most appropriate specialist. The team approach is especially useful in areas such as the periorbital area and external auditory canal. Mohs surgery is most commonly performed under local anesthesia. Conscious sedation may be an option for managing patients with multiple tumors who wish to be treated in one session.

DESCRIPTION OF TECHNIQUE

Table 150.5 provides a flow sheet for performing Mohs surgery and Figure 150.6 depicts the procedure.

VARIATIONS/REFINEMENTS/SPECIAL SITUATIONS

Over the past several decades, there have been several refinements made to the Mohs technique. The goals of these innovations are to improve the speed of tissue processing, the efficiency of tumor removal and the recognition of individual tumor cells in order to improve cure rates. Surgical improvements include: (1) the single section method; (2) geometric staged excision; (3) non-beveled 90° incisions; and (4) wide excision. Improvements to better recognize tumor cells include: (1) immunostains for frozen sections (see Table 150.4); and (2) submission of tissue specimens for routine histology ("rush" permanent sections) and immunohistochemistry (see Ch. 0). For example, the latter is done in the "slow" Mohs surgery method and in geometric staged excision.

Single Section Method

The single section (specimen) method for tissue processing of smaller tumors was described by Randle et al.[35]. The single section involves a highly beveled specimen processed with relaxing incisions on the superior, tumor-bearing portion of the specimen that allow all peripheral edges to fold outward into a single plane. The single section method is particularly useful for tumors in which a shallow Mohs layer can be taken, with the goal of allowing the resulting wound to heal by second intention. Additionally, the single section method allows unaltered examination of the complete deep margin, with no possibility of areas being missed by tissue subdivision.

Geometric Staged Excision

Geometric staged excision (GSE) is a process by which facial lentigo maligna is excised with perpendicular skin margins. Some surgeons use two closely spaced, parallel blades to create a square-shaped defect (thin

MOHS SURGERY FLOW SHEET
PREOPERATIVE ASSESSMENT
• Upon arrival, the patient's demographic information is confirmed, allergies, pertinent medications and vital signs are recorded, and the preoperative biopsy is reviewed • Any prophylactic antibiotic, anti-anxiety drug or cardiac device is either administered or managed as needed • The tumor is closely examined (Fig. 150.6A) and the clinical margin is marked (e.g. with gentian violet) • Reference to diagrams, landmarks and photographs is made to ensure correct site identification and every patient is asked to confirm the tumor location with a mirror • The planned procedure and possible reconstruction are reviewed and consent obtained
PREPARATION OF THE SITE AND FIRST MOHS SURGERY LAYER
• The site is then wiped with alcohol, local anesthetic (see Ch. 143) is infiltrated and the site is prepped with chlorhexidine or povidone-iodine • The central portion of the tumor is de-bulked with a curette to further define subclinical tumor extension (Fig. 150.6B) • The first Mohs surgery layer includes all clinically evident tumor plus a small margin of normal-appearing tissue (Fig. 150.6C) – Depending on the histologic subtype and likelihood of subclinical tumor extensions, the margin of normal skin may range from 1 to 10 mm (with narrower margins taken in areas where tissue sparing is essential) – For shallow tumors or those at sites favorable for second intention healing, the first Mohs layer is planned as a shallow excision – For deep tumors or at sites where second intention healing is not a good option, a full-thickness excision to subcutaneous fat is performed • For recurrent tumors, the most thorough approach is to resect all tissue involved by the previous treatments, including the primary site and reconstruction scar; if the recurrence is clearly isolated to only one site and/or complete resection would cause difficulties, then a localized resection of the clinically recurrent area can be considered • When excising the Mohs layer, the scalpel is held at a 30–60° angle to the skin surface to create a beveled incision (Fig. 150.6C) • Before the layer is completely removed, both the layer and the adjacent surrounding tissue are marked with one or more shallow scalpel cuts or notches to help orient the specimen to the defect (Fig. 150.6D) • The layer is removed with either a scalpel or iris scissors and placed on a transfer card or marked gauze while maintaining correct orientation relative to the defect (Fig. 150.6E) • Hemostasis is then obtained using electrocoagulation or thermocautery as indicated • A sterile pressure dressing is placed on the wound and the patient is discharged to a waiting room for 1–2 hours while the tissue is being processed
HANDLING OF THE TISSUE SPECIMEN
• A map of the specimen is drawn that is relative to anatomic landmarks and includes the skin notches (Fig. 150.6H) • The specimen is cut precisely into sections of sufficient size so that they can fit on the cryostat chuck and microscope slide (Fig. 150.6F) • Particular attention must be paid to maintain proper numbering, inking and mapping of specimens • All cut margins, except the epidermal edge, are inked systematically with different colored dyes and recorded on the specimen map (Fig. 150.6G, H) • The technician prepares the tissue pieces for freezing by flattening them so that the epidermis lies in the same plane as the dermis and deep margins, using one of several available techniques; if any edge or portion of the specimen curves upward, relaxing cuts are placed on the top surface of the specimen • The histotechnician embeds the tissue piece (deep surface upward) on a chuck with embedding medium and freezes it in the cryostat • Frozen sections are then cut, mounted on slides and stained with H&E – Some Mohs surgeons prefer the toluidine blue stain because it is rapid and the purplish metachromatic stromal staining helps to distinguish BCCs from adnexal structures
HISTOPATHOLOGIC ASSESSMENT AND ADDITIONAL LAYERS
• The surgeon examines the frozen sections and marks any residual tumor foci on the specimen map (Fig. 150.6J) • In patients requiring further resection, the surgeon precisely removes additional tissue only in the area of residual tumor, using the map and skin notches present on the patient for orientation (Fig. 150.6K) • This process is repeated until all tissue margins are microscopically free of tumor • Once the tumor is completely removed, the final defect is measured and photographed and wound management options are discussed and implemented

Table 150.5 Mohs surgery flow sheet. Figure 150.6 depicts the procedure. BCCs, basal cell carcinomas.

and frame-like) with the tumor and presumed adequate margins left intact. If the excised peripheral tissue is found to contain no tumor cells, then the central square is removed surgically. Others have found it easier to excise the entire specimen in a geometric pattern, ink the margins and then cut off strips along the margins; the latter are then oriented, inked, processed and cut *en face* while the central portion is cut vertically to determine the thickness of the tumor. These variations of GSE differ from the "slow" Mohs surgery method that uses beveled skin edges and creates an oval outline of excision. Whether the skin margin is vertical or beveled, "rush" paraffin-embedded sections are read the next day. If there are residual tumor cells, another peripheral thin square is removed until a negative (tumor-free) margin is achieved. The disadvantage of GSE is that there are a few extra millimeters of skin that are sacrificed in order to provide the straight lengths of tissue. For small tumors, i.e. when one to two layers are required to complete treatment, this difference is marginal. However, GSE loses its advantage when several layers are required and/or the tumor is irregularly shaped, because reconstruction becomes more complex. GSE is requested by dermatopathologists who prefer to read non-ovoid nuclei created by tangential sections and who find it easier to process the tissue so as to see the entire perpendicular epidermal margin.

Non-Beveled 90° Incisions

Some dermatologic surgeons perform non-beveled 90° incisions for most Mohs surgical procedures on the extremities. An advantage of this technique is that the vertical edges created are ideal for reconstruction. A disadvantage is that it requires excision of more tissue. Although a traditional beveled edge can be trimmed in preparation for reconstruction, a true, sharp, straight 90° angle is more difficult to obtain after resection of tissue. The 90° Mohs incisions do necessitate more extensive manipulation during tissue preparation, principally by creation of relaxing incisions in the upper portion of the specimen, in order to induce the tissue to flatten into a single plane.

Wide Excision Mohs Surgery

Wide excision Mohs surgery ("wide Mohs") is a modification of traditional Mohs surgery in which a larger, clinically tumor-free margin is taken either before or after Mohs histologic margin evaluation. This is performed on tumors that have a high propensity for recurrence or metastases (including satellite metastases), in particular melanoma, Merkel cell carcinoma and cutaneous sarcomas[8]. In utilizing wide Mohs margins, the surgeon is actively deciding to prioritize tissue processing speed over tissue sparing for high-risk tumors. Wide Mohs margins of 5–20 mm can be taken with high-risk tumors, while maintaining the advantages of 100% margin examination, in cases where tissue sparing is a lower priority.

Supplementation with Permanent Sections and Immunostains

During the removal of skin cancers, it is not uncommon for the surgeon to encounter a second neoplasm or to acquire evidence that the type of tumor being removed and the preoperative diagnosis differ (see Fig. 150.4). Reassessment and review of permanent sections can provide clarification. If the tumor is a spindle cell neoplasm, submission for routine histology (permanent sections) and immunohistochemistry is also reasonable (Fig. 150.7).

When confronted with tumors where histologic features in frozen sections may be challenging, e.g. lentigo maligna and DFSP, some Mohs surgeons elect to supplement the usual frozen sections with additional immunostained frozen sections, especially for high-risk tumors[26]. Alternating tissue sections are stained with H&E versus rapid immunostains; the latter are outlined in Table 150.4.

Tumors that Invade Bone

Invasion of bone by skin cancer occurs as a result of previous treatment, anatomic site, cancer type and biologic behavior, and patient comorbidities. For example, previous irradiation can damage the bone while direct invasion of bone favors sites where the overlying skin is thin (e.g. scalp, sinuses, sternum, distal phalanx). Bone involvement is also seen with difficult cancers in strategic sites such as a

desmoplastic SCC of the scalp, an invasive DFSP of the anterior chest or a metatypical BCC over the maxillary sinus. In addition, an SCC or BCC with perineural invasion can gain access to the bony canal through which the nerves pass.

Although skin cancer invades bone infrequently, when it does the following strategies are used to control its growth and potentially effect a cure: (1) establish the diagnosis and mode of invasion of the tumor histologically; (2) obtain an X-ray, CT scan and/or MRI to determine the macroscopic extent of bone involvement and status of the regional lymph nodes; and (3) refer to a related subspecialist for wide excision as indicated. In difficult or tumors with perineural invasion, additional Mohs layers should be taken to assure a tumor-free plane. Small foci of sinus, nasal or scalp bone may be excised locally with a bone rongeur or a chisel and mallet. Even when bone is exposed during tumor surgery, healing by second intention is possible. If sufficient granulation tissue can be stimulated to cover the exposed facial or scalp bone quickly, cellulitis and osteomyelitis are rarely problems[36]. Other options include coverage with an acellular dermal matrix or a split-thickness skin graft. These three methods of wound management are preferred over more complex flaps that may hide and bury residual tumor. Of course, patients who are immunosuppressed by age, illness or drugs will require close surveillance.

CHALLENGES AND PITFALLS OF FROZEN SECTIONS

The challenges and pitfalls encountered with frozen sections fall into four broad categories: (1) excisional factors; (2) physician factors; (3) laboratory processing; and (4) pathologic interpretation (Table 150.6).

MOHS SURGERY – CHALLENGES AND PITFALLS
EXCISIONAL FACTORS
• Includes patient skin characteristics such as thickness, contour and texture • Severely sun-damaged skin is more fragile and will tear and fragment, resulting in an incomplete Mohs layer and/or more pieces of skin to process • Some sites have complex tissue components such as muscle, cartilage and bone (must be decalcified before sectioning) • Each tissue component must be flattened and frozen to a single plane • Fatty tissue requires intense freezing, which can lead to an increase in epidermal freeze artifacts, tissue fractures and specimen chipping
PHYSICIAN FACTORS
• Includes proper numbering, inking and mapping • Excessive electrocautery can cause elongation of the nuclei and cytoplasm of epidermal keratinocytes as well as basement membrane retraction artifact, thus resembling BCC histologically – If the surgeon leaves excess epidermal tissue centrally within the layer, when the layer is divided and flattened, these cells may be pushed to the surface and be misinterpreted as residual tumor – "Persistence" of epidermal cells may lead to removal of an unnecessary Mohs layer
LABORATORY PROCESSING
• Include microsection preparation, cutting, staining and mounting • Improper cutting techniques lead to specimens that are too thick, too thin, folded or fractured • Dull knife blades result in fragmented or incomplete sections and "chatter" marks • Poor-quality staining with H&E and/or dehydration can compromise cancer cell recognition • Problems with mounting include inappropriate amounts of media, air trapping and dry slides
PATHOLOGIC INTERPRETATION (Fig. 150.8)
• Includes inability to recognize minute cancer foci that are hidden by inflammation or tissue camouflage • For some tumors, paraffin-embedded ("rush" permanent) sections may be easier to interpret as compared to frozen sections (e.g. lentigo maligna) • In cancers like DFSP, EMPD, and/or tumors that demonstrate perineural extension, frozen sections may be used to achieve a preliminary tumor-free margin and then an additional final layer may be removed and submitted for routine histology (i.e. permanent sections) and immunohistochemistry[37]

POSTOPERATIVE CARE

Multiple options exist for management of tissue defects after tumor clearance with Mohs surgery. The management strategy will take into account anatomic location, patient comorbidities, likelihood of surgery in the future, severity of the tumor, and the aesthetic needs of the patient. With guidance from the Mohs surgeon, patients are able to select the best options for reconstruction.

Allowing surgical defects to heal by second intention may result in excellent cosmetic results in areas that are concave, as demonstrated by the experience of Dr Mohs and others. Second intention healing can also be used for recurrent tumors in which flaps or grafts might hinder surveillance of the treatment site. Patients must be willing to meticulously cleanse the area over a 2- to 8-week healing period. Typically, wound care regimens involve cleansing the wound daily with a saline solution or soapy water, applying a layer of ointment, and then covering with a non-adherent dressing. Wound care after cutaneous reconstruction is similar to second intention wound care, although limited to 1–2 weeks. A discussion of cutaneous reconstruction can be found in Chapters 146–148.

Antibiotics may be given postoperatively for wound infection prophylaxis if surgery is extensive[34]. Additionally, surgical reconstruction on highly sebaceous noses and other sites with significantly high bacterial colonization may require prophylactic antibiotics. Pain control is assessed on a case-by-case basis. Substantial pain following Mohs surgery is uncommon, and, usually, acetaminophen is sufficient for postoperative discomfort. If warranted, oral narcotic analgesics may be prescribed for patients with low pain thresholds, large tumors, complex reconstruction, or wounds in anatomic locations of high tension.

Ongoing surveillance at least annually for new primary and recurrent cancer is recommended for all patients, given that 50% of patients with non-melanoma skin cancer will experience another skin cancer during the subsequent 5 years.

COMPLICATIONS

Fortunately, complications from Mohs surgery are uncommon. Intraoperative considerations include anxiety, pain (with local anesthesia injection), bleeding, nerve damage and allergic reactions. If warranted, oral midazolam can be given in the range of 5–15 mg for healthy adults. Hemorrhage is a potential risk during surgery, which is minimized with meticulous hemostasis and pressure bandaging. Epinephrine (adrenaline) included in the local anesthetic temporarily augments hemostasis. To date, there is no evidence that patients taking aspirin or warfarin for serious medical problems experience increased risks of serious hemorrhage or bleeding complications. In addition, while there is a significantly increased risk of bleeding complications in patients on thienopyridines (e.g. clopidogrel, ticlopidine) undergoing dermatologic surgery, these medications are typically continued due to the possible risk of internal thrombotic complications[37a,37b]. The most common site for major arterial transection is the superficial temporal artery, which usually requires suture ligation.

Injury to cutaneous sensory nerves occurs during all cutaneous surgery. Transection of significant motor nerves is occasionally necessary for removal of deeply invasive tumors, especially in the temporal region. Whenever possible, the surgeon should inform the patient before surgery of any possible loss of function or sensation. Before beginning surgery, the patient should be thoroughly questioned regarding allergies. Considerations include past reactions to local anesthetics, antibiotics, iodine, latex, and tape products. Fortunately, lidocaine allergy is rare, but the surgeon should be prepared for an emergency response if necessary.

Postoperative complications include bleeding, hematoma/seroma formation, infection, necrosis, dehiscence and scarring (see Ch. 151). The infection rate after Mohs surgery is very low (0.7%)[38]. Antibiotics should be considered for reconstructed sites on sebaceous noses and distal lower extremities (below the knee) as well as those near the nares and mouth. Antibiotics should also be considered when multiple Mohs layers were required for tumor clearance and for any debilitated patient when proper wound care is a concern.

Potential pitfalls result from lack of attention to detail, incorrect interpretation of histopathology (Fig. 150.8), and lack of appreciation of aggressive tumor characteristics[39].

FUTURE TRENDS

The history of Mohs surgery is one of continuous innovation and improvement. Given increases in the incidence of skin cancer, the demand for Mohs surgery services will continue to rise. Preoperative tumor definition with confocal scanning laser microscopy is being explored to assist in efficient removal of tumors[40]. Digital technology has been applied to Mohs surgery, enabling telepathology confirmation. The use of newer immunostains for either frozen or microwave-processed paraffin-embedded tissue continues to enhance the diagnostic sensitivity and specificity of pathologic examination. Finally, these and other innovations that are beyond the scope of this chapter promise to bolster the status of Mohs surgery as the gold standard for removal of cutaneous tumors[41–44], as will evidence gathered from computerized databases.

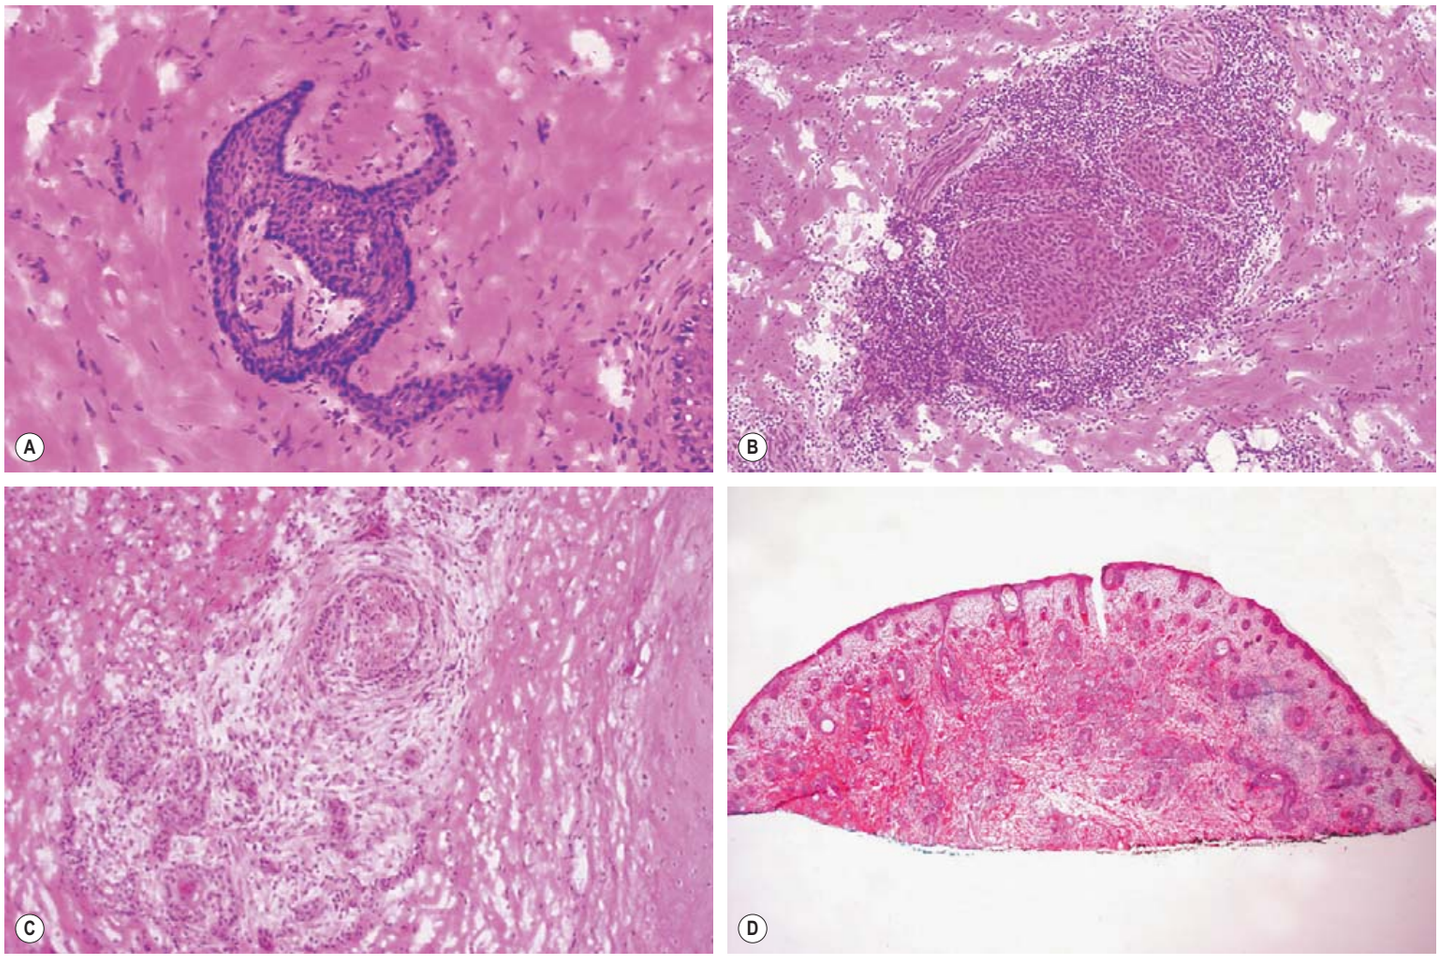

Fig. 150.8 Histologic challenges in Mohs surgery. A Folliculocentric basaloid hyperplasia may mimic basal cell carcinoma; however, the lack of clefting adjacent to the cells, apoptosis or mitotic figures as well as the presence of a fibrous sheath permits distinction. **B** Dense inflammation can obscure tumor cells, as seen here with a squamous cell carcinoma in a patient with chronic lymphocytic leukemia. **C** Careful evaluation is required to identify subtle foci of perineural squamous cell carcinoma. **D** Incomplete histologic margins (e.g. due to a small portion of missing epidermis) can lead to false-negative readings. *Courtesy, Clark C Otley, MD and Randall K Roenigk, MD.*

Surgical Complications and Optimizing Outcomes

151

Anna S Clayton and Thomas Stasko

Key features

- A thorough preoperative assessment of the patient is required to increase the chances for a successful outcome for any surgical procedure
- Attention to detail, selection of the simplest procedures that will produce the desired result, and meticulous intraoperative technique will prevent many complications
- Anticipation of avoidable complications and careful management of unavoidable ones optimize the results
- Clear communication between patient and surgeon must begin before the start of the procedure and continue through every stage, including the recovery and healing phases
- Many complications do not manifest until several days to months postoperatively; the patient must be monitored periodically to ensure that all parties are satisfied with the final outcome

INTRODUCTION

The verb "to complicate" means to make or become intricate and/or difficult. Surgical complications are deviations from the original planned outcome, which usually occur as the result of a series of multiple interrelated events (Fig. 151.1)[1]. Because of the nature of cutaneous surgery, the unexpected can and does happen; however, with careful planning and meticulous attention to technique and detail, many potential complications can be avoided or minimized.

Complications can threaten the patient's life, the ability to heal, and the cosmetic appearance of the scar. Life-threatening emergencies in cutaneous surgery are rare, but the surgeon must be prepared to deal with such problems as cardiac arrhythmias and anaphylaxis. Proper, well-maintained resuscitation equipment must be readily available, and the staff should be trained in Basic Life Support. Physicians in offices where extensive cutaneous surgery is performed should also have training in Advanced Cardiac Life Support. A full discussion of this topic is beyond the scope of this chapter, but it is well covered in other sources[2,3].

The surgeon should conduct a thorough preoperative assessment of the patient, including history and directed physical examination, to identify pre-existing conditions that may affect the patient's ability to heal. Informed consent obtained at this time and again just prior to the procedure ensures that the patient is well educated about what to expect. This education may minimize future misunderstandings. An outcome that the patient perceives as unexpected may in reality be an expected outcome for the given procedure. A discussion of the possible risks prior to the procedure may avoid this confusion.

Prevention of an unsatisfactory outcome starts in the planning stage of the procedure, then continues with good intraoperative surgical technique and careful postoperative care. Anticipation of avoidable complications and management of unavoidable ones optimize the results. Throughout the process, it is essential to involve the patient in his or her own care.

DISCUSSION

Preoperative Assessment

A thorough preoperative assessment is an invaluable tool for identifying conditions that could lead to surgical complications. A simple one-page preoperative questionnaire can be completed by the patient – with help from the nurse, technician or physician, as needed – at the time of the initial evaluation. "Yes" or "no" answers to specific questions can indicate a need for further evaluation or for a change in operative procedure or plan (Fig. 151.2).

Potential for bleeding

Although some bleeding is an expected part of any surgical procedure, excessive bleeding is a common complication. The discovery of a bleeding disorder prior to surgery allows for an attempt to correct the condition if it is reversible, or postponing or changing plans for surgery if it is not. The bleeding disorder may be due to abnormalities in the *coagulation cascade* (inherited deficiencies in coagulation factors, as in hemophilia) or with the *platelets*, or a combination of the two[4]. Platelet problems can be subdivided into problems with *production* (leukemia, use of myelosuppressive drugs), problems with *survival* (disseminated intravascular coagulation, idiopathic thrombocytopenic purpura), or problems with *function* (drugs, Hermansky–Pudlak syndrome).

If there is no history indicative of a bleeding disorder, and the patient is otherwise well, laboratory testing is usually unnecessary; however, appropriate screening laboratory tests should be checked if there is a suspicion of a hereditary or acquired bleeding disorder. A platelet count as part of the CBC (complete blood count) identifies only a quantitative problem. The bleeding-time test measures platelet function, but it can be difficult to perform and interpret as the results are very much operator-dependent. An *in vitro* bleeding-time assay, the platelet function analyzer 100 (PFA-100), provides an easy method for rapidly assessing platelet function. Unlike the bleeding time, the PFA-100 can be performed on a collected blood specimen. It is useful in detecting platelet defects, most cases of von Willebrand disease, and the effects of aspirin and other antiplatelet agents[5,6]. Additional standard screening tests include a PT (prothrombin time) test, which can determine a defect in the extrinsic clotting pathway and an aPTT (activated partial thromboplastin time) test, which can determine a defect in the intrinsic pathway[7].

A review of medications and nutritional supplements should be a part of the preoperative assessment. *Aspirin* and aspirin-containing products are well-documented sources of bleeding problems. Platelet aggregation is irreversibly affected when the aspirin acetylates cyclooxygenase. One aspirin affects a platelet throughout its lifespan of 6–10 days. Medically indicated aspirin should not be stopped. However, if the patient can safely discontinue aspirin without a high risk for stroke or myocardial infarction, it should be withheld for 10 days before surgery and then 5–7 days after surgery. Nonsteroidal anti-inflammatory drugs affect the same enzyme, though the block is not as severe or irreversible[8]. If possible, the patient should stop these medications 1–4 days prior to surgery, depending on the half-life of the drug. *Thienopyridines* (e.g. clopidogrel, ticlopidine) irreversibly inhibit platelet aggregation via inhibition of an ADP receptor on platelets. Normal platelet function usually returns 5–7 days after discontinuing these medications. In patients who take a thienopyridine for cardiac or neurologic indications, it is typically not advisable to stop the drug. Although there is a slightly increased risk of complications associated with dermatologic surgery in patients receiving thienopyridines, these medications can typically be continued without significant issues[9,9a].

Warfarin is a commonly used anticoagulant. Several studies have been published in the vascular, oral and dermatologic surgery literature that support the viewpoint that surgery can be performed without stopping warfarin as long as the international normalization ratio (INR) equals 2 to 3 or less[9–11]. The surgeon should minimize unnecessary undermining and ensure that intraoperative control of bleeding is meticulous. An INR should be checked just before surgery. The oral direct thrombin inhibitor, *dabigatran*, is increasingly been used as an

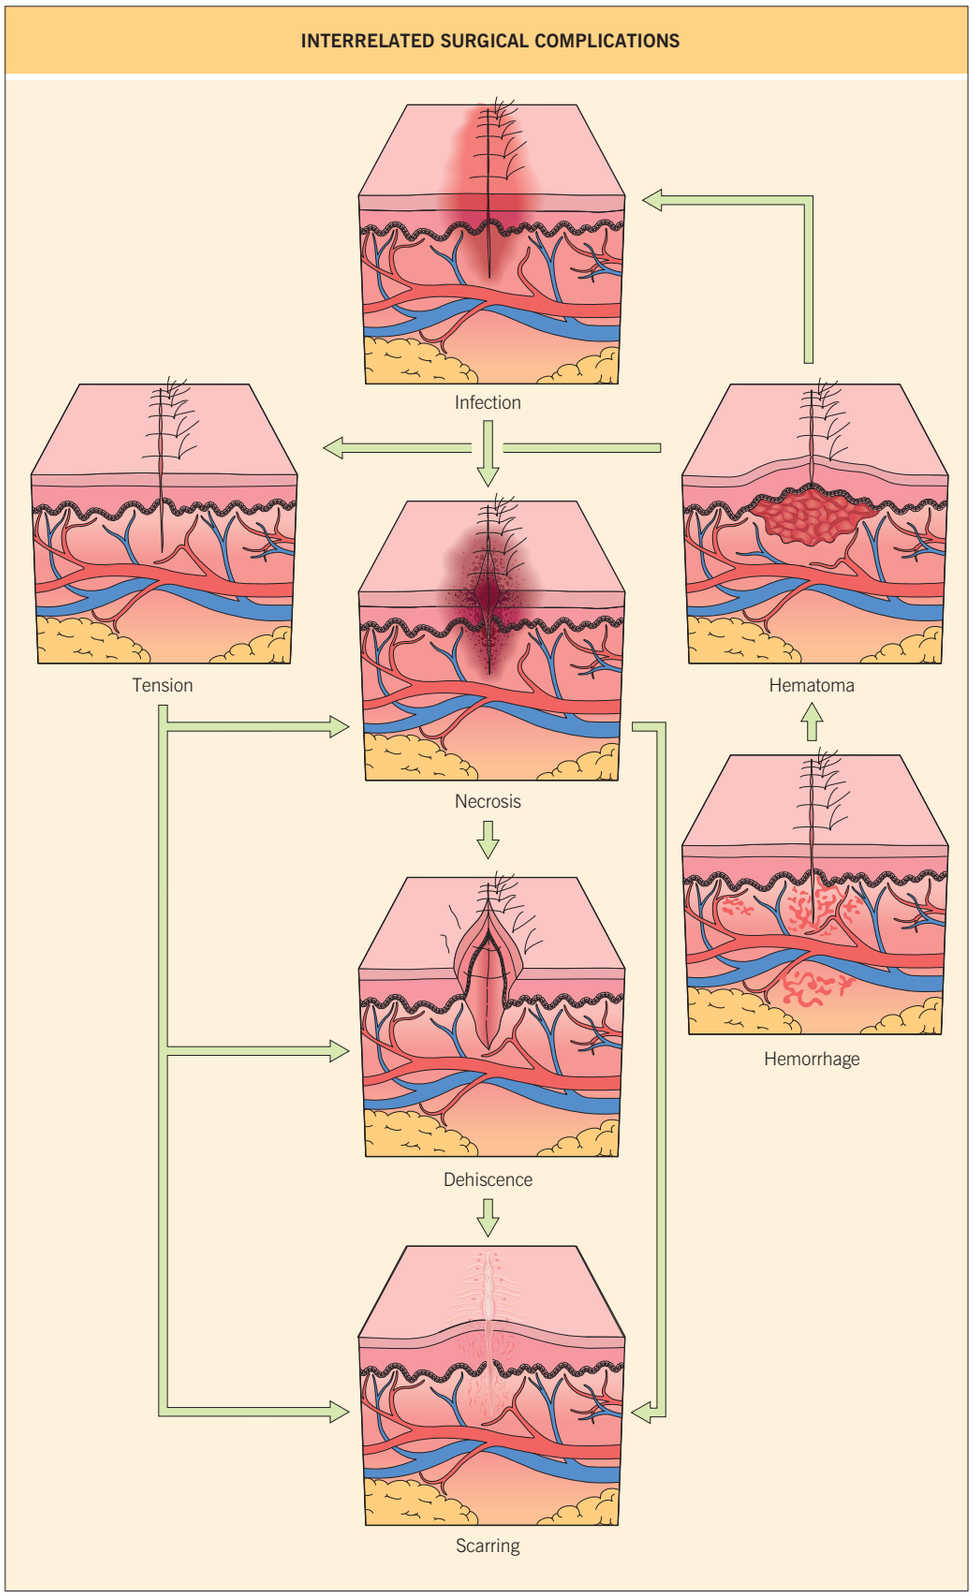

Fig. 151.1 Interrelated surgical complications.

alternative to warfarin[12a]. Literature is not yet available regarding the use of dabigatran in patients undergoing dermatologic surgery, but the authors would take similar intraoperative precautions as were mentioned above for patients on warfarin.

Heparin is given parenterally and acts as an antithrombin factor. When administered intravenously, heparin has a short half-life of approximately 1 hour and can be rapidly reversed by intravenous protamine sulfate. Heparin can be used to bridge patients who need an operative procedure that the surgeon feels should not be attempted in the presence of warfarin, but who cannot go without anticoagulation for prolonged periods of time. In a controlled setting, either subcutaneous low-molecular-weight heparin or intravenous unfractionated heparin is substituted for warfarin. Immediately before the surgery, heparin is discontinued or reversed with protamine sulfate. The heparin is then restarted post-procedure, again in a controlled setting[13].

Studies have shown that *vitamin E* in doses of 200–400 IU per day reduces platelet adhesion. Patients with abnormal platelets, such as diabetics and renal dialysis patients, treated with vitamin E have

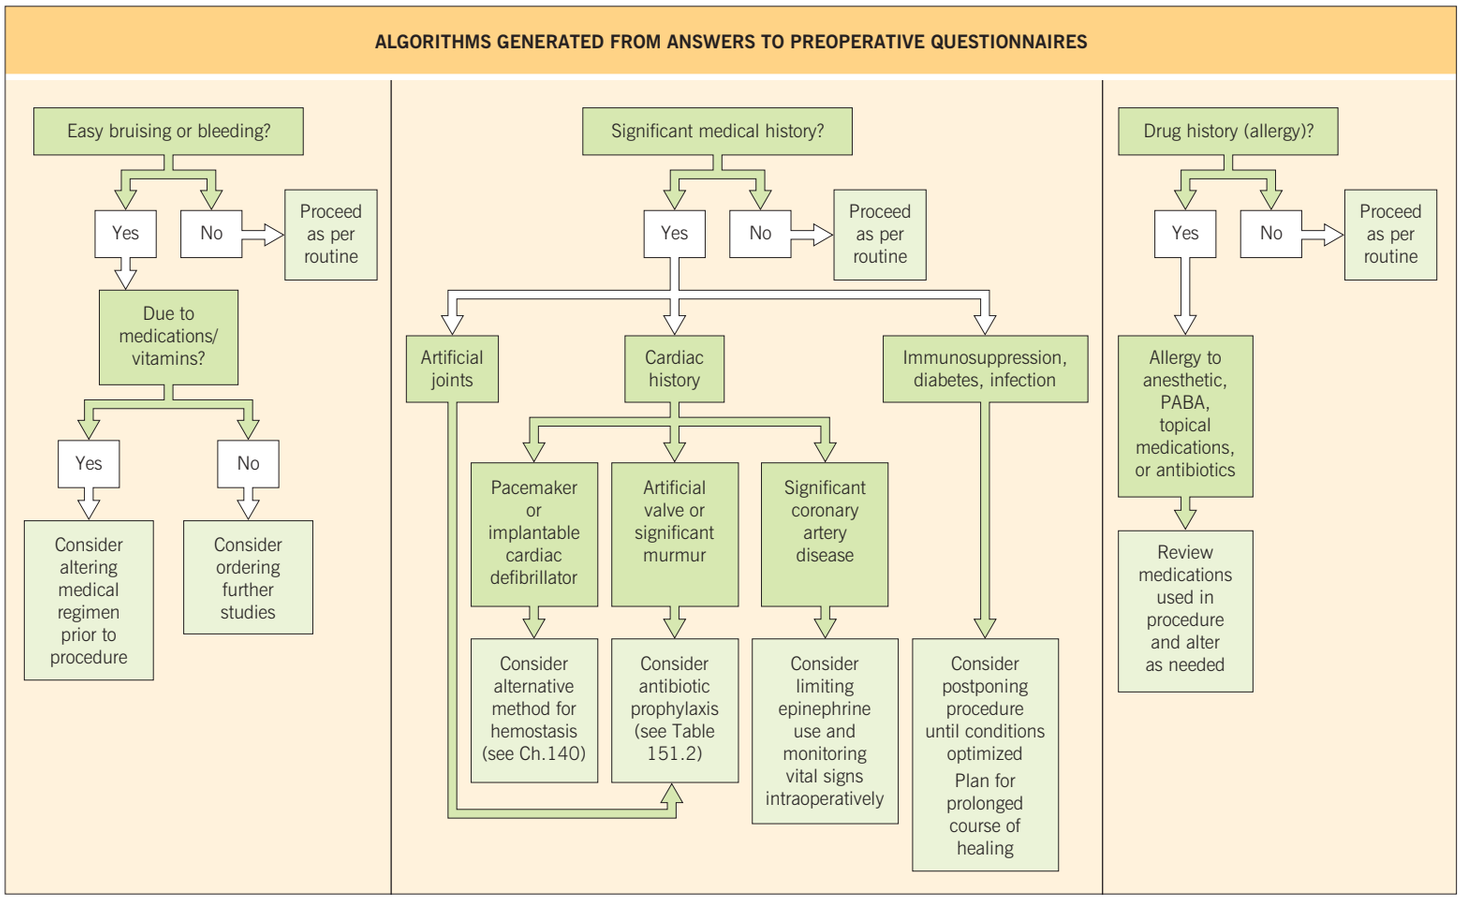

Fig. 151.2 Algorithms generated from answers to preoperative questionnaires. PABA, para-aminobenzoic acid.

decreased platelet aggregation. The effect is synergistic when vitamin E is taken with other antiplatelet agents such as aspirin and garlic. *Garlic* decreases platelet aggregation, and it significantly increases fibrinolytic activity at a dose of 900 mg/day. *Eicosapentaenoic acid* (fish oil) decreases platelet aggregation and adhesion and increases bleeding time. Many *other dietary supplements* such as dong quai, licorice, devil's claw and danshen have the same effect (see Table 133.3)[14]. Patients should be advised to discontinue supplements containing these substances in preparation for a surgical procedure.

Ethanol is a potent vasodilator. It may cause bleeding by inhibiting platelet aggregation and platelet granule release. It may also accentuate the increase in bleeding time caused by aspirin[15]. In addition, excessive alcohol consumption may decrease the patient's attention to optimal wound protection. Patients should be advised to avoid alcohol consumption during the immediate perioperative period.

Wound healing

The principles of wound healing are covered in detail in Chapter 141. To forestall complications due to poor wound healing, close attention should be paid to pre-existing medical conditions and medications that may affect wound healing. If the patient is a brittle diabetic, is suffering acutely from congestive heart failure, or has uncontrolled hypertension or a myriad of other severe conditions, it may be best to postpone the procedure until the patient's medical problems are under better control. If the procedure cannot be postponed, the patient should be forewarned that there might be a prolonged postoperative healing phase. In addition, any chronic debilitating illness may predispose patients to developing secondary infections.

Medications such as corticosteroids may also delay healing and predispose the patient to secondary infections and a prolonged postoperative course. Patients on other immunosuppressive medications such as cyclosporine may also be prone to infections and prolonged healing.

Cigarette smoking interferes with wound healing, and areas repaired by flaps or grafts are particularly susceptible. There is a dose-dependent decrease in the ability to heal after dermatologic surgery, with heavier smokers having an increased risk of post-operative necrosis as compared to lighter- and non-smokers[16]. In the authors' opinion, if the patient refuses to stop smoking, he or she should be strongly encouraged to decrease consumption to less than half a pack per day for 1 week preoperatively and for 3–4 weeks postoperatively, to attempt to maximize wound healing.

There is literature to support delaying procedures on patients who are on, or have recently completed, isotretinoin therapy, because of poor wound healing and the formation of excessive granulation tissue. In keloid fibroblast cultures, retinoids have been shown to modulate connective tissue metabolism. Most reported problems have been individual case reports involving resurfacing procedures after courses of isotretinoin for acne therapy. It may be prudent to postpone cosmetic procedures in such patients for up to 1 year after the cessation of isotretinoin therapy[17–19]. However, more recent data suggest that in select patients, acne scars can be treated with dermabrasion while taking isotretinion without side effects[19a].

Reactivation of a herpes simplex virus (HSV) infection can dramatically interfere with the postoperative course. Patients with a history of herpes labialis or other facial herpetic infections should receive prophylactic antiviral therapy prior to dermabrasion, laser resurfacing or chemical peels. Antiviral therapy, such as oral acyclovir at a dose of 200 mg five times a day, should start 2–5 days prior to the procedure and continue for 5 days postoperatively or until the skin has re-epithelialized[20]. Similar regimens consisting of oral famciclovir 250 mg three times daily or oral valacyclovir 1 g twice daily can also be utilized as they have more convenient dosing which can increase compliance.

The shoulders, central chest, upper arms and upper back are more prone to the development of hypertrophic scars, keloids and spread scars. The patient should be counseled before surgery about the increased risk of scarring in these areas.

Prophylactic antibiotics

Antibiotic prophylaxis is administered to prevent surgical site wound infection, the development of bacterial endocarditis, or infection in

WOUND CLASSIFICATION		
Class	**Attributes**	**% that develop infections**
Clean	Technique immaculate Non-inflammatory	1–4
Clean-contaminated	Small breaks in technique Gastrointestinal, respiratory or genitourinary tracts entered without gross contamination	5–15
Contaminated	Major breaks in technique Gross contamination from gastrointestinal, genitourinary or respiratory tracts	6–25
Dirty and/or infected	Wound with acute bacterial infection ± pus	>25

Table 151.1 Wound classification[1]. Technique in the table refers to sterile surgical technique.

implanted prosthetic devices. The risk and consequences of infection must be weighed against the risk and cost of administration of the antibiotic.

Wounds are placed into four general categories (Table 151.1). The majority of dermatologic surgical procedures fall into the clean or clean-contaminated categories and do not need prophylaxis. However, prophylactic antibiotics may be helpful in certain clean-contaminated wounds. Patients undergoing procedures involving the oronasal mucosa or genitourinary, axillary and gastrointestinal tissues should be considered for prophylactic antibiotics. In addition, procedures that approach the ear canal may be at higher risk for infection with Gram-negative organisms. Long procedures are also more likely to develop wound infections: the infection rate almost doubles with each hour of operation. Prophylactic antibiotics should be considered for procedures involving the lower extremities as well as more complicated procedures such as wedge excisions of the lip or ear, flaps on the nose and all grafts[21]. Antibiotics are therapeutic, not prophylactic, for contaminated or dirty and infected wounds; in such cases, a bacterial culture is helpful to best guide the antibiotic regimen.

When considering antibiotic prophylaxis, two special categories of patients should be addressed: (1) those at risk for infective endocarditis; and (2) those at risk for bloodborne infection of total joint replacements (Table 151.2)[21]. In the case of patients with total joint replacements (but not cardiac disease), prophylactic antibiotics are also recommended for surgery in non-infected sites at high risk of surgical site infection. However, if the surgical procedure and uncomplicated repair is to be performed in a non-infected, low-risk site, no antibiotic prophylaxis is indicated. Table 151.3 summarizes suggestions for antibiotic prophylaxis regimens. If any question arises, consultation with the patient's cardiologist, internist or orthopedic surgeon may prove quite helpful in determining the need for prophylaxis and the regimen to be used.

Defibrillators and pacemakers

The electrosurgical instruments often used in cutaneous procedures have the potential to interfere with the function of pacemakers and implantable cardioverter-defibrillators (ICD; see Ch. 140). If the patient's preoperative history reveals the presence of such devices, caution should be exercised to avoid inducing arrhythmias. Alternatives to electrosurgery may be considered. Battery-operated and AC-powered thermal cautery units have been used successfully in dermatologic surgery. They do not produce high-frequency electromagnetic interference or electrical currents traversing the body. Bipolar instruments concentrate the current across the tips, minimizing the chance of interference with implanted devices. If conventional electrosurgery must be used, the active tip should not be applied to an area within 15 cm of the implanted device whenever possible. Electrocoagulation should also be kept at as low a setting as possible, and it should be delivered in bursts lasting <5 seconds in order to minimize the chance of prolonged inhibition[22].

In consultation with the patient's cardiologist, the ICD can be deactivated for the duration of the procedure. The pacemaker can also be

ANTIBIOTIC PROPHYLAXIS FOR DERMATOLOGIC SURGERY – PATIENT GROUPS AT RISK FOR INFECTIVE ENDOCARDITIS AND INFECTION OF TOTAL JOINT REPLACEMENTS
HIGH-RISK CARDIAC CONDITIONS (INFECTED SKIN OR BREACH OF ORAL MUCOSA)
• Prosthetic heart valve • History of infective endocarditis • Unrepaired cyanotic congenital heart disease (includes palliative shunts) • Completely repaired congenital heart defects with prosthetic materials or devices* • Repaired congenital heart disease with residual defects at or adjacent to site of prosthetic patch or device • Cardiac transplant recipients who develop cardiac valvulopathy
TOTAL JOINT REPLACEMENTS (INFECTED SKIN, BREACH OF ORAL MUCOSA, OR NON-INFECTED SITE AT HIGH RISK OF SURGICAL SITE INFECTION)
• First 2 years after joint placement • Previous prosthetic joint infections • Type 1 diabetes mellitus • Immunosuppression (HIV infection, medications, underlying malignancy) • Malnourishment • Hemophilia
*First 6 months after procedure.

Table 151.2 Antibiotic prophylaxis for dermatologic surgery – patient groups at risk for infective endocarditis and infection of total joint replacements. Adapted from the American Heart Association, the American Dental Association, and the American Academy of Orthopedic Surgeons[21].

RECOMMENDATIONS FOR ANTIBIOTIC PROPHYLAXIS IN PATIENTS AT RISK FOR INFECTIVE ENDOCARDITIS AND INFECTION OF TOTAL JOINT REPLACEMENTS			
Surgical site/procedure	**Allergy**	**Antibiotic**	**Dose**
Non-oral – wedge excisions of lip or ear, nasal flaps, all grafts	None	Cephalexin* or dicloxacillin* *– or –* cefazolin/ceftriaxone*	2 g PO† 1 g IM/IV
Non-oral – wedge excisions of lip or ear, nasal flaps, all grafts	Penicillin	Clindamycin or azithromycin/ clarithromycin* *– or –* clindamycin	600 mg PO 500 mg PO 600 mg IM/IV
Oral mucosa breached	None	Amoxicillin *– or –* cefazolin/ceftriaxone or ampicillin	2 g PO 1 g IV/IM 2 g IV/IM
Oral mucosa breached	Penicillin	Clindamycin or azithromycin/ clarithromycin *– or –* clindamycin	600 mg PO 500 mg PO 600 mg IM/IV
Lesions in the groin or on the legs	None	Cephalexin* or TMP-SMX DS *– or –* ceftriaxone*	2 g PO 1 tablet PO 1–2 g IV
Lesions in the groin or on the legs	Penicillin	TMP-SMX DS or levofloxacin* *– or –* clindamycin and gentamicin	1 tablet PO 500 mg PO 600 mg and 2 mg/kg IV
*In communities with increased risk for methicillin-resistant *Staphyloccoccus aureus*, consider prophylaxis with TMP-SMX DS (1 tab PO) or clindamycin (600 mg PO). †Give PO single dose 30–60 minutes before procedure.			

Table 151.3 Recommendations for antibiotic prophylaxis in patients at risk for infective endocarditis and infection of total joint replacements (Mayo Clinic)[21]. IM, intramuscular; IV, intravenous; PO, by mouth; TMP-SMX DS, trimethoprim–sulfamethoxazole double-strength.

placed in a fixed rate mode, rather than the sensing mode, to minimize the possibility of interference. During the procedure, if conventional electrosurgery is to be used, continuous cardiac monitoring with an ECG and possibly a pulse oximeter should be strongly considered. A contingency plan should be in place to deal with an arrhythmia should it occur and an automated external defibrillator (AED) should be immediately available. If the device is deactivated or its function altered for the procedure, it is the surgeon's responsibility to ensure that the patient returns to his or her cardiologist within a reasonable time, for readjustment and evaluation post-procedure. Electrical equipment should be properly grounded during the procedure. If bipolar forceps or true electrocautery is used instead of electrosurgery, intraoperative monitoring, cardiology consultation and postoperative evaluation may be unnecessary for most stable patients[23].

Allergies

True allergic reactions to local anesthetics may be type I (immediate) or type IV (delayed-type hypersensitivity) (see Ch. 143). Patients who have a type IV sensitivity to one major group of local anesthetics (ester or amide) are usually not allergic to members of the other group. However, patients with a history of para-aminobenzoic acid (PABA) allergy can cross-react with anesthetics in the ester group (e.g. procaine). Type I reactions are more commonly associated with the ester anesthetics and their PABA metabolite. Although the lack of cross-reactivity between ester and amide anesthetics is true for type IV sensitivity, it has not been adequately studied for anaphylaxis. If there is a possibility of a type I amide allergy by history, or if the surgeon is reluctant to substitute an amide in an ester-allergic patient, referral to an allergist for a progressive challenge protocol can be considered to identify a suitable amide anesthetic[24]. It is also important to consider the possibility that the allergic reaction is due to the preservative (e.g. methylparaben, metabisulfite) and the use of preservative-free anesthetics can resolve this problem.

Epinephrine (adrenaline) is a vasoconstrictive agent commonly added to local anesthetics because it lessens bleeding and prolongs the duration of anesthesia. Patients will occasionally report a history of an "allergy" to local anesthetic, describing their symptoms of palpitations, headache, tachycardia, tachypnea or tremor (see Ch. 143). These reports may, in truth, be reactions to epinephrine given in high dosages or inadvertently injected intravascularly. Since the half-life of epinephrine in serum is short, when these reactions do develop, specific therapy is usually not necessary. In order to avoid them, the lowest dosage and concentration of epinephrine (less than 1 : 200 000) should be used and injection of significant amounts intravascularly should be avoided using proper infiltration technique[25].

Another very commonly encountered systemic side effect often mistaken by the patient as an allergic reaction is the vasovagal reaction. The patient recalls becoming pale, sweaty and lightheaded, perhaps even fainting. In contrast to a true toxic or allergic reaction, the pulse remains slow and regular and the blood pressure and respiratory rate are normal (see Table 143.3). No loss of bowel or bladder control or prolonged tonic-clonic movement occurs unless the patient has a seizure secondary to brain hypoxia during the vasovagal reaction. Treatment consists of keeping the patient supine or in the Trendelenburg position and giving reassurance until the patient recovers sufficiently to be allowed to gradually sit up and ambulate[26].

Chlorhexidine gluconate is a frequently utilized surgical skin preparation. It is a broad-spectrum antibacterial of the halogenated phenol class. Though it has a very weak sensitizing potential, it has been reported to cause allergic contact dermatitis[27]. Similar reactions have also occurred with the iodophor povidone-iodine (Betadine®)[28]. Both compounds can also be skin irritants, especially when occluded. Care must be taken to ensure that all traces of skin cleanser are removed prior to application of the dressing.

Topical antibiotics can cause allergic contact dermatitis. Neomycin is the most common sensitizer, though bacitracin can also cause sensitization. Co-reactivity against both neomycin and bacitracin is common. Cross-sensitivity between neomycin and gentamicin, kanamycin, streptomycin and tobramycin can also occur. Mupirocin or erythromycin ointment are alternatives if the patient is allergic to both neomycin and bacitracin. As there is no convincing evidence that topical antibiotic ointment prevents infection, plain petrolatum (paraffin) ointment may be the best agent for wound dressing.

Informed consent

The lines of communication should be open between the surgeon and the patient before the procedure begins. The physician should make the patient aware of his or her condition, how it affects overall health, if treatment is imperative, and what different treatment options might be available. Pros and cons of surgery as well as alternative therapies should be discussed in a language that the patient can easily understand. To assess how much the patient understands, it helps to ask the patient to describe the procedure in his or her own words. The patient should also be informed about the risks of the procedure and the results to be reasonably expected. Common complications (like bleeding, infection, allergic reactions, scarring) should be addressed and strategies for dealing with them discussed. In turn, the patient must accept responsibility for preoperative preparation and postoperative wound care.

It is the surgeon's responsibility to provide oral and written, clear, detailed information delineating the indications for the procedure and describing the procedure, the risks involved, and the postoperative care necessary to ensure the best outcome possible. Should complications arise, as they inevitably will in some cases, the surgeon should be honest with the patient about treatment options and outcome.

Intraoperative Considerations

Contamination

Although good statistics are lacking, the risk of infection in cutaneous surgery is very low. It is certainly less than 5%, and most probably is in the range of 1–2%. The indications for prophylactic antibiotics were discussed previously. Although wound infections usually do not become evident until 4–8 days postoperatively, in most cases the infection truly begins at the time of surgery. The surgical team should prepare the skin and the surgical field, prepare the instruments, and wear the correct protective equipment in order to help reduce the incidence of infection and protect both the patient and caregivers.

The skin cannot be sterilized, but it is possible to remove the majority of the resident flora and pathogenic bacteria by using mechanical cleansing and antiseptic agents. The extent of skin preparation varies with the invasiveness and complexity of the proposed surgical procedure. A 2-second wipe with 70% isopropyl alcohol or a 10-second cleansing with an iodophor swab may be adequate for most shave and superficial biopsies[29]. Chlorhexidine produces rapid bacterial destruction, is effective against a wide range of Gram-positive and Gram-negative bacteria, and binds with the protein of the stratum corneum, providing residual action. These properties make it the most frequently used preoperative preparation for skin surgery. It is, however, irritating to the conjunctiva, and it may be toxic to the cornea or tympanic membrane and middle ear, so caution must be exercised in these areas. Iodophors are another excellent antiseptic; one advantage is that the area that has been prepared is readily apparent because of the brownish-orange color. They are effective against Gram-positive and Gram-negative bacteria and some fungal spores, but they have a slower and shorter duration of action than chlorhexidine. Also, as noted earlier, they can cause skin irritation, and there are patients who may develop an allergic contact dermatitis to this cleanser.

The preparation and sterilization of surgical instruments is covered in Chapter 144. Use of the surgical mask may help protect the patient from surgical personnel with active upper respiratory tract infections. The mask protects the surgical team from contamination by saliva droplets or blood from the patient. It is also essential to protect the eyes from accidental splashes of body fluid. Appropriate surgical attire and glove use is advocated in all surgical situations as part of universal precautions. In cases where sterility is not essential, such as superficial shave biopsies and electrodesiccation and curettage, non-sterile examination gloves can be used. Some dermatologic surgeons perform Mohs surgery in a sterile fashion while others use a clean technique. Recent data suggest that Mohs surgery can be performed as a clean procedure with low infection rates[29a].

Bleeding and hemostasis

Hemostasis can be approached based on the amount of bleeding encountered (Fig. 151.3). Bleeding that occurs during shave biopsies, i.e. superficial dermal oozing, can be controlled through the use of mechanical pressure or topical hemostatic agents such as aluminum

chloride[30] or electrodesiccation. Bleeding which occurs during more extensive procedures such as excisions or Mohs procedures, i.e. vascular bleeding or muscle oozing, may require suturing, use of other hemostatic agents (Table 151.4), electrocoagulation, or a combination of techniques.

Intraoperative bleeding can obscure the surgical site. It can be upsetting to both the surgeon and the patient. If it continues after closure, it can cause a hematoma that can lead to infection, increased tension on wound edges, and dehiscence (see Fig. 151.1). A careful history should have helped to identify patients prone to bleeding, and

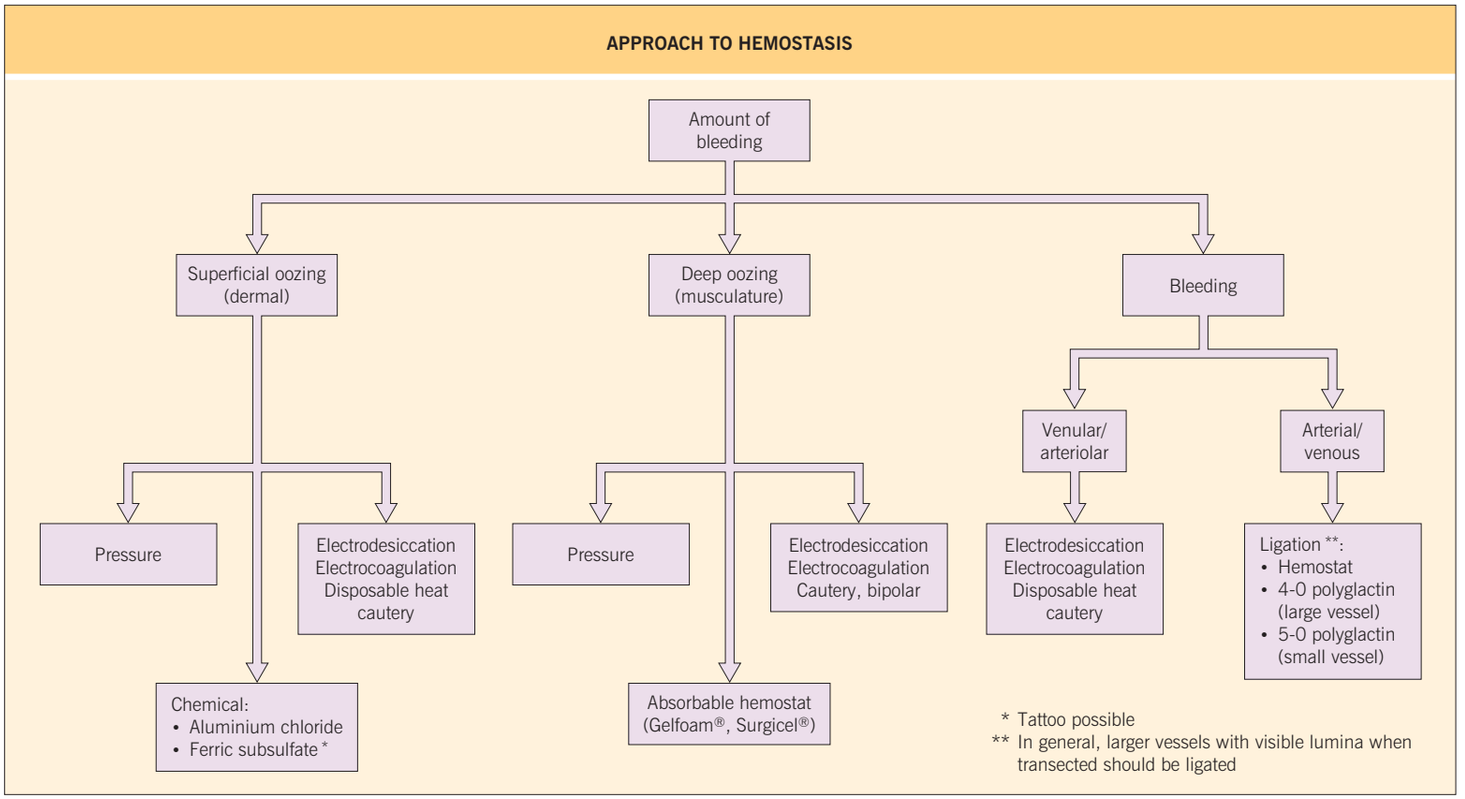

Fig. 151.3 Approach to hemostasis. *Courtesy, Glenn Goldman, MD.*

HEMOSTATIC AGENTS

Generic name	Trade name®,™	Advantages	Disadvantages
Bone wax	Bone wax	Effectively controls bony surface bleeding (skull)	Impedes bacterial clearance; nidus for infection
Gelatin foams	Gelfoam, Gelfilm, Surgifoam	Non-antigenic; absorbed within 4–6 weeks; controls small vessel and bony bleeding	Significant swelling occurs
Oxidized cellulose	Surgicel, Oxycel	Low pH has antimicrobial effect; dissolves in 2–6 weeks	May cause foreign body reaction; can not combine with thrombin
Microfibrillar collagen	Avitene, Helistat, Instat, Collastat	Swelling not significant; absorbed in <8 weeks	Less effective in thrombocytopenic patients
Thrombin	Thrombin-JMI, Evithrom, Recothrom	Fast, controls minor capillary and small venule bleeding	Do not use in individuals who react to human blood products
Thrombin with gelatin	Floseal	Controls moderate arterial bleeding	Can swell up to 20%; needs contact with blood which serves as fibrinogen source
Fibrin sealants	Tisseel, Evicel	Controls venous oozing from raw surfaces	Can be denatured by antiseptics containing alcohol, iodine or heavy metal ions
Ferric subsulfate (20% solution)	Monsel's solution	Inexpensive; low pH resists bacterial contamination	Can cause tattoo/discoloration; for superficial oozing
Silver nitrate (applicator sticks)		Easily stored; some bacteriostatic properties	Tattoo risk; for superficial oozing
Aluminum chloride (20–40% solution)	Drysol, Xerac AC, Certain Dri	Inexpensive	Some formulations flammable; may delay wound healing; for superficial oozing
Powders composed of hydrophilic polymers with potassium salts	QR powder	Fast, inexpensive	Can only be used on wounds healing by second intention
Powders composed of microporous polysaccharide hemospheres	Bleed-X	Absorbed by body so can be used on wounds that will be closed	

Table 151.4 Hemostatic agents.

it may have allowed for changes in medical management or medications preoperatively, to reduce intraoperative bleeding. When not contraindicated (e.g. procedures on toes or fingers in patients with peripheral vascular disease), use of epinephrine with the anesthetic is helpful (see Ch. 143). Suction can also maintain good visualization in an otherwise bloody field. An assistant can provide traction across the wound surface or pressure at the periphery of the site. Frequent blotting with sponges or cotton-tipped applicators also helps to keep the field clear.

Bleeding should be controlled as soon as is practical; individual small vessels should be isolated and precisely cauterized (to avoid excessive char) or ligated. It may be prudent to ligate visible vessels lying proximal to the wound bed, since they might be nicked or partially cut during the procedure. Large vessels noted in the surgical wound should be tied off or cauterized at both visualized ends as long as the surgeon is sure there is adequate collateral circulation to the area. Tying off visible vessel ends using a figure-of-eight technique with an absorbable suture provides reliable hemostasis (see Fig. 146.2). Of note, bleeding, which may not be apparent at the time of the closure, may develop once the effect of epinephrine diminishes. The surgeon must ensure that the surgical field is as dry as possible prior to closure. Particular attention should be paid to apices or cut muscle that can steadily ooze.

If, at the beginning of the procedure, bleeding is more than usual, undermining should be minimized and consideration should be given to a linear closure rather than a flap or graft. Blood easily accumulates unnoticed in non-visualized "dead space". Placement of a drain should be considered for larger flaps or complex multilayered linear closures, to allow egress of small amounts of continued bleeding and to avoid hematoma formation. Drains can be classified into open and closed systems. An example of an open system, which lacks an enclosed network or collecting system, is a Penrose drain. It is a passive drain, allowing fluids to flow passively by gravity into gauze. For dermatologic surgery, a simple fenestrated small Penrose drain can often suffice (Fig. 151.4). It should be removed 24–48 hours later, once bleeding has lessened and the chance for hematoma formation has diminished. Closed systems are sealed, with a draining tube connected to a container with the potential for generating active suction to draw the fluid from the tissue cavity into the container. Examples of closed systems include the vacuum mini-flap drain[31] and the Jackson–Pratt drain.

In open wounds that continue to bleed in spite of adequate attempts at hemostasis, hemostatic agents[32,32a] such as gelatin foams (Gelfoam®), oxidized cellulose (Oxycel®, Surgicel®), microfibrillar collagen (Avitene®, Collastat®) or topical thrombin can be applied to the wound to provide a matrix to speed coagulation (see Table 151.4). Caution should be exercised when using oxidized cellulose, because the use of excessive amounts can result in foreign body reactions[33].

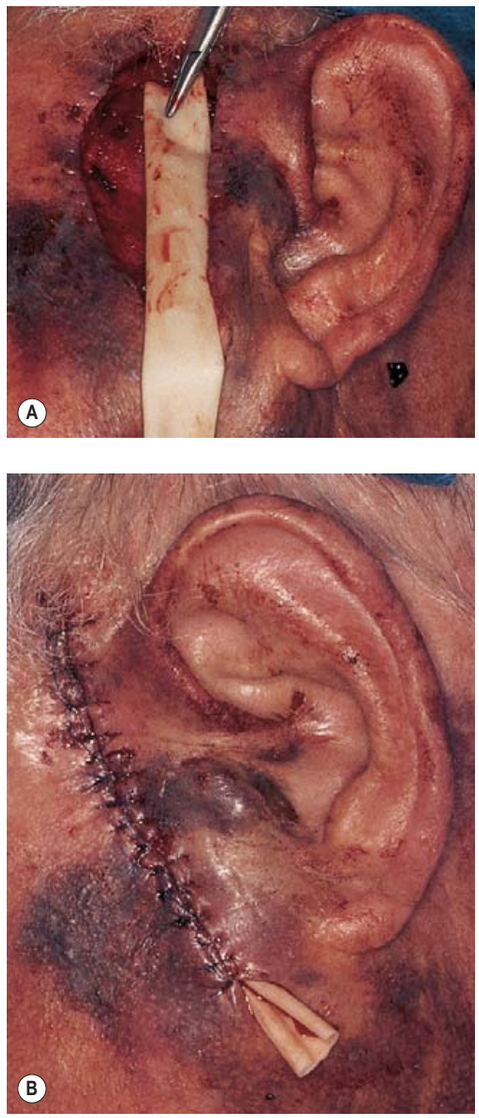

Fig. 151.4 Placement of Penrose drain because of excessive bleeding.

Tissue injury

Because of the nature of invasive procedures, some tissue injury is unavoidable. Gentle handling of the wound edges during the procedure minimizes trauma and allows the viable tissue to heal more rapidly. Skin hooks or single-toothed forceps should be used carefully to grasp tissue without crushing it. When using electrocautery or electrocoagulation to control bleeding, avoid indiscriminate and excessive burning. Large areas of charred and necrotic tissue left in the wound increase the risk of inflammation and infection.

Tension

Excessive tension at the closure site can cause tissue necrosis and dehiscence (see Fig. 151.1). Postoperatively, tension can be a source of increased discomfort for the patient once the local anesthesia has dissipated. There is a tendency for the surgeon to tighten surface sutures when wounds gape open. Such action can lead to "train track" scars. At the time of surgery, the operative site should be thoroughly evaluated and the closure planned to minimize wound tension. Adequate undermining should be accomplished. Buried absorbable sutures should bear the burden of the tension, minimizing the need for tight surface sutures. The closure should be oriented to take advantage of maximal tissue movement. Instead of a linear closure, using a flap or graft to close the defect can minimize tension in appropriate circumstances. Relaxing incisions can also be performed 2–3 cm from the wound edge, parallel to the incision site, to share tension over a larger area. If the defect cannot be completely closed due to excessive tension, partial closure can be accomplished and the remainder of the wound allowed to heal secondarily. If the site is chosen well (usually in concave areas), this method yields an excellent cosmetic result. Intraoperative or preoperative tissue expansion may also allow for the safe closure of large defects[34]. If a wound appears too tight at the time of closure, it probably is, making complications more likely (Fig. 151.5).

Necrosis

Necrosis is usually the result of a hematoma, an infection, or wound tension compromising blood flow to the skin edge, resulting in necrotic tissue (see Fig. 151.1). Although pale, poorly perfused tissue at a flap or wound edge may be a warning of future problems with perfusion, actual necrosis will not become evident until the postoperative time period. The factors leading to necrosis begin preoperatively and continue into the perioperative period. The hazards of smoking have been discussed earlier, but they cannot be overemphasized. Smoking decreases perfusion and increases the risk of necrosis. Patients should be counseled repeatedly to stop, or at the very least decrease, their exposure to tobacco or other nicotine-containing products.

The blood supply to the skin arises primarily from the subdermal plexus. Extensive superficial undermining may damage this plexus and the segmental arteries supplying it. Hematoma formation may compromise blood flow to and from the area through pressure on this plexus. Even normal postoperative edema may compromise blood flow. Sutures tied too tightly may also decrease perfusion, leading to necrosis. The use of a loop stitch, leaving space between the first and second

Fig. 151.5 Postoperative appearance of wound closed under tension with resulting necrosis.

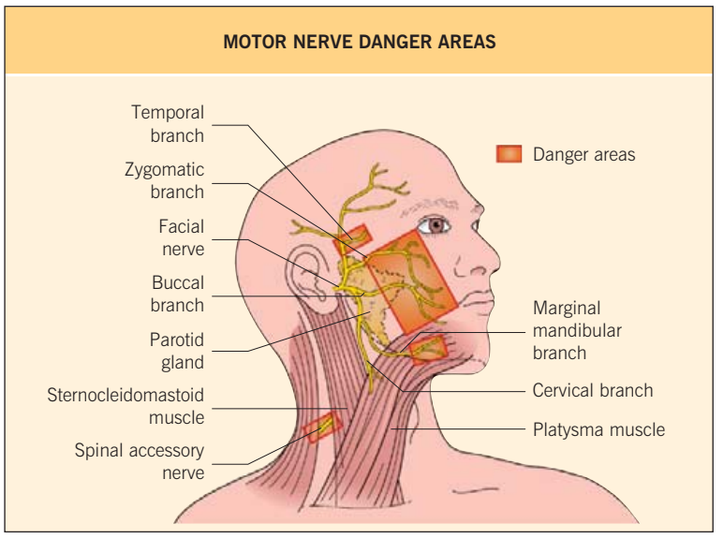

Fig. 151.6 Motor nerve danger areas.

loops of the surgeon's knot, may allow for tissue expansion from post-surgical edema, decreasing the risk of tissue necrosis.

The vasoconstrictive properties of epinephrine that make it ideal in most locations may be extremely detrimental in areas with limited collateral circulation such as the digits. In such cases, it would be prudent to use smaller amounts of an anesthetic that contains epinephrine, a more dilute epinephrine concentration (e.g. 1 : 500 000 instead of 1 : 100 000), or a local anesthetic without epinephrine.

Flap tips may become necrotic because of an inadequate blood supply. If the 3 : 1 length-to-base ratio is exceeded, circulation to the distal tip may be poor. When correcting redundancies caused by rotation at the base of a flap, the surgeon must ensure that the pedicle is not narrowed. Correction of the redundancy may need to be delayed in order to protect the vascular supply to the flap.

Grafts may become necrotic if an adequate blood supply from the wound bed is not established. In general, full-thickness skin grafts require more nutrients than split-thickness grafts (see Ch. 148). Areas with a poor or absent vascular supply, such as exposed bone, exposed cartilage or sites of previous therapeutic radiation, often cannot support full-thickness grafts and may not fully support even split-thickness grafts. In particular, sites with greater than 1 cm^2 of exposed bone or cartilage have a greater incidence of graft failure. Delaying graft placement for about 10 days after the initial surgery may improve graft take.

The graft must also be well apposed to the wound bed. Strict hemostasis is required to prevent blood from accumulating in the space between the graft and the wound. However, excessive electrocoagulation should also be avoided because of the resulting necrotic debris created. Absorbable hemostatic agents may also interfere with the engrafting of the new tissue. The placement of basting sutures and tie-down bolsters may help ensure adequate contact between the graft and the wound bed (see Ch. 148).

Nerve deficits

The preoperative evaluation should include a quick survey of neurologic function in the areas that could be affected by the proposed procedure. During cutaneous surgery, sensory and motor nerves may be injured or cut (see Ch. 142). It is essential to document – and, more importantly, make the patient aware of – pre-existing deficits prior to infiltrating the anesthetic (see Ch. 143). Local anesthesia or nerve blocks can lead to temporary nerve deficits lasting 6–12 hours. Full evaluation of the extent of the injury may have to wait until a day to several weeks after surgery.

Skin surgery will result in the transection of cutaneous nerves. Patients frequently note sensory deficits at the site of primary closures or flaps. Almost all will experience hypoesthesia in skin grafts. Most areas have diverse sensory innervation, and, unless a major nerve is injured, there are very few significant permanent deficits. Sensory nerves often do regenerate, though this process may take a number of months. The patient should be aware preoperatively that there may be paresthesias in the area as it heals. Occasionally, completely normal sensation never returns. The areas most prone to sensory nerve injury leading to noticeable sensory defects are the digits, the forehead and the scalp.

Injury to motor nerves can be more alarming, since this can result in paralysis of the denervated muscles. The closer to the nerve root that the injury takes place, the more severe the consequence. Thankfully, most of the larger branches of the facial nerve are deep to the muscle fascia and well protected. As a result, injuries to the main trunk of the facial nerve (or its zygomatic and buccal branches) rarely occur in dermatologic surgery, because these nerves lie relatively deep and are somewhat protected. Injuries to these nerves do, however, result in significant sequelae, including an inability to close the eyelids, loss of sphincter control around the mouth leading to drooling, and a distorted face.

The area of highest consequence on the cheek lies lateral to a line drawn from the lateral canthus of the eye to the angle of the mouth and medial to where the nerve divides into five major branches near the surface of the parotid gland (Fig. 151.6). Medial to this area, innervation is usually diverse enough to render the results of transection of a single nerve mild. Lateral to this area, the main trunk lies deep within the parotid gland and is relatively well protected by it[35]. Unless the procedure is a deep excision of an infiltrative skin cancer, the majority of cutaneous surgeons are unlikely to cause significant motor nerve injury except in the following important danger zones:

- The *temporal branch of the facial nerve* courses very superficially as it crosses the zygomatic arch and traverses the temple where it is covered only by the superficial temporalis fascia, with very little subcutaneous fat. The nerve lies deep to the superficial temporal artery. Paralysis of the frontalis muscle results from transection of the nerve in this location. The ability to elevate the forehead on the affected side is lost (Fig. 151.7A). This loss is often of only cosmetic concern; however, if there is pre-existing brow ptosis, the paralysis may result in a severe ptosis that interferes with vision and requires surgical correction with a brow pexy.
- The *zygomatic branch of the facial nerve*. Damage to this nerve, although less common than damage to the temporal branch, can lead to an inability to completely appose the upper and lower eyelids and subsequent corneal desiccation. This is due to its innervation of the obicularis oculi muscles.
- The *mandibular branch of the facial nerve* is subject to injury as it crosses the mandible, near the facial artery and vein. It is covered at this point only by skin and thin platysma muscle. This nerve innervates the lip depressors, and injury can cause asymmetry visible when the patient smiles or attempts other facial expressions using these muscles. In addition, mouth function may be compromised, resulting in drooling.
- The *spinal accessory nerve* can be damaged as it exits from behind the sternocleidomastoid muscle at Erb's point in the posterior

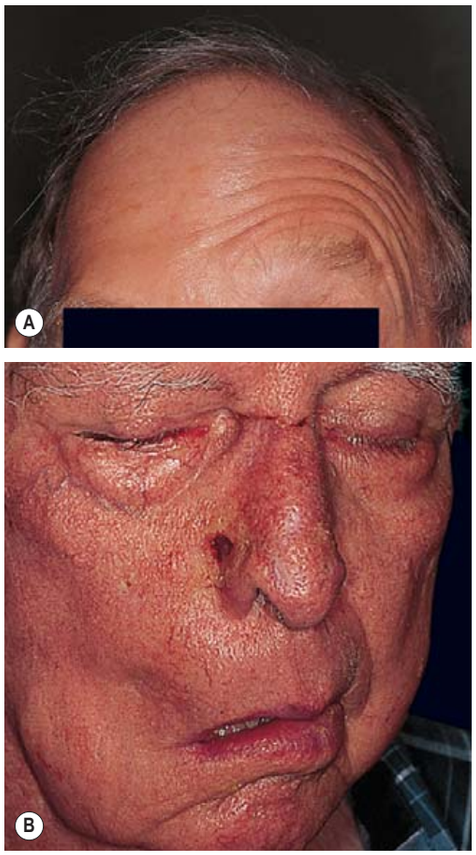

Fig. 151.7 Damage to the facial nerve. A Loss of the ability to elevate the forehead due to transection of the temporal branch. **B** Loss of function of the main branch of the facial nerve. The ability to close the right eye has been restored by the placement of a gold weight in the eyelid.

Fig. 151.8 "Trapdoor" or "pincushion" appearance of a flap reconstruction.

triangle of the neck. Damage leads to winging of the scapula and difficulty abducting the arm, because of paralysis of the trapezius muscle. Pain is a frequent accompaniment of injury to the spinal accessory nerve.

The surgeon must be aware of these danger zones and be on the lookout for these nerves (see Fig. 151.6). Injury is sometimes unavoidable even with the most careful dissection, especially if a neoplasm involves the nerve. Early consultation, even preoperatively, with the appropriate specialties (neurology, neurosurgery, radiation oncology) may allow for optimal management of the problems. Regeneration of motor nerves is possible, but unpredictable. When major motor branches are cut, surgical reapproximation or nerve grafts may be necessary. Muscle stimulation may prevent atrophy while awaiting return of function. At times it may be practical to simply address the functional problems created, such as placing gold weights to allow eye closure (Fig. 151.7B).

Unsatisfactory scarring

Although scars do not acquire their final appearance until months postoperatively, operative techniques can greatly affect the appearance. Spread scars were discussed earlier. Though they may be unavoidable in certain anatomic areas, the surgeon may choose to use longer-lasting absorbable or non-absorbable sutures in the deeper layers of the closure, in order to reduce the risk of early spread scars[36].

A trapdoor or pincushion-like appearance may develop in the area of transposition flaps (Fig. 151.8). Wide undermining at the time of repair and squaring off the corners, rather than trimming more circular wound edges, may reduce the incidence of this complication[37]. Removing excess subcutaneous tissue underneath the flap and trimming the flap so that it just covers the defect without any redundancy may also help.

Postoperative Considerations

After the procedure is complete and the patient has left the office, complications may still occur. Before the patient leaves, detailed wound care instructions should be reviewed with the patient and whomever else may be helping to care for the wound site. The surgeon must also ensure that the patient has been provided with easy-to-understand, written postoperative wound care instructions. These instructions should include answers to the most commonly asked questions, for example, "How do I know if it is infected?" "How much bleeding is too much bleeding?" "When can I take a shower/bath?" "When can I play golf/ tennis?" The patient should also have a direct method of contacting the physician or a suitable representative if there are questions or concerns not answered by the handout provided. A little foresight and education can greatly reduce the number of midnight calls or quickly bring to the attention of the physician a complication best addressed earlier rather than later. It is imperative that the contact physician be available and responsive. It is helpful for the physician or designee to call the patient postoperatively to check on his or her progress and answer questions.

Bleeding/hematoma/ecchymosis

Some cases of postoperative bleeding will occur despite exhaustive preoperative evaluation, preparation, and careful intraoperative hemostasis. Most bleeding occurs within the first 24 hours, with the majority occurring within 6 hours. During this period, clots are still fragile and movement can easily dislodge them. As the epinephrine dissipates, small vessel bleeding may increase. A pressure dressing applied immediately after the procedure helps to prevent this problem. The patient should be instructed to leave the dressing in place for at least 24 hours. If the surgical procedure was more involved than a superficial shave or punch biopsy, the dressing should consist of multiple layers: ointment, then an initial non-adherent contact layer (e.g. Telfa®, Release®), followed by a bulky absorbent layer consisting of gauze, cotton, sponges or eye pads. An outer layer of tape or stretchable gauze (e.g. Ace Wrap®, Coban®) then covers all of these. The bandage should provide pressure but not cause ischemia.

A small amount of bleeding is normal; however, the patient should be told that bleeding which soaks the dressing needs attention. The patient should be instructed to remove the old dressing, as saturated dressings no longer provide any meaningful pressure, and apply firm pressure without release to the site for 15–20 minutes as timed *by the clock*. If pressure stops the bleeding, then the dressing should be reinforced with additional gauze and tape. If bleeding persists, then the patient needs to be evaluated by the surgeon.

The surgeon can once again attempt direct pressure, but, if this fails, the wound should be exposed, and the area reanesthetized and explored. If a single bleeding vessel is identified, then it can be electrocoagulated or ligated. Frequently, a single source is not identified. Bleeding can occur in multiple areas and each must be addressed. A drain may be helpful if a very dry surgical field cannot be achieved. If possible, surgical procedures should be scheduled early in the day to prevent having to bring the patient in during the wee hours of the morning to accomplish this.

If blood collects in the open space of a wound instead of seeping out through the wound edge, a hematoma forms. The presenting symptom

may be an acute, throbbing pain if the hematoma is a large, expanding one. Smaller hematomas cause more of a pressure sensation. Early, expanding hematomas should be evacuated. Hematomas can lead to dehiscence or necrosis due to pressure, and they may act as a nidus for infection. Hematomas consist of gelatin-like clots that are usually too firm to evacuate without removing sutures (anesthetize the area first!). After evacuation (Fig. 151.9), the site should be irrigated and any residual bleeding controlled. The wound may be re-closed, with particular attention paid to closing any dead space. Placing a drain is often appropriate. Many surgeons advocate empirical antibiotics after hematoma evacuation, because of an increased risk of infection.

If the hematoma goes unnoticed and untreated for several days after surgery, the clot becomes organized (Fig. 151.10). It is then thick, fibrous, and adherent to the surrounding tissue. If large or actively expanding, it should still be evacuated. In most circumstances, the resulting wound should be allowed to heal by second intention with possible delayed closure, instead of primary closure (Fig. 151.11).

Small, organized hematomas can be allowed to reabsorb without evacuation. If at around 1–2 weeks postoperatively there is significant liquefaction leading to a fluctuant mass, the fluid can be aspirated with a large bore (16–18-gauge) needle. Warm compresses applied for 30- to 60-minute intervals several times daily, can speed resolution.

Bromelain (bromelin), found in the pineapple plant, has been used as a medicinal throughout the ages. One placebo-controlled study found that bromelain decreased the time required for resorption of surgery-associated hematoma. The recommended dose was 500 mg immediately postoperatively and then three to four times a day on an empty stomach until the hematoma resolved. Patients not allergic to pineapple reported no side effects[14].

Ecchymoses occur when there is leakage of a small amount of blood into the interstitial space. A bruised appearance is common following surgical procedures involving areas with loose distensible tissue, such as the periorbital area or the upper chest in the elderly. It can be alarming to the patient who is not counseled to expect this possibility. The involved area changes in color from deep purple, black and blue, to green, and then to yellow as the hemoglobin is degraded to bilirubin.

Fig. 151.9 Hematoma. **A** Postoperative hematoma formation. **B** Evacuation of gelatin-like clot.

Fig. 151.10 Organized hematoma of the upper back.

Fig. 151.11 Evacuation of an organized hematoma. Prior to (**A**) and immediately after (**B**) evacuation of the clot. **C** After 2 weeks of healing by second intention.

The ecchymosis can extend widely, usually migrating to dependent areas. The concern is mainly cosmetic and temporary, because most resolve with time and leave no sequelae.

Infection

Although most cases of infection begin at the time of surgery, postoperative contamination is possible if good wound care does not occur. Blood-soaked dressings are excellent breeding grounds for bacteria. The patient or caregiver should be instructed to wash their hands carefully prior to changing any dressings or cleaning the wound site. Excessive exposure or manipulation of the wound site during the first 24–48 hours after the procedure should be avoided.

Infection usually does not become evident until 4–8 days after surgery. The patient may note increasing erythema (Fig. 151.12). Instead of dissipating with time, pain and tenderness may increase. Ascending red streaks (lymphangitis), swelling, and a purulent discharge may develop. Systemic symptoms of fever and chills indicate spread of the infection.

The area should be placed at rest, elevated, and heat applied. If the infection seems more than just mild, sutures should be removed and the defect left open. If an abscess is present, it should be drained. Deep cavities should be packed lightly with iodoform gauze. Packing needs to be changed daily until drainage stops. Discharge or exudate should be sent for Gram stain and culture. Antibiotics should be initiated based on the most likely causative organism(s) and a Gram stain if available. The choice of antibiotic should be adjusted as necessary once the culture results are available. *Staphylococcus aureus* is the most frequent culprit in the skin. A first-generation cephalosporin, a β-lactamase-resistant penicillin or a penicillin/β-lactamase inhibitor combination would be an appropriate choice (see Ch. 127). If *Pseudomonas aeruginosa* is suspected, as in postoperative chondritis of the external ear, a fluoroquinolone would be appropriate. If there is rapid spread, systemic symptoms, or extensive lymphangitis, the patient may need parenteral antibiotics, more aggressive wound care, and possible hospitalization.

The rise in the incidence of methicillin-resistant *S. aureus* (MRSA) is concerning. It would be wise for the surgeon to familiarize him- or herself with the rates of MRSA in the local community. Although the incidence of MRSA surgical site infections in dermatologic surgery is unknown, it is important to consider this as a possibility. After culture of the site, if there is a high index of suspicion for MRSA infection, consider the use of oral trimethoprim–sulfamethoxazole or clindamycin while awaiting culture results[21].

Contact dermatitis, or candidal or dermatophyte infections, may mimic bacterial infection. Contact dermatitis due to topical antibiotics frequently presents with pruritus rather than pain and with erythema corresponding to all areas of ointment application rather than being confined to limited portions of the wound (Fig. 151.13). Contact dermatitis from bandage adhesives will usually be strikingly limited to the area of adhesive contact. Inflammatory suture reactions may occur without infection (Fig. 151.14).

Necrosis

The earliest sign of necrosis may be pallor. There may also be cyanosis at the periphery of the flap or graft. Early intervention could include judicious suture removal or replacement to reduce tension, elevation to reduce edema, thereby improving blood flow, and gentle heat applied to the area to improve circulation. Treatment with hyperbaric oxygen may be appropriate in the face of early necrosis of a large or vital reconstruction[38].

Once necrosis is established, very minimal cleaning and debridement should be undertaken until the full extent of necrosis is clearly demarcated. More vigorous debridement may extend the process further. An eschar eventually forms and will separate from the wound base as it heals by second intention (Fig. 151.15). If infection is present, it should be treated appropriately. Delayed scar revision is an option if the site does not heal with an acceptable appearance.

Dehiscence

Wound edges can separate because of excessive tension, infection and necrosis (see Fig. 151.1). Dehiscence most often occurs at the time of suture removal, though it can certainly happen before or after. Scar tensile strength never exceeds 80% of the strength of uncut skin and maximum tensile strength is not achieved until months after the procedure. At 2 weeks after surgery, tensile strength is less than 10% of normal (Fig. 151.16)[1]. Patient education must emphasize and re-emphasize this lack of tensile strength. Patients should be told specifically in which activities they may or may not engage (i.e. no lifting more than "x" pounds, no running, no jogging, no sit-ups, etc.).

Fig. 151.15 Necrosis of a full-thickness skin graft. Two weeks after placement.

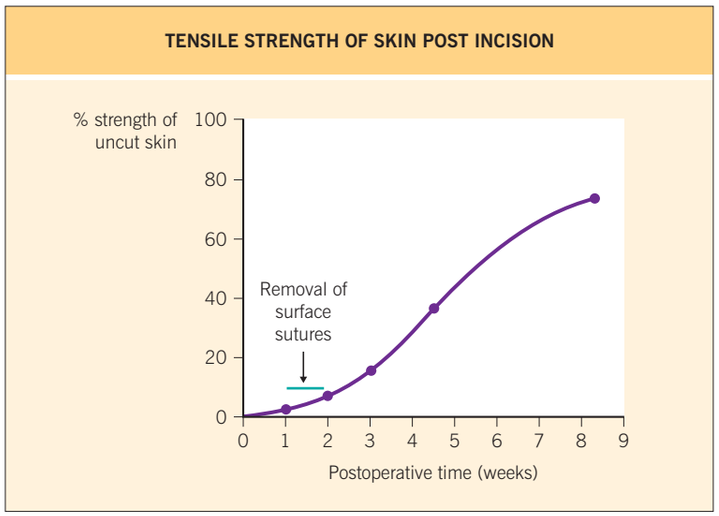

Fig. 151.16 Tensile strength of skin post-incision.

Fig. 151.17 Wound dehiscence after suture removal.

If prolonged support is needed, sutures may be removed in stages. Adhesive strips can provide some short-lived support for 1–2 days after suture removal. If the wound opens at suture removal because of excessive tension or too much activity (Fig. 151.17), the surgeon can consider resuturing if there is no infection, hematoma or necrosis. If dehiscence is due to another underlying complication, such as infection or hematoma, that condition should be treated first.

Wound appearance

Postoperative wound appearance may be a source of anxiety for both patient and surgeon. Problems may range from the simple (e.g. a spitting subcutaneous suture) to the more complex (e.g. a trapdoor deformity or spread scar). A key to dealing with most of these problems is continued and open communication between patient and surgeon. The patient who does not feel free to express concern or dissatisfaction in the office may all too readily do so in other places where the surgeon may not hear about it and cannot act to correct what can be corrected.

Buried sutures should be absorbed uneventfully by the body within the period of time specified by the manufacturer. Unfortunately, nature does not always adhere to package inserts. As digestion of the suture takes place, sterile abscesses may form as pustules along the suture track as well as granulomatous reactions (Figs 151.18 & 151.19). In addition, sutures may extrude or be "spit" from the skin intact (Fig. 151.20); while some authors believe this is more likely to occur if the sutures are placed too superficially within the dermis, even deeply placed sutures can be extruded in some patients. These events may occur anywhere from 1 to 4 months postoperatively, most commonly at about 6 weeks. The pustules can be opened with a sterile needle and the remaining suture gently removed. Sometimes, the papules are deeper. If the appearance is consistent with a suture reaction, reassure the patient that it is not a recurrence of the excised malignancy, then instruct the patient to gently massage the site. Perform a biopsy if warranted. If the suture is protruding, it can be carefully removed. The ultimate appearance of the scar is usually unaffected by this process.

A, B The suture material present within the dermis is cut both en face and longitudinally; on higher power, histiocytes and multinucleated giant cells surround the suture (**B**) and the giant cells have engulfed the suture material (**C**). *Courtesy, Lorenzo Cerroni, MD.*

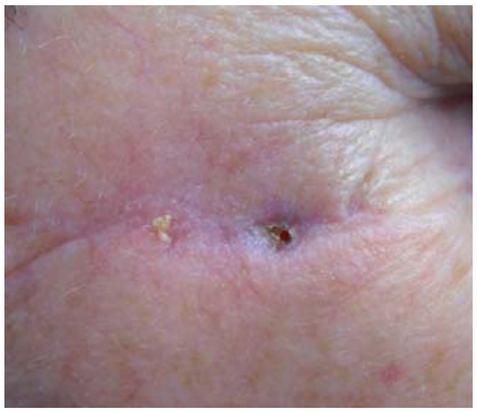

Fig. 151.20 Spitting suture within the incision line.

Fig. 151.21 Suture "tracks" in a spread scar.

Fig. 151.22 Hypertrophic scar. One month after excisional surgery.

Suture tracks or railroad tracking is caused by tight sutures left in place too long (Fig. 151.21). The best way to avoid this appearance is to minimize wound tension and to allow for early suture removal. Proper placement of buried sutures can help relieve wound edge tension.

Some anatomic sites are more prone to the development of keloids and hypertrophic scars (Fig. 151.22), and some individuals may have a genetic predisposition to keloid development. Keloids differ from hypertrophic scars by growing beyond the margins of the original wound (see Ch. 98). Intervention at the early stages of a hypertrophic scar can yield a more acceptable result. High-potency topical corticosteroids or intralesional corticosteroids may decrease the thickness of the scar and the accompanying symptoms of pain and pruritus. However, there is a risk of telangiectasias, atrophy or widening of the scar. Smaller hypertrophic scars may respond to simple massage. Silicone gel sheeting applied to the scars and worn for 12–24 hours per day for at least 2 months has been shown to improve the appearance of hypertrophic scars and keloids[39]. Simple occlusion and hydration may be just as effective without silicone[40]. One study using topical onion extract found that it was ineffective in improving erythema or pruritus of postsurgical scars, while petrolatum-based ointment alone did improve appearance[41].

Scar appearance can also be improved by dermabrasion or ablative laser resurfacing. When performed during the 4–8-week interval following the initial injury, it superimposes the mechanisms of second intention wound healing on the remodeling phase of the primary scar. This in turn appears to re-establish a normal-appearing epidermis across initial scar boundaries[42]. Lasers such as the pulsed carbon dioxide (CO_2) laser, fractionated ablative and non-ablative lasers, and the 585 nm pulsed dye laser, or a combination of these lasers, are also used in the treatment of hypertrophic scars and keloids[43,44].

Keloids tend to develop more frequently on the earlobes, neck and trunk. In predisposed individuals, especially those with a personal or family history of keloid formation, even superficial shave biopsies can result in keloid formation. Patients at risk should be counseled about this prior to the procedure. There are several treatment modalities used for keloids, with varying degrees of success (see Ch. 98).

Even well-approximated wound edges can produce spread scars. Like hypertrophic scars and keloids, they are more prevalent in certain anatomic areas such as the back, chest and shoulders. Patients who need excisions in these areas should be counseled preoperatively about the possibility that what may initially appear as a thin scar may widen over time. Most of this process occurs within 6 months after the surgery.

If a trapdoor deformity forms in the area of a flap, corticosteroid injections can improve the appearance. The patient should also be instructed to massage the area. Revision can be considered if these interventions do not produce an acceptable cosmetic result. Multiple small Z-plasties along the scar as well as peripheral undermining can also improve the appearance[45]. However, patience often produces the best results.

Any time the epidermis is injured, hyper- or hypopigmentation can result. This is more pronounced in dark-skinned individuals. Again, patients should be warned about this possibility pre- and postoperatively. The wound site should be strictly protected from UV exposure. Early epidermal hyperpigmentation can be improved with the use of topical hydroquinones, though this is ineffective unless combined with UV protection.

CONCLUSIONS

Avoiding complications requires planning and careful evaluation at each stage of the procedure: preoperative, intraoperative and postoperative. Despite the best of intentions, careful planning, and the most expert of hands, complications still occur. The surgeon must learn from experience, and the experience of others, to improve patient care. Finally, the surgeon must always remember to treat the patient, not just the condition. The patient's expectations and concerns must be addressed, not simply the surgeon's. Like beauty, complications are in the eye of the beholder. The patient who feels abandoned by his or her physician may not be happy with any outcome, no matter how technically perfect.

INTRODUCTION

"It is amazing how complete is the delusion that beauty is goodness."

~Leo Tolstoy

Nancy Etcoff, in *Survival of the Prettiest: the Science of Beauty*, explains that beauty is a universal component of the human experience which promotes pleasure, rivets attention, and impels action that helps ensure survival of our genes[1].

Striving to be more beautiful is not a new phenomenon. Human preoccupation with beauty and a youthful appearance dates back as far as recorded history. Anthropologists have determined that over 40 000 years ago, red ochre paints were used in southern Africa for facial and body ornamentation[2]. In 5 BC, the Roman author Ovid wrote *The Art of Beauty*, the first known book on beauty and cosmetics, detailing the use of black eye shadow made from wood ash and golden eye shadow made from saffron.

Few human traits are as ingrained as beauty. It is thought to be hardwired into our brains and can even be detected in infants. Studies have shown that by the age of 3 months, babies stare longer at attractive faces than those judged to be less attractive. Also, 1-year-old toddlers will play longer with attractive dolls than more plain dolls[3]. In functional magnetic resonance imaging studies where subjects were shown photographs of attractive men and women, viewing beautiful faces activated reward circuitry within the brain and dopamine pathways[4].

If examined from an evolutionary standpoint, this innate attraction to beauty certainly makes sense. Those who are attracted to the opposite sex and likewise are found to be attractive are more likely to mate and pass on their genes. Attraction to beauty also makes sense from a disease perspective. It is said that "beauty is a burden that only the healthy can carry." In other words, the sickly are by nature not attractive. Those with an ideal physique and youthful proportions are much more likely to be healthy and be able to reproduce. Again, by choosing an attractive mate, one is increasing the odds that his or her genes will be passed on.

In one study, 20 subjects were asked to grade graduates from a 1920s high school yearbook on their attractiveness. When the actual lifespans of these graduates were determined, facial attractiveness correlated with increased lifespan. Correlations between beauty and health help to explain why, from an evolutionary standpoint, the concept of beauty may become an innate concept within a species[5].

Besides being considered a more ideal mate, attractiveness may also have a number of other benefits. Nancy Etcoff has stated that people tend to respond positively to good-looking people without expectation of reward, and, further, that good-looking people tend to be less penalized for everything from shoplifting to cheating at exams[1]. In the same workplace, attractive people were found to earn up to 12% higher wages as compared to co-workers who were considered average-looking[2]. Also, pharmaceutical representatives have been shown to have a 1.9% increase in sales for every unit increase in the Likert Scale for attractiveness. While the average height of a man in the US is 5′ 7″ (170.2 cm), the average height of Fortune 500 CEOs is 6′ 1″ (185.4 cm). Statistically, US Presidents have also been found to be significantly taller than their constituents. Lastly, even West Point graduates who had higher scores on an attractiveness scale rose to higher military ranks.

EVALUATION OF BEAUTY

Recognizing beauty and understanding its significance may be far easier than actually defining it[6]. Anthropometry represents the quantitative

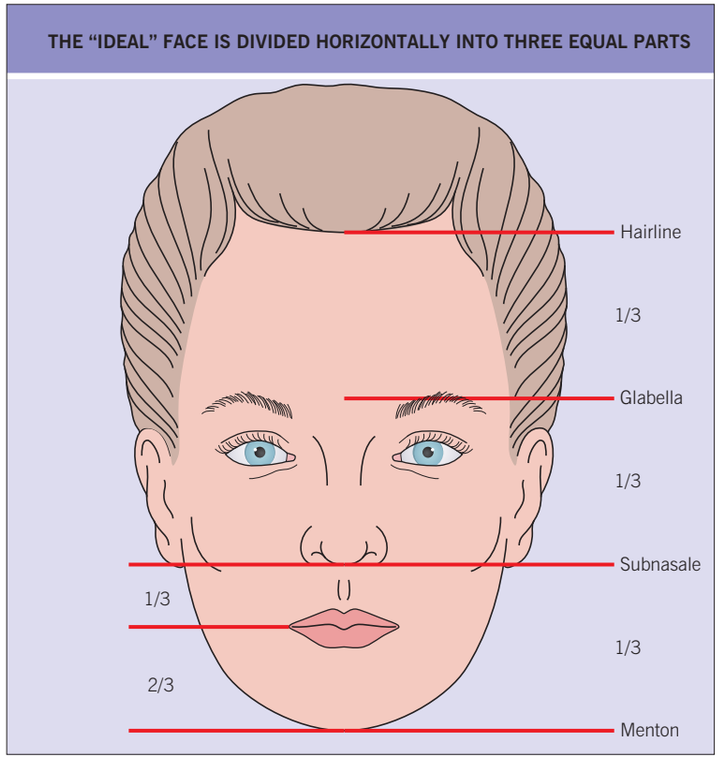

Fig. 152.1 The "ideal" face is divided horizontally into three equal parts. These three parts are composed of the distances between: (1) the frontal hairline and the top of the brow; (2) the brow and the base of the nose; and (3) the base of the nose and the inferior aspect of the chin. The divisions were originally proposed by Leonardo DaVinci.

FACIAL ANALYSIS OF WOMEN OF DIFFERENT ETHNIC GROUPS						
	Caucasian	African-American	Latino-American			Southern Chinese
			Caribbean	Central	South	
Horizontal proportions*	1:1:1	1:1.2:1.3 or 1:1.2:1.2				
Nasofrontal angle	125°–135°	127.6° or 136.8°–137.4°	110°	137°	136°	137.9° (119–166)
Nasofacial angle	36°–40°	33.4° or 38.9°	41°	44°	46°	36.4° (20–46)
Alar width: intercanthal distance	1:1	1.2:1	1.2:1	1:1	1.1:1	>1:1
Columella:lobule	2:1	1.3:1 or 1:1.2 or 1:1.3	1.5:1	1.1:1	1.5:1	1.2:1
Nasolabial angle	90°–120°	73.9° or 85.6°–90.3°	110°	99°	100°	87.8° (55–108)
*Horizontal proportions derived from relationship of: trichion to glabella, glabella to subnasale, subnasale to gnathion ratio.						

Table 152.1 Facial analysis of women of different ethnic groups. *Adapted from Powell N, Humphreys B. Proportions of the Aesthetic Face. Thieme-Stratton: New York, 1984.*

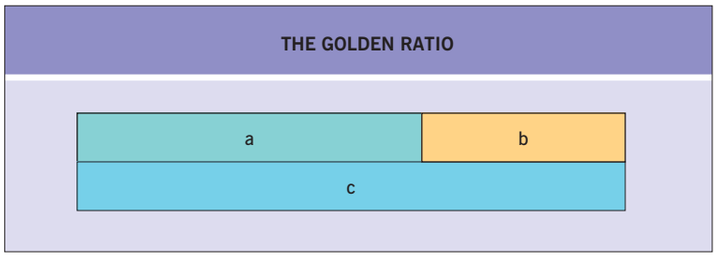

Fig. 152. 2 The golden ratio based upon Phi. Phi is the unique point on a line that divides the line into two lines in such a manner that the ratio of the smaller portion (b) to the larger portion (a) is the same as the ratio of the larger portion (a) to the whole line (c). In other words, b is to a as a is to c. This ratio is a repeating number that is rounded off to 1:1.618. A triangle composed of lines with lengths in the Phi ratio is referred to as a golden triangle.

measurement of facial features and an assessment of resultant ratios. It is based on proportional relationships of the face that are known as the neoclassical canons, which have been studied and revised for centuries. As originally proposed by Leonardo DaVinci, the ideal face can be divided horizontally into three equal parts; these parts are composed of the distances between: (1) the frontal hairline and the top of the brow; (2) the brow and the base of the nose; and (3) the base of the nose and the inferior aspect of the chin (Fig. 152.1). In general, mathematically idealized facial proportions translate into a symmetric, oval- or heart-shaped face, with prominent cheekbones, tapered jaw line, narrow nasal base and thin lips. These proportions, however, are largely based on facial features in Caucasian women. Ethnic variations of these "ideal" proportions may exist and are outlined in Table 152.1.

Another method for calculating beauty via mathematical proportions is the concept of "Phi", or the golden ratio. A ratio of 1:1.618 was described by ancient Greeks as a mathematical method for calculation of the optimal proportions for all structures in nature. In fact, some authorities believe that the neoclassical canons (see above) are modifications of Phi. Phi represents the unique point on a line that divides the line into two lines in such a manner that the ratio of the smaller portion to the larger portion is the same as the ratio of the larger portion to the whole line (Fig. 152.2). This ratio is a repeating number that is rounded off to 1:1.618. Of note, there are innumerable examples of the use of the Phi ratio in nature and art, including the Parthenon, the sculpture Venus de Milo, the shell of a nautilus and the petals of a sunflower.

A triangle composed of lines with lengths in the Phi ratio is referred to as a golden triangle. When expanded, one can even create golden pentagons and golden decagons. Stephen Marquardt trademarked the "Phi mask", a facial mask composed of proportions that incorporate the 1:1.618 ratio, to describe the mathematically ideal attractive face (Fig. 152.3). Although the Phi mask has been applied to persons of all races and ethnicities, Marquardt recognized that ethnic variations may exist and has incorporated modifications for three different ethnic groups – Caucasian, Asian, and African.

ANATOMIC BASIS FOR THE AGING APPEARANCE

Knowledge of facial anatomy and anatomic changes that occur with aging is essential for properly evaluating and treating the aesthetic patient. With aging, both the golden ratio (Phi) and the neoclassical canons start to shift. The upper one-third of the face *elongates* due to recession of the frontal hairline and brow ptosis, while proportionately the middle third remains relatively stable (but may elongate with nasal tip ptosis). However, mid-face volume loss can occur as a result of fat redistribution and skeletal changes. The lower third of the face becomes *shortened* with perioral fat redistribution and significant resorption of the bony mandible.

The appearance of the aging face is multifactorial and does not appear to simply be a matter of sagging from the effect of years of gravitational forces pulling the face downwards. Rather, a complex ongoing alteration in proportions occurs as one ages. Notably, recent studies by Rohrich and Pessa[7] have shown that there is not one large confluent layer of subcutaneous fat in the face but rather multiple distinct compartments that act independently from one another (see below). For example, the malar fat pad in the mid cheek is composed of three separate compartments; as these compartments change in size, the ligaments separating the compartments become more evident and a smooth, rounded, youthful appearance transforms into the multi-contoured aged face.

After examining numerous photographs of patients as they aged, Lambros[8] concluded that there is actually very little positional change in the midface region. Despite the common perception that the face drops inferiorly with age, he noted that the eyelid–cheek margin did not change with advancing years, nor did facial nevi of the midface descend with age. Just as individual water molecules simply move up and down rather than actually traveling with waves at sea, the wave of downward motion "seen" in an aging face may simply represent shifts in subcutaneous tissue.

Rhytides also play a key role in producing an aged appearance. The underlying causes of rhytides are multiple and include ultraviolet radiation-induced damage, loss of skin elasticity, repetitive movement of underlying facial musculature, changes in volume from fat redistribution, and bone as well as cartilage resorption (Fig. 152.4).

PHOTOAGING

Cumulative exposure to sunlight is a major factor in aging skin. Clinical signs of cutaneous photoaging include: rhytides, lentigines, keratoses, telangiectasias, loss of translucency, loss of elasticity, and a sallow color[9,10]. The Fitzpatrick Skin Phototype System (see Table 0.5) serves as a good indicator of the potential for developing signs of photoaging as well as developing dyschromia following epidermal/papillary dermal injury from trauma or cosmetic procedures.

A simple systematic classification of patient photoaging types (types I through IV) was developed by Dr. Richard Glogau (Table 152.2; Fig. 152.5)[11]. However, the generalizations outlined in Table 152.2, and explained below, usually apply at a later age and to different degrees in

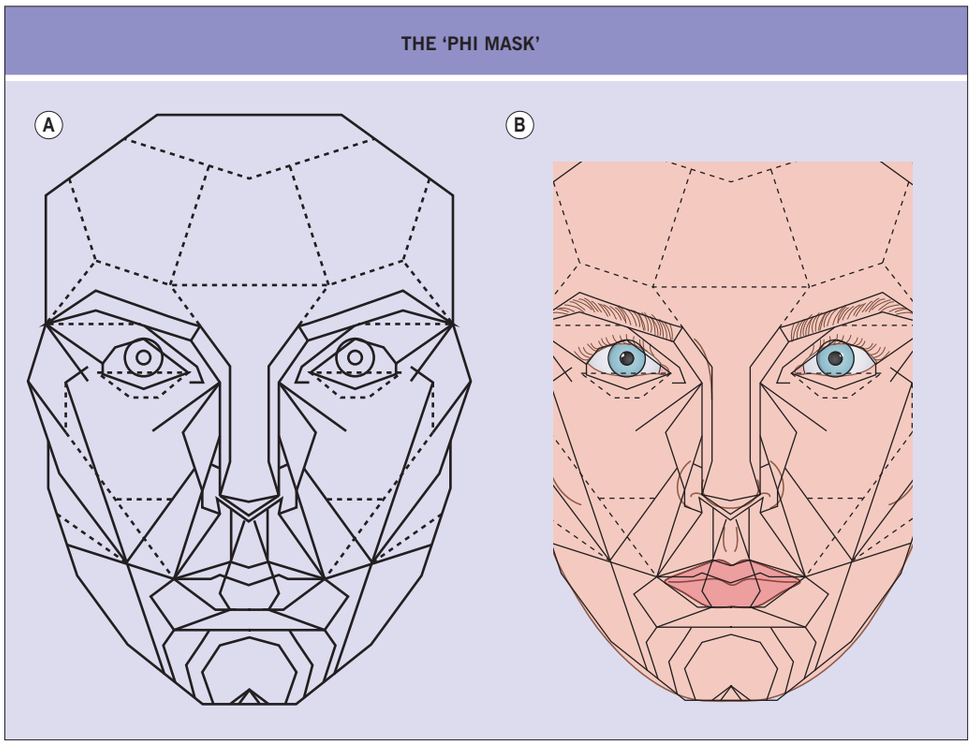

Fig. 152.3 The "Phi mask". A By incorporating the 1:1.618 ratio into numerous golden triangles and hexagons, the Phi mask reflects the mathematically ideal face. **B** The Phi mask superimposed on the human face.

Fig. 152.4 Rhytides of the aging face. Rhytides form as a result of UV radiation-induced damage, loss of skin elasticity, repetitive movement of underlying facial musculature, changes in volume from fat redistribution, and bone as well as cartilage resorption.

GLOGAU PHOTOAGING CLASSIFICATION – WRINKLE SCALE
TYPE I – "NO WRINKLES"
• Early photoaging – Mild pigmentary changes – No keratoses – Minimal wrinkles • Patient age (yrs) – 20's or 30's • Minimal or no makeup
TYPE II – "WRINKLES IN MOTION"
• Early to moderate photoaging – Early senile lentigines visible – Keratoses palpable but not visible – Parallel smile lines beginning to appear • Patient age (yrs) – late 30's or 40's • Usually wears some foundation
TYPE III – "WRINKLES AT REST"
• Advanced photoaging – Obvious dyschromia, telangiectasias – Visible keratoses – Wrinkles even when not moving facial muscles • Patient age (yrs) – 50's or older • Wears heavy foundation
TYPE IV – "ONLY WRINKLES"
• Severe photoaging – Yellow–gray color of skin – Prior skin malignancies – Wrinkled throughout with no normal skin • Patient age (yrs) – 60's to 70's • Can't wear makeup – "cakes and cracks"

Table 152.2 Glogau photoaging classification – wrinkle scale. yrs, years

more darkly pigmented skin, partially depending upon the degree of sun exposure. Type I refers to younger patients with no rhytides, even when the face is animated by talking or expression. Type II refers to patients with "wrinkles in motion", who demonstrate the influence the underlying musculature has on the skin.

As the photoaging process advances, there is greater damage to collagen and elastic fibers. Of note, collagen production is maintained by dynamic mechanical tension placed on fibroblasts by intact collagen fibers. With age and particularly sun-related damage, type I collagen (most prevalent form with a half-life of 15 years) becomes more and more fragmented. As more collagen becomes fragmented, there is less stretching tension placed on fibroblasts and they respond by making more metalloproteases and less collagen. This creates a vicious cycle of increasing collagen loss and subsequent thinning of the skin[12]. Eventually, with substantial breakdown of collagen and elastic fibers, the wrinkles produced by dynamic movement of the face persist, even when the face is at rest.

Generally, by the sixth or later decade of life, there are visible parallel lines lateral to the eye ("crow's feet"), at the corners of the mouth, and

Fig. 152.5 The Glogau wrinkle scale. A Type I ("no wrinkles"): skin is uniform in color. There is an absence of lines even at the corners of the eyes and mouth. **B** Type II ("wrinkles in motion"): when the face is at rest, the patient appears similar to type I. But when the face is animated by expression, there are many parallel lines which appear, first at the corners of the mouth, then parallel to the melolabial folds, then at the corners of the eyes, and finally over the malar cheeks. **C** Type III ("wrinkles at rest"): this patient clearly shows the parallel lines seen with animation in type II, except they are now present with the face at complete rest. **D** Type IV ("only wrinkles"): the perioral skin in particular is likely to demonstrate the total replacement of normal skin with minute, rhomboid and geometric rhytides, clearly seen in this patient. The entire face shows similar rhytides on close inspection.

radiating down from the lower eyelids onto the malar cheeks, as well as around the upper lip and lower lip. These patients appear lined, even when their face is at rest, and are classified as type III, "wrinkles at rest". The repetitive effect of underlying muscular expression is now permanently "ingrained" into the skin i.e. lines are readily visible, even without active muscular contraction.

With continued photoaging, the wrinkles gradually spread to cover the majority of the facial skin, while the dermis becomes totally engorged with accumulations of poorly staining ground substance, giving a thickened, coarse quality to the skin. This is classified as photoaging type IV, "only wrinkles".

PIGMENTARY SYSTEM

Patients should also be categorized according to their Fitzpatrick Sun-Reactive Skin Type[13]. This classification scheme (see Table 0.5) is based upon the skin's response to erythema-producing doses of UV light. Patients differ in their reactivity to sunlight, and the skin type serves as a very good indicator of the potential for developing dyschromia following epidermal/papillary dermal injury. The scale also reflects the likelihood of developing postinflammatory hyperpigmentation during the near-term postoperative period, and the potential for permanent leukoderma resulting from destruction of melanocytes.

VOLUME CHANGES – THE LOSS OF SUBCUTANEOUS FAT

A major component of aesthetic disharmony in the aging face is the loss or redistribution of subcutaneous fat. Detailed studies by Rohrich and Pessa[7], utilizing cadaver dissections, have demonstrated that facial fat (unlike fat elsewhere in the body) is partitioned into discrete compartments which may age independently of one another (Fig. 152.6). Redistribution and loss of these fat pads contribute to formation of the nasojugal fold, malar crease, nasolabial fold, pre-jowl sulcus and marionette lines as well as wasting of the temples, superior brow and buccal fat (Fig. 152.7).

While in some areas (e.g. the submental region), unwanted subcutaneous fat may lend itself to removal via liposuction, in general there is

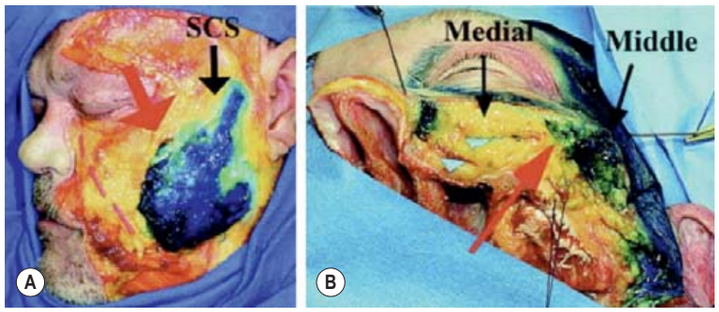

Fig. 152.6 Multiple distinct subcutaneous fat compartments of the face. A The middle cheek (blue) fat compartment lies between the medial (yellow) and lateral temporal-cheek (yellow) fat compartments. The superior border is defined by the superior cheek septum (SCS; green). A zone of fixation (red arrow) is noted where this compartment adjoins the middle compartment and inferior orbital (yellow) compartment. **B** Cross-sectional anatomy illustrates the anatomic principle that fusion planes exist between adjacent fat compartments. A dense fascial system (red arrow) exists where the medial and middle fat compartments meet. The red zygomaticus major muscle is noted deep to this fusion plane. From ref. 7.

a modern appreciation that removal of fat should be done with caution due to the flattening or hollowing of contours that could result and possibly lead to a more aged appearance. Due to a loss of subcutaneous fat, the older face has a flattened quality to the cheekbones, a sunken appearance to the lips, a bulging of the inferior fat pads of the eye, and, in general, a loss of the fullness and roundness of youth. Experienced aesthetic surgeons have recognized this, and are moving away from excessive fat removal to fat repositioning or augmentation. Dr Steven Hoefflin has written, "In the aging face it is not the tightness of the SMAS (platysma aponeurosis) or skin that makes the difference, but the quantity and position of subcutaneous fat"[14].

As an example, the routine removal of the infraorbital fat as a part of blepharoplasty, which often accentuated the deep grooves between the lower eyelid and the cheek, has become outdated. Now surgeons prefer to utilize an arcus marginalis release and mobilize the fat medially and anteriorly to fill in the groove and return a more youthful appearance to the lower eyelids through restoration of lower lid convexity. Similarly, repositioning of the premalar fat has become an important part of routine facelifting, reversing the aged appearance that comes from flattening of the cheekbone contours.

Restoration of volume loss can also be readily achieved less invasively with the use of injectable fillers (see Ch. 158).[15]

CHANGES IN FACIAL MUSCULATURE

Perhaps nothing has driven home the impact of facial musculature on facial aging like the introduction of botulinum toxins for selective chemical denervation of muscles of the face. Paralysis or partial weakening of the glabellar corrugator/procerus complex, the forehead frontalis muscle, and the lateral orbicularis muscles has revolutionized the management of the upper third of the aging face. In addition, judicious use and careful placement of neuromodulators into the orbicularis oris, depressor anguli oris, and platysmal neck bands can aid in managing creases, wrinkling and banding of the lower face and neck.

Brow position is closely associated with emotional states, and the medial and lateral portions of the brow function independently in this regard. Surgeons must be conscious of the strong impact that brow shape and position can have on appearance and even interpersonal relationships. For example, people tend to treat you better if you do not have a glabellar scowl, if your eyebrows arch properly (if you are female), and if the relationship between the lateral and medial brow is flattering.

In young women, the arch of the brow has been found to be most attractive when located above the lateral limbus (Fig. 152.8). Photographs of patients following botulinum exotoxin A injection were rated by 40 subjects to be 40% less angry, 49% less fearful, 10% less sad, and 71% more happy than photographs of the same patients prior to their injections[16]. In a small series of 10 patients suffering from depression,

Fig. 152.7 Laser resurfacing. This patient has undergone laser resurfacing to her full face. She looks "better" but not "younger", because no attention has been paid to volume changes.

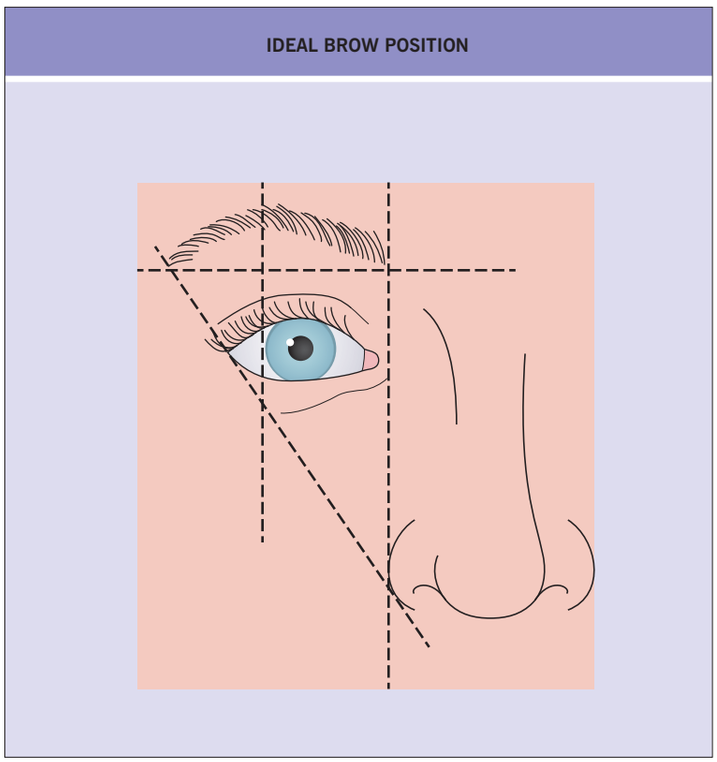

Fig. 152.8 Ideal brow position. In young women, the arch of the brow has been found to be most attractive when it peaks above the lateral limbus.

nine reported significant improvement in their symptoms to the point of no longer feeling depressed 2 months following botulinum toxin injection[17]. It may be that when people feel that they are more attractive, they become more confident and have more positive interactions with others. Alam et al.[18] postulate that muscular manipulations which result in more positive facial expressions may lead to more positive emotional states. Likewise, reducing external signs of anger, fear and sadness may reduce internal negative emotions.

CHANGES IN UNDERLYING CARTILAGE AND BONE

Due to changes in the underlying cartilage, the aging nose elongates and the tip droops. The aging mouth is affected by bony resorption and remodeling of the maxilla, while the chin sharpens and protrudes. The ears appear to lengthen as the lobes droop. The tarsal plate softens and no longer holds the lower lid margin in its proper position or curve. Various surgical procedures address these problems, including tip rhinoplasty, tarsal lid tightening, canthoplasty and chin implants. Newer dental implant procedures and maxillofacial surgery can also address intrinsic changes affecting the lower face. In addition, some of the newer soft tissue fillers can be used to correct the aging changes associated with bony resorption and may result in a more natural appearance and feel than an implant. For example, these fillers may be placed in the nasal dorsum, jawline, marionette lines, ear lobes, tear troughs, and mid-face.

The diagnostic eye of the cosmetic surgeon should not overlook the contribution of the underlying hard structures of the face, particularly when assessing for the presence (or, more commonly, absence) of facial symmetry. Patients often present with requests for the treatment of facial problems without appreciating the contribution of underlying structures to their facial asymmetry. Recognizing, photographing and discussing pre-existing facial asymmetry due to underlying bony or cartilaginous structural differences is an important component of setting realistic patient expectations.

INHERENT LOSS OF ELASTICITY

As the facial soft tissue ages, both the skin and the underlying supporting structures, while sagging under the effects of gravity, also lose their inherent resiliency or ability to resist stretching. Skin laxity occurs as a result of a decreased underlying framework, a thinned and damaged dermis, and a breakdown in elastic and collagen fibers[12].

In the lower third of the face, a facelift procedure is often essential for a successful aesthetic outcome. Redraping, repositioning and judicious removal of skin and soft tissue that has lost its elasticity can lead to the restoration of a youthful appearance that cannot be achieved with resurfacing, fillers, fat transfer or botulinum toxin.

GENDER DIFFERENCES IN CHARACTERISTICS OF ATTRACTIVE HUMAN FACES	
Idealized female facial features	**Idealized male facial features**
A larger, smooth forehead with a smaller nose	An overhanging, horizontal brow with minimal arch
Eyebrows that have an arch or gull-wing shape	Deeper set eyes that look closer together
Eyes that are set wider apart, creating a bigger look	A somewhat larger nose
Prominent cheekbones	A wider mouth
A heart-shaped taper to the lower face, with a smaller lower : upper face ratio	A squared lower face with a more equal ratio of lower : upper face
Full vermilion lips	A beard or coarser texture to the lower facial skin

Table 152.3 Gender differences in characteristics of attractive human faces. These characteristics are cross-culturally persistent.

OBJECTIVE DIFFERENCES IN SKIN STRUCTURE AND PHYSIOLOGY BASED ON RACE		
Evidence supports:	**Insufficient evidence* for:**	**Inconclusive:**
• Increased melanin content and melanosomal dispersion in persons of color • Multinucleated and larger fibroblasts in black persons compared with white persons • pH black skin < pH white skin • Larger mast cell granules, increased PLS, and increased tryptase localized to PLS in black compared to white skin • Variable blood vessel reactivity	Racial differences in: • Skin elastic recovery/ extensibility • Skin microflora • Facial pore size†	Racial differences in: • Transepidermal water loss • Water content • Corneocyte desquamation • Lipid content
*Categorized under this heading because only two studies or fewer examined these variables. †Sugiyama-Nakagiri Y, Sugata K, Hachiya A, et al. Ethnic differences in the structural properties of facial skin. J Dermatol Sci. 2009;53:135-9.		

Table 152.4 Objective differences in skin structure and physiology based on race. PLS, parallel-linear striations (seen within mast cells by electron microscopy). *Adapted from Wesley NO, Maibach HI. Racial (ethnic) differences in skin properties: the objective data. Am J Clin Dermatol. 2003;4:843–60.*

GENDER DIFFERENCES

The idealized female face tends to exhibit several characteristics that are reproducible from culture to culture and across the ages. On the other hand, the attractive masculine face tends to have a very different set of characteristics (Table 152.3), although they have not been studied as extensively as those for women.

ETHNIC DIFFERENCES

According to the American Society of Plastic Surgery, since 2001 there has been an increase in cosmetic procedures performed on ethnic minorities in the US. Based upon US Census Bureau projections, by the year 2056, >50% of the US population will be of non-Caucasian descent. While mathematical anthropometric measurements of the ideal facial structure have been determined, most of these measurements were based on the Caucasian face. Future anthropometric facial analyses need to take into account not only ethnocentric variations in facial structure and the effects of aging, but also ethnically diverse perceptions of beauty. Ethnic patients do not necessarily desire a Westernized look, as what constitutes beauty is influenced by racial, cultural and environmental factors. Descriptions of ethnocentric variability in these ideals have begun to appear in the dermatologic literature[19].

The cosmetic concerns of ethnic patients also vary due to inherent differences in skin structure and physiology (Table 152.4), mechanisms of aging, and facial anatomy (see Table 152.1). While lentigines and facial rhytides can occur decades later in darkly pigmented individuals (as compared to age-matched fair-skinned individuals) due to the protective effects of melanin, dyschromia can be a significant cosmetic concern in the former group.

COMBINATION THERAPIES

Optimal improvement in appearance can more often be obtained by combining procedures. At one end of the therapeutic spectrum, topical agents such as tretinoin, α-hydroxy acids, hydroquinone and 5-fluorouracil can inhibit or reverse UV radiation-associated changes in aging skin. At the other end of the therapeutic spectrum, rhytidectomy, blepharoplasty, brow lift, and suction-assisted lipectomy often provide dramatic results in facial rejuvenation. The choice of specific therapies rests on the ability of the surgeon to look at the face, analyze the anatomic components of the aging appearance, and then prioritize them, matching the risk : benefit ratios of various procedures to each element. Is the predominant problem photodamage, dynamic rhytides, sagging, or the loss or shift of facial volume? Often there are also overriding constraints, e.g. the "down time", surgical risk, cost, likelihood of benefit, that all weigh in on the selection of the appropriate therapy. However, underlying all of these choices must be a rational analysis of the various elements that comprise the aging face. The more an aesthetic surgeon is able to specifically tailor treatments to the individual patient, the more likely the outcome will be aesthetically optimal and be associated with a higher degree of patient satisfaction.

Cosmetics and Cosmeceuticals 153

Zoe Diana Draelos

Synonyms: ■ Cosmetics ■ Skin care products ■ Cosmeceuticals ■ Bioactive cosmetics ■ Nail products ■ Hair care products ■ Exfoliants ■ Moisturizers ■ Cleansers

Key features

- Colored cosmetics and skin care products have an important role in the prevention of dermatologic disease and the maintenance of skin health
- Hair is a non-living structure whose appearance and behavior can be improved via the use of shampoos and conditioners
- Nail cosmetics primarily adorn the nails, but improper use can lead to nail disease
- Cosmeceuticals are non-prescription products designed to improve the functioning of the skin, primarily through a reversal of the aging process
- Skin, hair and nail care products have a profound impact on these structures, and they should be part of the knowledge base of the dermatologist

INTRODUCTION

Cosmetics and skin care products are assuming an increasingly important role in dermatology as the sophistication of raw materials and the resulting formulations provide for the development of products that impact the functioning of the skin. It was traditionally thought that the stratum corneum was a non-living, biologically inert layer of skin upon which skin care products and cosmetics impinge. It was also thought that the stratum corneum was a complete barrier unaffected by the application of non-prescription topical agents. An improved understanding of stratum corneum function, primarily obtained through the use of non-invasive bioengineering techniques, has demonstrated that the stratum corneum can be dramatically influenced by non-prescription topical agents, and that these agents can indeed penetrate the stratum corneum and influence skin function.

This new understanding of the biologic importance of the stratum corneum to skin health led to the development of a new category of skin care product, known as the cosmeceutical[1]. A cosmeceutical is a scientifically designed, useful product intended for external application to the human body that has desirable aesthetic effects and meets rigid chemical, physical and medical standards[2]. Even though many cosmeceuticals currently exist for use on the skin, hair and nails, there is no regulatory description that acknowledges the current scientific sophistication of these formulations. Rather, a cosmetic is defined by the US Federal Food, Drug and Cosmetic Act, written in 1938, as "articles intended to be rubbed, poured, sprinkled, or sprayed on, introduced into, or otherwise applied to the human body or any part thereof for cleansing, beautifying, promoting attractiveness, or altering the appearance", without affecting structure or function[3].

Cosmeceuticals are now a reality due to the expanding dermatologic knowledge-base, which has rendered obsolete the prior outdated clear distinction between cosmetics and drugs[4]. It is somewhat bewildering to realize that water is a cosmeceutical. Water profoundly influences the structure and function of the viable epidermis. Many substances can function as cosmeceuticals if entry into and through the stratum corneum is facilitated via the use of penetration enhancers, such as propylene glycol, isopropyl myristate, and pyrrolidone derivatives. Propylene glycol profoundly alters the barrier characteristics of the stratum corneum, while isopropyl myristate is capable of penetrating into the lipid bilayer of cell membranes. Pyrrolidone derivatives interact with both keratin and stratum corneum lipids to drive substances into the skin. These substances are commonly found in cosmetic formulations; however, new understanding of skin physiology allows recognition of their profound effects on the skin, which were previously unknown.

DISCUSSION

Skin Care Products

The three basic categories of skin care products are cleansers, astringents and moisturizers. Cleansers are designed to remove sebum, desquamating corneocytes, bacteria, fungi and environmental dirt from the face and body, while leaving the intercellular lipid barrier intact. Astringents are actually a subset of cleansers designed to supplement the failure of the cleanser to perform its intended function. Moisturizers are designed to minimize the barrier damage induced by cleansing. Thus, these three skin care products work together to balance the hygiene needs of the skin with the important task of preserving barrier function.

Cleansers

The development of soaps designed to cleanse the skin has been the single most important advance in decreasing disease worldwide. Even though soap is ubiquitous in the developed world, one of the main goals of world health organizations is to introduce the concept of cleansing with soap to areas of the globe where contagious diseases run rampant. In basic chemical terms, soap is a fatty acid salt resulting from a reaction between a fat and an alkali[5]. The soap solubilizes sebum and environmental dirt, such that it can be rinsed away with water. The mechanics of rubbing the soap over the skin with the hand or a bathing implement results in the physical removal of skin scale, bacteria and fungi from the skin surface. In high-income countries, where bathing has become a daily ritual, excessive use of soap has resulted in dermatologic conditions such as xerotic eczema. This has led to the development of cleansers with skin conditioning benefits that are chemically not true soaps, and they are referred to as detergents.

Cleansers, whether formulated as bars or liquids, can be divided into three basic types: soaps, syndets and combars (Table 153.1). True soaps, discussed previously, are composed of long-chain fatty acid alkali salts with a pH of between 9 and 10. This alkaline pH raises the pH of the skin following cleansing, resulting in stratum corneum barrier disruption and the resultant feeling of tightness following bathing. Alkalinization of the skin disrupts the natural acid mantle, which may be significant in dermatitic skin. Recognition of the need to preserve skin pH at 5.4 led to the development of *syn*thetic *det*ergents, known as syndets, such as sodium cocoyl isethionate. Syndet cleansers, also known as beauty cleansers, contain less than 10% soap, and are designed with a pH of 5.5–7.0 in order to minimize cutaneous alkalinization[6]. The third type of cleanser, known as a combar, is composed of an alkaline soap to which surface active agents with a pH of 9–10 have been added. Combars are milder cleansers than true soaps, but induce more thorough cleansing than syndets. For example, true soap is a good cleansing choice for excessively oily or dirty skin, while a combar is a good cleanser for normal skin with a moderate amount of environmental dirt. Syndets would be the least damaging to the cutaneous barrier in persons with dry skin or any form of dermatitis.

CATEGORIES OF CLEANSING PRODUCTS		
Product type	**Composition**	**Product examples®,™**
Bar soap	True soap in bar form; pH 9–10	Ivory Bar Soap (Procter & Gamble) Cashmere Bouquet (Colgate-Palmolive)
Syndet bar cleanser	Synthetic detergents (no soap), in bar form; pH 5.5–7	Cetaphil Bar (Galderma) Dove Bar (Unilever) Olay Quench Moisturizing Bar (Procter & Gamble)
Syndet liquid	Synthetic detergents, in liquid form; pH 5.5–7	Dove Liquid (Unilever) Oil of Olay Foaming Face Wash (Procter & Gamble)
Combar soap	Combination of true soap and synthetic detergent; pH 9–10	Dial (Dial Corporation) Irish Spring (Colgate-Palmolive)
Body wash	Emulsion system applied with a puff, allowing synthetic detergent cleansing combined with enhanced skin moisturization and emolliency	Aveeno Body Wash (Johnson & Johnson) Dove Body Wash (Unilever) Oil of Olay Daily Renewal Body Wash (Procter & Gamble)
Lipid-free cleanser	Cleans without fats; may contain glycerin, cetyl alcohol, stearyl alcohol, sodium lauryl sulfate and, occasionally, propylene glycol	Aquanil (Person & Covey) CeraVe Cleanser (Coria) Cetaphil (Galderma)
Cleansing cream	Waxes and mineral oil with detergent action from borax	Noxema (Noxell Corporation) Pond's Cold Cream
Astringent/toner	Alcohol-based product that may contain witch hazel, salicylic acid or glycolic acid	Clarifying Lotion 2, 3, 4 (Clinique)
Moisturizing astringent/toner	Glycerin-based humectant moisturizer	Clarifying Lotion 1 (Clinique)
Exfoliant cleanser	Glycolic or salicylic acid-containing cleanser	Oil-free Acne Face Wash (Neutrogena)
Abrasive cleanser	Polyethylene beads or other small particles within the syndet cleanser	Clinique 7 Day Scrub Cream Olay Age Defying Daily Renewal Cleanser (Procter & Gamble)

Table 153.1 Categories of cleansing products.

SPECIALTY SOAP FORMULATIONS	
Type of soap	**Unique ingredients**
Superfatted soap	Increased oil and fat and fat ratio up to 10%
Castile soap	Olive oil used as main fat
Deodorant soap	Antibacterial agents
French milled soap	Additives to reduce alkalinity
Floating soap	Extra air trapped during mixing process
Oatmeal soap	Ground oatmeal added (coarsely ground to produce abrasive soap; finely ground for gentle cleanser)
Acne soap	Sulfur, resorcinol, benzoyl peroxide or salicylic acid added
Facial soap	Smaller bar size, no special ingredients
Bath soap	Larger bar size, no special ingredients
Aloe vera soap	Aloe vera added to soap, no special skin benefit
Vitamin E soap	Vitamin E added, no special skin benefit
Cocoa butter soap	Cocoa butter used as major fat
Nut or fruit oil soap	Nut or fruit oils used as major fat
Transparent soap	Glycerin and sucrose added
Abrasive soap	Pumice, coarse oatmeal, maize meal, ground nut kernels, dried herbs or flowers added
High impact soap	Strong, high-concentration fragrance added to scent skin after cleansing
Soap-free soap	Contains synthetic detergents (syndet bar)

Table 153.2 Specialty soap formulations.

The many brands of cleansers currently on the market fall into one of the three aforementioned groups, yet there must be something unique, for marketing purposes, about each cleanser. The unique aspects of each cleanser are created through the addition of specialty additives (Table 153.2). Common cleanser additives include various fragrances and foaming agents designed to alter the aesthetics of the lather, but the most dermatologically relevant additives are antibacterial agents. The most widely used antibacterial in both bar and liquid cleansers is triclosan[7]. Triclosan works by blocking lipid synthesis in the bacterial cell wall, thus decreasing the skin biofilm bacteria count and reducing odor.

Another important dermatologic need with regard to skin cleansing is minimization of skin barrier dysfunction. Unfortunately, surfactants cannot distinguish between unwanted sebum and oil-soluble dirt and the intercellular lipids. Thus, increases in transepidermal water loss are typically noted in direct proportion to the cleansing ability of the cleanser. An attempt to provide cleansing and barrier restoration in the same product has led to the development of body washes. Since body washes are liquids, incorporating both hydrophilic and lipophilic ingredients emulsified into a single phase, it is possible to cleanse and moisturize simultaneously while allowing for rinsing away of the surfactants. Body washes must be used with a puff to induce both water and air into the cleanser emulsion in sufficient quantity to allow cleansing and moisturization to occur. The syndet detergent, primarily ammonium laureth sulfate, solubilizes oil-soluble dirt into the rinse water for removal during the cleansing phase when the body wash concentration is high and the water concentration low, while occlusive moisturizing substances (e.g. petrolatum) and emollients (e.g. soybean oil) are left behind to retard transepidermal water loss and improve skin smoothness during the rinse phase when the body wash concentration is low and the water concentration is high.

Other cleanser variants for persons with dry, dermatitic skin include lipid-free, non-foaming cleansers and cold creams. These products are excellent at removing cosmetics and low levels of environmental dirt. Lipid-free cleansers are non-foaming, soap-free liquid products applied to dry or moistened skin, rubbed to produce minimal lather, and rinsed or wiped away. They possess low surfactant capabilities, and they can only remove bacteria through mechanical means, yet they are important in persons with barrier disruption[8]. The classic cleanser for dry, dermatitic skin is cold cream, which combines the effect of a lipid solvent, such as wax or mineral oil, with detergent action from borax[9].

Occasionally, a dermatologic need arises for specialty cleansers designed to offer a skin benefit beyond pure removal of sebum and environmental dirt. For example, it may be desirable to induce corneocyte disadhesion in older patients requiring an exfoliant cleanser. This can be accomplished through the addition of chemical exfoliants, such as salicylic acid or glycolic acid, to the cleanser formulations discussed previously. Exfoliant cleansers containing benzoyl peroxide or salicylic acid are sometimes used as an adjunct in topical acne treatment. Exfoliation can also be induced mechanically through the incorporation of fine abrasive particles (such as polyethylene beads, aluminum oxide, ground fruit pits, or sodium tetraborate decahydrate granules) in a liquid syndet cleanser to remove skin scale. Lastly, mechanical exfoliation can be encouraged through the use of specially woven face cloths, designed to remove skin scale without inducing epidermal damage.

The development of novel detergents and cleansing specialty additives has created a confusing plethora of consumer products, yet the goal remains the same: to allow adequate skin hygiene without barrier damage. Our next concern is the discussion of moisturizers, designed to replace skin sebum in instances where the stratum corneum barrier has been damaged from exuberant cleansing.

Moisturizers

The term "moisturizer" is somewhat misleading to the consumer, who assumes that the cream or lotion actually puts moisture or water back into the skin[10]. Moisturizers do not put water back into the skin externally, nor do they get incorporated into the intracellular lipids. Moisturizers simply attempt to retard transepidermal water loss and create an optimal environment for restoration of the stratum corneum barrier[11]. The optimal water content for the stratum corneum is between 10% and 30%, depending on the measurement technique employed, and moisturizers can function to raise the cutaneous water content through occlusion or humectancy with a variety of active agents (Table 153.3)[12].

Occlusive moisturizers prevent evaporative water loss to the environment by placing an oily substance on the skin surface through which water cannot penetrate, thus replenishing the stratum corneum moisture by water movement from the lower viable epidermal and dermal layers[13]. There are many different classes of chemicals that can function as occlusive moisturizers[14], for example, hydrocarbon oils and waxes (petrolatum, mineral oil, paraffin, squalene), silicone (cyclomethicone, dimethicone), vegetable oils (castor oil, corn oil, grape seed oil, soybean oil), animal oils (mink oil, emu oil), fatty acids (lanolin acid, stearic acid), fatty alcohol (lanolin alcohol, cetyl alcohol), polyhydric alcohols (propylene glycol), wax esters (lanolin, beeswax, stearyl stearate), vegetable waxes (carnauba wax, candelilla wax), phospholipids (lecithin) and sterols (cholesterol, ceramides)[15].

The most effective occlusive moisturizer is petrolatum, since it reduces transepidermal water loss by 99%[16]. Total occlusion of the stratum corneum is undesirable, since transepidermal water loss is the cellular signal that initiates barrier repair and the resulting synthesis of intercellular lipids[17,18]. Complete cessation of transepidermal water loss results in no barrier repair, allowing water loss to return to its normal pretreatment level once the complete occlusion has been removed[17–19]. Petrolatum allows barrier repair while permeating throughout the interstices of the stratum corneum[20].

Another technique for rehydrating the stratum corneum is the use of humectants. Humectants are substances that attract moisture; they include glycerin, honey, sodium lactate, urea, propylene glycol, sorbitol, pyrrolidone carboxylic acid, gelatin, hyaluronic acid, and some vitamins and proteins[14,21]. The body utilizes hyaluronic acid and other glycosaminoglycans in the dermis as biologic humectants to prevent desiccation of the skin. Humectants can only hydrate the skin from the environment when the ambient humidity exceeds 70%. Consequently, rehydration of the stratum corneum generally occurs by water that is attracted from the deeper epidermal and dermal tissues. Most moisturizers combine both occlusive and humectant moisturizing ingredients, since water drawn by a humectant to a damaged stratum corneum barrier will be lost to the atmosphere unless trapped by an occlusive[22,23]. Humectants also help to improve the smoothness of xerotic skin by inducing corneocyte swelling and minimizing voids between the desquamating corneocytes[24].

In summary, remoisturization of the skin must occur in four steps:

- initiation of barrier repair (see Ch. 124)[25]
- alteration of surface cutaneous moisture partition coefficient
- onset of dermal–epidermal moisture diffusion
- synthesis of intercellular lipids[26].

Moisturizers attempt to increase stratum corneum water content through the principles of occlusion and humectancy. The discovery of aquaporin 3 channels in the skin and their modulation by glycerin and urea has increased research into osmotic cell balance as another mechanism for moisturization.

Astringents

Occasionally, patients use skin care products that either correct the deficiencies of the cleanser or supplement the effects of the moisturizer. These products are known as astringents or toners (see Table 153.1). They are used after cleansing but before moisturizing, and they are left on the face following use. Astringents are usually liquids wiped over the face with a cotton ball. Originally, astringents were intended to remove soap scum left behind on the face from the use of lye-based soaps and hard water. If left behind, this soap scum could cause irritant contact dermatitis. The original astringents were fragranced isopropyl alcohol or propylene glycol solutions designed to remove oil-soluble residue. The development of synthetic detergents and treated water has made this original intent obsolete, yet astringents remain popular.

Currently, astringents are used to remove the oily residue left behind after cleansing of the face with lipid-free cleansers or cleansing creams, discussed previously. Oily complexion astringents are formulated to remove any remaining sebum from the face following synthetic detergent cleansing or to deliver keratolytics, such as salicylic acid, glycolic acid or witch hazel. Some astringents designed for dry skin contain a humectant liquid moisturizer, such as propylene glycol or glycerin, and skin soothing agents, such as allantoin, guaiazulene or quaternium-19[27]. A complete cosmetic-counter facial treatment routine involves a cleanser followed by an astringent and then a moisturizer. Once the skin has been prepared in this manner, colored cosmetics are applied.

Colored Facial Cosmetics

Colored facial cosmetics are intended to adorn the eyes, lips and cheeks with color for the purposes of creating a fashionable appearance, highlighting certain desirable features, and camouflaging facial flaws. Colored cosmetics are of importance to the dermatologist for their role in maintaining skin health, inducing dermatitis, and camouflaging surgical defects.

Facial foundations

Formulation

Facial foundations are the first cosmetic applied to the face following the use of a moisturizer and, therefore, represent the colored facial cosmetic with the greatest impact on the integrity of the skin. Facial foundations are basically pigmented moisturizers worn for 8 hours or longer before removal. Consequently, this class of color cosmetics, more than any other, has an impact on the integrity of the skin. Facial foundations are available for every complexion type and skin color, fulfilling the needs listed in Table 153.4.

There are four basic facial foundation formulations: oil-based, water-based, oil-free, and water-free or anhydrous forms[28]. Oil-based products are designed for dry skin, while water-based products can be adapted

DIFFERENT TYPES OF MOISTURIZERS

Moisturizer type	Composition	Product examples®,™
Oil only	Petrolatum	Vaseline petroleum jelly (Chesebrough Ponds)
Oil-in-water emulsion	Water, petrolatum	Eucerin cream (Biersdorf)
Polymer-based	Water, polyglycerylmethacrylate, petrolatum	Cetaphil cream (Galderma)
Vegetable oil and wax	Castor oil, corn oil, ozokerite, beeswax, paraffin, carnauba wax	Lip moisture (Neutrogena)
Glycerin-rich	Water, glycerin, petrolatum	Norwegian formula hand cream (Neutrogena) Curel lotion (Andrew Jergens)
Dimethicone and ceramides	Water, petrolatum, dimethicone, ceramides	CeraVe (Coria) EpiCeram (Ceragenix)

Table 153.3 Different types of moisturizers. Additional prescription moisturizers are based upon glycyrrhetinic acid and shea butter (Atopiclair®), palmitoylethanolamide (MimyX®), paraffin (Biafine®), and sodium hyaluronate (Hylira™, Hylatopic™).

FUNCTIONS OF FACIAL FOUNDATION
Add facial color
Blend facial color
Camouflage pigmentation irregularities
Normalize facial skin
Provide sun protection
Act as a treatment product

Table 153.4 Functions of facial foundation.

for all skin types. Oil-free formulations are used in oily skin foundations, while anhydrous forms are extremely long-wearing and used for camouflage or theatrical purposes.

Oil-based foundations are water-in-oil emulsions containing pigments suspended in oil (e.g. mineral oil) or lanolin alcohol. Vegetable oils (grape seed, coconut, sesame, safflower) and synthetic esters (isopropyl myristate, octyl palmitate, isopropyl palmitate) may also be incorporated. The water evaporates from the foundation following application, leaving the pigment in oil on the face. This creates a moist skin feeling, especially desirable in dry complected patients. Oil-based foundations do not shift color as they mix with sebum, since the color is fully developed in the oily phase of the formulation. These foundations are easy to apply, since the pigment can be spread over the face for up to 5 minutes, prior to setting.

Water-based facial foundations are oil-in-water emulsions containing a small amount of oil, in which the pigment is emulsified, and a relatively large quantity of water. The primary emulsifier is usually a soap, such as triethanolamine, or a non-ionic surfactant. The secondary emulsifier, present in smaller quantity, is usually glyceryl stearate or propylene glycol stearate. These popular foundations are appropriate for minimally dry to normal skin. Since the pigment is already developed in oil, this foundation type is also not subject to color drift. The amount of time the product can be moved over the face, known in the industry as playtime, is shorter than with oil-based foundations.

Oil-free facial foundations contain no animal, vegetable or mineral oils. They contain other oily substances, such as dimethicone or cyclomethicone. These foundations are usually designed for oily complected individuals, since they leave the skin with a dry feeling. Dimethicone is non-comedogenic, non-acnegenic and hypoallergenic, accounting for the tremendous popularity of this type of facial foundation formulation. Both water-based and oil-free foundations are usually packaged in a bottle.

Water-free, or anhydrous, foundations are waterproof. Vegetable oil, mineral oil, lanolin alcohol and synthetic esters form the oil phase, which may be mixed with waxes to form a cream. High concentrations of pigment can be incorporated into the formulation, yielding an opaque facial foundation. The coloring agents are based on titanium dioxide with iron oxides, occasionally in combination with ultramarine blue. Titanium dioxide acts both as a facial concealing agent and sunscreen. These products can be dipped from a jar, squeezed from a tube, wiped from a compact, or stroked from a stick. Water-free foundations are well suited for use in people who require facial camouflaging. They can be combined with a high-coverage powder foundation to increase the opacity of the cosmetic.

Application and cutaneous effects

Facial foundations must be evenly applied to create the optimal cosmetic appearance and achieve the secondary benefit of sun protection. The iron oxide pigment and other covering agents, for example, titanium dioxide, zinc oxide and kaolin, are physical particulates that block both UVA and UVB radiation (see Ch. 132). A facial foundation *without* any added organic sunscreen ingredients, such as ecamsule, octyl methoxycinnamate, oxybenzone or avobenzone, usually has a sunburn protection factor (SPF) of at least 4. Facial foundations that have greater coverage in order to camouflage underlying pigmentation defects usually possess an SPF of at least 8. The inclusion of additional sunscreen agents to the facial foundation can raise the SPF to 15. Thus, facial foundation is an excellent, cosmetically elegant facial photoprotectant.

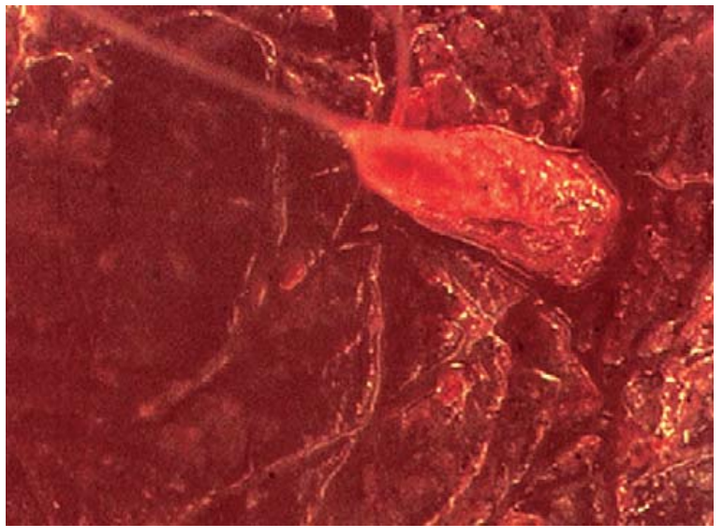

Fig. 153.1 Migration of iron oxide particles in facial foundation to follicular ostia. As seen by video microscopy (400×), this migration tends to occur as sebum and eccrine secretions mix with the cosmetic film.

An even, cosmetically acceptable application of facial foundation begins with a proper color match to the skin at the jawline and application with the fingertips. A dab of foundation should be placed on the forehead, nose, cheeks and chin, and blended with a light circular motion until it is evenly spread over the entire face, including the lips. Finally, a puff or sponge should be used, stroking in a downward direction, to remove any streaks and to flatten vellus facial hair. Special care should be taken to rub the foundation into the hairline, over the tragus, and beneath the chin. Foundation should also be blended around the eyes, and it may even be applied to the entire upper eyelid if desired. The foundation should be allowed to set or dry until it can no longer be removed with light touch. If additional coverage is desired, a second layer of foundation can be applied.

The most common adverse dermatologic effect related to the use of facial foundation is a condition patients describe as "breakouts". Patients typically note small perifollicular papules 48 hours after using a new facial foundation. The appearance is that of acne; however, the 48-hour time course is inconsistent with a diagnosis of acne. This condition may represent a perifollicular irritant contact dermatitis, since facial foundations tend to migrate to the follicular ostia as they mix with eccrine secretions and sebum, which break down the cosmetic film (Fig. 153.1). This observation may explain why facial foundations that have been found on clinical testing to be non-comedogenic and non-acnegenic cause acneiform eruptions in individuals with self-diagnosed sensitive skin. Overall, however, facial foundations are an infrequent cause of dermatologic problems.

Powders

One of the ways of preventing migration of facial foundation, improving its sun protective capabilities, and increasing oil absorption, is to apply powder over the foundation. Facial powders contain predominantly talc (hydrated magnesium silicate) and increased amounts of covering pigments. The covering pigments used in face powder are listed in order of increasing opaqueness in Table 153.5. It is generally accepted that the optimum opacity is achieved with a particle size of 0.25 μm. Black dermographism from earrings can result when face powders contain ingredients, e.g. zinc oxide, that are harder than platinum, silver or gold.

Facial powders usually also contain magnesium carbonate and/or kaolin (hydrated aluminum silicate) to absorb oil and perspiration. Full-coverage face powders with increased pigments and light reflective particles are usually packaged as a cake in a compact and applied to the face with a puff, loose in a jar and dusted over the face with a brush, or stroked over the face from an automatic brush dispenser. These face powders with increased pigments can be used as a facial foundation

COVERING ABILITY OF FACE POWDER INGREDIENTS
1. Titanium dioxide
2. Kaolin (hydrated aluminum silicate)
3. Magnesium carbonate
4. Magnesium stearate
5. Zinc stearate
6. Prepared chalk
7. Zinc oxide
8. Rice starch
9. Precipitated chalk
10. Talc (hydrated magnesium silicate)

Table 153.5 Covering ability of face powder ingredients. Listed in order of increasing opacity.

PIGMENTS ALLOWED BY THE US FDA IN EYE SHADOW COSMETICS
Iron oxides
Titanium dioxide (alone, or combined with mica)
Copper, aluminum and silver powder
Ultramarine blue, violet and pink
Manganese violet
Carmine
Chrome oxide and hydrate
Iron blue
Bismuth oxychloride (alone, or on mica or talc)
Mica

Table 153.6 Pigments allowed by the US Food and Drug Administration (FDA) in eye shadow cosmetics.

and are known as mineral make-ups. They are recommended for persons with sensitive skin and rosacea as they contain no liquids, fewer preservatives, and fewer ingredients. As a result, there is decreased potential for allergic and irritant contact dermatitis. Specially pigmented powders are used to redden the cheeks, known as blushes, and to color the eyelids, known as eye shadows.

Facial blushes

Facial blushes are typically powders designed to simulate rosy cheeks, occasionally an unwanted finding in rosacea patients. Blushes have the same basic formulation as face powders, except for the presence of different surface characteristics that can vary from a matte dull finish, to a frosted shine, to a metallic glow, depending on current fashion trends[29]. Some of the rough-edged particles designed to produce light reflection can cause irritation in people with sensitive skin. Powder blush can be used to absorb facial oil, blend the facial erythema of rosacea across the cheeks, and add color to a sallow face, by dusting on the central chin, cheeks, nasal tip and forehead.

Eye shadows

Eye shadows are similar to powder blushes in formulation and surface characteristics, except that the color variation is broader, but limited in the US by the Food and Drug Administration (FDA) to the purified natural colors or inorganic pigments listed in Table 153.6[30]. Eye shadow can be used to camouflage misshapen eyes, provide sun protection to the upper eyelid, and minimize the appearance of unwanted periorbital pigmentation. Eye shadows are a common concern to dermatologists, since they may be responsible for eyelid dermatitis. They may contain the same light-reflective particles as blushes and cause pruritus of the eyelids due to irritant contact dermatitis until discontinued (Fig. 153.2).

The North American Contact Dermatitis Group has determined that 12% of cosmetic reactions occur on the eyelid, but only 4% could be linked to eye make-up use[31]. Unfortunately, it can be difficult to determine the etiology of allergic contact eyelid dermatitis with routine patch testing[32], since many substances can be transferred to the eye area by the hands, complicating the dermatologic evaluation[33]. However, eye shadows are a rare cause of eye infections, since the dry powder cake does not support bacterial growth.

Fig. 153.2 Upper eyelid dermatitis. Upper eyelid dermatitis may be exacerbated by the use of heavily pigmented, light-reflective eye shadows.

Mascaras

Mascaras are eyelash cosmetics, as opposed to eye shadows, which are eyelid cosmetics. Mascaras are designed to color, camouflage, elongate and thicken the eyelashes, which are the frame to the eyes. They must be carefully formulated to allow easy and even application without smudging, irritancy or toxicity. Some of the coloring agents employed include iron oxide to produce black, ultramarine blue to create navy, and umber, burnt sienna or synthetic brown oxide to create brown[34].

Most modern mascaras are formulated as liquids, then stored in a tube with a multitufted applicator brush or comb. The applicator is inserted into the tube between uses, providing numerous opportunities to inoculate bacteria into the cosmetic. The most dangerous bacterial infection is a *Pseudomonas aeruginosa* corneal infection, which can permanently diminish visual acuity[35,36]. *Staphylococcus epidermidis, S. aureus* and fungal organisms may also proliferate in contaminated mascaras[37,38]. Infections are more common if the globe is traumatized with the infected mascara wand. Even though mascaras contain antibacterials, it is still wise to discard all mascara tubes after 3 months and not allow multiple persons to use the same mascara tube[39].

DIFFERENT TYPES OF MASCARA FORMULATIONS		
Mascara formulation	**Composition**	**Advantages/Disadvantages**
Water-based	Waxes, pigments, resins	Easy to remove with water; runs with tearing; supports bacterial growth
Solvent-based waterproof	Petroleum distillates, pigments, waxes	Must be removed with solvent; waterproof; does not support bacterial growth
Water-resistant water/solvent hybrid	Oil-in-water emulsion, pigments	Removal with water and cleanser; resists running with tearing; less likely to support bacterial growth
Compressed cake	Pigments, talc	Removal with water; runs with tearing; least allergenic; does not support bacterial growth

Table 153.7 Different types of mascara formulations.

There are several mascara formulations that are less likely to support bacterial and fungal growth (Table 153.7). Mascaras are available as water-based, solvent-based, and a water/solvent hybrid. Water-based mascaras are easily removed with water and less likely to cause eye area irritation, but the presence of water provides welcome media for bacterial growth. Solvent-based mascaras are manufactured without water, must be removed with a special cleanser, and are more irritating; however, they are less likely to support bacterial growth, and they are the formulation of choice for individuals who are carriers of *Staphylococcus* or *Streptococcus* spp[40]. The water/solvent hybrid mascaras are

an attempt to provide a water-resistant cosmetic with the benefits of both.

Another dermatologic side effect of the use of mascara is conjunctival pigmentation, resulting from the washing of mascara into the conjunctival sac by lacrimal fluid[41]. This colored particulate matter can be observed on the upper margin of the tarsal conjunctiva. Histologically, the pigment is seen within macrophages and extracellularly in association with a variable lymphocytic infiltrate. Electron microscopy suggests that ferritin, carbon and iron oxides are present within the tissues[42]. Unfortunately, there is no treatment for the condition, which is usually asymptomatic.

Specialty mascaras are available for curling and elongating the eyelashes. These mascaras contain pigmented polymers that polymerize on the lash as they dry. The polymer then shrinks, curling the eyelash and placing a thin, long-wearing, pigmented film around the hair which thickens and elongates the lash. In addition, a prescription cosmeceutical containing bimatoprost 0.03% (Latisse®; originally indicated for the treatment of glaucoma) is available to elongate eyelashes via prostaglandin modulation (see Ch. 70)[43]. Side effects include iris and eyelid pigmentation, which may be permanent.

Lipsticks

Lipstick is a lip cosmetic designed to frame the teeth. Traditional lipsticks are mixtures of waxes, oils and pigments in various concentrations to yield the characteristics of the final product. For example, a lipstick designed to remain on the lips for a prolonged period of time is composed of high wax, low oil and high pigment concentrations, whereas a product designed for a smooth creamy feel on the lips is composed of low wax and high oil concentrations[44]. The waxes commonly incorporated into lipstick formulations are white beeswax, candelilla wax, carnauba wax, ozokerite wax, lanolin wax, ceresin wax and other synthetic waxes. Usually, lipsticks contain a combination of these waxes carefully selected and blended to achieve the desired melting point. Oils for pigment dispersion are then selected, such as castor oil, white mineral oil, lanolin oil, hydrogenated vegetable oils or oleyl alcohol, to form a film suitable for application to the lips[45,46].

Newer lipstick formulations contain long-wearing polymers that create a waterproof film over the lips that remains in place indefinitely until worn away with speech or eating. These long-wearing lip products can cause cheilitis, due to their non-moisturizing formulations. In addition, lip products are marketed that claim to plump the lips. These products contain irritants, such as capsaicin, that create a mild irritant contact dermatitis resulting in short-lived lip edema.

Certain common lipstick ingredients can cause difficulty in the sensitized patient[47]. Castor oil, found in almost all lipsticks due to its excellent ability to dissolve bromo acid dyes, can cause allergic contact dermatitis[48–50]. Even the bromo acid dyes, such as eosin (D & C Red No. 21), found in indelible lipsticks can cause allergic contact dermatitis[51]. Other lipstick ingredients reported to cause allergic contact dermatitis include: ricinoleic acid[52], benzoic acid[53], lithol rubine BCA (Pigment Red 57–1)[54], microcrystalline wax[55], oxybenzone[56], propyl gallate[57] and C18 aliphatic compounds[58].

Facial cosmetics for camouflaging

All of the colored cosmetics previously discussed are used together for facial camouflaging purposes to minimize facial defects while accentuating attractive facial features. Camouflage cosmetics are used by paramedical aestheticians, dermatologists, plastic surgeons, and cosmetic consultants[59]. Their successful use requires a well-formulated, quality product applied with the skill of a stage make-up technician and the artistic abilities of a painter[60]. Facial defects requiring camouflaging are defects of pigmentation, contour, or a combination of both[61].

Pigmentation defects represent abnormalities limited to the color of the skin, whereas contour defects are defined as areas where the facial skin is hypertrophic or atrophic, with textural changes due to the absence of appendageal structures. Table 153.8 lists examples of pigmentary abnormalities frequently encountered by dermatologists that arise from inflammatory disorders, systemic diseases or extrinsic effects (e.g. sun exposure). Pigmentation defects can be camouflaged either by applying an opaque cosmetic that allows none of the abnormal underlying skin tones to be appreciated or by applying foundations of complementary colors. For example, red discoloration can be camouflaged by applying a green foundation, since green is the complementary color to red. The blending of the red skin with the green foundation yields a brown tone, which can be readily covered by a more conventional facial foundation. Furthermore, yellow skin tones can be blended with a complementary-colored purple foundation to also yield brown tones.

CAMOUFLAGE FOR ABNORMALITIES OF FACIAL PIGMENTATION		
Facial color	**Disease process**	**Undercover foundation color**
Red	Psoriasis, lupus erythematosus, rosacea	Green
Yellow	Solar elastosis, chemotherapy, dialysis	Purple
Brown hyperpigmentation	Melasma, lentigines, nevi	White
Hypopigmentation and depigmentation	Postinflammatory, congenital, vitiligo	Brown

Table 153.8 Camouflage for abnormalities of facial pigmentation.

The camouflaging of facial contour abnormalities is based on the principle that dark colors make protuberances appear to recede while light colors make surface depressions appear more shallow. Creating an even-appearing surface on a scarred face is achieved through artistic shading. Powdered blush-type products are best suited for this purpose. Areas of the face that need to be lightened should be brushed with a light pink or peach pearled blush or buffer. Areas of the face that need to be darkened should be brushed with a deep plum or bronze matte-finish blush or highlighter.

There are special cosmetics manufactured for these camouflaging purposes. A reference list of the websites of the recommended camouflaging cosmetic companies is given in the Appendix.

Hair Care Products

Some of the material discussed above is applicable to hair care products, since shampoos can be likened to skin cleansers, while conditioners are similar to skin moisturizers.

Hair shampoos

Shampoos are simply designed to cleanse the hair; however, this is a complicated task considering that the average woman has 4–8 m^2 of hair surface area to clean[62]. Shampoos are intended to remove sebum, sweat components, desquamated stratum corneum, styling products and environmental dirt from the hair and scalp[63]. They contain detergents, foaming agents, conditioners, thickeners, opacifiers, softeners, sequestering agents, fragrances, preservatives and specialty additives[64]. Synthetic detergents remove sebum and dirt; however, excessive removal of sebum leaves the hair dull, susceptible to static electricity, and difficult to comb, creating the need for hair conditioners[65]. Shampoo detergents can be chemically classified as anionics, cationics, nonionics, amphoterics and natural surfactants (Table 153.9)[66]. The basic difference between bar soap and shampoo is the addition of a higher concentration of sequestering agents to chelate magnesium and calcium ions, preventing the formation of other salts or insoluble soaps known as soap scum. Without sequestering agents, shampoos would leave the hair dull and contribute to scalp pruritus. There are many different types of shampoo, designed to meet various hair cleansing needs (Table 153.10).

Hair conditioners

The need for hair conditioners arises from the inability of shampoos to remove just enough sebum to leave the hair clean, without removing too much sebum and creating dry, unmanageable, dull hair[67]. Conditioners are also required because permanent waving, permanent coloring and other chemical hair treatments damage the cuticle, making the hair harsh, brittle and difficult to disentangle (Table 153.11; Fig. 153.3)[68]. Hair conditioners are designed to reverse this hair damage by improving sheen, decreasing brittleness, decreasing porosity, increasing strength, and repairing degradation in hair protein[69,70].

SHAMPOO DETERGENTS		
Surfactant type	**Chemical class**	**Characteristics**
Anionics	Lauryl sulfates, laureth sulfates, sarcosines, sulfosuccinates	Deep cleansing; may leave hair harsh
Cationics	Long-chain amino esters, ammonio esters	Poor cleansing; poor lather; impart softness and manageability
Non-ionics	Polyoxyethylene fatty alcohols, polyoxyethylene sorbitol esters, alkanolamides	Mildest cleansing; impart manageability
Amphoterics	Betaines, sultaines, imidazolinium derivatives	Non-irritating to eyes; mild cleansing; impart manageability
Natural surfactants	Sarsaparilla, soapwort, soap bark, ivy, agave	Poor cleansing; excellent lather

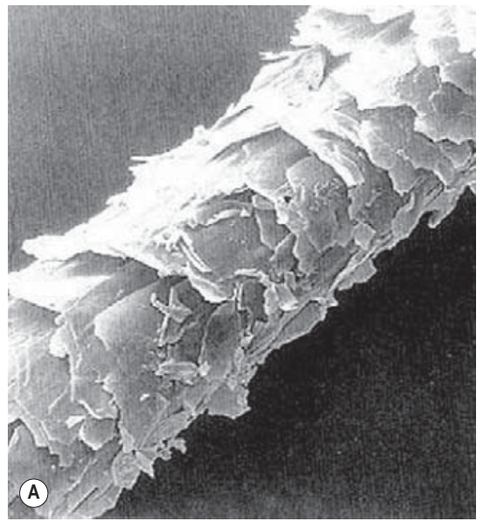
Table 153.9 Shampoo detergents.

SPECIALTY SHAMPOOS		
Shampoo type	**Function**	**Unique ingredients**
Oily hair	Provide excellent cleansing to remove sebum with minimal conditioning	Strong surfactants such as sodium lauryl sulfate or the sulfosuccinates
Dry hair	Provide mild cleansing and excellent conditioning	Milder surfactants such as sodium laureth sulfate
Conditioning	Contain added conditioners to enhance shine and minimize static electricity	Hydrolyzed proteins designed to penetrate the hair shaft
Baby	Utilize mild detergents that anesthetize the conjunctiva to prevent stinging, burning and irritation	Detergents from the amphoteric group such as the betaines
Medicated	Designed to treat dandruff and seborrheic dermatitis through the use of keratolytics as well as antiproliferative and anti-inflammatory agents	Tar, salicylic acid, sulfur, selenium disulfide, ketoconazole, and zinc pyrithione
Professional	Designed for use following hair coloring to reduce hair shaft swelling	Cationic acidic shampoos to neutralize residual hair shaft alkalinity following permanent hair coloring

Table 153.10 Specialty shampoos.

Hair conditioners improve manageability by decreasing static electricity. Following combing or brushing, the hair shafts become negatively charged, causing the hairs to repel one another. Conditioners deposit positively charged ions on the hair shaft, neutralizing the electrical charge. They also improve manageability by reducing hair shaft combing friction by as much as 50%, leading to enhanced disentangling, and conditioners smoothe the cuticular scale to increase hair shine (Fig. 153.4)[71,72]. Maximum hair shine is produced by large-diameter, elliptical hair shafts with a sizable medulla and intact, overlapping cuticular scales[73]. Hair that lacks shine is missing its cuticle (Fig. 153.5).

Special hair conditioner formulations attempt to repair split-ends by temporarily reapproximating the frayed remnants of remaining medulla and cortex. This is accomplished through the use of hydrolyzed animal proteins that can minimally penetrate the hair shaft, enhancing hair tensile strength by 5% until the hair is next shampooed. There are several types of conditioners formulated for a variety of needs (Table 153.12). Leave-in conditioners are specially designed for Afro-textured hair in order to maintain hair water content despite the unavoidable loss that occurs following hair straightening.



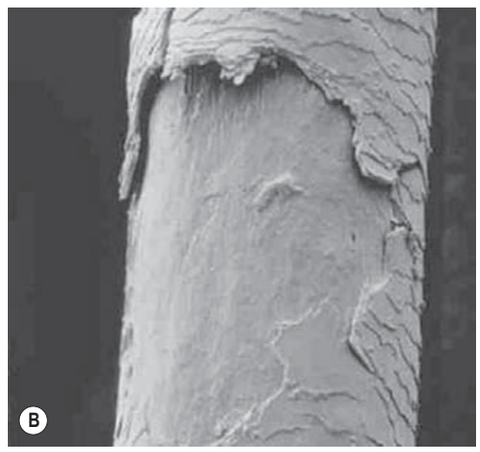


Fig. 153.3 Electron photomicrographs of chemically damaged hair shafts. A Loose cuticle, compared to the tightly overlapping cuticle of normal hairs (see Fig. 153.5). **B** Missing cuticle with exposed cortex.

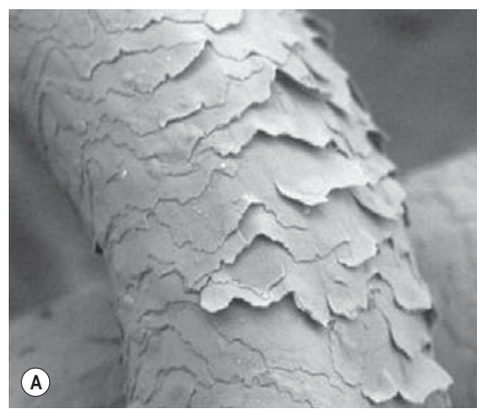

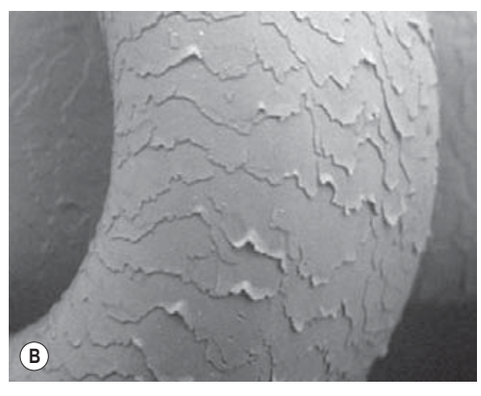

Fig. 153.4 Electron photomicrographs demonstrating the effect of hair conditioners. A Unconditioned hair shaft with uplifted cuticle. **B** Conditioned hair shaft with tightly adherent cuticle.

CHEMICAL HAIR TREATMENTS: COLORING, PERMANENT WAVING AND RELAXING				
Treatment	**Definition**	**Chemicals used**	**Process**	**Adverse effects**
Permanent coloring	Color persists indefinitely (until new growth appears)	• H_2O_2 (referred to as the developer or oxidizing agent) • Ammonia • Dye (e.g. *p*-phenylenediamine, aminophenols)	• H_2O_2 lightens ("lifts") the previous color by oxidizing melanin, and it causes the dye to "develop" and deposit color • Alkaline pH leads to swelling and disruption of the cuticle, allowing the dye to penetrate into the cortex • To dye dark hair to a light blonde color, the hair must first be bleached (e.g. with a mixture of ammonium persulfate and H_2O_2)	• Dull, brittle hair (especially with permanent color) • Allergic contact dermatitis • Staining of the skin
Demi-permanent coloring	Color lasts 2–3 months (12–24 shampoos)	• Low concentration of H_2O_2 • Non-ammonia alkali (e.g. monoethanolamine) • Dye (e.g. *p*-phenylenediamine, aminophenols)	• Similar to permanent color (but to a lesser degree)	
Semi-permanent coloring	Color lasts 4–6 weeks (6–12 shampoos)	• No H_2O_2 • Mild non-ammonia alkali • Azo dyes, henna, polymerized dyes, aminophenols ± *p*-phenylenediamine	• Small dye particles both coat the cuticle and penetrate into the cortex, or dye polymers coat the cuticle • The hair is not lightened	
Gradual coloring	Color slowly builds up over time	• Metallic dyes (e.g. salts of lead, bismuth or silver)	• Dye particles slowly accumulate in the cuticle, darkening the hair within a limited (brown–black) range	
Temporary coloring	Color is removed with 1–2 shampoos	• Azo and other FD&C dyes	• Dye coats the cuticle of the hair shaft (particles are too large to penetrate the cuticle)	
Permanent waving ("perm")*	Chemical treatments "permanently" curl hair (until new growth appears)	• Ammonium or sodium thioglycolate (pH 9–10; "alkaline perm") *– or –* • Glycerol monothioglycolate (pH 6.5–8; "acid perm"; requires application of heat) *– or –* • Bisulfites or mercaptamine (low/neutral pH, "thioglycolate-free perms")	• The hair is wrapped around rods and the chemical solution is applied to break disulfide bonds between keratin polypeptide chains • Neutralizing solution is then used to reform the disulfide bridges, and the hair takes the shape of the rod	• Dull, brittle hair (especially with alkaline perms) • Irritant contact dermatitis • Allergic contact dermatitis • Glycerol monothioglycolate may be retained in hair for up to 3 months
Chemical relaxing (lanthionizing)*	Chemical treatments "permanently" straighten hair (until new growth appears)	• Sodium hydroxide (lye) *– or –* • Guanidine hydroxide (calcium hydroxide cream + guanidine carbonate activator solution; "no-lye" relaxers) *– or –* • Ammonium thioglycolate ("thio" relaxers)	• Disulfide bonds between keratin polypeptide chains are broken and reformed in a similar manner to permanent waving • Relaxer cream is brushed onto the hair, which is mechanically smoothened section by section; this is followed by use of a neutralizing shampoo	• Dull, brittle hair (breakage may be substantial, especially with sodium hydroxide) • Irritant contact dermatitis/chemical burns • Allergic contact dermatitis

*Permanent waving or relaxing should be performed before coloring hair, since the former procedures can produce irreversible color loss; to minimize damage to the cuticle, it is best to wait 2–4 weeks before color is applied.

Table 153.11 Chemical hair treatments: coloring, permanent waving and relaxing. Brazilian keratin straightening is a semi-permanent method in which a keratin-containing solution is applied to the hair prior to the use of a straightening iron; concerns have been raised regarding the inhalation (as fumes) of formaldehyde present in some of the keratin solutions. FD&C, Federal Food, Drug and Cosmetic Act; H_2O_2, hydrogen peroxide.

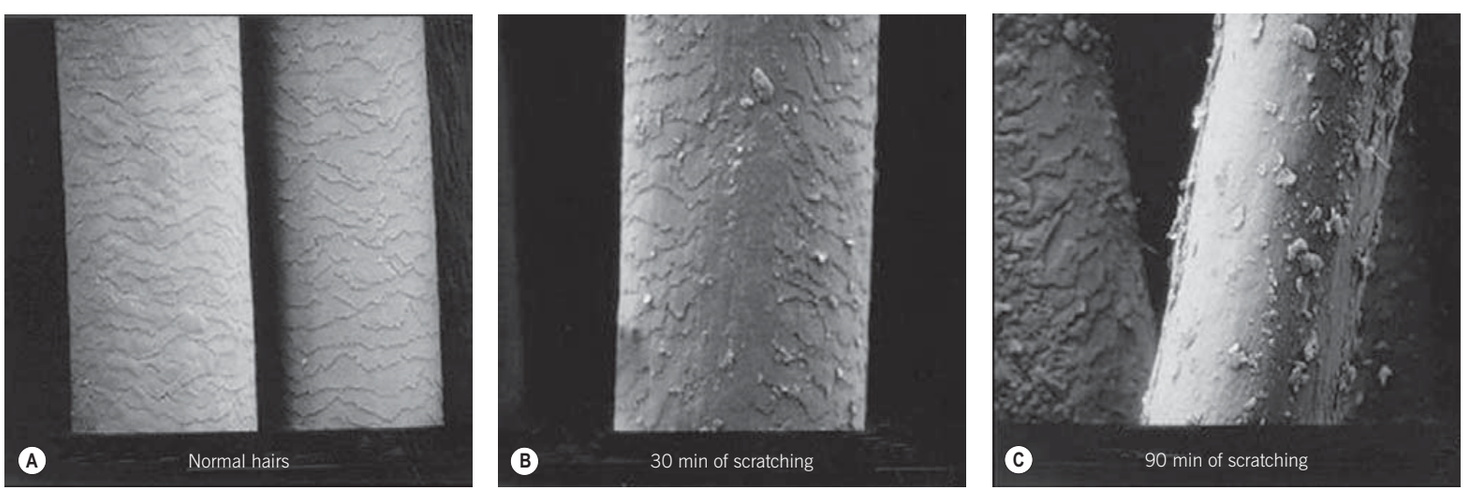

Fig. 153.5 Electron photomicrographs demonstrating the progressive removal of the hair cuticle as a result of scratching. The most common cause of cuticle removal is scratching and this leads to dull fragile hair. Note that the normal hairs have a tightly overlapping cuticle.

HAIR CONDITIONERS		
Type	**Use**	**Indication**
Instant	Apply following shampoo; rinse	Minimally damaged hair; aids wet combing
Deep	Apply for 20–30 minutes; shampoo; rinse	Chemically damaged hair
Leave-in	Apply to towel-dried hair; style	Prevents hair-dryer or hair-straightening damage; aids in combing and styling
Rinse	Apply following shampoo; rinse	Aids in disentangling if creamy rinse; removes soap residue if clear rinse

Table 153.12 Hair conditioners.

NAIL COSMETICS			
Nail cosmetic	**Main ingredients**	**Function**	**Adverse reactions**
Nail polish	Nitrocellulose, tosylamide formaldehyde resin*, plasticizers, solvents, colorants	Add color and shine to nail plates	Allergic contact dermatitis to tosylamide formaldehyde resin; nail plate staining
Nail hardener	Formaldehyde, acetates, acrylics or other resins	Increase nail strength and prevent breakage	Allergic contact dermatitis to formaldehyde
Nail enamel remover	Acetone, alcohol, ethyl acetate or butyl acetate	Remove nail polish	Irritant contact dermatitis
Cuticle remover	Sodium or potassium hydroxide	Destroy keratin that forms excess cuticular tissue on nail plate	Irritant contact dermatitis Paronychia
Nail white	White pigments	Whiten free nail edge	Practically none
Nail bleach	Hydrogen peroxide	Remove nail plate stains	Irritant contact dermatitis
Nail polish drier	Vegetable oils, alcohols or silicone derivatives	Speed drying time of nail polish	Practically none
Nail buffing cream	Pumice, talc or kaolin	Smooth ridges in nails	Practically none
Nail moisturizer	Occlusives, humectants, lactic acid	Increase water content of nails	Practically none

*Also referred to as toluene sulfonamide-formaldehyde resin.

Table 153.13 Nail cosmetics.

Nail Care Products

There are a variety of nail care products (Table 153.13). The focus of this section is on nail polish and the use of nail sculptures, since these are of most concern to the dermatologist. Nail changes associated with a manicure or a pedicure are outlined in Table 71.10.

Nail polish

Nail polish is a cosmetic designed to temporarily place a pigmented layer over the natural nail plate, and it consists of pigments suspended in a volatile solvent to which film-forming agents have been added[74]. Nitrocellulose is the most commonly employed primary film-forming agent in nail lacquer. It produces a shiny, tough film that adheres well to the nail plate. The film is somewhat oxygen-permeable, thus allowing gas exchange between the atmosphere and the nail plate, which is required to maintain nail strength. It also decreases nail water vapor loss from 1.6 to 0.4 mg/cm^2/h, preventing nail plate dehydration[75].

Fig. 153.6 Yellow nail staining due to wearing deeply pigmented red and orange nail polishes. This type of staining is common and reversible.

A resin, such as tosylamide formaldehyde (also referred to as toluene sulfonamide-formaldehyde resin), must be added to the nitrocellulose to decrease hardness, but some individuals are sensitive to this substance, which is found on the standard dermatology patch test tray. This resin has been eliminated in hypoallergenic nail enamels, which instead contain a polyester resin or cellulose acetate butyrate, but allergic contact dermatitis is still possible and the enamel is less durable[76].

A professional nail enamel application requires three layers of polish: a base coat, a pigmented nail enamel, and a top coat. The base coat ensures good adhesion to the nail plate and prevents polish chipping. The second layer is the actual pigmented nail enamel, while the third layer or top coat provides gloss and resistance to chipping.

Problems associated with nail enamels include nail plate discoloration and allergic contact dermatitis. Nail staining is most commonly seen following the use of deep red nail polishes containing D & C Reds No. 6, 7, 34, or 5 Lake[77]. The nail plate will be stained yellow after 7 days of continuous nail polish wear and will fade without treatment in approximately 14 days, once the enamel has been removed (Fig. 153.6)[78]. Allergic contact dermatitis is seen in persons sensitive to tosylamide formaldehyde, who may develop proximal nail fold erythema and edema, fingertip tenderness and swelling, and/or eyelid dermatitis[79]. The North American Contact Dermatitis Group determined that 4% of positive patch tests were due to tosylamide formaldehyde resin allergy[32].

Nail sculptures

Nail polish is designed to color the nail plate, and it may make the nail somewhat stronger due to the presence of the resin layer, but it cannot elongate fingernails. Since long fingernails are considered attractive by some women, this has led to the development of a new industry dedicated to the application of nail prostheses. These nail prostheses, known as nail sculptures, are applied over the natural fingernails and toenails (Table 153.14).

Nail sculptures are formed by mixing liquid ethyl or isobutyl methacrylate monomers with powdered polymethyl methacrylate polymer. The mixture is allowed to polymerize in the presence of a benzoyl peroxide accelerator and a formable acrylic is made, which hardens in 7–9 minutes[80]. Usually, hydroquinone, monomethyl ether of hydroquinone, or pyrogallol is added to slow down polymerization[81].

Many patients are not aware that the finished nail sculptures require more care than natural fingernails. With continued wear of the sculpture, the acrylic loosens from the natural nail, especially around the edges. These loose edges must be clipped and new acrylic applied approximately every 3 weeks to prevent infection and onycholysis[82,83]. However, damage to the natural nail plate is inevitable with the use of nail sculptures (Fig. 153.7). After 2 to 4 months of wear, the natural nail plate becomes yellowed, dry, thin and bendable. This is due to interference with the nail's normal vapor exchange, nail plate trauma during the removal process, and damage to the underlying nail bed[84]. For this reason, it is not advisable to wear sculptured nails for more

NAIL SCULPTURE APPLICATION
Nail sculpture application is an involved process requiring approximately 2 hours to sculpt 10 fingernails. The basic process is as follows: 1. All nail polish and oils are removed from the nail. 2. The nail is roughened with a coarse emery board, pumice stone or grinding drill to create an optimal surface for sculpted nail adhesion. 3. An antifungal, antibacterial liquid, such as decolorized iodine, is applied to the entire nail plate to minimize onychomycosis and paronychia. 4. The loose edges of the cuticle are trimmed, removed or pushed back, depending on the operator. 5. A flexible template is fitted beneath the natural nail plate, upon which the elongated sculpted nail will be built. Or, a preformed nail tip is used for this purpose. 6. The acrylic is mixed and applied with a brush to cover the entire natural nail plate and extended onto the template or preformed nail tip to obtain the desired nail length. 7. The final sculpture is sanded to a high shine. 8. Nail polish, jewels, decals, decorative metal strips or airbrushed designs may be added.

Table 153.14 Nail sculpture application.

Fig. 153.7 Onychodystrophy of the central nail due to wearing a nail prosthesis. The nail prosthesis grows out with the nail plate and new polymer must be applied to the proximal nail fold. The polymer has damaged the cells of the central nail matrix.

Fig. 153.8 Continuous use of a nail prosthesis can result in dramatic nail plate damage.

than 3 months consecutively, allowing 1 month between applications (Fig. 153.8).

Allergic contact dermatitis is an important dermatologic issue, since isobutyl, ethyl and tetrahydrofurfuryl methacrylate are strong sensitizers[85,86]. However, the polymerized, cured acrylic is not sensitizing, only the liquid monomer[87]. Therefore, a careful operator who avoids skin contact with the uncured acrylic can avoid sensitizing the patient. Patch testing should be performed in suspected sensitized individuals with methyl methacrylate monomer (10% in olive oil) and methacrylate acid esters (1% and 5% in olive oil and petrolatum)[88].

CHEMICAL STRUCTURE OF GLYCOLIC ACID

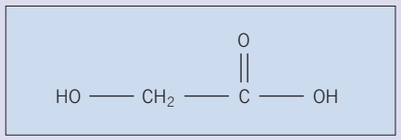

Fig. 153.9 The chemical structure of glycolic acid, accounting for its hydrophilic properties.

Hydroxy Acid Cosmeceuticals

The discussion so far has focused on products intended to function purely in a cosmetic realm, yet there are cosmeceuticals in the current marketplace known as hydroxy acids. These hydroxy acids address the scaliness and roughness of aged skin that is not due to an inherently lower stratum corneum water content[89]. The roughness associated with mature skin may be due to an abnormal desquamation associated with a possible failure in intercellular communication[90]. This observation has led to the enormous popularity of α- and β-hydroxy acids.

Alpha-hydroxy acids

This group of organic carboxylic acids is distinguished by a substituted hydroxy group covalently bonded to the α-carbon of a carboxylic acid. The linear, aliphatic nature of the α-hydroxy acid (AHA) structure accounts for its water-soluble or hydrophilic properties (Fig. 153.9). The three subcategories of AHA consist of: (1) monocarboxylic acids – glycolic (2-hydroxyethanoic acid), lactic (2-hydroxy-propanoic acid) and mandelic acid (2-hydroxy-2-phenylethanoic acid); (2) dicarboxylic acids – malic (2-hydroxy-1,4-butanedioic acid) and tartaric acid (2,3-dihydroxy-1,4-butanedioic acid); and (3) tricarboxylic acids – citric acid (2-hydroxy-1,2,3-propanetricarboylic acid). The intricacies of the formulation are more important than the nature of the AHA, since the exfoliative effect is similar[91].

AHAs induce immediate epidermal effects through corneocyte disadhesion, which is thought to require disruption of ionic bonding[92,93]. The corneocyte disadhesion occurs initially in the stratum corneum at the level of the stratum granulosum; once the cutaneous barrier has been disrupted, this is followed by dermal penetration[94]. The epidermal effects of AHAs are a thinned stratum corneum with acanthosis and decreased melanogenesis. The dermal effects of AHAs are delayed and include increased synthesis of glycosaminoglycans, prevention of topical corticosteroid atrophy, and increased dermal thickness, possibly due to enhanced production of collagen via fibroblast proliferation, in a dose-dependent manner[95,96].

Disruption of corneocyte adhesion is ultimately valuable in a large variety of dermatologic conditions (Table 153.15)[97]. For example, AHAs can be incorporated into an acne treatment regimen, given their ability to induce epidermolysis and dislodge comedones; however, AHAs cannot enter the milieu of the pore[98]. Benefit has also been shown by Briden and Rendon-Pellerano[99] in the treatment of rosacea with monthly glycolic acid peels. Sloughing of corneocytes and smoothing of seborrheic keratoses, verrucae and calluses can also be achieved[100,101]. Glycolic acid preparations, either formulated as topicals or short-contact peels, appear to be appropriate for both lightly and darkly pigmented skin[102]. Lastly, AHAs have been purported to function as anti-inflammatory agents and antioxidants by alleviating the erythema associated with cutaneous UV exposure[103]. Glycolic acid appears to confer an SPF of 2.4 to the skin[104].

Beta-hydroxy acid

The previously discussed α-hydroxy acids form only one component of the hydroxy acid family, which has been demonstrated to enhance cutaneous functioning. A similar, but chemically different, hydroxy acid is salicylic acid (ortho-hydrobenzoic acid), the only so-called β-hydroxy acid (BHA). Salicylic acid is an organic aromatic carboxylic acid with a hydroxy group in the beta position (Fig. 153.10). This

DERMATOLOGIC USES OF HYDROXY ACIDS AS TOPICAL PREPARATIONS AND PEELS
SKIN CONDITIONS
Photodamaged skin
Ichthyosis
Xerotic eczema
Acne
Acne rosacea
Seborrheic keratoses (improves appearance)
Actinic keratoses
Lentigines (improves appearance)
Verrucae
CUTANEOUS EFFECTS
Moisturizing exfoliant
Skin peeling agent
Penetration enhancer
Preventative for corticosteroid-induced skin atrophy

Table 153.15 Dermatologic uses of hydroxy acids as topical preparations and peels.

CHEMICAL STRUCTURE OF SALICYLIC ACID

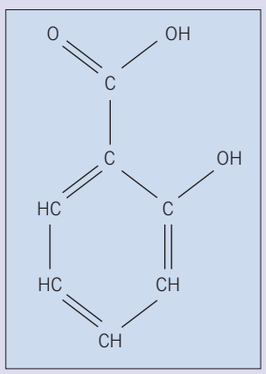

Fig. 153.10 The chemical structure of salicylic acid, accounting for its lipophilic properties.

Fig. 153.11 Lightening of facial lentigines. **A** Numerous facial lentigines due to photodamage. **B** Lightening of lentigines after treatment with a formulation containing kojic acid, emblica extract and glycolic acid.

phenolic, hydrophobic, lipophilic compound is a white crystalline powder chemically unrelated to the α-hydroxy acids. Perhaps even labeling it as a hydroxy acid is somewhat of a marketing misnomer.

Salicylic acid is unique among the hydroxy acids, since it can enter the milieu of the sebaceous unit, inducing exfoliation in the oily areas of the face[105]. For this reason, it has been used for years by dermatologists as a comedolytic in over-the-counter (OTC) preparations designed to improve comedonal acne[106,107]. Salicylic acid is approved for the treatment of acne as an OTC drug, monographed by the FDA at a level of 2% or less. It is also an excellent keratolytic, inducing exfoliation of calluses, corns and warts[108]. Salicylic acid is incorporated into many shampoos designed to remove undesquamated corneocytes from the scalp of patients with seborrheic dermatitis and psoriasis[109].

Salicylic acid is thought to function through solubilization of intercellular cement, thereby reducing corneocyte adhesion. It appears to eliminate the stratum corneum layer by layer from the outermost level downward[110]. This is in contrast to the α-hydroxy acids, which appear to diminish cellular cohesion between the corneocytes at the lowest levels of the stratum corneum. This difference is probably due in part to the water-soluble characteristics of the α-hydroxy acids, which readily penetrate into the stratum corneum, and the oil-soluble characteristics of salicylic acid, which remains on the stratum corneum. Differences in penetration also explain the decreased stinging and burning experienced with topical salicylic acid compared with glycolic acid, since the salicylic acid does not readily penetrate to the dermis.

Topical application of salicylic acid can also take the form of short-contact cutaneous peels. Salicylic acid can be used alone in concentrations of 10–50% or combined with the α-hydroxy acid lactic acid in Jessner's solution. Salicylic acid will remain in solution at concentrations of ≤20% in 95% ethyl alcohol; however, at concentrations of 30% and above, it precipitates, necessitating shaking of the solution prior to its use. In contrast to glycolic acid peels, salicylic acid is a self-neutralizing peel that ends with the formation of white salicylic acid crystals on the skin[111]. The crystals are easily rinsed from the skin surface with water, but they remain in the follicular ostia, providing a prolonged keratolytic effect. Thus, salicylic acid peels are useful for general exfoliation in patients with photoaging, comedolysis in acne patients, and patients with sensitive skin, such as rosacea patients, where dermal penetration should be minimized.

In addition to α- and β-hydroxy acids, there are water-soluble polyhydroxy acids (e.g. gluconolactone, lactobionic acid) which can act as exfoliants but have less dermal penetration.

Additional Cosmeceuticals

As a group, cosmeceuticals can offer other skin benefits in addition to those previously described for the hydroxy acids (Table 153.16; Fig. 153.11).

POPULAR INGREDIENTS IN COSMECEUTICAL FORMULATIONS		
Cosmeceutical category	**Ingredient**	**Comments**
Antioxidant carotenoids	Retinol	Oxidized to retinaldehyde and then retinoic acid for activity
	Astaxanthin	Found in high concentration in salmon
	Lutein	Extensive conjugated double bonds in polyene side chain
Antioxidant flavonoids	Soy	Contains genestein and diadzein which function as phytoestrogens and protect against lipid peroxidation
	Curcumin	Active ingredient is tetrahydrocurcumin – quenches oxygen radicals and inhibits NFκB
	Silymarin	Milk thistle plant extract; contains antioxidants silybin, silydianin, silychristin
	Pycnogenol®	French marine bark extract; contains antioxidants taxifolin, catechin, procyanidins
Antioxidant polyphenols	Green tea	Contains antioxidant polyphenols: epicatechin, epicatechin-3-gallate, epigallocatechin, epigallocatechin-3-gallate
	Pomegranate	Extract contains pantothenic acid, polyphenols
Endogenous antioxidants	Vitamin E	Primary antioxidant in skin
	Vitamin C	Secondary antioxidant in skin
	Ubiquinone (coenzyme Q10)	Tertiary antioxidant in skin
Anti-inflammatory	Aloe vera	Mucilage contains choline, choline salicylate
	Gingko	Contains bilobalides, ginkgolides, ginkgolic acid
Pigment lighteners	Vitamin C	May interrupt melanogenesis by interacting with copper ions
	Licorice extract	Contains liquiritin and isoliquertin, which disperse melanin, and glabridin, which inhibits tyrosinase
	Kojic acid	A hydrophilic fungal derivative; inhibits tyrosinase activity *in vitro*
	Aleosin	Naturally occurring hydroxymethylchromone; inhibits tyrosinase by competitive inhibition
	Arbutin	A naturally occurring gluconopyranoside; decreases tyrosinase activity and may inhibit melanosomal maturation
Peptides		Peptides (e.g. lysine, threonine), attached to palmitic acid (penetration enhancer), mimic proteins such as collagens 1 and 3

Table 153.16 Popular ingredients in cosmeceutical formulations. These are in addition to the hydroxy acids. NFκB, nuclear factor kappa-light-chain-enhancer of activated B cells. Adapted from refs 112–116.

FUTURE DIRECTIONS

Improved understanding of the physiology of the stratum corneum is leading to new dermatologic developments within the realm of cosmetics and skin care products. This has spurred the growth in cosmeceuticals that promise to improve cutaneous function and enhance appearance. In addition, technology that was originally developed for skin keratin can be directly transferred to hair and nail keratin. Future research will undoubtedly explore methods of preventing cutaneous inflammation, which represents a common thread between dermatologic disease and potential adverse effects of cosmetics.

Chemical and Mechanical Skin Resurfacing

154

Gary D Monheit and Mark A Chastain

Chapter Contents

Preoperative history and considerations *2494*
Chemical resurfacing procedures *2496*
Mechanical resurfacing procedures *2502*
Postoperative care *2505*
Complications *2506*

Synonyms: ■ Chemical resurfacing: chemical peeling, chemexfoliation ■ Mechanical resurfacing: dermabrasion (includes dermasanding) ■ Cosmeceutical: topical agent possessing pharmacologic and physiologic effects but promoted to a variable degree as a cosmetic ■ Jessner's peel: Combes' peel ■ Baker–Gordon peel: deep phenol peel

Key features

- Chemical peeling, dermabrasion and laser ablation are the three main methods of skin resurfacing
- Chemical and mechanical resurfacing procedures have a long history of safety and efficacy in ameliorating various skin conditions
- Resurfacing procedures represent one part of a comprehensive skin care program that should include photoprotective measures and topical medical and/or cosmeceutical agents
- Each resurfacing procedure injures the skin to a specific depth in order to promote the regrowth of new skin with improved surface characteristics
- The degree of clinical improvement, the length of the recovery period, and the risk of complications are all proportionate to the depth of tissue injury
- Selection of suitable patients and proper choice of resurfacing procedure are critical to success
- Both dermabrasion and the "TCA Cross" technique are methods for treating acne scars
- Prolonged erythema, pigmentary or textural irregularities, infection, delayed healing and scarring are potential complications of resurfacing
- Resurfacing procedures are a rewarding part of dermatologic practice, both for the patient and for the physician

INTRODUCTION

Resurfacing procedures to improve the health and appearance of the skin have been utilized by humans for thousands of years. The ancient Egyptians applied various chemicals to the skin and may have even used sandpaper in order to obtain a smoother skin surface[1,2]. Resurfacing methods within the practice of dermatology were initially described over 100 years ago, but their role has expanded dramatically over the last several decades. Our society's increasing emphasis on a youthful image and aesthetic appearance has resulted in an explosion in public demand for commercial skin care products, professional assistance from physicians and non-physicians to assure proper medical and cosmeceutical skin therapy, and procedural intervention by physicians.

All ablative resurfacing procedures injure the skin, in a controlled fashion, to a specific depth and thereby promote the growth of new skin with improved surface characteristics. The three fundamental methods used to create the controlled injury are chemical resurfacing (chemical peeling), mechanical resurfacing (motorized dermabrasion or manual dermasanding) and laser resurfacing (see Ch. 137). Chemical resurfacing entails the application of irritating chemical substances, mechanical resurfacing involves skin contact with an abrasive surface, and laser resurfacing is accomplished by irradiating the skin with a laser beam. In general, skin resurfacing procedures can be classified as superficial, medium-depth or deep, according to their level of injury (Table 154.1). Skin resurfacing is usually performed only on the head and neck, in part because of the critical aesthetic value of this area. Caution must be exercised in treating the neck, due to its propensity for complications; only superficial procedures should be performed on the lower one-third of the neck. Resurfacing of other areas, including the hands and arms, has yielded less predictable and less impressive results.

CLASSIFICATION OF ABLATIVE SKIN RESURFACING METHODS
SUPERFICIAL – VERY LIGHT
• Low-potency formulations of glycolic acid or other α-hydroxy acids • 10–20% TCA (weight-to-volume formulation) • Tretinoin • 20% salicylic acid • Jessner's solution
• Microdermabrasion
SUPERFICIAL – LIGHT
• 50–70% glycolic acid • Jessner's solution (see Table 154.4) • 25–30% TCA • Solid CO_2 slush • 30% salicylic acid
• Microdermabrasion
MEDIUM-DEPTH
• Jessner's–35% TCA (the most popular combination) • 70% glycolic acid–35% TCA • Solid CO_2–35% TCA (most potent combination) • 40% TCA (not recommended) • 88% phenol (rarely used)
• Conservative manual dermasanding • Erbium:YAG laser resurfacing • Conservative CO_2 laser resurfacing • Ablative fractional erbium:YAG laser resurfacing
DEEP
• Unoccluded or occluded Baker–Gordon phenol peel (see Table 154.5) • TCA in concentrations > 50% (not recommended)
• Wire-brush or diamond-fraise dermabrasion • Aggressive manual dermasanding • Manual dermasanding or motorized dermabrasion after a medium-depth peel • Aggressive erbium:YAG laser resurfacing • CO_2 laser resurfacing • Combination erbium:YAG/CO_2 laser resurfacing • Ablative fractional CO_2 laser resurfacing

Table 154.1 Classification of ablative skin resurfacing methods. Although this classification represents an oversimplification because the depth of injury actually varies somewhat along a continuum for each different type of resurfacing procedure, it is helpful when discussing the various options with a patient. The lighter shade represents chemical methods and the darker shade mechanical methods. TCA, trichloroacetic acid.

MAJOR INDICATIONS FOR CHEMICAL AND MECHANICAL SKIN RESURFACING
• Actinically damaged skin and rhytides
• Scarring
• Pre-neoplastic or neoplastic lesions (e.g. actinic keratoses)
• Underlying skin diseases such as acne
• Pigmentary dyschromias (including tattoos)
• Demarcation lines secondary to other resurfacing procedures

Table 154.2 Major indications for chemical and mechanical skin resurfacing.

CONTRAINDICATIONS TO CHEMICAL AND MECHANICAL SKIN RESURFACING
ABSOLUTE
• Poor physician–patient relationship
• Lack of psychological stability and mental preparedness
• Unrealistic expectations
• Poor general health and nutritional status
• Isotretinoin therapy within the last 6 months*
• Complete absence of intact pilosebaceous units on the face
• Active infection or open wounds (such as herpes simplex, excoriations or open acne cysts)
RELATIVE
• Medium-depth or deep resurfacing procedure within the last 3–12 months*
• Recent facial surgery involving extensive undermining, such as a rhytidectomy*
• History of abnormal scar formation or delayed wound healing
• History of therapeutic radiation exposure
• History of certain skin diseases (such as rosacea, seborrheic dermatitis, atopic dermatitis, psoriasis and vitiligo) or active retinoid dermatitis
• Fitzpatrick skin types IV, V and VI*
*These contraindications apply only to medium-depth and deep resurfacing procedures.

Table 154.3 Contraindications to chemical and mechanical skin resurfacing.

In comparison to the other resurfacing modalities available for skin rejuvenation, chemical resurfacing probably has the longest and most well-documented history[1]. Experimentation with various peeling compounds in the late nineteenth and early twentieth centuries led to sporadic reports describing their use in the medical literature. The initial reports were met with skepticism, but further investigation by both dermatologists and plastic surgeons verified their effectiveness in facial skin rejuvenation. Over the past several decades, chemical peeling has experienced a tremendous growth in popularity and has become an important part of our armamentarium in the management of various cosmetic as well as non-cosmetic skin problems.

Since Kromayer's original report of motorized dermabrasion in 1905, there has been considerable growth not only in chemical resurfacing procedures, but also in other forms of mechanical resurfacing. Mechanical resurfacing is most often known as dermabrasion but it refers to any procedure that involves surgical planing of the skin using an abrasive surface. The use of dermabrasion was originally limited to the treatment of scars, but its role expanded during the latter half of the twentieth century to include a multitude of indications[2]. Recent adaptations of the traditional techniques of dermabrasion have led to the development of a less invasive procedure, known as microdermabrasion[3]. Dermasanding, which is a manual technique for dermabrasion utilizing abrasive paper, has been in use since the early days, but has experienced a recent resurgence in interest[4,5]. Although overshadowed by ablative laser resurfacing, mechanical resurfacing procedures remain a popular option for both patients and physicians.

Over the past two decades, the practice of skin rejuvenation has been revolutionized by the development of resurfacing lasers. Carbon dioxide (CO_2), erbium and fractional laser resurfacing is invaluable in treating cutaneous photoaging because it can consistently deliver impressive results. However, the deep wounds and extensive recovery time seen with CO_2 laser resurfacing have led to the development of less invasive modalities, such as erbium:YAG laser resurfacing, non-ablative laser treatments, and fractional laser ablation. Despite the capabilities of lasers in facial rejuvenation, their use is limited by the considerable monetary cost to either rent the equipment or purchase and maintain it. Furthermore, while nearly all the complications associated with chemical peeling and dermabrasion can occur with laser resurfacing, the use of lasers carries additional risks, such as exposure to infectious agents in the smoke plume, fire hazards and ocular injury by the laser beam. There may also be an increased risk of anesthesia-related problems, as well as higher financial costs of surgery, because of the greater level of sedation often required. The following discussion will focus on chemical peeling and dermabrasion, as laser therapy is covered in Chapter 137.

PREOPERATIVE HISTORY AND CONSIDERATIONS

Indications

The preoperative consultation is important in identifying at-risk patients who are best avoided or who require an extra-cautious approach, as well as in selecting patients who are ideal candidates for intervention. The dermatologist must evaluate the prospective patient and his or her skin condition carefully, in order to determine if a chemical or mechanical resurfacing procedure is indicated. When resurfacing is deemed appropriate, selection of the proper procedure for each patient is critical to assure that the desired results are achieved in a safe and effective manner. In general, the degree of skin surface irregularities is proportional to the depth of the injury that must be created by resurfacing in order to achieve significant improvement. There are six major indications for resurfacing (Table 154.2).

Pre-neoplastic or neoplastic skin lesions can certainly be improved with resurfacing procedures. Those originating in the epidermis, such as actinic keratoses or lentigines, are more amenable to treatment than those with a dermal origin. Although some dermatologic conditions may be aggravated by resurfacing, acne and pigmentary dyschromias such as melasma respond favorably to superficial chemical peeling or microdermabrasion. Another indication for chemical and mechanical skin resurfacing is to blend the effects of other procedures by preventing or eliminating lines of demarcation.

Photoaging is probably the single condition for which skin resurfacing procedures are most often performed. For patients with photoaging and acne scarring, the Glogau system (see Ch. 152) is helpful in deciding upon the most appropriate skin rejuvenation program. It classifies patients into one of four groups based on degree of severity. Patients in category I are often young with minimal to mild photoaging and are best managed with superficial chemical peels or microdermabrasion in conjunction with medical or cosmeceutical therapy (e.g. topical retinoids, glycolic acids, active cosmeceutical preparations). Patients in category II would likely benefit from a medium-depth chemical peel as well as long-term medical therapy to include a retinoid and/or an α-hydroxy acid (AHA). Individuals in category III typically need prolonged medical treatment in conjunction with one of the following: a medium-depth chemical peel (with or without dermasanding), a deep chemical peel, dermabrasion or laser resurfacing. A medium-depth or deep chemical peel, dermabrasion or laser resurfacing as well as adjunctive medical therapy would certainly be indicated in patients with category IV photoaging. However, an invasive surgical operation such as a rhytidectomy, blepharoplasty or scar revision is often required in addition to resurfacing in order to achieve the desired results.

Contraindications and Patient Selection

When evaluating a patient for chemical or mechanical resurfacing, a careful history and physical examination are important to assess the skin problems which prompted his or her presentation and to identify any factors that may contribute to intraoperative or postoperative difficulties (Table 154.3) The patient should be asked about prior resurfacing procedures, rhytidectomy (facelift) or oral isotretinoin therapy within the last 6 months, as these can increase the risk of complications following medium-depth and deep resurfacing[6,7]. Any history of abnormal scar formation or therapeutic radiation exposure warrants extreme caution when considering a patient for skin resurfacing. Individuals with prior radiation exposure should be examined closely for the presence of intact facial hair in order to ensure that there are enough pilosebaceous units to promote re-epithelialization[8]. Another important element of the patient's history is the presence or absence of a prior herpes simplex infection. Recurrence of oral herpes simplex can

be triggered by a resurfacing procedure, especially in the perioral and periorbital regions. Risk factors for HIV infection or viral hepatitis should be identified, and routine laboratory screening is recommended in individuals undergoing dermabrasion with a powered engine. The general health and nutritional status of the patient is also an important consideration, especially for medium-depth and deep resurfacing procedures, to ensure timely and complete healing.

Patients with certain cutaneous disorders, such as rosacea, seborrheic dermatitis, atopic dermatitis, psoriasis or vitiligo, may be at increased risk for postoperative complications, including disease exacerbation, prolonged erythema, contact dermatitis or even delayed healing. In particular, individuals with rosacea have vasomotor instability and may develop an exaggerated inflammatory response to the resurfacing procedure. Caution should also be exercised for patients with autoimmune connective tissue diseases (e.g. cutaneous lupus, scleroderma) as the trauma of chemical peeling may activate the disease. Evaluation of the patient's Fitzpatrick skin type (see Ch. 134) is helpful in predicting the chance of postoperative pigmentary dyschromias. Individuals with Fitzpatrick skin types I or II are at low risk for hyperpigmentation or hypopigmentation after medium-depth or deep resurfacing, whereas those with types III through VI are at greater risk for these complications[9].

The patient should understand that chemical and mechanical resurfacing procedures cannot reliably reduce pore size and their ability to improve lax skin or deeper wrinkles and scars is limited, depending on the type of intervention being performed. While dermabrasion may sometimes eliminate telangiectasias, chemical peels cannot accomplish this and can even unmask them by removing the pigmentary irregularities. The patient must fully understand the potential benefits, limitations and risks of the procedure, and an informed consent must be signed. A test spot (e.g. along the lateral hair line) may be useful in some patients to assess their suitability for resurfacing and may be particularly helpful when there is a great deal of concern about the chances of postoperative pigmentary dyschromias[10]; test spots are definitely recommended for individuals with skin types III–VI. Although a favorable test spot result does not guarantee a positive outcome following full-face resurfacing, an unfavorable test spot result is useful in identifying high-risk patients. If the dermatologist feels any uncertainty about the patient's suitability or the likelihood of a favorable result, the procedure should not be performed.

Preoperative and Intraoperative Preparations

Another purpose of the preoperative consultation is to ensure that the patient is adequately prepared for the procedure. Almost every patient desiring facial rejuvenation for cutaneous photoaging would benefit from botulinum toxin injections to alleviate dynamic wrinkles (see Ch. 159). These injections appear to enhance the results of deeper resurfacing procedures by immobilizing the muscles implicated in the development of dynamic rhytides during the critical time of postoperative collagen remodeling. It is recommended that botulinum toxin injections be administered as an adjunctive therapy preoperatively in patients with photoaging undergoing medium-depth or deep chemical peels, dermabrasion or laser resurfacing.

Due to the significant morbidity associated with herpetic infections during the healing period, patients who undergo medium-depth or deep resurfacing (see Table 154.1) should be treated prophylactically with an antiviral agent, regardless of whether there is a history of herpes simplex infection[11]. These drugs are not routinely given to patients having a superficial chemical peel or microdermabrasion, because the injury is generally not sufficient to activate the virus. However, therapy may be considered in conjunction with superficial resurfacing in patients with a strong personal history of recurrent herpes simplex. Recommended prophylaxis consists of acyclovir 400 mg three times daily, valacyclovir 500 mg twice daily or famciclovir 250 mg twice daily, beginning on the day of the procedure. It is advisable to administer the drug for at least 10 to 14 days[12]. The reason for such a long duration of therapy is that viral replication is possible only in intact epidermal cells, making clinical infection unlikely during the first few days postoperatively. The risk of an eruption increases dramatically with the onset of re-epithelialization and remains high until this process is complete.

It is important that the patient adhere to a strict skin care regimen during the immediate preoperative and postoperative periods in order to achieve optimal results. The authors treat patients with topical tretinoin on a nightly basis prior to the procedure. Retinoids increase epidermal proliferation and presumably lead to more rapid re-epithelialization after the chemical peel. Because of the tendency for retinoids to cause irritation within 1 to 2 weeks of starting therapy (i.e. retinoid dermatitis), a weaker, more gentle tretinoin formulation should be used in patients with sensitive skin. In patients with active retinoid dermatitis, resurfacing should be delayed, because this condition may lead to a prolongation in postoperative erythema. Decreasing the frequency of application or switching to a less irritating retinoid will allow the inflammation to subside, so that the procedure can be performed[13].

All-*trans*-retinoic acid, or tretinoin, has been classified as a superficial chemical peeling agent, but it is best considered as an integral component of a complete skin rejuvenation program. With chronic use, this drug has been shown to improve actinically damaged skin both clinically and histologically[14]. The use of tretinoin prior to chemical peeling, dermabrasion or laser resurfacing speeds epidermal healing and enhances the effects of the procedure[13,14]. Tretinoin increases the depth of a chemical peel by decreasing the thickness of the stratum corneum. Its use is restricted, however, during the postoperative healing period, until there is complete re-epithelialization and diminished inflammatory erythema.

Hydroquinone blocks the enzyme tyrosinase and can reduce the production of epidermal melanin during the healing phase. Patients with skin type III or higher may benefit from twice-daily application of a 4% to 8% topical hydroquinone in the preoperative and postoperative (post-healing) periods – even if there is no history of pigmentary abnormalities[9]. It is also necessary to use hydroquinone when peeling for the treatment of pigmentary dyschromias, such as melasma, in patients of any skin type[9]. While a Wood's lamp was used in the past to localize melanin pigment to either the epidermis or dermis (i.e. epidermal versus dermal melasma), histopathologic studies and confocal microscopy have shown that there is often a mixture of the two forms in an individual patient. Nonetheless, in both melasma and postinflammatory hyperpigmentation, increased melanin within the epidermis responds better to superficial peels than does dermal pigment. The use of non-inflammatory peeling agents such as salicylic acid are preferred for disorders such as melasma as there is less tendency for postinflammatory hyperpigmentation (Fig. 154.1).

All patients undergoing any type of skin resurfacing procedure must adhere to strict photoprotective measures during the postoperative period. This issue is critical in patients whose Fitzpatrick skin type is III or higher, in patients with pigmentary disturbances, in patients taking exogenous estrogens, as well as in all patients having medium-depth or deep resurfacing. Specific methods to minimize sun exposure and proper use of sun blocks should be discussed. Patients are also counseled to avoid tobacco use, as smoking in the postoperative period may limit the effectiveness of the resurfacing and increase the risk of poor wound healing.

The need for intraoperative sedation and analgesia is also discussed with the patient preoperatively, so that plans are made accordingly. Superficial resurfacing procedures usually require only "talkesthesia", a

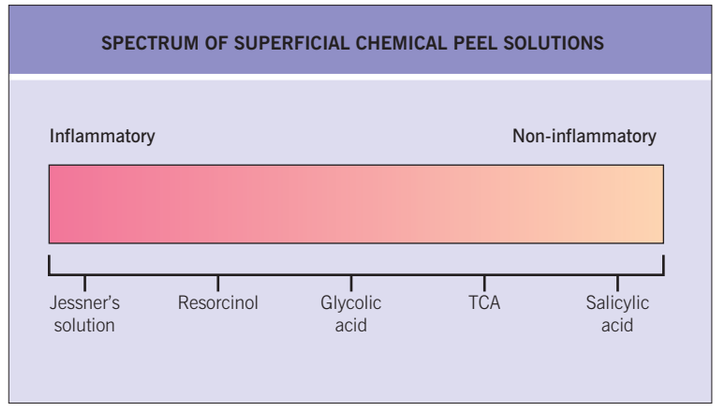

Fig. 154.1 Spectrum of superficial chemical peel solutions. Inflammatory chemical peel solutions are used primarily for photoaging, while non-inflammatory chemical peel solutions are best for Fitzpatrick skin types III–VI, melasma and postinflammatory hyperpigmentation. TCA, trichloroacetic acid.

technique that is extremely helpful in awake patients undergoing a procedure (talking calmly to the patient with encouragement during the procedure). Medium-depth chemical or mechanical resurfacing usually requires a limited degree of perioperative sedation and analgesia, which may include the application of topical amide anesthetics, regional blocks of the supraorbital, infraorbital and mental nerves (see Ch. 143), as well as oral diazepam, intramuscular meperidine hydrochloride and/or intramuscular hydroxyzine hydrochloride. Although deep resurfacing procedures can be accomplished entirely with nerve blockade, local injections of lidocaine and mild sedatives, some patients require intravenous or general (endotracheal tube) anesthesia. Application of the tumescent technique (see Ch. 156) to resurfacing has allowed many patients to undergo deep resurfacing procedures without the additional risks of intravenous or general anesthesia[15]. The patient's inherent pain tolerance, level of anxiety, concomitant medical conditions, and willingness to pay the extra costs of heavier sedation are important topics in the preoperative consultation that are used to plan for appropriate anesthesia.

The patient must be given specific instructions to follow on the day of the procedure. Upon awakening, the patient washes his or her face with a gentle cleanser and preferably avoids the application of any cosmetics. Individuals undergoing procedures requiring minimal or no sedation are encouraged to eat a light breakfast, but patients receiving deeper anesthesia should have nothing by mouth except their usual medications. Particularly for the medium-depth and deep resurfacing procedures, the dermatologist should meet with the patient and his or her family preoperatively to re-establish rapport, answer last-minute questions, discuss perioperative and postoperative expectations and instructions, and assure compliance with antimicrobial prophylaxis as needed.

CHEMICAL RESURFACING PROCEDURES

Although there is currently a wide variety of resurfacing procedures available for facial rejuvenation, chemical peeling remains a popular choice for both patient and physician. In comparison to some of the newer options, chemical peels have a longstanding safety and efficacy record, are performed with ease, are low in cost, and have a predictable and relatively quick recovery time. Various acidic and basic compounds are used to produce a controlled skin injury and are classified as superficial, medium-depth and deep peeling agents, according to their level of penetration, destruction and inflammation (see Table 154.1). In general, superficial peels cause epidermal injury and occasionally extend into the papillary dermis, medium-depth peels cause injury through the papillary dermis to the upper reticular dermis, and deep peels cause injury to the mid-reticular dermis.

Prior to the application of peeling solutions, the skin surface must be vigorously cleansed to remove residual oils, debris and excess stratum corneum. The authors use gauze pads containing 0.25% triclosan (an ingredient found in some deodorant soaps), followed by rinsing with water and drying. Because of the defatting and degreasing properties of acetone, gauze pads moistened with an acetone preparation are then used to cleanse the skin even further. Finally, the cleansed skin is palpated immediately prior to peeling, in order to check for the presence of residual oil, and if any is felt, the process is repeated. The importance of cleansing prior to the peeling procedure cannot be overemphasized. A thorough and evenly distributed cleansing and degreasing of the face assures uniform penetration of the peeling solution and leads to an even result without skipping areas (Fig. 154.2).

The effect of a chemical peel is dependent upon the agent used, its concentration, and the techniques employed before and during its application. Each wounding agent used in peels has unique chemical properties and causes a specific pattern of injury to the skin[15–20]. It is important for the physician using these solutions to be familiar with their cutaneous effects and proper methods of application, to assure correct depth of injury. The marketplace has been flooded with numerous proprietary formulations of these peeling agents, with each product claiming unique advantages. These products are often expensive and have not been shown to be safer or more effective than the conventional solutions. Their advantage rests in the prepackaging of materials and ease for the physician. The following discussion on superficial, medium-depth and deep peeling will therefore focus on the specific chemical agents that are actively responsible for producing the various patterns of injury.

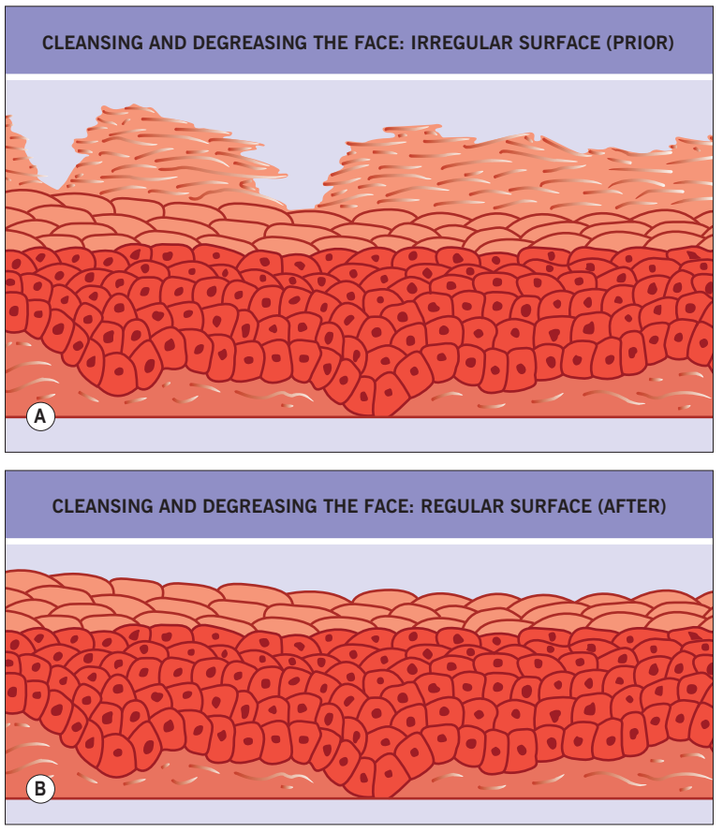

Fig. 154.2 Cleansing and degreasing the face. A Irregular surface (prior). **B** Clean, regular surface (after).

Superficial chemical peeling

Superficial chemical peels are indicated in the management of acne and its postinflammatory erythema, mild photoaging (Glogau I and II), epidermal lesions such as lentigines and keratoses, as well as melasma and other pigmentary dyschromias. Multiple peels on a repeated basis are usually necessary to obtain optimal results. The frequency of peels and degree of exposure to the peeling agent may be increased gradually as necessary. Results are enhanced by medical or cosmeceutical therapy, including a retinoid and, if necessary, a bleaching agent. All superficial chemical peels share the advantages of only mild stinging and burning during application as well as minimal time (a few days) needed for recovery.

Superficial chemical peels are divided into two varieties – very light and light (see Table 154.1). With *very light* peels, the injury is usually limited to the stratum corneum and only creates exfoliation; however, the injury may extend into the stratum granulosum. The agents used for these peels include low-potency formulations of glycolic acid, 10–20% trichloroacetic acid (TCA), tretinoin, 20% salicylic acid and Jessner's solution (Table 154.4)[21–23]. *Light* peels injure the entire epidermis down to the basal layer, stimulating the regeneration of a fresh new epithelium. Agents used for light peels include 50–70% glycolic acid, 25–30% TCA, Jessner's solution, 30% salicylic acid and solid CO_2 slush[21,22]. During the application of superficial peeling agents, there may be mild stinging followed by a level I frosting, defined as the appearance of erythema and streaky whitening on the surface (Fig. 154.3).

Alpha-hydroxy acids (AHAs) are naturally found in foods and have been used widely in skin rejuvenation programs since the early 1990s. The depth of injury is determined by the specific AHA used, its pH, the concentration of free acid, the volume applied to the skin, and the duration of contact. In low concentrations, AHAs have been shown to decrease the cohesion of corneocytes at the junction of the stratum corneum and the stratum granulosum[24]. Higher concentrations are associated with complete epidermolysis. With chronic use of AHA-containing products on a daily basis, there is an increase in skin

JESSNER'S SOLUTION (COMBES' FORMULA)

thickness, acid mucopolysaccharides, and the density of collagen, as well as an improvement in elastic fiber quality[19]. The most popular of the AHAs, glycolic acid, is available in a variety of over-the-counter preparations and can be purchased by physicians in buffered as well as unbuffered concentrations as high as 70% for chemical peels. Weekly or biweekly applications of 40–70% glycolic acid (with cotton swabs, a sable brush, or 2-inch × 2-inch gauze pads) have been used most often for acne, mild photoaging and melasma[25]. The time of application is critical for glycolic acid, as it must be rinsed off with water or neutralized with 5% sodium bicarbonate after 2 to 4 minutes. It is the only peeling agent requiring neutralization to end its action.

Application of 10–20% TCA with either a saturated gauze pad or sable brush produces erythema and a very light frost within 15 to 45 seconds. The depth of penetration of the peeling solution is related to the number of coats applied. Protein precipitation results and leads to exfoliation without vesiculation. Concentrations of TCA up to 25% can also be used alone as a superficial peeling agent, but may create an injury that extends partially into the upper dermis. Jessner's solution is a combination of keratolytic ingredients that has been used for over 100 years in the treatment of inflammatory and comedonal acne as well as hyperkeratotic skin disorders (see Table 154.4). Jessner's solution has intense keratolytic activity, initially causing loss of corneocyte cohesion within the stratum corneum and subsequently creating intercellular and intracellular edema within the upper epidermis if application is continued[26]. The mode of application for the Jessner's peel is similar to that of the 10–20% TCA peel. The clinical endpoint of treatment is erythema and blotchy frosting.

Salicylic acid, also referred to as a β-hydroxy acid, is one of the ingredients in Jessner's solution. It can be used alone for superficial chemical peeling and is a preferred therapy for comedonal acne and inflammatory rosacea as it is lipophilic and concentrates within the pilosebaceous apparatus (Fig. 154.4)[23]. Salicylic acid is quite effective as an adjunctive therapy for both open and closed comedones and for resolving postacne erythema. As noted previously, salicylic acid produces less inflammation than other superficial peeling agents (see Fig 154.1) and therefore is associated with a lower risk of postinflammatory hyperpigmentation. As a result, it is preferred for the removal of excess cutaneous pigmentation.

Prior to the initial treatment, the patient must understand that the net effect of repetitive superficial chemical peels never approaches the beneficial effect obtained with a single medium-depth or deep peel. The improvements in cutaneous photoaging following superficial peels are usually subtle because there is little to no effect on the dermis. These peels thus cannot produce an appreciable effect on textural changes such as deep wrinkles and furrows which originate within the

Fig. 154.4 Salicylic acid peels. These peels are effective for the treatment of acne, including comedones. Repetitive peels over 6 weeks combined with medical acne treatment will hasten resolution of the condition. Note the perifollicular frosting seen with salicylic acid, a lipophilic chemical.

Fig. 154.5 Medium-depth chemical peel used to treat moderate photoaging of the skin. dermis. Nevertheless, their ease of use and minimal downtime makes these "lunchtime" peels rewarding for patients with realistic expectations and are a favorite of busy patients. Superficial peels can also be used in combination with cosmeceutical agents and other minimal to no downtime procedures such as botulinum toxin A injections and intense pulsed light treatments.

Medium-depth chemical peeling

Medium-depth chemical peels consist of controlled damage through the epidermis and papillary dermis, with variable extension to the upper reticular dermis. Both medium-depth and deep chemical peeling produce epidermal necrosis, papillary dermal edema and homogenization, and a sparse lymphocytic infiltrate within the first several days[15]. Postoperatively, over a period of 3 months, there is increased collagen production with expansion of the papillary dermis and the development of a mid-dermal band of thick fibers. These changes correlate with continued clinical improvement during this time.

For many years, 40–50% TCA was the prototypical medium-depth peeling agent because of its ability to ameliorate fine wrinkles, actinic changes and "pre-neoplasias". TCA as a single agent for medium-depth peeling has fallen out of favor because of the high risk of complications, especially scarring and pigmentary alterations, when used in strengths approaching 50% and higher[27]. Today, most medium-depth chemical peels are performed utilizing 35% TCA in combination with Jessner's solution, 70% glycolic acid or solid CO_2 as the "priming" agent. These combination peels have been found to be as effective as 50% TCA alone, but with fewer risks. The level of penetration is better controlled with these combination peels, thereby preventing the "hot spots" seen with higher concentrations of TCA that can produce dyschromia and scarring.

Brody and Hailey[28] developed the use of solid CO_2 to freeze the skin prior to the application of 35% TCA. This causes epidermal necrosis and significant dermal edema, thereby allowing deeper penetration of the TCA in selected areas. This technique is particularly useful for effacing the edges of mild acne scars and destroying thicker epidermal growths. Monheit[26] then described a combination medium-depth peel in which Jessner's solution is first applied, followed by 35% TCA. Similarly, Coleman and Futrell[29] have demonstrated the usefulness of 70% glycolic acid prior to the application of 35% TCA for medium-depth peeling. The Jessner's solution and glycolic acid both appear to effectively weaken the epidermal barrier and allow deeper, more uniform and more controlled penetration of the 35% TCA.

Current indications for medium-depth chemical peeling include Glogau group II photoaging, epidermal lesions such as actinic keratoses, pigmentary dyschromias and mild acne scarring, as well as blending of the effects of deeper resurfacing procedures. The most popular of the medium-depth peels for facial rejuvenation is the Jessner's–35% TCA peel, with other combination peels being utilized less frequently. This peel has been widely accepted because of its broad range of uses, the large number of individuals in whom it is indicated, its ease of modification according to the situation, and its excellent safety profile.

The Jessner's–35% TCA peel is particularly useful for the improvement of mild to moderate photoaging (Fig. 154.5). It freshens sallow, atrophic skin and softens fine rhytides, with minimal risk of textural or

Fig. 154.6 Combination of medium-depth peel of the face plus CO_2 laser ablative resurfacing of the periorbital region. A before, **B** after treatment.

pigmentary complications. Collagen remodeling occurs for as long as 3 to 4 months postoperatively, during which time there is continued improvement in texture and rhytides. Deep furrows, however, are not eliminated with this peel and there is no significant skin retraction as is seen with ablative fractional laser resurfacing. When used in conjunction with a retinoid, bleaching agent and sunscreens, a single Jessner's–35% TCA peel lessens pigmentary dyschromias and lentigines more effectively than repetitive superficial peels. Epidermal growths such as actinic keratoses also respond well to this peel. In fact, the Jessner's–35% TCA peel has been found as effective as topical 5-fluorouracil chemotherapy in removing both grossly visible and clinically undetectable actinic keratoses, but has the added advantages of lower morbidity and greater improvement in associated photoaging[30,31].

Another indication for the Jessner's–35% TCA peel is to blend the effects of other resurfacing procedures with the surrounding skin[31a]. Patients who undergo CO_2 or ablative fractional laser resurfacing, deep chemical peeling or dermabrasion to a localized area such as the periorbital or perioral region often develop a sharp line of demarcation between the treated and untreated skin. The treated skin may appear hypopigmented (also known as pseudohypopigmentation) in comparison to the untreated skin. These irregularities are often conspicuous and are troubling to the patient. A Jessner's–35% TCA peel performed on the adjacent untreated skin helps to blend the treated area into its surroundings. For example, a patient with advanced photoaging in the periorbital region and moderate photoaging on the remaining face may desire CO_2 laser resurfacing only around the eyes. In this patient, medium-depth chemical peeling of the areas not treated with the laser would improve the photoaging in these regions and avoid a line of demarcation[32] (Fig. 154.6). Similarly, a patient having spot dermabrasion or ablative fractional laser resurfacing to a localized scar would benefit from a Jessner's–35% TCA peel to the remainder of that cosmetic unit or to the rest of the face. It is important to note that when used in combination with other resurfacing procedures such as laser ablation or dermabrasion, the peel should be performed first, in order to avoid accidental application of the peeling agent onto previously abraded areas of skin which may lead to scarring (Fig. 154.7).

Using either cotton-tipped applicators or gauze pads, a single, even coat of Jessner's solution is applied first to the forehead, then the cheeks, nose and chin, and, lastly, the eyelids. Proper application of Jessner's solution causes minimal discomfort and creates a faint frost within a background of mild erythema (level I; Fig. 154.8A)[32a]. After waiting 1 to 2 minutes for the Jessner's solution to completely dry, 35% TCA is applied evenly with one to four cotton-tipped applicators (Fig. 154.8B). The ultimate effectiveness of this peel is directly dependent upon the depth of penetration of the peeling solutions, and this depth is a function of the adequacy of degreasing and the amount of both solutions applied. The use of cotton swabs, particularly for the application of TCA, is advantageous because is allows the surgeon to quantitatively vary the amount of solution applied according to the patient's specific needs. The amount of TCA delivered to the skin surface is determined by the number of applicators used, their degree of saturation, the amount of pressure applied to the skin surface, and the duration of their contact with the skin. Four moist cotton-tipped applicators are applied in broad strokes over the forehead and on the medial cheeks. Two mildly soaked cotton-tipped applicators can be used across the lips and chin, and one damp cotton-tipped applicator on the eyelids (Fig. 154.8C).

When applying TCA, anatomic areas of the face are peeled sequentially from the forehead to the temple to the cheeks and finally to the lips and eyelids. Careful feathering of the solution into the hairline and around the rim of the jaw and brow conceals the demarcation line between peeled and non-peeled skin. Areas of wrinkled skin are stretched taut with the help of an assistant, to allow even application of the solution into the folds and troughs. This technique is particularly helpful on the skin of the upper and lower lips. For perioral rhytides, TCA is applied with the wooden portion of a cotton-tipped applicator and extended onto the vermilion border (Fig. 154.8D).

Eyelid skin must be treated delicately and carefully to avoid overapplication to this thinner skin and to prevent exposure of the eyes to the TCA solution. The patient should be positioned with the head elevated at 30°. Excess peel solution on the cotton tip should be squeezed out so that the applicator is semi-dry. With the eyes closed, a single applicator is rolled gently from the periorbital skin onto the upper eyelid skin without going beyond the superior aspect of the supratarsal plate. Another semi-dry applicator is then rolled onto the lower eyelid skin within 2 to 3 mm of the lid margin while the patient is looking superiorly. Excess peel solution should never be left on the lids, because it can roll into the eyes. Any tears should be immediately dried with a cotton-tipped applicator because they may pull the solution into the eye by capillary action (see Fig. 154.8C). Tears can also travel down the cheek and carry TCA onto the neck, resulting in a linear streak.

The white frost from the TCA application appears on the treated area within 30 seconds to 2 minutes. This response is representative of keratocoagulation and indicates that the TCA's physiologic reaction is complete. The Jessner's–35% TCA combination takes longer to frost than phenol preparations, but a shorter period of time than the superficial peeling agents. The desired endpoint for medium-depth peeling is level II to level III frosting. Level II frosting is defined as a white-coated frosting with a background of erythema (see Fig 154.3B). Level III frosting, which is associated with penetration to the reticular dermis, is a solid white enamel frosting with no background of erythema (see Fig. 154.3C). A deeper level III frosting should be restricted only to areas of thick skin and heavy actinic damage. Most medium-depth chemical peels achieve a level II frosting and this is especially important over the eyelids and areas of sensitive skin. Areas with a greater tendency to form scars, such as the zygomatic arch and the bony prominences of the jawline and chin, should receive no greater than level II frosting.

Before re-treating an area, the surgeon should wait at least 3 to 4 minutes after the application of TCA, to ensure that frosting has reached its peak. Each cosmetic unit is then assessed, and areas of incomplete or uneven frosting are carefully re-treated with a thin

Fig. 154.7 Combination procedure utilizing perioral–periorbital CO_2 laser resurfacing with Jessner's–35% trichloroacetic acid peel to the remainder of the face. The peel will blend the color and texture of the laser-treated areas. **A** Preoperative: the eyelids and lips need deeper resurfacing than do the cheeks, which require only medium-depth injury. **B** Four days postoperative: note difference in the rate of healing between laser- and peel-treated areas. **C** One year postoperative.

The wooden shaft is used to rub peel solution further into the lip rhytides.

application of TCA. Additional applications of TCA increase the depth of penetration as well as the risk of complications, so one should apply more solution only to the underfrosted areas. In other words, do not apply 35% TCA to fully frosted areas. Thicker keratoses do not frost as well as the surrounding skin, so vigorous rubbing of the lesion may be needed for adequate TCA penetration. If necessary, thicker epidermal lesions may be treated with liquid nitrogen cryotherapy for several seconds prior to the application of TCA. As will be discussed later, mechanical abrasion can also be performed in selected areas at the completion of the Jessner's–35% TCA chemical peel, to enhance the results.

Although there is an immediate burning sensation as the peel solution is applied, the discomfort begins to subside as frosting occurs and resolves fully by the time of discharge. If necessary, a topical amide anesthetic can be applied under occlusion prior to a medium-depth peel, for pain relief[33]. Cool saline compresses offer symptomatic relief at the conclusion of the peel. Unlike the compresses utilized in glycolic acid peels, the saline following a TCA peel simply provides relief and does not "neutralize" the acid.

TCA Cross

The "TCA Cross" technique is a newer innovative approach to deep ice-pick and fibrotic acne scars (Fig. 154.9A). Rather than a peel or method of exfoliation, it is the use of 90% TCA as a full-thickness destructive tool. When applied to an ice-pick scar, it destroys the epidermis and deep dermal tunnel, creating a full-thickness skin wound which will heal with the formation of new collagen, thus filling the depressed scar. This method offers a new, simpler approach to these full-thickness depressions in which the alternatives are surgical: punch grafts, excision and scar revision. The procedure is performed independently of other resurfacing procedures such as peeling, laser resurfacing or dermabrasion.

After the face is cleansed and degreased with acetone (see above), the ice-pick and depressed fibrotic scars to be treated are outlined with a

Fig. 154.9 "TCA Cross" technique used as a destructive method for ice-pick scars. **A** Preoperative with ice-pick scars of the nose and cheek. **B** Frosting limited to just the ice-pick scars. **C** Postoperative.

THE BAKER–GORDON FORMULA	
88% liquid phenol, USP	3 ml
Tap water	2 ml
Septisol® liquid soap	8 drops
Croton oil	3 drops

Table 154.5 The Baker–Gordon formula. Septisol®, 0.25% hexachlorophene.

skin marker and photographed. This serves as a guide for further treatment sessions. The 90% TCA is applied to the interior of the ice-pick scar with a toothpick, being careful not to drip the acid onto normal skin. Of note, this is a full-thickness destruction of skin and not a peel, so the TCA should be applied *only* to the scar itself[33a]. Each of the scars is treated until a brilliant white frosting appears (Fig. 154.9B). A topical antibiotic is then placed on each treated site. The procedure is performed with no anesthesia or sedation, as it only produces a brief stinging equivalent to the sensation of cryosurgery.

Healing occurs over the next 2 to 3 weeks, with granulation tissue, fibroplasia and remodeling of new collagen, which will elevate and soften the depressed scars (Fig. 154.9C). The procedure is then repeated during two to six sessions at 6-week intervals until substantial elevation is achieved. Then, a more superficial resurfacing procedure such as medium-depth peeling, laser resurfacing or dermabrasion can be performed to smooth the more superficial scars and blend them with other treated areas.

The clinician must warn the patient about potential dyschromia, especially in Fitzpatrick skin types III through VI, as skin destruction of this depth can depigment the treated areas. The multiple procedures may not be able to raise all the scars to the surface but they will surely provide improvement. The TCA Cross technique does add another simple therapeutic option for treating scars and for facial resurfacing.

Deep chemical peeling

Patients in Glogau groups III and IV may require deep chemical peeling, motorized dermabrasion or laser resurfacing to improve their greater degree of skin damage. Deep chemical peeling leads to production of new collagen and ground substance down to a level in proportion to the depth of the peel. Deep chemical peels create an injury through the papillary dermis and into the superficial reticular dermis, which may extend into the mid-reticular dermis. For deep peeling, either TCA in concentrations above 50% or a phenol-containing preparation is used. Because of the risk of scarring and other complications with such potent concentrations of TCA, this agent is not recommended for deep chemical peeling. Therefore, solutions containing phenol remain the preferred formulation for deep chemical peels.

The application of pure, undiluted, 88% phenol to the skin causes rapid and complete coagulation of epidermal keratin proteins and is thought to block itself from further penetration. Classified as a medium-depth peeling agent, pure phenol is rarely used for chemical peeling because its limited depth of penetration results in a lesser degree of effectiveness. In contrast, the Baker–Gordon peel utilizes phenol in a formulation that permits deeper penetration into the dermis than is achieved with full-strength phenol[34] (Table 154.5). First described in 1961[35], the Baker–Gordon peel has been used successfully for over 50 years. The Baker–Gordon formula consists of Septisol® (hexachlorophene 0.25%; Vestal Laboratories), croton oil and tap water added to a solution of phenol, reducing its concentration to 50% or 55%. The mixture of ingredients is freshly prepared and must be stirred vigorously prior to application due to its poor miscibility. The liquid soap, Septisol®, is a surfactant that reduces skin tension, allowing a more even penetration. Croton oil is a vesicant and epidermolytic agent that enhances phenol absorption. More recent investigations into the effects of this peel, using varying concentrations of both phenol and croton oil, have suggested that the procedure's efficacy is more related to the amount of croton oil than it is to that of phenol[34,36]. Modifications of the original Baker–Gordon formula, in order to improve the risk-to-benefit ratio of deep peeling, are currently being investigated[37].

There are two major variations of deep chemical peeling with the Baker–Gordon phenol formula – occluded and unoccluded. Occlusion of the peeling solution with tape is thought to increase its penetration and extend the injury into the mid-reticular dermis. This technique is particularly helpful for deeply lined, "weather-beaten" faces, but should be utilized only by experienced surgeons because of the higher risk of complications[38]. The latter include hypopigmentation and a "plastic" or alabaster appearance with an effacement of normal skin texture. The unoccluded technique as modified by McCollough involves more cleansing of the skin and the application of more peel solution. This may enhance the efficacy of the solution but without its penetrating as deeply as in an occluded peel. In the hands of a skilled and knowledgeable surgeon, both methods are safe and reliable in rejuvenating severely photoaged skin. Deep chemical peeling can significantly improve or even eliminate deep furrows as well as other textural and pigmentary irregularities associated with advanced photoaging (Fig. 154.10). When performed properly on carefully selected patients, a remarkable degree of improvement is the expected result from deep chemical peeling.

Patients must be made aware of potential complications, including scarring, textural changes such as "alabaster skin", and pigmentary

Fig. 154.10 Advanced photoaging in the form of perioral rhytides treated with a Baker–Gordon phenol peel. **A** Preoperative, demonstrating perioral rhagades, textural and pigmentary changes, and epidermal lesions. **B** Postoperative: 2 years later. Note the phenol peel maintains correction for many years.

Fig. 154.11 Complications from a Baker–Gordon phenol peel. There was prolonged non-healing, resulting in hypopigmentation and marbled scarring.

disturbances (Fig. 154.11). Patients often experience postoperative erythema that may require many months to resolve and can be followed by variable hypopigmentation. Male patients and patients with darker complexions are less favorable candidates for deep chemical peeling, since the hypopigmentation is more difficult to camouflage. Because phenol is cardiotoxic and undergoes hepatic and renal elimination, preoperative evaluation includes a complete blood count, serum levels of liver enzymes, blood urea nitrogen, creatinine and electrolytes, and a baseline electrocardiogram. Any patient who has a history of cardiac arrhythmias or who is taking a medication known to precipitate arrhythmias should not undergo a full-face Baker–Gordon phenol peel. Patients with a history of hepatic or renal disease are also poor candidates.

Compared to medium-depth and superficial peeling, the Baker–Gordon phenol peel is a time-consuming procedure that must only be performed in a properly equipped facility. The required waiting period after the treatment of each cosmetic unit limits the rate of cutaneous absorption, thereby preventing the serum levels of phenol from reaching a dangerous peak during the procedure[39]. Intravenous hydration with a liter of lactated Ringer's solution before the procedure and another liter during the peel also promotes phenol excretion and prevents toxicity. Continuous electrocardiography, pulse oximetry and blood pressure monitoring are mandatory during the entire perioperative period. Any abnormalities, such as a premature ventricular contraction (PVC) or premature atrial contraction (PAC), necessitate abrupt discontinuation of the procedure and careful evaluation for toxicity[40]. Oxygen is supplemented throughout the procedure, as some physicians feel that it has a protective effect against cardiac arrhythmias.

On the morning of the procedure, the patient shaves and cleanses the face and does not eat breakfast or apply cosmetics. Before the administration of anesthesia (general or deep sedation), the patient is examined while he or she is in a seated position and appropriate landmarks are noted. After thorough cleansing and degreasing of the skin, the chemical agent is applied sequentially to six aesthetic units: forehead, perioral region, right cheek, left cheek, nose and periorbital region. There is a 15-minute time interval between the treatment of each cosmetic area, allowing 60 to 90 minutes for the entire procedure. Cotton-tipped applicators are used with a similar technique as discussed for the medium-depth Jessner's–35% TCA peel. However, less solution is used because frosting occurs very rapidly. Occlusion of the peel can be accomplished with strips of waterproof zinc oxide tape applied to each cosmetic unit just after the phenol has been applied and then removed on postoperative day 1 (see below). Care is exercised to extend the peel slightly beyond the mandibular rim to conceal the demarcation between treated and untreated skin.

The last aesthetic unit, the periorbital skin, is treated cautiously and conservatively to avoid overpenetration, which can lead to ectropion or scarring. It is important to remember that diluting a phenol compound with water may increase its penetration, so mineral oil rather than water should be used to flush the eyes if contact occurs. As noted previously, the croton oil may be an important factor in determining the depth of penetration of the phenol peel[34]. Using one or two drops of croton oil, rather than the three in the Baker–Gordon formula, can limit the risk of phenol complications such as textural effacement or hypopigmentation.

Application of the peeling agent creates an immediate burning sensation which lasts for 15 to 20 seconds, subsides for 20 minutes, and then returns for the next 6 to 8 hours. Ice packs may be applied as necessary for patient comfort. Narcotics are usually prescribed upon discharge for adequate pain control. Systemic corticosteroids are also administered by some surgeons to lessen the inflammatory response. For untaped (unoccluded) peels, petrolatum is applied and a biosynthetic dressing can be used for the first 24 hours.

MECHANICAL RESURFACING PROCEDURES

For over 50 years, dermabrasion utilizing a rotating abrasive surface attached to a power-driven hand engine has been considered the premier skin resurfacing procedure for facial scars. It has generally been regarded as a deep resurfacing modality based on its depth of injury and its prolonged healing time. The original descriptions of modern dermabrasion involved the use of a wire brush (which remains in use today), but there has been a slow movement towards more superficial methods of mechanical resurfacing. In 1957, the diamond fraise was introduced and became the preferred instrument for dermabrasion by some surgeons because it is less aggressive and more forgiving than the wire brush[41]. There has also been a resurgence of interest in manual dermasanding, which allows for more deliberate and controlled skin planing[4,5]. Microdermabrasion, the mechanical resurfacing procedure developed most recently, is the most conservative of all forms of mechanical resurfacing[3].

Microdermabrasion

Because microdermabrasion removes the stratum corneum and superficial spinous layer and the injury rarely extends past the basal layer, this modality is considered superficial in depth. Whether it is classified as very light or light in comparison to other superficial resurfacing procedures depends upon the techniques and aggressiveness of the operator. The microdermabrasion unit's handpiece is a closed system which propels aluminum oxide crystals at the skin at high speeds and simultaneously removes them with suction (Fig. 154.12). These units were developed commercially in the mid-1990s and are currently in widespread use in both physicians' offices and non-medical aesthetic spas.

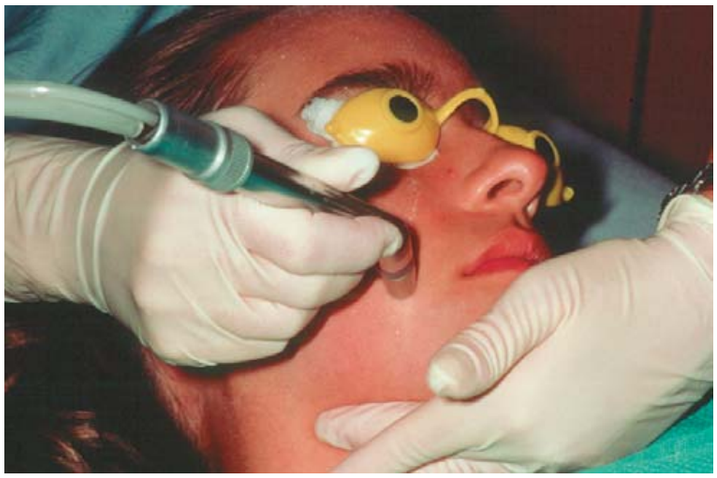

Fig. 154.12 Microdermabrasion. Aluminum oxide crystals are propelled at high speeds within a closed system and removed with suction.

ADVANTAGES OF MANUAL DERMASANDING OVER MOTORIZED DERMABRASION
• Greater control over depth of injury, particularly on the lips and orbital rims
• Blending of abraded areas into adjacent unabraded areas accomplished more easily and with better results
• Lower cost and greater simplicity of instrumentation and set-up
• Risk of aerosolizing infectious particles is far less
• Possibly lower incidence of postinflammatory hypopigmentation

Table 154.6 Advantages of manual dermasanding over motorized dermabrasion.

Fig. 154.13 Dermasanding. Manual dermasanding utilizing #320 grit silicon carbide sandpaper to blend CO_2 laser resurfacing into the eyebrow area.

Microdermabrasion may be indicated for acneiform conditions, pigmentary dyschromias, and as a "lunchtime" procedure for facial rejuvenation in all skin types[42], but in general it is not considered effective for improving the appearance of rhytides[43,44]. Its use in improving the appearance of scars is controversial, but it has been explored with favorable results[3]. Both the patient and physician must understand that the degree of objective improvement with microdermabrasion may be limited. Ideal candidates for microdermabrasion typically desire facial rejuvenation without "downtime". Appropriately selected patients have a subjective perception of improvement usually exceeding the objective signs depicted with photographs. Patients often report that their skin has a smoother texture and that cosmetics are easier to apply and blend in with their skin more easily. Microdermabrasion has also been successfully combined with intense pulsed light (IPL) therapy in order to enhance penetration of the light.

Although the role of microdermabrasion in facial rejuvenation grew dramatically after these units were initially developed, the scientific data to justify their use were lacking until more recently. An increase in epidermal and dermal thickness, flattening of the rete pegs, vascular ectasia with perivascular inflammation, papillary dermal hyalinization, and newly deposited collagen and elastic fibers have all been observed[45]. Following microdermabrasion, there also appears to be a significant alteration in epidermal barrier function[46]. Investigators have also observed an elevation of transcription factors, cytokines and matrix metalloproteinases following microdermabrasion[47].

Manual dermasanding

Manual dermasanding involves abrading the skin by hand using silicon carbide sandpaper or wallscreen that is commercially available at any hardware store. It is gaining in popularity for skin resurfacing because it has several advantages over power-driven dermabrasion (Table 154.6). Its classification as a wounding agent is entirely dependent upon the type of paper used, the force applied by the surgeon, and the duration of contact with the skin. Although manual dermasanding can be used to produce a wound as deep as with wire-brush dermabrasion or several passes with a pulsed CO_2 laser, it is probably most commonly used as a medium-depth or "minimally deep" resurfacing modality.

Manual dermasanding can be used to resurface an entire face, but because it is so labor-intensive it is most often utilized for resurfacing localized regions to minimize the appearance of a scar[48] or to blend or enhance the effects of a medium-depth chemical peel or a combination procedure[49]. It can be used following CO_2 laser resurfacing to feather the transition into hair-bearing areas that are inaccessible to the laser. Manual dermasanding of the eyebrows and hairline and gently abrading the upper neck at the inferior aspect of the laser-irradiated zone are all effective at minimizing lines of demarcation between treated and untreated skin (Fig. 154.13). It can also be useful immediately after laser resurfacing for stubborn rhytides, particularly in the perioral region; manual dermasanding can improve the outcome by producing a slightly greater depth of injury in a controlled fashion where further thermal injury would be risky. It will also remove adherent necrotic debris and thermal damage, thus enhancing the healing process. Similarly, a medium-depth chemical peel can be immediately followed by manual dermasanding of the more troublesome areas to enhance the results and also along the borders of the peeled skin to blend the effects.

Our clinical experience suggests that dermasanding after a Jessner's –35% TCA peel may yield impressive postoperative results that approach those seen with either motorized dermabrasion or CO_2 laser resurfacing in patients with cutaneous photoaging (Fig. 154.14). This combination is particularly helpful in patients who may not tolerate the greater degree of sedation often necessary with CO_2 laser resurfacing or who cannot afford the additional fees to cover anesthesia services.

The necessary materials for manual dermasanding include silicon carbide sandpaper or wallscreen. Both may be purchased in a variety of grades: fine grade (#400), medium grade (#220–320) and coarse grade (#180). The sandpaper is easier to use because of its flexibility and it is also more easily cut into smaller pieces which can be steam autoclaved. A 1.5-inch (4 cm) × 3-inch (8 cm) piece of sterilized sandpaper is wrapped around either the barrel of a 3 ml syringe or a rolled-up gauze pad and moistened with saline or a soap-free cleanser for lubrication. A 1% solution of lidocaine with epinephrine (adrenaline) may be used if additional anesthesia is necessary. The skin is stretched and both back-and-forth and circular motions are used to gradually abrade the skin, layer by layer, until the hills and valleys are softened or adjacent areas are blended to the desired degree. Coarse grades may be used initially for "debulking", followed by finer grades later in the procedure. The fine grade is used to blend delicate areas of skin such as around the eyelids. At the completion of the procedure, the dark-colored silicon carbide particles remaining on the skin surface should be rinsed off because there is a risk of their becoming implanted, creating a pigmented tattoo.

Fig. 154.14 Medium-depth chemical peel plus manual dermasanding. Jessner's–35% trichloroacetic acid was applied to the face followed immediately by manual dermasanding of the cutaneous lips and chin. **A** Preoperative with obvious perioral rhytides. **B** Postoperative with significant improvement.

Fig. 154.15 Mechanical dermabrasion. This technique is performed with a diamond fraise over rigid skin cooled with a topical refrigerant spray.

Motorized dermabrasion

Although various abrasive materials have long been used for mechanical resurfacing, the development of a power-driven unit to facilitate the procedure was revolutionary. Some of the units most commonly used today are the Bell hand engine (Bell International), the AEV-12 hand engine (Ellis International), and the Osada surgical handpiece (Osada, Inc.). A topical refrigerant spray is used to produce anesthesia and to harden the skin as it is abraded (Fig. 154.15). The spray immobilizes the topographic features so that there is no distortion by the pressure of the abrasive instrument. Concerns regarding potential harm to the environment from cryogenic sprays has limited the availability of topical refrigerant sprays in several countries, including the US. Utilizing liquid nitrogen or agents that cryopreserve tissue specimens is *not* recommended because they create a colder temperature that can lead to hypopigmentation and/or scarring. Options include tumescent anesthesia as a means of firming the tissue or use of the diamond fraise without a cryogen.

The two abrasive instruments most often employed with these units are the wire brush and the diamond fraise. The wire brush has numerous small-caliber, stainless steel wires that project circumferentially from the curved side of a cylindrical hub. A diamond fraise consists of a stainless-steel cylinder to which industrial-grade diamonds are bonded to create the abrasive surface. Compared with wire-brush instruments, diamond fraises are manufactured with a greater variety in their shape, width of abrasive surface, wheel diameter, and coarseness of grit. While there continues to be considerable controversy regarding which one of these instruments is superior[41], surgeons generally agree that the wire brush is more aggressive. The wire brush cuts more quickly and more deeply into the skin with each stroke, thereby posing a greater risk for injury and requiring more skill to operate. Although the diamond fraise is generally safer and more forgiving, it may not yield the degree of improvement possible with the wire brush, especially for more stubborn conditions such as acne scarring.

Because dermabrasion with either instrument is highly technique-dependent and the learning curve is steep, there may be considerable variability in the clinical results obtained by different operators. It is very important for beginner dermabraders to receive hands-on instruction from an experienced operator in order to be adequately trained. The proper techniques for motorized dermabrasion have also been the subject of comprehensive reviews in the literature[41]. Careful evaluation of the depth of injury throughout the procedure is critical in order to assure a sufficient depth for optimal results without penetrating beyond the desired level and risking scar formation. Because of the potential for aerosolization of infectious particles during dermabrasion, appropriate precautions are mandatory to protect the operating room staff (see Ch. 136).

All of the conditions amenable to treatment with manual dermasanding can also be managed with motorized dermabrasion. Although manual dermasanding is very well suited to combination resurfacing procedures for enhancement and blending, this concept was originally popularized with the use of the motorized dermabrasion[50]. The latter motor-driven technique may still be preferable to manual dermasanding for full-face resurfacing because less time and energy are expended. It also continues to be widely utilized for resurfacing localized areas, a procedure known as spot dermabrasion. This procedure, which can also be performed with the manual technique, is most useful for improving the appearance of surgical or traumatic scars[51]. Spot dermabrasion yields the greatest amount of improvement when performed about 6 weeks after the initial injury. A medium-depth peel can be performed on the remainder of the cosmetic unit or on the rest of the face to assure that the adjacent areas are blended.

The resurgence of manual dermasanding and the development of laser technology have led to a decline in the number of motorized dermabrasion procedures. Although all of the major indications for skin resurfacing that were mentioned earlier also apply to dermabrasion, many dermatologic surgeons only use this modality for selected conditions in which dermabrasion can consistently achieve superior results. A list of these conditions, as compiled by the authors according to their experience, is found in Table 154.7. It should be noted that any such list must be viewed with some degree of hesitation because very few controlled studies have been performed to evaluate the safety and efficacy of power-driven dermabrasion in comparison with either CO_2 laser resurfacing or manual dermasanding[52–56].

Moderate to severe acne scarring is the most notable of these conditions, for which laser resurfacing has yielded variable results and

CONDITIONS FOR WHICH MOTORIZED DERMABRASION MAY BE THE PREFERRED RESURFACING MODALITY
• Acne scarring
• Surgical or traumatic scars
• Benign neoplasms (multiple trichoepitheliomas, syringomas, angiofibromas)
• Malignant and pre-malignant neoplasms (skin cancer treatment and prevention in nevoid basal cell carcinoma syndrome and xeroderma pigmentosum, as well as management of extensive carcinoma *in situ*)
• Extensive epidermal lesions such as epidermal nevi
• Decorative or traumatic tattoos unresponsive to the pigmented lesion lasers
• Rhinophyma

Table 154.7 Conditions for which motorized dermabrasion may be the preferred resurfacing modality.

chemical peeling is generally disappointing. Dermabrasion selectively planes off the "hilltops" that surround the atrophic "valleys", whereas chemical peeling and laser irradiation may produce an injury of equivalent depth in both areas (Fig. 154.16). Effacing the edges of atrophic scars can be accomplished with the CO_2 laser or the solid CO_2–35% TCA peel[28], but these methods may be more difficult and their results less predictable as compared with dermabrasion. It is our opinion that conventional motorized dermabrasion remains the gold standard in resurfacing procedures for this condition. That said, the recently developed fractional CO_2 resurfacing laser has the advantage of creating greater skin contraction (due to deeper penetration of the microthermal zones) and can produce significant improvement in acne scars, in some cases equal to dermabrasion.

The physician must choose the scars most amenable to dermabrasion alone. These include shallow fibrotic scars, hypertrophic scars and undulating, rolling scars. The deeper fibrotic scars, ice-pick scars and scars with significant tissue loss may require a lifting or filling procedure prior to dermabrasion. In these patients, the results are significantly enhanced with one or more of the following adjunctive procedures 4 to 6 weeks preoperatively: punch or scalpel excision, TCA Cross technique, punch grafting, dermal grafting, fat grafting, or scar undermining (subcision)[57].

POSTOPERATIVE CARE

Because superficial resurfacing procedures generally do not extend beyond the epidermis, the dermal wound healing mechanisms are not activated. In contrast, medium-depth and deep resurfacing procedures stimulate the following four stages of dermal wound healing (see Ch. 141): (1) inflammation and coagulation; (2) re-epithelialization; (3) fibroplasia and matrix formation; and (4) collagen remodeling.

Because the pronounced edema following medium-depth and deep resurfacing procedures may minimize the appearance of scars, rhytides and other irregularities, the patient's initial perception of his or her improvement may be exaggerated. As swelling subsides postoperatively, patients should be reassured and advised that collagen remodeling continues for several months and leads to further clinical improvement. At some point in the postoperative course, patients often want to know when another resurfacing procedure can be performed if it is necessary. The presence of persistent postoperative erythema may indicate continued collagen remodeling and may serve as a warning that a similar resurfacing procedure performed prematurely could produce scarring. To assure their safety, patients undergoing medium-depth resurfacing should not undergo another medium-depth or deep procedure for the next 3 to 9 months. An individual having a deep resurfacing procedure should avoid another one for at least 12 months postoperatively. Touch-up procedures for revision of a prior suboptimal outcome are also best avoided during these time periods, so repeated efforts to counsel and reassure the patient are necessary.

The length of the healing time is generally proportional to the depth of the resurfacing procedure. Superficial resurfacing procedures cause minimal downtime and necessitate little postoperative care. They usually produce mild erythema and desquamation that lasts from 1 to

Fig. 154.16 Full-face dermabrasion performed for acne scars. A Preoperative: shallow and atrophic scars that are most amenable to dermabrasion. **B** Postoperative: dermabrasion prior to biosynthetic dressing. **C** Three months postoperative.

4 days depending on the wounding agent and the techniques used. Regular washing with a mild cleanser and the use of routine moisturizers and sunscreens are generally sufficient during the healing period.

Following medium-depth resurfacing procedures, there is a considerably longer healing time and more intensive postoperative care is necessary. Follow-up visits are scheduled regularly in order to monitor the patient's postoperative course. After a medium-depth chemical peel, occlusive dressings are not necessary because the epidermis, which is not removed intraoperatively, functions as a biologic dressing until peeling occurs. Because areas of medium-depth peeling which have been enhanced by manual dermasanding do not possess residual epidermis, occlusive dressings may be used on these areas during the first 3 days postoperatively.

The patient is instructed to soak the areas four times daily with warm compresses and to apply an emollient after each soak and during the intervening periods as necessary. A solution of 0.25% acetic acid (one tablespoon of white vinegar added to one pint of warm water) is preferred for the soaks because the mild acidity is physiologic for healing granulation tissue. It is also a mild debridant and has antibacterial effects, especially against *Pseudomonas* spp. and other Gram-negative organisms. Occlusive emollients, such as petrolatum, Aquaphor® or Eucerin® Creme, speed the process of re-epithelialization and lessen the tendency for delayed healing[58]. These emollients are also helpful in wound debridement and in the prevention of crust formation and infection.

Following medium-depth resurfacing, edema begins to appear almost immediately and progressively worsens during the first 48 hours. It can even be severe enough to close the eyelids and impair the patient's visual fields. If tolerated, aspirin or others nonsteroidal anti-inflammatory drugs (NSAIDs) can be administered, preoperatively and during the first 24 hours postoperatively to alleviate discomfort and reduce swelling. After a medium-depth chemical peel such as the Jessner's–35% TCA peel, there is initially a brawny, dusky erythema which is followed by the formation of a brownish crust that begins to separate from the skin surface between days 4 and 8 postoperatively. The underlying, newly formed epithelium is brightly erythematous but fades to a pink color that resembles a sunburn (see Fig. 154.5D). By postoperative day 7 to 10, re-epithelialization has occurred and the erythema can be camouflaged with cosmetics. Within 2 to 4 weeks after the procedure, the erythema usually resolves fully and retinoids and sunscreens can be restarted as tolerated.

Deep resurfacing procedures, such as the Baker–Gordon phenol peel or dermabrasion, require a follow-up visit the next day, several visits during the first week, and very close monitoring thereafter. At each visit, instructions for wound care are reviewed with the patient and any questions are answered. The immediate postoperative course after deep resurfacing is similar to that following medium-depth procedures, except that edema and erythema may be even more severe and persistent. NSAIDs can provide some relief, but an intramuscular corticosteroid injection is often administered on the day of surgery, even though its effects on wound healing are not completely understood. Pruritus may occur during the healing phase following a resurfacing procedure of any depth, but is particularly prevalent after deeper resurfacing. This problem can be alleviated by the use of emollients, ice packs, NSAIDs and antihistamines until the pruritus spontaneously resolves. Milia formation, which commonly occurs 3 to 4 weeks after deep chemical peeling or mechanical resurfacing, is easily managed with needle extraction.

Patients undergoing deep mechanical resurfacing with either motorized dermabrasion or manual dermasanding can have an occlusive biosynthetic dressing applied immediately after the procedure. In patients undergoing a Baker–Gordon phenol peel, occlusive tape or a biosynthetic dressing is usually utilized postoperatively. Occlusive tape dressings must be removed on the first postoperative day and this procedure may require analgesia and sedation. For this reason, the authors prefer untaped phenol peels with application of ointment or bio-occlusive dressings. Whenever a biosynthetic dressing is used, it must be removed daily and replaced with a new one for the first 2 or 3 days postoperatively so that the face can be gently debrided with saline soaks and moistened cotton tips. The patient should be instructed to regularly apply an occlusive ointment to areas around the mouth, eyelids and hairline that are not adequately covered by the dressing. Occlusive biosynthetic dressings have been shown to enhance collagen synthesis and hasten re-epithelialization in superficial wounds. They also minimize the amount of discomfort and obviate the need for repeated soaks by the patient during the first few days after the procedure.

By the third day following deep mechanical or chemical resurfacing, the patient begins open wound care with 0.25% acetic acid soaks four to six times daily and regular applications of an occlusive ointment. By the 7th to the 14th day postoperatively, re-epithelialization is usually complete and the ointment is replaced by a heavy moisturizer. The marked edema and erythema typically seen after dermabrasion or dermasanding generally resolve after several weeks. The erythema resulting from deep peeling may be more persistent, but is rarely present beyond 2 to 4 months. Strict sun avoidance is critical for 3 to 6 months after dermabrasion or deep chemical peeling. The patient typically restarts sunscreens and retinoid therapy within a couple weeks of re-epithelialization, as tolerated.

COMPLICATIONS

Complications may occur following any method of skin resurfacing involving injury to any depth, but are more common after medium-depth and deep procedures. It is far simpler to prevent the development of a complication than to manage it once it has occurred. Complications may be prevented by proper selection of suitable patients and appropriate resurfacing modalities, precise intraoperative technique, and proper patient management before and after the procedure (see Table 154.3). The dissatisfied patient represents a complication even when the cosmetic result is favorable. Improper wound care, trauma to healing areas resulting from overzealous debridement, compulsive picking or scratching, and premature use of irritating substances such as depilatories or wax for the removal of hair can each cause the depth of injury to extend beyond the threshold of safety. As discussed below, the development of infection in the postoperative period can also extend the depth of injury and increase the risk of permanent sequelae.

With specific regard to chemical peeling, excessive injury to the skin can result from poor technique during application or problems with the chemical agents utilized. The degree of frosting is monitored closely to assure that the agent has been applied evenly and that the injury extends to the proper depth (Table 154.8). Although it does not always correlate completely with the depth of injury, the level of frosting is a very valuable guide for determining the appropriate endpoint of treatment (see Fig. 154.3). Injuring the skin too deeply during a chemical peel, as suggested by an excessive degree of frosting, may result not only from over-application but also from the use of excessively concentrated peeling solutions. The latter error can be caused by the surgeon's choice of an improper peeling agent, such as 50% TCA, or it can be related to unexpected disturbances in a solution's pharmacologic mixture. For Baker–Gordon peels, a new batch should be mixed by the surgeon prior to each procedure in order to be certain that the preparation is made correctly. The other peeling solutions are available in various formulations and strengths for purchase directly from medical supply dealers. Reputable dealers mix and label these solutions properly according to the standard weight-to-volume formula. Storage of peeling solutions in proper containers away from sunlight and immediate replacement of expired solutions are important measures to ensure chemical stability of the agents being used[59]. Immediately prior to peeling, an ample volume of the solution should be poured from the primary storage container into a smaller, secondary cup. The peeling agent is applied directly to the skin surface from this cup and the excess subsequently discarded in order to avoid contamination of the storage container and to avoid the accidental transfer of concentrated crystals from the neck of the storage container to the patient's skin.

CLINICAL SIGNS THAT REFLECT DEPTH OF WOUNDING
• Level of frosting (see Fig. 154.3)
• Time for frosting to appear
• Time for frosting to disappear
• Skin turgor
• Epidermal slide*
*Sliding of the epidermis off the dermis due to separation of the two tissues.

Table 154.8 Clinical signs that reflect depth of wounding.

Errors during mechanical resurfacing procedures may also lead to an injury of excessive depth and a higher risk of adverse sequelae. This problem can result from poor technique in the handling of the instruments or from failure to recognize the appropriate treatment endpoint. The beginner should first start by conservatively dermasanding small areas to get a comfortable feel for the skin's response to this type of injury. As knowledge and experience is gained, one can then progress on to diamond fraise dermabrasion and later to the use of the wire brush. Observation of experienced surgeons and hands-on training are invaluable. The beginner should always err on the side of conservatism, while still yielding favorable results, in order to avoid excessively deep tissue injury that could produce long-term complications.

During chemical peeling or mechanical resurfacing, intraoperative exposure of vital structures to the resurfacing agent may occur and can have serious adverse consequences. Extreme care must be exercised when dermabrading with a power-driven, rotating instrument, assuring that the dominant hand maintains complete control continuously and free skin edges (e.g. eyelid, lip) are not caught up in the wire brush or diamond fraise, as the latter may result in tearing of the skin. During chemical peeling, the moistened applicator should never be passed over the central face, in order to avoid inadvertent exposure of a vulnerable surface such as the eye to the solution. There should always be appropriate fluids readily available to rinse the area in case such an exposure does occur. In particular, saline is used to dilute TCA, mineral oil is used to dilute Baker–Gordon phenol solutions, and sodium bicarbonate is used to neutralize glycolic acid.

Adverse systemic effects related to a resurfacing procedure are very uncommon but can usually be traced to an identifiable causative factor in the perioperative period. Peeling with phenol solutions has been associated with systemic toxicities, so these procedures must be performed slowly and only on properly selected, healthy patients in an appropriate clinical setting. The use of Jessner's solution poses a theoretical risk of systemic salicylate or resorcinol toxicity, but this is probably not clinically significant when application is limited to the face and neck. Undoubtedly, the most common cause of systemic problems related to resurfacing procedures is an adverse allergic or physiologic reaction to a medication used for anesthesia. It is imperative that the surgeon knows all the physiologic effects and the potential adverse consequences of each drug administered systemically, unless there is an attending anesthesiologist who assumes this responsibility. Fortunately, the chemical and mechanical resurfacing procedures utilized most often can be performed with little or no sedation.

It is important to make a distinction between a true complication and an expected side effect of a resurfacing procedure. With medium-depth and deep resurfacing, transient erythema, flushing, increased skin temperature, pruritus, edema, milia formation and mild alterations in mood are typical occurrences, so they should not be classified as true complications. Patient reassurance may be all that is necessary, since these problems usually resolve spontaneously. True complications that may develop within a treated area include infection, delayed wound healing, persistent erythema, scarring, and pigmentary or textural abnormalities[60,61]. Any of these true complications can occur despite proper patient and procedure selection, perfect surgical technique, and appropriate management before and after the operation.

Infection is an uncommon complication that develops during the postoperative period and may be caused by bacterial, viral or fungal organisms. An important preventive measure is the continuous use of soaks for adequate wound debridement. Frequent postoperative visits are helpful to assure early recognition and treatment of any infection so that scarring does not result. An infection may present with delayed wound healing, ulcerations, excessive necrotic material and crusting, purulent drainage or odor. An acneiform eruption or pustular folliculitis can even be a manifestation of infection and should initially be treated as such. Infection with streptococcal and staphylococcal organisms can occur under biosynthetic membranes or thick, occlusive ointments, so these are best avoided, except in the immediate postoperative period. Other organisms, such as *Escherichia coli* or *Pseudomonas* spp., may even infect the area if there is improper wound care. *Candida* infections can also occur and are sometimes related to the use of prophylactic antibiotics or occlusive wound care. Clinical suspicion of a wound infection necessitates immediate institution of empiric antimicrobial therapy, laboratory culture for identification of the organism(s), and wound debridement as necessary[62].

Herpes simplex infection can occur during the healing period following medium-depth or deep resurfacing and has the potential for devastating sequelae. An outbreak can even occur in patients on the recommended 10–14-day prophylactic antiviral regimen. The keys to avoiding scar formation are rapid recognition and aggressive therapy begun early in the course of the infection. The dosage of antiviral drug should be increased to the recommended maximum in cases of active herpetic infection.

Persistent erythema beyond 2 months after a medium-depth procedure may be precipitated by the use of topical or systemic retinoid therapy, contact with various allergens or irritants, an underlying skin condition or genetic susceptibility, or the presence of active infection[60,63]. Persistent erythema may indicate the impending development of scar formation. Especially when indurated, it should be treated promptly and aggressively. Management includes massage therapy, topical, intralesional or even systemic corticosteroids, silicone gel sheeting, and pulsed dye laser therapy. In most cases, scarring can be prevented. Mild scarring may even fade away spontaneously. Rarely, ectropion can occur when aggressive resurfacing creates scarring or excessive tightening of periorbital skin in a susceptible patient.

Textural abnormalities, skin atrophy and dyspigmentation are additional complications that may occur with medium-depth and deep resurfacing procedures. The return of normal pigmentation in patients whose Fitzpatrick skin type is IV or higher is less predictable, so an extra measure of caution is necessary. Postoperative hyperpigmentation may be prevented and/or treated with a topical retinoid, a 4–8% hydroquinone preparation and strict photoprotection, but the hypopigmentation that can follow deeper resurfacing is typically permanent. Another potential pigmentary problem following deeper resurfacing procedures is a conspicuous demarcation line separating the untreated and treated areas. Although this problem can usually be avoided with adequate planning and proper technique, the approach to its management should focus on lightening the pigment in the adjacent untreated areas.

CONCLUSIONS AND FUTURE TRENDS

The sheer number of patients demanding medical therapy or procedural intervention to rejuvenate their skin mandates that dermatologists be well versed in this area. The field of resurfacing is constantly changing, with the development of new techniques and procedures as well as fluctuations in patient demands and expectations. In all areas of cosmetic surgery, there has been a recent trend in favor of less invasive procedures. Dermatologists often choose to learn and implement only a handful of resurfacing procedures that best fulfill the needs of their practice and meet the demands of their patient population.

Phlebology and Treatment of Leg Veins 155

Mitchel P Goldman and Robert A Weiss

Chapter Contents

Venous anatomy, physiology and pathophysiology 2509
Physical examination of the phlebology patient 2510
Laboratory evaluation of the superficial venous system 2512
Compression in sclerotherapy and venous disease 2512
Sclerosing solutions 2513
Techniques for treating telangiectasias and reticular veins 2515
Larger varicose veins 2517
Postsclerotherapy compression 2518
Complications 2518
Ambulatory phlebectomy 2520
Endovenous laser and radiofrequency ablation 2522

Key features

- Superficial telangiectasias, reticular veins and varicose veins of the lower extremities are interconnected and develop after impairment of venous return
- Poor venous return results from venous valvular incompetence or primary muscle pump failure
- A pretreatment physical examination to assess the extent and cause of the venous abnormalities should be performed with the patient in a standing position
- The physical examination should be supplemented by Doppler or duplex ultrasonography
- Both preoperative and postoperative compression are important in the management of venous insufficiency
- Sclerosing agents should destroy the entire vascular wall, producing permanent fibrosis of the vessel
- The minimal concentration and volume of sclerosing agent should be used to achieve the desired results
- All of the affected portions of the superficial venous system should be treated, starting with the most proximal
- Large veins should be treated before smaller veins, and veins should be treated from proximal to distal
- FDA-approved sclerosing agents are sodium tetradecyl sulfate, polidocanol and sodium morrhuate; hypertonic saline (11.7–23.4%) and glycerin (72% mixed 2:1 with 1% lidocaine, with or without epinephrine) are not approved for vein sclerosis and represent off-label usage
- The most common local side effects following injection of sclerosing agents are hyperpigmentation, telangiectatic matting, and cutaneous ulcers
- Patients generally require one to three sclerosant injection treatment sessions spaced at 6- to 8-week intervals

INTRODUCTION

Varicose and telangiectatic leg veins increase in extent and severity with increasing age. The evolution of safe and effective treatment options has made sclerotherapy, ambulatory phlebectomy, and endovenous radiofrequency (RF) and laser ablation (LA) an expanding area of the dermatologic surgeon's practice. The utilization of improved diagnostic modalities, more efficient sclerosing agents and simplified surgical techniques have made the treatment of venous disease safe, efficient and highly satisfying for both physician and patient. This chapter presents the most recent advances in sclerotherapy, ambulatory phlebectomy, and endovenous RF and LA as they relate to the management of telangiectasias, reticular veins and varicose veins, both non-saphenous and saphenous.

VENOUS ANATOMY, PHYSIOLOGY AND PATHOPHYSIOLOGY

The peripheral venous system functions both as a reservoir to hold extra blood (e.g. during pregnancy) and as a conduit to return blood from the periphery to the heart and lungs. The correct function of the venous system depends on a complex series of pumps and valves that are individually frail, yet the system as a whole performs well under extremely adverse conditions[1] (Fig. 155.1). Superficial veins carry less than 5% of venous blood, while the deep venous system carries 95% of the blood.

The superficial venous system is a complicated variable network of interconnecting veins, most of which are unnamed[2]. A few larger

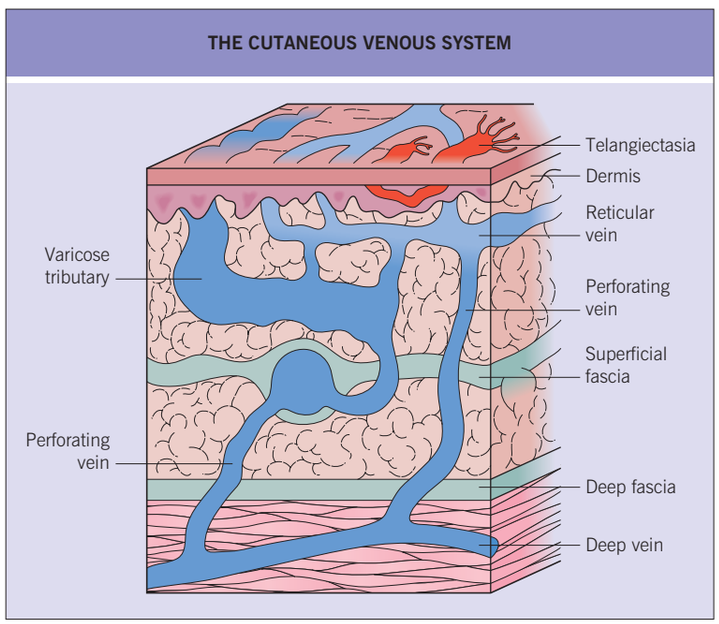

Fig. 155.1 The cutaneous venous system. The deep venous system drains the superficial venous system, which, in turn, is fed from the skin surface by telangiectasias in the dermis. The latter drain via reticular veins into the larger venous channels located in the reticular dermis and subcutaneous compartments. *Redrawn from: Somjen GM, Ziegenbein R, Johnston AH, Royle JP: Anatomical examination of leg telangiectases with duplex scanning. J Dermatol Surg Oncol. 1993;19:940.*

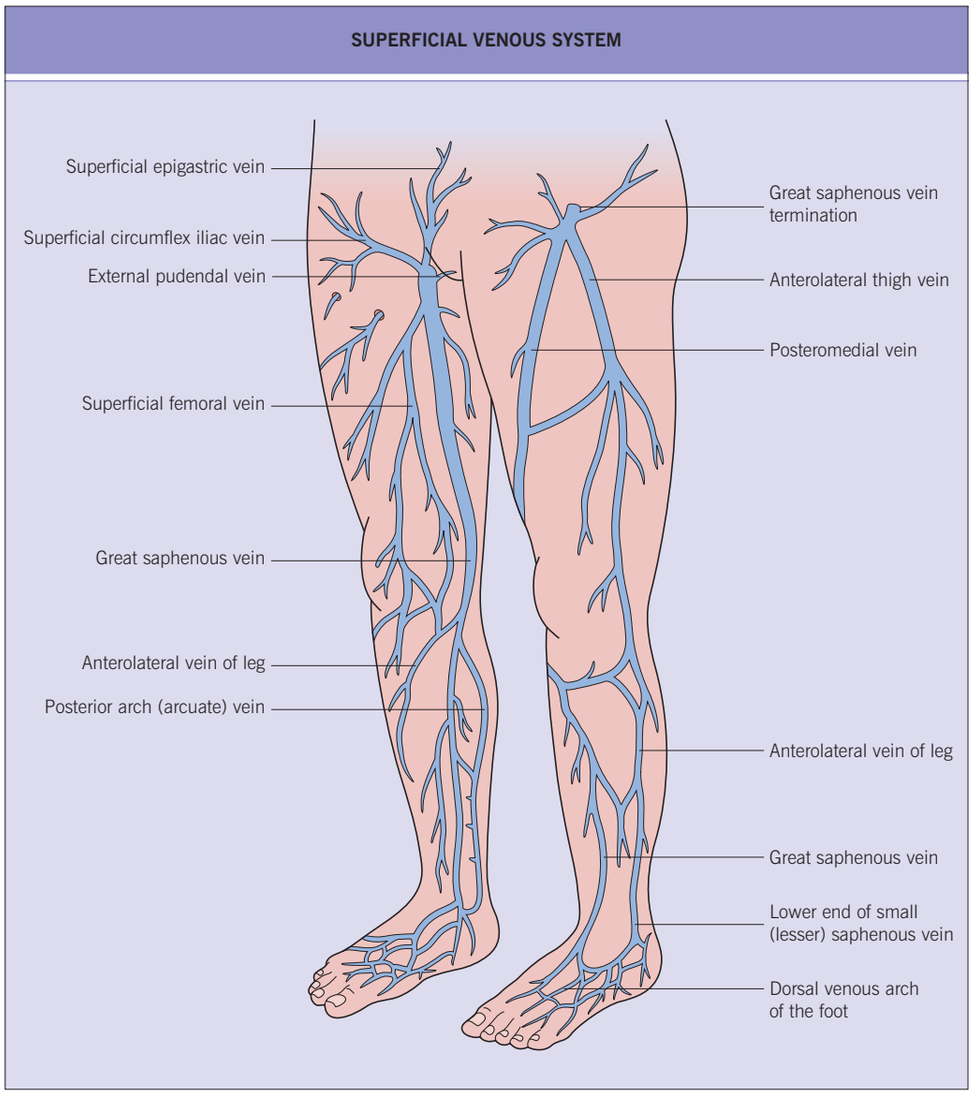

Fig. 155.2 Superficial venous system. Lateral and medial views of the distribution of the major axial trunks of the superficial venous system, the great and small saphenous veins, and associated tributaries. The anterolateral thigh vein was previously referred to as the lateral circumflex vein.

truncal superficial veins are fairly constant in location. These truncal superficial veins serve as a conduit to pass blood centrally into the deep venous system. The principal named superficial veins are the small saphenous vein (SSV), which runs from the ankle to the knee, and the great saphenous vein (GSV), which runs from the ankle to the groin[3] (Fig. 155.2).

An interconnecting system of perforating veins that pass through the deep fascia connects the superficial veins to the deep veins of the calf or thigh (Figs 155.1 & 155.3). All venous blood eventually is received by the deep venous system on its way back to the right atrium of the heart.

Blood is propelled back to the heart via the pumping action of the foot and calf muscles, which squeeze blood out of a venous segment through one-way valves when muscle contractions increase the pressure within the fascial muscle compartment (Fig. 155.4). Venous pathology can result from primary muscle pump failure due to venous obstruction (thrombotic or non-thrombotic) or from venous valvular incompetence[4].

A genetic predisposition for the development of varicose veins has been observed, and both dominant and recessive patterns of inheritance have been described. Approximately 70% of patients can identify superficial venous disease as a familial trait. Hormonal influences from pregnancy or estrogen and progesterone supplementation are believed to be additional predisposing factors[5].

In summary, telangiectasias, reticular veins and varicose veins are derived from a hereditary substrate that is influenced by hormones as well as static gravitational pressures and dynamic muscular forces transmitted through failed venous valves. The hereditary substrate cannot be altered, but the influence of hemodynamic forces and hydrostatic pressure can be modified, both by sclerotherapy and by surgical techniques.

PHYSICAL EXAMINATION OF THE PHLEBOLOGY PATIENT

The purpose of the clinical examination is to survey the main venous trunks in order to determine where the primary or highest points of reflux are located. During the examination, the patient should be standing, preferably on a platform. It is important to determine the grade of venous insufficiency[6]. The recommended CEAP classification system is based on clinical manifestations (C), etiologic factors (E), anatomic distribution of disease (A), and the underlying pathophysiologic findings (P)[7]. The venous severity scoring (VSS) system is based on three elements: the number of anatomic segments affected, grading of symptoms and signs, and disability. The consensus statement on this approach to clinical assessment was published in 25 journals and books in eight languages, truly a worldwide distribution.

For the practicing physician, CEAP is an instrument for establishing the correct diagnosis, guiding treatment and assessing prognosis. It is important to stress that CEAP is a descriptive classification, while VSS and quality-of-life (QoL) scores represent instruments for longitudinal research in order to assess outcomes. In modern phlebologic practice, the vast majority of patients will have a duplex scan of the venous system of the leg, which will provide data on E, A and P. In basic CEAP, the single highest descriptor should be used for clinical class, e.g. a patient with varicose veins, swelling and lipodermatosclerosis will be C4b (Table 155.1). However, use of just the C-classification provides no advantage

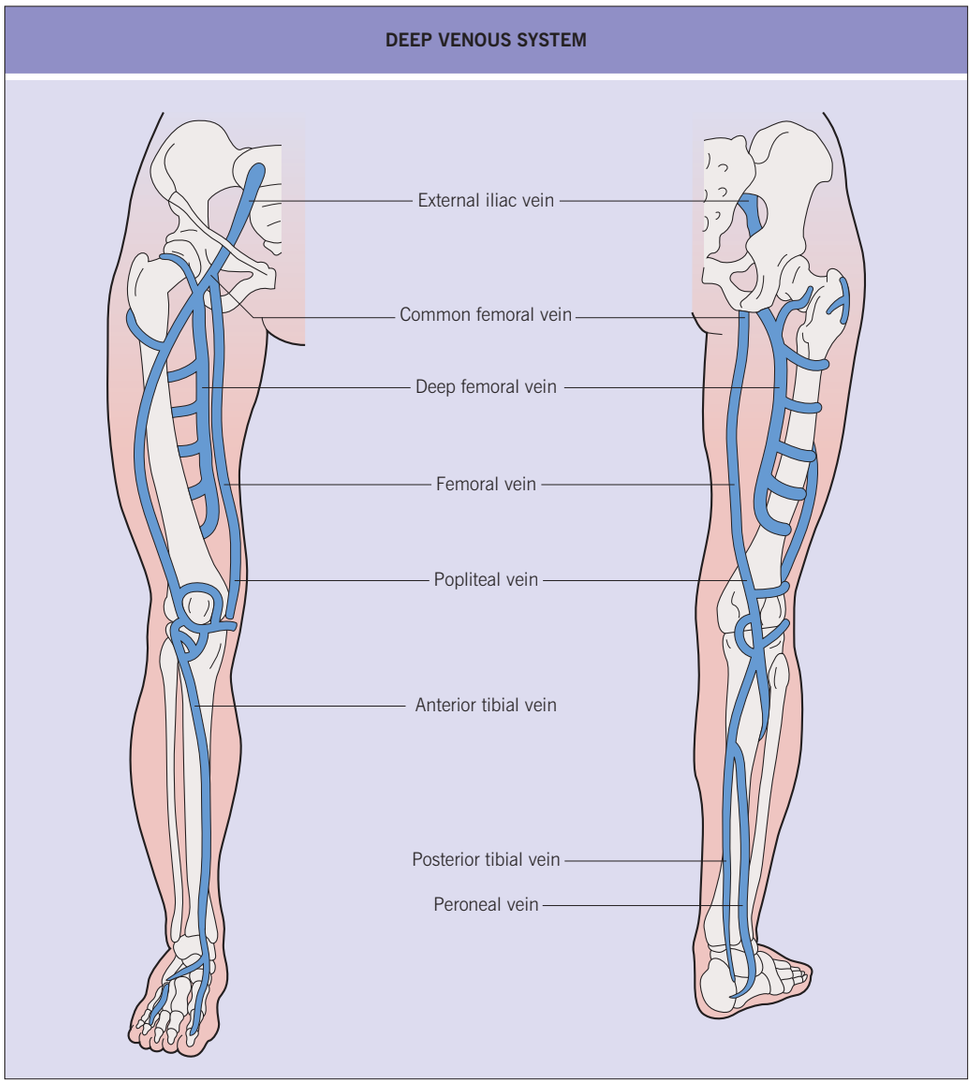

Fig. 155.3 Deep venous system. The major drainage vessel below the knee is the popliteal vein, while the femoral vein is the major portal of drainage in the inguinal area of the groin (great saphenous distribution).

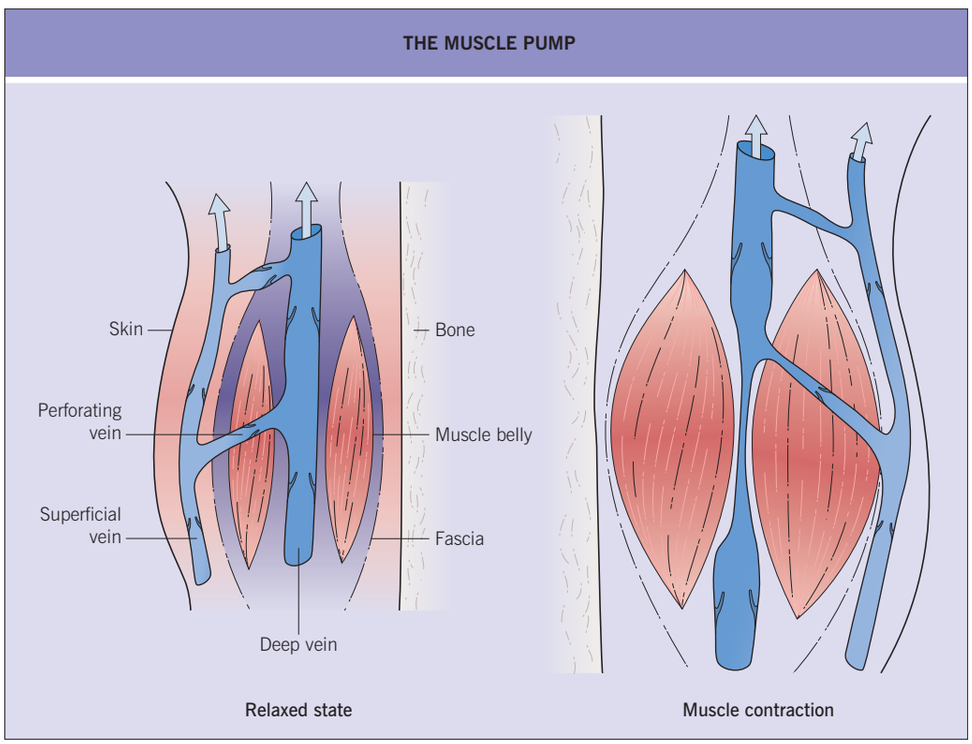

Fig. 155.4 The muscle pump, or "peripheral heart". This is located primarily in the calves. During muscle contraction, compression of veins transports blood to the heart by means of the deep venous system.

CEAP CLASSIFICATION OF CHRONIC VENOUS DISORDERS
CLINICAL CLASSIFICATION (C)
C0: no visible or palpable signs of venous disease
C1: telangiectasias or reticular veins
C2: varicose veins
C3: edema
C4a: hemosiderin pigmentation, eczematous dermatitis (stasis dermatitis)
C4b: lipodermatosclerosis, atrophie blanche (livedoid vasculopathy)
C5: healed venous ulcer
C6: active venous ulcer
S: symptoms including aches, pains, tightness, skin irritation, heaviness, muscle cramps, and other complaints attributable to venous dysfunction
A: asymptomatic
ETIOLOGIC CLASSIFICATION (E)
Ec: congenital
Ep: primary
Es: secondary (post-thrombotic)
En: no venous etiology identified
ANATOMIC CLASSIFICATION (A)
As: superficial veins
Ap: perforator veins
Ad: deep veins
An: no venous location identified
PATHOPHYSIOLOGIC CLASSIFICATION (P)
Pr: reflux
Po: obstruction
Pr,o: reflux and obstruction
Pn: no venous pathophysiology identified

Table 155.1 CEAP (Clinical, Etiologic, Anatomic, Pathophysiologic) classification of chronic venous disorders.

over previous classification schemes that were based solely on clinical appearance. Even in basic CEAP, where a duplex scan is performed, classification of E, A and P with multiple descriptors is recommended. For A (anatomic classification), the simple s, p and d descriptors should be used, e.g. a patient with primary disease of the superficial and deep veins could be classified as C4aS; Ep; As,d; Pr. While venous disease is complex, it can be described using this system, and clinicians are encouraged to use all four components of CEAP (see Table 155.1).

A disposable sclerotherapy garment is an excellent means for preserving patient modesty while gaining full access to the entire lower extremity. A two-step examination stool also aids in the clinical assessment. The medial plantar and ankle regions are examined for the presence of specific skin changes, including clusters of telangiectatic veins (referred to as "corona phlebectasia"), hemosiderin deposition, atrophie blanche (livedoid vasculopathy), lipodermatosclerosis, and/or active or healed ulceration (see Ch. 105). These findings suggest a chronic state of venous insufficiency, located in either the saphenous veins or the deep venous systems. The lateral posterior malleolar region is similarly examined. Skin changes in this area most often indicate small saphenous vein insufficiency.

There are three branch veins that are important for evaluating the saphenofemoral junction (SFJ)[8]. Attention is first directed toward the anterior abdominal wall. The presence of varices in this area ("caput medusae") indicates insufficiency of the superficial epigastric vein (see Fig. 155.2); this is always abnormal and should alert the phlebologist to underlying deep venous obstruction, usually in the iliofemoral segment (see Fig. 155.3). The posteromedial thigh vein and the anterolateral thigh vein are often also insufficient in patients with GSV insufficiency and this usually presents as dilated reticular veins and telangiectasias within the involved anatomic zones[7].

LABORATORY EVALUATION OF THE SUPERFICIAL VENOUS SYSTEM

Vascular testing is indicated for symptomatic patients in whom the source of reflux is unclear by physical examination and in other clinical situations as outlined in Table 155.2. A key instrument is a Doppler device which detects increased or decreased frequency shifts from

INDICATIONS FOR VASCULAR TESTING
1. Any varicosity greater than 2 mm in diameter extending the length of the calf or thigh
2. Presence of a "starburst" cluster of telangiectasias over sites of perforating veins (medial distal calf, mid-posterior calf, medial knee, medial midthigh)
3. Evidence of incompetent perforating veins (connect the superficial and deep venous systems)
4. Varicose veins, either truncal or saphenous
5. Clinical signs of venous insufficiency
6. Symptomatic veins of any diameter
7. History of deep venous thrombosis and/or thrombophlebitis
8. History of previous venous surgery or sclerotherapy with poor results or recurrence of varicosities

Table 155.2 Indications for vascular testing.

ultrasound waves that are reflected from blood cells coming toward or going away from the Doppler ultrasound probe, respectively[9]. A bidirectional Doppler can produce a hard copy, while a unidirectional Doppler cannot (the former may be useful for insurance purposes). Bidirectional Doppler devices have 4 MHz probes that are deeper penetrating (up to 8 cm) and 8 MHz probes that penetrate more superficially (0.5–2 cm).

When utilizing a Doppler device, the examiner places the probe over the vein in question, and then compresses distal to the probe to create a flux sound (Fig. 155.5)[10]. Because the veins have one-way valves, if a vein is normal there will be no reflux or reversal of flow upon release of the distal compression. If a reflux sound is heard after release of the distal compression, this is abnormal and diagnostic of venous valvular insufficiency. It is best to hold the probe at a 30° to 45° angle[11]. Reversal of blood flow, as the patient increases abdominal pressure with the Valsalva maneuver, indicates incompetent valves from the SFJ to the distal-most site of the probe. When placed on the medial superior thigh over the GSV a few centimeters distal to the SFJ, reversal of blood flow for >0.5 seconds indicates an incompetent SFJ. These patients require endovenous RF or laser closure of the GSV before any treatment is given to the distal varicose, reticular and/or telangiectatic leg veins.

Duplex ultrasonography is a highly accurate, non-invasive technique that can provide both anatomic and physiologic information regarding the venous system[12] (Table 155.3). For this reason, it is rapidly becoming the modality of choice, not only for pretreatment assessment of varicose veins, but also for guidance during endovenous RF and laser procedures and for performance of follow-up studies. Duplex examination of normal veins involves the use of a ≥7.5 MHz high-resolution β-mode scanner and a 5 MHz Doppler probe. While the β-mode scanner provides real-time anatomic images, the Doppler probe supplies physiologic information in the form of blood flow data (Fig. 155.6). Incorporation of the real-time image allows reproducible positioning of the Doppler probe at a known anatomic site. Using this method, the physician can obtain longitudinal and transverse images of veins and arteries that are up to 8 cm below the skin surface. For deeper assessment, a <7.5 MHz scanner may be needed.

COMPRESSION IN SCLEROTHERAPY AND VENOUS DISEASE

Graduated compression has many benefits in patients with venous disease. It reduces the diameter of the veins, thereby increasing flow velocity and decreasing the chance of thrombus formation. Following sclerotherapy (which is essentially a *controlled* thrombophlebitic reaction), compression reduces the diameter of the resulting thrombosis of the treated vein, which minimizes the inflammatory reaction, thereby decreasing the extent and incidence of post-treatment hyperpigmentation, recanalization of the vein, and telangiectatic matting. Compression also increases the contact between the sclerosant and the endothelial lining of the vessel wall, potentiating pan-vessel obliteration. There are three main types of graduated compression: graduated elastic compression stockings or bandages, inelastic compression garments or bandages, and pneumatic compression pumps[13]. Compression bandages are not recommended, as they are difficult to apply in a graduated manner and hold their compression for only a few hours after application.

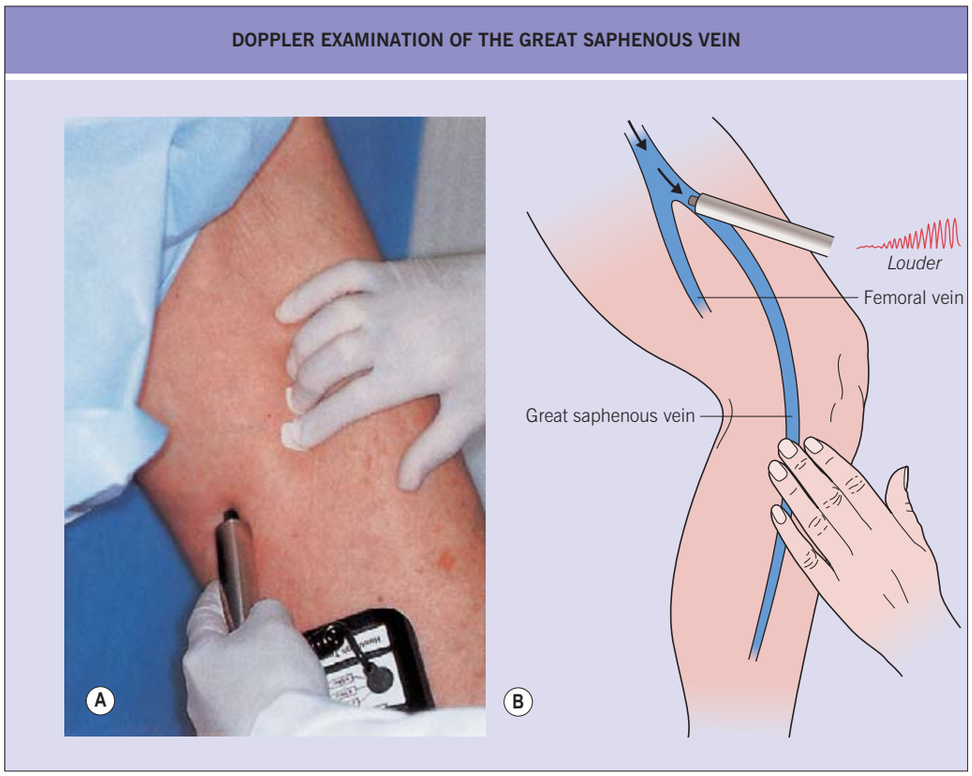

Fig. 155.5 Doppler examination of the great saphenous vein. A Doppler probe held at a 30° to 45° angle. **B** Doppler examination of the great saphenous vein; a reflux found after the release of distal compression denotes venous valvular insufficiency. *Courtesy, Neil Sadick, MD*

COMPARISON OF DOPPLER ULTRASOUND AND DUPLEX SCANNING FOR PRESCLEROTHERAPY EVALUATION

	Doppler	Duplex
Portability	Yes	Yes
Easy to use	Yes	Yes
Cost (2012) (approximate in US dollars)	Unidirectional: $500–$750	Color: $25 000–50 000
Information obtained	1. Patency, competence of venous valves 2. Detection of deep venous thrombosis in thigh	1. Patency, competence of venous valves 2. Detection of deep venous thrombosis with greater accuracy (thigh > calf) 3. Velocity of reflux 4. Anatomy and anomalies of venous system (number of great saphenous veins) 5. Termination of small saphenous vein 6. Thrombosis versus sclerosis
Reliability	Less reliable because of blind, non-timed pulsed sound beam	More reliable because of actual visualization of venous anatomy

Table 155.3 Comparison of Doppler ultrasound and duplex scanning for presclerotherapy evaluation.

Fig. 155.6 Duplex ultrasonography. In the duplex image (**A**) reverse flow (shown in blue) is seen coming from a branch of the great saphenous vein (GSV); the branch is superior to the GSV. **B** The Doppler signal shows reverse flow.

Graduated elastic compression stockings are most commonly employed following sclerotherapy. They come in four classes, based upon the pressure generated by the stocking at the level of the ankle, that range from 20–30 mmHg (class I) to 50–60 mmHg (class IV) (see Ch. 105)[14]. Most sclerotherapy patients wear thigh-high or panty-hose stockings. In addition, most manufacturers now offer so-called "fashion hose" which approximate 18 mmHg pressure and are sheer, leading to greater patient compliance. In a multicenter study performed by Weiss et al[15], 20–30 mmHg graduated compression stockings were shown to increase sclerotherapeutic efficacy and diminish post-treatment hyperpigmentation. At least 3 days of compression were necessary to produce this positive effect and 3 weeks of daytime wear was found to be the optimal time required for the maximal effect[15].

We recommend that all patients wear graduated compression stockings for 1 week ("24/7") after the procedure. It is important for the patient to wear the stockings 24 hours a day, even while in the shower and when sleeping. If one removes the stockings in the shower, the veins dilate. If one removes the stockings at night, the superficial system also dilates. For this reason, it is recommended that all patients wear the thigh-high stockings, as these are more hygienic and easier to use than panty-hose, which extend higher up to the waist.

SCLEROSING SOLUTIONS

The optimal sclerosing agent is one that induces pan-endothelial destruction or removal[16]. Thrombosis alone will not obliterate vessels because intact endothelium contains tissue plasminogen activator that can dissolve thrombi, leading to recanalization. The ideal sclerosing

A GUIDE FOR THE SELECTION OF SCLEROSING SOLUTION CONCENTRATION AND VOLUME BY VESSEL TYPE		
Vessel	**Solution concentration**	**Volume (per region)**
Telangiectatic matting (after previous treatment)	Glycerin, 72%, diluted 2:1 with 1% lidocaine with epinephrine	0.1–0.2 ml
Telangiectasias (up to 1 mm)	Glycerin, 72%, diluted 2:1 with 1% lidocaine with epinephrine Sodium tetradecyl sulfate, 0.1–0.25% Polidocanol, 0.25–0.5% Hypertonic saline, 11.7% Hypertonic saline, 10% and dextrose, 25% Polyiodide iodide, 0.1%	0.1–0.3 ml
Venulectasias (1–2 mm)	Sodium tetradecyl sulfate, 0.25–0.5% Glycerin, 72% Polidocanol, 0.5–0.75% Hypertonic saline, 11.7–23.4% Hypertonic saline, 10% and dextrose, 25%	0.2–0.5 ml
Reticular veins (2–4 mm subcutaneous blue veins)	Sodium tetradecyl sulfate, 0.1–0.25%, *foam* Polidocanol, 0.25–0.5%, *foam* Polyiodide iodide, 0.3–1.0%	0.5 ml (may increase to 1–3 ml if filling of reticular vein by foam is observed)
Non-saphenous varicose veins (3–8 mm)	Sodium tetradecyl sulfate, 0.5–1.0%, *foam* Polidocanol, 1.0–3.0%, *foam* Polyiodide iodide, 1.0–2.0%	0.5 ml for liquids, 3 ml of foam per injection site in a large-capacity vein
Saphenous varicose trunks (usually >5 mm)	Sodium tetradecyl sulfate, 1.0–3.0%, *foam* Polidocanol, 3.0–5.0%, *foam* Polyiodide iodide, 2.0–6.0% (rarely to 12%)	0.5 ml for liquids (low-volume injection critical at high concentrations), 3 ml with foam

Table 155.4 A guide for the selection of sclerosing solution concentration and volume by vessel type. The sclerosing agents are listed in order of preference.

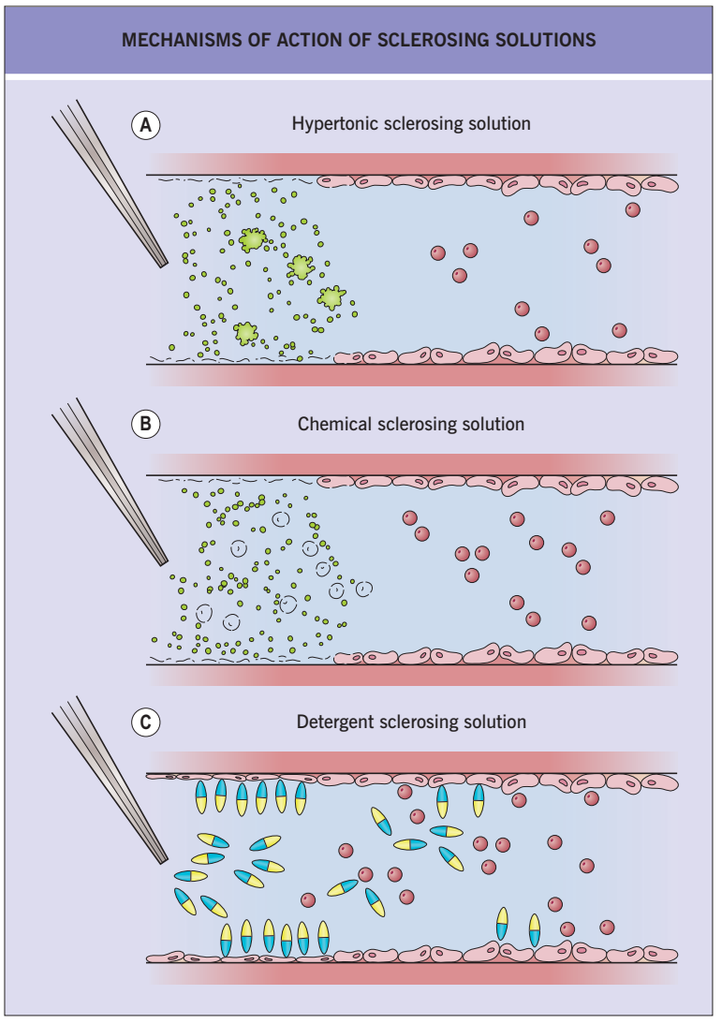

Fig. 155.7 Mechanisms of action of sclerosing solutions. A Hypertonic, which induces endothelial damage via a gradient dehydration effect. **B** Chemical, which injures cells by acting as a corrosive. **C** Detergent, where the hydrophobic portion of the detergent molecule (blue) attaches to the endothelial cell wall while the hydrophilic portion (yellow) draws water into the cell, leading to an overhydrated maceration effect. *Adapted from Goldman MP, et al. Sclerotherapy, 5th edn. London: Mosby, 2011.*

agent should possess no systemic toxicity and produce local endothelial destruction that fully extends to the adventitia with minimal thrombus formation[17]. The resultant vascular destruction induces an inflammatory reaction which leads to fibrosis and eventually obliteration of the vessel.

There are several important points to remember when choosing a particular sclerosing solution and determining the appropriate sclerosant concentration (Table 155.4)[18]:

1. If the sclerosant is too weak, insufficient endothelial damage will occur, leading to thrombosis secondary to varicose vessel wall damage. However, there will be no fibrosis and recanalization of the vessel occurs.
2. Too strong a solution may lead to uncontrolled destruction of vascular endothelium and other layers, which may eventuate in hyperpigmentation, neoangiogenesis (telangiectatic matting) and ulceration secondary to sclerosant extravasation.
3. Choose the minimal sclerosant concentration (MSC) that will cause irreversible damage to the cellular wall of the abnormal vessel.

Sclerosing agents are classified into three groups based upon the mechanism whereby they cause injury to the endothelium (Table 155.5):

1. Hyperosmotic agents – the osmotic agents include hypertonic saline and hypertonic saline–dextrose. Their primary mechanism of action involves endothelial cell damage via dehydration (Fig. 155.7A).
2. Chemical irritants – the chemical irritants include chromated or non-chromated glycerin and polyiodide iodide. They injure cells by acting as corrosives; their cauterizing effect is thought to be due to the associated heavy metal (Fig. 155.7B).
3. Detergent sclerosants – the detergent sclerosants include sodium tetradecyl sulfate, polidocanol and sodium morrhuate. This group of agents causes vascular injury by altering the surface tension around endothelial cells (Fig. 155.7C).

The only agents that are Food and Drug Administration (FDA)-approved for sclerotherapy in the US are sodium tetradecyl sulfate, sodium morrhuate (fatty acids in cod liver oil) and polidocanol[19]; hypertonic saline is approved as an abortifacient rather than for the treatment of varicose veins. Glycerin is approved as a hyperosmotic agent for the treatment of acute intracerebral edema and acute angle glaucoma. Polyiodide iodide, a chemical irritant, lacks FDA approval for any indication. Glycerin, hypertonic saline (11.7–23.4%), polidocanol (0.25–5%), and sodium tetradecyl sulfate (0.1–3%) are the current sclerosants of choice in the US.

Determining the minimal volume and minimal concentration of the most appropriate sclerosing agent is a key factor in producing effective sclerotherapy results. This concept, termed the minimal sclerosant concentration (MSC), will enable the sclerotherapist to achieve maximal results while minimizing the complication profile[20,21]. A guide to suggested sclerosing agents and initial choices of sclerosant concentrations and volumes for instillation as related to vessel type and diameter is presented in Table 155.4.

It is also important to have a working knowledge of the complication profile of each sclerosing solution (see Table 155.5). The osmotic sclerosants such as hypertonic saline are associated with burning and cramping on injection and an increased incidence of ulcerative necrosis secondary to extravasation.

IMPORTANT CHARACTERISTICS OF SCLEROSING SOLUTIONS					
Sclerosing solution (Brand name)	**Class**	**Allergenicity**	**Risks**	**FDA approval**	**Dose limitation**
Hypertonic saline [11.7–23.4%]	Hyperosmotic	None	Pain* and cramping Necrosis of skin Hyperpigmentation	Yes, as abortifacient [18–30%]	6–10 ml
Hypertonic saline [10%] and dextrose [25%] (Sclerodex®)	Hyperosmotic	Low (due only to added phenethyl alcohol)	Pain* (much less than with hypertonic saline alone)	No (sold in Canada)	10 ml of undiluted solution
Sodium tetradecyl sulfate (Sotradecol® [USA], Fibrovein®, Thromboject®)	Detergent	Very rare anaphylaxis	Pain* with perivascular injection Necrosis of skin (with higher concentrations) Hyperpigmentation	Yes	10 ml of 3%
Polidocanol (Asclera® [USA], Asklerol®, Aethoxysklerol®, Aetoxisclerol®, Sclerovein®)	Detergent	Very rare anaphylaxis	Lowest risk of pain Necrosis usually from arteriole injection Hyperpigmentation (with higher concentrations) Disulfiram-like reaction	Yes	5 ml of 3% (depends on body weight, see ref. 5)
Sodium morrhuate (Scleromate®)	Detergent	Anaphylaxis, highest risk	Pain* Necrosis of skin Hyperpigmentation	Yes	10 ml
Ethanolamine oleate	Detergent	Urticaria, anaphylaxis	Pain* Necrosis of skin Hyperpigmentation Viscous, difficult to inject Acute renal failure Hemolytic reactions	Yes (used primarily for esophageal varices)	10 ml
Polyiodide iodide (Varigloban®, Variglobin®, Sclerodine®)	Chemical irritant	Anaphylaxis Iodine hypersensitivity reactions	Pain* Necrosis of skin Dark brown color makes intravascular placement more difficult to confirm	No	5 ml of 3%
Glycerin [72%] with chromium potassium alum [8%] (Chromex®, Scleremo®); glycerin [72%] diluted 2:1 with 1% lidocaine, with or without epinephrine)	Chemical irritant (plain glycerin may be an osmotic agent as well)	Very rare anaphylaxis (none for glycerin alone)	Pain* and cramping Low risk of hyperpigmentation Viscous, difficult to inject Hematuria with injections >10 ml	Yes (for treatment of acute intracerebral edema and acute angle glaucoma)	10 ml

*Includes burning.

Table 155.5 Important characteristics of sclerosing solutions. Sclerosing agents are classified into three groups: hyperosmotic agents, detergents and chemical irritants.

Sodium tetradecyl sulfate and polidocanol have been associated with a low incidence of allergic reactions, ranging from urticaria to anaphylaxis (<0.01%)[5]. However, with increasing usage, it is now thought that the risk of type I (i.e. immediate hypersensitivity) reactions is extremely low. In fact, after over 25 years of use in over 25 000 patients, the authors have never seen an allergic reaction except for one case of urticaria. Hyperpigmentation has been reported in 5–30% of patients treated with all sclerosing solutions except glycerin, which has a <1% incidence of pigmentation. In the authors' experience, the incidence of hyperpigmentation is related more to the concentration of the sclerosing agent as well as host skin type, vessel type and other vascular fragility factors[22–24].

Creating foaming detergent solutions by mixing them with air or CO_2 (typically in a mixture of 1 ml of solution with 4 ml of air or CO_2) has been found to increase the potency of the sclerosing solution twofold while decreasing its adverse effect profile fourfold. Foam displaces blood and remains for an extended time in the target vessel. This makes the sclerosing solution more efficient, so that it may be utilized at lower concentrations. The use of CO_2 rather than room air allows the gas–sclerosant bubbles to breakdown more quickly, minimizing the possibility of gas embolization into the arterial circulation via a patent foramen ovale.

TECHNIQUES FOR TREATING TELANGIECTASIAS AND RETICULAR VEINS

The treatment of telangiectasias and reticular veins is most commonly performed for cosmetic improvement, but up to 50% of these patients also report a variety of symptoms, from dull aching legs to throbbing pain over the telangiectasia[25]. Telangiectasias are best defined as flat, red to blue vessels 0.1–1 mm in diameter (Table 155.6). Venulectasias are blue- to violet-colored vessels, sometimes distended above the skin surface and most often 1–2 mm in diameter. Reticular veins have a cyanotic blue to blue–green hue and are visually 2–4 mm in diameter. When a complex of reticular veins is located on the lateral thigh, it is felt to be a vestige of embryonal development known as the lateral subdermal plexus[26,27].

The treatment of telangiectasias and reticular veins is undertaken only after all sources of reflux have been addressed, as it is important to treat proximal sites of reflux first and to treat larger vessels before smaller veins. Alone or in combination with laser or intense pulsed light technology, sclerotherapy of small-diameter vessels is the most common challenge faced by the dermatologic surgeon who performs sclerotherapy. Preoperative photographic documentation and full informed consent outlining all possible risks and complications as well as treatment expectations should be obtained prior to therapy[28–30].

Materials employed in the treatment of telangiectasias and reticular veins are relatively simple. They may include:

- cotton balls soaked with 70% isopropyl alcohol
- protective gloves
- 3 and 5 ml disposable syringes
- 30-gauge disposable ½-inch transparent hub needles
- magnifying lens (2–3×)
- nitroglycerin paste for prolonged blanching
- bronchodilator inhaler in case of bronchospasm
- epinephrine (adrenaline) in case of anaphylaxis.

CLASSIFICATION OF VEINS AND CLINICAL APPROACH TO TREATMENT OF VENOUS PATHOLOGY

Type	Description	Diameter (mm)	Color	Treatment
I	Telangiectasias (spider veins) Telangiectatic matting	0.1–1	Usually red network	• Microsclerotherapy • Intense pulsed light • Laser (e.g. pulsed dye, 1064 nm Nd:YAG)
II	Venulectasias	1–2	Violaceous	• Sclerotherapy • Laser (e.g. 1064 nm Nd:YAG)
III	Reticular varicosities	2–4	Cyanotic blue to blue–green	• Sclerotherapy • Ambulatory phlebectomy • Laser (e.g. 1064 nm Nd:YAG)
IV	Varicosities (secondary saphenous branch or perforator-related)	3–8	Blue to blue–green	• Ambulatory phlebectomy • Sclerotherapy
V	Saphenous varicosities (truncal or axial varicosities including main saphenous trunks and first-generation branch varicosities)	≥5	Blue to blue–green May be palpable and not visible	• Ambulatory phlebectomy • Endovenous radiofrequency closure • Sclerotherapy • Endovenous laser ablation (EVLA)

Table 155.6 Classification of veins and clinical approach to treatment of venous pathology. ND:YAG, neodymium-doped yttrium aluminum garnet. *Photographs, Courtesy, Jean L Bolognia, MD.*

Flow sheets with segmental numerical division of the legs are helpful in documenting areas that are treated at each session. Because successful sclerotherapy that results in pan-luminal endofibrosis can take up to 6 weeks, it is recommended that treatment sessions should not be repeated for at least this interval of time.

There are four variable components that may be employed in the treatment of telangiectatic and reticular veins[30–32]. They include:

1. ***Aspiration.*** Aspiration of a small amount of blood into the needle hub may ensure that the dermatologic surgeon has adequately cannulated the vein. Of note, the vein may collapse if aspiration is too strong.
2. ***Direct puncture without aspiration.*** This technique relies on the feeling associated with perforating the vein wall. Although it is slightly more precarious for beginners, this technique can be mastered with time.
3. ***Air bolus variant*** (Fig. 155.8)**.** Injection of <0.5 ml of air prior to introduction of the sclerosant will displace blood in the vein. Once intravascular access is confirmed, the sclerosant can be safely injected. Air inadvertently introduced into the tissues is not as damaging as the sclerosant might be. Too strong of a push may lead to truncal distention and rupture. The small air bolus technique is ideal for hypertonic saline, as even slight extravasation of solution will cause epidermal ulceration.
4. ***Empty vein variant.*** In an attempt to remove as much blood as possible, the leg is elevated and kneading with gentle pressure is performed before the sclerosant is injected. The persistence of varicose veins after treatment is usually due to recanalization of the intramural thrombus that develops, and the empty vein technique may reduce the amount of thrombus. This concept is more important when treating larger veins. Other advantages of this technique are that an empty vein has minimal volume and therefore the endothelium is exposed to a concentration of sclerosant similar to that injected. Also, a smaller volume of sclerosant is necessary to ensure contact with the endothelial surface and lower concentrations of sclerosant may be employed since there is less blood in the vein to dilute the solution[33]. Foamed sclerosing agents, discussed later, displace blood from veins, thereby automatically resulting in the empty vein technique with an enhanced efficacy.

Injection Technique

Injection is carried out utilizing one or more of the previously described techniques. The needle may be bent at an angle of 30°. Hand traction is used by either the dermatologic surgeon or an assistant to keep the skin taut. Large vessels are injected before smaller vessels, i.e. injection of the reticular veins feeding smaller telangiectasias or venules may

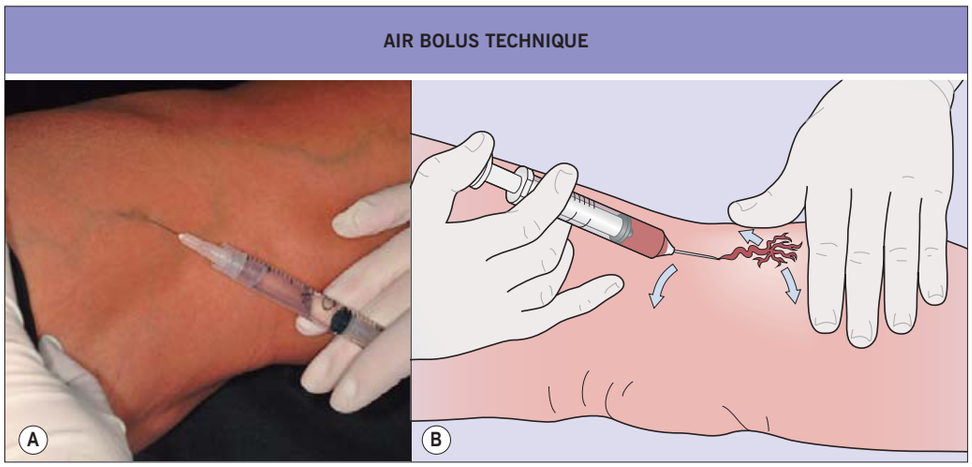

Fig. 155.8 Air bolus technique. A Injection of an air bolus (<0.5 ml) prior to injection of sclerosant can displace blood in the vein and ensure intravascular needle location. Air inadvertently introduced into the tissues is not as damaging as the sclerosant might be. **B** Three-point stretching of the skin allows for more accurate cannulation of the vessel. *B, Redrawn from Goldman MP, et al. Sclerotherapy, 5th edn. London: Mosby, 2011.*

eradicate the latter, minimizing side effects such as hyperpigmentation. Areas of vascular arborization (Fig. 155.9) should be treated before single discrete linear vessels are cannulated[34].

The utilization of alcohol in swabbing the skin prior to injection will decrease the index of refraction of light and thus make the vessels more visible at the skin surface. Brisk cannulation of veins causes minimal vascular trauma, less vasoconstriction, and less chance of extravasation of blood. Injection pressure is kept to a minimum by performing the injection slowly in order to prevent vascular distention, and to allow adequate time for the sclerosing agent to interact with the endothelium. A small amount of sclerosant is used at each injection site (0.1–0.4 ml) in order to minimize side effects such as telangiectatic matting, post-sclerosis pigmentation, and ulcerative necrosis due to extravasation. The sclerosing injection is stopped when the solution has filled the targeted veins. Injections are carried out at approximately 3–6 cm intervals until the entire vessel has been treated.

Foamed Detergent Solutions

A detergent solution such as sodium tetradecyl sulfate and polidocanol can be foamed to a thick consistency by rapidly agitating it with air or CO_2 in a ratio of solution to gas of 1 : 4 (see above). There are numerous advantages of using foam when treating larger varicosities. For instance, an increased quantity of solution can be injected over longer segments of veins. Also, a foamed sclerosing solution retains more of its potency, as the full concentration of the sclerosant is present on each microbubble, residing on the outer micelle. Due to persistence and increased potency, foamed agents reduce the number of necessary treatments and allow treatment of larger vessels. In contrast, for smaller vessels, non-foamable glycerin and hypertonic saline are rapidly diluted and they act only within their concentration gradients, thus limiting the extent and intensity of sclerosing action. It is not practical to treat large veins with glycerin or hypertonic saline, as more frequent injections would be necessary and the potency rapidly diminishes due to the concentration being rapidly diluted by blood within the treated vein.

Treatment sessions are carried out at 6- to 8-week intervals in order to allow enough time for full endosclerosis to occur and for post-treatment inflammation to resolve, and to evaluate the results of the previous treatment session. Most patients will require one to three treatment sessions in order to clear their legs of unwanted telangiectatic and reticular vessels. If a poor response is seen at the end of this treatment schedule, the dermatologic surgeon may:

- increase the concentration of sclerosant
- switch to another sclerosant
- re-examine the patient to find a possible source of reflux previously missed.

Lasers and Intense Pulsed Light Sources for Treatment of Telangiectasias

Laser and intense pulsed light (IPL) therapy of lower extremity vessels may have a synergistic effect when used in combination with sclerotherapy (see Ch. 137).

Fig. 155.9 Treatment of arborizing feeder veins. This therapeutic approach (arrow) diminishes the number of injections required in a given sclerotherapy treatment session, thus minimizing potential side effects. *Courtesy, Jean L Bolognia, MD.*

LARGER VARICOSE VEINS

The treatment of large-diameter blood vessels requires greater and more precise attention to details regarding anatomy and points of reflux[35]. Contraindications to treatment of large-diameter veins include pregnancy, lactation, allergy to the sclerosing agent, thrombophilia or a hypercoagulable state (see Table 105.9), non-ambulation, and non-compliance[36]. A foamed detergent is currently recommended as the sclerosing agent, with the concentration determined by the size of the vein to be injected (see Table 155.4).

Factors of importance in the treatment of large-diameter veins include:

1. An understanding of the precise anatomy of the varicosity under consideration for treatment.
2. Adherence to a rational treatment plan in which injections begin at the highest point of reflux, with progression to the next highest point in a proximal-to-distal direction.
3. Determination of the most significant reflux point[37,38].

The dermatologic surgeon must determine whether reflux originates in the deep venous system, GSV or SSV, or a perforator (see Figs 155.2 & 155.3). The veins which represent the primary source of reflux must be treated before secondary sources of reflux are treated. Duplex ultrasound guidance (see Table 155.3) is often helpful in the therapeutic approach to larger-diameter vessels, particularly those cases where the anatomy is so intricate that the point of reflux would otherwise be difficult to detect.

Several slightly modified techniques and/or positions for large-vein sclerotherapy have been described. Three positions for treating

large-diameter vessels are: (1) the standing supine elevation direct cannulation technique; (2) the multiple precannulation sites (MPS) technique; and (3) the supine cannulation (SC) technique[5,38,39].

In the *standing supine elevation direct cannulation* technique, the patient stands at first, causing the varices to bulge and become more visible (Fig. 155.10)[27]. Injection points are marked at primary sites of reflux into the superficial venous system and approximately every 3–4 cm along the vein to be treated. The patient is then placed in a supine or prone position, the vein is emptied to maximize sclerosant–endothelial contact, and a small volume of sclerosant is injected at each of the marked points along the vein to be treated. A 27- to 30-gauge needle on a 3 ml syringe is often employed for this technique. The needle is advanced while aspirating into the syringe until aspiration of dark venous blood indicates penetration of the lumen. Concentrated sclerosant (0.5–1.5 ml) is injected at each site, followed by massage, again to ensure maximum sclerosant–endothelial contact. The vein will appear visually contracted at the end of the treatment. Leg elevation for a minute following the injection of foam allows the larger veins to contract. This may result in further spread and better contact of the sclerosant with the endothelium, improving the clinical results.

In the *multiple precannulation sites* (MPS) variation, the patient initially stands, in order to induce the varices to bulge and become more visible. Injection points are marked at proximal as well as distal sites along the distended vein. The veins are subsequently cannulated with either a 23-gauge butterfly needle and tubing or a plastic intravenous cannula and extension tubing at *both* the proximal and distal sites[40].

The butterfly needles or cannulas must be firmly secured, as the patient then moves to the treatment table and elevates the extremity undergoing treatment. After an intravascular position has been verified, 2–3 ml of sclerosant is infused into the cannula and subsequently into the vein while the surrounding area is observed for swelling or other evidence of extravasation. In the majority of cases, a single proximal and a single distal injection point are sufficient to sclerose a large tortuous vessel[41].

The authors routinely use the *supine cannulation* (SC) position, as it is faster and has less risk of a vasovagal reaction when compared to the upright position. Just prior to injection, the detergent sclerosing solution is foamed by mixing one part sclerosing solution with four parts air or CO_2[42]. Larger veins are treated proximally to distally with an appropriate concentration of sclerosing solution (see Table 155.4).

In addition to delineating vascular anatomy, duplex ultrasonography (see Fig. 155.6) can be used to assess the vascular response to sclerotherapy, including that of large non-junctional varicose veins. Incomplete endosclerosis has a pattern of intravascular thrombosis (multiple echoes), with the vein lumen remaining partially patent. When sclerotherapy has been successful, the vein wall is thickened and non-compressible (non-echogenic)[35,43]. Duplex ultrasonography can also provide guidance during sclerotherapy with *foamed* sclerosing agents. The distribution of foamed sclerosant as it flows into the targeted vein is easily visible as a sparkling. This also decreases the chance for inadvertent arterial injection. Nowadays, Doppler guidance is no longer recommended.

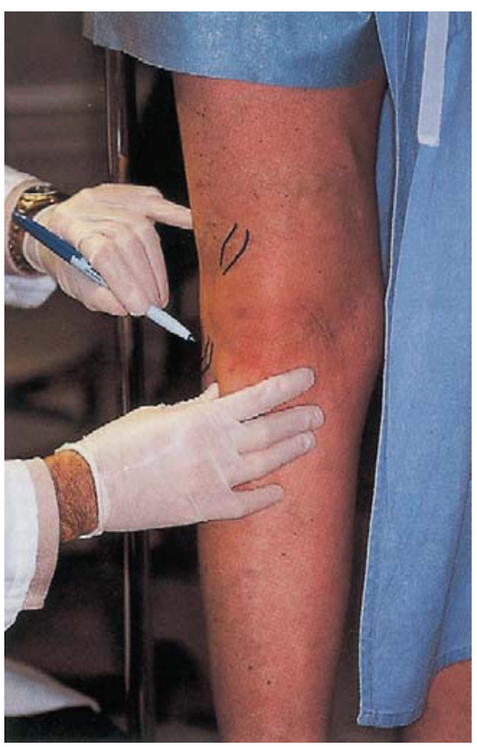

Fig. 155.10 Initial step prior to large-vein sclerotherapy. Marking of treatment sites in a standing position by indelible marker is performed. *Courtesy, Neil Sadick, MD*

POSTSCLEROTHERAPY COMPRESSION

Cotton-roll pads or foam pads may be applied along the entire course of the treated vessels and they are held in place by a compression garment. Graduated compression stockings that are class I (20–30 mmHg) or preferably class II (30–40 mmHg) are suggested for all patients following sclerotherapy of telangiectasias and reticular veins[15]. Patients should be instructed to walk 30 minutes after each treatment session, in order to minimize thromboembolic events as well as decrease the diameter of the superficial veins. The optimal duration of compression was shown in a recent study to be a minimum of 3 weeks of daytime wear, although 3 days of compression led to better results than no compression[15]. After large-vein sclerotherapy, we recommend 7 days of uninterrupted compression (24/7), during which the patient may bathe or shower by either placing a large plastic bag over the compression bandage or stocking or just allowing the stocking to get wet and then drying it with a hairdryer. After the first 7 days, the compression pads or cotton rolls are discarded and patients are permitted to remove the stocking, as needed, for bathing and sleeping. Ambulation is begun immediately post-treatment.

COMPLICATIONS

There are three major considerations when anticipating and managing complications of sclerotherapy (Table 155.7). The first is that fastidious technique will minimize the incidence of side effects. Second is an appropriate understanding of maneuvers that may be instituted if something is felt to go wrong. Finally, an appreciation of the management options available for adverse sequelae can minimize the intensity of complications when they occur[44].

Postsclerotherapy Pigmentation

The incidence of postsclerotherapy hyperpigmentation (Fig. 155.11) varies from 5% to 30%[24,42,45,46]. The purple–brown pigmentation has been shown to be due to extravascular deposits of hemosiderin[47]. Hypercoagulability syndromes such as antithrombin III, protein C or protein S deficiencies, use of nonsteroidal anti-inflammatory drugs

SCLEROTHERAPY COMPLICATIONS	
Cutaneous complications	**Extracutaneous complications**
EARLY	**EARLY**
• Localized urticaria • Bruising • Edema • Ischemia/necrosis (e.g. due to arterial injection, vasospasm, extravasation)	• Systemic allergic reactions (e.g. anaphylaxis) • Scotomata (with foam sclerosants) • Vasovagal syncope
DELAYED	**DELAYED**
• Superficial thrombophlebitis • Ulceration (secondary to ischemia/necrosis) • Hyperpigmentation • Telangiectatic matting (neoangiogenesis) • Hypertrichosis • Compression-related problems (folliculitis, irritant contact dermatitis)	• Deep venous thrombosis/pulmonary embolus • Nerve damage

Table 155.7 Sclerotherapy complications.

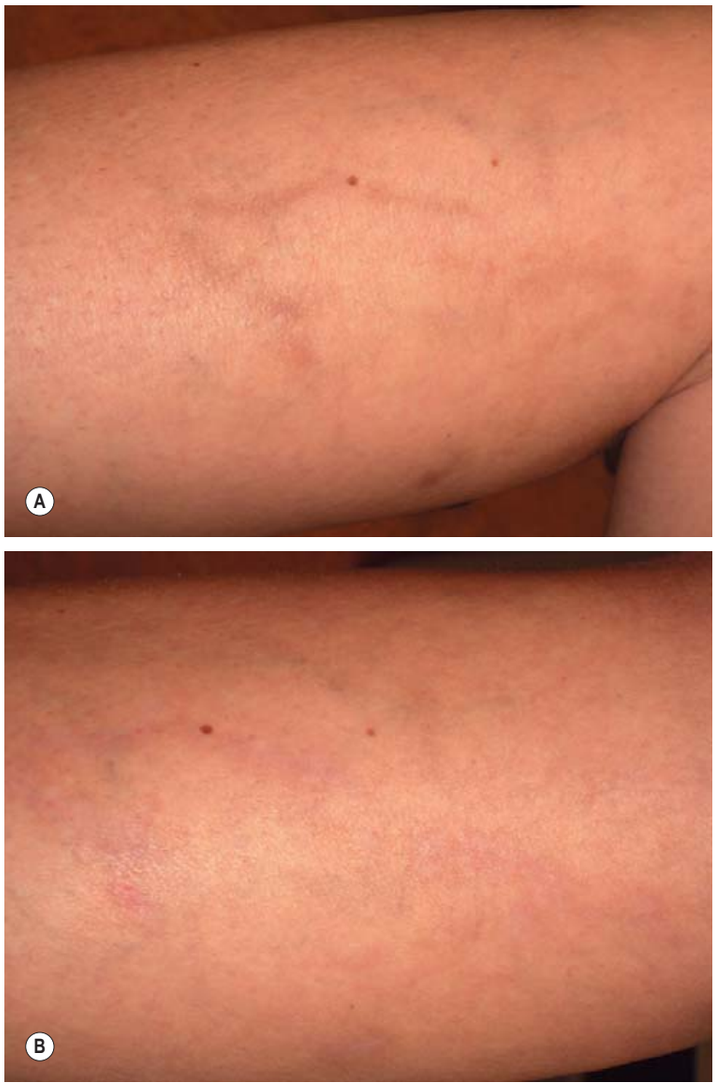

Fig. 155.11 Sclerotherapy-induced hyperpigmentation. A Development of hyperpigmentation along the course of a 3–4 mm diameter reticular vein 3 months after treatment with sodium tetradecyl sulfate 0.5% foam. **B** Six months after treatment with the Q-switched ruby laser at 6 J/cm^2, 5 mm diameter spot. Note complete resolution of hyperpigmentation.

(NSAIDs), high total body iron stores, use of minocycline, or the vessel fragility commonly noted in the elderly may predispose to this adverse sequela[48]. Methods to minimize the incidence of postsclerotherapy pigmentation are outlined in Table 155.8. Although various treatment modalities have been tried for this complication, only the utilization of the Q-switched ruby laser has shown any degree of reproducible success[49–51]. Pigmentation usually lasts for 6–12 months. If it persists, the dermatologic surgeon should search for a vessel with persistent reflux into the area or an underlying predisposition.

Telangiectatic Matting

Blushes or nets composed of very fine telangiectasias may occur around sites of previously injected veins or sites of previous surgical interruption, e.g. ligation or ambulatory phlebectomy (Fig. 155.12). They may occur from days to months after treatment and are seen in 5–15% of patients[24,42,52]. Sites of predilection include the thighs, medial malleolus, and medial and lateral calves. Risk factors include obesity, use of estrogen-containing medications, pregnancy and a family history of telangiectatic veins. Excessive postsclerotherapy inflammation may also predispose individuals to this complication, due to inadequate compression or exceeding the minimal sclerosant concentration (MSC) of the sclerosing solution.

Generally, telangiectatic matting resolves within 3–12 months without specific treatment. Persistence should lead the dermatologic surgeon to attempt to locate a source of reflux in the area (usually a feeding reticular vein), although matting may be a sign of underlying saphenous insufficiency. Low injection pressure utilizing the MSC is the most effective way to minimize this complication. Additional measures include the use of no more than 1 ml of sclerosant per injection site, limiting the injection blanch to 1–2 cm, encouraging normalization of weight, and discontinuation of oral contraceptives for 1 month prior and 2 months following sclerotherapy. Short-wavelength lasers (595–600 nm) and intense pulsed light sources as well as reinjection of vessels utilizing a glycerin solution are the most effective ways of managing this problem (see Table 155.4)[53].

Fig. 155.12 Telangiectatic matting (neoangiogenesis). This developed after vein surgery at the site of the scar.

METHODS TO MINIMIZE POSTSCLEROTHERAPY HYPERPIGMENTATION
PRETREATMENT PLANNING
• Evaluate for a hypercoagulable state in patients with a history of venous thrombosis (see Table 105.9) • Avoid treating patients with known defects in iron transport (e.g. hemochromatosis) • Avoid concomitant use of minocycline, aspirin or NSAIDs
TREATMENT TECHNIQUE
• Eliminate high-pressure reflux before treating smaller vessels • Select a sclerosant with the least inflammatory effects • Use a sclerosant concentration appropriate for the vessel size (see Table 155.4) • Minimize intravascular pressure by elevating the leg during treatment • Direct treatment at the deepest site in a telangiectatic cluster • Minimize risk of vessel rupture (e.g. by slow injection) • Avoid excessive syringe pressure
POST-TREATMENT CARE
• Apply compression immediately after treatment • Remove postsclerotherapy thrombi as early as possible

Table 155.8 Methods to minimize postsclerotherapy hyperpigmentation. NSAIDs, nonsteroidal anti-inflammatory drugs.

Ulceration

Cutaneous necrosis may occur with any sclerosing agent (although the authors have never seen this with glycerin). It may be the result of extravasation of a sclerosing agent into the perivascular tissues, which is especially common with the use of hypertonic saline and non-foamed sodium tetradecyl sulfate that is >1% in concentration (Fig. 155.13); injection into a dermal arteriole or an arteriovenous anastomosis; reactive vasospasm of such a vessel; or excessive cutaneous pressure created by compression techniques[54]. If there is extravasation of hypertonic saline into the perivascular tissue, infiltration of the area with normal saline may dilute the sclerosant. A hemorrhagic bulla may form over the area within 12–24 hours and later progress to an ulcer. If a porcelain-white area appears within the skin immediately after injection, this indicates arteriole injection or spasm. To reduce the likelihood of ulceration, the physician may rub a small amount of 2% nitroglycerin ointment into the area until a reactive hyperemia is seen. Since most ulcerations are less than 4 mm in diameter, second intention healing usually results in an acceptable scar. Larger ulcerations may be excised (as early as possible) and closed for faster healing and a smaller scar. Application of topical antibiotic ointments (e.g. mupirocin) and hydrocolloid or hydrophilic dressings may reduce the pain associated with the ulcer and speed the rate of healing[55].

Fig. 155.13 Postsclerotherapy necrotic ulceration due to extravasation of hypertonic saline. *Courtesy, Neil Sadick, MD*

Systemic Allergic Reaction

True allergic reactions following sclerotherapy treatments are extremely rare. Delayed hypersensitivity reactions, which may be urticarial or morbilliform in nature, can occur from 8 to 16 hours after treatment. Type I immediate reactions varying from urticaria to bronchospasm to anaphylaxis eventuating in cardiovascular collapse have been rarely reported. Intrinsically, only hypertonic saline has no potential to act as an allergen. However, the presence of additives such as benzoate or lidocaine may lead to the development of hypersensitivity reactions.

Sodium tetradecyl sulfate has a surprisingly low allergic potential (< 0.01%). The most commonly reported hypersensitivity reactions are morbilliform eruptions developing 30–90 minutes after injection[56]. Reactions to polidocanol are similarly rare (<0.01%). Both urticarial and morbilliform reactions have been reported, as well as a rare anaphylaxis-related fatality[56].

Antihistamines and oral corticosteroids (e.g. prednisone 40–60 mg/day for 7–10 days) can be used for the milder reactions, whereas intravenous corticosteroids and subcutaneous epinephrine are often required for more serious reactions.

Arterial Injection

The most feared complication in sclerotherapy is inadvertent injection into an artery. Arterial injection of a sclerosing agent produces a sludge embolus that obstructs small arteries as well as the microcirculation. The most common location for an arterial injection to occur is the popliteal fossa, when attempting to inject the small saphenous vein. After an intra-arterial injection, the patient usually notes immediate pain, but not always. A dusky cyanotic hue and pallor in the distribution of the injected artery usually occurs within a few minutes to several hours. Arterial pulsations in the posterior tibial or dorsalis pedis are not usually affected. Sloughing of superficial tissues may result in significant scarring or may even require amputation[57].

Arterial injection is a true sclerotherapy emergency. Immediate intervention has been advocated, but has never been proven to affect outcome. Procaine (1%), administered via periarterial infiltration, forms a complex with sodium tetradecyl sulfate, rendering it inactive; however, procaine is not effective for polidocanol. Cooling of the limb to minimize tissue anoxia, followed by immediate heparinization for 7–10 days and administration of intravenous dextran (10%, 500 mg daily) for 3 days is recommended. Thrombolysis and the utilization of long-term vasodilator therapy (e.g. calcium channel blockers) should be considered.

Miscellaneous Complications

Localized urticaria following injection is common and most likely related to mast cell degranulation and cytokine release. No treatment is indicated, although pretreatment with an H_1 antihistamine or immediate application of a class I ultra-potent topical corticosteroid may ameliorate the erythema, if bothersome to the patient. Compression-related problems such as ulcers, pressure bullae, contact dermatitis and folliculitis may be minimized by adherence to appropriate compression guidelines[44].

Nerve damage may occur secondary to direct injection of sclerosant or as a result of perivascular inflammation around nerve sheaths. The saphenous and sural veins of the inner leg and foot are high-risk locations and special care should be taken when injecting these locations. The utilization of NSAIDs may shorten the duration of symptoms[58].

Superficial thrombophlebitis develops 1–3 weeks after injection, presenting as tender erythematous induration of the injected vein. This complication is observed less often if compression is maintained for an adequate period of time following sclerotherapy. When superficial thrombophlebitis occurs, the thrombus should be evacuated and adequate compression, frequent ambulation, and aspirin or an NSAID instituted. The concomitant presence of deep vein thrombosis (DVT) must be considered[44], and a search for underlying causes for thrombophlebitis other than the sclerotherapy procedure may be warranted.

AMBULATORY PHLEBECTOMY

Ambulatory phlebectomy is an in-office surgical procedure designed for the complete removal of diseased venous segments by means of hook avulsion of the targeted vessel, developed in the 1950s by the Swiss dermatologist Robert Mueller[59]. All superficial veins, with the exception of the groin termination of the GSV, may be easily avulsed utilizing this technique. Large veins – in particular, well-demarcated branches of the GSV, SSV or perforators – can be avulsed through microstab incisions[59,60].

Preoperative Considerations

Doppler and duplex ultrasound evaluations are necessary in order to confirm the competence of the saphenofemoral and saphenopopliteal junctions, as well as that of the deep venous system[61]. The varicose veins to be removed are outlined with an indelible pen with the patient in a standing position. Marking of appropriate venous segments is the most important aspect of this procedure because it allows rapid isolation of desired venous segments to be removed. Because of potential shift of the vein up to 3 to 4 cm when moving from an upright vertical to a transverse horizontal position, the patient is then asked to lie in the operative position and confirmation of venous position by either Doppler or transepidermal illumination (Vein-Lite® or Venoscope®) with separate marking over the veins is performed. This double-marking technique has been found to be helpful in determining positional shift[62,63] (Fig. 155.14).

Anesthesia and Intraoperative Materials for Ambulatory Phlebectomy

Tumescent anesthesia has several advantages when performing ambulatory phlebectomy. These include: rapid anesthesia of an extensive segment of diseased vein; compression of the vein, allowing it to be removed through a 2–3 mm incision; and easier location of the vein owing to the temporary swelling and firmness of the soft tissues which press the vein against the skin. In addition, tumescent anesthesia reduces blood loss, diminishes bruising, eliminates multiple needle

Fig. 155.14 Double-marking technique for ambulatory phlebectomy. Outlining of the varicose veins while the patient is standing (black ink) and then while the patient is lying down in the operative position (green ink) utilizing transillumination.

sticks, and produces greater postoperative comfort. Most commonly, tumescent anesthesia comprised of 0.05% lidocaine with 1 : 1 000 000 epinephrine is employed (see Table 156.2)[64,65].

Instrumentation for the ambulatory phlebectomy procedure involves the use of a number of varied hook devices, which come in small, medium and large diameters (sizes 2 to 4) from various manufacturers. The ideal hook should have a comfortable grip to prevent fatigue and a sharp harpoon to catch the adventitia of the vein[59,66] (Fig.155.15).

Ambulatory Phlebectomy Technique

Microincisions measuring from 1 to 3 mm in length and parallel to the long axis of the extremity are made with an 18- or 16-gauge hypodermic needle or a #11 blade. The microincisions are made vertically and should follow the relaxed skin tension lines. The interval between incisions varies between 3 and 5 cm according to the patient and type of vein being removed. Separation of the vein from the surrounding adventitia may be accomplished by utilizing an iris scissor or blunt probe and should follow the tension lines of Langer[63].

The vein is then exteriorized utilizing the phlebectomy hook. Next, the exteriorized vein is clamped proximally and distally and pushed or pulled, depending on operator preference, from each end until the vein is avulsed (Fig. 155.16). A gentle rotation or rolling motion of the clamp in the same and/or opposite direction pulls and frees the vein from its secondary connective tissue sheath. The process is repeated at 3–5 cm intervals along the entire length of the marked vein, until the entire diseased vein has been removed or adequate interruption has been made[67,68].

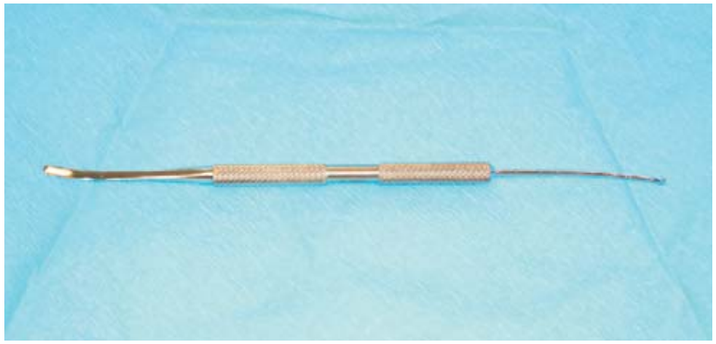

Fig. 155.15 Phlebectomy hook. A classic Mueller type of hook at one end and a Varaday dissector at the other end ("Goldman hook").

Special care is required in difficult anatomic zones such as the knees, ankles and feet. The "hooking" should be gentle and slow. Once the vein is hooked, it should come out easily. If it is difficult and if removal of the vein requires a lot of traction, it is possible that a fascial strand structure has been hooked. The hook should be removed, reintroduced, and another attempt should be made. Ambitious "hooking" in the ankle and foot region should be avoided in order to eliminate complications such as swelling, hematomas and nerve damage. Phlebectomy in the pretibial area should also be performed very carefully because many lymphatic vessels are normally located in this area. Aggressive damage to lymphatic vessels can result in a lymphocele. Phlebectomy in the popliteal area should be particularly gentle since the skin of the back of the knee is very soft and microincisions are very easily enlarged by overzealous "hooking".

Postoperative Considerations for Ambulatory Phlebectomy

Postoperatively, the area is cleansed and antibiotic ointment applied to the puncture sites. The leg is then wrapped, first with cotton gauze and then with an elastic compression dressing extending from the dorsum of the foot to the groin. This dressing helps to promote hemostasis, reduces swelling of the foot and leg, and speeds wound healing. The bandage is removed in 24 hours and a class II (30–40 mmHg) graduated compression stocking is then worn continuously for 1 week (24/7) and after that during working hours for 2–4 weeks.

Walking while the patient is still in the office is encouraged, to help mold the pressure wrap and uncover any persistent bleeding. This allows the patient to quickly return to a normal gait, thus generating normal function of the calf muscle pump, minimizing potential thromboembolic complications.

Complications of Ambulatory Phlebectomy

Ambulatory phlebectomy satisfactorily removes varicosities of different sizes, and it results in a series of micro-scars that are cosmetically pleasing to the patient and dermatologic surgeon. The entire procedure can be performed under local anesthesia on an ambulatory basis in all but the most severe and complicated cases[69,70]. Complications may be divided according to the system that has been affected (Table 155.9). The most common complication is the development of a lymphocele, which presents as a firm subcutaneous nodule. Simple aspiration with a 22-gauge needle of yellow–clear lymphatic fluid should be performed every few days, with immediate compression over the drained area. Resolution typically occurs after two to three drainage sessions.

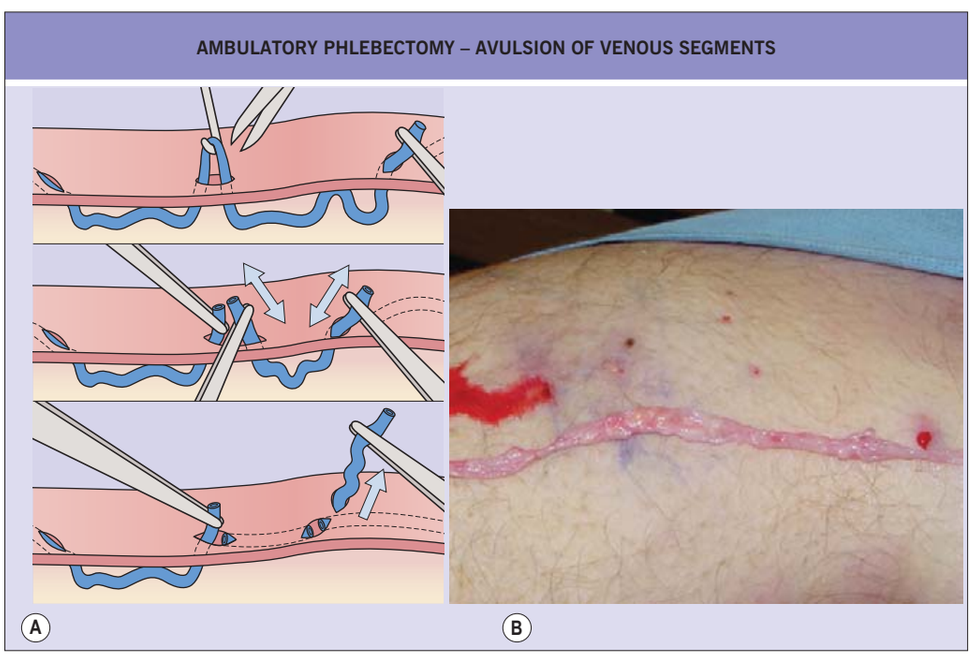

Fig. 155.16 Ambulatory phlebectomy – avulsion of venous segments. A After pinpoint incisions, the dilated vein is hooked at several sites and incised; the venous segments are clamped both proximally and distally and then pulled and rolled to free them from their attachments to the surrounding adventitia. **B** Avulsed segment of the varicose vein next to pinpoint incisions. *A, Redrawn from Ricci S, Georgiev M, Goldman MP. Ambulatory Phlebectomy: A Practical Guide to Stab Avulsion Variectomey, 2nd edn. London: Taylor & Francis, 2005.*

COMPLICATIONS OF AMBULATORY PHLEBECTOMY
ANESTHETIC COMPLICATIONS
Allergic reaction
VASCULAR COMPLICATIONS
Bleeding, seroma Superficial thrombophlebitis Deep venous thrombosis/pulmonary embolus Telangiectatic matting Lymphocele Persistent edema
NEUROLOGIC COMPLICATIONS
Nerve damage around the ankle Hypesthesia (temporary) Dysesthesia (temporary or permanent) Traumatic neuroma
CUTANEOUS COMPLICATIONS (OTHER THAN VASCULAR SEQUELAE)
Skin necrosis (blistering, ulceration) related to the procedure or compression bandage Postoperative infection (e.g. cellulitis) Hypo- or hyperpigmentation of the microincision Dimpling Tattooing with marking pen ink Talc granuloma

Fig. 155.17 Endovenous laser ablation. Insertion of the diode laser fiber (815 nm) into the great saphenous vein under duplex ultrasonography guidance. *Courtesy, Neil Sadick, MD.*

ENDOVENOUS LASER AND RADIOFREQUENCY ABLATION

Endovenous technologies, which incorporate either laser- or RF-induced thermal damage, have replaced saphenofemoral/saphenopopliteal ligation and stripping procedures. Lasers can be used by placing an optic fiber endoluminally and utilizing various lasers (810, 940, 980, 1064, 1320, 1440, 1500 nm). Typically, the laser fiber or the catheter containing the insulated electrode is inserted into the GSV either under duplex guidance (Fig. 155.17) or through exteriorization of the GSV via a variation of ambulatory phlebectomy.

Mechanism of Action

With the 810–1064 nm lasers, the heat energy created by heating of blood causes thermal destruction and contraction of the vein wall[71–75]. The 1320, 1440 and 1500 nm lasers operate by targeting water, not blood, so that the vein wall absorbs most of the energy and results in a more controlled, uniform heating. Also, because tissue water is the target of these lasers (1320, 1440, 1500 nm), the presence of red blood cells (and hemoglobin) within the vessels is not required as it is for the other lasers with shorter wavelengths.

In endovenous RF closure (ablation), a catheter containing an insulated electrode delivers RF energy-generated heat directly to the vein wall, resulting in endothelial denudation, collagen fibril shortening and thickening, and contraction of the vein, with subsequent vein occlusion.

Comparative Clinical Results

In a comparison of GSVs treated endovenously with the 810 nm diode laser (n = 36), the 1320 nm Nd:YAG laser (n = 42), or RF closure (n = 174), a 95% success rate and no adverse effects were observed with the latter two modalities[76]. Treatment with the 810 nm diode laser led to an 86% success rate and adverse effects in 53% of patients. The most common adverse effects were significant pain with ambulation for 2–3 days and significant bruising. The 1320 nm Nd:YAG laser was also associated with fewer side effects when compared to the 940 nm diode laser for endovenous treatment of the GSV[77]; treatment-related pain and the use of analgesics were significantly less.

In a group of 24 patients treated with the 1320 nm Nd:YAG laser, and then observed for 6 to 12 months, 100% efficacy was reported without evidence of vessel perforation[78]. With over 10 years of clinical follow-up, one author (MG) has observed a 10% recurrence rate of GSV incompetence, while the other author (RW) has not observed any recurrences.

Surgical Technique

The patient is evaluated clinically in both a standing and a supine position and double-marked, as with ambulatory phlebectomy (see above). Tumescent anesthesia is then delivered along the course of the vein to be treated.

Endovenous laser ablation (EVLA)

A laser fiber with a 600 micron diameter is inserted into the vein. When the laser is on, a helium–neon (He:Ne) aiming beam is continuously illuminated, helping to ensure that the laser fiber is in the superficial venous system. Correct placement of the laser fiber tip 20 cm distal to the SFJ is confirmed via direct visualization with duplex ultrasonography and secondarily by laser fiber measurement and viewing of the He:Ne aiming beam through the skin. Utilization of an automated catheter drawback system, set at 1 mm/second, provides uniform heating of the vessel.

Endovenous laser treatment is stopped when the distal tip of the fiber reaches a point 1 to 3 cm from the vein entry site. This can also be confirmed with direct visualization of the aiming beam through the skin or more typically by duplex ultrasonography. Total laser application time is then recorded. Repeat duplex ultrasonography of the saphenous vein is performed to confirm successful treatment. If unsuccessful, it is typically difficult to retreat the vein at this point and a subsequent session may be required. After the terminal portion of the vein (immediately adjacent to the point of entry) has been treated, the catheter/sheath and fiber are withdrawn and manual pressure is applied to the puncture site. If clinically indicated, ambulatory phlebectomy and/or sclerotherapy of tributaries are then performed (see below).

Endovenous radiofrequency (RF) closure (ablation)

Heat generated by RF energy is also used to occlude veins. An endovenous catheter-based approach is employed in which a specially designed insulated electrode that is 7 cm in length delivers the RF energy-induced heat directly to the vein wall (VNUS Closure™ procedure). The vein is treated in fixed 7 cm segments.

In the most recent design modification (VNUS ClosureFAST™ catheter; Fig 155.18), the endovenous catheter is held in place while energy heats it to the specified temperature of 120°C. Because the temperature increase remains localized to a narrow rim around the active electrode, this process is believed to be relatively safe. Proper use of the RF device does require close, stable contact between the active electrode and the vessel wall and it requires tumescent anesthesia to allow contact of the vein wall with the central 7 cm metal core. By strictly controlling the temperature, boiling, vaporization and carbonization of the tissue

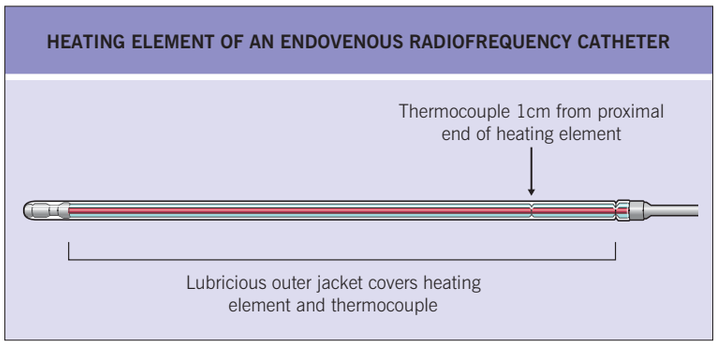

Fig. 155.18 Heating element of an endovenous radiofrequency catheter (VNUS ClosureFAST™ catheter). After heating to 120°C, 7 cm segments of the varicose vein are treated.

is avoided. Ten years of clinical experience suggest that the RF endovenous procedure is highly effective at occluding saphenous veins and abolishing reflux. Of note, it is associated with a rapid reduction in lower extremity pain, fatigue, aching and CEAP clinical class.

General anesthesia is the most significant risk factor for developing DVT and the failure to use tumescent local anesthesia is the major risk factor for developing skin burns. In our clinical practices, tumescent anesthesia is always used in non-sedated patients and no skin injuries or thrombi have been observed to date. Some bruising from the tumescent anesthesia can occur and anesthesia of the treated portion of the leg may persist for 8 to 24 hours. It is advisable to limit endovenous RF treatment to the GSV segment above the knee in order to minimize the risk of paresthesias due to injury to the saphenous nerve. Collectively, two of our patients have developed focal numbness (4 cm in diameter) on the lower medial leg, which resolved within 6 months.

Combination with Ambulatory Phlebectomy

Based upon our experience in over 500 patients, the combination of endovenous ablation techniques with ambulatory phlebectomy can be very effective in eliminating saphenous reflux along with varicose tributaries. As outlined above, following the double-marking of varicose veins, the area surrounding the GSV and distal tributaries to be treated is infiltrated with tumescent anesthesia. Usually 20 cm inferior to the SFJ (mid medial thigh), the GSV can be accessed through a 2–3 mm incision. The GSV is then treated with the endovenous ablation technique (RF or laser) and the varicose tributaries are removed via standard ambulatory phlebectomy technique. A ligature is placed on the exposed portion of the GSV.

At the conclusion of the surgery, the entire leg is wrapped in a short stretch compression bandage over copious padding that has been placed on the sites where the varicose veins were removed via phlebectomy. The tiny incisions are not sutured as these open 2 mm incisions allow for drainage of the anesthetic solution over the next 24 hours. This helps to minimize swelling and bruising. The patient is seen the next day, the compression bandage is removed, and the leg is examined for hematoma formation or other adverse sequelae. All incisions are covered with antibacterial ointment and a Band-Aid® and a class II (30–40 mmHg) graduated stocking is applied. The latter is left on 24 hours a day for 1 week (as compared to 3 days if only RF ablation is performed).

The major complications of endovenous laser or RF treatment plus ambulatory phlebectomy are temporary pigmentation over the treated vein, temporary nerve damage, hematoma, localized superficial thrombophlebitis, and temporary lymphocele. All other adverse effects are extremely rare. For a complete discussion, see reference 79.

CONCLUSIONS

Sclerotherapy, ambulatory phlebectomy, and endovenous vein ablation techniques are excellent techniques for both cosmetic and symptomatic venous disease[80]. Although they all require some additional training and knowledge of superficial venous anatomy and physiology, remarkable medical and cosmetic improvements in the sensation and appearance of legs can be achieved. Thus, the dermatologic surgeon now has the ability to treat all forms of varicose and telangiectatic leg veins from the largest to the smallest.

Chapter Contents

Description of techniques 2528
Instrumentation 2529
Postoperative care 2532
Complications 2533

Synonyms: ■ Liposculpture ■ Tumescent liposuction ■ Lipoplasty ■ Fat suction

Key features

- Liposuction is indicated for spot reduction of localized adiposities
- Liposuction is ideally suited for healthy patients who are near their ideal body weight
- The tumescent local anesthetic technique is the safest approach to anesthesia for liposuction
- Liposuction consists of destruction and aspiration of lipocytes through criss-crossing tunnels in the subcutaneous tissue
- Non-cosmetic uses for liposuction include treatment of hyperhidrosis and lipomas as well as breast reduction

INTRODUCTION AND BACKGROUND

Liposuction is an effective method for surgically improving localized areas of excess subcutaneous fat. Modern liposuction is performed using dilute local anesthesia via the tumescent technique, together with small cannulas connected to a vacuum aspirator. Liposuction can be safely performed in an office setting, and conservative techniques ensure few complications. Substantial amounts of fat can be aspirated with minimal blood loss and excellent aesthetic results.

The history of modern liposuction traces its roots back to 1975, when Drs Arpad and Giorgio Fischer developed hollow cannulas attached to a suction source which, when placed subcutaneously, were capable of aspirating subcutaneous fat[1]. In Paris, Illouz developed updated equipment for performing liposuction. He also promoted the concept of a "wet technique" in which saline was injected into the fat before suctioning[2]. Pierre Fournier further refined the techniques of liposuction, teaching many physicians around the world. He popularized the idea of postoperative compression to help support the suctioned tissue following surgery[3].

American dermatologic surgeons including Lawrence Field, Rhoda Narins, Samuel Stegman, William Coleman and Bruce Chrisman learned the technique early on and advanced the field[4]. Jeffrey Klein developed the tumescent technique in 1985, which allowed liposuction under local anesthesia with minimal blood loss, vastly increasing the safety of the procedure[5–8]. The American Academy of Dermatology and the American Society for Dermatologic Surgery promoted education in liposuction in the Core Surgical Curriculum in Dermatology as early as 1987[9]. Importantly, the American Academy of Dermatology was the first specialty organization to approve and publish clinical guidelines of care for liposuction in 1991, which have been subsequently updated[10].

Liposuction is currently among the most common cosmetic procedures performed in the US. A conservative estimate is that there are now between 300 000 and 400 000 procedures performed in the US annually[11].

INDICATIONS AND CONTRAINDICATIONS

Tumescent liposuction is indicated for improving localized adiposities. Certain areas of subcutaneous fat are often not fully responsive to diet and exercise alone[12], and excessive dieting or caloric expenditure as a means of improving body shape can have serious health consequences.

Most liposuction patients complain that the troublesome areas of fat excess "run in the family". Furthermore, these areas of excess subcutaneous fat can be resistant to caloric restriction or exercise. Tumescent liposuction is a procedure that is able to specifically target these localized areas of excess subcutaneous fat. Thus, it is a complement to, not a replacement for, diet and exercise.

Liposuction can be used to treat localized areas of adiposities from the face to the ankles. Common areas improved by liposuction include the abdomen (Fig. 156.1) and inner and outer thighs on women (Fig. 156.2). Other sites include the neck and jowls (Fig. 156.3), male and female breasts, back, flanks (Fig. 156.4), hips (see Fig. 156.2), buttocks, upper arms, knees (Fig. 156.5), calves and ankles. Genetic predisposition determines the location of excess fat storage in each individual.

Non-cosmetic indications for liposuction include aspiration of lipomas[13–15] (Table 156.1). Liposuction is an effective technique for debulking these benign tumors, and, often, large lipomas can be successfully treated, leaving only minimal scars. Liposuction is also an excellent alternative for treating axillary hyperhidrosis by destroying eccrine and apocrine glands (Fig 156.6)[15].

Contraindications are outlined in Table 156.2.

PREOPERATIVE HISTORY AND CONSIDERATIONS

As with any other medical or surgical consultation, a pertinent review of the past medical history, medications and allergies is essential. The review of systems should be comprehensive enough to exclude any underlying abnormalities which would preclude or modify surgery. Social and psychiatric histories may reveal details which would make the patient an inappropriate candidate for cosmetic surgery.

The physical examination for liposuction should be performed with patients completely unclothed in the body areas of concern to them. Tight-fitting undergarments can distort fatty bulges and mask contours. The patient should be examined standing up so that the full effects of gravity are apparent. Physical examination consists of both observation and palpation. Grasping the skin and fatty tissues using a "pinch test" technique will reveal the thickness of areas of adiposity as well as the firmness of underlying fat. The surgeon should look for asymmetries, scars, hernias, musculoskeletal abnormalities, signs of previous liposuction, dimples, skin laxity, and overlying cutaneous lesions. During this examination, it is useful to describe any abnormalities detected to the patient. This will add to the patient's understanding and can show him or her what may or may not be able to be achieved through liposuction. It is important to accurately describe individual body parts in words that the patient will understand, pointing them out as reinforcement. Colloquialisms may lead to confusion about which anatomic part is being discussed. A diagram of typical anatomic sites for liposuction may prove helpful (Fig. 156.7). Also, it is important to remember that the patient has a different vantage point looking down at the areas of adiposity; photography may be helpful during this

consultation period to be sure that the physician and patient are in agreement.

The presence of obesity and/or poor muscle tone are warning signs that the patient may not be an appropriate candidate for liposuction. A small minority of physicians perform liposuction on obese patients. These large-volume extractions are intrinsically more dangerous, especially when performed on patients who are poor-risk candidates for anesthesia due to their obesity. The notion that atherosclerotic heart disease and diabetes mellitus can be improved with liposuction is still unproven[15].

Some patients are relatively slender except for the abdominal area. Upon physical examination, it is obvious that most of their fat is stored around the viscera. Palpation of the abdominal tissues reveals a firm underlying musculature with very little fat on the pinch test. These patients not only are poor candidates for liposuction but also are at increased risk for cardiovascular disease. This physical finding is most common in men but can be seen in women as well. The surgeon should have a frank discussion with these patients about the implications of the genetic tendency to store fat around the viscera and recommend consultation with an internist and appropriate nutritional experts.

In general, operating on over 10% of the body increases liposuction risks. Guidelines of care published by dermatologic organizations recommend fat extractions of less than 4500–5000 ml[16,17]. This volume should be considered as an uppermost limit; beyond this, profound fluid shifts may occur, resulting in cardiovascular compromise. Many experienced liposuction surgeons rarely, if ever, remove anywhere near 5000 ml in a single session. Larger extractions also necessitate larger infiltrations of local anesthetics. When the tumescent technique is employed, guidelines of care recommend not exceeding a lidocaine dose of 55 mg/kg[10,17,18]. In slender patients, this should probably be adjusted down to 45 mg/kg. These dose limits also restrict the number of areas that can be treated during a single liposuction procedure.

If, in the physician's judgment, it is risky to treat all of the areas that concern the patient, serial liposuction should be recommended. These separate surgeries can be spaced days or months apart, according to the patient's preference.

If there are any questions about the patient's medical status, consultation with the appropriate specialist should be planned well ahead of the anticipated date of liposuction to be certain that the patient is healthy enough to undergo surgery. In some cases, psychiatric evaluation or consultation with the patient's current psychiatrist may be needed to help the surgeon determine if the patient is an appropriate candidate.

NON-COSMETIC INDICATIONS FOR LIPOSUCTION
Lipomas
Familial multiple lipomatosis
Adiposis dolorosa (Dercum disease)
Gynecomastia
Pseudogynecomastia
Insulin-induced lipohypertrophy
"Buffalo hump" due to Cushing's syndrome
HIV/ART-associated lipodystrophy
Axillary bromhidrosis
Axillary hyperhidrosis (Fig. 156.6)
Undermining flaps
Aspirating hematomas
Lymphedema following axillary lymphadenectomy

Table 156.1 Non-cosmetic indications for liposuction. ART, antiretroviral therapy.

CONTRAINDICATIONS TO TUMESCENT LIPOSUCTION
ABSOLUTE
Severe obesity
Individuals seeking liposuction as a weight-loss procedure
Body dysmorphic syndrome
Untreated psychiatric illness
Excessive scarring in the areas to be improved
RELATIVE
Moderate obesity
Poor wound healing (including Ehlers–Danlos syndrome)
Hypertrophic or keloidal scarring
Coagulation or bleeding disorders
Allergy to lidocaine
Adverse reaction to epinephrine (e.g. tachycardia)
Significant medical illnesses
Unstable psychiatric illnesses

Table 156.2 Contraindications to tumescent liposuction.

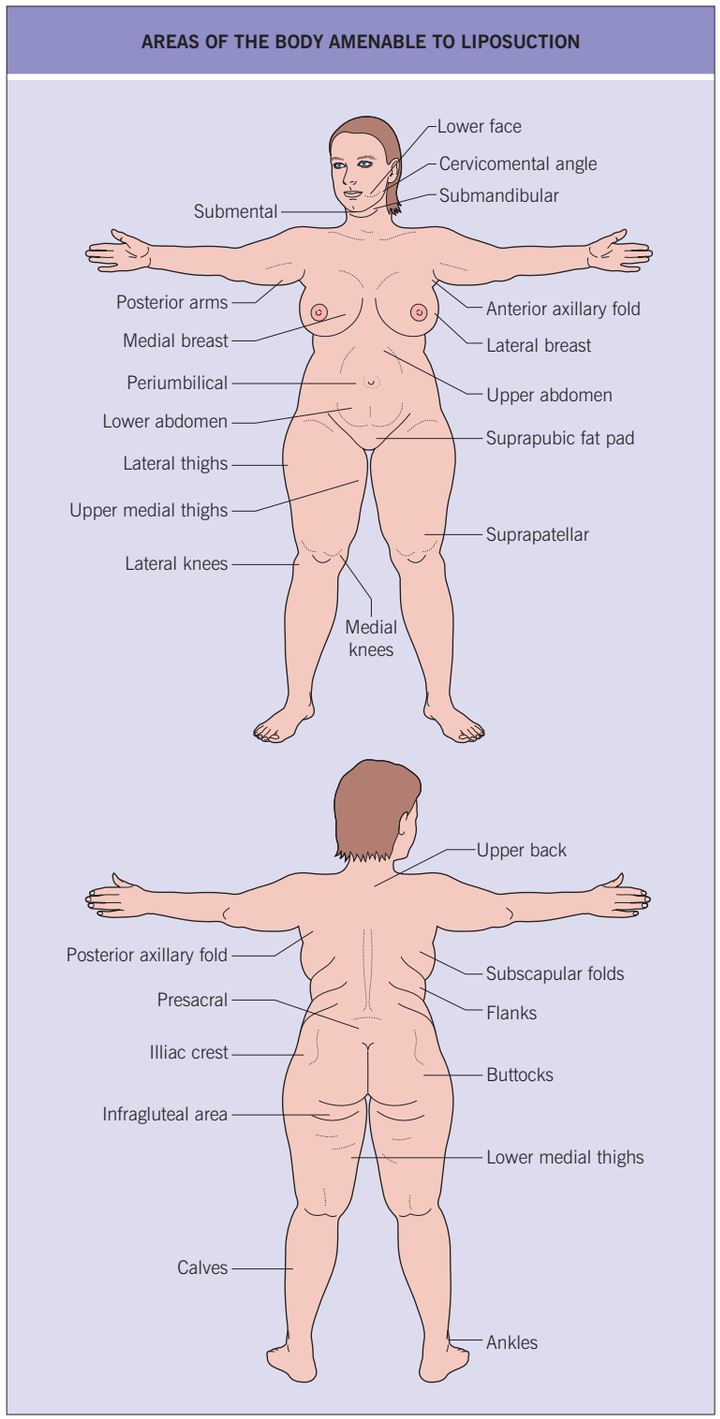

Fig. 156.7 Areas of the body amenable to liposuction.

THE PREOPERATIVE VISIT

A carefully planned preoperative visit, usually scheduled two or more weeks prior to the actual date of the surgery, is an important component of risk management for liposuction surgery. Generally, a complete blood count, a prothrombin time, a partial thromboplastin time, and a general chemistry panel are obtained. Some physicians also perform a urinalysis and tests for infectious diseases such as viral hepatitis and HIV. One reason for scheduling the preoperative visit 2 weeks or so before the surgery is to allow time for the laboratory evaluation to be completed so that the physician can detect any abnormalities. Also, occasionally laboratory tests are incorrectly performed and must be repeated.

Detailed pre- and postoperative instructions should be provided to the patient during this visit. Preoperative instructions should include a list of over-the-counter medications that should be avoided. Aspirin,

nonsteroidal anti-inflammatory drugs (e.g. ibuprofen), vitamin E, fish oil and alcohol are common anticoagulants that patients should carefully avoid preoperatively. Herbal remedies may also have anticoagulant activity (see Table 133.3). It is wise to discontinue all herbal remedies for 2 weeks preoperatively to be certain. Drugs that affect the hepatic cytochrome P450 system should be discontinued if possible (see later). Patients should also be counseled about proper nutrition. Trying to lose weight rapidly or eating excessively should both be discouraged. Many patients benefit from nutritional counseling on a pre- and postoperative basis.

DESCRIPTION OF TECHNIQUES

Tumescent Anesthesia

The technique of using tumescent local anesthesia for liposuction was developed by the dermatologist Dr Jeffrey Klein. In 1987, Klein published his technique for the infiltration of a dilute solution of lidocaine with epinephrine (adrenaline) into fat[5]. The technique allowed for liposuction to be performed totally by local anesthesia as well as significantly reducing bleeding. The previous common complications of seroma formation and hematomas became uncommon[7]. Bruising was also minimized. The procedure has been proven to be remarkably safe.

Klein demonstrated that dilute concentrations of lidocaine with epinephrine are not absorbed to the same degree as commercially available solutions of lidocaine, even when the total dose is equal. He confirmed that tumescent liposuction performed using only dilute solutions of lidocaine with epinephrine safely allowed dosages of up to 35 mg of lidocaine per kilogram of body weight[6]. This advance allowed larger amounts of fat to be removed with only local anesthesia.

A typical tumescent anesthetic formulation is shown in Table 156.3. Dilute solutions of lidocaine with epinephrine provide safe local anesthesia with excellent vasoconstriction. Sodium bicarbonate is added to adjust the solution to a more physiologic pH closer to the pKa of lidocaine[8]. The combination of dilute solutions of lidocaine with the vasoconstrictive effects of epinephrine ensures minimal systemic absorption of lidocaine[19].

The tumescent technique provides a number of advantages (Table 156.4). There is complete regional anesthesia without the need for nerve blocks. Local anesthesia persists for up to 24 hours after tumescent liposuction, reducing the needs for postoperative analgesia[8]. There is minimal blood loss, and the extensive vasoconstriction produced by the dilute epinephrine reduces the volume of whole blood for each liter of pure fat removed by liposuction to less than 12 ml[7,8]. Because there is little blood loss, there is minimal postoperative bruising and risk of hematoma formation. Patients can thus return to their normal lives quickly, with a rapid postoperative recovery. Improved aesthetic results are also seen with tumescent liposuction because smaller cannulas can be used, reducing irregularities of the skin[20].

An important advantage is the decrease in anesthetic risk observed with tumescent anesthesia for liposuction, as compared to intravenous or general anesthesia[11,21–23]. Systemic anesthesia is associated with a significant risk of serious complications[24] and converting liposuction to a procedure performed with local anesthesia increases safety. More recent research has indicated that the maximum safe dosage of lidocaine, when used with the tumescent technique for liposuction, is 55 mg/kg[17,18]. Klein recommends an upper limit of 45 mg/kg for thinner individuals[20].

Fresh tumescent anesthetic solution must be correctly and carefully prepared prior to each procedure by a trained healthcare professional. Personnel must be familiar with the importance of careful records and drug preparation. All individuals who prepare tumescent anesthesia must be familiar with sterile technique. Normal saline should be used as the vehicle for the dilute solutions of lidocaine with epinephrine. Standardization is important in preparing tumescent anesthesia, i.e. by using the same commercial solutions of lidocaine as well as individual 1 ml ampules of 1 : 1000 epinephrine. This minimizes confusion and limits risk.

The concentrations of lidocaine and epinephrine can be varied depending on the anatomic site. The standard formula of 0.05% lidocaine with 1 : 1 000 000 epinephrine plus sodium bicarbonate works well for most areas of the body (see Table 156.3). Occasionally, individual "hot spots" such as the periumbilical area or breast require increased concentrations of lidocaine, up to 0.1%, in the tumescent anesthetic solution.

Proper infiltration of tumescent anesthesia is important. The skin is initially cleansed with an antimicrobial scrub to reduce bacterial contamination. Insertion sites for the infiltration needles are anesthetized with small wheals of 1% lidocaine with epinephrine. While waiting for the intradermal anesthetic to provide cutaneous anesthesia, the prepared tumescent anesthetic bags are suspended from an intravenous pole. Commercially available infiltration tubing is connected to the bag containing the tumescent anesthesia, and the tubing is connected to a peristaltic pump. Air is removed from the infiltration tubing and a small-gauge, blunt-tipped infiltrating cannula or spinal needle is connected to the tubing. Warming the anesthetic solution to body temperature prior to infiltration may reduce the pain of infiltration.

The anesthesia may initially be infiltrated into the subcutaneous fat using 20-gauge spinal needles. More extensive infiltration is then performed using a blunt-tipped side-port 16–18-gauge infiltrating cannula (Fig. 156.8). These small-diameter infiltration cannulas can be passed through slit incisions created in the skin with a #15c or #11 blade; other authors recommend using 1–2 mm punch biopsy instruments to create openings for cannula insertion. A peristaltic pump (Fig. 156.9) facilitates infiltration of the anesthetic fluid into subcutaneous fat. The cannula must be repositioned from site to site to ensure an even distribution of the tumescent anesthetic. Moving the needle while infiltrating is associated with increased pain; consequently, a gentle, slow infiltration technique is preferred. In certain areas where the patient

TYPICAL TUMESCENT ANESTHETIC FORMULATION (LIDOCAINE 0.05%, EPINEPHRINE 1 : 1 000 000)
50 ml 1% plain lidocaine (500 mg)
1 ml 1 : 1000 epinephrine from ampule (1 mg)
10 ml sodium bicarbonate (of an 8.4% $NaHCO_3$ solution)
1 liter normal saline (0.9% NaCl solution)

Table 156.3 Typical tumescent anesthetic formulation (lidocaine 0.05%, epinephrine 1 : 1 000 000).

ADVANTAGES OF TUMESCENT LIPOSUCTION
Complete regional anesthesia without the need for nerve blocks
Local anesthesia persists for up to 24 hours, reducing the need for postoperative analgesia
Minimizes blood loss
Minimal postoperative bruising
Rapid postoperative recovery
Smaller cannulas can be used, reducing irregularities of the skin
Decreased anesthetic risk compared to intravenous or general anesthesia

EXAMPLES OF POSSIBLE DRUG INTERACTIONS WITH LIDOCAINE	
Drug	**Comments**
Anesthetics	
• Bupivacaine	Lidocaine is displaced from plasma binding proteins by bupivacaine
• Halothane plus nitrous oxide	Increase in lidocaine plasma concentration (lowers maximum safe dose)
Amiodarone	Sinus bradycardia, seizures; competes with lidocaine for binding to CYP3A4
Beta-blockers	Decrease in systemic clearance (including hepatic); propranolol and lidocaine both metabolized by CYP2D isoenzymes
Cocaine	Increased risk of seizures and death
Phenytoin	Additive cardiac depressant effects
Benzodiazepines, e.g. alprazolam, diazepam, flurazepam, midazolam	Inhibit lidocaine metabolism
Azole and triazole anti-fungals, e.g. ketoconazole, itraconazole, fluconazole	Inhibit lidocaine metabolism

Table 156.5 Examples of possible drug interactions with lidocaine. *Adapted from Klein JA. Lidocaine toxicity and drug interactions. In: Tumescent Technique. Tumescent Anesthesia and Microcannular Liposuction. St. Louis: Mosby, 2000.*

has more sensitivity, infiltration must be done more slowly than in others. Sensitive areas include the inner thighs, breasts, upper abdomen, and periumbilical area. An infiltration speed of 100 ml/min is usually tolerated quite well.

Once sufficient tumescent anesthesia has been infiltrated, the surgeon should wait at least 15 minutes to allow for maximal vasoconstrictive effect of the epinephrine before beginning surgery. An overlying blanching of the skin which is cool to the touch will gradually appear. The patient is then properly "tumesced" and ready for aspiration of adipose tissue. Allowing even up to an hour between conclusion of infiltration and the onset of suctioning may result in fat removal with less infranate.

Drug interactions must be considered when using any form of anesthesia[25]. Caution must be exercised with patients on β-blockers, especially those that are non-selective. Although rapid absorption of epinephrine may result in hypertension and bradycardia in these patients, when the epinephrine is absorbed slowly, as in the case of tumescent anesthesia, there is minimal risk[20]. In other words, while tumescent liposuction performed in the setting of β-blockade has not led to any evidence of hypertension, one must still be cautious in these patients[20]. Of note, patients on propranolol may also experience chest pain following subcutaneous injection of concentrated epinephrine.

Tumescent anesthesia and certain sedatives may have significant interactions[25]. Some sedatives (such as diazepam and flurazepam) can reduce the rate of lidocaine metabolism after liposuction. Lidocaine is rapidly eliminated by hepatic metabolism, but a number of drugs can inhibit lidocaine metabolism, and there is a long list of medications associated with an increase in lidocaine toxicity[20]. Examples of such drugs are provided in Table 156.5. These medications should be avoided or discontinued prior to liposuction, or the total dose of lidocaine should be reduced.

Bupivacaine should not be substituted for lidocaine, as the former is contraindicated for tumescent liposuction[26]. Bupivacaine cardiac toxicity can be subtle and is not preceded by convulsions. Lidocaine usually gives warning signs of CNS toxicity long before the onset of dangerous cardiotoxic effects. Furthermore, the cardiotoxicity of bupivacaine is often unresponsive to resuscitation efforts. Prilocaine has been used in Europe for tumescent anesthesia instead of lidocaine[27]. However, rigorous comparative studies have not been performed, and, in the US, prilocaine does not have Food and Drug Administration (FDA) approval to be marketed for local anesthesia for dermatologic surgical procedures. Prilocaine can also produce methemoglobinemia (see Ch. 143)[27]. Ropivacaine is a new long-acting amide local anesthetic that resembles bupivacaine[28]. Insufficient data are available at this time to compare dilute tumescent solutions of ropivacaine and dilute solutions of lidocaine in terms of safety and efficacy.

Surgical Technique

The patient is taken to the preparative area, where he or she changes into a surgical gown. Vital signs are taken, including blood pressure and heart rate. Photographs should then be taken if they have not been done preoperatively. These should include multiple views of the sites of surgery with the areas completely unclothed so as not to distort the areas to be treated.

Next, the surgeon marks the patient, who is standing to allow for the effects of gravity. Marking can be done according to the custom of the surgeon, but should be devised so that the subsequent distortion by local anesthetic infiltration will not obscure the various thicknesses of the adiposity. One way to mark is to use concentric circles, as in a topographic map (see Fig. 156.8). Pluses or minuses can be drawn on the patient to indicate areas where more or less fat should be removed. Existing dimples and dents should also be outlined for later identification during surgery so that they can be avoided.

The previously marked patient is then positioned on the surgical table. If significant sedation is to be employed, intravenous lines and monitoring devices such as pulse oximeters and cardiac monitors can be utilized. While patients undergoing the tumescent technique usually require very little ancillary sedation, most patients do appreciate presedation with mild oral sedatives such as lorazepam. Those who are pain-sensitive, or afraid they will be so, can receive minor additional sedation such as 25 mg of meperidine intramuscularly, a dose which does not impair protective reflexes.

Once the patient is relaxed, tumescent infiltration can begin (see Fig. 156.8). Slow infiltration is much less painful than rapid infiltration. Peristaltic pumps can be regulated for a comfortable rate of infiltration, e.g. 100 ml/min (see Fig 156.9). Of note, physicians who use rapid infiltration techniques also typically employ more aggressive forms of systemic anesthesia. Furthermore, rapid infiltration is associated with an increased potential for abdominal perforation. This is compounded by the fact that deeply sedated patients are not awake enough to complain of discomfort associated with muscular penetration. Another disadvantage of moderate and deep sedation is that because of concerns about total anesthesia time, there is usually little or no delay between infiltration of the tumescent fluid and the beginning of the procedure. Significant vasoconstriction from the infiltration of the tumescent fluid does not occur for at least 10–15 minutes after infiltration.

INSTRUMENTATION

The basic instruments required for liposuction are suction cannulas, tubing and an aspirator[29]. Each surgeon must make individual decisions about instrumentation based on personal style and experience. However, liposuction can be performed using many different types of cannulas and aspirators. The number of holes arranged along the shaft of the

Fig. 156.10 A variety of small-diameter liposuction cannulas. The presence of two or more holes increases the flow of fat through the instrument, and while longer cannulas allow the surgeon to work from fewer skin insertion sites, shorter cannulas are easier to control. *Courtesy, WP Coleman III, MD.*

Fig. 156.11 Reciprocating powered cannula. This reciprocating powered cannula has a 3 mm to-and-fro motion. *From Coleman WP III, Katz B, Bruck M, et al. The efficacy of powered liposuction. Dermatol Surg. 2001;27:735–8.*

cannula is probably unimportant, although two or more holes increase the flow of fat through the instrument. The most important parameter for choosing cannulas is size: the smallest possible cannula should be employed. Smaller-diameter cannulas (≤3 mm) create smaller tunnels through the fat and achieve smoother results (Fig. 156.10). Also smaller-diameter cannulas penetrate the fat more easily and create less tissue trauma. Longer cannulas allow the surgeon to work from fewer skin insertion sites, leaving fewer scars. However, depending on the shape and location of the adiposity, better access often requires multiple incision sites. Shorter cannulas are easier to control as they pass through subcutaneous tissue. The tiny incisions required for insertion of 3 mm cannulas leave nearly invisible scars in most patients, but can be an issue if the patient has a tendency towards keloids or hyperpigmentation.

Over the years, a number of instruments have been developed with the goal of making liposuction easier for the surgeon to perform. For example, ultrasound was introduced in the 1990s, but has largely been abandoned by most dermatologic surgeons. *External* ultrasound involves preoperative use of an ultrasonic probe over the areas to be suctioned, in an attempt to liquefy or loosen the fat. However, double-blind studies found no benefit to this approach[30]. *Internal* ultrasonic liposuction employs a probe or cannula with an ultrasonic vibration at the tip. These instruments have been shown to liquefy fat prior to suction. Although this makes subsequent liposuction easier, studies have shown increased potential for seromas and burns[31]. Ultrasonic probes pass through the tissue like a "hot knife through butter" and do not provide the usual tactile feedback from tissue resistance that manual cannulas do. This makes it difficult for the surgeon to determine in exactly what level of the fat the cannula is located and increases the possibility of intra-abdominal perforation or "end hits" to the opposing dermis.

Another innovation in liposuction technology has been powered liposuction. These instruments feature a motorized cannula, which moves in a "to-and-fro" motion, from 800 to 10 000 repetitions per minute (Fig. 156.11). The short motorized strokes vary from 2 to 12 mm, according to the instrument, and allow the surgeon to precisely sculpt

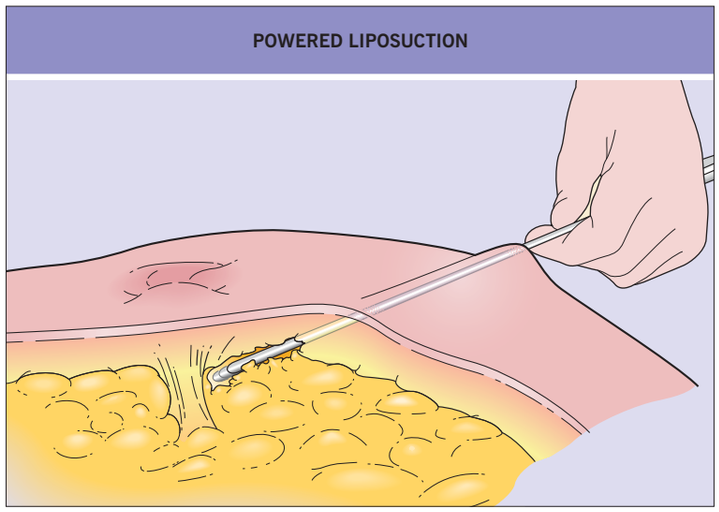

Fig. 156.12 Powered liposuction. Using powered liposuction to more precisely sculpt small areas of fat around the umbilicus.

small areas of excess fat (Fig. 156.12). Powered liposuction instruments also allow easier penetration of fat, when compared to manual cannulas, but retain the feel of tissue resistance[32]. The key to properly using this technology is to move the cannula slowly and allow the motorized motion to work efficiently. Studies have shown that powered liposuction increases the fat aspirated (per minute) by 30% or more[32]. There have been no significant complications reported with the use of this approach, although some early users described increased problems with seromas. This was probably due to the incidental radial movement of these instruments which enlarges the subcutaneous tissue tunnel. Thus, a 4 mm cannula might have the effect of a 5 or 6 mm cannula in the tissue. Therefore, 2 or 3 mm powered liposuction cannulas are preferable and usually avoid problems with seromas.

"Laser-assisted liposuction" is the latest "buzz word" in liposuction technology. These devices are designed to be placed subcutaneously during liposuction in order to generate heat. However, to date, there are no good studies confirming their efficacy. In fact, one study demonstrated no difference in clinical results between laser liposuction and manual liposuction[33]. Representatives from laser companies claim increased skin tightening, but this has not been validated. Diode and Nd:YAG laser liposuction devices are available from several manufacturers in a variety of wavelengths. As of this writing, there is no consensus as to what is the ideal wavelength for laser liposuction. Internal radiofrequency devices for liposuction are being researched as well. The major risk of both lasers and radiofrequency devices for liposuction is dermal burns and dents in the superficial fat. Laser liposuction also takes more time to perform and increases costs. With many devices, manual liposuction must also be performed after use of the laser device. It is unclear at the current time if this technology will overcome these drawbacks.

Water jets have been used for years in general surgery to remove tissue, and liposuction devices based on this technology have been available for the last few years. Powerful streams of concentrated water are directed into the fat layer to create tunnels. Proponents of this approach claim that this reduces the volume of tumescent fluid required. This makes very little sense since the anesthetic effects of the fluid take several minutes to take effect, long after the tunnel is already bored by the water jet.

All of these alternative instruments for liposuction claim less physical force is needed and bleeding is reduced. In fact, manual liposuction requires very little physical strength and bleeding is minimal, so the benefits are suspect. Some companies tend to exaggerate the advantages of their liposuction instruments, and the costs of many of these are staggering, especially when one takes into account the required disposables. Each surgeon needs to determine which instrument he or she is most comfortable with and stick with the approach that is most successful. Each instrument has a steep learning curve. Excellent liposuction results can be achieved with any of these devices, but only if the surgeon is experienced and well trained.

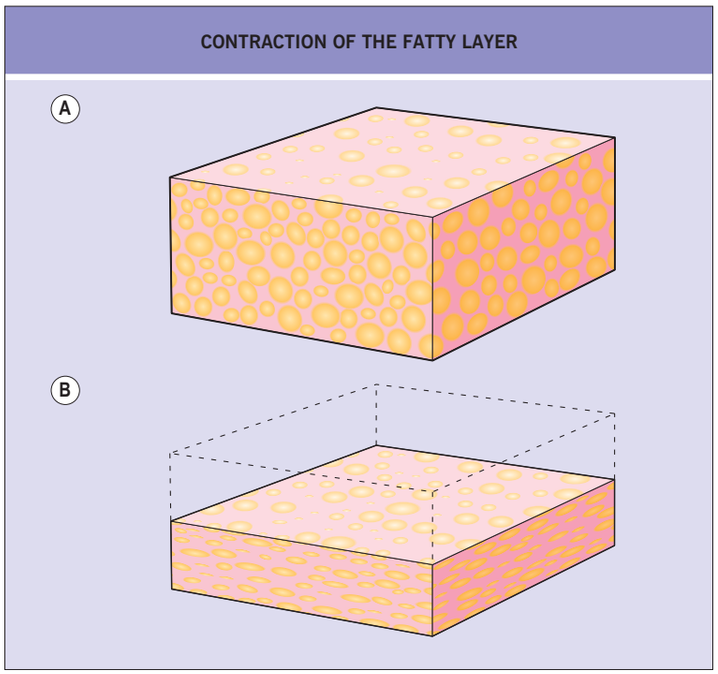

Fig. 156.13 Contraction of the fatty layer. A Immediately after liposuction, the fatty layer resembles a wet sponge. With subsequent subtraction of the fat cells, the thickness of the subcutaneous tissue decreases. **B** Much like a dry sponge, the subcutaneous tissue has compacted.

Fig. 156.14 Bloodless liposuction aspirate. Typical, nearly bloodless liposuction aspirate using the tumescent technique. *Courtesy, WP Coleman III, MD.*

Liposuction is based on the technique of criss-crossing tunnels (from multiple insertion sites) through the subcutaneous tissue. Each area to be suctioned should be tunneled from at least two different directions, but often three or four are more effective. For instance, in the lower abdomen, suctioning can be performed from multiple pubic and flank incisions. Multiple small tunnels ultimately provide the smoothest contraction of the overlying skin and the most thorough removal of fat. Subsequent contraction of the fatty layer occurs much like a wet sponge contracting into a dry one (Fig. 156.13).

The liposuction aspirate should be yellow or slightly blood-tinged (Fig. 156.14). A red aspirate in the suction tubing indicates excessive bleeding and the surgeon should immediately move on to a different tunnel. The surgeon's dominant hand acts as the piston moving the instrument in and out of the tissue, while the non-dominant hand pulls, presses and squeezes the skin to facilitate penetration of the cannula and provides important tactile information about the thickness of the underlying fat. The final surgical endpoint should be a skin thickness in the suctioned areas which is similar to that of the surrounding non-treated skin.

Surgeons may safely aspirate several liters of fat during one operative session. The guidelines of care published by the American Academy of Dermatology recommend a maximum fat removal of 4500 ml[10]. However, it is in fact very unusual to extract 4500 ml of fat in a patient who is healthy and near their ideal body weight. Larger fat extractions imply an obese patient. In these cases, consideration should be given to proper dieting and exercise before the procedure. In larger patients, serial liposuction may be performed at different times to avoid exceeding the recommended volume extraction.

Cannula insertion sites are routinely left open rather than being sutured closed. Experience has shown that closing insertion sites with sutures leads to a greater increase in postoperative edema as well as greater bruising. Closing cannula insertion sites also decreases tissue drainage out of the subcutaneous space. Klein[20] has advocated the use of small adits: 1–2 mm openings made with a common punch biopsy instrument. These are more likely to stay open during the initial postoperative period than are "stab"-type incisions with a #11 or #15c blade, but may leave worse scars.

VARIATIONS/UNUSUAL SITUATIONS

Guidelines of care published by dermatologic organizations recommend that liposuction be performed as a solo procedure and not combined with other techniques[10,16]. However, there are cases in which liposuction is employed as a fundamental part of a combined surgical technique. For instance, in face lifting, liposuction of the neck and pre-tunneling of the cheeks are often performed prior to flap dissection and advancement. In patients in whom the neck alone is to be treated, liposuction may be combined with submental resection and platysmal plication, with each surgical component contributing to the final result. Cook[34] has also described a technique of CO_2 laser desiccation of fat over the platysma and subdermally, as an added component to improve neck tightening. External light-based and radiofrequency devices may also be combined with neck liposuction to improve skin contraction.

In other anatomic sites, skin excision may be combined with liposuction. Where there is a significant abdominal panniculus, a suprapubic incision may be used to remove excess skin in conjunction with liposuction of the rest of the abdomen. In most patients, however, even with a large panniculus, this is unnecessary because of the significant skin retraction that occurs after liposuction of the lower abdomen. Experience shows that most patients who consult for abdominoplasty achieve excellent results with liposuction alone. Abdominoplasty is a much more aggressive procedure, with significantly increased morbidity and mortality. The final scar is significant and often unattractive as well.

Liposuction is an excellent option for improvement of pseudogynecomastia in men. In these patients, the breast enlargement results primarily from excess fat rather than the excess glandular tissue present in true gynecomastia. Multiple insertion sites are used, usually one in the anterior axilla, one submammary and one presternal. Aggressive liposuction is required to remove what is usually thicker and more fibrotic fat. Powered or ultrasonic liposuction is sometimes useful in tunneling through this more fibrous fat. In patients with true gynecomastia, the glandular tissue must also be removed, usually through a submammary or periareolar incision, to obtain sufficient flattening of the breast. Liposuction can also be used for moderate breast reduction in females. The best results are seen in women with soft breasts. Very firm glandular breasts of younger patients do not respond well to liposuction, nor do ptotic breasts, which may sag more after the procedure. These patients are better served with excisional breast reduction.

Liposuction of the arms can provide excellent recontouring, particularly in women. Excessive fatty accumulations over the triceps make the arms unattractively large. Liposuction here is typically performed through incisions in the axilla and superior to the elbow. Relatively aggressive liposuction is usually indicated in order to achieve sufficient tightening of the overlying skin. In rare cases, a Z-plasty skin excision on the posterior surface of the arm is required to further tighten up loose skin. Liposuction should not be carried over to the ventral surface of the arms by anyone other than the most experienced surgeon, as this is an area prone to irregularities.

NON-COSMETIC LIPOSUCTION

Liposuction may also be used for non-cosmetic indications (see Table 156.1). The chief among these is hyperhidrosis[13]. Patients with excessive eccrine and apocrine axillary sweating are often miserable, with constantly wet armpits which can ruin clothing. When prescription antiperspirants and iontophoresis are ineffective, the three major options comprise botulinum toxin injections, sympathectomy and liposuction. Botulinum toxin injections are efficient and require no recovery, but must be repeated every 6–12 months. Since 100 units or more of botulinum A are typically required, this treatment is quite expensive and therefore not economically feasible for many individuals. Sympathectomy is also expensive and has the potential for associated morbidity. Liposuction of the axilla is a permanent option preferred by many patients and physicians. For axillary hyperhidrosis, subdermal liposuction is used aggressively to remove as much of the subdermal fat in the axilla as possible (see Fig. 156.6). Since many of the eccrine and apocrine sweat glands reside in the upper fat, sweating is diminished postoperatively. The goal is to make the patient sweat normally, but not to become anhidrotic. Preoperatively, a starch iodine test identifies the areas of greatest sweating (see Ch. 39). The axilla is most efficiently approached from inferior and superior insertion sites. The liposuction should be aggressive enough to create some subdermal fibrosis, in an attempt to eliminate as many dermal eccrine and apocrine structures as possible. Patients are usually comfortable within 24 hours and able to resume normal activities within 2–3 days. Often, there is immediate diminished sweating with a rebound 2–3 weeks postoperatively, followed by a gradual decrease in sweating as fibrosis develops in the subdermal region.

Larger lipomas can also be removed efficiently using liposuction. The goal here is to flatten out the lipoma but not necessarily remove the entire lesion. A portion of it should be submitted for pathologic examination. The advantage of liposuction over standard excisional surgery is that a much smaller scar results. As with any adiposity, the lipoma is tunneled in a criss-cross direction until flat. Subsequent healing and fibrosis usually flattens the remaining lipoma further, resulting in a normal contour. It is difficult to suction smaller lipomas and these are best removed through direct puncture excision. However, lipomas the size of a golf ball or larger are excellent candidates for liposuction. Since the entire lesion is not surgically removed, lipomas treated in this fashion may be more likely to recur; the patient should be made aware of this possibility. Liposuction should be reserved for lesions that are in cosmetically sensitive areas or those of a size which would necessitate a larger incision.

POSTOPERATIVE CARE

Following liposuction, patients are usually quite comfortable during the initial postoperative period. It is important to remind patients, well before the procedure takes place, that they are going to have significant drainage for the first day following liposuction surgery. Barrier protection is recommended for car seats, furniture and bed linens. Large plastic trash bags or plastic-lined absorbent drapes (such as Chux blue pads) may be used for this function.

The patient's insertion sites may be coated with petrolatum or antibiotic ointment prior to application of absorbent materials. Modern absorbent pads are capable of absorbing significant amounts of drainage from the insertion sites. Alternatively, diapers or sanitary napkins may be used to absorb the drainage.

Following the application of sufficient amounts and layers of absorbent pads (held in place with tape), a compression garment or a compression bandage is fitted. Numerous styles of postoperative liposuction compression garments are available (Fig. 156.15). Postoperative compression minimizes bruising and aids in drainage. Gravitational drainage minimizes postoperative edema. It is important to use firm compression immediately following tumescent liposuction[35]. Mild compression is sufficient after 3 or 4 days. Mild compression assists patients in feeling more secure and decreases pain by restricting movement of the treated tissue. Many patients actually enjoy the comfort and feel of a compression garment due to the soreness sometimes associated with movement in the immediate postoperative period.

Fig. 156.15 Examples of liposuction compression garments. *Courtesy, Miller Medical, Tuscon, AZ.*

Infections have occasionally been reported with liposuction and oral antibiotics may provide prophylaxis against more serious infections. Of note, lidocaine is bactericidal[36]. This may explain, in part, the relatively few infections seen with tumescent liposuction. Careful local wound care and cleanliness are essential in producing a good liposuction outcome.

Patients are asked to change the absorptive pads and bandages the morning after their liposuction. Most individuals will experience continued drainage for 24–48 hours following liposuction. Patients are advised to take their first shower with the absorbent bandages and the tape in place, as the shower assists in the removal of the tape. Patients then follow the shower by reapplying antibiotic ointment, absorbent pads where needed, and their compression garment on top of the pads.

Most patients can return to work within 48 hours following their liposuction. It is important to ask the patients to ambulate regularly beginning the day after surgery. This movement encourages further drainage as well as remodeling of the subcutaneous tissue. Movement has the additional benefit of increasing lymphatic drainage through intermittent pumping action of skeletal muscles. Light exercise may begin 24 hours after surgery, but patients should be advised to start at 30–50% of their normal routine. Exercise keeps the patient from losing lean body mass during the postoperative period.

All patients are given a set of written postoperative liposuction instructions including important phone numbers should the patient need to contact the doctor. These postoperative instructions remind the patient that swelling and firmness beneath the skin and a reduced sensation in the skin are common. This will usually resolve over the first 3 to 4 weeks after the surgery. The postoperative instructions also remind patients that the final results are not seen until 6–12 months following the liposuction.

Patients return for their first postoperative appointment 1 day following liposuction. This visit is important to check for problems and reassure the patient. The next visit usually occurs at 3 weeks. The areas that have been treated are examined and palpated by the liposuction surgeon and the patient's progress is assessed. It is often necessary to remind patients that improvement from liposuction is a gradual process. This postoperative visit is a good opportunity for encouraging patients to exercise, maintain an active and healthy lifestyle, and eat a reasonable diet. Many liposuction surgeons recognize that liposuction may be used to "jump-start" a patient's conversion to a healthy lifestyle and an improved dietary pattern. Patients are seen for 3-month and 6-month follow-up visits. If touch-ups are required, it is wise to wait 1 year before proceeding, to be certain that the final results have been achieved. Secondary liposuctions that are performed too early in the postoperative period may lead to skin irregularities.

POSSIBLE COMPLICATIONS OF LIPOSUCTION
Infection (e.g. bacterial, atypical mycobacterial)
Hematomas
Seromas
Skin indentations
Erosions, ulcerations
Thrombophlebitis (non-septic, septic)
Pulmonary embolism
Abdominal perforation

Table 156.6 Possible complications of liposuction.

COMPLICATIONS

Complications of liposuction (Table 156.6) must be differentiated from common sequelae. After liposuction, it is common to have prolonged swelling, areas of numbness, bruising, and red incisions. Infections, hematomas and seromas are uncommon complications that require medical attention, but can usually be resolved rapidly.

Serious complications of liposuction are closely linked to the type of sedation employed. There have been a number of deaths from liposuction in patients who had moderate or deep sedation[11,21,37]. The authors are not aware of any deaths from liposuction in patients who underwent the procedure with true tumescent local anesthesia[38].

Thrombophlebitis and pulmonary embolism postoperatively are surgical complications associated with non-ambulatory patients and prolonged procedures under general anesthesia. This is also true for liposuction. An advantage of the tumescent local anesthetic technique is that patients are ambulatory immediately after surgery, thus minimizing the risks of this potential problem. Patients who are obese and inactive are more at risk for the development of this complication; this should be taken into consideration during the preoperative evaluation.

Abdominal perforation is one of the leading causes of liposuction deaths[39]. This is exclusively a complication of liposuction under general anesthesia[22]. Deeply sedated patients have decreased muscle tone and are unable to alert the physician to the pain of penetration of the liposuction cannula. Occult abdominal hernias may contribute to this complication. The treating physician should be aware of any abdominal scars and palpate for hernias during the preoperative visit.

General anesthesia also increases risks of respiratory failure and cardiac death[24]. Besides the direct effect of the systemic anesthesia, fluid overload may contribute to these problems. Anesthesiologists or anesthetists who are not accustomed to working with patients who have been infiltrated with tumescent anesthetic fluids may inadvertently overhydrate the patient with additional intravenous fluids. A significant amount of the saline infused subcutaneously is absorbed systemically, automatically correcting for surgical fluid losses. No additional intravenous fluids are usually required. Compounding this problem is the recent discovery that intravenous fluid bags are typically overfilled by at least 10%, leading to further errors in calculating fluid replacement in liposuction[40].

The keys to avoiding complications in liposuction lie in proper patient selection, appropriate patient evaluation, monitoring according to the degree of sedation, good surgical technique, avoidance of excessive fat removal or overzealous additional simultaneous procedures, and adequate postoperative care.

ALTERNATIVE TRENDS

Liposuction is now a mature procedure and most patients obtain predictable results[41,42]. However, as with all cosmetic procedures, there is a general trend toward trying to accomplish similar results with less invasive techniques. Several *external* modalities are currently under investigation for the treatment of localized subcutaneous fat. Some of these treatments, such as mesotherapy, have been in existence for many years, but recently have garnered more interest; other technologies, such as external ultrasonic devices, external cryolipolysis, and low-level laser treatments, are relative newcomers to the field.

Mesotherapy, which was originally developed in the 1950s, has re-emerged as a treatment for localized adiposities. Most commonly, this technique involves the subcutaneous injection of a formulation containing phosphatidylcholine plus a detergent solvent that leads to the dissolution of fat cells[43]. Recent work has shown that the detergent solvent, usually deoxycholic acid, is more likely the active ingredient in this solution[44]. The injections are followed by a 1–2-month period of panniculitis which is associated with significant edema and discomfort. Unfortunately, the injections produce varying and unpredictable results. There is also a general lack of standardization of the injectable material as well as the technique of injection. Mesotherapy has led to complications such as scarring, ulcerations and mycobacterial infections[45]. Currently, in the US, mesotherapy does not have FDA clearance, and it is banned in Brazil and the UK due to concerns about its safety.

Several *external* light- and energy-based therapies are in use for the treatment of the appearance of subcutaneous fat and cellulite. For example, there is an external 635 nm diode laser (Zerona™; Erchonia) that theoretically reduces the size of subcutaneous fat by induction of a photochemical reaction which creates small pores in the adipocyte cell membrane; it is FDA-approved for external laser-assisted liposuction[46]. Patients must undergo at least six treatments (no greater than 72 hours apart) to achieve results. Patients are also asked to decrease their caloric intake and to drink extra water. There is no downtime from the procedure and no pain associated with treatments. However, results of these treatments have been variable and were not comparable to those achieved with liposuction surgery. The long-term results are also still in question. In addition, there is a device which combines intense pulsed light, suction and radiofrequency that is FDA-approved for the reduction of the appearance of cellulite (VelaSmooth™; VelaShape). Unfortunately, the results appear to be only transient and not very impressive.

As of the writing of this chapter, there are two *external* ultrasound devices that are being evaluated for localized fat reduction. One is a high-frequency ultrasound device (LipoSonix™; Medicis) that relies upon ultrasound-induced thermal destruction of adipocytes. This device is based on technology currently employed in the treatment of malignant tumors, in particular prostate cancer. The other is a non-thermal, external ultrasound device (Contour I™; UltraShape) that produces targeted cavitation of fat cells without producing significant heating; this allows the device to achieve lipolysis without destruction of blood vessels and nerves[47–49]. Although early reports seem promising, the results are clearly not comparable to liposuction.

Another interesting technology is cryolipolysis. This technology involves the targeted production of adipocyte apoptosis via thermal energy extraction (without damage to the epidermis). Porcine models have shown significant reduction in subcutaneous fat, but there is still a question regarding the possibility of sensory nerve injury[50–52]. In early clinical trials, modest, localized fat reduction has been achieved without significant complications.

Technology is constantly providing physicians with new ways to minimize localized adiposities. As we gain more experience with each new treatment and device, we can determine if it provides any benefit over existing technology. Regardless of what instrumentation is used, it is likely that liposuction will remain one of the most popular and predictable cosmetic procedures in the future.

Hair Restoration 157

Marc R Avram, Sharon A Keene, Dowling B Stough and Nicole E Rogers

INTRODUCTION

Hair frames our face and its length, color and style reflect our personality and how we perceive ourselves. The framing preserves a youthful facial appearance by shortening the face and returning the viewer's focus to the center of the face. While hair is one of the few physical characteristics we can easily control, the inability to correct hair loss can lead to concerns regarding appearance and psychological stress. In the case of androgenetic alopecia, some individuals accept the hair thinning as an unavoidable aging phenomenon whereas others actively seek medical and/or surgical treatment options.

HISTORICAL PERSPECTIVE

The first hair transplantation procedure for male pattern hair loss was successfully performed in the 1950s, using large punch autografts. Alternative techniques such as hair-bearing flaps and scalp reductions were also performed in an effort to redistribute hair or reduce the size of bald scalp. However, because of unsightly large "plugs", obvious scars due to continued hair loss and an unnatural orientation of hair, these techniques were largely abandoned in favor of follicular unit grafts. The latter are placed into small "recipient" sites (0.5–1 mm in diameter) produced by a blade or needle. Utilizing CO_2 lasers to create recipient sites was briefly investigated, but the associated thermal injury to surrounding skin led to poor wound healing and necrosis.

MALE AND FEMALE PATTERN HAIR LOSS (ANDROGENETIC ALOPECIA)

Pathogenesis

Miniaturization of terminal pigmented anagen hairs to fine hypopigmented vellus hairs is the hallmark of androgenetic alopecia (AGA; Fig. 157.1). Androgens, in particular testosterone and dihydrotestosterone (DHT), are required for the progressive reduction in hair follicle size with each cycle. The enzyme 5α-reductase, which is inhibited by drugs such as finasteride (see Fig. 69.6), converts testosterone to DHT. Multiple androgen-metabolizing enzymes actually reside within the hair follicle itself, providing an explanation for "end-organ" sensitivity (see Fig. 69.2).

Stem cells, which reside in the hair follicle bulge, are responsible for hair follicle cycling and when these cells are destroyed, there is loss of the follicle. In mice, combining bulge cells with neonatal dermal cells can give rise to a hair follicle as well as the sebaceous gland and epidermis[1]. Within the hair follicle, stem cells give rise to secondary germ cells with each hair cycle; the latter cells represent a progenitor population that is responsible for the production of the hair shaft during anagen (but undergoes apoptosis at the end of anagen)[2]. In a recent study comparing bald scalp with hair-bearing scalp in men, the stem cell population was maintained in the bald scalp but there was a marked reduction in progenitor cells, suggesting that study of this second population of cells could provide further insight into male pattern hair loss[3].

Population studies have pointed to a polygenic inheritance pattern, with both maternal and paternal genetic influences. Of the associated genes identified to date, the androgen receptor (AR) gene, present on the long arm of the X chromosome (Xq11–12), has been identified as a major determinant of hair loss in men[4–6]. Within exon 1 of the AR gene is the AR-CAG polymorphism, which refers to the number of repeat sequences of cytosine–adenine–guanine (CAG) present, with the normal range of CAG repeats being 13–40. The number of CAG repeats appears to *inversely* correlate with the degree of androgen sensitivity. Men with fewer CAG repeats have an increased risk of developing AGA and a higher cellular sensitivity to androgens; they also demonstrate a greater response to finasteride treatment[7]. In contrast, men with >40 repeats appear to be protected and have androgen insensitivity[8]. Variants in the AR gene may influence hair loss in women as well[8a].

The AR gene also has single nucleotide polymorphisms (rs6152; see Ch. 54) and Caucasian men with the A (adenine) allele have a low likelihood of developing AGA[9] while those with the G (guanine) allele have a 70% lifetime risk of developing AGA, which increases to >80% if there is a positive paternal family history. Other implicated genes include *EDA2R*, which encodes the ectodysplasin A2 receptor and is also found on the X chromosome (see Ch. 63)[10], as well as genes located at 20p11[11] and 3q26[12]. As more insight is gained into the interplay of these genes, it may be possible to diagnose androgenetic alopecia at an early age and predict who may benefit from therapy. Of note, it is important for patients to realize that while a family history of androgenetic alopecia provides useful information, it does not predict the rate and extent of hair loss in a particular individual.

Clinical Features

The diagnosis of androgenetic alopecia is usually straightforward, especially in men. This is based upon the characteristic pattern, the miniaturization of hairs and the lack of clinical inflammation (see Ch. 69). Occasionally, an unusual presentation requires clinicopathologic correlation. In women, the patterned alopecia may first become clinically apparent as a result of a superimposed telogen effluvium, perhaps following a febrile illness or birth of a child. These patients require an evaluation for telogen effluvium as outlined in Table 69.2 and possible hyperandrogenemia (e.g. serum free testosterone, DHEA-S), especially in the setting of hirsutism and/or recalcitrant acne vulgaris or any signs of virilization. Female pattern hair loss has to be distinguished from other causes of alopecia, including central centrifugal cicatricial alopecia, early lichen planopilaris or frontal fibrosing alopecia and diffuse alopecia areata; as a result, histologic evaluation may be required.

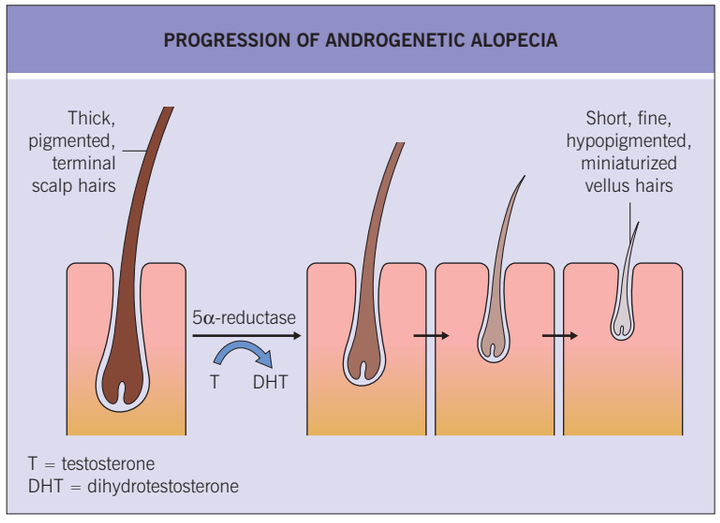

Fig. 157.1 Progression of androgenetic alopecia. Testosterone is metabolized into dihydrotestosterone (DHT) by the enzyme 5α-reductase and this conversion can occur within the hair follicle.

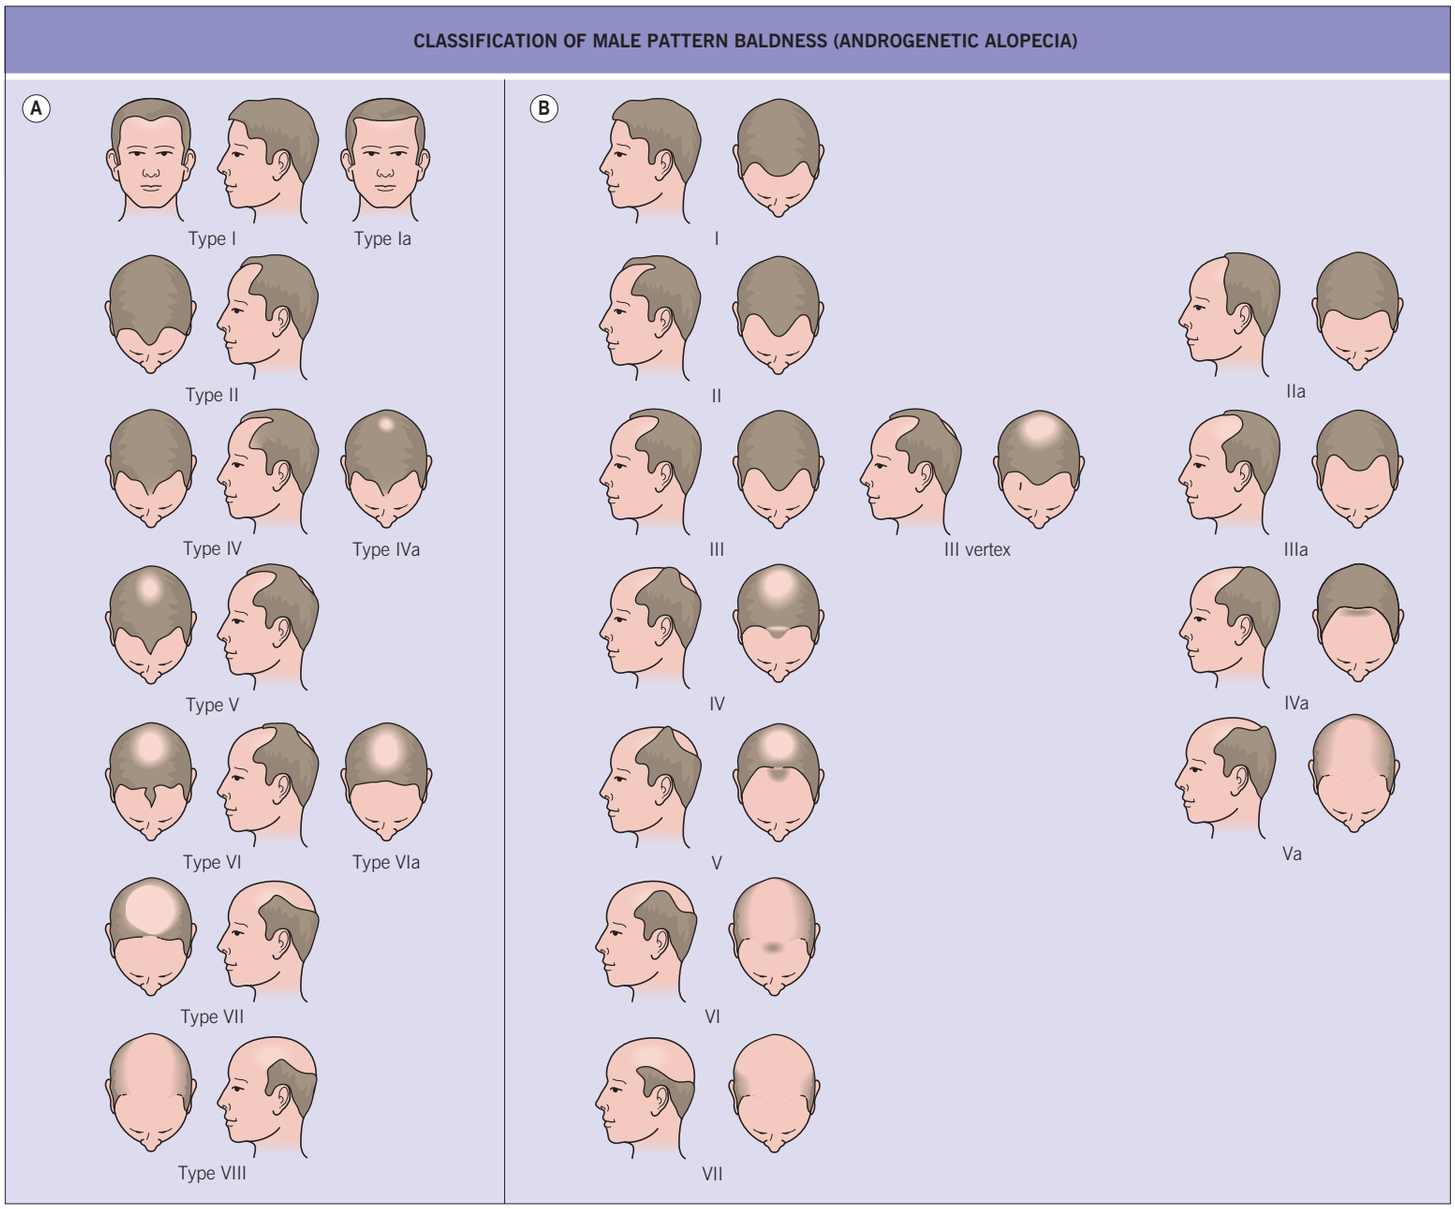

Fig. 157.2 Classification of male pattern baldness (androgenetic alopecia). A Hamilton grading scale. **B** Norwood grading scale.

There are grading systems for androgenetic alopecia that allow assessment of severity, progression and response to therapy. In men, the Norwood classification (Fig. 157.2) is used more often than the Hamilton classification system. Patterned hair loss in women is classically given a Ludwig grade (I, II or III; Fig. 157.3), even though the hair loss often has a Christmas tree pattern. Occasionally, the classification scheme for men is used.

Treatment (Other Than Transplant Surgery)

Medical therapies

Topical minoxidil (5% solution or foam) is FDA-approved for men[13] and the 2% solution is approved for both women and men. In general, the therapeutic effects are modest, but it can prove helpful as an adjunct to hair transplantation[14]. Although there is ongoing debate as to minoxidil's exact mechanism of action, it is thought to be related to its vasodilatory or angiogenic properties and perhaps its effect on potassium channels[15]. Increased proliferation of dermal papilla cells[16], an increase in hair caliber, and more time spent in the anagen phase have all been observed[17].

A possible explanation for the variability in therapeutic responses amongst individuals is differing levels of sulfotransferase activity (which catalyzes minoxidil sulfate) in their hair follicles[18]. Side effects of topical minoxidil include unwanted hypertrichosis of the cheeks or forearms, headache, ankle edema, and allergic or irritant contact dermatitis. With regard to the latter, propylene glycol in the vehicle is often the culprit and it has been removed from the 5% foam product (Rogaine®). Fetal hypertrichosis has also been reported and so use of topical minoxidil is discouraged in pregnant or breastfeeding women.

Finasteride inhibits 5α-reductase, which converts testosterone to DHT (see Fig. 69.6) and is present in hair follicles. Oral finasteride (1 mg daily) is FDA-approved for men with AGA. In a randomized trial of 1553 men given either finasteride 1 mg or placebo for 1 year (with a blinded extension for a second year), significantly greater hair counts in the balding vertex were observed in those receiving finasteride[19]. Five-year results from the same study demonstrated that hair growth peaked at 1–2 years, but hair counts remained well above baseline for 90% of patients[20]. Its use in combination with hair transplantation has yielded statistically greater hair counts 48 weeks after surgery in comparison to the control/placebo group[21]. Recent evidence suggests that finasteride may work better in men with higher levels of DHT (such as those in their mid-twenties)[22].

Patients are advised to allow at least 6 months before expecting to see a therapeutic effect. If they discontinue the finasteride, the AGA will return to its pre-treatment appearance. Because finasteride is metabolized extensively in the liver, it should be used with caution in

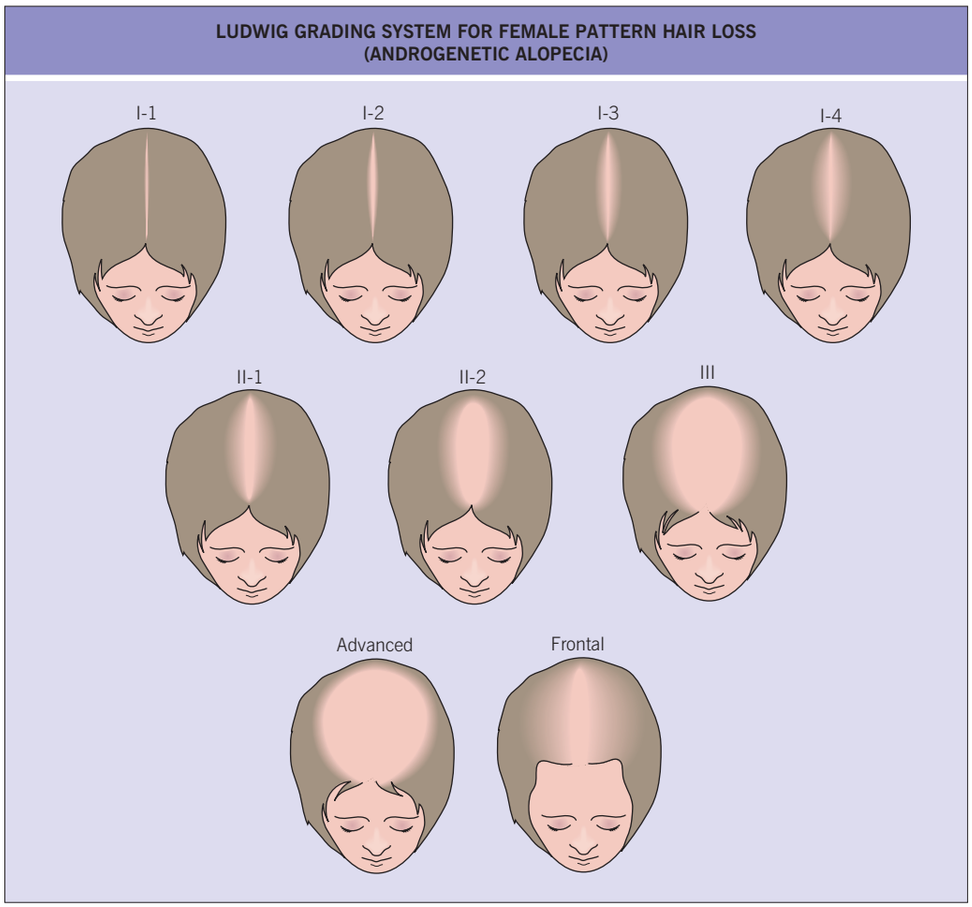

Fig. 157.3 Ludwig grading scale for female pattern hair loss (androgenetic alopecia).

patients who have known liver disease[23]. Finasteride also artificially lowers the serum prostate-specific antigen (PSA) level by approximately 50%[24]. Therefore, both the primary care physician and the patient need to be made aware of this effect. Although early data from prostate cancer trials suggested that finasteride might increase the histologic grade (i.e. severity) of prostate cancer[25], subsequent analyses suggested a detection bias[26].

Overall, the drug is well tolerated. Side effects that occur in less than 2% of men taking finasteride include decreased libido, erectile dysfunction and ejaculation disorder, compared with their occurrence in 1% of the placebo group. Rarer side effects include gynecomastia, breast tenderness and depression[27]. In a double-blind, placebo-controlled, multicenter trial in young men, no changes in spermatogenesis or semen production were observed[28]. However, there have been two reports of severe azoospermia leading to impaired fertility[29]. While the authors feel comfortable prescribing finasteride for men who are planning to have children, it should be discontinued if there are fertility issues, before embarking upon more invasive infertility treatments.

We encourage surgical candidates to stabilize their hair loss by taking finasteride for 6 to 12 months prior to hair transplantation. As stated previously, most men benefit from combination therapy (Fig. 157.4). Patients who report sexual dysfunction side effects should discontinue the medication and, after an interval of 1–2 weeks, try every second- or third-day dosing.

Finasteride is not FDA-approved for women with AGA, and at a dosage of 1 mg daily, no improvement was observed in clinical trials[30]. Of note, finasteride can cause feminization of the male fetus. In uncontrolled series of normoandrogenic women, higher doses of 2.5 mg and 5 mg daily led to improvement in hair density in 62% and 81% of patients, respectively[31,32]. If a decision is made to try higher-dose finasteride in a women with female pattern hair loss, counseling regarding fetal risk and its off-label use is essential.

Dutasteride differs slightly from finasteride in that it blocks both the type I and type II 5α-reductase isoenzymes (see Fig. 69.1). It has been used off-label at a dosage of 0.5 mg daily for AGA in men who did not respond to finasteride, and increased hair counts were observed in a randomized, placebo-controlled trial[33]. However, the drug's half-life is 5 weeks, compared with 6–8 hours for finasteride. Thus, side effects are longer-lasting (several months) and more difficult to reverse. In a double-blind, placebo-controlled trial, men who received oral dutasteride (0.5 mg daily) versus placebo for 1 year had significant decreases from baseline in sperm count: by 28.6% at 26 weeks, 25% at 52 weeks, and 23% at 24 weeks after the trial ended[34]. Sperm motility was also reduced at the latter time point. This potentially irreversible drop in sperm count and motility is an issue for men who still desire to have children.

Low-level light therapy

There has been emerging interest in the use of low-level light therapy (LLLT) for photo-biostimulation of hair growth. This was initially based upon the observation that laser hair removal can sometimes trigger paradoxical hair growth in the surrounding skin[35]. Based upon their approval by the FDA as a medical device (rather than a drug), multiple LLLT products are commercially available. The patient combs light (650–700 nm) through the hair two to three times per week with the expectation of hair growth. To date, there have been only two published studies examining the effects of LLLT on hair growth[36,37]. Although skepticism regarding the therapeutic effects of LLLT still exists, it may be an option for patients who cannot tolerate medical therapy or are not yet candidates for hair transplantation.

HAIR TRANSPLANTATION

Hair transplantation is a procedure performed in an outpatient setting under local anesthesia. It is based on the theory of donor dominance, i.e. terminal hair from the unaffected posterior scalp will continue its growth pattern even when transplanted to the balding frontal scalp[38]. Unfortunately, until the 1990s, hair transplants often had an unnatural appearance due to unsightly and obvious "plugs", sometimes likened to a "Barbie-doll" appearance. Over the past two decades, there has been a revolutionary movement away from 3–4 mm grafts containing 15–30

Fig. 157.4 Combination of hair transplantation and oral finasteride (1 mg daily). A 38-year-old man with male pattern hair loss (baseline). **B** Appearance following 1 year of finasteride plus hair transplantation (500 grafts).

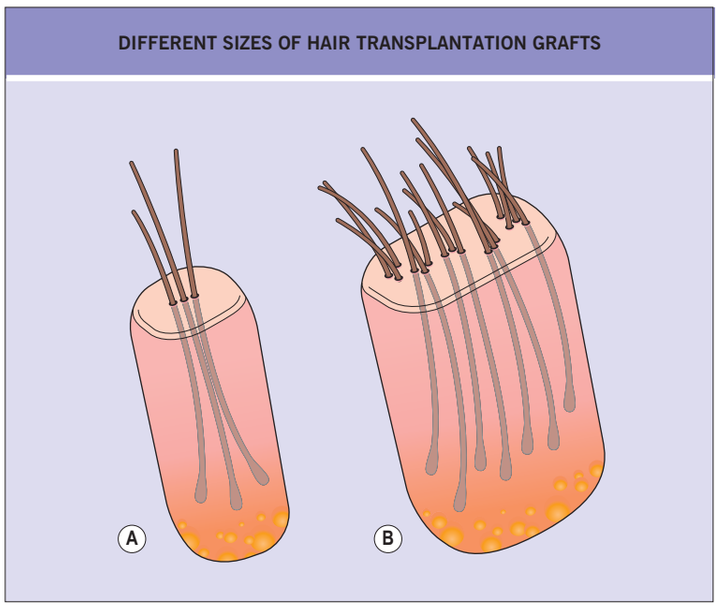

Fig. 157.5 Different sizes of hair transplantation grafts. A The newer technique uses 1- to 4-hair follicular unit grafts. **B** The older technique uses larger 10- to 15-hair grafts.

Fig. 157.6 Hair transplantation for male pattern hair loss. A Norwood IV pattern (baseline). **B** Appearance following transplantation of 900 hair grafts, each with one to three hairs.

hair follicles to grafts containing groupings of one to four hair follicles, referred to as individual follicular units (Fig. 157.5). This has resulted in the transplanted hair having a more natural appearance (Figs 157.6 & 157.7).

The net perceived density from a hair transplant is equal to the number of follicles transplanted minus ongoing hair loss. In order to maximize long-term results, all patients undergoing this surgical procedure are encouraged to continue topical minoxidil and/or oral finasteride (see above). Halting or at least slowing the miniaturization process allows for the perception of greater hair density.

Candidate Selection

As with all surgical procedures, the preoperative consultation is key to the success of the procedure. The consultation establishes whether the patient is an appropriate or inappropriate candidate for hair transplantation, both from a medical and a psychological perspective. In addition, it allows for an assessment of areas of greatest concern and whether the patient has realistic expectations of what a hair transplant can achieve.

A complete medical, surgical and hair loss history is obtained, including previous hair transplants and scalp surgeries as well as scar formation. The etiology of the hair loss is determined, primarily via physical

Fig. 157.7 Hair transplantation for female pattern hair loss. A Ludwig II pattern (baseline). **B** Appearance following transplantation of 750 hair grafts, each with one to three hairs.

examination of the scalp. Occasionally, additional sites need to be examined and/or clinicopathologic correlation is required. The stage of patterned hair loss also needs to be established (see Figs 157.2 & 157.3). All medications, prescription, over-the-counter and herbal, are reviewed with regard to their effects on hair growth and hemostasis.

The basic criteria for assessing the appropriateness of a candidate for hair transplantation are outlined in Table 157.1. In particular, the density of donor hair in the occipital scalp and the caliber of the hair need to be appraised, as both have an impact on the perceived density of the transplant (Table 157.2). Obviously, greater donor density and more grafts to transplant as well as thicker hairs lead to a fuller-appearing transplant.

FIVE BASIC CRITERIA FOR ASSESSING CANDIDATES FOR HAIR TRANSPLANTATION	
Age	Patients over the age of 25 years are preferable. While patients younger than 25 years of age often seek consultation, there is a hesitancy to operate. The predictive value of future hair loss is much lower for individuals between 15 and 25 years of age. Even with the theoretical safety net of finasteride, physicians should carefully choose candidates under 25 years of age. This subgroup also tends to desire a return to a full head of hair as opposed to a mature pattern of restoration that is routinely performed in older age groups
Hair shaft caliber	The caliber of the hair shaft is crucial. Those with large-caliber hair shafts (greater than 70 microns) obtain much denser coverage than individuals with corn silk quality hair. This can be demonstrated mathematically in that very small volume increases in hair shaft diameter result in exponential increases in surface area coverage
Donor hair	A variety of instruments are available to measure donor hair density. Measuring a 0.25 cm^2 field and multiplying by four is the preferred method. Patients seeking hair transplantation who have >80 follicular units/cm^2 are excellent candidates. Those with donor hair density <40 follicular units/cm^2 are considered poor candidates
Degree of baldness	The degree of baldness is perhaps the most important criterion in candidate selection. Those with complete baldness of the frontal scalp as opposed to baldness limited to the vertex are excellent candidates. When frontal baldness is corrected, this creates the most dramatic positive change in appearance
Hair color	Follicular unit grafting has made hair color less of an issue than when punch grafts were employed. Color contrast between hair and skin can make grafts apparent if not transplanted with great care. Individuals with "salt-and-pepper" hair, red hair or blonde hair are preferential to those with jet-black hair. Black-haired individuals are not exempt as hair transplant candidates, but should receive only one-hair follicular units in the frontal hairline for the most natural result. Proper technique eliminates most problems with dark-haired candidates

Table 157.1 Five basic criteria for assessing candidates for hair transplantation.

HAIR TRANSPLANTATION – CLINICAL FINDINGS AND REALISTIC EXPECTATIONS		
Clinical findings	**Realistic expectations**	**Comment**
• High donor density • Large-caliber (thick) hair • Stabilized hair loss via topical minoxidil and/or oral finasteride	1000–1500 graft sessions will create the perception of increased hair density	Need to plan the procedure *assuming* the patient may stop the medication(s) and the hair loss will resume
• Poor donor density • Thin-caliber hair • Ongoing hair loss	1000–1500 graft sessions may create little increase in *perceived* density	Although the transplant will result in more hair, this may not be apparent due to ongoing hair loss and thin-caliber hair

Table 157.2 Hair transplantation – clinical findings and realistic expectations. The net density from a transplant = number of follicles transplanted minus ongoing hair loss.

Key Concepts

Both men and women should be made aware that AGA represents an ongoing process, i.e. it will progress despite undergoing hair transplantation. Medications (e.g. oral finasteride) can help to maximize hair density from a transplant by minimizing ongoing hair loss. However, in planning for the transplant procedure, the surgeon should always assume that in the future these medications may be discontinued (see Table 157.2). Also, the progressive nature of AGA means that additional hair transplants may be required, perhaps in another 5 or 10 years. The physician should therefore emphasize *before* the procedure how ongoing hair loss will affect the density and cosmetic appearance of the transplant as well as how this influences the placement of the grafts so as to assure a long-term natural appearance.

The number of expected procedures to accomplish both short- and long-term goals should be reviewed, as well as the limits on available donor hairs. Reasons for preferring to transplant the frontal scalp as opposed to the vertex need to be explained – the vertex can consume donor grafts, it exhibits a continued 360° progression of hair loss which can lead to a peripheral rim of bald scalp, and this area of the scalp remains visible due to a central gravity pull. Concentrating the transplants in the frontal scalp will allow maximum long-term density with minimal long-term cosmetic risk.

Patients have to realize that elliptical donor harvesting will lead to a permanent scar of the posterior scalp (Fig. 157.8). The scar is of no practical concern unless the patient has his or her hair closely cut. If the patient expresses an interest in having closely cropped hair, follicular unit extraction should be considered (see below). Lastly, the patient must appreciate the need for a conservative approach to placement of the anterior hairline so that it will have a natural appearance over a lifetime.

Fig. 157.8 Occipital scalp scar secondary to elliptical donor harvesting.

Staff Training

Contemporary hair transplantation is a team procedure, and an efficient, high-quality transplant requires a well-trained surgical team. Assistant technicians should be motivated and interested in learning and mastering the procedure. In addition, they need to be able to do repetitive tasks without tiring, losing concentration or become frustrated. Technicians are utilized primarily for cutting and planting. The first task involves sectioning of the donor strip into slivers, followed by further meticulous sectioning into follicular units and prompt placement into chilled saline (Fig. 157.9). The second task requires creation of recipient sites and proper insertion of follicular unit grafts. Even with highly trained and efficient staff, it will take twice as long to place grafts into pre-made recipient sites at a density of 35–40 follicular units/cm^2 as it does to place the same number of grafts loosely (i.e. 20–25 follicular units/cm^2).

During the procedure, the physician closely monitors the quality of graft creation and placement. It is recommended that physicians learning the procedure have a staff member train at the same time. In order to avoid repetitive strain syndrome, technicians should position their elbows or forearms on a firm, supportive surface while using wrist and

COMPARISON OF ELLIPTICAL DONOR HARVESTING VERSUS FOLLICULAR UNIT EXTRACTION		
	Elliptical donor harvesting	**Follicular unit extraction**
Visible scar if short hair cut	Yes	No
Transection of hair follicles	Minimal	Variable
Time required to perform harvest	10–20 minutes	30–90 minutes
Need to create grafts	Yes	No
Quality of resulting transplant	Excellent	Excellent

Table 157.3 Comparison of elliptical donor harvesting versus follicular unit extraction.

finger movements to plant grafts. Rotation of duties can also prove helpful.

Donor Region

The amount of available donor hair is the primary limiting factor in hair transplantation. In general, there are 65–85 follicular groupings/cm^2 in the occipital donor scalp[39]. If there are <40 follicular units/cm^2, the patient is considered a poor candidate (see Table 157.1). The mid occipital scalp between the upper and lower occipital protuberances is the recommended donor site, given its density of hair and the ability to camouflage the donor scar given the lack of involvement by AGA. Of note, the donor density does not correlate with the extent of current or future hair loss in the frontal scalp or vertex.

Harvesting of donor hair is performed via two different techniques: elliptical donor harvesting and follicular unit extraction (Table 157.3).

Elliptical donor harvesting

In the vast majority of patients, elliptical donor harvesting is performed because it allows for the safe and rapid removal of large numbers of hair follicles, with minimal transection of hairs[40]. The width of the donor ellipse ranges from 7 mm to 1.2 cm, while the length should be less than 30 cm. The number of follicular groupings required determines the dimensions of the donor ellipse. For example, if 1000 follicular groupings are needed for the frontal scalp and a patient has an average donor density of 75 follicular units/cm^2, a 13.5 cm by 1 cm strip should contain approximately 1000 follicular grafts. It is important to remember that increasing the width of a donor ellipse creates more wound tension which may lead to a hypertrophic or wide scar.

The ellipse is removed under local anesthesia. Ideal anesthesia is obtained by infiltrating 0.5–1% lidocaine with epinephrine (adrenaline) superficially in the dermis. Once anesthesia is obtained, 20 ml of normal saline can be injected to provide further anesthesia, hemostasis and dermal turgor; the latter helps to reduce the transection of hair follicles. Initial scoring of the excision may be done with a single or double #15 blade scalpel. The blade should be oriented parallel to the exiting follicles, again to avoid transection of hair follicles. The incision should be into the subcutaneous fat and not deeper, in order to avoid transecting the occipital arteries and nerves (Fig. 157.10). Lateral retraction using fine skin hooks exerts tension away from the excision and creates good visibility for the surgeon harvesting the ellipse[41] (Fig. 157.11). The ellipse can be removed by scissors or a scalpel, being careful to avoid damage to any follicles in the subcutaneous tissue.

If the incision does not go any deeper than the subcutaneous fat, the ellipse can be removed without the use of electrocoagulation or thermal coagulation. The donor ellipse can often be primarily repaired with no undermining if it is <1 cm in width. Some surgeons utilize a two-layer closure while others perform a single-layer closure. Staples or sutures can placed and then removed 7–10 days later. Absorbable sutures may be used for those patients who live a long distance away from the physician's office.

Follicular unit extraction

Follicular unit extraction (FUE) represents the removal of individual follicular groupings from the posterior scalp via an approximately 0.75–1.2 mm punch device[42,43]. The incisions are so small that they leave no visible scar after they heal. For patients who like to have closely cropped hair and do not want a visible scar, FUE is an excellent alternative technique for harvesting donor hair. It is also an option for those patients with extensive scarring from previous transplant procedures. However, FUE requires more time than elliptical donor harvesting, fewer follicular groupings are obtained from each procedure, and there is a higher rate of transection of the follicular groupings. In the future, refined instruments and robotics will hopefully lead to more rapid and precise harvesting of individual follicular groupings.

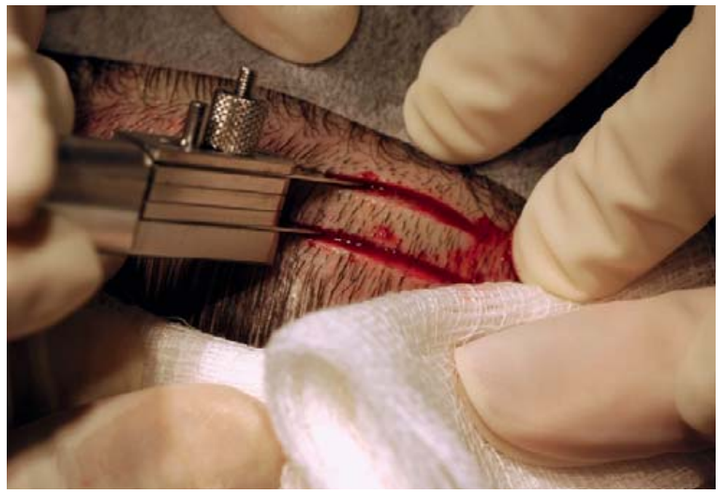

Fig. 157.10 Elliptical donor harvesting. To avoid transection of the hair follicles, the double blades should be oriented parallel to the exiting follicles. The incision should extend into the subcutaneous fat but not deeper (~5 mm into the scalp). Some surgeons prefer a single blade for performing the ellipse.

Fig. 157.11 Elliptical donor harvesting. Lateral retraction using fine skin hooks exerts tension away from the excision and creates good visibility. The ellipse can be removed by scissors or a scalpel, being careful to avoid damage to any follicles in the subcutaneous tissue.

Follicular Grafts

Hair naturally grows in bundles of one to four hair follicles, referred to as a follicular unit (see Fig. 157.5)[44]. Earlier punch grafts that measured 3–4 mm in diameter were often oriented in a perpendicular fashion and contained multiple follicular units, leading to an unnatural appearance. Nowadays, each graft contains just one follicular grouping and is oriented at an acute, 30–45° angle toward the front and slightly toward the midline (see below). Thus, these grafts mimic the natural grouping and orientation of scalp hairs.

Over several hours, surgical teams can carefully separate 500–2000 follicular units from the donor strip (see Fig. 157.9). Cutting instruments include #11 and #15 blades as well as #10 prep blades. Good lighting, comfortable chairs and well-designed instruments are prerequisites for producing follicular units with minimal transection.

Fig. 157.12 Use of magnification to separate follicular units from the donor strip.

Fig. 157.13 Immediate postoperative appearance with graft placement and hairline design.

Some surgeons believe microscopic dissection or magnification reduces transection of follicles during the separation process (Fig. 157.12)[45]. However, the data are still inconclusive. What is not debated is the need to create intact, minimally traumatized follicular units and place the transplanted hair into the recipient sites as efficiently and quickly as possible. As soon as the follicular unit grafts are separated from the donor ellipse, they must be put into chilled saline or an equivalent medium until they are placed into the recipient sites. If grafts desiccate for even a few minutes they will die and not grow.

The number of follicular units required for each surgery depends on the extent of hair loss, available donor hair and density of pre-existing terminal hair follicles in the recipient area. This can vary from 100 to 2500 follicular groupings per procedure.

Hairline Design and Recipient Site Creation

In men, the hairline defines the cosmetic success of a hair transplant. Because women have stable frontal, temporal and posterior hairlines, recreating a hairline in them is usually not necessary. As with hair graft creation, hairline design should mimic as closely as possible what occurs in nature. Unfortunately, patients and physicians often try to recreate the hairline a patient had before the hair loss began. Even if all the available follicular units are utilized, this approach often leads to cosmetic failure. The explanation is the slow steady recession of the temporal and posterior hairlines as well as the frontal hairline.

The design of the frontal hairline should be such that it will remain balanced with the temporal and posterior hairlines. This requires re-creating a frontal hairline which is higher and more receded than the one which was present before the process began. Initially, some patients will resist this idea, but explaining and demonstrating with a mirror how recession of their temporal and posterior hairlines precludes such a low frontal hairline will hopefully convince them of the wisdom of this recommendation.

Rather than viewing the hairline as a fixed boundary, it should be considered a natural transition zone of gradually increasing density from skin to terminal hair-bearing skin. This ill-defined "feathering zone" is re-created by randomly placing, in an irregular pattern, follicular unit grafts along the newly created hairline (Fig. 157.13)[46]. Dense packing of grafts should not be performed because this will lead to a hairline with an unnatural appearance. The level at which the hairline is placed varies from individual to individual and it is important to first examine each patient in a global, 360° manner.

While male pattern hair loss is progressive, transplanted hair will have long-term growth. Therefore, when evaluating patients, the surgeon must assume that all patients will progress to the highest grade of involvement (see Fig. 157.2) with only transplanted hair remaining. This assumption allows transplanted hair to look equally natural 1 year and 20 years after surgery. As noted previously, for several reasons, transplanting into the vertex is ill-advised (see above).

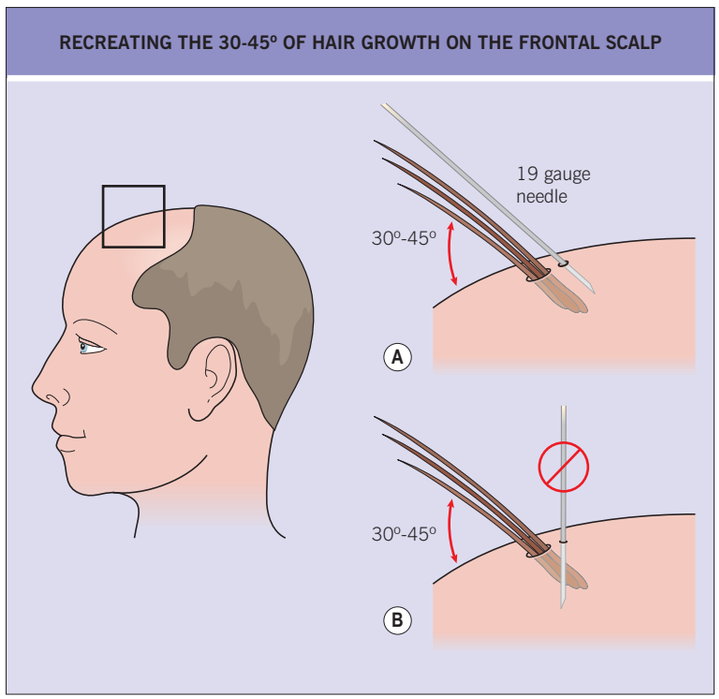

Fig. 157.14 Recreating the 30–45° of hair growth on the frontal scalp. Correct **(A)** versus incorrect technique **(B).** Grafts should not be oriented perpendicular to the scalp surface.

Anesthesia and Recipient Site Creation

While the hair grafts are being harvested from the donor ellipse, the physician anesthetizes the recipient zone. A combination of supraorbital/supratrochlear nerve blocks, field blocks and local infiltration with 1% lidocaine with epinephrine can be performed. Hemostasis is essential for good visibility when creating recipient sites and for graft placement. The epinephrine in the local anesthetic (placed into the dermis and not the subcutaneous space) creates excellent hemostasis.

Recipient sites should mimic the natural 30–45° angle of hair growth on the scalp (Fig. 157.14). There are a variety of needles, including 19- and 20-gauge needles, that are used to make sites large enough to place individual follicular units. When making recipient sites, surgeons must be careful not to transect existing hair follicles. Some advocate using magnification to create recipient sites, in order to limit the loss of existing hair during surgery[47]. The key to success is to create recipient sites in a random, highly irregular pattern with 10–30 follicular units/cm^2, depending on the density of existing hair on the scalp. Sometimes multiple sessions are required when lower densities are utilized.

Graft Placement and Postoperative Course

Two to three surgical assistants place the grafts with microvascular forceps. These forceps are used to gently grasp the follicular units by their perifollicular tissue, avoiding trauma to the hair follicles. Regular surgical forceps are not recommended. Placement of the grafts into recipient sites is often the most challenging component of the hair transplant procedure, both for novice and experienced hair transplant teams. The major challenges include hemostasis and "popping" of grafts from recipient sites after they are placed. With the use of smaller-caliber needles to create recipient sites, hemostasis has become less of a problem. However, it is difficult to predict which patient will have "popping" grafts. This phenomenon is overcome by applying light pressure over a placed graft for 5–15 seconds with a saline-soaked cotton swab (e.g. Q-tip®) before placing the next graft.

After the procedure, an overnight dressing to protect the grafts is placed. The entire dressing should be non-adherent and removed by the patient the next morning (Table 157.4). Staples or sutures are removed during a postoperative visit 7–10 days after surgery. The transplanted hair begins to appear 3–6 months after the procedure and is fully grown by 9–14 months. Patients must be warned of the possibility of post-transplant telogen effluvium.

HAIR TRANSPLANTATION – POSTOPERATIVE INSTRUCTIONS	
Day of the procedure	• Apply non-adherent dressing overnight • Oral acetaminophen (paracetamol) 300 mg/codeine 30 mg [Tylenol #3®] every 4–6 hours as needed with food* • Oral prednisone 40 mg daily for 3 days to reduce frontal scalp edema • Resume regular activities, but no heavy lifting or strenuous exercise until staples/sutures removed • Sleep with head elevated
Postoperative days 1–3	• Day 1 – remove dressing • Shower each day and allow water to run over grafts • Comb hair without allowing comb's teeth to hit perifollicular crusts • Do not pick or scratch at perifollicular crusts • Apply emollient to the donor site(s) daily • Days 1, 2 – continue prednisone (see above)
Postoperative days 4–7	• Resume light exercise • Follow instructions outlined above for showering, combing and emollient application
Postoperative days 7–10	• Staples/sutures removed • Resume regular exercise regimen • Perifollicular crusts gradually disappear
*In general, only required the day of surgery.	

Table 157.4 Hair transplantation – postoperative instructions. Patients should not wear a hairpiece for at least 2 weeks after the procedure.

Complications

Medical and surgical complications from a hair transplant procedure are unusual. The extensive vascular supply to the scalp results in rapid wound healing and a low risk of infection. In addition to reactions to medications and vasovagal episodes, complications include excessive swelling (~5%), postoperative bleeding (<0.5%), folliculitis, a temporary headache, and temporary pruritus or numbness of the scalp. Persistent problems include permanent numbness in the donor or recipient sites, abnormal scarring around the grafts, hypertrophic scarring of the donor site, and poor growth of hair grafts. The latter can be minimized by keeping the grafts constantly moist.

Corrective Hair Transplant Surgery

When patients present for corrective surgery due to previous transplantation of 3–4 mm punch grafts that have led to unnatural large "plugs", i.e. a "pluggy" transplant, three major options exist: (1) add a large number of follicular unit grafts containing one to four hairs between the larger plugs to soften their appearance; (2) surgically remove the large grafts; and/or (3) perform laser-assisted hair removal. Which option is best suited for an individual patient is determined during the consultation.

Adding follicular unit grafts

Transplantation of a large number of follicular unit grafts containing one to four hair follicles – in front of, in between and behind large grafts – will soften the "pluggy" appearance (Fig. 157.15). This option is appealing for many patients because it allows for both cosmetic improvement and increased density (Fig. 157.16). Unfortunately, some patients with an unnatural hairline have a depleted donor supply from previous transplant procedures while others are reluctant to have another surgery following the emotional trauma from the initial transplant.

Surgical removal of grafts

Some hairlines are so cosmetically inappropriate that there is no worthwhile corrective option other than surgically removing the grafts. This option is also indicated for large grafts with perifollicular white scar tissue. The grafts can be removed by either a 2–4 mm punch instrument or an elliptical excision. Another option is to perform follicular unit extractions from larger grafts via 1 mm punch instruments. The latter procedure reduces the "pluggy" appearance of the larger grafts while allowing a more natural appearing graft to remain.

In general, scars on the scalp heal well with minimal evidence of the surgical procedure. However, all patients should be warned that cosmetically evident scars develop in a small minority of cases. If unacceptable scars do arise, pulsed dye, ablative, non-ablative, or fractional ablative laser treatments can be used to help improve the cosmetic appearance.

Laser-assisted removal of large grafts

As with other parts of the body, lasers only remove pigmented terminal hair follicles[48]. Typically 5–10 treatments are needed to permanently

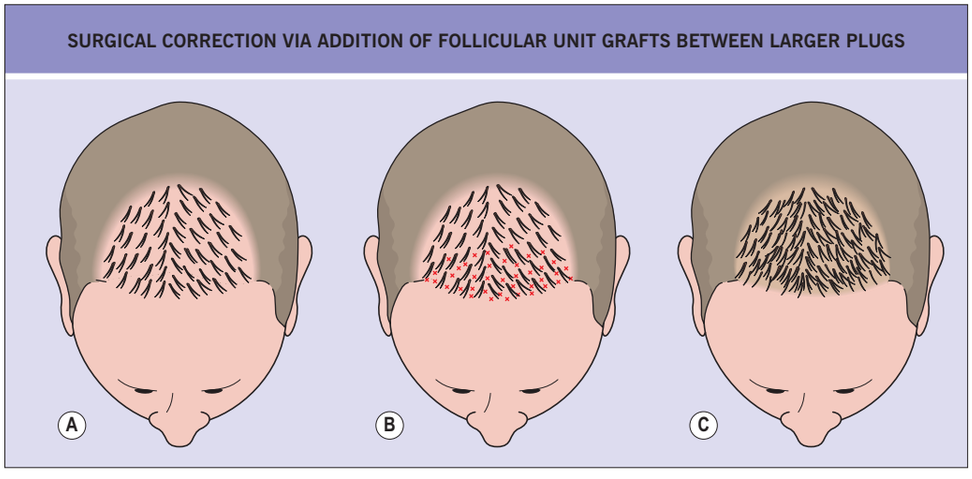

Fig. 157.15 Surgical correction via addition of follicular unit grafts between larger plugs. **A** Previous transplantation of 3–4 mm punch grafts can lead to unnatural large "plugs" of hair. **B**, **C** Addition of follicular unit grafts between and in front of the larger grafts softens the hairline and the overall appearance.

Fig. 157.16 Corrective hair transplant surgery. A Widely scattered large plugs with significant contrast between the lightly pigmented scalp and the black hairs. **B** Softened and improved appearance after the transplantation of 1000 follicular unit grafts containing one to three hairs.

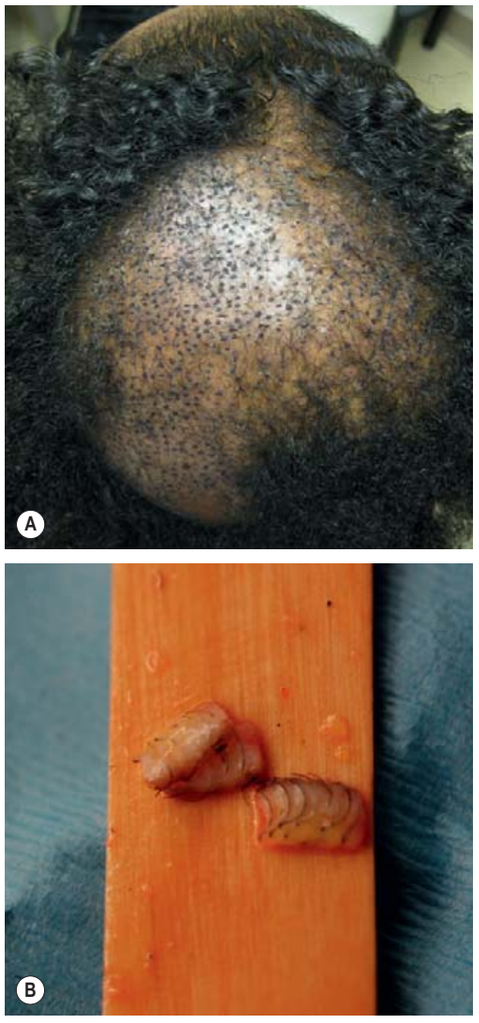

Fig. 157.17 Hair transplantation for central centrifugal cicatricial alopecia. A Appearance 1 week following transplantation of 1200 follicular unit grafts in an African-American woman. **B** Cross-section of African-American hair follicles demonstrating their characteristic C-shaped curve.

remove the majority of follicles. Similar to follicular unit extraction of larger grafts, laser-assisted removal eliminates the majority, but not all, of the hairs, thus providing a substantial cosmetic improvement of the unnatural plugs while retaining some of the transplanted hair for a more natural appearance. Laser therapy is an excellent option for patients who want to improve their cosmetic appearance in a safe, non-invasive manner.

Hypertrophic or broad scars in the donor region

All patients have a permanent scar from elliptical donor harvesting, but the majority of scars are 1–2 mm wide and are of no practical concern (see Fig. 157.8). That said, patients should be made aware of this permanent donor scar *before* they have a transplant. If the patient expresses a possible interest in having their hair cut short, follicular unit extraction should be considered (see above).

When wide donor scars occur, they can be a major cosmetic problem without an easy solution for repair. Scar revision leads to variable improvement. Pulsed dye, non-ablative or fractional ablative lasers may be used to help reduce the thickness and erythema of hypertrophic scars. The best method for minimizing the risk of a wide scar is to keep the width of the donor strip to ≤1 cm. While this does not guarantee a fine, thin scar, it does reduce the risk of a wide scar. Another option is to transplant a large number of follicular groupings into the scar in an attempt to provide camouflage.

Hair Transplantation in Scarring Alopecias

Hair transplantation can be successfully performed in scarred skin. However, it is important that any inflammation, whether from a primary scalp dermatosis, infection or surgery, be resolved completely before hair is transplanted. In the case of inflammatory scalp dermatoses, patients should have no evidence of inflammation for 6 months off therapy before the transplant procedure is performed. If there is any concern regarding active inflammation, a biopsy specimen should be obtained. When there is any active inflammation, the transplanted hair may not grow. All patients should also be told *before* their first transplant that any future flare of scalp inflammation will likely affect the growth of the transplanted hair. Compared to sites without scarring, the yield is less when hair is transplanted into scar tissue. How large the difference will be varies from patient to patient. In general, more transplant sessions are needed in patients with scarring alopecia. Although more surgeries are required to create equal or less density, patient satisfaction is high.

Hair Transplantation in African-Americans

In addition to pattern hair loss in men and women of African ancestry, traction alopecia and central centrifugal cicatricial alopecia (CCCA) are also commonly seen in women (see Ch. 69)[49]. For CCCA, as stated previously, there should be no evidence of inflammation for 6 months (off therapy) before the transplant procedure is performed. While patients can wear wigs or hair pieces, hair transplantation is the only way to permanently fill in the areas of alopecia (Fig. 157.17A).

When transplanting Afrocentric hair, it important to note that the curl of the follicles and the C-shaped curve of the hairs make separation of the follicles slightly more difficult (Fig. 157.17B). Rather than using a straight blade, the blade must be bent in order to not transect the

hair follicles. Also, there is an increased risk of keloid formation, more often in the donor region than in the recipient sites.

FUTURE TRENDS

Regeneration and cloning of hair follicles represents the next step in revolutionizing hair transplantation. With an unlimited supply of hairs, there will no longer be constraints based upon the density of hairs in the donor region. In recent studies, keratinocyte tubulogenesis has been induced by cultured dermal papilla cells[50]; bone marrow- and umbilical cord-derived mesenchymal stem cells were shown to be a reservoir for follicle regeneration[51]; and epidermal wounding, with upregulation of Wnt proteins, led to hair follicle regeneration in adult mouse skin[52]. In addition, erythropoietin has been found to promote the growth of dermal papilla cells as well as to prolong the anagen phase of cultured human hair follicles[53]. Lastly, ongoing research utilizing a mouse model for androgenetic alopecia should provide insights into mechanisms of disease and therapies[54].

Filler materials and general injection technique 2548
Temporary fillers 2550
Semi-permanent fillers 2554
Permanent fillers 2555

Key features

- Fillers are used to soften the appearance of superficial wrinkles and to recontour and smooth the deep folds of the face
- Other indications include reducing the appearance of atrophic, traumatic and acne scars; lip augmentation; and volumizing the face in areas of lipoatrophy or senescence-associated fat loss
- Agents include autologous fat grafts, hyaluronic acid derivatives, bovine collagen and synthetic materials
- Selection of an agent depends on the size, depth and location of the volume deficiency
- Agents are injected into the dermis or subcutaneous fat by various techniques, such as serial puncture, linear threading, fanning, cross-hatching or depot injection
- Fillers can be used as monotherapy or as an adjunct to other rejuvenating injectable techniques or surgical procedures in order to maximize longevity and aesthetic correction
- Complications are technique-dependent or material-related, and include hypersensitivity reactions, granuloma formation, bacterial biofilms, contour irregularities and vascular occlusion

Interventions for the aging face can be broadly categorized into the four "R's" of facial rejuvenation: **R**esurfacing (chemical peels, dermabrasion, and ablative and non-ablative lasers); **R**edraping (the various pulling and lifting facial surgical procedures); **R**elaxing (chemodenervation with paralytic agents); and **R**eplacement/Recontouring (the use of filling agents for superficial and deep soft tissue augmentation). This fourth "R" has recently witnessed remarkable growth, and as patient demand for safe and effective minimally invasive aesthetic techniques has increased, the menu of available dermal fillers and agents for soft tissue augmentation has expanded exponentially. More recently, there has been a shift from filling wrinkles and lines to volumization of atrophied fat and bone[1].

Patients often do not adequately appreciate the degree and significance of their volume defect, and must first be educated about the underlying anatomy of what is producing their "wrinkle". In addition to explaining the significance of volume deficits adjacent to the areas of primary concern, a distinction must be made between dynamic versus static lines as well as cutaneous changes due to photodamage versus those due to chronologic aging (senescence) and gravity (Table 158.1). Although these defects often appear in combination, they must be assessed individually. Patients should be made aware of newer, commercially available injectable products so that the physician is able to personalize their treatment and cater to subtle nuances of their faces. Many of the newer products have unique characteristics and indications that make them more suitable for some patients. Although once a physician becomes enamored with a particular product, it may become the "workhorse" filler in his or her clinical practice.

While the type of defect is clearly important, so are its size, depth and location, as well as the appearance and integrity of the adjacent tissue (Table 158.2). A discussion regarding therapeutic options should include alternatives such as surgery (e.g. rhytidectomy, excision, punch grafting), resurfacing (see Ch. 137) and chemodenervation agents (see Ch. 159), as well as no intervention at all. Patients should understand the indications, technique, advantages, disadvantages and inherent risks of each procedure, with an estimation of the financial cost and recuperation time ("downtime"). As with any treatment, the degree of overall success is largely proportional to the creation (and achievement) of realistic and appropriate goals and expectations by both the physician and the patient. Patients undergoing elective rhytid effacement with soft tissue augmentation must realize that replacing lost or atrophic subcutaneous tissue is often temporary (Table 158.3). Monotherapy with one agent may not be adequate and multiple agents may be required. All wrinkles are not created equal; they come in many shapes and sizes, and, as such, there is no one filler agent that is suitable for all defects. The choice of an appropriate dermal or subcutaneous implant whether temporary, semi-permanent or permanent – requires knowledge of the available options and their characteristics.

CAUSES OF CUTANEOUS DEFECTS
CHRONOLOGIC AGING
• Loss of subcutaneous fat • Gravity
PHOTODAMAGE
• Degradation of collagen, elastin, hyaluronic acid and other components of the extracellular matrix • Neoplastic changes
TRAUMA
• Disease • Inflammation • Surgery

Table 158.1 Causes of cutaneous defects.

SOFT TISSUE AUGMENTATION: PREINJECTION CONSIDERATIONS	
Defect parameters and medical background	**Patient goals**
Medications (anticoagulants) History of hypersensitivity reaction History of herpes simplex viral infections of the face Volume required Location Alternative/simultaneous treatments Medical history (e.g. autoimmune connective tissue disease) Prior procedures (e.g. facelifts, reconstruction, implants and/or injections) Pregnancy/lactation	What defect is of concern to the patient? Expectations regarding degree of correction (facilitated by standardized photoscales) Expectations regarding product longevity Morbidity ("downtime") patient is willing to tolerate and sustain Risk/benefit ratio

Table 158.2 Soft tissue augmentation: preinjection considerations.

SOFT TISSUE AUGMENTATION INDICATIONS
• Non-dynamic rhytides – nasojugal and nasolabial folds, jowls and marionette lines
• Volume deficits – lipoatrophy (associated with antiretrovirals, senescence), sunken temples, tear trough deformity, atrophic dorsal hands
• Building up volume – malar prominence, chin, eyebrow elevation
• Distensible scar
– Acne scar
– Traumatic/surgical scars
• Perioral – vermilion, vertical "bar code" lines, oral commissure
• Combination therapy
– Multiple fillers
– Paralytic agents (botulinum A toxin)

Table 158.3 Soft tissue augmentation indications.

PARTIAL LIST OF CHARACTERISTICS OF THE IDEAL FILLER SUBSTANCE	
Material	**Administration**
Non-allergenic (minimal risk of hypersensitivity)	Basic instrumentation
FDA-approved	Painless
Non-carcinogenic/non-teratogenic	Outpatient
No migration	Minimal recuperation
Minimal inflammation	User-friendly product (e.g. easy flow, ergonomic syringe)
No overt cutaneous change (undetectable)	Versatile syringe volumes (i.e. touch up syringes)
Reproducible	Easy storage (no need for refrigeration)
Durable	Long shelf-life
Minimal adverse sequelae (infection, ecchymosis)	
Stable (inert)	
Affordable	
Malleable post-injection	
Correctable post-injection (e.g. with hyaluronidase, collagenase)	

Table 158.4 Partial list of characteristics of the ideal filler substance. FDA, Food and Drug Administration.

HISTORICAL PERSPECTIVE

Dating back to 1893, Neuber used blocks of autologous fat harvested from the arms for tissue augmentation of depressed facial defects. In 1899, Gersvny injected paraffin into the scrotum as a testicular prosthesis for a patient with advanced tuberculosis. Twelve years later, Brunings first described using the syringe technique to transfer free fat. Then, in 1953, Baronders published a review of permanent soft tissue augmentation with liquid silicone. Finally, in 1981, bovine collagen (Zyderm® I) became the first US Food and Drug Administration (FDA)-approved xenogenic agent for soft tissue augmentation, followed by Zyderm® II and Zyplast®.

It was not until 20 years later that the FDA rapidly began to approve new fillers for temporary soft tissue augmentation. The CosmoDerm® family of injectable collagens, derived from a single human fibroblast source, was soon followed by the fast-track release of an entirely new class of agents – the hyaluronans. Restylane®, a non-animal stabilized hyaluronic acid (NASHA), was shortly followed by hyaluronans derived from rooster combs (Hylaform® and then Hylaform Plus®). A survey by the American Society for Aesthetic Plastic Surgery in 2004 revealed that the hyaluronans had become the most popular filling agents and this trend has continued to the present. The release, popularity and safety of these new agents prompted further investigation and this was shortly followed by the availability of the longer-lasting synthetic products – calcium hydroxylapatite (Radiesse®) and poly-L-lactic acid (Sculptra®) – and a renewed interest in permanent fillers such as silicone oil and polymethylmethacrylate microspheres[2].

FILLER MATERIALS AND GENERAL INJECTION TECHNIQUE

There is an ever-expanding array of materials and devices for soft tissue augmentation (Tables 158.4 & 158.5). They can be subdivided, based on site of cutaneous placement (subcutaneous space or dermis), derivation (autologous, xenograft, allograft, synthetic or semi-synthetic) or, most commonly, duration of effect. In this chapter, the soft tissue fillers are categorized as *temporary* (effect <6 months), *long-lasting* (6 months to 2 years), *semi-permanent* (2 to 5 years), and *permanent*

COMPARISON OF FILLERS CURRENTLY EMPLOYED IN THE US								
Filler trade name (®,™)	**Source**	**Material**	**Duration of effect**	**Advantages**	**Disadvantages**	**Use in lips**	**Approved by the FDA**	**Volume filler**
Zyderm*, Zyplast*	Bovine	Collagen	2–4 months	Natural appearance, little swelling, less painful to inject	Bovine, requires two skin tests, short-lived	Yes	Yes	No
Cosmoderm*, Cosmoplast*	Human	Collagen	2–4 months	Natural appearance, little swelling, less painful to inject, no skin test	Short-lived	Yes	Yes	No
Restylane Fine Lines	Bacteria-derived	Hyaluronic acid (smaller particle size)	4–6 months	No skin testing, effective for vertical lip lines	Short-lived	Yes	No	Yes
Restylane/ Restylane-L*	Bacteria-derived	Hyaluronic acid	6–12 months	No skin testing, relatively long-lasting, versatile	Lip swelling, painful to inject without lidocaine	Yes	Yes	No
Perlane/Perlane-L*	Bacteria-derived	Hyaluronic acid	6–12 months	No skin testing, relatively long-lasting	Lip swelling, painful to inject without lidocaine	Yes	Yes	Yes
Hylaform	Rooster comb	Hyaluronic acid	3–4 months	No skin testing, less lip swelling, versatile	Short-lived, painful to inject†	Yes	Yes	No
Hylaform Plus	Rooster comb	Hyaluronic acid (larger particle size)	4 months	No skin testing, less swelling	Short-lived, painful to inject†	Yes	Yes	Yes
Belotero Balance	Bacteria-derived	Hyaluronic acid	6 months	No skin testing, excellent for treating fine and superficial rhytides	Cannot treat deep rhytides, painful to inject†	No	Yes	No
Juvéderm/ Juvéderm XC*	Bacteria-derived	Hyaluronic acid	6–12 months	No skin testing	Painful to inject if without lidocaine	Yes	Yes	Yes

*Contains lidocaine.
†Pain of injection reduced by addition of lidocaine.

Table 158.5 Comparison of fillers currently employed in the US. FDA, Food and Drug Administration. *Adapted from Wesley N, Dover J. The filler revolution: a six year retrospective. Drugs Dermatol. 2009;8:903–7.*

Continued

COMPARISON OF FILLERS CURRENTLY EMPLOYED IN THE US								
Filler trade name (®,™)	**Source**	**Material**	**Duration of effect**	**Advantages**	**Disadvantages**	**Use in lips**	**Approved by the FDA**	**Volume filler**
Juvéderm Ultra/ Juvéderm Ultra XC*	Bacteria-derived	Hyaluronic acid	6–12 months	No skin testing, less lip swelling, versatile	Painful to inject if without lidocaine	Yes	Yes	Yes
Juvéderm Ultra Plus/Juvéderm Ultra Plus XC*	Bacteria-derived	Hyaluronic acid (double cross-linked)	6–12 months	No skin testing, less lip swelling, versatile	Painful to inject if without lidocaine	Yes	Yes	Yes
Prevelle Silk*	Bacteria-derived	Hyaluronic acid	4–8 months	No skin testing	Short-lived, less painful to inject	Yes	Yes	No
Artefill	Synthetic	Bovine collagen and polymethyl-methacrylate beads (PMMA)	Permanent	Long-lasting, permanent	Skin testing (contains collagen), problematic injecting lips, permanent, including side effects (e.g. formation of nodules and granulomas)	No	Yes	Yes
Sculptra	Synthetic	Poly-L-Lactic acid	>1 year	Long-lasting, good volume filler	Tricky to inject, suspension preparation requires hours to days, multiple sessions required for correction, occasionally formation of long-lasting palpable, but not visible, papules‡	No	Yes	Yes
Radiesse	Synthetic	Calcium hydroxylapatite	>1 year	Long-lasting, good volume filler, equivalent volume appears to produce greater correction than the same volume of hyaluronic acid	Problematic injecting lips, painful to inject unless premixed with lidocaine	No	Yes	Yes
Silicone	Synthetic	Polydimethylsiloxane	Permanent	Versatile, permanent	Permanent, difficult injection technique (microdroplets), need for multiple sessions for correction, formation of permanent nodules	Yes	Yes (but not for aesthetic indication)	Yes
SoftForm	Synthetic	Expanded polytetrafluoroethylene	Permanent	Permanent	Permanent, not widely used, difficult to place	Yes	Yes	Yes
Gore-Tex Subcutaneous Augmentation Material	Synthetic	Expanded polytetrafluoroethylene	Permanent	Permanent	Permanent, not widely used, difficult to place	Yes	Yes	Yes
Autologous fat	Human	Fat	Permanent (in some patients)	Good for large areas of volume loss, permanent (in some patients)	Less predictable effects, permanence technique-dependent, requires more instrumentation	Yes	Not applicable to autologous tissue	Yes
Fascian	Human (allograft)	Fascia	Months to years	Duration	Not widely used, difficult to place	Yes	Yes	Yes

*Contains lidocaine.
†Pain of injection reduced by addition of lidocaine.
‡Reduced to 1–2% by using larger volumes for dilution

Table 158.5 Comparison of fillers currently employed in the US (cont'd). FDA, Food and Drug Administration. *Adapted from Wesley N, Dover J. The filler revolution: a six year retrospective. Drugs Dermatol. 2009;8:903–7.*

(>5 years). While it is true that a filler is either "permanent" or not, these terms were originally introduced as marketing terms to differentiate those fillers that are relatively rapidly absorbed (months) from those that last for years or longer.

To reduce ecchymosis, patients should be instructed to abstain from medications that would inhibit platelet aggregation for at least 10 days prior to injection. In order to fully appreciate the depth and scope of the defect, patients should be placed in a gravity-dependent or seated position, and there should be adequate lighting and, if necessary, magnification. Lighting at an acute angle to the skin surface can help to accentuate surface irregularities and deficits. Prior to the procedure, written consent should be obtained and cosmetic makeup and cutaneous debris removed.

Percutaneous injections of fillers can be painful, especially in the central face and perioral areas. Surface anesthesia can be achieved by using a topical preparation or ice approximately 15 minutes prior to administration. Some injectable products may require nerve blocks and/or regional anesthesia. Although fillers can be extemporaneously combined with lidocaine (by the physician) in order to reduce the pain of injection, a number of commercial products now contain a combination of lidocaine plus filler (see Table 158.5).

Proper placement of the filler material is crucial. Injection techniques that are commonly used include serial puncture, linear threading, fanning, cross-hatching and depot injection[3]. In the *serial puncture technique*, small amounts of filler are sequentially deposited along the wrinkle or fold. The injections are placed close to one another so that

the filler can blend in a continuous fashion; postinjection massage can also help to blend the filler so that it is evenly distributed. Using the *linear threading technique*, the full length of the needle is inserted into the proper dermal or subcutaneous plane and the filler is injected in a retrograde manner as the needle is withdrawn. Conversely, the material can be injected as the needle is advanced (anterograde), creating blunt dissection within the tissue space. The latter version may be particularly useful when an anesthetic is combined with the product.

The *fanning technique* involves multiple passes in different, but evenly spaced, directions without withdrawing the needle from the skin. A relatively recent trend is to use this technique to treat the nasolabial fold. The *cross-hatching* or *radial injection technique* involves linear injections in a grid-like pattern, and the pattern of lines needs to be evenly spaced. This technique is used for filling large areas and for the oral commissures[4]. Finally, *depot injections* are useful when placing volumizing fillers within the subcutaneous fat or along the periosteum near the malar eminence. Occasionally, small depot aliquots are also placed along the infraorbital ridge. Depot placement of filler is immediately followed by massage by the injector in order to blend the product into the natural contour of the region.

TEMPORARY FILLERS

Bovine Collagen

Bovine collagen is an injectable filler with a long safety track record of use in more than a million patients[5]. However, its use has declined markedly with the introduction of other fillers, in particular hyaluronic acid. The three forms (Zyderm® collagen I, Zyderm® collagen II and Zyplast®) are all derived from a closed US cattle herd that is carefully monitored to prevent transmission of bovine spongiform encephalitis, a prion-mediated disease. The products consist primarily of a sterile, purified fibrillar suspension that contains 98% type I dermal bovine collagen, with the remainder consisting of type III collagen, suspended in phosphate-buffered physiologic saline containing 0.3% lidocaine[2].

Zyderm® I, the original implant (1981), has a concentration of 35 mg/ml, and Zyderm® II (1983) has a concentration of 65 mg/ml. Zyplast®, the third form (1985), is cross-linked by the addition of glutaraldehyde. The latter characteristic decreases digestion by collagenase and makes it less immunogenic and longer-lasting than the 3 months anticipated for the Zyderm® products[6].

All three products are supplied in boxes of preloaded syringes, each containing 0.5–1.5 ml of product that should be kept refrigerated (4°C) to assure homogenicity and fluidity of the fibrils. A 30-gauge, 0.5-inch needle is usually used, but the company also supplies an adjustable depth gauge (ADG) needle to manually adjust the length of the needle.

Hypersensitivity to all three formulations can be reduced with double skin testing. The skin test is available in 1.0 ml tuberculin syringes that contain 0.3 ml of Zyderm® I, which screens for allergy to all three forms of bovine collagen. Approximately 0.1 ml of the contents is injected subcutaneously in an inconspicuous area, such as the volar aspect of the forearm or in postauricular skin. Localized hypersensitivity is found in 3% of patients and is manifested as swelling, induration, tenderness or erythema that persists or occurs 6 or more hours following implantation. Despite a negative preliminary test, an additional 1–2% of people will subsequently develop an allergic reaction to the products. Therefore, performance of a second skin test 2 weeks after the initial skin test is recommended. This test, using a similar volume, can be injected into the contralateral arm or the periphery of the face (pretragal area, anterior hairline), and should be monitored for an additional 2 weeks. A positive reaction occurring with either test is a contraindication and should preclude further therapy with bovine collagen. Conversely, negative double skin testing allows the patient to proceed with treatment 4 weeks after the initial test or 2 weeks after the second test. For patients who have not had collagen injected for a year or longer, a single re-test with a 2-week observation period is suggested, prior to initiating further treatment.

Zyderm® I is implanted into the superficial dermis by introducing the needle at a 20–30° angle to the plane of the skin. Proper placement should be apparent with a flat, yellow blanching of the skin. Because a significant portion of Zyderm® I is water, overcorrection is commonly utilized to maximize the aesthetic result. It is primarily suited to smooth out and fill superficial wrinkles such as perioral and periocular rhytides. Zyderm® I is the most forgiving and versatile of the three collagen preparations. Zyderm® II is more viscous than Zyderm® I; it is suitable for shallow scars and can be used synergistically with botulinum toxin in the glabellar region. When injected too superficially, persistent whiteness can be appreciated.

Zyplast® is injected with the needle at more of an angle (45–90°) to the defect and it is placed into the mid dermis. If placed properly, it does not cause immediate blanching, but a more subtle and somewhat delayed blanch. Deep nasolabial folds, marionette grooves and lip augmentation respond best to Zyplast®. Lip enhancement is the most common use of bovine collagen; it is indicated only for the vermilion border and is not FDA-approved for the mucosa. The different types of collagen may be used simultaneously, particularly when the cosmetic defect has multiple depths or is quite deep. This is well illustrated in the perioral area, where Zyplast® can be injected in a continuous flow along the vermilion border and Zyderm® into the radiating vertical lines. Similarly, a deep nasolabial fold can be softened by first injecting Zyplast® into the deep dermis, then layering Zyderm® above it in the superficial papillary dermis.

In addition to a delay in initiating treatment, a common source of frustration for patients receiving bovine collagen injections is the short-lived correction. In general, patients can anticipate 3 to 6 months of improvement, with gradual diminution of results; however, patients can receive additional treatment or maintenance therapy at any time. Adverse treatment responses to injectable collagen can be divided into non-hypersensitive and hypersensitive reaction patterns (Fig. 158.1) and are outlined in Table 158.6[7,8]. Of note, Koken Atelocollagen® and Resoplast® are non-fibrillar forms of implantable bovine collagen that are not approved for use in the US.

Porcine Collagen

A novel form of injectable collagen was Evolence®, a type I collagen extracted from porcine tendons and cross-linked with the sugar ribose. It came in a 35 mg/ml concentration and was approved in 2008 for the correction of moderate to deep facial wrinkles, such as the nasolabial folds. Benefits, as compared to bovine collagen, included the rarity of hypersensitivity reactions (so skin testing was not required) and a possibly longer duration of correction (up to 1 year)[9]. It was recommended that Evolence® not be injected into the lips because of the risk of nodule formation following lip augmentation[10]. In November 2009, the manufacturing of Evolence® was discontinued.

Fig. 158.1 Bovine collagen – "hypersensitivity" reaction. Formation of granulomas at the site of injection. This reaction can be seen in ~1% of patients who have had two negative skin tests.

COMPLICATIONS FROM SOFT TISSUE FILLERS		
Complication		**Methods to reduce complication**
GENERAL		
Ecchymoses		• Avoid aspirin and vitamin E for 10–14 days prior to procedure • Use blunt-tipped needle
Beading		• Inject smoothly and not superficially
Painful blanching or necrosis due to vascular injury or occlusion		• Exercise caution in the glabellar region* • For blanching, warm compresses and topical nitroglycerin • For necrosis, appropriate wound care • Frequent visits and emotional support • If due to HA, can inject hyaluronidase during the blanched phase
Foreign body granulomas (see Ch. 93)		• NSAIDs • Intralesional triamcinolone • Topical tacrolimus • Occasionally, oral immunosuppressants • If due to HA, inject hyaluronidase
Sterile abscesses		• Incision and drainage • Intralesional triamcinolone • If due to HA, inject hyaluronidase
Bacterial biofilms		• While waiting for culture results, oral broad-spectrum antibiotics, e.g. chlarithromycin, minocycline • If due to HA, inject hyaluronidase to reduce biofilm
Vision loss		• Exercise caution in the glabellar region* • Avoid intravascular injection by pulling back plunger prior to injection • Do not use a lot of pressure when injecting • Use fillers that can be injected intradermally
Reactivation of facial herpes simplex viral (HSV) infection		• Treat prophylactically with oral acyclovir if history of previous post-procedure reactivation • Review signs and symptoms with patient and state if they occur to alert the physician • Treat suspected HSV infections with oral acyclovir, famciclovir or valacyclovir
SPECIFIC		
Persistent papules	Artefill®, Sculptra®, silicone	• For Artefill®, inject smoothly • For Sculptra®, greater volume dilution • For silicone, use microdroplet technique
Delayed granulomas	Artefill®, silicone	• Oral antibiotics, e.g. clarithromycin, minocycline • Intralesional corticosteroids (may require 10–40 mg/ml)
Papulonodules	Hyaluronic acid	• Incision and drainage • Inject hyaluronidase • Oral antibiotics (see bacterial biofilms)
*Zyplast® is contraindicated in this location.		

Table 158.6 Complications from soft tissue fillers. HA, hyaluronic acid; NSAIDs, nonsteroidal anti-inflammatory drugs.

Human Collagen – Cadaveric

In the late 1980s, research began on extracting intact collagen fibers and acellular dermal matrix from human cadavers for soft tissue augmentation. Dermalogen® and Cymetra® are examples of products derived from human cadavers and they were available as preloaded syringes and implantable grafts. However, as with bovine collagen, their use has declined with the introduction of newer fillers.

Dermalogen® was an injectable allograft material of human tissue origin composed predominantly of intact collagen and elastin fibers as well as glycosaminoglycans harvested from the dermal layer of human cadaveric skin. The indications were similar to those for bovine collagen: facial rhytides, atrophic scars and lip enhancement. Compared to bovine collagen, correction may have been longer-lasting[8] and no skin testing was required.

Cymetra® consisted primarily of micronized human collagen fibers and the indications were the same as for Dermalogen®. To date, there have been no reports of hypersensitivity reactions. One distinction of Cymetra® is that it was a powder, prolonging its shelf-life. It was rehydrated prior to injection with 1.0 ml of 1% lidocaine. Once completely saturated, the product changed from a white powder to a cream color with a paste-like consistency.

Human Collagen – Bioengineered

The risk of hypersensitivity to bovine collagen led to the development of human collagen as a dermal filler. The CosmoDerm® family of dermal fillers has a reassuring safety profile based historically on the extensive use of this synthetic human collagen in burns and wounds. All three formulations – CosmoDerm® 1, CosmoDerm® 2 and CosmoPlast® – closely resemble the bovine-sourced products. They have the same consistency, concentration (dispersed in phosphate-buffered saline with 0.3% lidocaine) and injection technique as their Zyderm®/Zyplast® counterparts. The primary distinction is that they are grown from a single human fibroblast cell culture and, unlike other human-derived products, are not cadaveric in nature. They are the result of tissue-engineering technology and have undergone extensive pathology screening for viral and bacterial contamination to avoid the possibility of disease transmission. As these products are non-animal-based, they do not require an initial skin test for hypersensitivity. Therefore, they can be injected on the same day as the initial consultation.

Similar to its bovine analogue Zyderm® I, CosmoDerm® 1 has a concentration of 35 mg/ml and is placed into the superficial papillary dermis with a comparable degree of blanching and overcorrection, and it is also primarily indicated for superficial lines and defects. CosmoDerm® 2 has a concentration of 65 mg/ml human-based collagen and has similar indications as Zyderm® II. CosmoPlast®, like Zyplast®, contains 35 mg/ml of human-derived collagen cross-linked with glutaraldehyde, which makes it less immunogenic and increases its durability. It is a deeper implant, to a depth of approximately 2.0 mm, and *does not* require overcorrection to improve deep folds and wrinkles.

All three CosmoDerm® products are packaged similarly to the three bovine products and are prepackaged as an opaque white material in preloaded syringes with adhesive labels and 30-gauge, 0.5-inch and adjustable depth gauge (ADG) needles. The cost of the CosmoDerm® group is slightly higher than that of the Zyderm® group, even though the initial screening process with skin tests is eliminated. The cosmetic result and duration of correction appear to be comparable[7]. Anecdotally, some physicians have noted that human-derived products have better flow characteristics and are easier to inject than bovine-derived collagens.

Human Fascia – Cadaveric

Fascia lata has long been utilized in surgery, first as suture material and later for repair of hernias and eyelid ptosis as well as for reconstructive purposes in orthopedic surgery and otolaryngology[11]. Preserved particulate fascia, harvested primarily from cadaveric fascia lata, became FDA-approved in 1999 (Fascian®) and is registered as a tissue product designed to replace areas of lost fascia or collagen. It is supplied in 3 ml syringes and, as it is in powder form, can be stored at room temperature. Prior to injection, it is hydrated with 1.5 to 3.0 ml of 0.5% lidocaine with 1 : 100 000 epinephrine (adrenaline) or with normal saline. A Luer-to-Luer lock syringe connector is used to emulsify the powder. Syringes containing five different particle sizes (0.1, 0.25, 0.5, 1.0 and 2.0 mm) are available, all with 80 mg of the product. The larger-sized particles give a greater volumetric correction, but they are also more likely to clog in the syringe upon injection. Obstructions can be released by aspirating an additional 0.5 ml of saline or replacing the needle. Skin testing is not required[12].

Using a 16- to 18-gauge needle, the reconstituted Fascian® is injected above the superficial subcutaneous fat. Pretunneling (subcision) with the needle prior to injection will create a pocket for the deposition of Fascian®. Overcorrection is recommended, to anticipate reabsorption of the diluent. Perhaps due to relatively limited use, few adverse reactions have been reported; however, postinjection edema can be

significant and should be addressed with cool compresses and, if necessary, systemic corticosteroids.

Unlike other fillers, Fascian® is not marketed as a "device" in the US, but rather is supplied under the criteria of the Tissue Reference Group (TRG) and comes with no prescribed indications. The grafts are, in theory, applicable to any body defect that would be amenable to other forms of soft tissue augmentation. Fascian® is advantageous not only because of its ease of storage, availability in multiple sizes, and lack of need for skin testing, but also because of the potential for large volumetric correction and applicability to deep subdermal defects. It is, however, limited by the need for preparation and the use of large-bore needles for administration, as well as the lack of controlled studies documenting its longevity.

Autologous Fibroblasts and Collagen

Several of the initial products that were based upon the concept of utilizing autologous fibroblasts are no longer commercially available in the US (e.g. Autologen®, Fibrel®, Isolagen®). Basically, a punch biopsy of skin is obtained from the patient and shipped to the manufacturer, where fibroblasts are isolated and expanded *in vitro*. After a period of months, the cells are then sent back to the clinician for injection. Shortcomings have included the limited yield of product (1–2 ml), the need for shipments, the wait time, and concern regarding the extent to which the fibroblasts continue to produce collagen and lead to soft tissue correction. Recently, azfibrocel-T (laViv®) was FDA-approved for treating rhytides on the basis of 57% of patients noting an improvement compared to 30% who received the placebo.

Hyaluronic Acid Derivatives

The hyaluronic acid derivatives have become the most widely used soft tissue fillers and have spawned an entire new industry, complete with competing products and brand loyalty. Presently, there are at least three manufacturers, with well over a dozen hyaluronic acid-based injectable agents; all are remarkably similar (see Table 158.5). Hyaluronic acid is named for its glassy appearance and is derived from the Greek word for glass, *hyalos*. Hyaluronic acid is an acid mucopolysaccharide (glycosaminoglycan) that resides within the cutaneous dermal ground substance and fills the extracellular spaces between collagen fibers. It is a ubiquitous component of connective tissue and is identical in chemical and molecular form in all tissues and all mammals, making it species-nonspecific.

The hyaluronic acid molecule has a simple chemical structure consisting of a high-molecular-weight, long-chain polysaccharide that is composed of repeating disaccharide units of N-acetylglucosamine and D-glucuronic acid (see Ch. 95). The intertwining coils are polar in nature and have an enormous ability (up to 1000 times their weight) to attract water (hydrophilic) and impart skin turgor. Within connective tissue, hyaluronic acid's major biologic function is to create volume and lubricate extracellular structures by forming a gelatinous matrix in which collagen and elastin fibers are held together in proper alignment. It also regulates cell movement and function, and is particularly important in development and remodeling of tissues. A direct correlation exists among the amount of hyaluronic acid in dermal tissue, the dermal water content, and the viscoelastic properties of the extracellular matrix. The concentration of naturally occurring hyaluronic acid in the skin decreases with age, resulting in decreased ability to hold water (hydration), which renders the dermis less voluminous and increases its propensity to wrinkle.

A dual mechanism of action accounts for the correction of facial wrinkles: hyaluronic acid integrates into dermal tissue, then attracts and binds water molecules to sustain augmentation. In its natural unmodified state, implanted exogenous hyaluronic acid is rapidly degraded by hyaluronidase and has a half-life of only 12 to 24 hours. It was not until the hyaluronic acid molecule was "stabilized" via chemical cross-linking that its enzymatic breakdown was slowed and its viability and *in situ* residency was increased; it could then be used as an acceptable, durable filler.

Its viscoelastic properties, lack of hypersensitivity and migration, and relative insolubility make it an appropriate agent for soft tissue augmentation. After implantation into tissues, injectable hyaluronic acid is metabolized into carbon dioxide and water and eliminated by the liver[13–15] (Table 158.7).

There are two broad categories of injectable cross-linked hyaluronic acids. One category, the Hylaform® group, is animal-derived (rooster combs), stabilized hyaluronic acid. The second is non-animal stabilized hyaluronic acid (NASHA). The NASHA group, Restylane®, Belotero® and Juvéderm®, is generated from bacterial (*Streptococcus*) fermentation. The two categories share many characteristics: they are clear, non-particulate, colorless, thick gels that contain no lidocaine. Without the addition of an anesthetic, they are fairly painful to administer and therefore require some type of topical or regional nerve block anesthesia prior to injection, especially in the perioral region.

All are similarly packaged and are available in preloaded single-use syringes that are accompanied by 30-gauge, 0.5-inch needles as well as labels with lot numbers that can be removed and affixed to the patient's record. The products do not require skin testing and can be stored at room temperature. Placement should be in the mid to deep dermis to the point of correction but without overcorrecting the defect. These products are more viscous than many other injectables, especially the collagen products. Therefore, they have different flow characteristics (rheology), requiring greater pressure to the plunger of the syringe for injection. However, they are more malleable and contour irregularities are responsive to postinjection, manual massage. Augmentation lasts approximately 6–9 months, which is longer than with most other temporary fillers (Table 158.8)[16]. They are approved for "correction of moderate to severe facial wrinkles and folds, such as the nasolabial

BENEFITS OF HYALURONIC ACID DERIVATIVES
• Identical in all species and all tissue types
• No skin test required
• Room temperature storage
• Biodegradable
• Long-lasting/stable
• High degree of safety (biocompatible, resorbable, reversible)

Table 158.7 Benefits of hyaluronic acid derivatives.

COMPARISON OF COLLAGEN AND HYALURONANS		
	Collagen (Cosmoderm® and Zyderm® series)	**Hyaluronans**
Compatibility	Species- and tissue-specific	Identical in all species and tissues
Duration	3–4 months	4–10+ months (longer with subsequent injections)
Origin	Bovine or human	Animal (avian) or bacterial (streptococcal fermentation)
Augmentation	Filler replacement	Water absorption
Pattern of loss	Steady volume loss	Isovolemic degradation*
Viscosity	Constant	Dynamic
Anesthesia	0.3% lidocaine	May require topical/block, though newer formulations contain 0.3% lidocaine
Discomfort	Minimal	Minimal with lidocaine, moderate without lidocaine
Correction	50–100% overcorrection	No overcorrection
Preinjection skin test	Double skin test	Not required
Allergy prevalence (hypersensitivity)	~3% of population	~0.4% of population
Shipping & storage	Refrigerated	Room temperature

*It would seem that isovolemic degradation implies a cliff-drop loss of correction once most of the material has been absorbed, i.e. constant correction with rapid drop-off at the end of the life of the correction.

Table 158.8 Comparison of collagen and hyaluronans.

folds" but are routinely used off-label for other facial indications, including lip augmentation. Perhaps due to the durability or malleability of the product, the non-traditional use of injectable hyaluronic acids has greatly expanded. They are used on the face in the suprabrow area to assist in elevating the brow, in the infraocular sulcus, and even in the periauricular area to rejuvenate the appearance of the senescent/atrophic ear. Additionally, on the extremities, using hyaluronic acid instead of autologous fat in the dorsum of the hand provides volume and camouflages the vasculature and tendons that appear with increasing age.

More recently, there have been studies evaluating the safety of NASHA dermal fillers in patients with more darkly pigmented skin, i.e. Fitzpatrick skin phototypes IV, V and VI. They were shown to be safe for the correction of moderate to severe facial folds and there were no reports of immunogenicity or keloid formation (to date). Only mild to moderate local adverse effects at the injection sites were observed[17]. When non-Caucasian patients were compared to Caucasian patients, there was no increase in the incidence of hyperpigmentation or hypopigmentation[18].

Adverse reactions reportedly occur in fewer than 2% of patients. One of the major advantages of hyaluronic acid gels over bovine collagen is the decreased incidence of delayed hypersensitivity reactions (see Table 158.8). Since it should be nearly impossible to react to pure hyaluronic acid, as it is identical in all species and tissue types, any such reactions are thought to be due to impurities in hyaluronan production: residual avian proteins (Hylaform®) or by-products of bacterial fermentation (Restylane®; Fig. 158.2)[19]. Similar to all injectables, other adverse reactions include ecchymosis, acneiform eruptions and reactivation of herpes simplex[20,21]. Injection discomfort and postinjection ache, erythema and edema are expected sequelae.

With most fillers, if the placement is too superficial, a contour irregularity results and resolution occurs only with time. However, with the hyaluronic acids, a "lump" can often be redistributed into the desired location by physician massage. If the lump persists, the irregularity can be treated via one of two methods. The easiest is to express the material by simple incision and drainage. With manual pressure, the clear intact hyaluronan is readily extruded. If the administration has been too deep and the localized bump is not readily accessible to drainage, local injection of small amounts of hyaluronidase (Vitrase®) can reduce its size (Fig. 158.3).

When the hyaluronic acid is placed too superficially, it causes the formation of a cutaneous bead that is blue–gray in color due to the Tyndall effect. The scatter of different wavelengths of light depends on the size of the substance they encounter; in the skin, long red wavelengths penetrate deeper into the tissue while the shorter blue wavelengths are scattered and reflected[22]. The Tyndall effect also explains the blue–green color of cutaneous veins. Fortunately, this filler "complication" responds to the intralesional injection of hyaluronidase[23]. A rare complication is skin necrosis, with the glabella being the most commonly reported site. Prompt recognition of skin blanching followed by injection of hyaluronidase may prevent or reduce the area of necrosis (see Table 158.6).

Animal-derived hyaluronic acid

The avian-derived form of hyaluronic acid (extracted from rooster combs) is distributed as Hylaform® in three concentrations: Hylaform Fine Lines® for superficial lines and wrinkles, Hylaform® for moderate rhytides, and Hylaform Plus® for deep folds. At the time of publication, only the last two agents have received FDA approval. They all have a high molecular weight but low concentration of hyaluronic acid (5.5 mg/ml).

Non-animal stabilized hyaluronic acid (NASHA)

There are currently three major injectable hyaluronic acids produced by streptococcal fermentation (non-animal stabilized hyaluronic acid [NASHA]). In the Restylane® family, three forms are available: Restylane Fine Line®, Restylane® and Perlane®; however, only Restylane® and Perlane® are currently FDA-approved and available in the US. Each has a concentration of 20 mg/ml of hyaluronic acid; the difference is the size of the gel particles. Restylane Fine Line® is injected into the

upper dermis for superficial lines and contains 500 000 gel particles per ml. Restylane®, for mid-dermal applications, has 100 000 gel particles per ml, and it is FDA-approved for deep wrinkle correction, lip augmentation, nasolabial fold correction, and for glabellar creases (Fig. 158.4). Restylane® has also been used with success for the treatment of tear trough deformities[24]. Perlane®, with 8000 gel particles per ml, is appropriate for deep dermal augmentation and more profound facial folds. Postinjection swelling, erythema and bruising are not atypical and may be more prolonged than with other hyaluronic acid fillers. When small particle gels are compared to large particle gels, they demonstrate similar efficacy, durability and safety. In one study, the incidence of adverse reactions was higher when the fanning technique was used and when a faster rate of injection was employed[25].

Juvéderm® is similar to Restylane® in that it is based on non-animal, cross-linked technology. There are three forms: Juvéderm® with a concentration of 18 mg/ml of hyaluronic acid, designed for the superficial dermis; Juvéderm® Ultra with 24 mg/ml of hyaluronic acid for deeper mid-dermal defects; and Juvéderm® Ultra Plus, which contains 30 mg/ml of hyaluronic acid for correction of the deepest contour irregularities (Figs 158.5 & 158.6)[21]. The two thicker forms, Juvéderm® Ultra and Juvéderm® Ultra Plus, were granted FDA approval in January 2007. The most recently approved NASHA (2011) is Belotero Balance® which contains 22.5 mg/ml of hyaluronic acid (see Table 158.5).

Captique® was a re-formulation of Hylaform® with 5.5 mg/ml of hyaluronic acid, but, as opposed to being of avian derivation, it was non-animal stabilized hyaluronic acid (NASHA). This product had FDA approval for mid-dermal defects, but is no longer commercially available. Although it did not have the erythema and reactivity of other NASHA products, its low hyaluronic acid concentration did not sustain long augmentation.

Fig. 158.4 Hyaluronic acid – lip and perioral augmentation. A Prior to injection of Restylane® into the perioral area. **B** Three months postinjection with correction maintained. *Courtesy, Seth L Matarasso, MD.*

Elevess® was also a bacteria-derived hyaluronic acid. It was produced by fermentation of *S. equi* and then suspended in a buffered solution of 0.3% lidocaine hydrochloric acid. Elevess® was the first FDA-approved soft tissue filler that contained both hyaluronic acid and lidocaine, but it is no longer commercially available[3]. Prevelle® Silk was then the next hyaluronic acid plus lidocaine to be FDA-approved[26]. It is supplied in preloaded single-use syringes (0.9 ml) with 30-gauge needles. Although the injections are less painful, the duration of correction is shorter-lived at 3 to 6 months.

Formulations of the Juvéderm® family, Restylane® and Perlane® that contain lidocaine have been FDA-approved; members of the first group are labeled with "XC" and the latter two with "-L" (see Table 158.5).

SEMI-PERMANENT FILLERS

Poly-L-Lactic Acid

Polymerized poly-L-lactic acid (Sculptra®) can also serve as a soft tissue filler as it stimulates the production of collagen. In 2004, it was FDA-approved for the correction of shape and contour deficiencies secondary to the lipoatrophy associated with antiretroviral therapy for HIV infection[27]. Five years later, the FDA approved Sculptra® for the correction of shallow to deep nasolabial fold contour deficiencies and other facial wrinkles. It can also be used for re-volumizing the face of healthy individuals (Fig. 158.7) and for hand rejuvenation.

Sculptra® is powdered lyophilized suture material (Vicryl® [polyglactin 910]) and therefore the freeze-dried preparations of poly-L-lactic acid can be stored at room temperature. Prior to injection, each vial is reconstituted with a total of 5 ml of liquid: 4 ml of sterile water and 1 ml of lidocaine. The result is a thick 5 ml suspension of 4.45% poly-L-lactic acid. To adequately saturate the powder and obtain a uniform suspension and homogeneous deposition of material, it is recommended that the diluent be added approximately 2 to 4 hours prior to use; however, it is often added 24 hours in advance to ensure a more uniform suspension. In addition, higher dilutions (up to 9 to 11 ml) are used by some physicians to try to reduce the risk of papule formation.

Immediately prior to injection, the mixture is vigorously agitated. A 26-gauge needle is used to place the filler high in the subcutaneous plane without overcorrection. Frequent needle changes may be necessary, as the material has a tendency to form clumps. There may be the appearance of some immediate augmentation due to edema, but in order to achieve desired dermal thickness and prolonged neocollagenesis, the recommended protocol is a series of three or more injections at 3- to 6-week intervals. Persistence of augmentation has varied, but some improvement can be seen at 1.5 to 2 years.

Palpable, but not visible, papulonodules develop in some patients and a granulomatous reaction at sites of injection can also arise. All of these complications tend to persist for a year or more. To try to minimize papule formation, the following can be done: greater dilution, increasing the time interval between reconstitution and injection, deeper injections, injecting smaller aliquots per site, and vigorous massage of the injected areas to eliminate any lumpiness.

Calcium Hydroxylapatite

Initially approved for laryngoplasty (vocal cords) and stress-related bladder sphincter incompetence, Radiesse® has found a niche in the filler market because its duration is estimated to be up to 1 to 2 years, with reports that it may last 2 to 5 years[28]. It is a milky white suspension comprised of two components: (1) an aqueous gel carrier containing glycerin, sodium carboxymethylcellulose and water; and (2) the matrix particle. As the gel carrier correction gradually dissipates via dissolution, longer-term correction from new collagen formation (stimulated by the 25–125 μm microspheres of calcium hydroxylapatite) replaces it. Calcium hydroxylapatite is a non-allergenic (inert) bioceramic that is identical to the primary mineral constituents found in bone and teeth. This biocompatible product contains no human, bacterial or animal products and therefore does not pose a risk of hypersensitivity. The material is individually packaged in 1.0 ml syringes and requires the use of a larger-bore needle (25- to 27-gauge). Utilization of the product was initially limited due to the significant discomfort and throbbing after injection, but the FDA has cleared the practice of

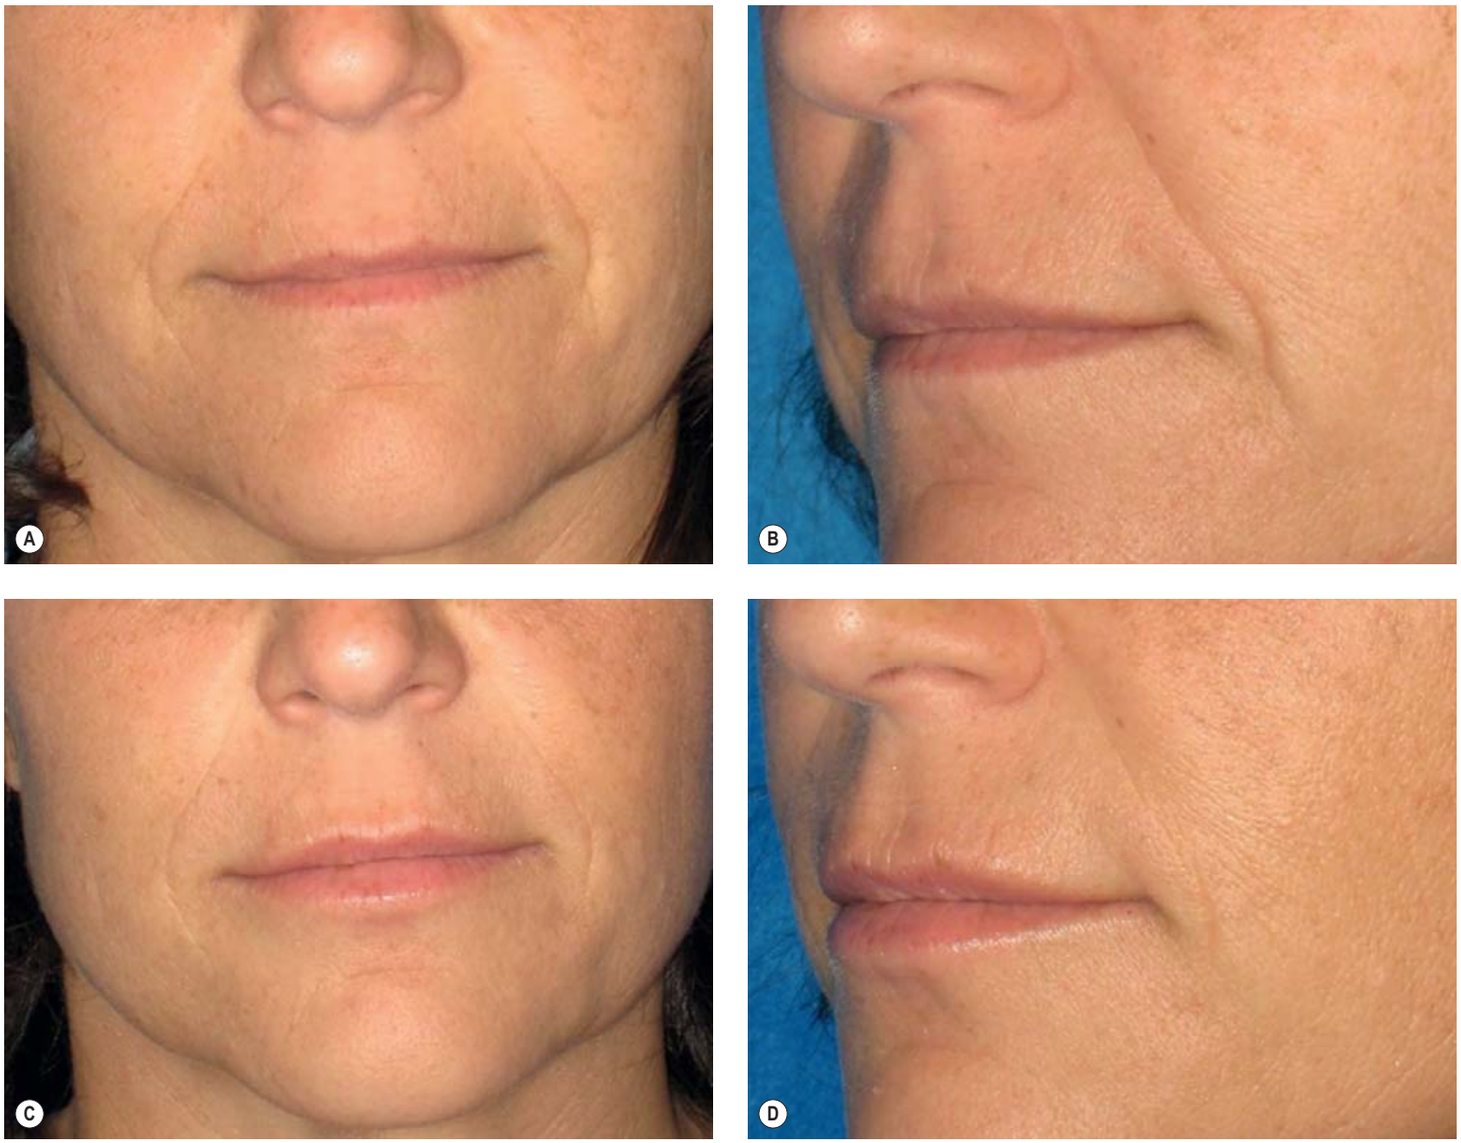

Fig. 158.5 Hyaluronic acid – augmentation of nasolabial folds, lips and oral commissures. A,B Pre-treatment. **C,D** Following injection of Juvéderm Ultra®.

pre-mixing Radiesse® with 1% or 2% lidocaine immediately prior to injection. The material is deposited deeply at the dermal–subcutaneous junction. Injection provides immediate results, and no overcorrection or undercorrection is required[1].

Like Sculptra®, this product stimulates neocollagenesis around the injected microspheres, and the latter are eventually degraded over several years. This product was approved in 2006 for the correction of facial wrinkles and folds and also for antiretroviral-associated facial lipoatrophy. It is particularly suited for patients who have had prior experience with fillers but request a longer duration (Fig. 158.8). Lip augmentation is contraindicated, as mucosal granulomas may form and the constant motion of the lip and compression from contraction of the orbicularis oris may cause migration and clumping of the filler (Fig. 158.9)[29,30]. Off-label uses of this product include correction of volume loss in the infraorbital region[1], re-volumizing the face of healthy individuals (Fig. 158.10), and hand rejuvenation.

Since the Radiesse® implant is radio-opaque, the patient should be informed that it may be visible on dental radiographs as well as CT scans. The safety of calcium hydroxylapatite in patients with Fitzpatrick skin phototypes IV to VI has been studied. When used to treat nasolabial folds, individuals with darkly pigmented skin did not form keloids or hypertrophic scars nor did they develop hyper- or hypopigmentation[31].

PERMANENT FILLERS

Expanded Polytetrafluoroethylene

Expanded polytetrafluoroethylene (ePTFE) is a synthetic solid material that is soft, pliable and clinically inert, with minimal tissue reactivity and high tensile strength. These characteristics have made it useful as a vascular graft in cardiac, urogynecologic, ophthalmologic, and plastic and reconstructive surgery since 1975. In 1993, it received FDA approval for soft tissue augmentation, and currently there are two major products with aesthetic indications. Gore-Tex® Subcutaneous Augmentation Material comes in two forms, single- and multi-stranded, which are both 15 cm in length. In addition, SoftForm® is available as hollow tubes of three lengths (50, 70 and 90 mm) with varying external diameters (2.4, 3.2 and 4.0 mm). They are useful, either as solitary filling agents or in conjunction with other fillers, for addressing deep nasolabial folds, atrophic lips, and lipoatrophy associated with antiretrovirals. Following a combination of nerve blocks and local anesthesia, entry and exit incisions are made and the ePFTE is implanted.

A straight Keith needle with a suture (0-silk) attached to the Gore-Tex® implant is used to perpendicularly enter and exit the skin. The Gore-Tex® is pulled through the subcutaneous tissue by pulling the attached suture. There will be some resistance and steady constant

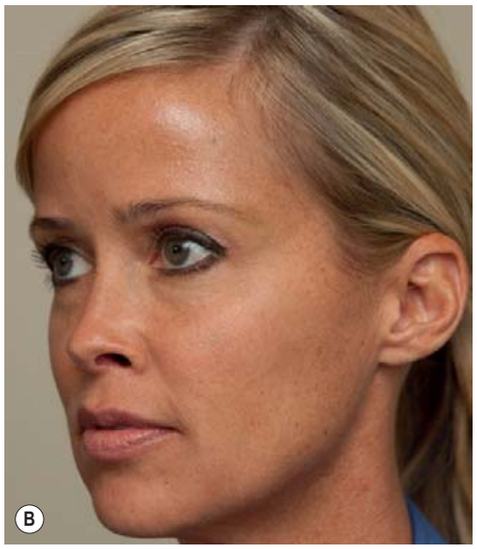

Fig. 158.6 Hyaluronic acid – volumization in a patient with lean body mass. A Pre-treatment. **B** Following injection of large volumes of Juvéderm Ultra Plus® to the cheeks and Juvéderm Ultra® to the brow area, nasolabial folds and oral commissures. *Courtesy, Derek H Jones, MD.*

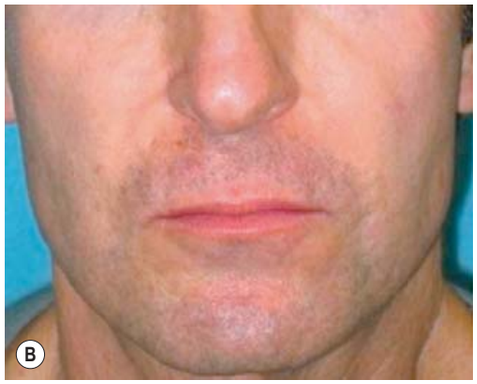

Fig. 158.7 Poly-L-lactic acid – correction of facial fat loss. A Pre-treatment in a patient with facial fat loss related to aging and lean body mass. **B** Eight months post-treatment of the cheeks (and temples) with 10 vials of Sculptra® (five treatments, two vials per treatment) over 4 months.

pressure will be required. With the implant in place, the sutures are cut free and the tips of the implant are buried in the deep dermis. Closure of the incision sites may not be necessary. The porosity of the implant leads to fibrous in-growth, improving the degree of augmentation and anchoring the implant via decreased movement[32].

SoftForm® is inserted via a preloaded trochar delivery system. Once the thick delivery apparatus is removed, the implant ends are tapered and buried subdermally; the incision sites need to be sutured. The hollow-tube configuration of SoftForm® is designed to promote ingrowth of fibroblasts with subsequent neocollagenesis. Placement of both ePTFE products is unforgiving and should be directly beneath and parallel to the overlying defect, high in the subcutaneous fat, just underneath the deep reticular dermis[6].

The primary advantages of ePTFE are that it is not degraded, it remains intact, and it is essentially permanent. However, the disadvantages include: the potential for small incisional scars; the risk of infection, extrusion and migration; and the fact that, even under the best of circumstances, patients can palpate it. In addition, a solid implant placed in a mobile area may intrinsically be counterintuitive and, in fact, may create a new defect. Fortunately, should an adverse event occur, the ePTFE can be removed in a similar fashion to the original insertion. However, the longer the implants remain in place, the more fibrosis there is, and it becomes increasingly difficult to remove them. Compared to other agents, these fillers are technically more difficult to place, and their use seems to have decreased significantly[33].

Lipotransfer

Historically, autologous fat has always been considered one of the safest fillers, with estimates of success as high as 50%, but two concerns have remained. The original *en bloc* technique required excision of the donor tissue and a resultant second defect; essentially, patients traded one defect for another. Furthermore, the non-particulate solid nature of the tissue required implantation, with the potential for incisional scars. The arrival of liposuction in the 1980s solved many of these existing problems. A by-product of liposuction, the suctioned fat was easily accessible and could be reinjected through small cannulas and needles. Consequently, there has been a renaissance of autologous fat transplantation.

For many, autologous fat is considered to be the optimal filler. The advantages remain the biocompatibility and avoidance of allergy, the relative abundance of graft supply, the ability to address three-dimensional volume correction, and the possibility of permanent correction. Theoretical disadvantages include the inability to place material into the dermis to address fine lines and wrinkles or small scars, the cumbersome aspects of harvesting the fat and determining the optimal donor site, the inability to predict the percentage of graft survival, and the debate over viability of stored fat. Perhaps the major drawback is that it requires two procedures: harvesting and insertion of the fat[34,35].

Fat may be harvested from any site where there is excess adiposity. Ironically, those patients who most often request this procedure have limited donor subcutaneous supply. Definitive studies have not yet determined if one area is preferable to others; however, areas with easy access, with limited postoperative morbidity, and which appear to be relatively insensitive to dietary fluctuation include the abdomen, medial knee, and upper outer buttock areas[36].

The donor and recipient sites are photographed and prepared, and the patients are provided with an oral anxiolytic. The subcutaneous space of the donor site is infiltrated with tumescent anesthesia (see Ch. 143)[37]. Through a percutaneous stab incision made with a #11 blade, the donor fat can be aspirated using a 12- to 14-gauge single-holed microcannula (1.5–4.0 inches [3.8–10.2 cm]) that has a beveled edge. The needle is mounted on a conventional hypodermic (10–20 ml) Luer-Lok® syringe. Similar to standard liposuction, the non-dominant hand grasps the subcutaneous adipose tissue and, with the dominant hand holding the syringe under negative pressure, the needle/microcannula is placed in the subcutaneous fat. Moving up and down in a vertical motion perpendicular to the skin, a mixture of yellow fat, some anesthetic solution and, as the procedure progresses and the fat store is depleted, some blood will appear in the syringe. The filled syringes are placed upright in a dependent position, allowing gravity to separate the supernatant fat from the infranatant blood and anesthetic fluid, which can be discarded.

The relatively pure supernatant fat is injected using a large-bore (16- or 18-gauge) needle. After a small bleb of local anesthesia is introduced, the needle is inserted almost parallel to the skin and is advanced to the farthest point of interest. The plunger is then drawn back to aspirate, to ensure that intravascular placement does not occur. The fat is threaded as the needle is withdrawn; frequently, it dissects along the subcutaneous plane without assistance. Although there is some discomfort associated with the injection, it relates primarily to the sudden stretch and expansion of the subcutaneous space and is generally well tolerated by most patients. Molding is undertaken by firm massage to encourage proper subcutaneous fat distribution and a uniform contour. There remains a great deal of variability in technique. Some physicians prefer multiple passes with an intricate layering of small fat droplets, while others have recently found success with intramuscular placement[38,39].

Sterile pressure dressings are applied to the donor site and ice compresses to both the donor and recipient sites. The patient is instructed in postoperative care, including systemic antibiotics, and pain management without aspirin-containing products. Any remaining fat can be meticulously labeled and frozen. When properly stored, it has been suggested that frozen fat can be utilized for up to 12–18 months[40].

Areas amenable to autologous fat transfer on the aging face include the nasolabial folds, cheeks (Fig. 158.11), infraorbital area, marionette lines, lips, scars from acne, and stable disease processes associated with idiopathic facial subcutaneous atrophy (e.g. linear morphea [including coup de sabre], Parry–Romberg syndrome)[41,42]. The dorsum of the hand often shares all of the signs of aging found in sun-exposed areas, but the advances available for facial rejuvenation often compound the disparity between the aging face and hand. Replacing fat in the dorsal hand masks the appearance of protruding tendons and vessels (Fig. 158.12). This imparts a more youthful appearance that is compatible with a rejuvenated face. Adipose transfer has also been shown to be effective in treating partial lipodystrophies associated with antiretrovirals.

Despite the expanding use of transplanted adipose tissue, the literature has few objective studies documenting persistence of grafted material and rate of resorption[43]. Results seem to depend on repeated injections with smaller amounts over time, rather than single injections of larger amounts, which seem to be subject to lower survival rates and higher volume resorption. Presumably because large volumes cannot be sustained by passive diffusion of the recipient bed, overcorrection is discouraged, with the transplanted area corrected to 100%.

Fig. 158.12 Lipotransfer. Before (**A**) and after (**B**) injection of approximately 10 ml of autologous fat into the dorsum of each hand. *Courtesy, Seth L Matarasso, MD.*

There are still many unanswered questions with regard to lipotransfer technique, viability and persistence of the transplant, and storage[44,45].

Silicone

Silicone (polydimethylsiloxane) consists of repeating units of dimethylsiloxane terminated with trimethylsiloxane. Centistoke (cs) refers to the viscosity of silicone oil and is directly related to the chain length of the repeating units. A 1 cs product is equivalent in consistency to water, 350 cs products are oils similar in consistency to mineral oils, and a 1000 cs product is similar in texture to honey. Although useful when injected by an experienced physician, silicone has had a tumultuous history and continues to be controversial. Pure injectable-grade (350 cs) liquid silicone was never approved by the FDA and remains prohibited in the US. However, injectable intraocular silicone (AdatoSil® 5000 centistoke) was approved in 1994 for tamponade to treat complicated retinal detachment. Silikon 1000® was approved for intraocular use in 1997. Under the US FDA Modernization Act, which afforded physicians the right to use medical devices under the same off-label provisions applicable to drugs, physicians could legally use standardized silicone oils for soft tissue augmentation. Since this off-label ruling, there has been an increase in interest and use of silicone for permanent soft tissue augmentation. In 2001, the FDA approved a clinical study of SilSkin®, a highly purified 1000 cs oil, for the treatment of nasolabial folds, marionette lines, and mid-malar depressions. In 2003, the FDA also approved SilSkin® for investigational treatment of antiretroviral-associated lipoatrophy[46,47].

The only form of injectable liquid silicone currently available for soft tissue augmentation is Silikon® 1000 (an off-label use; see above). As the placement of the product results in permanent augmentation, there is very little margin for error, and meticulous technique is essential. Many practitioners prefer to use a glass syringe attached to a 30-gauge needle. The silicone is deposited using a microdroplet serial puncture technique, using 0.005–0.01 ml aliquots placed at 2 mm to 5 mm intervals within the dermis without overcorrection. The average treatment should not exceed 0.25–0.75 ml of silicone and the intervals between sessions are usually monthly until the collagen response and cumulative fibroplasia achieve the desired result (Fig. 158.13). As the endpoint of treatment approaches, the volume injected per visit diminishes and the time interval between treatments lengthens. Patients can expect slow and gradual, but permanent, improvement of 30–90%.

Common post-treatment events include erythema, edema and ecchymosis. The incidence of overcorrection with superficial beading, granulomatous and inflammatory reactions, and movement of the product to a distant site (drift) have improved with purer (unadulterated) silicone oil and strict adherence to indications and protocol[48,49]. Nonetheless, delayed granuloma formation can occur and management options include intralesional injections of triamcinolone.

Polymethylmethacrylate (PMMA) Microspheres

Known as Artecoll® outside of the US and designated by the manufacturer as Artefill® for FDA approval, the product contains polymethylmethacrylate (PMMA) microspheres suspended in a solution of 3.5% bovine collagen and 0.3% lidocaine. The collagen serves as a carrier, and by 1–3 months following injection, it is degraded. The remaining intact, inert, non-biodegradable 30–40 μm PMMA beads, commonly known as Lucite™ or Plexiglas™, are large enough to avoid phagocytosis but small enough to promote permanent augmentation. Once the host's collagen has encapsulated the microspheres, the augmentation has been purported to be permanent.

Prepackaged in a 1.0 ml syringe, Artefill® is injected with a 27-gauge needle and by subdermal tunneling, with placement at the dermal-subcutaneous junction. However, as with bovine collagen alone (see above), it is prudent to perform a skin test prior to augmentation to screen for a hypersensitivity reaction. In an inconspicuous site, a small aliquot (0.05 ml) can be injected at the junction of the dermis and subcutaneous tissue. In addition to hypersensitivity reactions, there is also a risk of delayed granuloma formation.

It is likely that a history of reformulations, name changes and varied manufacturers has led to significant confusion regarding the safety of Artefill® among clinicians already leery of permanent fillers. Primarily

Fig. 158.13 Silicone – correction of HIV lipoatrophy. A Pre-treatment. **B** Following soft tissue augmentation with injectable liquid silicone.

due to reports of granuloma formation, questions have been raised about PMMA manufactured outside the US. Positive outcomes from a large, long-term, prospective study beginning in 2008 that examined the safety and efficacy of Artefill® and involved 1000 patients has renewed interest in the product. As of 2009, Artefill® has been manufactured in the US.

CONCLUSION

The vast array of available filler products, and those that are on the horizon, are only one means to improve tissue loss associated with aging and trauma. The optimal result may be best achieved by combining fillers of different depth, origin and durability with other aesthetic procedures[29,50]. The science of soft tissue augmentation is clearly evolving. Keeping abreast of advances and perfecting a few techniques will be most advantageous for patients; it is not only what is injected, but how it is injected, that determines the degree of success. Finally, regardless of the treatment chosen, it is the combination of clinical judgment, realistic expectations, meticulous preparation, and surgical skill that provides optimal results.

Complications 2570

Synonyms: ■ Botulinum toxin type A, botulinum A exotoxin, BoNT-A; onabotulinumtoxinA – BOTOX®/BOTOX Cosmetic®; abobotulinumtoxinA – Dysport®, Azzalure®; incobotulinumtoxinA – Xeomin®/Bocouture® ■ Botulinum toxin type B, BoNT-B; rimabotulinumtoxinB – Myobloc®

Key features

- Botulinum toxin (BoNT) causes chemodenervation of muscles by blocking acetylcholine release
- Injections of botulinum toxin type A (BoNT-A) that weaken or relax muscles can smooth hyperfunctional lines and change the contour of the face and neck
- Adjunctive use of BoNT-A with laser resurfacing or soft tissue augmentation is beneficial, particularly in active regions such as the perioral and periocular areas
- The cosmetic effects of BoNT-A typically last months and may increase with subsequent injections
- In addition to its effect on musculature, BoNT-A successfully denervates sweat glands, serving as an effective alternative treatment for hyperhidrosis
- Complications (e.g. eyelid ptosis) are generally caused by diffusion of the toxin to non-targeted muscles and can be minimized by using concentrated doses and careful technique

INTRODUCTION

Botulinum exotoxin (BoNT) injections are commonly used to improve facial aesthetics by smoothing hyperdynamic rhytides in the upper face. In recent years, BoNT has been used increasingly in the mid- and lower face and neck, in part because of its demonstrated efficacy and safety for indications in the upper face, and in part because of awareness that muscular hyperactivity (in addition to volume depletion) contributes to the aesthetic appearance of the mid- and lower face and neck. Today, BoNT therapy is an integral aspect of most cosmetic practices.

PROPERTIES OF BOTULINUM TOXINS

Various strains of the bacterium *Clostridium botulinum* produce, as a group, seven distinct serotypes of BoNT that affect neural function: A, B, C1, D, E, F and G[1]. Although all serotypes produce chemodenervation and atrophy of skeletal muscles by blocking acetylcholine release from motor neurons at the neuromuscular junction (Fig. 159.1), they differ with regard to cellular mechanism of action and clinical profile.

BoNT type A (BoNT-A) was the first serotype developed for use in humans. Of the multiple formulations currently in use or undergoing clinical testing for cosmetic applications in North America (Table 159.1), three have been approved by the US Food and Drug Administration (FDA) for glabellar rhytides – onabotulinumtoxinA (BOTOX®/BOTOX Cosmetic®), abobotulinumtoxinA (Dysport®, Azzalure®), and incobotulinumtoxinA (Xeomin®/Bocouture®). AbobotulinumtoxinA differs from onabotulinumtoxinA in purification procedures, dosing, injection patterns, and adverse effects (AEs)[2]. Evidence suggests that abobotulinumtoxinA is associated with greater diffusion and migration[3,4], and early studies in a therapeutic setting found that abobotulinumtoxinA, while slightly more effective than onabotulinumtoxinA, had a higher incidence of adverse effects[5,6].

One formulation of BoNT type B (BoNT-B) is also available in North America (see Table 159.1). RimabotulinumtoxinB (Myobloc®/NeuroBloc®) was FDA-approved in 2000 for the treatment of cervical dystonia; it has been used off-label to treat facial rhytides, having been evaluated in several smaller clinical trials[7–9]. Research indicates that for the treatment of facial rhytides, there are key differences between BoNT-A and BoNT-B: BoNT-B has a more rapid onset of action but a shorter duration of effect, diffuses more widely, and is associated with greater pain and other side effects when compared to BoNT-A[10]. However, one study examining seven doses of BoNT-B found all to be safe and effective for the treatment of hyperfunctional rhytides, with a dose-related duration of effect[11].

CLINICAL USE OF BOTULINUM TOXIN TYPE A

Hyperkinetic lines result from the repeated contraction of muscles perpendicular to the rhytides. Weakening or relaxing these muscles with BoNT-A can smooth these lines, including horizontal lines on the forehead (from frontalis contraction), vertical lines in the glabellar region between the eyebrows (from corrugator contraction), horizontal creases across the bridge of the nose (from procerus contraction), "crow's feet" and lateral lines along the lower eyelid (from lateral orbicularis oculi contraction), and perioral lines (from orbicularis oris contraction). Deep grooves or folds elsewhere that are exacerbated by muscle activity are also amenable to treatment. Patients 30–50 years of age may be most responsive to BoNT-A, because their rhytides are more likely to be caused by muscle activity than by the loss of skin elasticity that occurs during aging.

The effects of BoNT-A injections are usually apparent within a day or two and are obvious for 3 or 4 months, although they may last for 6 months or longer. With repeated injections, there is a tendency for subsequent injections to provide aesthetic improvement that lasts longer. It is possible that over the course of treatment, individuals alter their habitual use of muscles that cause expression lines. Long-term remodeling of the dermis and epidermis that helps to sustain the cosmetic effects also occurs in most individuals, because the tissue is no longer subjected to the same forces of muscle contraction.

Of note, intramuscular injections of BoNT-A have also become the treatment of choice for a number of disorders characterized by muscular hyperactivity, such as strabismus[12], blepharospasm, hemifacial spasm[13] and cervical dystonia[14]. In addition, the ability of BoNT to block acetylcholine release from autonomic nerve endings innervating glandular tissue or smooth muscle has led to investigation of its use for other indications, including hyperhidrosis[15] and migraine[16] (see Table 159.1).

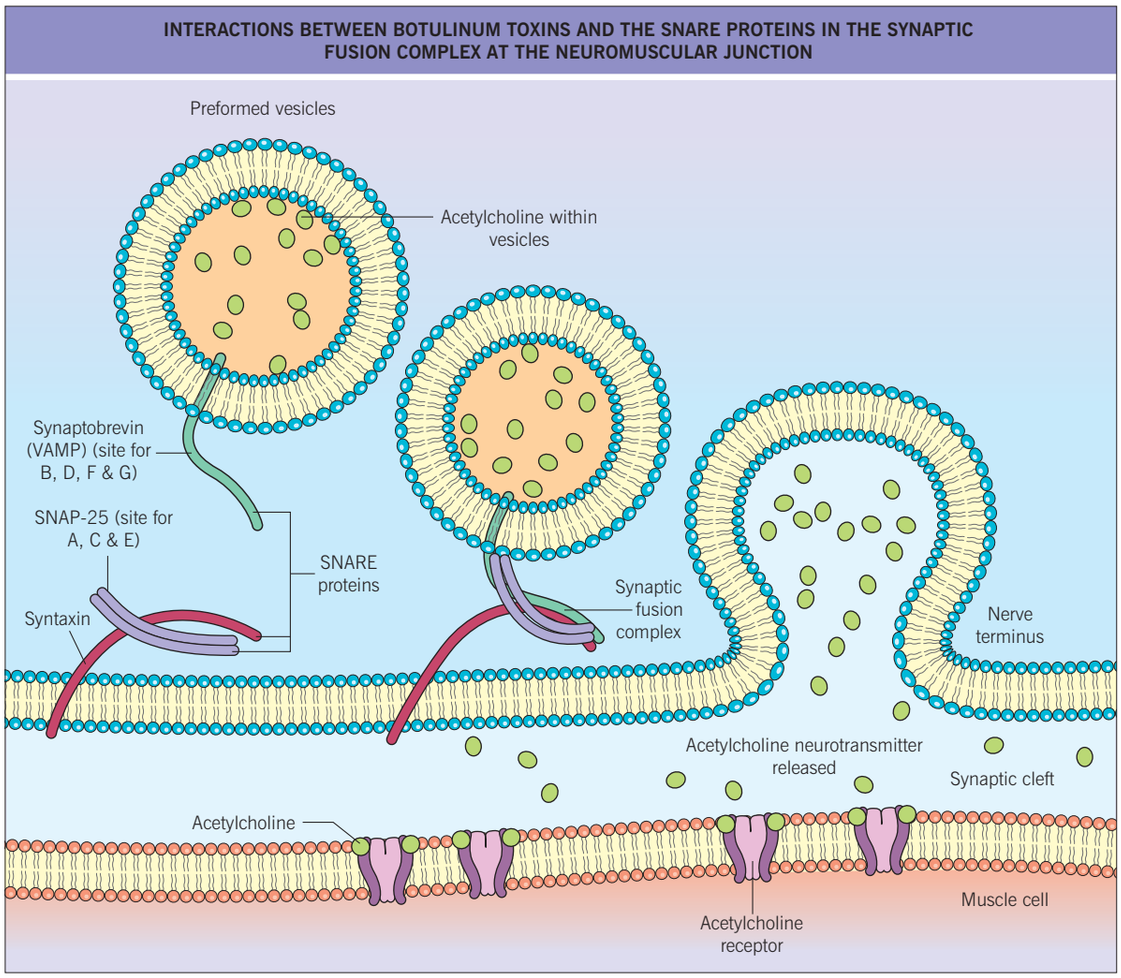

Fig. 159.1 Interactions between botulinum toxins and the SNARE proteins in the synaptic fusion complex at the neuromuscular junction. Botulinum toxins A, C and E catalyze the cleavage of the SNAP-25 protein. Botulinum toxins B, D, F and G catalyze the cleavage of synaptobrevin (or the vesicle-associated membrane protein, VAMP). *Adapted from Rohrer TE, Beer K. Background to botulinum toxin. In: Carruthers A, Carruthers J (eds). Botulinum Toxin. Philadelphia: Saunders, 2005.*

FORMULATIONS AND CLINICAL USE OF BOTULINUM TOXINS (BoNT) IN NORTH AMERICA

	Generic name [Trade name(s)®]	FDA indications or stages of development	Off-label uses
BoNT-A	OnabotulinumtoxinA [BOTOX®/BOTOX Cosmetic®/Vistabel®/Vistabex® (Allergan Inc.)]	Moderate-to-severe glabellar rhytides (approved dose = 20 U); primary axillary hyperhidrosis; blepharospasm; strabismus; cervical dystonia; chronic migraine	Dermatologic: upper, mid- and lower face rejuvenation; palmar hyperhidrosis
			Other: neck pain; back pain; bladder spasms; limb spasticity; tension headaches
	AbobotulinumtoxinA [Dysport® (Ipsen Ltd./ Medicis), Azzalure® (Galderma)]	Moderate-to-severe glabellar lines (approved dose = 50 U); cervical dystonia	Same as above
	PurTox® (Mentor Corporation)	Phase 3 testing for glabellar rhytides; various stages of development for therapeutic indications	
	IncobotulinumtoxinA [Xeomin® (Merz Pharmaceuticals)]	Glabellar rhytides	
BoNT-B	RimabotulinumtoxinB [Myobloc®/ NeuroBloc® (Solstice Neurosciences, Inc.)]	Cervical dystonia	Upper, mid- and lower face rejuvenation; limb spasticity

Table 159.1 Formulations and clinical use of botulinum toxins (BoNT) in North America.

A Note About Dosing

All preparations of BoNT differ in potency and clinical effect, and their units are not interchangeable. Clinicians are advised to consult official product inserts for more information on storage, dilution, dosing, and contraindications. Since most of the information available regarding the cosmetic uses of BoNT – both from published reports and from our personal experience – pertains to the use of onabotulinumtoxinA, the following discussion (including units and descriptions of techniques) focuses on those formulations specifically, unless otherwise stated.

DESCRIPTION OF TECHNIQUES

Injections for aesthetic indications may be given intramuscularly, subcutaneously or intradermally. We use intradermal injections, especially in the crow's feet area, to minimize bruising. All of the usual precautions prior to any injection should be followed. The area may be chilled with ice before the injections to minimize any discomfort in sensitive individuals. Alternatively, a topical anesthetic can be applied 15 to 30 minutes prior to injection to minimize discomfort, and some physicians report great benefits from vibration analgesia[17].

Electromyographic (EMG) guidance can be used to inject BoNT into the most active region of the muscle. Once a thorough understanding of the relevant facial anatomy is attained (see Fig. 142.8), injection with an EMG system provides little benefit. However, even experienced clinicians may find EMG guidance to be useful for the occasional difficult-to-treat patient.

Glabellar Frown Lines

Frown lines in the glabellar region are caused by contraction of the corrugator supercilii and orbicularis oculi muscles, which move the

brow medially, and the procerus and depressor supercilii muscles, which pull the brow inferiorly. Because the corrugator and procerus are used only to control facial expression, the goal of treatment should be to produce a significant weakening of these muscles. The treatment sites and doses should be individualized because the location, size and use of the frown muscles vary greatly between individuals. We currently use five injection sites when treating glabellar frown lines and vary the dosage depending on the individual brow (Fig. 159.2; Table 159.2). The procedure effectively smoothes the glabellar lines at rest and prevents their appearance when the patient attempts to frown, for an average of 3 to 4 months (Fig. 159.3).

Crow's Feet

Contraction of the lateral fibers of the orbicularis oculi muscle produces "crow's feet", lines that radiate from the lateral canthus. Since forceful closure of the eyelids requires orbicularis contraction, the goal of treatment is to produce weakening just in the lateral orbital area, rather than a complete paralysis of the muscle. Because the orbicularis oculi is diffusely innervated, multiple injections are required to weaken broad areas of the muscle.

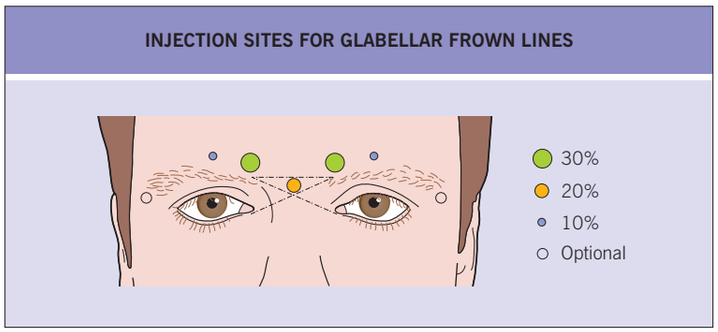

Fig. 159.2 Injection sites for glabellar frown lines. The authors currently use five injection sites when treating glabellar frown lines and vary the dosage depending on the individual brow. The injection in the midpupillary line may be omitted if eyebrow ptosis seems likely or possible. Sometimes, an injection is made above the lateral canthus or into the tail of the eyebrow.

USE OF BoNT-A [onabotulinumtoxinA] IN THE UPPER FACE: DOSING AND TECHNIQUES

Treatment area	Injection sites and tips
Glabellar rhytides	• Men: starting dose 60 U, titrate to 100 U; women: starting dose 30 U, titrate to 50 U • 7–10 U (women) or 15–20 U (men) just above the superior bony orbital rim directly above the inner canthus on each side (see Fig. 159.2) • 5–10 U into procerus muscle at midline • For horizontal brows: 4–5 U 1 cm above bony supraorbital rim in the midpupillary line* • Sometimes necessary to inject above lateral canthus or into the tail of the eyebrow to improve lateral eyebrow position
Lateral canthal rhytides (crow's feet)	• 12–15 U/side, distributed amongst 2–4 sites (see Fig. 159.4) • Inject when patient is *not* smiling to avoid affecting the ipsilateral zygomaticus complex (which can lead to upper lip ptosis) • Inject lateral to the lateral orbital rim; more medial injections can cause lower eyelid droop • Superficial injections (as few as possible) will avoid bruising • Avoid injecting superficial veins
Horizontal forehead rhytides	• 10–15 U amongst multiple sites horizontally across the midforehead, 2–3 cm above the eyebrows (see Fig. 159.7) • 5 injection sites for broad foreheads†; 4 injection sites and a slightly lower dose for narrow foreheads
Hypertrophic orbicularis oculi muscle	• Subcutaneous injections of 2–4 U in the midpupillary line, 3 mm below the ciliary margin (see Fig. 159.8) • Higher doses can result in keratoconjunctivitis sicca (dry eye)

*Injection site most likely to cause ptosis.
†More than 12 cm between the temporal fusion lines (the slight prominence at the point where the temporalis fascia joins the skull) at the midforehead level.

Table 159.2 Use of BoNT-A [onabotulinumtoxinA] in the upper face: dosing and techniques.

Fig. 159.3 Glabellar lines. In a subject at rest (**A**) and during frowning (**B**). Subject at rest (**C**) and attempting to frown (**D**) 1 week after BoNT-A treatment.

While doses and sites vary amongst clinicians, we evenly distribute the BoNT-A into two to four separate injection sites (Fig. 159.4; see Table 159.2). Results last approximately 3 months (Fig. 159.5).

Horizontal Forehead Lines

Deep horizontal creases in the forehead are produced by the repeated contraction of the frontalis muscle. This large, vertically oriented muscle is the brow elevator; it inserts superiorly into the galea aponeurotica and inferiorly into the skin of the brow. Unfortunately, weakening the frontalis muscle sufficiently to eliminate hyperkinetic forehead lines can result in undesired brow ptosis or a complete lack of expressiveness. Therefore, the goal of treatment is to only soften, rather than completely eliminate, forehead lines. Ideally, the individual will still be able to elevate the eyebrows, albeit to a lesser extent, after treatment (Fig. 159.6). We believe that the brow depressors should *always* be treated at the same time as the frontalis, and therefore we use the technique described in the next section. It is our practice to divide the BoNT-A among multiple sites distributed horizontally across the midforehead (Fig. 159.7; see Table 159.2). Effects typically last from 3 to 6 months.

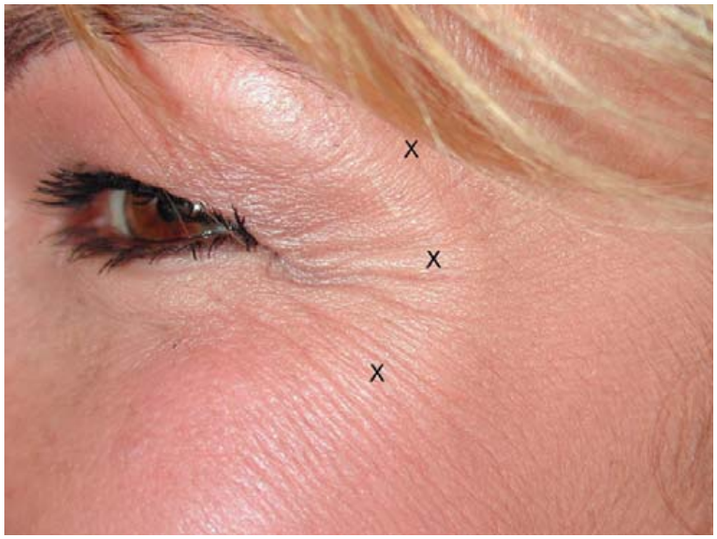

Fig. 159.4 Injection sites for crow's feet. The authors inject 12 to 15 U of BoNT-A [onabotulinumtoxinA] per side among two to four injection sites.

Brow Lift and Shaping

Brow ptosis often occurs during aging, resulting in an angry, scowling expression. Notably, the shape and height of the eyebrow are determined by the opposing activity of the frontalis muscle, which elevates the brow, and the brow depressors. The medial brow depressors are the corrugator supercilii, the procerus, and the medial portion of the orbicularis oculi; the lateral depressor is the lateral portion of the orbicularis oculi (that is lateral to the temporal fusion line). Previously, we believed that brow lifts were a result of the inactivation of the brow depressors[18–20]. However, additional analysis of a dosing study showed that central injections of 20 to 40 U of BoNT-A [onabotulinumtoxinA] into the glabella alone (with the most lateral injection at the midpupillary line) led to a dramatic lateral eyebrow elevation, followed by an entire brow lift that peaked at 12 weeks after treatment[21]. Interestingly, too little BoNT-A (10 U) led to a brief *fall* in eyebrow position. We now believe that the change in eyebrow position after glabellar injection in women is due to diffusion of BoNT-A into the lower frontalis muscle, which causes an improved resting tone in the remainder of the muscle and in eyebrow position.

Hypertrophic Orbicularis Oculi

The pretarsal portion of the orbicularis oculi muscle is involved in the blink reflex. Contraction of the pretarsal orbicularis during smiling tends to decrease the size of the palpebral aperture. Hypertrophy of this muscle can give a "jelly roll" appearance to the lower eyelid, enough that some individuals may complain that they look overweight. We have found that injection of 2 U (or occasionally 4 U) of BoNT-A [onabotulinumtoxinA] into the lower pretarsal orbicularis (Fig. 159.8) opens the palpebral aperture both at rest and during smiling (Fig. 159.9; see Table 159.2)[22,23].

Lateral orbital injections have a synergistic effect with lower eyelid injections and can be used as a safe way to enhance the lower eyelid effect without using too high a dose in the lower lid orbicularis. This procedure is used only for patients who respond well to a preinjection snap test, in which the lower eyelid is briefly pulled off the globe by

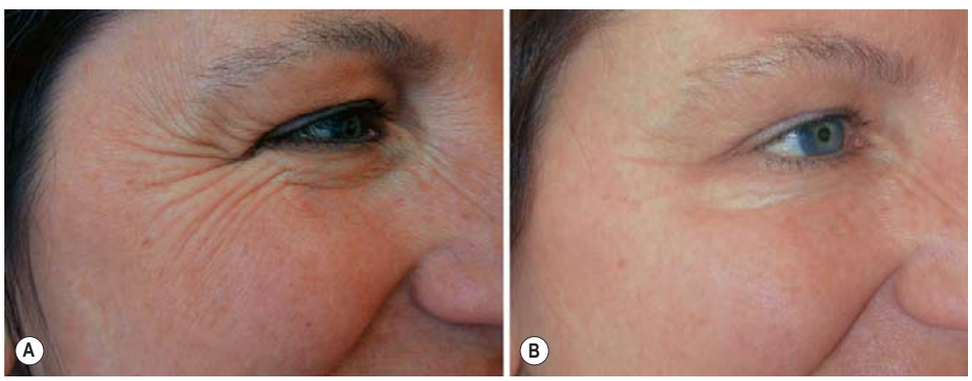

Fig. 159.5 Crow's feet. Subject with crow's feet before (**A**) and 3 weeks after BoNT-A treatment (**B**).

Fig. 159.8 Injection sites for hypertrophic orbicularis oculi muscle. 2–4 U of BoNT-A [onabotulinumtoxinA] are injected into the lower pretarsal orbicularis oculi muscle.

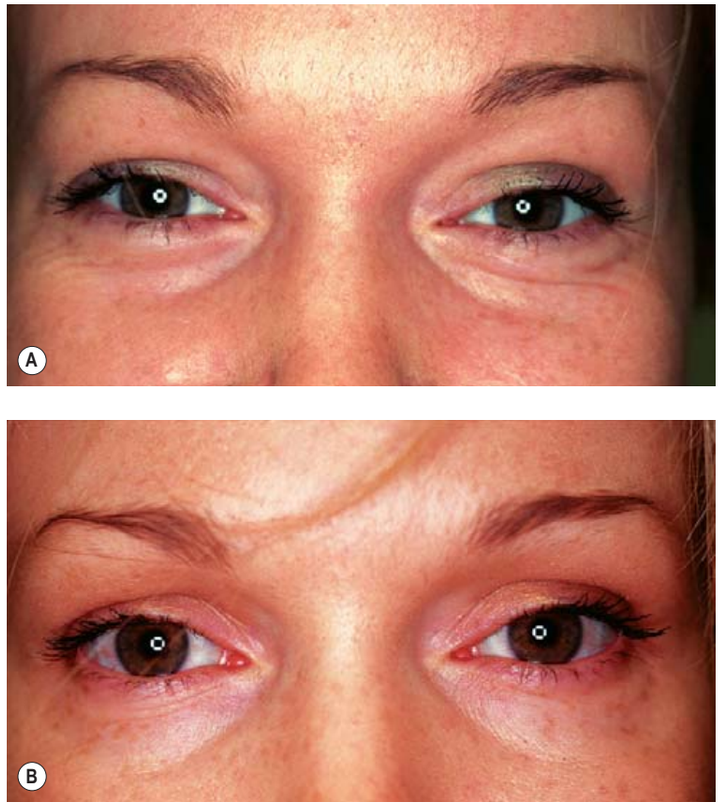

Fig. 159.9 Hypertrophic orbicularis oculi muscle. BoNT-A treatment of the lower pretarsal orbicularis opens the palebral aperture. Note the position of the lower eyelids in the subject before (**A**) and after treatment (**B**).

Fig. 159.10 Injection sites for "bunny lines". 2–4 U of BoNT-A [onabotulinumtoxinA] are injected into each belly of the upper nasalis as it traverses the lateral bony dorsum of the nose. Usually one injection per side is sufficient.

downward pressure on the lower eyelid skin, then quickly released, and the speed with which the eyelid snaps back to the globe assessed. Patients who have had previous lower eyelid ablative resurfacing or infralash blepharoplasty without a coexisting canthopexy to support the normal position of the lower eyelid are not good candidates for this procedure.

Midface Injections

Contraction of the upper nasalis muscle causes fanning rhytides ("bunny lines") at the radix (root) of the nose. BoNT-A treatment weakens the upper nasalis effectively and dramatically softens these lines. Bunny lines are typically treated in conjunction with the glabellar complex (Fig. 159.10; Table 159.3).

Some individuals repeatedly and embarrassingly dilate their nostrils in social situations. The sides of the columella/septum become visible when the nostrils are prominently flared. Contraction of the nasalis muscle accentuates the nasal flare. Small doses of BoNT-A can produce a satisfactory decrease in involuntary nostril flare in some patients for 3 to 4 months (see Table 159.3).

Nasolabial folds extend from the lateral nasal ala to a point lateral to the external angle of the mouth. Young adults have a shallow indentation, but older individuals who smile excessively or sustain photodamage can develop a permanent, deep crevice. The most common treatments for nasolabial folds have been soft tissue fillers and laser resurfacing. Although muscle contraction contributes to the appearance of the folds, injecting BoNT-A directly into the area of the fold is not the treatment of choice, because it is likely to result in an asymmetric smile, flaccid cheek and flattening of the midface, leading to incomplete or disappointing results; in addition, the cutaneous upper lip lengthens vertically, as is often seen during aging. However, for some individuals who have a naturally shorter cutaneous upper lip, very small doses of

USE OF BoNT-A [onabotulinumtoxinA] IN THE MIDFACE: DOSING AND TECHNIQUES	
Treatment area	**Injection sites and tips**
Bunny lines	• 2–4 U into the upper nasalis muscle, usually 1 injection/side (see Fig. 159.10) • Inject well above nasofacial groove* to avoid lip ptosis (due to relaxing the levator labii superioris muscle • Injection followed by gentle massage
Repeated nasal flare	• 5–10 U bilaterally into lower nasalis muscle fibers covering the lateral nasal ala • Inject the most active area of contraction
Nasolabial folds	• Select patients only, e.g. those with a naturally shorter cutaneous upper lip • 1 U into each lip elevator complex above the nasofacial groove
Nasal tip droop	• 2–3 U into depressor septi nasi muscle at the base of the columella
*Refers to groove between the nose and cheek.	

Table 159.3 Use of BoNT-A [onabotulinumtoxinA] in the midface: dosing and techniques.

BoNT-A can be beneficial for improving nasolabial folds (see Table 159.3), particularly when the injections are given concurrently with other treatment (fillers or resurfacing). Because the duration of effect of this procedure is relatively long (~6 months), it is important to be very careful in patient selection and to be clear about the potential results of the procedure.

Nasal tip droop is common during aging. Contraction of the depressor septi nasi, a small muscle located at the external base of the nasal septum, pulls the tip of the nose downward. Injection of BoNT-A slightly elevates the nasal tip (see Table 159.3). Caution should be taken with individuals who already have a long non-vermilion upper lip, because of an associated risk of lip ptosis.

Vertical Lip Rhytides (Perioral Lines)

During aging, the area of the mouth undergoes characteristic changes: the lateral portions of the lips recede to produce a "rosebud mouth"; the vertical distance between the columella and the vermilion border of the upper lip increases, and the substance of the vermilion lip rolls inside, producing the thin and disappointed lips characteristic of old age. Dense vertical perioral rhytides are often associated with the lengthening of the cutaneous upper lip during aging. These vertical lines are commonly referred to as "smokers' lines" but can have other causes, such as heredity, photodamage, or activities such as playing a musical instrument that require pursing of the lips. Radial upper lip rhytides are exaggerated by the pursestring-like action of the orbicularis oris sphincter muscle of the lip. Multiple fine rhytides of the upper lip can be effectively treated with fillers such as collagen or hyaluronic acid or with mid-depth or deeper resurfacing. However, deeper rhytides may be resistant to these treatments.

BoNT-A treatment of the lip sphincter is recommended only for deep lines. Small doses that produce localized microparesis of the orbicularis oris can dramatically reduce radial lip lines and improve the appearance of the lips (Table 159.4). To maintain competence of the mouth, it is important to be conservative with dosing, and superficial injections are recommended over deep injections (Fig. 159.11). Even with conservative dosing, however, BoNT-A treatment of perioral lines may result in lip sphincter weakening that subtly affects mouth function. This procedure may not be desirable for musicians who play wind instruments and professional singers or speakers. Some patients have difficulty with lip proprioception after treatment, but eating, drinking and singing are typically not affected. BoNT-A injections for radial lip lines may be particularly useful in combination with perioral laser or electrosurgical resurfacing or in combination with a soft tissue-augmenting agent such as hyaluronic acid.

Upper Gum Show

When some individuals smile, the upper lip is retracted too far, resulting in excessive exposure of the upper gum. The gum line, upper

USE OF BoNT-A [onabotulinumtoxinA] IN THE LOWER FACE AND NECK: DOSING AND TECHNIQUES	
Treatment area	**Injection sites and tips**
Perioral rhytides	• 4 U/lip (2 U/lip quadrant); typically 1 U/lip line (see Fig. 159.11) • Inject into area of muscle contraction adjacent to the creases at the vermilion border on either side of Cupid's bow • Avoid injecting lip corners (can lead to drooping of the lateral lip and drooling) as well as the midline (can lead to flattening of Cupid's bow)
Upper gum show	• 1–2 U into levator labii superioris alaeque nasi muscle (on each side of the bony nasal prominence) • Younger patients
Mouth frown	• 2–3 U into the posterior aspect of the depressor anguli oris (DAO) muscle on each side, close to the mandible (see Fig. 159.13) • Additional 3 U into each mentalis muscle insertion • Asking the patient to frown can aid in identifying the DAO muscle • Not recommended for singers or musicians
Marionette lines	• 2–5 U into each DAO muscle immediately above the angle of the mandible and 1 cm lateral to the lateral oral commissure; amount injected depends upon size of the muscle • Injection must be lateral and low, at the junction of the depressor and the superior margin of the mandible • An injection too medial or too high can cause ipsilateral weakness of the depressor labii inferioris muscle and flattening of the lower lip contour when the mouth attempts to form an "O"; an injection too high may compromise sphincter function and cause mouth incompetence
Mental crease	• 3–5 U/mentalis muscle band
Peau d'orange chin	• 5–10 U into mentalis muscle at the most distal point from the orbicularis oris muscle (i.e. the prominence of the chin; see Fig. 159.16)
Masseteric hypertrophy	• 20–35 U into each masseter muscle
Horizontal neck lines	• 10–20 U/treatment session (see Fig. 159.18) • 1–2 U into the deep *intradermal* plane at 2–3 cm intervals, followed by gentle massage
Platysmal bands	• 5 U into contracted platysma muscle; 3 sites at 1–1.5 cm intervals for a total of 15 U/band (see Fig. 159.19) • Single treatment typically involves 2 bands and a total dose of 30 U into the neck • Recommended only for patients who have obvious platysmal bands, good cervical skin elasticity and minimal submental fat accumulation

Table 159.4 Use of BoNT-A [onabotulinumtoxinA] in the lower face and neck: dosing and techniques.

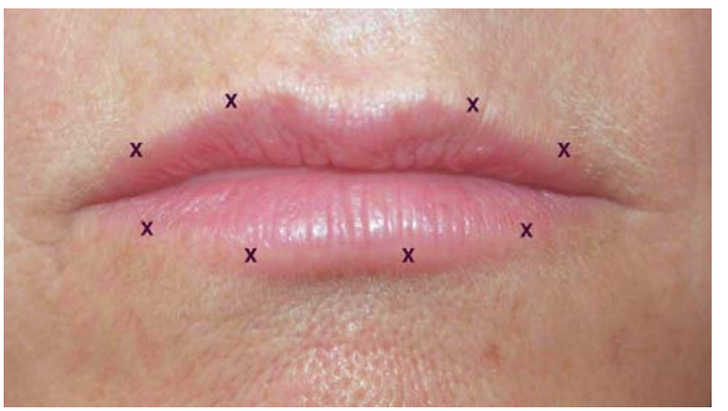

Fig. 159.11 Injection sites for perioral rhytides. The authors typically inject 1 U of BoNT-A [onabotulinumtoxinA] per lip line.

incisors and canines are fully revealed. The levator labii superioris alaeque nasi muscle retracts the upper lip; chemodenervation of the muscle with BoNT-A results in a moderate drop in the upper lip sufficient to cover the upper gum. Small concentrated doses are used (see Table 159.4), often injected with EMG guidance to accurately target the muscle. An undesired side effect of this treatment is the vertical elongation of the cutaneous upper lip. Because this effect is already an undesirable sign of aging, the procedure generally produces unsatisfactory results in patients who are middle-aged and older, and it is usually recommended only for younger patients. For most patients, the best results are obtained when this procedure is used in combination with soft tissue augmentation of the lip margins.

Facial Asymmetry: Functional Muscle Imbalance

Injections of BoNT-A can also be used to correct facial asymmetry resulting from facial nerve palsies[24], dystonias[13,25], surgery[26] or trauma[27]. In cases of hemiparesis, BoNT-A is used to decrease muscle activity on the unaffected side; for hyperkinesia, the affected muscles are treated. Physicians who are not thoroughly comfortable with facial surface anatomy are well advised to use an EMG guidance system for these injections.

Midfacial asymmetry may have bony tissue, soft tissue, innervational or muscular causes. BoNT-A treatment can be invaluable for patients with facial asymmetry caused by neuromuscular abnormalities. In hemifacial spasm, repeated clonic and tonic facial movements draw the facial midline over toward the hyperfunctional side. BoNT-A treatment of the hyperfunctional zygomaticus, risorius and masseter muscles allows the face to be centered at rest. Hypofunctional asymmetry, such as that seen in Bell's palsy due to unilateral seventh nerve dysfunction, can be relieved by small doses of BoNT-A injected into muscles on the normofunctional side. Only 1 to 2 U of BoNT-A [onabotulinumtoxinA] into the zygomaticus, risorius and orbicularis oris muscles and 5 to 10 U into the masseter muscle are needed to restore facial symmetry (Fig. 159.12).

For patients with asymmetric jaw movement, intraoral injection of 10 to 15 U of BoNT-A [onabotulinumtoxinA] into the internal pterygoid on the hyperfunctional side can relax the jaw and relieve discomfort. Unilateral surgical or traumatic injury of the orbicularis oris or the risorius muscle can cause the mouth to be pulled off-center by the unopposed actions of the partner muscles on the uninjured side. Chemodenervation of the risorius immediately lateral to the corner of the mouth on the uninjured side re-centers the mouth when the face is at rest. Similarly, facial asymmetry is evident in individuals with congenital or acquired unilateral weakness of the depressor anguli oris (DAO) muscle, who are unable to depress the corner of one side of the mouth. In these cases as well, BoNT-A treatment of the partner muscle restores aesthetic balance.

Fig. 159.12 Bell's palsy. Patient before **(A)** and after (**B**) treatment, with improvement in asymmetry**.** The authors typically inject 1–2 U of BoNT-A [onabotulinumtoxinA] into the zygomaticus, risorius and orbicularis oris muscles and 5–10 U into the masseter muscle.

Mouth Frown

The frowning expression created when the lateral corners of the mouth are permanently angled downward can create an impression of disapproval and unpleasantness. The DAO muscle pulls down the corner of the mouth in opposition to the zygomaticus major and minor muscles. BoNT-A can be used to weaken the DAO and reset muscular balance (Fig. 159.13), allowing the zygomaticus to elevate the corners of the mouth and return them to a horizontal position (Fig. 159.14; see Table 159.4) The effects of this procedure may be potentiated with repeated treatment.

Fig. 159.13 Injection sites for mouth frown. The authors typically inject 2 to 3 U of BoNT-A [onabotulinumtoxinA] into the posterior aspect of the depressor anguli oris muscle and 3 U into each insertion of the mentalis muscle.

Fig. 159.14 Mouth frown. The subject before (**A**) and after BoNT-A treatment (**B**) of the depressor anguli oris muscle.

It is always important to be cautious when injecting toxin close to the mouth. A misplaced injection could result in complications, including a flaccid cheek, incompetent mouth or asymmetric smile. This treatment is not recommended for singers or musicians, or for patients who use their perioral muscle with intensity. With this procedure, as for others in the perioral area, the most pleasing results may be obtained with BoNT-A injections in combination with laser resurfacing.

Melomental Folds (Marionette Lines)

Melomental folds ("drool grooves" or marionette lines) extending from the down-turned corner of the mouth to the lateral mentum involuntarily produce a sad expression and give the appearance of advancing age. Traditionally, soft tissue augmentation has been used; however, the effects are not long-lasting, because filling agents do not endure in this highly mobile and expressive region of the face. Because contraction of the DAO muscle exacerbates the melomental folds, BoNT-A treatment is a useful adjunct to soft tissue augmentation (see Table 159.4). Best results in this area are obtained with combined therapy as BoNT-A treatment prevents the repeated molding and contortion of the implant, enhancing and extending the duration of the soft tissue augmentation.

Mental Crease

The convexity between the lower lip and the prominence of the chin is called the mental crease. Contraction of the mentalis muscle can produce a deep groove in this region. This area is closely tethered to the bony mentum (chin), and soft tissue augmentation of the mental crease is often unsuccessful because the filling agent visibly beads. BoNT-A injections at the level of the crease may also give unsatisfactory results because the orbicularis oris is weakened, sometimes resulting in an incompetent mouth. However, injection of the mentalis muscle gives a satisfactory softening of the crease while avoiding complications from weakening of the orbicularis oris (see Table 159.4). Injections to the mentalis are especially valuable in individuals who have had previous trauma or surgery to this area (Fig. 159.15).

Peau d'Orange (Apple Dumpling) Chin

An "orange peel" appearance of the chin during aging results from the loss of dermal collagen and subcutaneous fat at the mentum. The appearance worsens when the mentalis and depressor labii inferioris muscles are used together with the orbicularis oris muscle during mastication or speech. *Peau d'orange* chin is frequently seen asymmetrically during and after recovery from unilateral facial paresis (Bell's palsy). Previous treatment options have included soft tissue augmentation to fill in the tissue gaps and ablative and non-ablative laser resurfacing. Depending upon the patient's aesthetic need for chin augmentation, BoNT-A and soft tissue augmentation can be used together, or BoNT-A can be used alone to improve the appearance of the chin (Fig. 159.16; see Table 159.4). Following treatment, the chin is massaged to facilitate diffusion of the toxin.

Masseteric Hypertrophy

A number of studies have observed a reduction of muscle thickness in Asian[28–30] and Caucasian[31] patients with masseteric hypertrophy who were treated with BoNT-A. Reductions in muscle bulk ranged from 19% to 50% and lasted from 3 to 6 months, depending upon the doses used. Effective sculpting of the jawline can be achieved (Fig. 159.17; see Table 159.4). When investigated in a Caucasian versus East Asian population, smaller doses were required for aesthetic improvement in the former versus the latter, and patients experienced a 6- to 7-month improvement in symptoms of bruxism[31], which had been reported previously[32].

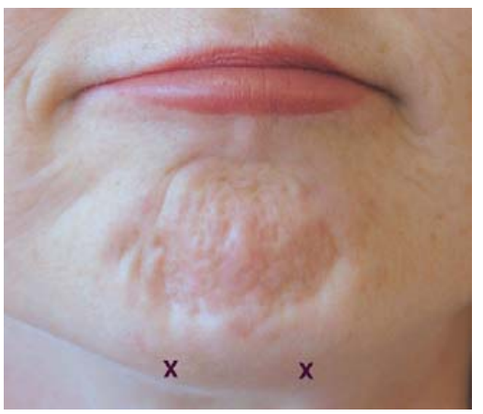

Fig. 159.16 Injection sites for *peau d'orange* chin. The authors inject 5 to 10 U of BoNT-A [onabotulinumtoxinA] into the mentalis muscle at these sites.

Fig. 159.18 Injection sites for horizontal necklace lines. Aliquots of 1 to 2 U of BoNT-A [onabotulinumtoxinA] are injected into the deep intradermal plane at 2 to 3 cm intervals.

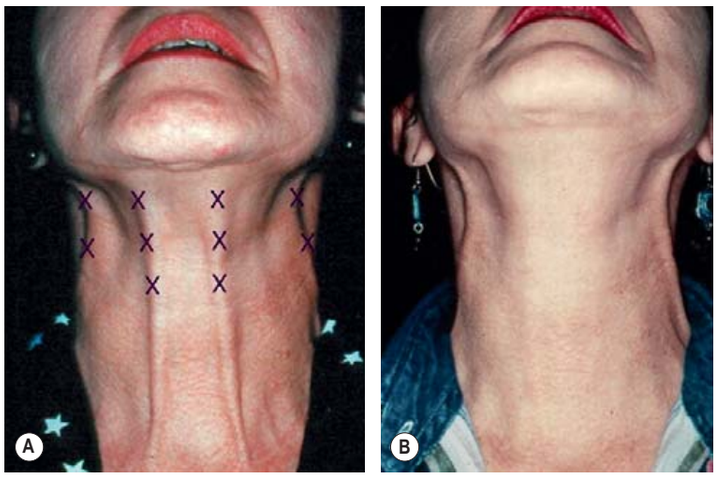

Fig. 159.19 Injection sites for platysmal bands. Before (**A**) and after treatment (**B**). Each band is injected in three sites at 1 to 1.5 cm intervals with 3–4 U of BoNT-A [onabotulinumtoxinA] per site. *Courtesy, M Carney, MD.*

Horizontal Neck Lines

Some individuals, especially those with chubbier necks, have two or three horizontal "necklace" lines of skin indentation caused by the superficial musculoaponeurotic system attachments in the neck. Our treatment approach for softening these lines is to inject small doses of BoNT-A at multiple sites along the horizontal lines (Fig. 159.18; see Table 159.4). The neck is gently massaged following the injections to avoid bruising. The physician is cautioned to use deep dermal rather than subcutaneous injections for two reasons: (1) venous perforators that are deeper in the neck, especially in the lateral neck, can bleed; and (2) the underlying muscles of deglutition are cholinergic and could potentially be affected.

Platysmal Bands

Platysmal bands are formed when the anterior fibers of the platysma separate into two discrete vertical bands. The bands often tighten and become more visible when the neck is animated, as when the patient speaks, exercises or plays a musical instrument. The emergence of platysmal bands during aging is often accompanied by other senescent changes, including loss of cervical skin elasticity and accumulation of submental fat. BoNT chemodenervation of the anterior part of the platysma muscle can soften the platysmal bands (Fig. 159.19) and produce a gentle anterior neck lift. However, in aging necks with jowl formation and bone resorption, BoNT-A treatment of the platysma may emphasize, rather than soften, the muscle cords. Thus chemodenervation of the platysma is recommended only for patients who have obvious platysmal bands, good cervical skin elasticity and minimal submental fat accumulation.

For many patients, BoNT-A may be most useful as an adjunct to traditional facelift surgery; residual muscular banding that becomes apparent in the postoperative period can be simply treated with BoNT-A rather than by a second invasive surgical procedure. BoNT-A treatment can also be used as a "rehearsal", so that individuals who are not ready to undergo traditional facelift surgery can experience immediate aesthetic enhancement without a significant period of convalescence. BoNT-A treatment might even slow the degenerative changes occurring in the neck and postpone the need for rhytidectomy.

Large doses of BoNT-A must be used cautiously in the neck. The platysma is external to the larynx and the muscles of deglutition and neck flexion. Doses from 75 to 100 U of BoNT-A can produce weakness in the neck flexors and dysphagia, and we have reported one patient treated with only 60 U in her neck who developed such profound dysphagia that she required a nasogastric tube until she could swallow again[33]. Therefore, we recommend that the physician proceed with caution and inject no more than 30–40 U of BoNT-A [onabotulinumtoxinA] spread over multiple sites per cervical treatment session (see Fig. 159.19A; see Table 159.4).

Adjunctive Use

BoNT-A is beneficial in many patients as an adjunct therapy to enhance or prolong the results of other cosmetic procedures. Prior to surgery, BoNT-A treatment to chemodenervate specific muscles can facilitate subsequent manipulation of tissues during the surgery and permit a greater surgical correction or a better concealment of the surgical incision. BoNT-A can also be used to reduce tension exerted on a wound or surgical incision by the underlying muscles, thereby promoting better healing with less scar formation.

Although BoNT-A can be used alone to create a mild brow lift, an endoscopic brow lift or facelift is often required when brow ptosis is moderate to severe and a greater elevation is desired. Preoperative relaxation of the brow depressors with BoNT-A can facilitate a greater brow elevation, and postoperative BoNT treatment can help prolong the benefits of surgery by relaxing the muscles that work to re-establish the depressed brow. With upper and lower lid blepharoplasty, BoNT-A pretreatment of the crow's feet area relaxes the orbicularis oculi muscle and permits a more accurate estimation of the amount of skin to be resected during surgery, as well as better placement of the incision so that it is concealed within the orbital margin. After lower eyelid ectropion and "roundeye" repair, dehiscence of the temporal incision can damage the results. Dehiscence can be prevented with BoNT-A treatment to temporarily weaken the lateral fibers of the orbicularis oculi, which pull on the medial side of the incision. BoNT-A injections can also be given in combination with all surgeries that correct hyperkinetic lines to delay or prevent the reappearance of rhytides, and BoNT-A treatment is often used adjunctively with traditional rhytidectomy surgery, as described above.

BoNT-A in conjunction with ablative resurfacing leads to optimal improvement of dynamic rhytides, with superior and longer-lasting outcomes[34]. Regular postoperative injections, given every 6 to 12 months, prolong the effects of resurfacing, and many clinicians now use BoNT-A injections as part of their standard laser resurfacing protocol. Of note, several studies have found that combined BoNT-A and laser resurfacing leads to longer-lasting improvement than either modality alone[35–37].

Likewise, combination treatment with BoNT-A and intense pulsed light (IPL) therapy may be a synergistic approach to the treatment of facial aging. In one study in which we compared the treatments alone and in combination, we found that patients treated with both therapies experienced a 15% greater global aesthetic improvement (reduction in crow's feet in addition to an improvement in skin tone and texture) compared to IPL alone[38]. Similarly, Khoury and colleagues found that a significantly higher proportion of patients had improvement in small rhytides and fine lines with IPL plus BoNT-A when compared to IPL alone (93% vs 29% at week 4), as well as an improvement in erythema[39].

BoNT-A is also frequently used in combination with soft tissue augmentation, where it prevents the distortion of the filler and prolongs the beneficial effects of tissue augmentation (see above). Preceding the injection of filling agents by approximately 1 week, BoNT-A may work on several levels, including reducing the dynamic component of rhytid formation in newly remodeled skin and allowing more permanent eradication of rhytides[34]. Studies have documented the synergistic effect of adjunctive BoNT-A and fillers, citing a greater aesthetic improvement of longer duration with combination therapy than with fillers alone[40–42].

Hyperhidrosis

BoNT-A has been used in the management of hyperhidrosis since early reports of its use to treat Frey's syndrome (see Ch. 39)[43]. Subsequently, a number of authors published reports demonstrating the therapeutic efficacy of BoNT-A in patients with hyperhidrosis, both palmoplantar and axillary[15,44–47].

Dramatically effective with minimal side effects, BoNT-A was approved for the treatment of axillary hyperhidrosis in Canada and the US in 2001 and 2004, respectively. Along with a decrease in perspiration lasting from 6 to 24 months[48], injections can improve quality of life and decrease body odor for up to 7 months[49,50]. In one long-term study, repeated injections over 16 months were safe and efficacious, with minimal side effects and 50% or greater reduction in sweating in 96% of patients after the first treatment[46]. Similarly, BoNT-A was well tolerated and highly effective in 322 patients with primary axillary hyperhidrosis treated over 52 weeks[51].

Typically, 50–150 U of BoNT-A per axilla are divided among 10–20 injection sites (defined by Minor's starch-iodine test, see Fig. 39.6). Because BoNT-A diffuses approximately 1 cm from its injection point, injection sites are located 1.5–2 cm apart and approximately 1 cm from the edge of the affected area. BoNT-A is injected intradermally or immediately subdermally. Injections are usually repeated at 6- to 12-month intervals, although, in the experience of the authors, most subjects are far below their preinjection degree of hyperhidrosis when they present for reinjection. Alternatively, large doses of topically applied BoNT-A (200 U), combined with a transport peptide molecule, has been shown to be safe and may prove to be an effective method for treating axillary hyperhidrosis, although further research is warranted[52].

The value of BoNT-A in the management of palmoplantar hyperhidrosis, while marked, is not as clear as in axillary hyperhidrosis. This relates to both the need for anesthesia to inject the palmar or plantar surface in the majority of individuals as well as the large surface area affected and therefore the high dose of BoNT-A required. Local anesthesia for the hand and foot is usually accomplished by using median and ulnar nerve blocks at the wrist or posterior tibial, sural, superficial peroneal, deep peroneal and saphenous nerve blocks at the ankle, respectively (see Ch. 143). Typical doses of BoNT-A for the palm or sole of the foot are 100–150 U distributed among 50–100 injection sites, including the distal wrist crease and the thenar and hypothenar eminences for the hand injection (Fig. 159.20). In a study involving 69 patients with palmar hyperhidrosis treated over a period of 44 months (using 80 to 100 U BoNT-A in each palm after regional nerve block), 27 had to be treated twice and 11 required a third treatment session[53]. At 1 month after treatment, 54% of patients reported an excellent improvement. Side effects included transitory hand weakness, wrist pain, and cramps.

Migraine

Early investigations into the use of BoNT-A for the treatment of migraine showed a decrease in the incidence and severity of headaches, as well as a decrease in the use of pain medications, for up to 4 months after a single or multiple injection sessions[16,54]. Migraine treatment typically requires 100 U of BoNT-A distributed between the brow, temples and occipital areas, with injections into any additional trigger sites.

More recently, it has become apparent that the response to treatment depends on several factors, including headache characteristics, disease duration, and the use or overuse of medications[55]. For example, trials involving patients with episodic migraine show little to no improvement after BoNT-A injections[56]. On the other hand, chronic migraine

Fig. 159.20 Injection sites for palmar hyperhidrosis. The authors inject 100 to 150 U BoNT-A [onabotulinumtoxinA] per hand (depending on size) in approximately 100 injection sites.

results are mixed: while some data suggest superiority over placebo in patients with or without medication overuse[57], others have found no statistically significant benefit as a prophylactic treatment[58,59]. Lastly, imploding or ocular migraine appears to have a greater likelihood of responding to prophylactic BoNT-A than does exploding migraine[60,61].

While some authors believe that BoNT-A treatment is probably ineffective for any migraine or chronic tension headache, regardless of type of headache or injection regimen[62], many researchers continue to consider it a promising therapeutic option for headache disorders[62]. In 2011, onabotulinumtoxinA received FDA approval for chronic migraine.

POSTPROCEDURAL CARE

Manual pressure can be applied to the injection site immediately after withdrawal of the needle to help prevent bruising. Depending upon the site of injection, the physician may massage the area after the injection to spread the toxin, but only if it is possible to do so without spreading the toxin to non-targeted muscles. To minimize undesired toxin diffusion, patients should be directed to remain upright for at least 2–4 hours after the procedure and to refrain from rubbing or manipulating the area for 24 hours. Because there is evidence suggesting that BoNT-A binds preferentially at actively stimulated muscles, patients are also asked to contract and relax the treated muscles as much as possible for 2–3 hours following the injections. Patients should be told to expect some transient redness, swelling or bruising at the injection sites, and advised that the effects of treatment will probably begin to diminish in 3–4 months.

COMPLICATIONS

BoNT-A occasionally affects non-targeted muscles or glandular tissue in the areas surrounding the injection, which can result in effects such as eyelid ptosis (Fig. 159.21), lower eyelid laxity, epiphora (excessive tearing), diplopia, brow ptosis, decreased strength of eye closure, dry eye, mouth incompetence, difficulties in speech, and the inability to whistle. Use of careful injection technique to target the toxin to the appropriate muscles and the use of concentrated low doses to limit its diffusion to non-targeted muscles or glands are recommended to try to prevent the occurrence of these adverse effects[63]. In general, a higher concentration allows for more accurate placement, greater duration of effect, and fewer side effects, since lower concentrations may encourage the spread of toxin. Of note, there is an area of denervation associated with each point of injection of about 1–1.5 cm (diameter, 2–3 cm) that is due to toxin spread.

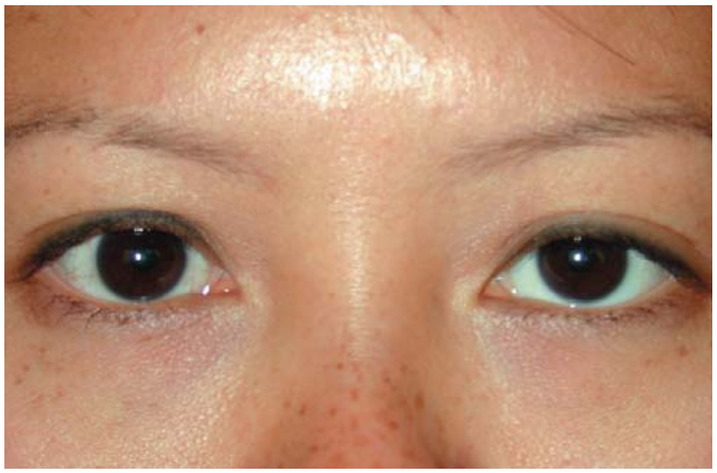

Fig. 159.21 Blepharoptosis. Diffusion of toxin to the levator of the upper eyelid resulted in eyelid ptosis (subject's left eye).

Fig. 159.22 "Cockeyed" brow. A quizzical appearance can occur when the lateral fibers of the frontalis muscle are not injected appropriately, and the untreated lateral fibers of the frontalis muscle pull upward on the brow.

A quizzical or "cockeyed" appearance can occur in the brow when the lateral fibers of the frontalis muscle have not been injected adequately and these untreated lateral fibers pull upward on the brow (Fig. 159.22). Brow ptosis may last upwards of 3 months, while upper eyelid ptosis can persist from 2 to 12 weeks. Bruising, diplopia, ectropion, a drooping lateral lower eyelid, and an asymmetric smile (caused by the spread of toxin to the zygomaticus major) are all reported complications of BoNT-A injections in the periorbital area. Transient local bruising, ptosis, dry eyes, diplopia and facial droop can occur with injections into the cheek.

Complications of the lower face involve effects on muscle function and facial expression, usually due to use of BoNT-A in large doses. Injections placed too close to the mouth, injection into the mental fold, and interaction with the orbicularis oris muscle can all result in a flaccid cheek, incompetent mouth or asymmetric smile. Large doses (>100 U) of BoNT-A [onabotulinumtoxinA] in the platysma have resulted in reports of dysphagia and weakness of the neck flexors.

Although one of the greatest concerns associated with the use of BoNT-A is the formation of neutralizing antibodies leading to non-response of subsequent injections, the overall risk is actually low (<1%) when BoNT-A is used at recommended doses for cosmetic applications. Of note, the protein content in current lots of BoNT-A is significantly lower than in previous batches and has been shown to be less antigenic than the original product. Although antibody formation has occurred with current lots of BoNT-A[64], it is usually associated with large doses and therapeutic, rather than cosmetic, use[65]. Injecting the lowest effective doses, with the longest feasible intervals between injections, minimizes the potential for immunogenicity.

Allergic reactions to BoNT-A are rare but have been described in the literature. Additional reactions include serious or non-serious cutaneous eruptions[66] as well as granulomas[67]. After large doses for therapeutic purposes, anaphylactic reactions[68,69] and severe respiratory failure have occurred.

Safety

No long-term adverse effects have been reported, and no systemic safety problems have been associated with FDA-approved uses of BoNT-A. A review of the long-term safety of BoNT-A for cosmetic purposes revealed no serious adverse events (AEs) in over 850 treatment sessions for up to 9 years[70]. An interim analysis of 768 patients enrolled in phase 3 clinical trials, who received up to six treatments of abobotulinumtoxinA, found that multiple treatments over 17 months were well tolerated[71].

However, the risk of serious complications increases with higher doses: in an analysis of 1031 AE reports submitted to the FDA, 407 occurred with higher therapeutic doses, including 28 deaths and other serious cardiovascular complications[66]. The FDA could not determine a causal relationship between the fatalities and BoNT-A injections, especially since 26 patients who died had underlying cardiovascular diseases with an elevated mortality risk. Notably, no deaths or cardiovascular complications were associated with cosmetic doses. Similarly, another investigation of 658 FDA-submitted AEs, which included 180 cases of aspiration, dysphagia and/or pneumonia and 16 deaths, involved only therapeutic doses in already compromised individuals[72]. As a result, the FDA requested safety label changes with black box warnings and a *r*isk *e*valuation and *m*itigation *s*trategy (REMS; a consumer guide outlining the risks associated with treatment) for all BoNT products[73].

FUTURE TRENDS

BoNT-A has become the treatment of choice for smoothing hyperkinetic lines in the face and neck, creating a more pleasant and youthful appearance. Alone or in combination with surgery, soft tissue augmentation, or ablative and non-ablative laser resurfacing, BoNT-A treatment is both an art and a science, with its use in facial sculpting and enhancing, along with dermatologic correction. Moreover, the number of dermatologic indications for BoNT-A is likely to continue to grow. Easy to use, minimally invasive, very well tolerated by patients and extremely safe, injections of BoNT-A can be used alone or in combination with other cosmetic procedures and are an integral part of most cosmetic practices.

  cysticercosis and echinococcosis 1419–1420
  filariasis 1416–1417
  onchocerciasis 1409–1416
  panniculitis 1658t
  schistosomiasis 1417–1419, 1600t
Woronoff's ring 139, 1047
wound appearance 2470–2471, 2470f–2471f

wound closure 2353–2363
  antiseptics and sterilization 2383t
  biopsy 2384–2387, 2385f–2386f, 2387t
  hemostasis 2384, 2384f, 2384t
  instruments 2358–2362, 2359f–2360f
    biopsy blades 2359
    curettes 2359
    forceps 2361
    hemostats 2361
    needle holders 2360, 2360f
    scalpels 2360, 2360f
    scissors 2361, 2361f
    skin hooks 2361–2362
    special 2362
    sterilization 2362, 2362t
  needles 2357–2358, 2358f–2359f
  sutures 2353–2354, 2354t
    absorbable 2354–2355, 2354t
    capillarity 2353
    coefficient of friction 2353
    complications 2357, 2357f
    elasticity 2353
    materials 2354
    memory 2353
    non-absorbable 2355–2356, 2356t
    physical configurations 2353
    plasticity 2354
    pliability 2354
    selection 2356–2357, 2356t
    tensile strength 2353
    tissue reactivity 2353
    USP size 2353
wound healing 1622t, 2313–2325
  abnormal 2322–2323
  and aging 2323
  angiogenesis 2319f
  cellular components 2317–2321
    endothelial cells 2318
    keratinocytes 2317–2318
    leukocytes and platelets 2317t, 2319–2320
  chronic wounds 2323
    cell-based therapies 2323
    dressings *see* dressings
    growth factors 2317t, 2323
  clinical implications 2314
  delayed 49
  gene therapy 2323–2324
  and immune response 2313, 2315f
  inflammatory phase 2314f, 2320f
  phases of 2315–2317, 2315t, 2316f, 2322f
  preoperative assessment 2461, 2462t
  primary versus secondary intention 2315, 2315f
  re-epithelialization 2318f
  regeneration vs repair 2313
  scars *see* keloids
  skin grafts *see* grafts
  species specificity 2313–2314
    amphibians 2313
    mammals 2313–2314
    zebrafish 2313
  stem cells 2321, 2324, 2324f
  and wound depth 2314–2315, 2314f
wound myiasis 1433
wound tension 2465, 2466f
wrestler's ear *see* traumatic auricular hematoma
wrinkles *see* rhytides
wrinkly skin syndrome 1593t
Wuchereria bancrofti 1416
Wyburn-Mason syndrome *see* Bonnet-Dechaume-Blanc syndrome
Wyeth, George A 2304

X Dendranthema cultivars *see* chrysanthemums
X inactivation 788, 943, 945t, 948
X-linked agammaglobulinemia 900t, 915, 916f
X-linked dominant chondrodysplasia punctata *see* Conradi-Hünermann-Happle syndrome
X-linked dominant inheritance 786t, 787
X-linked dominant protoporphyria 719t, 722–723
  biochemical findings 720t
  genetics 719t
  treatment 725t
X-linked hyper-IgM syndrome 917t
X-linked hypertrichosis 809t, 1116t
X-linked hypogammaglobulinemia 212t
X-linked hypohidrotic ectodermal dysplasia 817f, 952
X-linked ichthyosis 838t, 866–868
X-linked lymphoproliferative syndrome 906t
X-linked neutropenia 912t
X-linked recessive chronic granulomatous disease 910t
X-linked recessive ichthyosis *see* steroid sulfatase deficiency
X-linked recessive inheritance 786t, 787
X-linked reticulate pigmentary disorder 708, 952, 1065t, 1069–1070
  clinical features 1069, 1070f
  differential diagnosis 1070
  epidemiology 1069
  genetics 810t
  pathology 1069
  treatment 1070
xanthelasma 6t–7t, 1552, 1553f
xanthelasmoidal mastocytosis 1995–1996
xanthine oxidase 2170
xanthine oxidase inhibitors *see* allopurinol
xanthoerythrodermia perstans *see* parapsoriasis
xanthogranuloma
  juvenile *see* juvenile xanthogranuloma
  necrobiotic *see* necrobiotic xanthogranuloma
xanthomas 22, 1547–1555
  and anetoderma 1633t
  clinical features 23f, 1549–1553
    eruptive xanthoma 1550–1551, 1550f
    plane xanthomas and xanthelasma 1552–1553, 1552f–1553f
    tendinous xanthomas 1551–1552, 1551f–1552f
    tuberous/tuberoeruptive xanthomas 1551, 1551f
    verruciform xanthomas 1553, 1553f
  differential diagnosis 1554, 1554t
  epidemiology 1547
  eruptive 768t, 769f, 1550f, 1553
  monoclonal gammopathy 1553f, 2014t
  papular 1530t–1531t, 1533t
  pathogenesis 1547–1549
  pathology 1553–1554, 1553f
  treatment 1554, 1554t–1555t
xanthoma disseminatum 1544–1545
  antigenic markers 1533t
  clinical features 1530t–1531t, 1544, 1544f
  differential diagnosis 1545
  epidemiology 1544
  history 1544
  monoclonal gammopathy 2014t
  pathogenesis 1544
  pathology 1544–1545
  treatment 1545
xanthoma striatum palmare 1551–1552
xanthotoxin 281
xenon chloride lasers 2252t
xenon flashlamps 2257
Xenopsylla spp. 1440t
Xenopsylla cheopis 1244t
Xeomin *see* botulinum toxin
Xerac AC 2464t
xeroderma pigmentosum 49, 1072t–1073t, 1462t, 1475–1477, 1476t–1477t, 1771, 1854, 1857t
  clinical features 1460f, 1476t–1477t, 1477, 1477f
  epidemiology 1477
  genetics 813t
  history 1475
  and NMSC 1776
  pathogenesis 1477
  treatment 1477
Xeroform dressings 2366–2367
xerophthalmia 398–399
  retinoid-induced 2100t, 2101
  Sjögren's syndrome 677t
  vitamin A deficiency 740t–742t
xerosis 112f, 678
  atopic dermatitis 209t
  elderly patients
  HIV-related 1294
  renal patients 117–118, 117f
  vaginal 678
  see also asteatotic eczema
xerostomia 678
xerotic eczema 2479
XL-281 1887t
XL147 1887t
Xylocaine *see* lidocaine

Y-linked inheritance 787
YAG lasers 2254f
yarrow 274t, 276–277
yaws 1216, 1216f
yellow albinism 1031
yellow fever virus 1360t
yellow lesions 6t–7t
yellow nail syndrome 778t–779t, 1130f, 1139, 1139f
yellowtail moth 1441t
Yersinia spp., secondary cutaneous vasculitis 390t
Yersinia pestis 1213–1214, 1213f
yohimbine, and eccrine sweating 590t
yttrium-scandium-gallium-garnet laser 2273t

Z-plasty 2402
zafirlukast 2177f, 2177t
  urticaria 304
zalcitabine
  adverse reactions 1299t
    erythroderma 176t
ZAP-70 89
  deficiency 920t
Zea mays see corn
zebra-line hyperpigmentation *see* linear and whorled nevoid hypermelanosis
zebrafish, wound healing 2313
zemaphyte 2192t
zengse pill 2206t
zidovudine
  adverse reactions 1299t
    erythroderma 176t
    melanonychia 1295f
    nail changes 1141t
    pseudo-Hutchinson's sign 2443t
  interactions 2127t
Ziehl-Neelsen stain 26, 27t–28t
zileuton 2177f, 2177t
Zimmermann-Laband syndrome 1116t
zinc
  deficiency 746–748, 748f
    acquired 747
    anogenital manifestations 748f, 1183
    genetic 747
  dermatosis 749f, 1499t
  foreign body reaction 1574t, 1576t, 1579
zinc chloride 2211
  Mohs surgery 2445
zinc oxide 2199–2201, 2200f
Zincaband 2369
Zinsser-Engman-Cole syndrome *see* dyskeratosis congenita
ziprasidone
  adverse reactions 129t
  psychosis 134
Ziprkowski-Margolis syndrome 1038, 1072t–1073t
zirconium, foreign body reaction 1574t, 1579
  histopathology 1576t
zirconium salts
  hyperhidrosis 594t
  hypohidrosis/anhidrosis 595t
zoledronate 2080–2081, 2082f
zolmitriptan 2190t
zolpidem 2351–2352
zonisamide, hypohidrosis/anhidrosis 595t
zonula occludens 833–834
Zoon's balanitis/vulvitis 1175, 1175f
zoster sine herpete 1329–1330
zosteriform lentiginous nevus *see* nevus spilus
zosteriform speckled lentiginous nevus 955
zuclopenthixol 2190t
Zyderm 2548t–2549t, 2550
zygomatic arch 2327
zygomaticus major 2335
zygomycosis 1279f
  and drug abuse 1515t
  neonates 526t–528t
Zyplast 2548t–2549t
