Table 70.2 Hereditary diseases and congenital syndromes associated with hypertrichosis. Varying degrees of hypertrichosis (predominantly facial or generalized) have also been observed in children with chromosomal anomalies, e.g. partial trisomy of 1q, 3q, 4p or 17q. AD, autosomal dominant; AR, autosomal recessive; CEP, congenital erythropoietic porphyria; GR, growth retardation; HEP, hepatoerythropoietic porphyria; MR, mental retardation; PCT, porphyria cutanea tarda; VP, variegate porphyria.

Acquired generalized hypertrichosis

Acquired generalized hypertrichosis is most often related to drug ingestion (Table 70.3). Drug-induced hypertrichosis is characterized by slow growth of terminal hair of medium thickness. The findings are most evident on the forehead, temples, flexor aspects of the extremities, and trunk. Drug-related hypertrichosis is usually reversible, and differs in distribution from drug-induced hirsutism.

Generalized hypertrichosis can represent a sign or consequence of a variety of systemic conditions, including disorders of the CNS (e.g. traumatic brain injuries), POEMS syndrome (*p*olyneuropathy *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy and *s*kin lesions), juvenile hypothyroidism, juvenile dermatomyositis, acrodynia, malnutrition (including anorexia nervosa) and advanced HIV infection.

Localized hypertrichosis

Most cases of localized hypertrichosis involve a switch from vellus to terminal hair in sites that do not usually bear terminal hair. Localized hypertrichosis can develop as a component of a hamartoma, as an isolated congenital lesion, as a manifestation of a systemic disease (inherited or acquired), and as a consequence of cutaneous trauma or inflammation.

Congenital localized hypertrichosis

Hamartomas, including those with delayed clinical presentation, and congenital abnormalities characterized by hypertrichosis of a specific anatomic site (Fig. 70.2, Tables 70.4 & 70.5) are included in this category.

HYPERTRICHOSIS DUE TO DRUGS	
ANTIBIOTICS	
• Streptomycin	
ANTI-INFLAMMATORY DRUGS	
• Benoxaprofen	• Glucocorticosteroids
VASODILATORS	
• Diazoxide • **Minoxidil**	• Prostaglandin E1
DIURETICS	
• Acetazolamide	
ANTICONVULSANTS	
• **Phenytoin**	
IMMUNOSUPPRESSIVES	
• **Cyclosporine**	• Mycophenolate mofetil
PSORALENS	
• Trimethylpsoralen	• Methoxypsoralen
ANTISEPTIC AGENTS	
• Hexachlorobenzene	
CHELATORS	
• Penicillamine	
OTHER	
• Interferon-α • Fenoterol	• EGFR inhibitors (e.g. cetuximab, panitumumab, erlotinib, gefitinib)

Table 70.3 Hypertrichosis due to drugs. Most common drugs are in bold. EGFR, epidermal growth factor receptor.

HEREDITARY HYPERTRICHOSIS AFFECTING SPECIFIC ANATOMIC SITES			
Condition	**Inheritance**	**Onset**	**Other features**
Hypertrichosis cubiti (hairy elbow syndrome)	AD	Birth to early childhood	• Short stature*
Hairy palms and soles	AD	Birth	
Hypertrichosis of the auricle	AD†	Childhood or adolescence	• Primarily affects males
Hypertrichosis of the eyebrows	?	Adolescence	
Trichomegaly of the eyelashes	AD vs AR	Childhood	
Hypertrichosis of the nasal tip	?	Adolescence	• Primarily affects males
Anterior cervical hypertrichosis	AD‡	Birth to early childhood	• Sensory and motor neuropathy* • Mental retardation* • Hallux valgus*
Posterior cervical hypertrichosis	AD	Birth	• Kyphoscoliosis
Polythelia, including the hairy variant§	AD¶	Adolescence	• Urinary tract anomalies*

*Occasional finding.
†Recently shown not to be Y-linked in a cohort of Indian men; congenital hypertrichosis of the pinna can be seen in the offspring of diabetic mothers and in individuals with XYY syndrome.
‡Possible AR inheritance in one consanguineous family.
§Tuft of hair along the "mammary line".
¶Approximately 10% of cases are familial.

Table 70.4 Hereditary hypertrichosis affecting specific anatomic sites. AD, autosomal dominant; AR, autosomal recessive.

HYPERTRICHOSIS OF THE EYEBROWS AND EYELASHES
SYNOPHRYS
• Isolated trait • Waardenburg syndrome (see Ch. 66) • Cornelia de Lange syndrome (see Table 70.2) • Zimmerman–Laband syndrome (see Table 70.1) • Amaurosis congenita, cone–rod type, with hypertrichosis (see Table 70.1) • Mucopolysaccharidoses (see Ch. 48)
INHERITED AND/OR CONGENITAL TRICHOMEGALY
• Isolated trait • Oliver–McFarlane syndrome* • Cornelia de Lange and Rubinstein–Taybi syndromes (see Table 70.2) • Congenital hypertrichosis lanuginosa and Ambras syndrome (see Table 70.1) • Cantú, Coffin–Siris and Barber–Say syndromes (see Table 70.1) • Amaurosis congenita, cone–rod type, with hypertrichosis (see Table 70.1) • Hermansky–Pudlak syndrome (see Ch. 66) • Kabuki and floating harbor syndromes† • Fetal alcohol syndrome (see Table 70.2)
ACQUIRED TRICHOMEGALY
• HIV infection • Medications (systemic): cyclosporine, EGFR inhibitors (e.g. cetuximab, gefitinib), topiramate, tacrolimus, interferon-α • Medications (ophthalmic): latanoprost, bimatoprost • Hypothyroidism • Porphyrias • Dermatomyositis, systemic lupus erythematosus • Malnutrition, anorexia nervosa • Kala-azar
DISTICHIASIS (DOUBLE ROW OF EYELASHES)
• Lymphedema–distichiasis syndrome‡ • Setleis syndrome (double upper and absent lower lashes; see Ch. 64)

*Autosomal recessive (AR) disorder also featuring sparse scalp hair, mental retardation (MR), short stature, and retinal pigmentary degeneration.
†Autosomal dominant (AD) disorders featuring distinctive facies, growth retardation, and, in the former, MR.
‡AD condition due to *FOXC2* mutations (see Ch. 104).

Table 70.5 Hypertrichosis of the eyebrows and eyelashes. EGFR, epidermal growth factor receptor.

Fig. 70.2 Hypertrichosis cubiti. Multiple terminal hairs on both elbows in a child.

Fig. 70.4 Nevoid hypertrichosis of the scalp in a young boy. There was no underlying melanocytic nevus or hyperpigmentation. *Courtesy, Jean L Bolognia, MD.*

Congenital melanocytic nevus and plexiform neurofibroma
Congenital melanocytic nevi often have associated hypertrichosis. The increased hair growth may be noted at birth, but often becomes more prominent during infancy or early childhood. Hypertrichosis can be seen in small-, medium- and large-sized congenital melanocytic nevi (see Ch. 112). A particularly dense growth of terminal hairs may accompany scalp nevi. Plexiform neurofibromas can also have associated hyperpigmentation and hypertrichosis.

Becker's nevus (melanosis)
This is a hamartoma characterized by macular hyperpigmentation with irregular borders, usually located on the upper lateral trunk (anterior or posterior). Some patients have associated hypertrichosis while others do not. The pigmentation usually arises during the first decade of life, whereas the hypertrichosis typically appears in the second decade (Fig. 70.3). Becker's nevi most often occur in boys and men, and in rare instances are inherited in an autosomal dominant pattern.

Occasionally, asymmetry of the extremities and hyperplasia or hypoplasia of the affected areas (especially ipsilateral mammary hypoplasia in women or, less often, the Poland anomaly) may be present. Rarely, there may be an association with genitourinary tract abnormalities (SNUB syndrome: *s*upernumerary *n*ipples, *u*ropathies, *B*ecker's nevus)[4]. Because of their benign nature, surgical removal of Becker's nevi is not recommended. Epilation can be performed by various techniques, but attempts at decreasing pigmentation via laser therapy are often not successful.

A smooth muscle hamartoma (SMH; see Ch. 117), which exists on a spectrum with Becker's nevus, may present as a circumscribed hypertrichotic plaque with variable hyperpigmentation. Rarely, there is a generalized form of SMH that presents as extensive hypertrichosis and folding of the skin and has been reported under the term "Michelin tire baby". Lastly, the hypertrichosis observed in the setting of hemimaxillofacial dysplasia, which manifests with facial asymmetry due to unilateral maxillary enlargement, gingival hyperplasia and hypoplastic teeth, is often associated with a Becker's nevus or SMH.

Other hamartomas and infantile tumors
Hypertrichosis can also overlie the following skin lesions: plaque-type blue nevus, fibrous hamartoma of infancy, dermal dendrocyte hamartoma, eccrine angiomatous hamartoma, congenital plaque-like glomangioma, and tufted angioma.

Nevoid hypertrichosis
This is an uncommon congenital alteration characterized by the growth of terminal hairs in a circumscribed area. In general, there are no extracutaneous associations in *primary nevoid hypertrichosis*; the skin within the affected area is normally pigmented and there is no underlying hamartoma (Fig. 70.4). Nevoid hypertrichosis has been observed to follow Blaschko's lines, as reported in female "carriers" of X-linked hypertrichosis (see Table 70.1). *Secondary nevoid hypertrichosis* can be associated with lipodystrophy, hemihypertrophy, scoliosis and abnormalities of the underlying vasculature. Nevoid hypertrichosis can also occur together with epidermal nevi or nevoid hypopigmentation, likely reflecting the phenomenon of "twin spotting".

Spinal dysraphism and the hair collar sign
The term "dysraphism" is defined as an "alteration of the formation of a fold or elevation which is constituted in the midline of the human body as a consequence of the union of two lateral portions". In spinal dysraphism, abnormal closure of the neural tube leads to defects in the vertebral column and/or spinal cord (see Ch. 64). Skin lesions "marking" a hidden vertebral defect are usually located in the dorsal midline. The "faun tail" is most often a sign of spina bifida occulta or diastematomyelia (split spinal cord), and is typically located in the lumbosacral region. In addition, a ring of hypertrichosis ("hair collar sign") surrounding membranous aplasia cutis or ectopic neural tissue in the scalp reflects the origin of these midline lesions as "incomplete" neural tube defects.

Localized hypertrichosis in hereditary and acquired systemic diseases
There are multiple genodermatoses characterized by the presence of localized hypertrichosis as a major or secondary diagnostic feature (see Table 70.2)[5,6]. For example, hypertrichosis within sun-exposed areas is one of the signs of the porphyrias – in particular, porphyria cutanea tarda (Fig. 70.5) and congenital erythropoietic porphyria[7]. Likewise, the low frontal hairline and synophrys (confluent eyebrows) in the Cornelia de Lange syndrome are important diagnostic features of that entity[8]. Localized hypertrichosis may also be observed in acquired systemic diseases, such as infrapatellar hypertrichosis in juvenile dermatomyositis or hypertrichosis overlying pretibial myxedema, indurated plaques of Rosai–Dorfman disease, and areas affected by reflex sympathetic dystrophy.

Acquired localized hypertrichosis
After repeated trauma, friction, irritation or inflammation, the hair within affected areas of skin may become longer and thicker (e.g. hypertrichosis of the back in sack carriers, hypertrichosis of a fractured limb after the application of a plaster cast, hypertrichosis of the posterior neck in people who bear heavy weights) (Fig. 70.6)[9]. Sites of chronic rubbing and scratching due to pruritus may also develop hypertrichosis. Transient localized hypertrichosis has been observed within vaccination sites and varicella scars as well as sites of wart removal and laser epilation. In addition, hypertrichosis has been described overlying lipoatrophy following lupus panniculitis and within resolving lesions of psoriasis and morphea.

Localized hypertrichosis has been reported after PUVA therapy. Sites of application of potent topical corticosteroids, tacrolimus, and creams containing mercury or iodine can also develop localized hypertrichosis, as can sites of repeated irritation from anthralin. Prostaglandin F-2α

Fig. 70.6 Acquired localized hypertrichosis. Hypertrichosis, hyperpigmentation and epidermal hyperplasia at the site of friction.

analogues (e.g. latanoprost, bimatoprost), which are topical agents used for the treatment of glaucoma, were noted to induce trichomegaly of the eyelashes (Fig. 70.7) as well as brown iris pigmentation. Recently, bimatoprost was FDA-approved for the enhancement of eyelash growth[10,11]. Latanoprost has also been used to treat eyelash alopecia in alopecia areata universalis[11a].

Treatment

The therapies currently available to treat hypertrichosis are limited to "depilation" with creams, electrolysis, and hair removal with lasers. Various laser systems have been developed for epilation of unwanted hair, e.g. Nd:YAG, diode and alexandrite lasers; this is in addition to hair removal utilizing an intense pulsed non-coherent light source (see Ch. 137). Among the cream depilatories, those containing barium sulfate have been shown to be especially effective, although they cause irritation more frequently than the "calcium thioglycolate" depilatory creams. Shaving and other cosmetic maneuvers (e.g. plucking) may also be employed[1,12].

HIRSUTISM

Introduction

The term "*hirsutism*" is defined by the presence, in women, of terminal hairs in a male pattern, in contrast to *hypertrichosis*, which is simply an increase in the amount of hair (lanugo, vellus or terminal). Hirsutism reflects an increase in circulating androgens (whose source is primarily the ovary or adrenal gland) or an enhanced end-organ response to androgens[13–15]. At puberty, secondary sexual characteristics develop and, in men, this leads to the appearance of terminal hair on the face (mustache, beard), chest, shoulders, back, arms, thighs, pubic and lower abdominal areas, and buttocks. When this pattern of hair growth is seen in women, the diagnosis is hirsutism (see Fig. 70.14).

Epidemiology

Hirsutism, as defined by a score of ≥8 on the Ferriman and Gallwey scale (see below), affects approximately 5% of women of reproductive age in the general population. In a study of North American women, 35% had terminal hairs on the linea alba, 17% in the periareolar area, 16% in the lumbosacral area, and 10% in the upper pubic triangle[1,13].

Classification

For clinical and therapeutic purposes, hirsutism can be classified into several different types (Table 70.6)[13,16–18].

Clinical Features

Constitutional or dermatologic hirsutism

Hirsutism may be accompanied by seborrhea, acne and androgenetic alopecia, dermatologic manifestations that are the result of the actions of androgens on target tissues. In 1982, Orfanos[19] coined the term "SAHA syndrome" (*s*eborrhea, *a*cne, *h*irsutism and *a*lopecia) for this "dermatologic androgenization syndrome". Although the same constellation of clinical findings may occur in patients with polycystic ovary syndrome (PCOS) and other disorders of androgen excess, isolated SAHA can be distinguished by a lack of substantial hormonal abnormalities, anovulatory menstrual cycles, or ultrasonographic evidence of polycystic ovaries. The characteristics of the four types of dermatologic hirsutism are reviewed in Table 70.6 (Figs. 70.8 & 70.9)[16,17].

HAIR-AN syndrome

The "HAIR-AN syndrome" is a familial virilization syndrome characterized by *h*yper*a*ndrogenemia (HA) in association with *i*nsulin *r*esistance (IR) and *a*canthosis *n*igricans (AN)[20]. This is not part of the SAHA syndrome, but may overlap with PCOS. HAIR-AN is found in 2% to 5% of hirsute patients.

CLASSIFICATION OF TYPES OF HIRSUTISM		
Type	**Circulating hormone levels**	**Clinical findings**
CONSTITUTIONAL (DERMATOLOGIC) – NORMAL OR SLIGHTLY INCREASED CIRCULATING LEVELS OF TESTOSTERONE		
Familial	Normal values*	Generally facial with prolongation of preauricular hair implantation line (Fig. 70.9)
Adrenal (persistent adrenarche syndrome; adrenal SAHA syndrome)	Mild increase in DHEA-S	Thin young women who may feel "stressed"; predominantly central hirsutism (anterior neck → upper pubic area; Fig. 70.8); intense seborrhea, nodulocystic acne, FAGA I–II (occasionally male pattern); oligomenorrhea
Ovarian (excess ovarian androgen release syndrome; ovarian SAHA syndrome)	Mild increase in free testosterone (DHEA-S normal)	Young women; tend to be obese; mild lateral facial and mammary hirsutism; intense seborrhea, papulopustular acne, FAGA I; normal menses or polymenorrhea
Hyperprolactinemic (SAHA syndrome with hyperprolactinemia)	Slight increase prolactin	Central and lateral hirsutism; sometimes seborrhea, acne, FAGA I; oligomenorrhea; occasionally galactorrhea
ENDOCRINE ORGAN-BASED		
Adrenal hirsutism		See text
Congenital adrenal hyperplasia (e.g. 21-hydroxylase deficiency)	↑ 17-OH progesterone; ↑ DHEA-S; ↑↑ ACTH; normal–↑ free testosterone	
Hypercorticism (Cushing's syndrome) – primary nodular hyperplasia – adenoma – carcinoma	↑ cortisol; 17-OH progesterone normal / ↑; ↓ ACTH (adenoma or carcinoma); ↑–↑↑↑ DHEA-S (especially with adrenal tumors); ↑–↑↑ free testosterone	More rapid appearance with adrenal carcinoma
Ovarian hirsutism		See text
Polycystic ovary syndrome (PCOS)	↓ FSH; ↑ LH; LH/FSH > 3; normal DHEA-S; normal–↑ free testosterone; ↓ SHBG; ↑ estrone; insulin resistance; dyslipidemia	
Hyperthecosis	Normal LH, FSH; normal DHEA-S; ↑↑ estrone; higher testosterone than PCOS	
Ovarian tumors	Normal DHEA-S; ↑↑–↑↑↑ free testosterone	
Pituitary hirsutism		See text
Cushing's disease	↑ ACTH leading to ↑ DHEA-S and cortisol	
Prolactin-secreting pituitary adenoma	↑ Prolactin	
Psychogenic drugs†	↑ Prolactin	
ECTOPIC HORMONE PRODUCTION		
ACTH (e.g. small cell lung CA, carcinoids)	↑–↑↑ ACTH	More rapid appearance when due to malignancy
HCG (choriocarcinomas)	↑–↑↑ beta-HCG	
DRUGS (IATROGENIC)		
Anabolic steroids	Elevated parent drug or metabolite in blood, urine or hair	

*Hirsutism presumably due to increased end-organ sensitivity.
†Block dopamine-mediated inhibition of prolactin secretion.

Table 70.6 Classification of types of hirsutism. Patients with liver disease can have a decrease in sex hormone binding globulin (SHBG), and a subsequent increase in free testosterone, which may exacerbate other causes of hirsutism. There is also conversion of androgens (e.g. Δ-4-androstenedione > testosterone) into estrogens, both in the ovaries and in the periphery (adipose tissue, liver). In theory, a reduction in this conversion could lead to an increase in circulating androgens. ACTH, adrenocorticotropic hormone; DHEA-S, dehydroepiandrosterone sulfate; FAGA, *f*emale *a*ndrog*e*netic *a*lopecia (for Ludwig grading system, see Ch. 69); FSH, follicle-stimulating hormone; HCG, human chorionic gonadotropin; LH, luteinizing hormone; SAHA, *s*eborrhea, *a*cne, *h*irsutism, *a*lopecia; SHBG, sex hormone-binding globulin.

Adrenal hirsutism

Adrenal hirsutism should be considered in a patient of any age presenting with obvious central hirsutism (i.e. anterior neck to upper pubic area), together with *f*emale *a*ndrogenetic *a*lopecia (FAGA; Ludwig I–III) or male pattern androgenetic alopecia, signs of virilization, and a thin body habitus[13,14].

Non-tumoral adrenal hirsutism

Adrenal hyperplasias

Congenital adrenal hyperplasia (CAH) is due to a congenital deficiency of one of the enzymes involved in the synthesis of adrenal steroids (Fig. 70.10). This leads to an accumulation of the intermediate product normally metabolized by the deficient enzyme. As these intermediate products are not recognized by the pituitary, the negative feedback mechanism is not initiated, resulting in very high levels of ACTH.

21-Hydroxylase deficiency is responsible for 95% of all cases of CAH. The salt-wasting form of classic CAH presents during the first 2 weeks of life with dehydration and electrolyte abnormalities (due to cortisol deficiency); affected female neonates are typically noted to have ambiguous genitalia, while male neonates may manifest with only subtle hyperpigmentation of the genitals, flexural areas and palmoplantar creases. These patients, as well as individuals with less severe forms of classic CAH, show premature growth of axillary and pubic hair during early childhood (precocious pubarche), which is soon followed by hirsutism accompanied by acne and the onset of patterned alopecia. Virilization, which can be viewed as an advanced degree of defeminization, is often observed (Table 70.7). Lack of breast development in women and a large penis with small testicles and no spermatogenesis in men are associated findings.

Late-onset CAH (attenuated CAH) is due to partial enzyme deficiencies (e.g. of 21-hydroxylase), and it becomes clinically apparent when

Fig. 70.8 Central hirsutism (score 3 for the lower abdomen) in a woman with adrenal SAHA (*s*eborrhea, *a*cne, *h*irsutism and *a*lopecia) syndrome.

Fig. 70.9 Familial hirsutism. Prolongation of the preauricular hair implantation line with terminal hairs of the lateral lower face and neck.

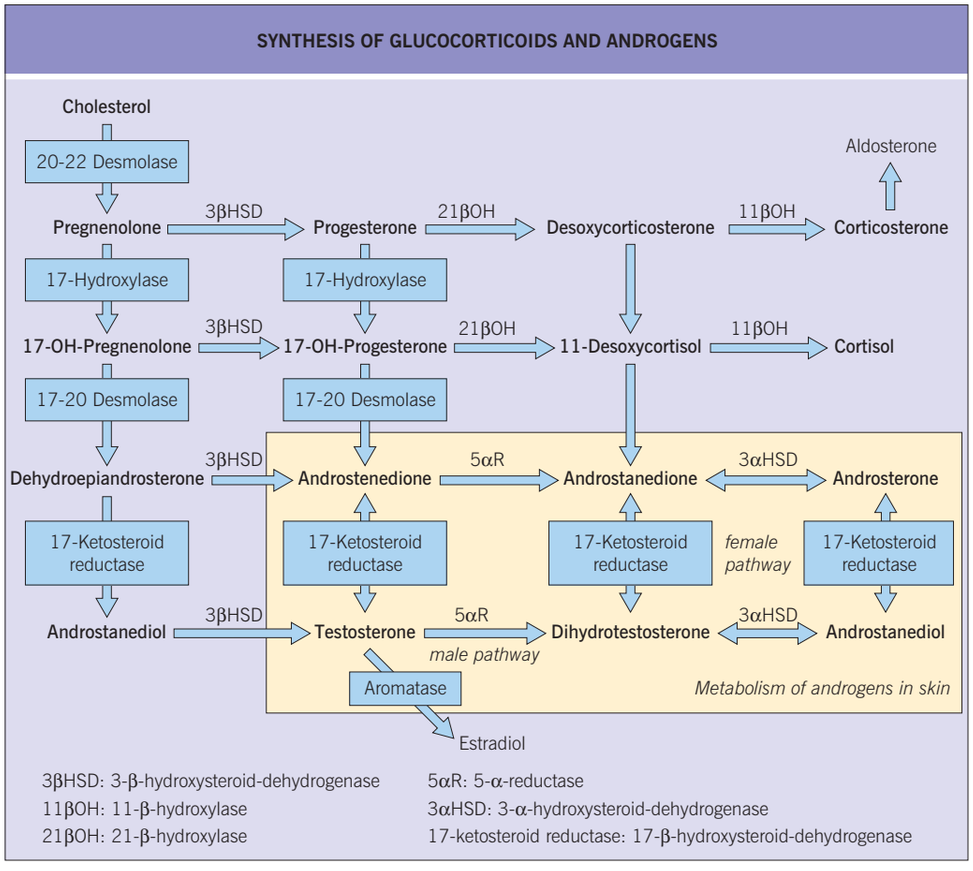

Fig. 70.10 Synthesis of glucocorticoids and androgens. The most common cause of congenital adrenal hyperplasia is 21-hydroxylase deficiency. This leads to an accumulation of 17-OH-progesterone.

DIFFERENCES BETWEEN DEFEMINIZATION AND VIRILIZATION

Defeminization	Virilization
Acne	Hirsutism
Female androgenetic alopecia (FAGA)	Female androgenetic alopecia of male pattern (FAGAM)
Menstrual alterations (e.g. oligomenorrhea)	Amenorrhea
Breast atrophy and loss of female body contours	Muscle mass increased
Decreased rugosity of the vaginal columns	Clitoromegaly
Infertility	Coarsening of the voice

Table 70.7 Differences between defeminization and virilization.

demand for steroids increases at puberty or thereafter. Virilization is again a clinical feature; however, 40% of patients only have hirsutism.

Cryptic CAH is a form of CAH described in family members of patients with CAH who have the same biochemical alterations as the affected individuals, but no clinical manifestations.

Hypercortisolism (Cushing's syndrome)

Cushing's syndrome may be associated with either high plasma ACTH levels (pituitary hyperproduction and "ectopic ACTH syndrome") or a nearly complete lack thereof (adrenal primary nodular hyperplasia, adrenal adenoma or carcinoma). All patients have an increase in plasma cortisol, which is the cause of the major clinical features, e.g. central obesity with "moon facies" and "buffalo hump", hypertension, glucose intolerance, purple striae, and ecchymoses. Patients with adrenal

hyperplasia (usually due to ACTH hyperstimulation by a pituitary adenoma) or adrenal adenomas typically have an insidious onset of symptoms, but with an adrenal carcinoma or ectopic ACTH production by a malignant tumor, manifestations appear more rapidly. If there is significant production of androgens, which is not the norm for adrenal adenomas, there will be a virilization syndrome with hirsutism in addition to the typical manifestations of Cushing's syndrome.

Tumoral adrenal hirsutism

A virilizing adrenal adenoma or carcinoma may be responsible for severe hirsutism. Acne, androgenetic alopecia, amenorrhea and seborrhea occur together with the other characteristic signs of Cushing's syndrome.

Ovarian hirsutism

If the patient presents with hirsutism greater than grade 2 that is predominantly lateral (i.e. on the neck and the breasts), FAGA I–II, acne, seborrhea, obesity and obvious menstrual disorders, the presumed diagnosis is hirsutism of ovarian origin. Like adrenal hirsutism, this may have a tumoral or non-tumoral etiology.

Non-tumoral ovarian hirsutism

Polycystic ovary syndrome

This syndrome was described by Stein and Leventhal in 1935, and is characterized by infertility, secondary amenorrhea or menstrual alterations, and, often, obesity, in association with large polycystic ovaries (Fig. 70.11)[21]. Biochemically, one can see a decrease in follicle-stimulating hormone (FSH) and an increase in luteinizing hormone (LH), as well as an increase in estrone and testosterone. Occasionally, the serum prolactin levels are also increased. PCOS is the most common cause of clinically evident androgen excess, affecting approximately 5% of women of reproductive age. It is a heterogeneous disorder that may be inherited in an autosomal dominant pattern or as a complex multigenic trait.

After a normal menarche, patients develop persistent oligo- or amenorrhea that is frequently accompanied by infertility. Acne is observed in 70% of patients and hirsutism in 90%. The associated hirsutism is usually lateral, i.e. on the breasts, lateral aspects of the face and neck, as well as on the abdomen (Fig. 70.12). At least 50% of patients are obese, and some develop acanthosis nigricans. There are no signs of genital virilization. These patients have large ovaries with a pearly gray surface, a thickened capsule and cysts with hyperplasia of the internal theca, but no signs of activity in the granulosa. Women with PCOS have a higher prevalence of insulin resistance[22], dyslipidemia and hypertension, as well as obesity, components of the "metabolic syndrome" that confer an increased risk of atherosclerotic cardiovascular disease. Patients should be screened for these conditions and followed accordingly (see Fig. 70.11).

Ovarian hyperthecosis

This is similar to PCOS, but with greater production of androgens, especially testosterone. The patients present with signs of virilization, hirsutism (Fig. 70.13), and even androgenic alopecia. Serum levels of LH and FSH are normal, but estrone levels are greatly elevated.

Tumoral ovarian hirsutism

If hirsutism is mild relative to the degree of virilization in an older (especially postmenopausal) woman, one should think about the possibility of an ovarian tumor. Arrhenoblastomas, hilus cell tumors, Brenner's tumors, and gonadoblastomas can all be causes of tumoral ovarian hirsutism.

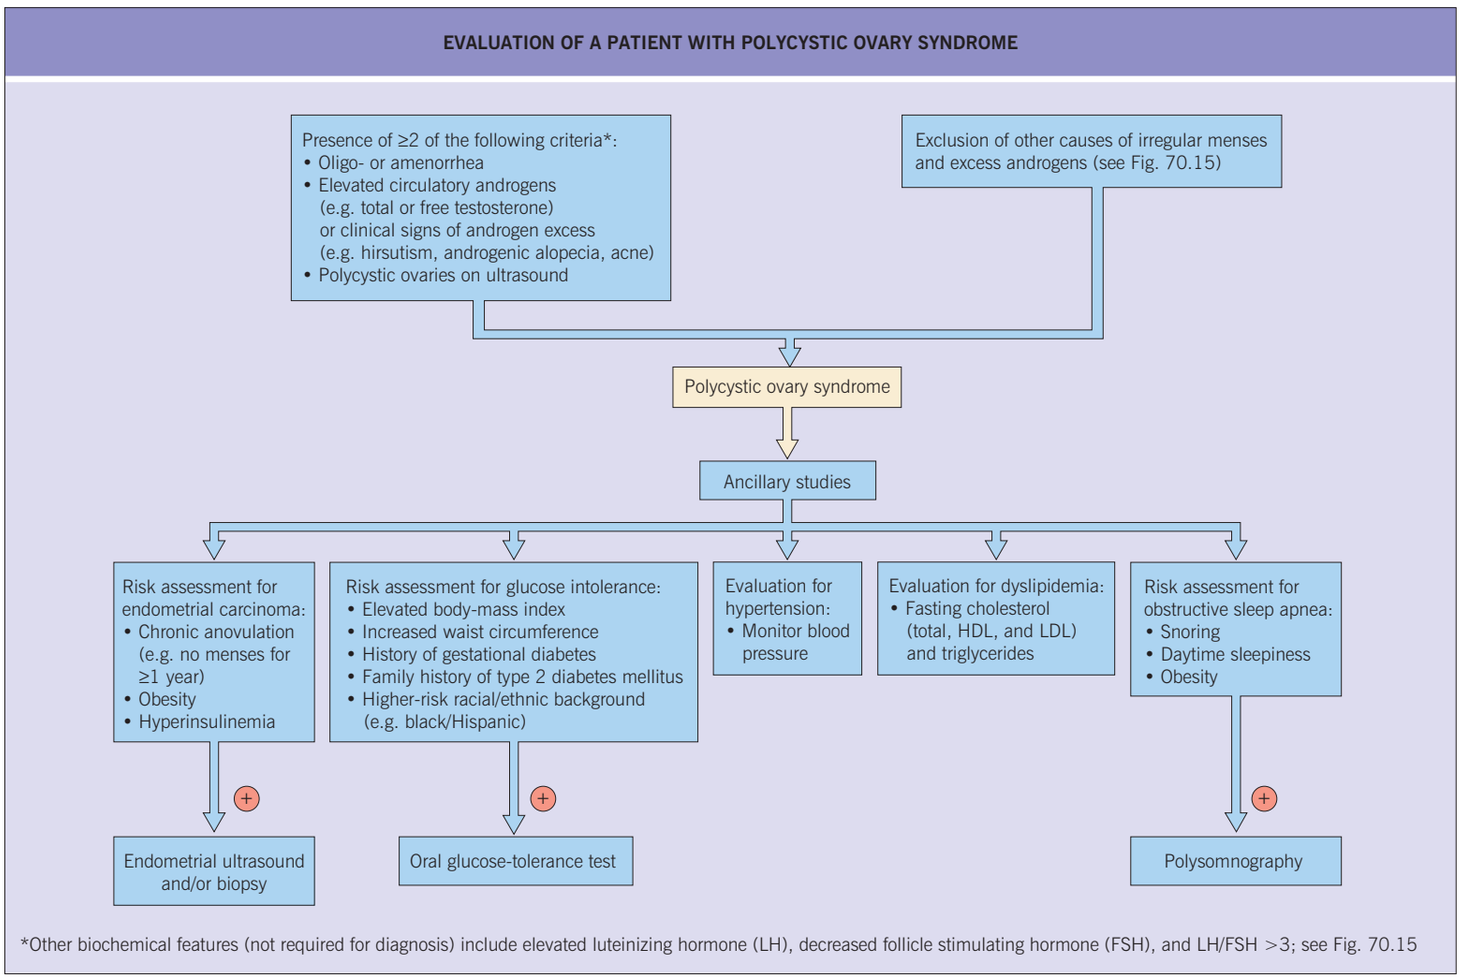

Fig 70.11 Evaluation of a patient with polycystic ovary syndrome (PCOS). Polycystic ovaries alone, without an ovulatory disorder or hyperandrogenism, constitute a risk factor for the development of PCOS[36,37]. *Adapted from Ehrman DA. Polycystic ovary syndrome. N Engl J Med. 2005;352:1223–36.*

Fig. 70.12 Hirsutism in a young woman with polycystic ovary syndrome.

Fig. 70.13 Facial hirsutism (score 4) due to ovarian hyperthecosis. *Courtesy, Robert Hartman, MD.*

Pituitary hirsutism

This type of hirsutism is due to the secretion of hormones from the anterior pituitary, particularly ACTH (see Cushing's syndrome above) and prolactin. There are a number of etiologies of hyperprolactinemia, although pituitary adenomas and drugs are the major causes. Clinical features are the "amenorrhea–galactorrhea syndrome" and infertility. Usually, women are younger than 50 years of age and present with FAGA, acne, seborrhea, and hirsutism; the latter is both central and lateral, with a slight predominance of central hirsutism. There are signs of virilization, and galactorrhea is present in 30–80% of the patients. Amenorrhea occurs in 70% of the cases and, conversely, 15–25% of amenorrheic (but not pregnant) women have hyperprolactinemia. Biochemical investigations will show, above all, an increase in prolactin.

Iatrogenic hirsutism

This type of hirsutism tends to be localized to the lateral aspects of the face and back. Anabolic steroids (e.g. danazol) and oral contraceptives of the nonsteroidal progestogen type have been reported to cause hirsutism. Once the anabolic steroids are discontinued, there are no associated laboratory abnormalities and the hirsutism improves or resolves.

Hirsutism due to ectopic hormones

Patients develop central or lateral hirsutism, depending on the hormone produced by the tumor.

Diagnosis

The first step in evaluating a woman with hirsutism is to determine the source of the responsible androgens, i.e. adrenal cortex or ovaries. The marker for adrenal gland androgens is DHEA-S, and the marker for androgens produced by the ovaries is Δ-4-androstenedione. Dihydrotestosterone (DHT), the androgen responsible for androgenetic alopecia and hirsutism, is produced from testosterone by 5-α-reductase type 2 in the hair follicles of the scalp, beard area and chest (see Ch. 69). In contrast, 5-α-reductase type 1 in sebaceous glands generates the DHT involved in the pathogenesis of acne[14].

It should be noted that, as a general rule, "whenever there is hirsutism which appears abruptly and which evolves quickly, one must first suspect that there is an ovarian, adrenal or pituitary tumor". When hirsutism is mainly localized on the areola and the lateral surfaces of the face and neck, the androgens usually have an ovarian origin, whereas if the location is central, with a distribution from the pubic triangle to the upper abdominal area and from the presternal region to the neck and the chin, the origin is usually adrenal. When there is only hair on the lateral aspect of the face and on the back, the hirsutism is usually iatrogenic. With time, however, the distribution can evolve to include both central and lateral involvement.

The Ferriman and Gallwey score reflects functional hirsutism when the score is 9–14, and organic hirsutism when the score is greater than 15 (Fig. 70.14). Abraham's classification of hirsutism is also used to assess degree of severity (Table 70.8)[13,23]. The different diagnostic possibilities in a patient presenting with hirsutism are outlined in Figure 70.15 and Table 70.6. After the patient has been examined for clinical signs that suggest a particular diagnosis (e.g. features of acromegaly or Cushing's syndrome, physical virilization or defeminization, hypertension and galactorrhea), a biochemical evaluation should be initiated. The author recommends measuring total and free testosterone, DHEA-S, prolactin, SHBG, Δ-4–androstenedione and 3-α-androstanediol glucuronide, a metabolite of DHT. Depending on the results of these tests, the laboratory evaluation can be expanded[13,18]. If substantial abnormalities are detected, referral to an endocrinologist or gynecologic endocrinologist is usually indicated.

Treatment

When SAHA syndrome is diagnosed in a patient with minimal clinical findings and no biochemical abnormalities (i.e. familial hirsutism), topical and "dermato-cosmetic" treatments are appropriate[13,24–26,26a] (see below).

Systemic treatment

Persistent adrenarche syndrome (adrenal SAHA syndrome)

Adrenal suppression is achieved with glucocorticosteroids. Dexamethasone at an initial dose of 0.5 mg every night for 3 months and then alternate nights for 3 months can be used versus a nightly dose of 0.25 mg. Prednisone at a nightly dose of 7.5 mg for 2 months, subsequently reduced to 5 mg nightly for 2 months and then 2.5 mg nightly until 6 months of treatment are completed, is an alternative regimen. Deflazacort at an initial dose of 30 mg daily for 1 month, with a maintenance dose of 6 mg daily for up to 2 years, can also be used.

Antiandrogen therapy includes cyproterone acetate, spironolactone, flutamide, finasteride and drospirenone (see Fig. 69.6). *Cyproterone acetate* (not currently available in the US) acts by interfering with the binding of DHT to the androgen receptor and by inhibiting the secretion of FSH and LH due to its progestogen action. The recommended dose is 50–100 mg/day from the 5th to the 15th days of the menstrual cycle, for a 6-month period. As cyproterone acetate can cause feminization of the male fetus as well as menstrual alterations, the addition of ethinyl estradiol is recommended. Side effects include loss of libido, mood swings, fatigue, mastodynia, hypertension, weight gain and venous thromboembolism. It is contraindicated in patients with

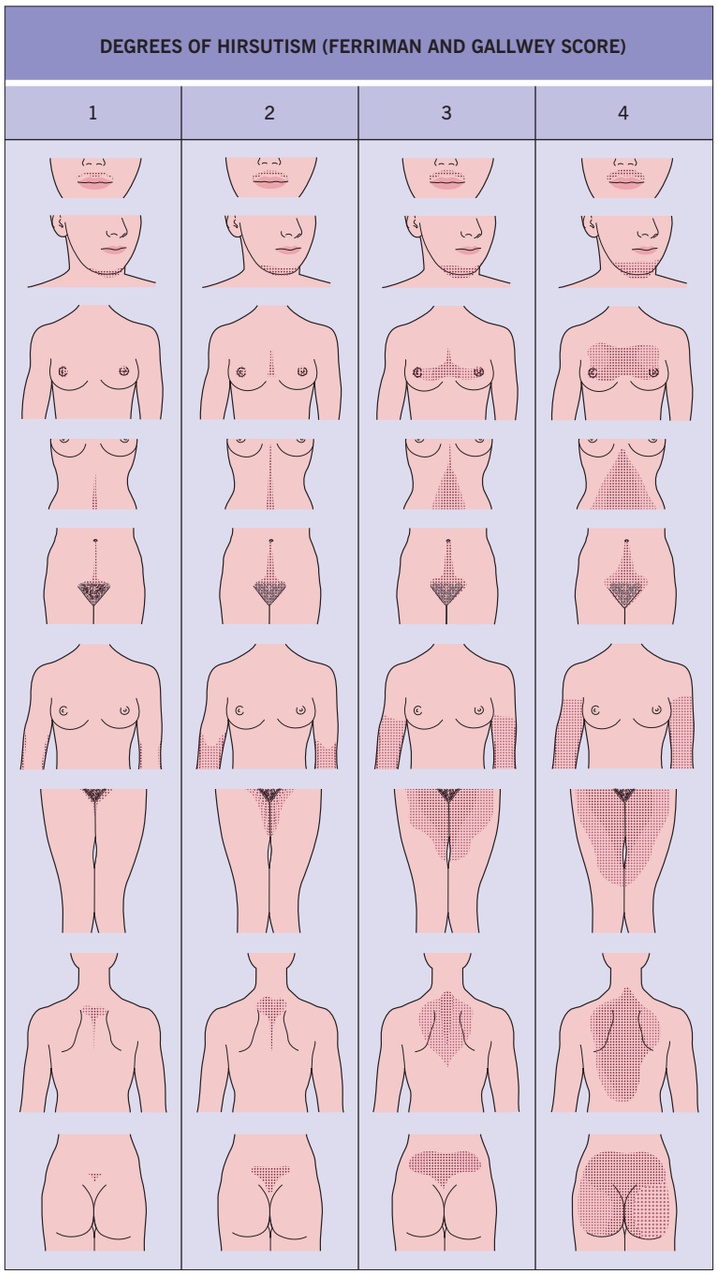

Fig. 70.14 Degrees of hirsutism. The Ferriman and Gallwey score is the sum of the values for each of the nine body areas illustrated. The score reflects functional hirsutism when it is 9–14 and organic hirsutism when it is >15.

ABRAHAM'S CLASSIFICATION OF HIRSUTISM	
Score	**Classification**
<8	Normal
8–16	Discrete
17–25	Moderate
>25	Important

Table 70.8 Abraham's classification of hirsutism. Based on the Ferriman & Gallwey score (see Fig. 70.14).

liver disease. Cyproterone acetate may be the most effective treatment for the alopecia of SAHA syndrome.

Spironolactone is an antagonist of aldosterone (pregnancy category C) that also has antiandrogen activity, decreasing the levels of total testosterone. It is used to treat SAHA with hirsutism and acne at a dose of 50–200 mg/day for at least 6 months. Potential side effects include menstrual irregularities, a decrease in libido, breast enlargement, hyperkalemia, headache, gastrointestinal complaints and fetal feminization[27]. This medication is also used in acne treatment, as discussed in Chapter 36.

Flutamide is a pure, nonsteroidal antiandrogen (pregnancy category D). It is used at a dose of 750 mg daily (in divided doses) for prostatic carcinoma. Side effects include xerosis and toxic hepatitis that may be severe; monitoring of liver function tests is recommended[28]. In the opinion of the author, this is the most effective antiandrogen currently available for the treatment of adrenal SAHA or hirsutism in women with normal ovaries. Low doses of 62.5–125 mg daily can be used[29,30]. As it may also cause feminization of the male fetus, contraception must be employed.

Finasteride is a potent nonsteroidal antiandrogen (pregnancy category X) that acts by inhibiting 5-α-reductase type 2, blocking the conversion of testosterone to DHT. When 72 patients with *persistent adrenarche syndrome* were treated with 2.5 mg daily for 2 years, a 93% reduction in facial hirsutism and a 73% reduction in corporal hirsutism was observed[23] (Fig. 70.16), with no prominent side effects. Other authors have demonstrated that hirsutism, as measured by the Ferriman and Gallwey score, was reduced by finasteride at a dose of 5 mg daily[31].

Drospirenone is a 17-α-spironolactone derivative with progestogenic, antiandrogenic and antialdosterone-like activities[32]. Doses of 3 mg/day during the 21-day cycle along with 30 mcg of ethinyl estradiol is currently considered as an option for the treatment of SAHA, especially because drospirenone does not cause weight gain.

Excess ovarian androgen release syndrome (ovarian SAHA syndrome)

Ovarian suppression includes the use of contraceptives containing an estrogen, ethinyl estradiol, and a progestogen with minimal androgenic activity (e.g. norgestimate). Ethinyl estradiol stimulates the production of SHBG (thereby reducing free testosterone) and it also decreases ovarian androgen production. Cyproterone acetate (see above) and ethinyl estradiol can be used in a sequential pattern for a period of up to 6 months.

Gonadotropin-releasing hormone (GRH) agonists such as leuprolide acetate at a dose of 3.75 mg IM every 28 days for 6 consecutive months suppress pituitary and gonadal function through a reduction in LH and FSH levels. Subsequently, levels of ovarian steroids, androstenedione, testosterone and free testosterone will also be reduced, especially in patients with PCOS. This treatment is expensive and is generally used in severe forms of ovarian hyperandrogenism or HAIR-AN syndrome[26]. More recently, triptorelin (another GRH agonist) was introduced as a therapy for ovarian SAHA, with excellent results. Its effect on hirsutism, as measured by the Ferriman and Gallwey score, was similar to that seen with cyproterone acetate and flutamide treatment. Triptorelin may result in increased levels of serum lipids[33].

Antiandrogens such as flutamide at a dose of 125 mg daily, always accompanied by oral contraceptives, can also be used to treat ovarian SAHA.

SAHA syndrome with hyperprolactinemia

These patients should be treated by a gynecologist with endocrinologic expertise or an endocrinologist. However, when the predominant clinical picture is dermatologic, 2.5 to 7.5 mg/day of *bromocriptine* can be prescribed. *Cabergoline*, another dopamine receptor agonist that suppresses pituitary prolactin production, may also be used in hyperprolactinemic hirsutism, with the advantage that it is only taken once weekly[34].

Iatrogenic hirsutism

The responsible drug must be eliminated. Dermato-cosmetic methods may also be required.

Topical therapy[35]

A topical formulation containing spironolactone and its metabolite, canrenone, at a concentration of 1–3% has been used, with acceptable results, in the treatment of hirsutism in SAHA. Topical eflornithine (15% cream), twice daily, represents another treatment for facial hirsutism. Its safety and effectiveness have been demonstrated in double-blind studies[25,32,35a].

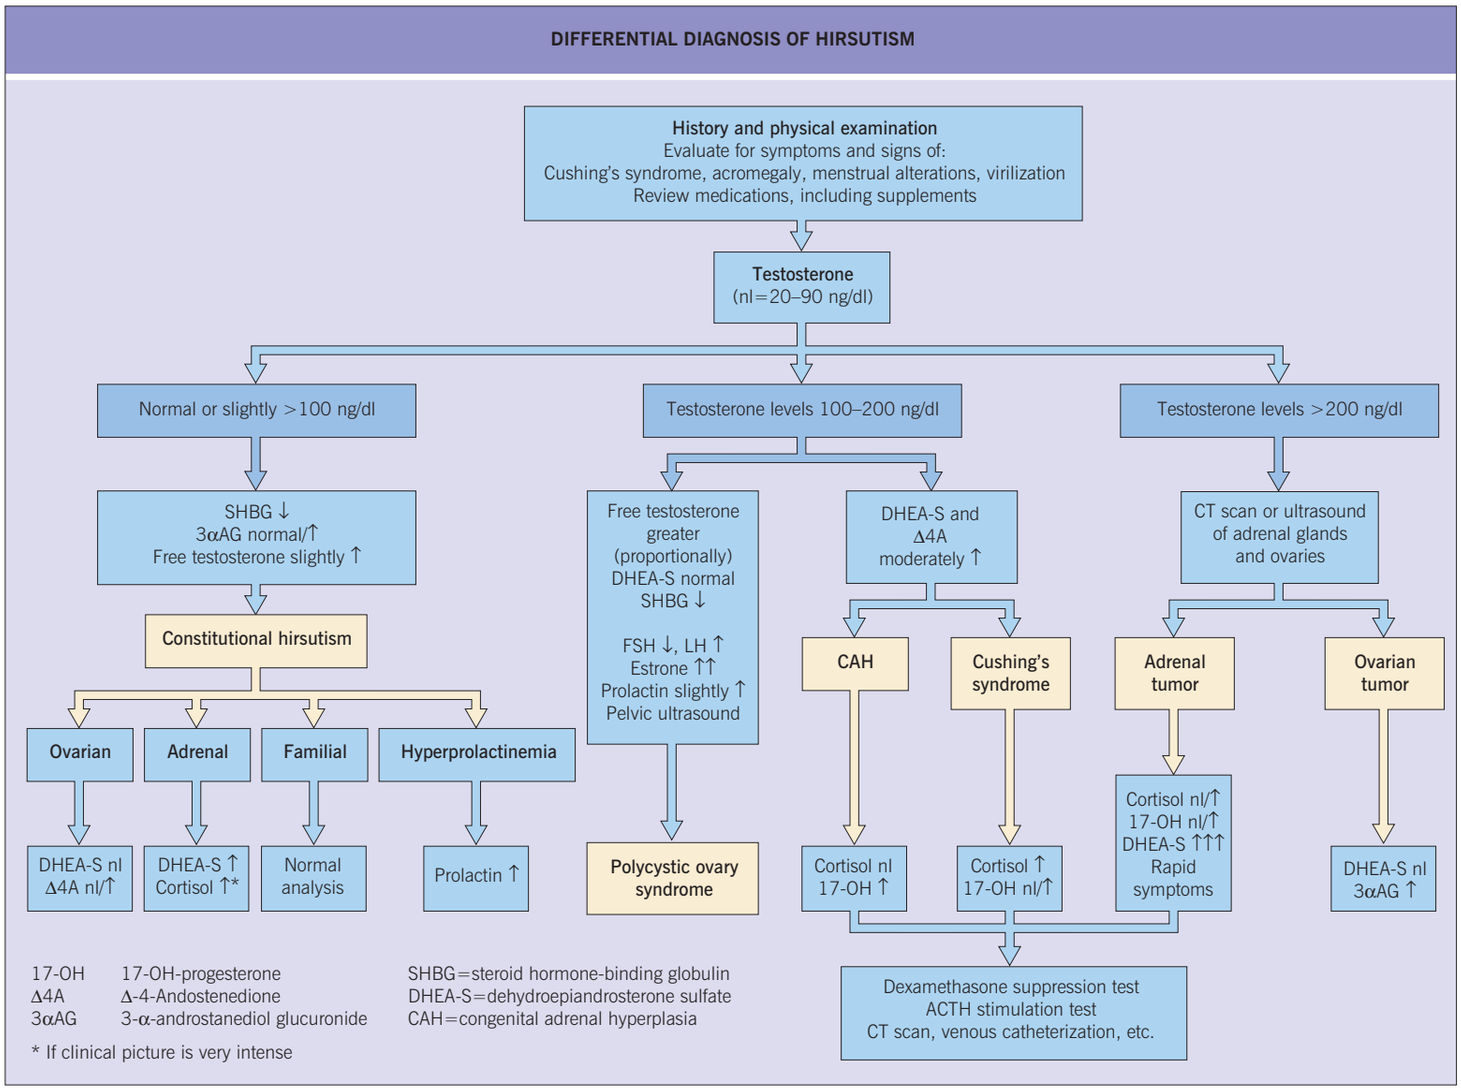

Fig. 70.15 Differential diagnosis of hirsutism. The optimum time to assess circulating follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels is 3–5 days after cessation of menses.

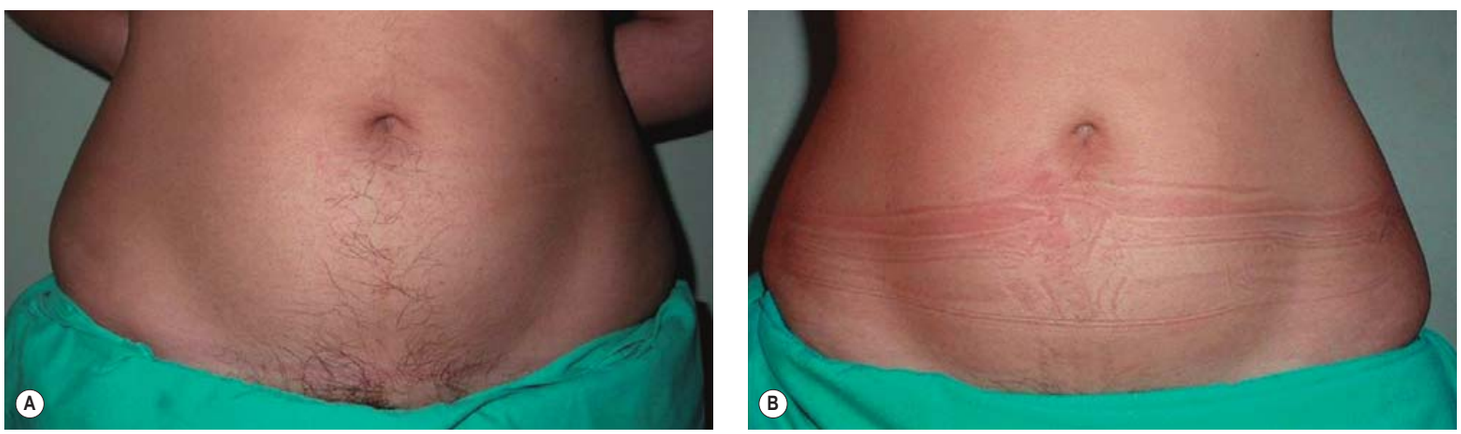

Fig. 70.16 Adrenal SAHA (*s*eborrhea, *a*cne, *h*irsutism and *a*lopecia) syndrome. Before (**A**) and after (**B**) finasteride treatment (2.5 mg daily) for 1 year.

Dermato-cosmetic therapy

There are many therapeutic options in this category, all of which have advantages and disadvantages[12,35]. Hair bleaching is a popular practice, and may be carried out with 6% hydrogen peroxide or a 20% ammonia solution. *Shaving* and *depilation with tweezers, wax or chemical substances* such as 2–4% calcium thioglycolate are also common maneuvers. Compliance often requires dissuasion of the belief that this will enhance thicker hair growth. Electrolysis (see Ch. 140) as well as laser and light-source epilation are, at least hypothetically, methods for "definite depilation". Alexandrite, Nd:YAG and diode are lasers used for this purpose (see Ch. 137). Lastly, *weight loss* improves hirsutism in some hyperandrogenic women.

Surgical therapy

In the case of ovarian and adrenal tumors, surgical intervention is usually required. Surgery is also an option for some pituitary tumors.

Nail tumors 1144

ANATOMY (Fig. 71.1)

Key features

- Nail matrix → nail plate production
  proximal matrix → dorsal nail plate
  distal matrix (lunula) → ventral nail plate
- Proximal nail fold → nail matrix protection
- Nail bed and hyponychium → nail plate adhesion and distal detachment
- Nail growth rate:
  fingernails: 3 mm/month
  toenails: 1 mm/month

The nail plate is a fully keratinized structure produced by the germinative epithelium of the nail matrix. As it grows, the nail plate emerges from the proximal nail fold and progresses distally, lying across and strictly adhering to the nail bed. As the nail plate approaches the tip of the digit, it detaches from the underlying tissues, forming the hyponychium. Proximally and laterally, the nail plate is surrounded by the nail folds. The proximal nail fold consists of two layers of epithelium – a dorsal layer, which is the distal continuation of the skin of the dorsum of the digit, and a ventral layer, which is continuous with the nail matrix.

The nail matrix is responsible for the production of the nail plate and consists of an epithelium that keratinizes without the formation of a granular layer. Nail matrix keratinization occurs along an oblique axis, reflecting the upward and distal movement of cells during the process of maturation and differentiation[1]. For this reason, the proximal portion of the nail matrix produces the dorsal portion of the nail plate, while the distal matrix is responsible for the production of the ventral nail plate. The distal portion of the nail matrix is visible through the transparent nail plate as a white, distally convex half moon known as the lunula. The matrix contains melanocytes that are normally quiescent; however, they may become activated and synthesize melanin, which is transferred to the surrounding keratinocytes. Distal migration of melanin-containing keratinocytes then gives rise to a pigmented nail plate[2].

Nail plate production occurs continuously, proceeding from the 15th week of embryonic life until death. Under normal conditions, the mean growth rate of a fingernail is 3 mm/month and that of a toenail is 1 mm/month. Nail growth rate can be influenced by several factors, including age, systemic diseases, and medications.

NAIL SIGNS

By clinical examination, it is possible to identify which site within the nail apparatus is affected by a particular disease process (Table 71.1 &

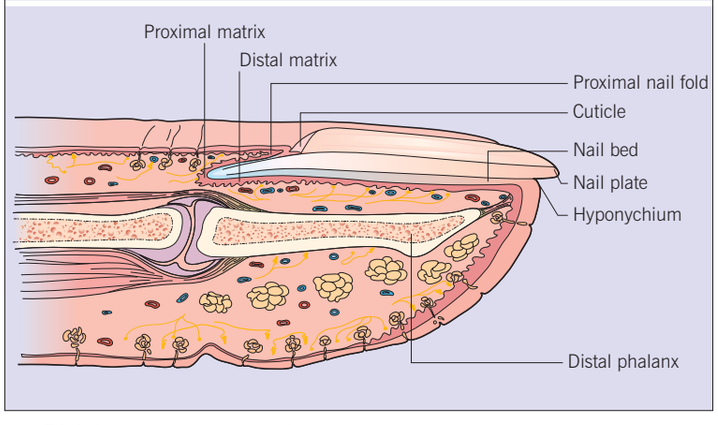

Fig. 71.1 Schematic drawing of the nail apparatus in longitudinal section.

CORRELATION OF NAIL FINDINGS WITH ANATOMIC SITE OF NAIL DAMAGE	
Affected site	**Clinical manifestation**
Proximal matrix	Beau's lines Pitting Longitudinal ridging Longitudinal fissuring Trachyonychia
Distal matrix	True leukonychia
Proximal + distal matrix	Onychomadesis Koilonychia Nail thinning
Nail bed	Onycholysis Subungual hyperkeratosis Apparent leukonychia Splinter hemorrhages

Table 71.1 Correlation of nail findings with anatomic site of nail damage.

Fig. 71.2). Recognizing specific nail signs is very important in understanding and diagnosing nail dystrophies[1,3,4]. Nail signs can be schematically divided into three major categories:

- signs due to abnormal nail matrix function
- signs due to nail bed disorders
- signs due to deposition of pigment within the nail plate.

Nail Signs due to Abnormal Nail Matrix Function

Beau's lines

Key features

- Transverse depressions
- More evident in the central portion of the nail plate
- Most often traumatic
- Involvement of multiple digits suggests a systemic cause

First described by Beau in 1846, these transverse depressions of the nail plate surface result from a temporary interruption of the mitotic activity of the proximal nail matrix. The depth of the depression indicates the extent of the damage within the matrix; the width of the depression (along the longitudinal axis) indicates the duration of the insult. Beau's lines grow distally with the nail plate, with multiple lines indicating repeated damage. Most commonly, Beau's lines are caused by mechanical trauma (e.g. manicures, onychotillomania) or dermatologic disease of the proximal nail fold (e.g. eczema, chronic paronychia). The presence of Beau's lines at the same level in all nails suggests a systemic cause (e.g. severe or febrile illness, erythroderma, drugs).

Onychomadesis (nail shedding)

Key features

- Proximal detachment of the nail
- Most often traumatic
- Involvement of multiple digits suggests a systemic cause

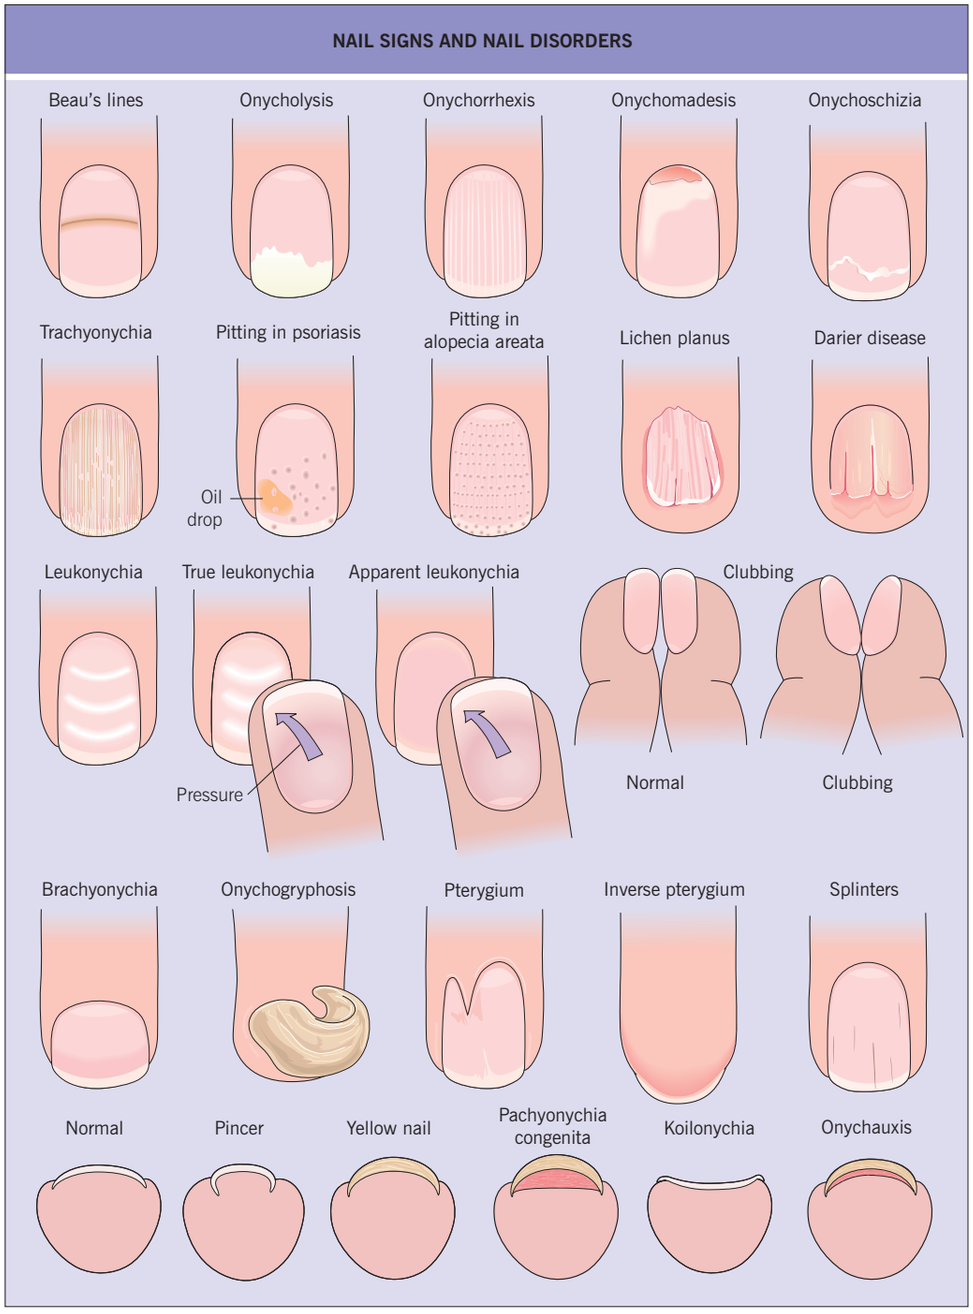

Fig. 71.2 Nail signs and nail disorders.

Fig. 71.3 Onychomadesis after an episode of acute paronychia.

The term "onychomadesis" describes the detachment of the nail plate from the proximal nail fold and is due to a severe insult that produces a complete arrest of nail matrix activity (Fig. 71.3). Onychomadesis appears as a sulcus that replaces the proximal nail plate. The causes of onychomadesis are the same as those for Beau's lines[4a].

Pitting

Key features

- Punctate depressions of the nail plate surface
- Migrate distally with nail growth
- Proximal nail matrix damage by psoriasis, alopecia areata, eczema

Pitting describes the presence of small depressions on the nail plate surface (Fig. 71.4). Pits are due to foci of abnormal keratinization of the proximal nail matrix that result in clusters of parakeratotic cells in the dorsal nail plate. These clusters are easily detached, leaving the pits. Diseases that produce nail pitting include psoriasis, alopecia areata and eczema.

Onychorrhexis

Key features

- Thinning
- Longitudinal ridging and fissuring
- Diffuse nail matrix damage by lichen planus is a possible cause
- Mild disease is a common manifestation of aging

Onychorrhexis produces longitudinal ridging and fissuring of the nail plate. Often associated with nail thinning, it indicates diffuse damage to the nail matrix. Diseases commonly responsible for onychorrhexis include lichen planus, impaired vascular supply, trauma, and tumors that compress the nail matrix. Mild longitudinal ridging of the nails is a common feature of aging.

Trachyonychia (twenty-nail dystrophy, sandpapered nails)

Key features

- Nail roughness
- Often associated with thinning
- Conditions that may cause trachyonychia include alopecia areata (common), lichen planus (rare), psoriasis (rare) and eczema (very rare)

Fig. 71.4 Nail pitting due to psoriasis. Pits are large, deep and irregularly scattered, in contrast with alopecia areata, where they are small, superficial and geometrically distributed.

Fig. 71.5 Trachyonychia (twenty-nail dystrophy). The nails seem sandpapered in a longitudinal direction.

Trachyonychia is a specific nail plate surface abnormality characterized by diffuse homogeneous roughness (Fig. 71.5). In most patients, the affected nails are opaque, lusterless and rough; the nail plate surface has longitudinal ridging due to fine superficial striations distributed in a regular, parallel pattern (sandpapered nails). A less common variant, referred as shiny trachyonychia, is characterized by multiple small punctate depressions distributed in a geometric pattern within parallel, longitudinal lines. Conditions that may cause trachyonychia include alopecia areata, lichen planus, psoriasis and eczema. Some authors use the term "twenty-nail dystrophy" for idiopathic cases of trachyonychia in children (see below), even though the disease does not necessarily involve all 20 nails.

True leukonychia

Key features

- White opaque discoloration
- Punctate, striate or diffuse
- Most often traumatic
- Distal nail matrix damage
- Needs to be distinguished from apparent leukonychia (nail bed discoloration)
- Needs to be distinguished from pseudoleukonychia (nail plate invasion by fungi), which is typical of superficial white onychomycosis. In this case the nail plate surface is friable due to the presence of keratin debris and fungal elements

The nail plate has a normal surface but loses its transparency and looks white because of the presence of parakeratotic cells within its ventral portion. True leukonychia is caused by diseases that disturb distal nail matrix keratinization and it presents with three morphologic variants:

- **Punctate leukonychia**. The nail plate shows small opaque white spots that move distally with nail growth and sometimes disappear before reaching the distal nail. It is caused by trauma and is most commonly observed in the fingernails of children.
- **Striate leukonychia**. The nail plate shows one or more transverse white opaque parallel lines. It is frequently observed in the fingernails of women, due to matrix trauma secondary to manicures. It may also occur in great toenails as a consequence of trauma from shoes. It is also typical of Mees' lines, the white transverse bands seen in arsenic and thallium poisoning[5].
- **Diffuse leukonychia**. The nail plate is completely or almost completely opaque and white. Total leukonychia is rare and sometimes hereditary. It may be associated with keratoderma and other congenital defects such as deafness.

Koilonychia (spoon nails)

Key features
- Thinned concave nails
- Physiologic in the toenails of children

The nail plate is thinned, flat and spoon-shaped due to upward eversion of its lateral edges. Although it is physiologic and resolves spontaneously in children's toenails, in adults it is most commonly occupational in origin or associated with severe iron deficiency.

Nail Signs due to Nail Bed Disorders

Onycholysis

Key features
- Distal nail plate detachment
- Detached nail looks yellow–white
- Commonly due to environmental trauma, psoriasis or onychomycosis

The nail plate is detached from the nail bed and appears white because of the presence of air in the subungual space. Pigmentation of the onycholytic area may occur as a consequence of microbial colonization or blood extravasation. In addition to environmental trauma, the nail bed disorders that most commonly produce onycholysis are psoriasis and onychomycosis (Fig. 71.6). Photo-onycholysis may be precipitated by UV light exposure, either alone or in combination with medications such as tetracycline.

Onychauxis

Key features
- Nail thickening
- Subungual hyperkeratosis
- Commonly due to psoriasis or onychomycosis

The nail plate appears thickened due to the presence of subungual scales. Causes of subungual hyperkeratosis include psoriasis, onychomycosis and eczema.

Apparent leukonychia

Key features
- White discoloration that fades with pressure
- Nail plate transparency maintained
- Often due to drugs (chemotherapeutic agents) or systemic diseases (e.g. hypoalbuminemia)

The nails are white because of abnormalities in the color of the nail bed and this is usually due to nail bed edema. Apparent leukonychia does not move distally with nail growth and the white discoloration fades with pressure (see below for different types).

Splinter hemorrhages

Key features
- Thin longitudinal dark-red subungual lines
- Most often traumatic
- Damage to longitudinally oriented nail bed capillaries

Splinter hemorrhages appear as dark-red, thin longitudinal lines, usually localized to the distal portion of the nail. The shape of the hemorrhages is due to the longitudinal orientation of nail bed capillaries.

The most common causes of splinter hemorrhages are trauma, psoriasis and onychomycosis. Proximal splinters are rare and possible indicators of systemic diseases, including endocarditis (infectious and marantic), vasculitis (including septic vasculitis), trichinosis and the antiphospholipid antibody syndrome.

A recently described vascular lesion of the nail bed is the "red comet", which occurs in ~30% of patients with tuberous sclerosis complex[5a]. Red comets appear as longitudinal short red streaks, partially blanchable with compression, with an enlarged distal end; they extend from the mid to the distal third of the nail and never reach the free edge of the nail. Red comets are thought to represent telangiectasias plus extravasated blood.

Nail Signs due to Deposition of Pigment

Key features
- Exogenous → convex proximal border
- Endogenous → concave proximal border (distally convex)
- Subungual deposition → often associated with onycholysis

Causes of nail pigmentation include staining from external pigment, presence of pigment under the nail plate, and deposition of pigment within the nail plate. Nail pigmentation from external staining typically follows the shape of the proximal nail fold. Common examples are yellow–brown nail discoloration due to nicotine in smokers or darkening of the nail plate due to hair dyes in hairdressers. Subungual deposition of pigment is often seen with *Pseudomonas* colonization, where the green discoloration of the nail results from the production of pyocyanin by the bacteria. Dermatophytes usually cause a yellow–white subungual pigmentation. The nail plate may be pigmented secondary to melanin deposition or deposition of other pigments such as iron or gold. A Fontana–Masson stain of a nail clipping is useful in differentiating melanin from other pigments.

Longitudinal melanonychia

Key features
- Longitudinal brown to black band
- Commonly seen in darkly pigmented individuals
- Single band may be a sign of nail melanoma
- Multiple bands often due to drugs or systemic disease

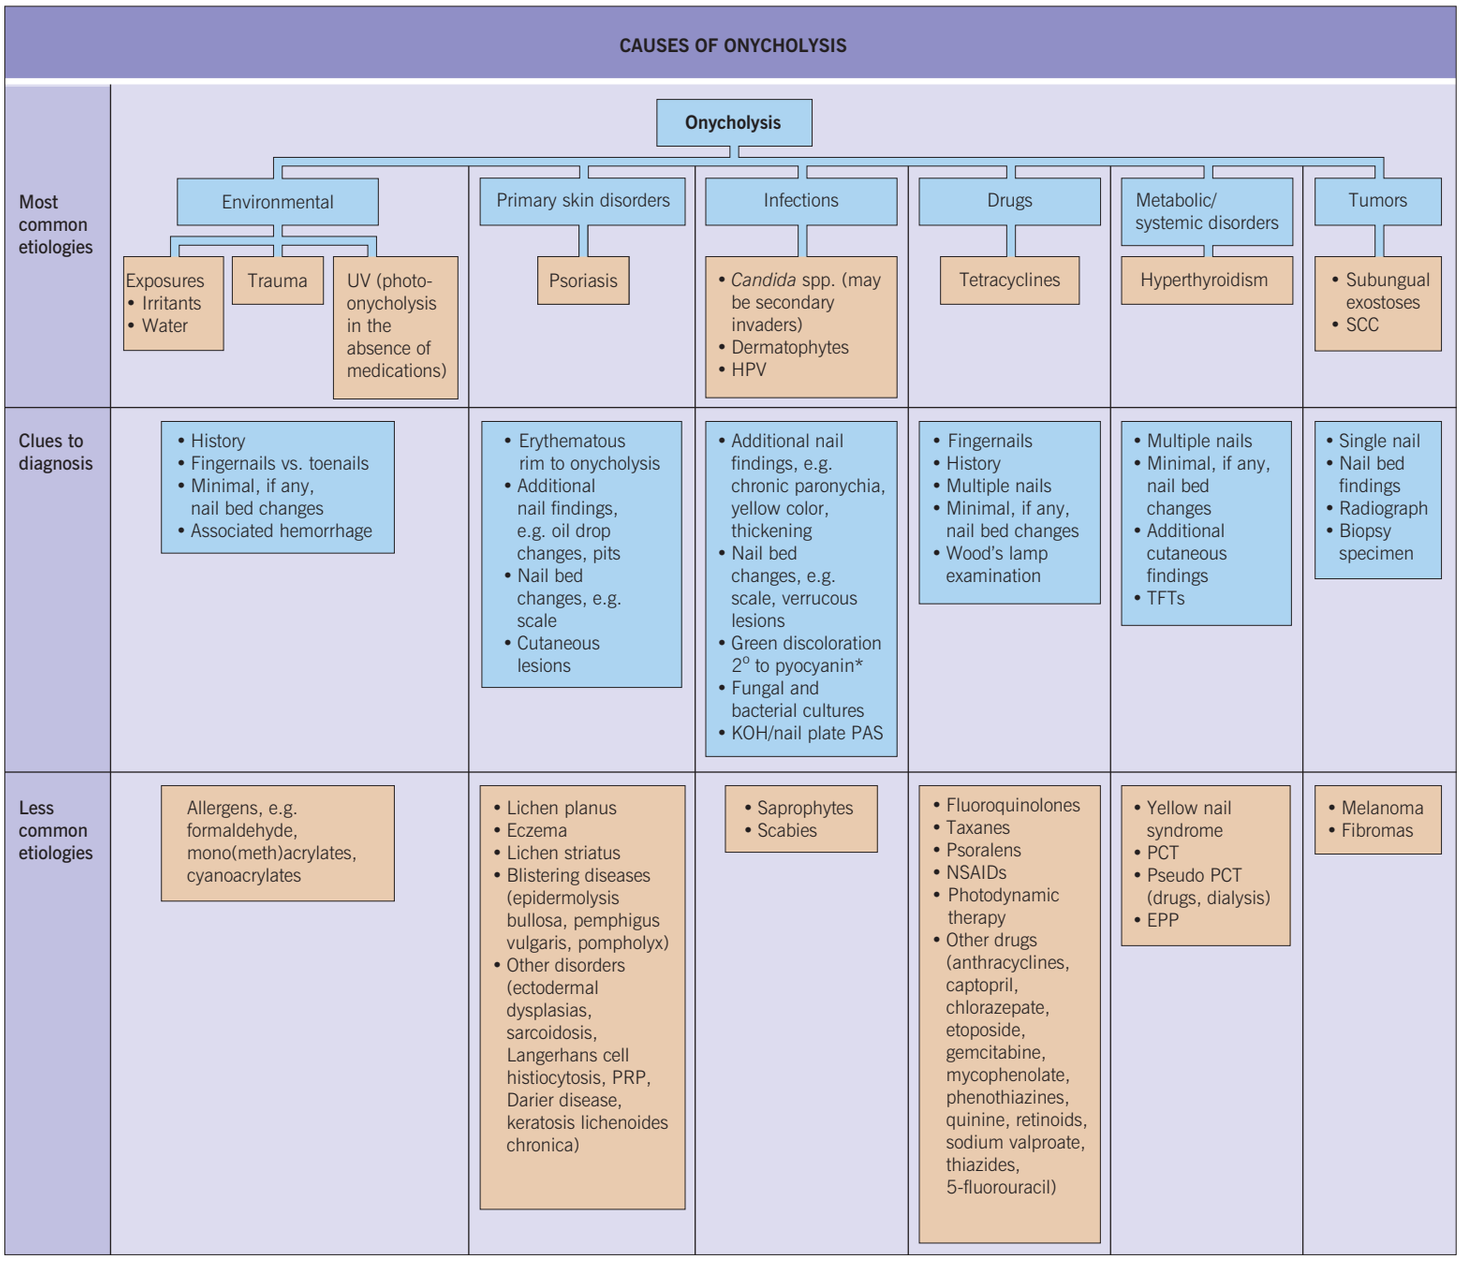

Fig. 71.6 Causes of onycholysis. *Due to secondary colonization with *Pseudomonas aeruginosa*. EPP, erythropoietic protoporphyria; HPV, human papillomavirus infection; NSAIDs, nonsteroidal anti-inflammatory drugs; PCT, porphyria cutanea tarda; PRP, pityriasis rubra pilaris; SCC, squamous cell carcinoma; TFTs, thyroid function tests.

Longitudinal melanonychia is very commonly observed in individuals with darkly pigmented skin, and up to 90% of adult African-Americans have one or more pigmented bands. It is seen much less frequently in Caucasians. Longitudinal melanonychia is due to the presence of melanin within the nail plate, and it may be caused by simple activation of nail matrix melanocytes or by melanocyte hyperplasia as in a lentigo, nevus or melanoma.

Clinically, melanonychia presents as one or more longitudinal pigmented bands extending from the proximal nail fold to the distal margin (Fig. 71.7)[6]. The band of melanonychia can vary in color from light brown to black and the pigmentation may be homogeneous or variable. The width ranges from a few millimeters to the whole nail width. Multiple bands are usually due to melanocyte activation (Table 71.2).

A range of dermoscopic patterns has been described for longitudinal melanonychia (e.g. regular, thin, parallel light brown lines reflecting melanocytic activation), but their accuracy with regard to the diagnosis of subungual melanoma has not been established (see below)[7,8]. Nonetheless, epiluminescence microscopy is increasingly being performed and further studies correlating dermoscopic patterns with histopathologic findings are anticipated. In addition, intraoperative dermoscopy is being employed to assist in determining margins for excision[8a].

A detailed description of biopsy procedures for longitudinal melanonychia is found in Chapter 149 (see Fig. 149.17).

Hutchinson's sign

Key features

- Brown–black periungual pigmentation
- Possible sign of nail melanoma
- Needs to be distinguished from pseudo-Hutchinson's sign (dark bands producing "illusory" pigmentation of the proximal nail fold due to cuticle transparency)

CAUSES OF LONGITUDINAL MELANONYCHIA	
Melanocyte activation	Racial Trauma • manicure • nail biting/onychotillomania • frictional, primarily in toenails Drugs • cancer chemotherapeutic agents, e.g. doxorubicin, 5-fluorouracil • zidovudine (AZT) • psoralens Radiation Pregnancy Laugier–Hunziker syndrome/Peutz–Jegher syndrome Addison's disease HIV infection Postinflammatory • lichen planus • pustular psoriasis • onychomycosis (*T. rubrum* and *Scytalidium* spp.)
Non-melanocytic tumors	Bowen's disease Verrucae Basal cell carcinoma Subungual keratosis Myxoid cyst
Melanocyte hyperplasia	
Nail matrix nevus	
Nail matrix melanoma	

Table 71.2 Causes of longitudinal melanonychia.

First described by Hutchinson in 1886, this eponymous sign represents pigmentation of the proximal nail fold or the hyponychium in association with longitudinal melanonychia. Hutchinson's sign, in the setting of nail melanoma, is due to horizontal growth of the tumor. Although pigmentation of the proximal and lateral nail fold or hyponychium is a feature of congenital melanocytic nevi[9], the development in adults of periungual pigmentation in conjunction with longitudinal melanonychia is very suggestive of melanoma.

Green nail syndrome

Key features

- Greenish-black or greenish-blue nail plate discoloration due to pyocyanin
- Predisposing factors include exposure to water, detergents and soaps
- Needs to be distinguished from a hematoma, melanocytic nevus, melanoma or an *Aspergillus* infection

In green nail syndrome, the nail has a greenish-black or greenish-blue color due to the deposition of pyocyanin, a blue–green pigment produced by *Pseudomonas aeruginosa*, underneath the onycholytic nail plate (see Ch. 74). It is often accompanied by paronychia. Predisposing factors include prolonged exposure to water, use of detergents and soaps, nail trauma and other causes of onycholysis. Not surprisingly, this disorder is seen in barbers, dishwashers, bakers and medical personnel. Green nail syndrome is important because affected hospital staff may spread *Pseudomonas aeruginosa* to debilitated patients. The diagnosis is usually clinical, and, if necessary, can be confirmed by Gram stain and culture of exudate and nail fragments. Treatment involves avoiding predisposing factors, wearing protective gloves, clipping back of the nail, and the use of topical solutions of 2% sodium hypochlorite or acetic acid for 1–4 months.

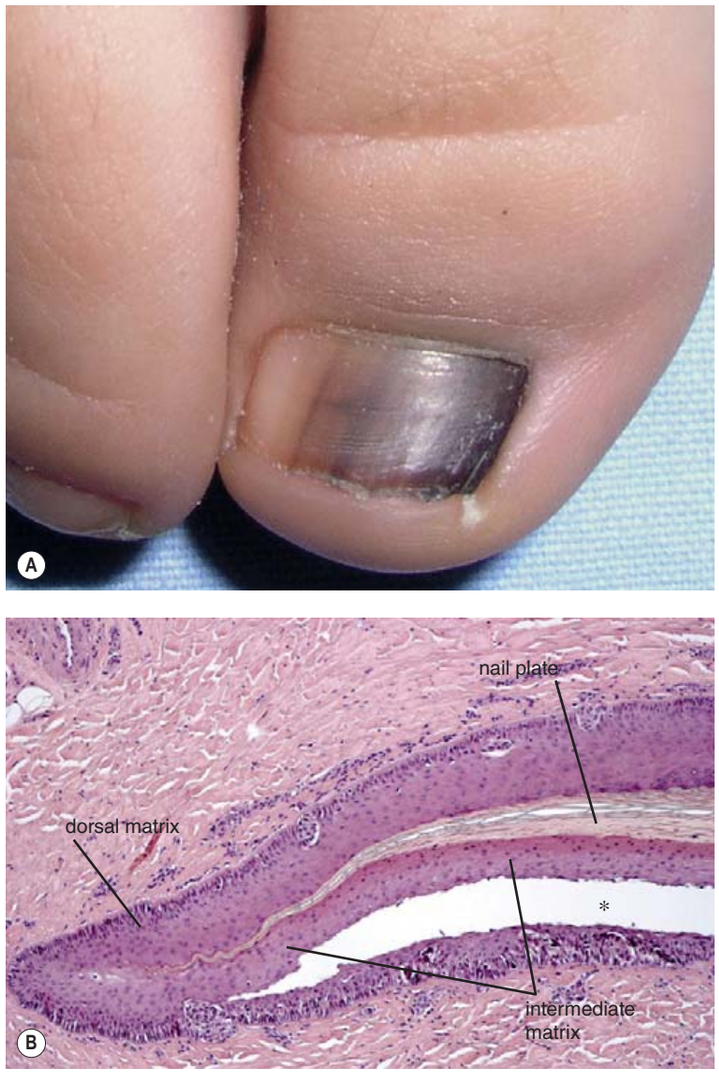

Fig. 71.7 Longitudinal melanonychia due to a congenital melanocytic nevus of the nail matrix. A The pigmentation involves approximately 75% of the nail plate and the color varies from light brown to black. **B** The biopsy specimen shows nests of melanocytes within the basal layer and lower portion of the nail matrix epithelium. The cleft (*) represents an artifact.

CONGENITAL AND HEREDITARY NAIL DISEASES

The congenital and hereditary nail diseases include a number of conditions in which nail abnormalities are present at birth or develop during infancy. In some cases, the nail abnormalities are key features for the diagnosis of syndromes or hereditary diseases.

Congenital Malalignment of the Great Toenails

Key features

- Lateral deviation of the nail plate
- Often bilateral
- Predisposing factor for ingrown toenails

Congenital malalignment of the great toenails was first described by Samman in 1978 and well characterized by Baran et al. in 1979. It is common, but no prevalence data are available. Congenital malalignment of the great toenails is possibly caused by an abnormality in the ligament that connects the matrix to the periosteum of the distal phalanx. The nail plate of the hallux is laterally deviated with respect to the longitudinal axis of the distal phalanx. This results in nail matrix damage with Beau's lines and onychomadesis (Fig. 71.8). The nail plate

Fig 71.8 Congenital malalignment of the great toenails. The longitudinal axis of the nail plate is deviated laterally. There is also onychomadesis of both great toenails and mild nail thickening with lateral ingrowing of the right great toenail.

is often thickened and transversely overcurved. Congenital malalignment of the great toenails is frequently bilateral and is the most common cause of ingrown toenails in children and adolescents. The condition often improves spontaneously[10].

Congenital Hypertrophy of the Lateral Fold of the Hallux

Key features

- Hypertrophic lateral nail fold
- Newborns and infants

Hypertrophic lateral nail folds in newborns were first described by Martinet et al. in 1984. The hypertrophy is usually present at birth; it is characterized by an overgrowth of the soft tissue of the internal portion of the lateral nail fold, resulting in a hypertrophic lip that partially covers the nail plate. This abnormal growth may deviate the nail laterally and/or cause nail embedding with an acute inflammatory reaction and pain. The abnormality is usually bilateral and may regress spontaneously after a few years[11].

Racquet Thumbs (Brachyonychia)

Key features

- Congenital
- Broad and short thumbnail

Racquet thumb is a common malformation due to shortening of the distal phalanx. It is usually inherited as an autosomal dominant trait. The nail is shortened and abnormally wide. Racquet nails are usually an isolated finding and radiologic examination demonstrates a short distal phalanx.

Nail–Patella Syndrome (Onycho-osteodysplasia; Fong Disease)

Key features

- Hypoplasia of the radial side of the thumbnails
- Triangular lunulae
- Presence of bone abnormalities

Nail–patella syndrome is an autosomal dominantly inherited condition first described by Chatelain in 1820. It has been associated with mutations in the *LMX1B* gene, which encodes a transcription factor that regulates collagen synthesis. The condition most frequently involves the thumb and may also involve the other fingers but to a lesser extent (Fig. 71.9). The nails are absent or hypoplastic, and the dystrophy is usually more marked on the radial side of the digit. A triangle-shaped lunula is commonly observed. The nail changes are typically associated with bony abnormalities, including absent or hypoplastic patellae, radial head dysplasia, and iliac crest exostoses ("horns"). In children, the diagnosis is best confirmed by the presence of iliac horns on pelvic X-ray.

Nephropathy develops in approximately 40% of patients. This leads to renal insufficiency in up to 8% of cases.

Fig. 71.9 Nail hypoplasia in nail–patella syndrome. There is hypoplasia of the nails of the first and second digits. This gradient of severity of nail involvement is characteristic.

Epidermolysis Bullosa

Key features

- Periungual/subungual blistering
- Periungual granulation tissue
- Onycholysis
- Nail thickening and shortening
- Pterygium and nail atrophy

Nail abnormalities are common in all forms of epidermolysis bullosa (EB). Repeated blistering produces onycholysis with shortening and thickening of the nail due to nail bed scarring. Involvement of the matrix can result in nail thinning and atrophy. Dystrophic or absent nails with periungual granulation tissue are characteristic of junctional EB, Herlitz type and laryngo-onycho-cutaneous syndrome. Nail abnormalities may precede the development of skin blistering, as in "late onset" junctional EB and pretibial dominant dystrophic EB, or the nail dystrophy may be an isolated finding, as in some families with dominant dystrophic EB.

Ectodermal Dysplasias

Key features

- Abnormal development of hair, teeth and/or eccrine glands
- Nail shortening and thickening
- Nail hypoplasia

Ectodermal dysplasias were first described by Weech in 1929 and classified by Freire-Maia in 1977. Nail abnormalities are an important sign in a large number of these syndromes, where they are associated with hair, teeth and/or eccrine gland abnormalities (see Ch. 63). Most frequently, the nails are short and thickened with onycholysis. All the fingernails and toenails are usually affected.

Pachyonychia Congenita

Key features

- Thickened and extremely hard nails
- Severe nail bed hyperkeratosis
- All digits eventually involved
- Palmoplantar keratoderma

Pachyonychia congenita was first described by Jadasson and Lewandowski in 1906. Pachyonychia congenita is due to mutations in keratin genes *KRT6a* and *KRT16* in type I and *KRT6b* and *KRT17* in type II.

Nail abnormalities are present in both of the two major forms of pachyonychia congenita. The nails are thickened with an increased transverse curvature due to severe nail bed hyperkeratosis. Nail trimming is extremely difficult. Associated findings include hyperhidrosis, oral leukokeratosis, follicular hyperkeratosis and palmoplantar keratoderma, with pain on ambulation. Premature dentition and pilosebaceous cysts are observed more frequently in type II (see Table. 58.4).

Darier Disease (Follicular Dyskeratosis)

Key features

- Red and white longitudinal streaks
- V-shaped indentation (notching) of the distal margin
- Multinucleated giant cells in the nail bed epithelium

Nail abnormalities of Darier disease are common and diagnostic, and were first described by Ronchese in 1965. The nail plate has multiple red and white longitudinal streaks (Fig. 71.10). Distally, wedge-shaped subungual hyperkeratosis and fissuring of the free margin of the nail plate are also seen. The latter occur in conjunction with the white and red bands. Histologically, there is hyperplasia of the nail bed epithelium with multinucleated epithelial giant cells, but not suprabasal clefts[12]. Nail changes do not improve with oral retinoid therapy. Similar nail abnormalities may be seen in patients with Hailey–Hailey disease. A single, red longitudinal band (longitudinal erythronychia) with distal subungual hyperkeratosis is not sufficient for diagnosing Darier disease of the nails, since single bands may be due to a subungual benign tumor (onychopapilloma) and, less often, Bowen's disease[13,13a].

THE NAIL IN DERMATOLOGIC DISEASES

Several dermatologic diseases often have associated nail abnormalities that may prove helpful in confirming the clinical diagnosis.

Fig. 71.10 Darier disease. Alternating longitudinal red and white streaks with wedge-shaped subungual hyperkeratosis, V-shaped notching of the distal margin, and fissuring.

Psoriasis

Key features

- Several nails affected
- Diagnostic signs (fingernails only): irregular pitting, salmon patches ("oil drop" sign), onycholysis with an erythematous border
- In toenails, psoriasis is usually clinically indistinguishable from onychomycosis
- Often associated with psoriatic arthropathy
- The Koebner phenomenon worsens nail symptoms

Nail abnormalities are present in up to 50% of patients with psoriasis and may be the only manifestation of the disease. Nail psoriasis is often associated with psoriatic arthritis and enthesitis[14]. Clinical findings that are diagnostic for nail psoriasis include irregular pitting, salmon patches of the nail bed, and onycholysis with an erythematous border. These signs are often seen together in the same patient and are localized to the fingernails. Psoriatic pits are large, deep, and irregularly scattered within the nail plate (see Fig. 71.4); they may be covered by whitish, easily detachable scales. The "oil drop" sign (salmon patches) appears as an irregular area of yellow–orange discoloration visible through the nail plate (Fig. 71.11). Onycholysis surrounded by an erythematous border is also typical in nail psoriasis. Patients with psoriasis often have other nail abnormalities that are not diagnostic, as they are commonly seen in other conditions. These include splinter hemorrhages, subungual hyperkeratosis, nail plate thickening and crumbling, and paronychia.

Diseases that should be differentiated from nail psoriasis are listed in Table 71.3.

Treatment

Nail psoriasis rarely responds to topical treatment and is often aggravated by sun exposure. Treatment measures are reviewed in the therapeutic ladder (Table 71.4).

Acrodermatitis Continua of Hallopeau (Hallopeau's Acrodermatitis, Dermatitis Repens)

Key features

- Recurrent, self-limited episodes of painful inflammation
- Pustules involving the nail bed and periungual skin
- Fingernails most commonly affected, often one digit

Fig. 71.11 Nail psoriasis. The nails show salmon patches ("oil drop" changes) and onycholysis with an erythematous border.

DIFFERENTIAL DIAGNOSIS OF NAIL PSORIASIS	
• **Onychomycosis** – psoriasis of the toenails may be difficult to distinguish from onychomycosis without mycologic or histologic examination of nail clippings	• **Alopecia areata** – pits are small and geometrically distributed
• **Idiopathic onycholysis and traumatic onycholysis** – the area of onycholysis is not surrounded by erythema and there is an absence of subungual hyperkeratosis	• **Acrokeratosis paraneoplastica (Bazex syndrome; paraneoplastic acrokeratosis)** – the psoriasiform eruption has a typical acral distribution with involvement of the nose and ears

Table 71.3 Differential diagnosis of nail psoriasis.

THERAPEUTIC LADDER FOR NAIL PSORIASIS
• Avoid trauma (3)
• Topical vitamin D_3 analogues: calcipotriene (calcipotriol) – nail bed psoriasis (2)
• Topical tazarotene 0.1% gel: nail bed psoriasis (2)
• Topical calcipotriene plus betamethasone dipropionate ointment – nail bed psoriasis (2)
• Intralesional corticosteroid (e.g. 2.5–5.0 mg/ml triamcinolone acetonide in saline) – nail matrix psoriasis (1)
• Acitretin (0.2–0.3 mg/kg/day) – nail matrix and nail bed psoriasis (1)
• Methotrexate – if indicated for additional manifestations (2)
• Cyclosporine – if indicated for additional manifestations (2)
• Targeted immunomodulators ("biologic therapies") – if indicated for additional manifestations (2)

Table 71.4 Therapeutic ladder for nail psoriasis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

Fig. 71.12 Acrodermatitis continua of Hallopeau. Recurrent pustular eruption of the nail bed and distal finger.

Acrodermatitis continua was first described by Crocker in 1888 and better classified by Hallopeau in 1890. Nail involvement is a typical feature of Hallopeau's acrodermatitis, which is usually limited to one digit. It can also occur in patients with palmoplantar or generalized pustular psoriasis. Patients complain of relapsing episodes of acute painful inflammation with pustules around and under the nail plate (Fig. 71.12). Other symptoms include onycholysis, onychomadesis, and scaling of the nail bed and periungual skin. Acrodermatitis continua of the nail is, in most cases, not associated with cutaneous plaques of psoriasis vulgaris. Proximal spread of the disease is unusual[15].

The differential diagnosis of acrodermatitis continua is outlined in Table 71.5.

DIFFERENTIAL DIAGNOSIS OF ACRODERMATITIS CONTINUA OF HALLOPEAU	
• **Acute contact dermatitis and dyshidrotic hand eczema** – lesions are usually vesicular rather than pustular, with palmar and/or plantar involvement	• **Onychomycosis due to non-dermatophyte molds** – may be associated with periungual or subungual inflammation and a purulent discharge. Toenails are most commonly affected and the nail plate contains fungal organisms; fungal cultures are required
• **Bacterial or viral paronychia** – a relapsing course is not typical of bacterial infection; relapses are seen in HSV infection, but the nail heals completely between episodes	

Table 71.5 Differential diagnosis of acrodermatitis continua of Hallopeau. HSV, herpes simplex virus.

Treatment

- Topical vitamin D3 analogues (calcipotriene [calcipotriol], calcitriol) or the combination of calcipotriene plus betamethasone dipropionate. Distal nail bed disease is most easily treated with a solution or lotion as the vehicle.
- Acitretin (0.3 mg/kg/day for 4–6 months) in severe cases.

Parakeratosis Pustulosa

Key features

- Exclusively seen in children
- Psoriasiform lesions
- One fingernail usually affected

Parakeratosis pustulosa was first described by Sabouraud in 1931 and better characterized by Hjorth and Thomsen in 1967. It is seen exclusively in children, in whom it is usually limited to one digit, most often the thumb or the index finger. In most patients, nail changes are preceded by erythema, scaling and vesicles of the fingertip. The affected digit shows mild psoriasiform changes with onycholysis and subungual hyperkeratosis. The nail abnormalities are usually more marked on one side of the nail. The disease usually regresses spontaneously, but some children develop psoriasis.

Treatment

Treatment is with emollients, topical corticosteroids and/or calcipotriene.

Lichen Planus

Key features

- Longitudinal fissuring of the nail plate (onychorrhexis)
- Possible cicatricial outcome (dorsal pterygium)
- Several nails usually affected
- Histologic examination is required for diagnosis when nail involvement is isolated

Nail abnormalities are present in approximately 10% of patients with lichen planus (see Ch. 11). However, nail lichen planus is most frequently seen in the absence of skin, scalp or mucosal involvement. Clinical findings that are diagnostic include nail thinning, ridging and fissuring, and dorsal pterygium[16] (Fig. 71.13). These signs indicate matrix involvement and require prompt treatment to avoid scarring. Dorsal pterygium results from adhesion of the proximal nail fold to the nail bed due to matrix destruction and disappearance of the nail plate. Nail bed lichen planus produces nonspecific nail changes such as onycholysis, nail thickening and yellow discoloration.

Fig. 71.13 Nail lichen planus. Note the nail thinning with longitudinal ridging and fissuring.

DIFFERENTIAL DIAGNOSIS OF NAIL LICHEN PLANUS
• **Systemic amyloidosis** – thinning and fissuring are associated with splinter hemorrhages; histologic examination demonstrates amyloid deposits within the nail matrix and nail bed dermis • **Lichen striatus** – the lichenoid nail changes are restricted to one or two digits and limited to one side of the nail plate • **Dyskeratosis congenita** – lichenoid nail changes are associated with oral leukoplakia and reticulated hyperpigmentation • **Nail pterygium due to bullous diseases** – the history differs and there are often associated cutaneous and/or mucosal lesions • **Nail pterygium due to digital ischemia** – the digits are typically cold and there is a history of Raynaud's phenomenon • **Graft-versus-host disease** – similar lichenoid nail changes • **Additional entities** – psoriasis, onychomycosis and the yellow nail syndrome

Table 71.6 Differential diagnosis of nail lichen planus.

When isolated, this diagnosis may be difficult to establish and it requires histologic evaluation. The differential diagnosis of nail lichen planus is outlined in Table 71.6.

Treatment

Treatment with systemic therapies may be required to avoid pterygium formation (see Ch. 11). Intralesional injections of corticosteroid (2.5–5.0 mg/ml triamcinolone acetonide in saline) may be utilized when the disease involves a few nails[16a].

Trachyonychia (Twenty-Nail Dystrophy, Sandpapered Nails)

Key features

- Nail roughness due to excessive longitudinal ridging
- Several nails are usually affected
- More common in children
- Often associated with alopecia areata
- Benign outcome

Trachyonychia was first described by Alkiewicz in 1950. Identical nail abnormalities were given the name "twenty-nail dystrophy" by Hazelrigg et al. in 1977. Twenty-nail dystrophy or trachyonychia describes a spectrum of nail plate surface abnormalities that produce nail roughness. Since the nail changes do not always involve all 20 nails, the term "trachyonychia" (from the Greek word meaning rough) is preferred over twenty-nail dystrophy by most authors. It may occur in association with alopecia areata (12% of children and 3% of adults with severe alopecia areata) or it may be idiopathic. The latter is more common in children.

The nails are thin, opaque and lusterless and give the impression of having been sandpapered in a longitudinal direction (i.e. vertically striated sandpapered nails) (see Fig. 71.5). The cuticles are often hyperkeratotic. Trachyonychia is fairly asymptomatic and patients complain only of brittleness and the cosmetic appearance. In addition to alopecia areata, this finding is occasionally caused by several inflammatory diseases that mildly disturb nail matrix keratinization, including lichen planus, eczema and psoriasis. Determination of the underlying inflammatory disease responsible for the trachyonychia requires a nail biopsy. However, this is generally not recommended because of the benign nature of the disease and trachyonychia improves spontaneously in the majority of patients.

When used to treat hair and cutaneous manifestations, systemic corticosteroids and systemic retinoids can also improve trachyonychia in patients with alopecia areata and psoriasis, respectively.

Alopecia Areata

Key features

- Geometric pitting
- Children are most commonly affected

Nail abnormalities are present in approximately 20% of adults and 50% of children with alopecia areata. Signs that are characteristic of nail alopecia areata include geometric pitting and trachyonychia. The pits are small, superficial and regularly distributed in a geometric pattern (grid-like). Additional nail abnormalities observed in alopecia areata include punctate leukonychia, erythema of the lunula, and onychomadesis. Trachyonychia is more common in children and most frequently seen in male patients with alopecia totalis or universalis.

Eczema (Dermatitis)

Key features

- Irregular pitting and Beau's lines
- Subungual hyperkeratosis
- Chronic paronychia

Hand eczema is often associated with nail changes. In acute eczema, there are vesicles and erythema of the proximal nail fold and the hyponychium. Nail matrix damage produces irregular pitting and Beau's lines; onychomadesis can occur in severe cases. Chronic eczema frequently localizes to the hyponychium, resulting in subungual hyperkeratosis, onycholysis and fissuring of the hyponychium. Chronic eczema of the proximal nail fold can lead to chronic paronychia. In atopic dermatitis, the nail plate frequently shows mild superficial abnormalities such as irregular pits and Beau's lines. Controlling the skin disease results in gradual improvement of the nails.

THE NAIL IN SYSTEMIC DISEASES

Abnormalities of the nails have been anecdotally reported in a number of systemic diseases, but most of these abnormalities are nonspecific. In this chapter, we will discuss only those nail changes that are useful in the diagnosis of systemic disorders.

The Nail Plate in Forensic Medicine

Key features

- Drug exposure
- Poisoning
- Genetic analysis

The slow growth rate of nails makes it possible to utilize nail clippings to detect previous exposure to drugs or toxins (e.g. heroin). Compounds that can be measured in the nails include heavy metals and drugs[5].

Clubbing (Hippocratic Fingers, Watch-Glass Nails, Drumstick Fingers)

Key features

- Bulbous digits
- Watch-glass nails
- Greater than 180° angle between the proximal nail fold and nail plate (Lovibond's sign)

First described by Hippocrates in the first century BC, clubbing may be congenital or acquired. Acquired clubbing is uncommon and in 80% of cases is associated with pulmonary diseases[17].

Clubbing is caused by enlargement of the soft tissue of the distal digit. The nail plate is enlarged and excessively curved, with a greater than 180° widening of the angle between the proximal nail fold and the nail plate (see Fig. 71.2). In hypertrophic osteoarthropathy, clubbing is associated with hypertrophy of the extremities and painful pseudo-inflammatory joint disease. Systemic conditions associated with clubbing are outlined in Table 71.7.

SYSTEMIC CONDITIONS ASSOCIATED WITH CLUBBING	
CONGENITAL/GENETIC	
Cardiovascular disorders	Congenital heart disease (usually cyanotic) Pulmonary arteriovenous malformations (often in the setting of hereditary hemorrhagic telangiectasia)
Bronchopulmonary disease	Cystic fibrosis
Other	Pachydermoperiostosis (see Ch. 98)
ACQUIRED	
Bronchopulmonary diseases	Neoplasms (primary or metastatic cancers, pleural tumors) Chronic infections (abscesses of the lungs, tuberculosis) Bronchiectasis Pulmonary fibrosis, sarcoidosis
Cardiovascular diseases	Aneurysm or dialysis fistula (unilateral clubbing); congestive cardiac failure; bacterial endocarditis
Gastrointestinal diseases	Inflammatory bowel disease Carcinomas Infestations, e.g. amebiasis, ascariasis Liver disorders, e.g. chronic active hepatitis, cirrhosis
Infection	HIV infection Arterial graft sepsis (clubbing limited to perfused extremities)
Endocrine diseases	Thyroid disease (primarily hyperthyroidism)* Secondary hyperparathyroidism
Other	POEMS syndrome Laxative abuse Hemiplegia (unilateral) Trauma, median nerve injury (unidigital)

*Most often in the setting of thyroid acropachy (clubbing together with digital swelling and periosteal reaction) in patients with autoimmune thyroid disease.

Table 71.7 Systemic conditions associated with clubbing.

Yellow Nail Syndrome

Key features

- Arrest in nail growth
- Yellow–green nails
- Absence of the cuticle
- Overcurvature and thickening
- All or most nails are affected

The yellow nail syndrome was first described by Samman and White in 1964. It is not common and its pathogenesis is still unknown. Linear nail growth is arrested or greatly reduced. The nails are thickened and transversely and longitudinally overcurved with disappearance of the cuticle. The nail color varies from pale yellow to dark yellow–green (Fig. 71.14). Onycholysis is frequently seen, as is nail plate shedding. In most patients, all 20 nails are involved. Characteristically, the nail abnormalities are associated with lymphedema and respiratory tract involvement, including chronic bronchitis, bronchiectasis, sinusitis and pleural effusions. The diagnosis of yellow nail syndrome, however, requires only the presence of the typical nail changes.

Treatment

Treatment is not effective in all cases and must be prescribed for several months:

- vitamin E 1200 IU/day
- pulse itraconazole (400 mg daily for 1 week a month) or fluconazole (150 mg daily for 1 week a month); theoretically, the drugs act by accelerating nail growth.

Fig. 71.14 Yellow nail syndrome. Note the overcurvature of the nail and loss of the cuticle, in addition to the yellow discoloration.

Apparent Leukonychia

Key features

- White discoloration that fades with pressure
- Nail plate transparency is maintained

On the basis of the pattern of the nail discoloration, three different types of apparent leukonychia can be distinguished. Nail bed edema may be a common factor.

- Terry's nails were described by Terry in 1954 as a common sign of liver cirrhosis, occurring in up to 80% of patients. The leukonychia affects the whole nail except for a 1 to 2 mm distal band. Terry's nails are also frequently seen in normal individuals.
- Muehrcke's nails were described by Muehrcke in 1956 in patients with hypoalbuminemia (nephrotic syndrome). They are a very common finding in patients receiving combination chemotherapy. The nail has multiple transverse whitish bands, parallel to the lunula (Fig. 71.15).

Fig. 71.15 Muehrcke's nails. There are multiple parallel transverse white bands. The curvature matches that of the lunula.

- Half-and-half nails. First reported by Bean in 1963, half-and-half nails are detected in up to 25% of patients with chronic renal disease who are undergoing hemodialysis. The leukonychia affects the proximal half of the nail. Half-and-half nails may also be seen in normal individuals.

Pseudoinflammatory Nail Changes

Key features
- Cold painful whitlow: digital ischemia
- Painless whitlow and normal temperature: bone metastases

The distal portion of the digit is greatly enlarged and red, simulating an acute paronychia, but the skin temperature is cold or normal. This picture may be caused by digital ischemia or metastases to the distal phalanges. In digital ischemia, the digit is cold and painful. The most common causes include arterial obstruction and autonomic neuropathies causing ischemia (including diabetes). Digital metastases are usually painless; metastases in the fingers are most commonly associated with pulmonary neoplasms and those in the toes with genitourinary neoplasms. X-ray examination is required for the diagnosis[18].

Peripheral Neuropathies

Key features
- Nail abnormalities limited to the first three digits: carpal tunnel syndrome
- Onychomadesis with pseudopyogenic granuloma: mild peripheral nerve injury

Examination of the nail may suggest the diagnosis in carpal tunnel syndrome, since nail abnormalities are limited to the first three fingers and are associated with fingertip paresthesias. Depending on the severity of nerve damage, nail changes vary from Beau's lines to onychomadesis and necrosis. Neurologic examination and electromyography confirm the diagnosis.

Onychomadesis associated with pseudopyogenic granuloma of the proximal nail fold is a sign of mild and transitory peripheral nerve injury. It is typically seen in patients with phalanx, metacarpal or wrist bone fractures during or after cast immobilization. Patients often report a history of pain or paresthesias of the hand during the period of immobilization. The condition spontaneously resolves over a few weeks[19].

Autoimmune Connective Tissue Disorders

Key features
- Nail fold capillary abnormalities
- Cuticular hemorrhages
- Ventral pterygium
- Nail beaking

Abnormalities in the proximal nail fold capillaries are frequently seen in autoimmune connective tissue disorders, as they occur in most patients[20]. Roughness, hemorrhages and necrosis of the cuticles are common in dermatomyositis and scleroderma, where capillaroscopy shows reduced capillary density and avascular areas alternating with dilated capillary loops. In systemic lupus erythematosus, capillaroscopy shows a normal capillary density with dilated tortuous capillaries.

Ventral pterygium (pterygium inversus unguis) is characterized by the adhesion of the distal nail plate to the hyponychium, resulting in pain during nail trimming. Ventral pterygium is a distinctive sign of scleroderma related to impaired peripheral perfusion[21]. In scleroderma, ischemic changes and bone resorption may result in nail beaking with bending of the nail plate around the shortened fingertip (see Fig. 43.2).

HIV Infection

Key features
- Proximal subungual onychomycosis due to *Trichophyton rubrum*
- *Candida* onychomycosis
- Longitudinal melanonychia
- Squamous cell carcinoma

Onychomycoses are common in HIV-infected patients, occurring in up to 25% of affected individuals. Dermatophytes are most commonly responsible, but *Candida* spp. and molds are also often isolated[22]. Although a large number of nail abnormalities have been reported in association with AIDS[17], only a few clinical entities can be considered typical of this disease.

- Proximal subungual onychomycosis due to *T. rubrum*. This variety of onychomycosis is considered a marker for HIV infection and immunodeficiency. The proximal nail plate is opaque and white due to the presence of fungi in its ventral portion.
- *Candida* onychomycosis. *Candida* does not invade the nail plate of immunocompetent individuals, and the diagnosis of true *Candida* onychomycosis indicates immunosuppression – often, HIV infection.
- Longitudinal melanonychia. Usually, several nails are involved, and it is often associated with skin hyperpigmentation.
- HPV-induced squamous cell carcinoma. Longstanding periungual warts in HIV patients should always raise the suspicion of squamous cell carcinoma and be examined histologically. HPV types 16 and 35 have been detected in such lesions[23].

Drug-Induced Nail Abnormalities (Table 71.8)

Key features
- Involvement of most or all nails
- Beau's lines and onychomadesis
- Painful hemorrhagic onycholysis
- Multiple bands of melanonychia
- Paronychia with pyogenic granulomas

Drug-induced nail changes usually involve several or all nails. The pathogenesis is most often toxic in nature[24].

DRUG-INDUCED NAIL ABNORMALITIES	
Nail abnormality	**Responsible agents**
Beau's line and onychomadesis	Chemotherapeutic agents
True leukonychia	Chemotherapeutic agents
Nail thinning and brittleness	Chemotherapeutic agents Retinoids
Onycholysis/photo-onycholysis (see Fig. 71.6)	Chemotherapeutic agents, particularly taxanes Tetracyclines Psoralens NSAIDs
Apparent leukonychia (e.g. Muehrcke's nails)	Chemotherapeutic agents, particularly polychemotherapy including anthracyclines, vincristine
Melanonychia	Chemotherapeutic agents Psoralens Zidovudine (AZT)
Discoloration (non-melanin)	Minocycline Antimalarials Gold
Paronychia and periungual pyogenic granulomas	Retinoids Antiretroviral drugs (indinavir, efavirenz, lamivudine) Epidermal growth factor receptor (EGFR) inhibitors (cetuximab, gefitinib, erlotinib, panitumumab) Methotrexate Capecitabine (prodrug of 5-fluorouracil) Sirolimus
Ischemic changes	Beta-blockers Bleomycin

Table 71.8 Drug-induced nail abnormalities.

- Cancer chemotherapeutic agents, due to their cytotoxic properties, are the most frequent cause of nail changes. These include Beau's lines, onychomadesis, fragility, pigmentation, onycholysis, paronychia, and vascular problems, including subungual hemorrhages, hematomas and ischemia. Painful subungual hemorrhages and abscesses are typically seen with taxanes (paclitaxel and docetaxel).
- Paronychia associated with pyogenic granulomas has been reported with epidermal growth factor receptor (EGFR) inhibitors used as chemotherapeutic agents (see Ch. 21). Nail changes appear from 1 to 3 months after starting treatment and disappear after interruption of treatment.
- Oral retinoids are frequently responsible for nail abnormalities, especially nail fragility, paronychia and pyogenic granulomas.
- Antiretroviral drugs often cause nail pigmentation, paronychia and pyogenic granulomas (Fig. 71.16).
- Although uncommon, photo-onycholysis is a characteristic side effect of tetracyclines, taxanes, psoralens and photodynamic therapy (see Fig. 71.6).
- Certain drugs (e.g. anticoagulants and anticonvulsants) taken during pregnancy may impair the development of the digits, leading to congenital nail hypoplasia.

INFECTIONS

Acute Paronychia

Key features
- Painful whitlow
- Recurrent when due to herpes simplex virus (HSV)
- Viral and bacterial cultures are mandatory

Fig. 71.16 Multiple periungual pyogenic granulomas in a patient taking indinavir.

Fig. 71.17 Acute paronychia. In addition to the erythema and purulent discharge, there is significant tenderness.

The affected digit becomes swollen, red and painful (Fig. 71.17). Compression of the nail fold may produce purulent drainage. Acute paronychia is most commonly due to bacteria, in particular *Staphylococcus aureus* or *Streptococcus pyogenes*, and it follows minor trauma to the nail. Recurrent episodes of acute paronychia should raise the suspicion of an HSV infection. Viral cultures, direct fluorescent antibody assay, and/or PCR should be obtained to identify the responsible agent.

Treatment

- Drainage of the abscess.
- Systemic antibiotics according to culture results.
- Systemic antivirals when due to HSV.

Warts (see Ch. 79)

Key features
- Periungual keratotic papules
- Hyperkeratosis of the cuticle
- Onycholysis and subungual hyperkeratosis
- In recalcitrant lesions, consider the possibility of squamous cell carcinoma

Periungual warts are common in nail biters, in whom they are multiple and involve several nails. The warts appear as keratotic papules, and when localized to the proximal nail fold, they frequently produce periungual hyperkeratosis simulating a hyperkeratotic cuticle. Nail bed warts lead to uplifting of the nail plate with onycholysis. Squamous cell

THERAPEUTIC LADDER FOR PERIUNGUAL WARTS
• Keratolytics (2)
• Cryotherapy (2)
• Topical cantharidin (2)
• Topical imiquimod (2)
• Intralesional injection of *Candida, Trichophyton* or mumps skin test antigens (1)
• Topical immunotherapy[§] (2)
• Laser: CO_2, erbium:YAG, pulsed dye (2)
• Photodynamic therapy (2)
• Ablative CO_2 fractional laser followed by PDT* (2)
*With methyl 5-aminolevulinic acid and red light.
[§]For details, see Table. 129.13.

Table 71.9 Therapeutic ladder for periungual warts. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. PDT, photodynamic therapy.

carcinoma can arise in or mimic a verruca; therefore, suspicious lesions must be further evaluated.

Treatment

See therapeutic ladder (Table 71.9).

Onychomycosis (Tinea Unguium)

See Chapter 77.

ENVIRONMENTAL NAIL DISORDERS

Brittle Nails (Fragility, Onychoschizia)

Key features

- Lamellar exfoliation (onychoschizia)
- Fingernails affected
- Nail dehydration due to environmental factors

Brittle nails are very common and usually affect women. Nail brittleness results from dehydration of the nail plate as a result of environmental factors such as frequent handwashing. In lamellar onychoschizia, the distal nail plate splits horizontally into multiple layers (see Fig. 71.2). Other signs of nail brittleness include splitting, softening and onychorrhexis.

Treatment

- Avoidance of water and chemical exposure.
- Biotin (2.5–5 mg/day).
- Topical moisturizers and humectants.

Chronic Paronychia

Key features

- Proximal nail fold inflammation
- Absence of the cuticle
- Fingernails affected
- Nail plate surface abnormalities

Chronic paronychia commonly involves the fingernails of adult women. Although the pathogenesis is still debated, there is accumulating evidence that the condition represents a contact reaction to irritants or allergens[25]. Occupational chronic paronychia is common in food handlers. Chronic paronychia is clinically characterized by inflammation of the proximal nail fold with erythema, edema and absence of the cuticle. One or several fingernails (especially the thumb and second or third fingers of the dominant hand) are affected. Damage to the nail matrix results in nail plate surface abnormalities such as Beau's lines[26]. Chronic paronychia usually assumes a prolonged course with superimposed, recurrent, self-limited episodes of acute exacerbation. Secondary infections with *Candida* spp. and *Pseudomonas aeruginosa* are common.

Treatment

- Avoidance of water and chemical exposure.
- Topical corticosteroids.
- Topical imidazoles.
- Topical antiseptics (e.g. 4% thymol in 95% ethanol).
- Systemic antifungals are not useful.

Idiopathic Onycholysis

Key features

- Limited to fingernails
- White or green discoloration
- Absence of subungual hyperkeratosis

Idiopathic onycholysis frequently involves the fingernails as a consequence of repetitive water immersion and exposure to irritants (see Fig. 71.6). The affected nail is detached from the nail bed and often shows an abnormal color due to secondary microbial contamination of the subungual space[26].

Treatment

- Avoidance of water and chemical exposure.
- Clipping of the detached nail plate.
- Topical antiseptics.

TRAUMATIC NAIL ABNORMALITIES (Table 71.10)

Onychotillomania

Key features

- Cuticle absent and proximal nail fold inflamed
- Nail plate surface abnormalities, e.g. longitudinal central depression
- Melanonychia
- Hemorrhages and crusts

Self-induced nail abnormalities are common, but often not recognized due to the wide variety of nail signs and the difficulty in obtaining a correct clinical history.

- Nail biting may affect the nail plate and/or the proximal nail fold; the trauma often produces nail matrix damage with secondary nail plate abnormalities, including surface irregularities and longitudinal melanonychia.
- Habit-tic deformity affects the thumb and is due to the nervous habit of rubbing and pushing back the mid-portion of the cuticle of the thumb with the index finger. The nail plate of the thumb shows multiple midline Beau's lines with a prominent longitudinal central depression. Median canaliform dystrophy of Heller, also known as dystrophia unguis mediana canaliformis, is characterized by an inverted fir tree-like split or canaliform defect in the nail plate (Fig. 71.18) and is possibly a variant of habit-tic deformity[27].
- Nail destruction associated with psychiatric disorders. The clinical picture is variable, with nail plate destruction, hemorrhages, and periungual crusts and erosions. Instruments (scissors, clippers, etc.) are often utilized to destroy the nails.

NAIL CHANGES ASSOCIATED WITH A MANICURE OR PEDICURE	
Nail abnormality	**Etiology**
Beau's lines	Matrix damage from cuticle removal
True leukonychia (transverse)	Matrix damage from cuticle removal
Nail brittleness (onychorrhexis, onychoschizia)	Nail varnish solvents; electric drills
Nail brittleness (superficial granulation)	Prolonged nail polish wearing
Distal onycholysis ("roller coaster")	Mechanical (nail tools utilized to clean the nail plate free edge)
Diffuse onycholysis	Mechanical (artificial nails acting as a lever)
Diffuse onycholysis	Chemical (acrylic nails)
Discoloration (yellow/orange)	Nail varnishes
Acute paronychia Chronic paronychia Periungual pyogenic granulomas Periungual warts	Periungual cuts from sharp instruments Contact allergy Constant cuticle removal Periungual wounds Mechanical trauma to the cuticle

Table 71.10 Nail changes associated with a manicure or pedicure.

Fig. 71.18 Median canaliform dystrophy (of Heller).

Treatment

- Topical preparations that taste unpleasant.
- Bandages.
- Serotonin reuptake inhibitors (fluoxetine, paroxetine, sertraline).

Subungual Hematoma

Key features

- History of acute trauma
- Purple–red to black in color
- Typical dermoscopic features
- Discoloration moves distally with nail growth

Acute hematomas occur after trauma severe enough to lead to accumulation of blood under the nail plate. Toenails are most commonly affected. Acute hematomas are typically associated with pain, and compression of the matrix may cause secondary nail plate dystrophy. An X-ray of the digit may be advisable to exclude a bone fracture.

Repeated microtrauma or hemorrhagic conditions produce asymptomatic small subungual hematomas of the nails that are incorporated within the ventral nail plate and migrate distally with nail growth. The color of subungual hematomas ranges from purple–red to black. Dermoscopy is useful for differentiating hematomas from melanin deposition[28].

Treatment

Acute hematomas require drainage of the blood by creating a hole through the nail plate.

Traumatic Toenail Abnormalities

Key features

- Onycholysis without subungual hyperkeratosis
- Leukonychia and melanonychia
- Often bilateral
- Podiatric abnormalities
- Retronychia characteristically affects the proximal nail fold

Traumatic toenail abnormalities are most commonly seen in women who wear high-heeled pointed shoes.

- Traumatic onycholysis of the hallux is the most common clinical presentation. The onycholysis may be distal, where the detachment is caused by compression of the distal pulp by poorly fitting shoes, or lateral, when there is overlapping of the second toe onto the first. Clipping of the detached nail plate reveals a normal nail bed. The differential diagnosis includes onychomycosis, but here the onycholysis is associated with subungual hyperkeratosis.
- Transverse leukonychia of the hallux results from repeated microtrauma by shoes to untrimmed, long, great toenails[29]. Multiple bands of true leukonychia move distally with nail growth.
- Frictional melanonychia affects the toenails of the fourth and/or fifth digits of women. It is due to activation of nail matrix melanocytes by friction from shoes or from the adjacent digit. The bands may be multiple and black in color.
- Retronychia is caused by embedding of the nail into the proximal nail fold following trauma and may present with inflammation of the proximal nail fold.

Onychogryphosis

Key features

- Ram's horn nails
- Thick, hard, yellow–brown nail plate
- Hallux most frequently affected
- Elderly patients

Onychogryphosis is common in elderly persons and almost exclusively affects the toenails, usually the hallux. The nail acquires a typical ram's horn shape due to asymmetric growth. The nail plate is thick, hard and yellow–brown. Multiple transverse striations are often present. Nail hardness and self-neglect may lead to monstrous deformities.

Pincer Nails (Trumpet Nails)

Key features

- Nail bed pinching by overcurved nail plate
- Toenails most frequently affected
- Severe pain
- Subungual exostosis should be excluded by X-ray examination

Pincer nails are usually seen on the toes and may be hereditary or acquired; the latter is most commonly due to ill-fitting shoes. The nail plate displays an excessive transverse overcurvature, especially in its distal portion (see Fig. 71.2). This results in compression of the distal nail bed with severe pain[30].

Treatment

Lateral matricectomy (see Ch. 149) is the treatment of choice. Surgery is necessary when a subungual exostosis is present.

Ingrown Toenails (Onychocryptosis)

Key features

- Teenagers and young adults
- Congenital malalignment often present
- Precipitated by improper nail cutting and hyperhidrosis
- Painful inflammation of the lateral fold
- Growth of granulation tissue

Lateral ingrowing usually affects the hallux of young adults with congenital malalignment of the great toenails. Precipitating factors include improper or aggressive nail cutting and trauma. Penetration of nail plate spicules into the lateral nail fold epithelium causes painful inflammation. Chronic onychocryptosis is characterized by the growth of granulation tissue that eventually undergoes epithelialization[1].

Distal embedding is a common complication of nail avulsion. The nail plate growth is blocked by the hyponychium, which forms a distal rim. Retronychia represents the ingrowth of the proximal nail plate into the proximal nail fold, with one to three nail plates misaligned beneath the uppermost nail plate[31]. There may be associated proximal periungual pyogenic granulomas.

Treatment

- Prevention through patient education.
- Removal of the embedded spicule.
- Uplifting of the lateral nail plate with cotton or dental floss.
- Granulation tissue may be prevented by topical antibiotics and topical corticosteroids or treated by cryotherapy, chemical cautery or electrodesiccation.
- Chemical (88% phenol), laser or excisional surgical removal of the lateral matrix is advisable in severe cases.
- In retronychia, surgical avulsion of the proximally embedded nail plate as well as the underlying plate(s) is necessary.

NAIL TUMORS

Nail surgery is discussed in Chapter 149.

Benign Tumors

Pyogenic granuloma (botryomycoma)

Key features

- Bleeding angiomatous papulonodule
- Periungual or subungual
- Often traumatic

Pyogenic granulomas commonly appear within the nail apparatus, where they may be periungual or subungual, and often follow penetrating trauma. Other common causes of pyogenic granuloma of the nail include ingrown toenails, systemic drugs (e.g. retinoids, EGFR inhibitors), peripheral nerve damage, and frictional onycholysis due to prolonged walking[32,32a]. The tumor appears as a bleeding, friable, soft red papulonodule (see Fig. 71.16). When subungual, it is associated with onycholysis. The differential diagnosis includes amelanotic melanoma. Treatment is surgical.

Fibromas/Fibrokeratomas

Key features

- Filiform growth
- Nail plate furrow
- Possible sign of tuberous sclerosis

Isolated periungual and subungual fibromas are not rare in the general population. Multiple lesions occur in 50% of patients with tuberous sclerosis (Koenen's tumors). Periungual fibromas appear as pink or skin-colored papules originating from the proximal nail fold. The fibroma may compress the nail matrix and produce a longitudinal groove in the nail plate. Subungual fibromas that grow underneath the nail plate produce longitudinal erythronychia or onycholysis. A fibrokeratoma is characterized by a hyperkeratotic tip and may be surrounded by a collarette of raised skin.

Subungual exostosis

Key features

- Subungual hard nodule
- Onycholysis
- Toenails (especially hallux)
- X-ray examination is diagnostic

Subungual exostoses, first described by Dupuytren in 1847, are the most common benign bony proliferations associated with nail abnormalities. Subungual exostoses are commonly precipitated by trauma and usually seen on the great toe of young patients (Fig. 71.19A). An exostosis produces a firm, tender subungual nodule that elevates the nail plate. The nodule may ulcerate or become hyperkeratotic. The diagnosis is confirmed by X-ray examination (Fig. 71.19B)[33].

Myxoid cysts (mucous cyst)

Key features

- Proximal nail fold swelling
- Nail plate depression and grooves
- Periodic fluid drainage

First described by Hide in 1883, myxoid cysts are the most common nail tumor, often occurring in middle-aged women. Typically located in the proximal nail fold of the fingernails, they appear as small soft nodules that often spontaneously drain a viscous jelly-like fluid. Compression of the matrix produces nail plate depression and grooves (Fig. 71.20). Occasionally, the cysts are subungual. These cysts are connected to the distal interphalangeal joint by a tract, and osteoarthritis of the distal joint is a frequent association[34].

Treatment

Possible treatments for myxoid cysts include sclerotherapy, cryosurgery, and intralesional corticosteroid injections. Caution must be taken because septic arthritis is a potential complication of surgical procedures that allow access of surface bacteria into the underlying synovial space. All of these procedures are associated with a high frequency of relapses. Definitive cure of myxoid cysts can be obtained with surgical procedures that include ligature of the pedicle that connects the cyst to the joint.

Fig. 71.19 Subungual exostosis. A Skin-colored subungual nodule elevating the nail plate. **B** Radiograph of the digit demonstrating the subungual bony proliferation.

Fig. 71.20 Myxoid cyst. The longitudinal nail groove is a result of the compression of the nail matrix by the cyst.

Fig. 71.21 Onychomatricoma. The nail is thickened and overcurved with longitudinal yellow streaks. The distal border shows several holes.

Glomus tumor

Key features
- Severe pain
- Temperature sensitivity
- Subjective symptoms contrast with minimal clinical signs

First described by Wood in 1812, a glomus tumor arises from the neuromyoarterial glomus cells of the nail bed dermis. It is associated with severe pain that radiates proximally and is often aggravated by physical or thermal stimuli (especially cold). Subjective symptoms typically exceed clinical signs. The tumor appears as a red–bluish nail bed macule visible through the transparent nail plate (see Ch. 149). MRI allows the diagnosis in doubtful cases (see Ch. 114).

Onychomatricoma

Key features
- Localized longitudinal thickening with transverse overcurvature
- Yellow–white discoloration
- Multiple, longitudinal, tumor-containing hollows
- Holes in the distal nail

First described by Baran and Kint in 1992, onychomatricoma is a rare neoplasm that produces localized or diffuse thickening of the nail plate with perforations consisting of multiple longitudinal hollows that contain the digitating tumor. Most commonly, onychomatricoma arises within the fingernails of middle-aged individuals[35] (Fig. 71.21). A frontal view of the nail typically reveals multiple holes in the thickened free margin. The affected nail is thickened and yellow–white in color, with multiple splinter hemorrhages.

Histologically, the tumor is characterized by multiple fibroepithelial projections that extend into the thickened nail plate. The tumor epithelium is identical to that of the normal nail matrix and keratinizes without a granular layer.

Melanocytic nevi of the nail matrix

Key features
- Longitudinal melanonychia
- Onset in childhood

Nail matrix nevi are an uncommon cause of longitudinal melanonychia, especially in comparison with melanocyte activation (see Table 71.2). They usually develop during childhood and often involve the fingers, especially the thumb[36,37]. The color, width and pigment

distribution may vary considerably and it is not unusual to observe fading or darkening of the pigmentation over time. Pigmentation of the periungual tissues is also possible.

Treatment

Optimal management of nail matrix nevi is still debated. The authors' approach is immediate excision of rapidly growing lesions and excision of all lesions after puberty (see Ch. 149).

Malignant Tumors

Malignant tumors of the nail are summarized below. For further details of the disorders and their treatment, see Chapters 108 and 113.

Bowen's disease (squamous cell carcinoma in situ)

Key features

- Verrucous lesion
- Onycholysis
- Melanonychia

Bowen's disease of the nail is uncommon and is seen most often in middle-aged men. Fingers of the left hand are most commonly involved[38]. Clinically, it may be difficult to differentiate Bowen's disease from warts. The affected digit shows periungual or subungual verrucous lesions with onycholysis and longitudinal melanonychia (Fig. 71.22). Predisposing factors include HPV infection and chronic X-ray exposure.

Fig. 71.22 Bowen's disease. The lateral portion of the nail plate is absent. The nail bed shows hyperkeratosis with scaling and fissuring of the epithelium.

Keratoacanthoma

Key features

- Painful subungual nodule
- Rapid growth
- Osteolysis on radiography

Keratoacanthoma is an extremely rare tumor that usually affects the thumb or the index or middle fingers. It appears as a painful subungual keratotic nodule that grows rapidly over a period of weeks. Deep invasion with bone destruction is frequent. A history of trauma is often reported. In contrast to cutaneous keratoacanthomas, keratoacanthomas of the nail do not regress spontaneously[39].

Squamous cell carcinoma

Key features

- Verrucous lesion
- Ulcerated nodule
- Onycholysis
- Nail plate destruction

Squamous cell carcinoma is the most frequent malignant tumor of the nail apparatus. It most commonly affects the fingernails of middle-aged men. A number of studies have confirmed a causative role for HPV, mostly HPV-16, in the development of this tumor. Clinically, there is a slowly growing periungual or subungual mass that may ulcerate and bleed. Periungual swelling and inflammation are often seen. Bony involvement may occur but metastases are extremely rare[40].

Verrucous carcinoma (carcinoma cuniculatum, epithelioma cuniculatum)

Key features

- Rapidly growing verrucous nodule
- Nail destruction

Fig. 71.23 Amelanotic melanoma. Note the diffuse nail destruction and ulceration.

Verrucous carcinoma is a rare, low-grade variant of squamous cell carcinoma characterized by locally aggressive clinical behavior but low potential for metastasis. It rarely involves the nail apparatus. Clinically, the tumor appears as a rapidly growing nodule that often destroys the nail. Bone resorption is common.

Melanoma

Key features

- Longitudinal melanonychia
- Thumb is the most frequent site
- Nail plate destruction
- Hutchinson's sign
- Amelanotic in 25% of cases

Nail melanoma is rare, accounting for 0.7–3.5% of all melanomas. It most frequently involves the thumb of middle-aged individuals, and patients often report a history of trauma. Diagnosis is often delayed, and in 25% of cases the tumor is amelanotic. The 5-year survival is only 15%[41]. From a clinical standpoint, nail melanoma may have the following features:

- Longitudinal melanonychia. The pigmented band is usually dark brown or black in color, with blurred margins. Nail plate abnormalities result from nail matrix damage. The dermoscopic

ABCDEF RULE FOR CLINICAL SUSPICION OF NAIL MELANOMA	
A	• age (peak incidence – 5th to 7th decades of life) • African-Americans, Asians and native Americans (1/3 of all nail melanoma cases)
B	• brown to black • breadth (3 mm or wider) • borders (variegated)
C	• change in the nail band (color/size) • lack of change in the nail morphology despite presumed adequate treatment
D	• digit most commonly involved (thumb and big toe)
E	• extension of the pigment into the proximal and/or lateral nailfold (Hutchinson's sign)
F	• family or personal history of dysplastic nevi or melanoma

Table 71.11 ABCDEF rule for clinical suspicion of nail melanoma. *Adapted from Levit EK, et al. The ABC rule for clinical detection of subungual melanoma. J Am Acad Dermatol. 2000;42:269–74.*

pattern that has been associated with melanoma is a brown background with longitudinal lines that are irregular in color, thickness and spacing. However, a recent study indicated that these dermoscopic patterns were not useful in the early detection of nail melanoma, as dermoscopy did not improve accuracy in the clinical diagnosis of melanoma[42].

- A subungual pigmented lesion that may have ulcerated and is associated with onycholysis and nail destruction.
- An amelanotic nodule that frequently ulcerates and bleeds, resembling a pyogenic granuloma (Fig. 71.23).

The presence of Hutchinson's sign (pigmentation of the periungual tissues due to superficial spreading of the tumor) should raise the suspicion of nail melanoma. An ABCDEF of nail melanoma has been proposed, to facilitate diagnosis (Table 71.11)[43].

Oral manifestations of systemic disease *1167*
Oral manifestations of HIV infection *1168*

Introduction

From a histologic standpoint, the oral mucosa is an amazingly diverse anatomic region. This is not surprising when one considers the various tasks and environmental interactions that take place within the mouth. Sites that are associated with the friction of mastication, such as the hard palate and attached gingivae, show prominent rete ridge formation and a thick layer of orthokeratin. The dorsal tongue has a papillary architecture with prominent parakeratin production, while the posterior lateral tongue has a surface epithelium with embedded taste receptors. The soft palate and labial mucosa exhibit only a modest degree of parakeratosis and are associated with numerous salivary glands; the buccal mucosa is similar, but variable numbers of heterotopic sebaceous glands (Fordyce granules) may be seen in this area.

DEVELOPMENTAL CONDITIONS OF THE ORAL CAVITY

Fordyce Granules

Synonyms: ■ Ectopic sebaceous glands ■ Heterotopic or anomalous sebaceous glands ■ Fordyce spots

Key features

- Common variation of normal sebaceous glands
- Multiple yellowish papules of the buccal mucosa and vermilion zone of the upper lip

Introduction

Fordyce granules are sebaceous glands that are located in the vermilion zone of the lips and the oral mucosa. Historically, these sebaceous glands have been considered ectopic; however, because they are such a common clinical finding in the oral cavity, Fordyce granules should be regarded as a variation of normal anatomy. "Free" sebaceous glands (see below) can also be found on the eyelids (meibomian glands), areolae (Montgomery tubercles), labia minora and prepuce (Tyson glands).

Epidemiology

Fordyce granules are found in both sexes and are less common in children. The prevalence of Fordyce granules is as high as 70% to 85% in the adult population[1].

Clinical features

Fordyce granules characteristically present as asymptomatic, usually multiple, yellow to yellow–white papules. The papules are usually no more than 1–2 mm in size, and they often occur bilaterally. They are most commonly found on the buccal mucosa and the vermilion portion of the upper lip. Puberty appears to stimulate their development[2].

Pathology

Fordyce granules are similar to sebaceous glands found in the skin, but they are not associated with hair follicles, i.e. they are "free" sebaceous glands[1].

Treatment

Since Fordyce granules are considered a normal variation of anatomy, no treatment is indicated.

Geographic Tongue

Synonyms: ■ Benign migratory glossitis ■ Glossitis areata migrans ■ Stomatitis areata migrans ■ Benign migratory stomatitis

Key features

- Red, well-demarcated patches on the lateral and dorsal tongue with scalloped thin white borders
- Psoriasiform mucositis of unknown etiology
- No treatment is generally necessary

Introduction

Geographic tongue is a common, benign clinical condition of unknown etiology that primarily affects the tongue, although rarely it can occur in other sites within the mouth, such as the buccal mucosa, labial mucosa and soft palate. When it occurs in sites other than the tongue, the tongue is almost always involved as well.

Epidemiology

Geographic tongue is a condition that affects both sexes, with a prevalence of 1–3% in the general population[2].

Clinical features

Geographic tongue typically presents on the dorsum of the tongue as multiple well-delineated areas of erythema surrounded by a yellowish-white serpiginous border (Fig. 72.1). Within the areas of erythema, there is atrophy of the filiform papillae. The lesions may begin as small white patches. These then develop a central red atrophic zone, which slowly increases in size. Many patients are unaware they have a geographic tongue, and it is often found on routine oral examination[3]. Patients who are aware of their lesions frequently report that the lesions appear to migrate. Geographic tongue is usually asymptomatic, although some patients may experience a burning sensation or sensitivity to hot or spicy foods. Some investigators have suggested that geographic tongue occurs with increased frequency in patients with psoriasis (including pustular psoriasis), in atopic individuals, and in patients with fissured tongue (discussed below).

Pathology

Because the microscopic features of geographic tongue are similar to those of psoriasis, the former is often termed "psoriasiform mucositis".

Fig. 72.1 Geographic tongue. A florid example, demonstrating well-delineated areas of erythema partially surrounded by white serpiginous borders.

Fig. 72.2 Fissured tongue. Numerous asymptomatic furrows and grooves on the dorsal tongue.

At the edge of the lesion, there is a characteristic loss of the papillary surface morphology of the tongue, elongation of rete ridges, a varying degree of hyperparakeratosis and spongiosis, and the presence of numerous, typically confluent, superficial intraepithelial neutrophilic microabscesses[2].

Treatment

Geographic tongue generally requires no treatment other than assuring the patient that it represents a benign condition. If symptoms such as burning, sensitivity, pain or tenderness are present to a severe extent and interfere with the patient's lifestyle, application of a potent topical corticosteroid gel may provide some relief.

Fissured Tongue

Synonyms: ■ Scrotal tongue ■ Plicated tongue ■ Lingua plicata ■ Furrowed tongue

Introduction

Fissured tongue is a common, benign clinical condition of unknown etiology that affects the dorsum of the tongue. As the name implies, few to numerous furrows or grooves are seen on the dorsum of the tongue. Heredity appears to be a factor, with some evidence suggesting that the condition represents a polygenic trait, or an autosomal dominant trait with incomplete penetrance or expressivity. As mentioned previously, fissured tongue is often found in association with geographic tongue, with some researchers suggesting that the same gene or genes may be associated with both conditions. Fissured tongue may be a component of the Melkersson–Rosenthal syndrome (see below). It is a common finding in Down syndrome and is occasionally seen in association with Cowden syndrome, pachyonychia congenita, and acromegaly (in the setting of macroglossia).

Epidemiology

Fissured tongue affects both sexes, with the reported prevalence ranging from 2% to 30% of adults, depending on the population studied[3].

Clinical features

Fissured tongue typically presents as multiple asymptomatic grooves on the dorsum of the tongue (Fig. 72.2). The grooves are usually 2–3 mm in depth, and can occur in isolated areas of the tongue (especially centrally) or involve the entire dorsal surface.

Treatment

Fissured tongue is a benign condition requiring no treatment.

Hairy Tongue

Synonyms: ■ Black hairy tongue ■ Lingua villosa nigra

Key features

- Retention of keratin on the tips of filiform papillae
- Not due to yeast infection
- Best managed using a tongue scraper

Introduction

Hairy tongue is a common, benign clinical condition that basically represents accumulation of varying amounts of keratin on the dorsum of the tongue. Normally, the rate of keratin production on the dorsal tongue equals the rate at which keratin is naturally debrided during chewing and swallowing. If a patient has reduced food intake or a primarily soft or liquid diet, then the keratin simply accumulates. It is not a sign of any underlying systemic disease in an otherwise healthy and non-debilitated patient, as was historically believed. Factors that may be associated with increased production of keratin include smoking, poor oral hygiene, use of oxidizing mouthwashes, and hot beverages.

Epidemiology

Hairy tongue affects both sexes, with a prevalence reported as 0.5–5% of the population.

Clinical features

Hairy tongue presents as confluent hair-like projections on the dorsum of the tongue, especially its mid portion (Fig. 72.3). The elongated papillae are usually yellow to brown–black, although a wide range of colors may occur due to differential exogenous staining from food, tobacco or chromogenic bacteria. Overgrowth of the latter may occur in the setting of oral or systemic antibiotic therapy. Some patients complain of bad breath, bad taste, or a gagging sensation when the tongue contacts the palate. A distinctly different entity is pigmented papillae of the tongue, in which multiple, uniformly spaced, tiny brown papules (representing normal fungiform papillae) are seen on the tip and lateral aspects of the tongue in darkly pigmented individuals.

Pathology

Microscopic examination reveals pronounced accumulation of parakeratosis at the tips of otherwise normal filiform papillae. Often, bacteria can be seen colonizing the surface.

Treatment

Hairy tongue is a benign condition requiring no treatment. Some patients desire treatment due to the unaesthetic nature of the process,

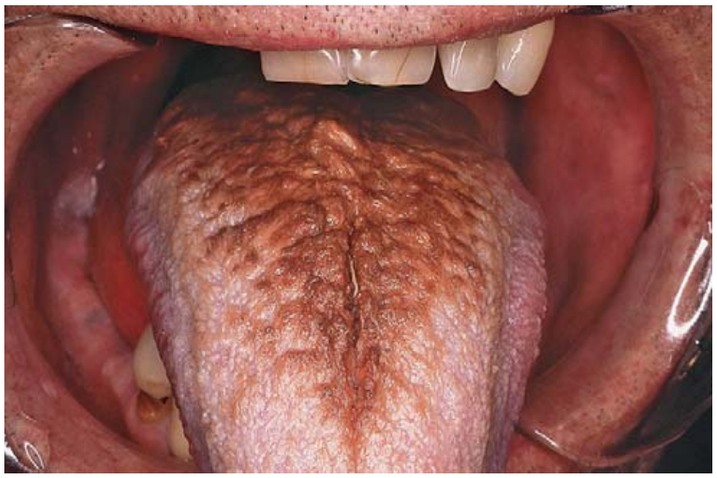

Fig. 72.3 Hairy tongue. The dorsum of the tongue exhibits marked accumulation of keratin and brown discoloration.

Fig. 72.4 Median rhomboid glossitis. On the dorsum of the tongue (anterior to the circumvallate papillae), there is a well-demarcated, smooth area with loss of the filiform papillae.

or because of the altered taste, bad breath, or gagging sensation. In such cases, patients should be encouraged to scrape the tongue with a tongue scraper or brush it while tooth brushing.

Median Rhomboid Glossitis

Synonym: ■ Central papillary atrophy

Key features

- Red, well-demarcated area in the midline of the posterior dorsal tongue
- Consistently associated with candidiasis
- Responds partially or completely to antifungal therapy

Introduction

Median rhomboid glossitis was formerly thought to be a developmental defect resulting from failure of the embryonic tuberculum impar to be covered by the lateral processes of the tongue. However, it is not usually seen in children but is found in up to 1% of adults, and it often resolves with anticandidal therapy.

Clinical features

Median rhomboid glossitis appears as a well-demarcated, diamond- or oval-shaped area of erythema and atrophy on the dorsum of the tongue (Fig. 72.4), anterior to the circumvallate papillae. The surface may be smooth or lobulated. It is usually asymptomatic but may also be associated with chronic multifocal candidiasis affecting the palate and angles of the mouth. Median rhomboid glossitis accompanied by palatal inflammation in the area of contact with the tongue lesion may represent a sign of HIV infection or other causes of immunosuppression.

Pathology

Histologically, there is loss of the filiform papillae and tubular hyphae of *Candida albicans* are embedded within the parakeratin layer. However, the diagnosis is usually made clinically and then confirmed by demonstration of pseudohyphae in a KOH preparation or a PAS-stained exfoliative cytologic preparation.

Treatment

The mucosal alteration resolves completely or partially after a course of appropriate anticandidal therapy such as clotrimazole troches or oral fluconazole.

SYNDROMES OF THE HEAD AND NECK

Nevoid Basal Cell Carcinoma Syndrome

Nevoid basal cell carcinoma syndrome (NBCCS) is an autosomal dominant disorder due to *PTCH* mutations (see Ch. 107), and up to 50% of cases may represent new mutations[4]. In addition to numerous cutaneous basal cell carcinomas (BCCs) and palmoplantar pits, patients develop skeletal anomalies and odontogenic keratocysts of the jaws (see Table 108.5). The latter are detected via a panoramic radiograph of the jaws (recommended annually). Odontogenic keratocysts should be removed completely as they can be very aggressive, leading to significant resorption of the jawbones and even pathologic fractures.

Gardner Syndrome

Synonym: ■ Familial colorectal polyposis

Introduction

Gardner syndrome is a rare autosomal dominant disorder characterized by multiple osteomas, premalignant colorectal polyps, epidermoid cysts, desmoid tumors and cutaneous fibromas (see Ch. 63). Because Gardner syndrome is due to mutations in the adenomatous polyposis coli (*APC*) gene, it is allelic with "familial adenomatous polyposis" (FAP). Without surgical intervention, development of colorectal carcinoma is inevitable.

Osteomas most commonly develop in the maxilla and mandible, and along with bilateral CHRPE (*c*ongenital *h*ypertrophy of the *r*etinal *p*igment *e*pithelium), represent the earlier manifestations of this syndrome. Screening and treatment recommendations are discussed in Chapter 63.

Multiple Endocrine Neoplasia Syndrome Type 2B

Synonyms: ■ Multiple endocrine neoplasia type 3 ■ Multiple mucosal neuroma syndrome

Key features

- Rare autosomal dominant syndrome, with high penetrance but variable expressivity
- Multiple mucosal neuromas involving the conjunctivae, lips and tongue
- Increased prevalence of pheochromocytoma
- Medullary thyroid carcinoma often develops as early as the first or second decade

Introduction

Multiple endocrine neoplasia syndrome type 2B (MEN 2B) is one of a group of inherited conditions characterized by hyperplasia or neoplasia of endocrine glands (e.g. thyroid, parathyroid, adrenal, pituitary; see Table 63.2). This syndrome is caused by missense mutations in the *RET* proto-oncogene (in particular, Met918Thr) which encodes a tyrosine kinase receptor[5].

Clinical features

The most distinctive feature of MEN 2B is the development of mucosal neuromas[6], which are present in almost all patients and are usually asymptomatic. Lesions often begin to appear during the first decade of life as soft, painless papules or nodules that favor the lips and tongue, but may also be found on the buccal mucosa, gingiva and palate. The most significant aspect of this condition is the development of medullary thyroid carcinoma in more than 90% of patients, usually during the first or second decade of life, with reports of occurrence as early as 7 months of age.

Pathology

The mucosal neuromas of MEN 2B are histopathologically distinct and are termed "plexiform neuromas". They consist of hyperplastic bundles of nerves that are surrounded by a thickened perineurium and are situated within otherwise normal-appearing submucosal connective tissue.

Treatment

Analysis of the *RET* gene should be performed in patients with clinical evidence of the disease as well as in asymptomatic individuals with an affected parent. Although detection of premalignant thyroid hyperplasia and medullary thyroid carcinoma is possible by measuring serum or urine calcitonin levels, especially after provocation with calcium and pentagastrin, this is less sensitive and specific than genetic analysis. Based upon the specific *RET* mutation detected, the recommended age for prophylactic thyroidectomy varies from age 1–6 months (level 3 risk group, e.g. codon 918 [>95% of patients]) to 10 years (level 1 risk group). Pheochromocytoma screening can be performed by measuring plasma free metanephrine or 24-hour urinary metanephrine and vanillylmandelic acid levels.

PERIODONTAL AND DENTAL DISEASE

Necrotizing Ulcerative Gingivitis

Synonyms: ■ Vincent infection ■ Trench mouth ■ Fusospirochetal gingivitis ■ Acute necrotizing ulcerative gingivitis ■ Necrotizing gingivostomatitis

Key features

- Painful, hemorrhagic, necrotic gingivae with classic "punched-out" interdental papillae
- Mixed bacterial infection in susceptible hosts with predisposing risk factors
- Predisposing risk factors include immunosuppression, malnutrition, stress, smoking, and poor oral hygiene

Introduction

Necrotizing ulcerative gingivitis is a condition of the gums characterized by pain, bleeding and necrosis of gingival interdental papillae. A mixed population of bacteria, including spirochetes, *Prevotella intermedia*, *Fusobacterium*, *Treponema* and *Selenomonas* spp., represents the primary etiology[7].

Epidemiology

Necrotizing ulcerative gingivitis affects both sexes and is seen primarily in young to middle-aged adults. Its prevalence in the normal population is less than 0.1%. This frequency increases in patients with predisposing factors such as underlying immunosuppression, malnutrition, poor oral hygiene, psychological and physical stress, and smoking.

Clinical features

It is characterized by ulcerated, "punched-out" lesions of the gingival interdental papillae. There is generalized edema, erythema, hemorrhage and necrosis of the gingivae. Other signs and symptoms include fever, malaise, lymphadenopathy, and often a foul odor from the mouth. Patients typically complain of "sore and bleeding gums".

Pathology

Because the primary etiologic agents are bacteria belonging to the normal oral flora, bacterial culture results are nonspecific, as are the histopathologic findings. The diagnosis is based chiefly on characteristic clinical findings.

Treatment

In general, the most appropriate therapy is provided by a dentist or a dental specialist, such as a periodontist. Debridement after topical or local anesthesia should be the first step; this is combined with broad-spectrum antibiotic therapy[8]. Chlorhexidine oral rinses (0.12%) may reduce the bacterial load, and warm salt water rinses may be recommended for comfort.

Desquamative Gingivitis

Key features

- A clinical descriptor for oral manifestations of an underlying immune-mediated vesiculoerosive disease
- Characterized by diffusely smooth, red, and sometimes painful gingivae
- Histopathology and immunofluorescence studies are required for appropriate diagnosis and subsequent treatment of the underlying condition

Introduction

The term "desquamative gingivitis" is used by clinicians to describe the gingival manifestations of several vesiculoerosive diseases. Clinically, the gingival epithelium is erythematous and it spontaneously sloughs or can be removed with manipulation. Desquamative gingivitis is not a diagnosis; rather, it is a characteristic clinical pattern that may be seen with a number of immune-mediated conditions[9]. Histologic and immunopathologic investigations are usually required to obtain a definitive diagnosis. This generally reveals a diagnosis of one of the following: lichen planus (Ch. 11), mucous membrane (cicatricial) pemphigoid (Ch. 30) or, less frequently, pemphigus vulgaris (Ch. 29), lichenoid mucositis (idiopathic, drug-induced or foreign body-related), linear IgA bullous dermatosis, lupus erythematosus, epidermolysis bullosa acquisita or chronic ulcerative stomatitis (Fig. 72.5).

Epidemiology

The majority of individuals affected with desquamative gingivitis are over 40 years of age, and most are women.

Clinical features

Patients with desquamative gingivitis usually present with the chief complaint of "sore gums". The most common clinical manifestations include diffuse gingival erythema with varying degrees of mucosal sloughing and erosion. Vesicle or blister formation involving the gingivae may also be seen.

Pathology

The histopathologic and immunopathologic features of desquamative gingivitis depend on which of the aforementioned vesiculoerosive diseases it represents. Patients should be evaluated by incisional biopsy and specimens should be processed for both routine histology and direct immunofluorescence microscopy[10]. In addition, serum can be sent for indirect immunofluorescence testing or ELISA to detect circulating

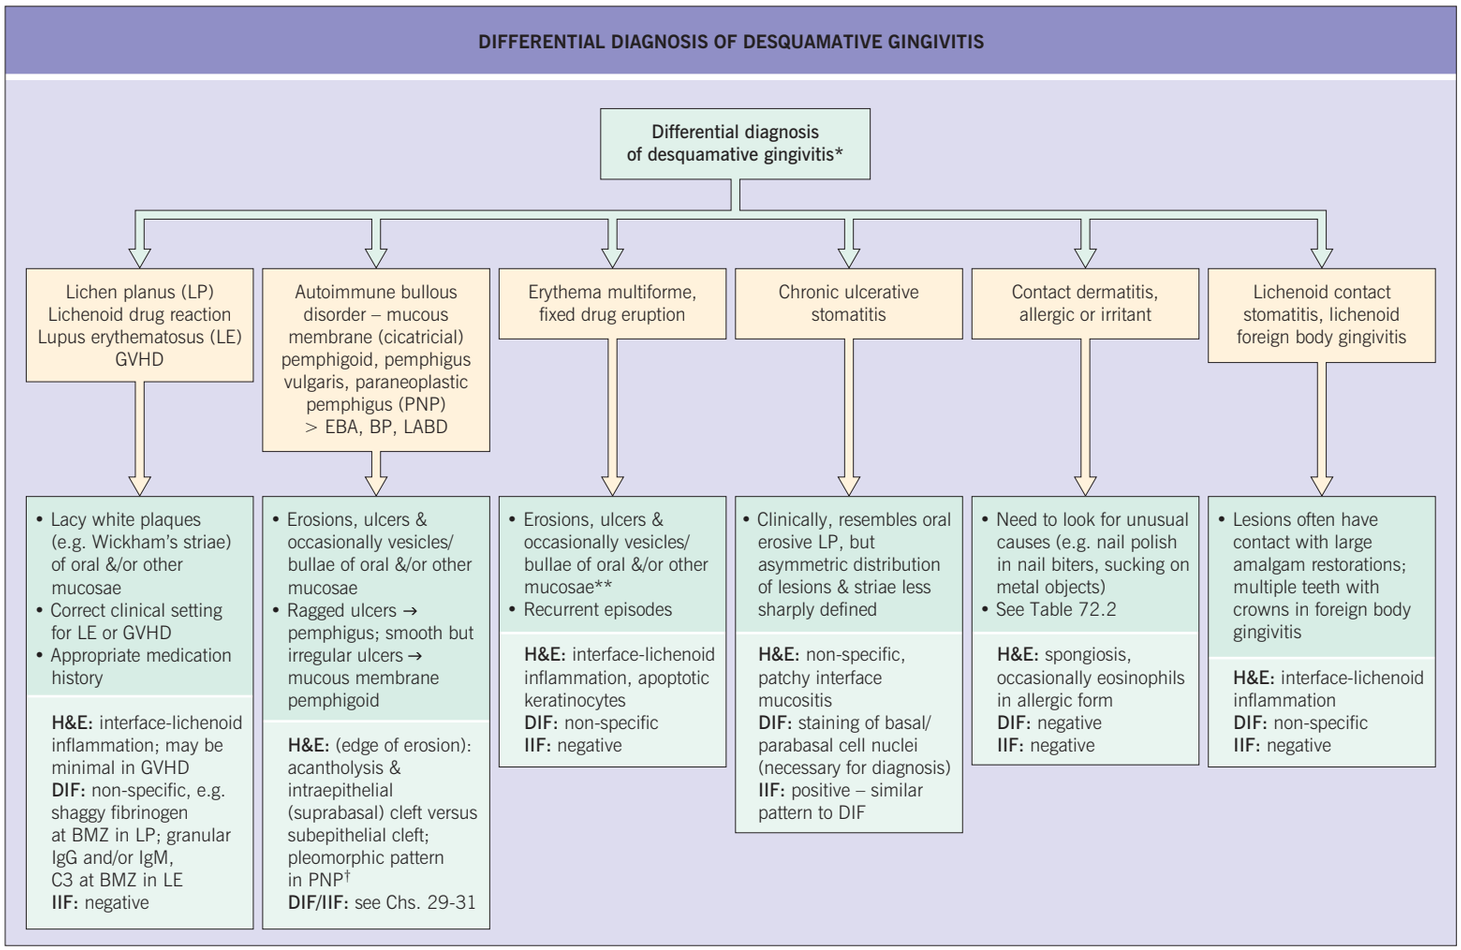

Fig. 72.5 Differential diagnosis of desquamative gingivitis. If the gingivae are painful, hemorrhagic and necrotic with punched-out interdental papillae, then necrotizing ulcerative gingivitis is the clinical diagnosis. For presumed chronic ulcerative stomatitis, the detection of circulating anti-p63 antibodies via ELISA may assist in diagnosis. *No cutaneous lesions present. **Other mucosae – more so for erythema multiforme. †The pleomorphic pattern in paraneoplastic pemphigus includes features of pemphigus and erythema multiforme as well as lichenoid inflammation. BP, bullous pemphigoid; BMZ, basement membrane zone; DIF, direct immunofluorescence (IF); EBA, epidermolysis bullosa acquisita; GVHD, graft-versus-host disease; IIF, indirect IF; LABD, linear IgA bullous dermatosis.

autoantibodies. Specific findings will depend upon the underlying disease.

Treatment

Once a diagnosis is established, appropriate treatment for the responsible condition can follow. Meticulous dental prophylaxis (cleaning), oral hygiene instructions, and longitudinal evaluation are recommended. Reducing bacterial plaque often decreases the severity of lesions and is an important adjunct to medical therapy[10].

Sequelae of Dental Caries

Key features

- Dental infections can spread beyond the periapical region of teeth
- Periapical abscess, osteomyelitis, cellulitis, intraoral dental sinus, and cutaneous sinus are potential sequelae
- Emergent cases require immediate treatment to avoid airway obstruction or possible sepsis

Introduction

Bacterial infections involving carious teeth can sometimes spread beyond the pulp of the tooth. When they do, they often invade the periapical area of the tooth within the bone. The accumulation of inflammatory cells and bacterial debris at the apex of a non-vital tooth is termed a "*periapical abscess*". Without resolution, there is the possibility that the abscess may extend further into medullary bone and cause *osteomyelitis*[11]. If the host immune defenses are compromised or if the invading bacteria are particularly virulent, this lesion may progress, perforating the cortical bone and extending into the overlying soft tissues and fascial spaces as *cellulitis*. This usually manifests as a painful, diffuse swelling of facial soft tissues. If the bacteria are only moderately virulent, the infection may be contained but will eventually erode through to either an oral mucosal surface (resulting in an *intraoral dental sinus tract*; "*parulis*") or facial skin, producing a *cutaneous sinus of dental origin* (Fig. 72.6). If a chronic path of drainage is achieved by an abscess, patients may be asymptomatic because of a lack of accumulation of purulent and inflammatory material. Without drainage, signs and symptoms of acute inflammation may become evident.

Clinical features

The clinical presentation of cellulitis includes diffuse, tender swelling of the facial soft tissues. The areas involved and the severity of the infection can vary tremendously. Dysphagia, headache, fever, lymphadenopathy and pain may be present. Sepsis is a less common complication. Two potential complications are mentioned because they represent a greater danger to patients and demand immediate attention. *Ludwig's angina* is the swelling of the submandibular, submental and sublingual spaces. This presentation of cellulitis is emergent because it can rapidly spread to the retropharyngeal space, obstructing breathing, and even spread to the mediastinum. *Cavernous sinus thrombosis* due to a dental abscess may initially present as swelling of the canine space. Infraorbital, ocular and eventually CNS involvement may develop.

An intraoral dental sinus tract is characterized by a soft, non-tender, erythematous papule that develops on the alveolar process, typically in

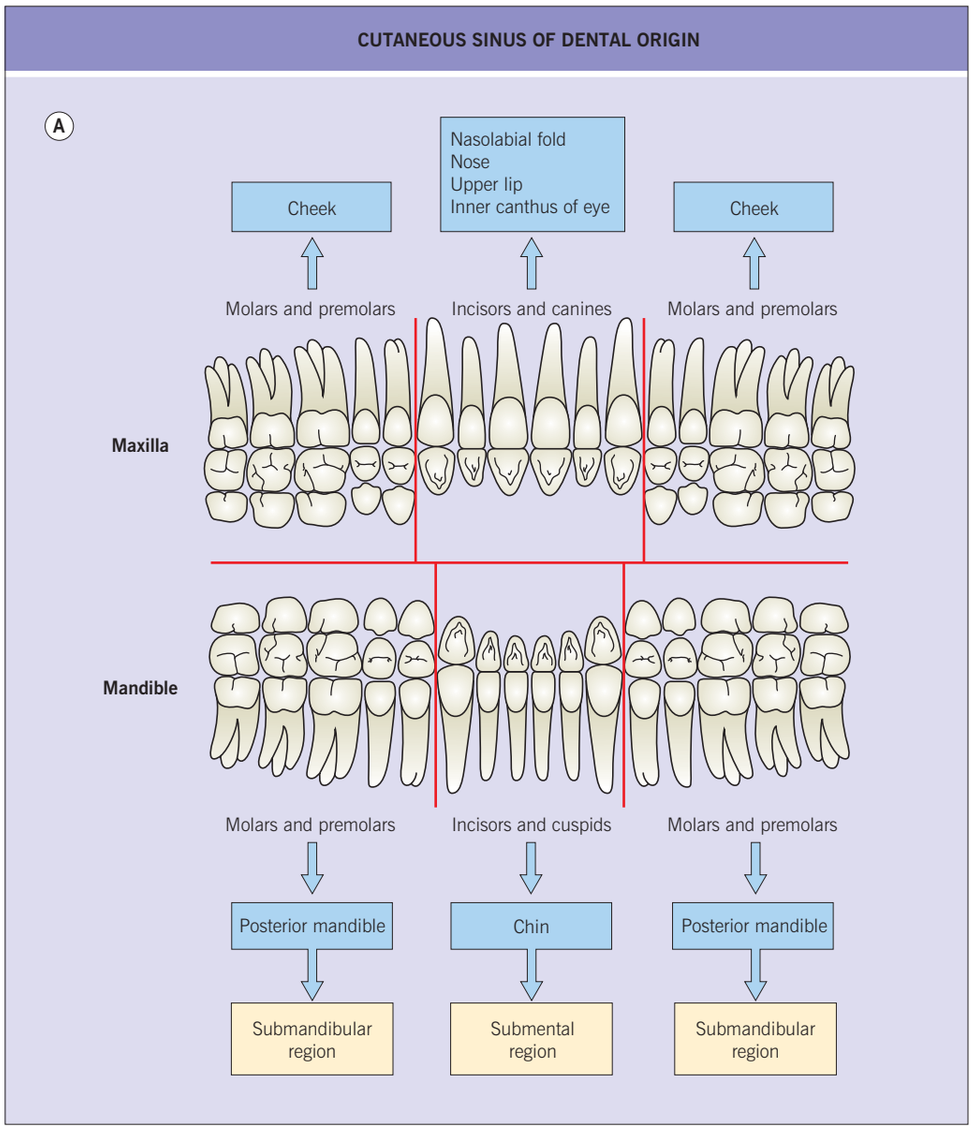

Fig. 72.6 Cutaneous sinus of dental origin. **A** Typical pathways and sites of extraoral drainage of dental sinuses. The majority of cutaneous sinus tracts are associated with mandibular teeth. Dental abscesses in the maxilla (**B**) and mandible (**C**) channelize and drain through the overlying skin. The lesion may be mistaken for a pyogenic granuloma or a neoplasm. *A, Adapted from Cioffi GA, Terezhalmy GT, Parlette HL. Cutaneous draining sinus tract: an odontogenic etiology. J Am Acad Dermatol. 1986;14:94–100, with permission. C, Courtesy, Judit Stenn, MD.*

the same region as the apex of the offending non-vital tooth. Such sinus tracts are frequently asymptomatic, but patients may describe periodic episodes of a salty or bitter taste that probably coincides with the discharge of purulent exudate. A cutaneous sinus of dental origin appears as an erythematous papule, often with an ulcerated or umbilicated center, or as a depression with associated fibrosis (see Fig. 72.6). Cervicofacial actinomycosis must be excluded (see Ch. 74).

Treatment

Treatment involves elimination of the focus of infection, which often requires extraction of the involved tooth, incision and drainage, appropriate antibiotic therapy, and airway management, if necessary.

PHYSICAL AND CHEMICAL INJURIES

Fibroma

Synonyms: ■ Irritation or traumatic fibroma ■ Fibrous hyperplasia or nodule

Key features

- Smooth, pink, soft nodule, typically on the buccal mucosa
- Asymptomatic unless persistently irritated or traumatized

Introduction

Fibroma is the most common "tumor" of the oral cavity, but it most likely represents reactive hyperplasia of fibrous connective tissue in response to local trauma.

Epidemiology

Irritation fibromas most commonly occur during the fourth to sixth decades. Women outnumber men 2:1, based on biopsy specimens submitted for examination.

Clinical features

The typical lesion is a sessile, soft, smooth-surfaced pink nodule similar in color to normal mucosa and located along the bite line of the buccal mucosa. They also occur on the labial mucosa, tongue and gingiva. Size varies, but fibromas are usually less than 1.5 cm in diameter.

Pathology

Microscopic examination shows an unencapsulated mass of hyperplastic fibrous connective tissue with minimal inflammation. The overlying epithelium may be atrophic or hyperkeratotic secondary to friction or biting; sometimes there is also ulceration.

Treatment

Irritation fibromas are cured by conservative surgical excision. It is important to submit the tissue for histopathologic examination

because other benign or malignant tumors may clinically resemble fibromas.

Chemical Burn

Synonyms: ■ Aspirin burn ■ Mucosal burn

Key features

- "Burns" can occur when caustic chemicals come into contact with the oral mucosa
- A superficial, white, sloughing membrane represents coagulative necrosis of the epithelium
- Treatment consists of removal of the offending agent and palliative care

Introduction

Numerous chemicals and drugs come into contact with the oral mucosa, and some of these are caustic enough to cause superficial burns[12]. A variety of agents have been reported as being responsible for these burns, including aspirin, vitamin C tablets, hydrogen peroxide, silver nitrate, phenol, eugenol, rubbing alcohol, battery acid, gasoline, various dental materials, and many over-the-counter toothache medicaments[2]. Aspirin (acetylsalicylic acid, pH 3.5) is one of the most commonly recognized medications responsible for mucosal damage[13]. Patients often place a tablet on the oral mucosa overlying a sore tooth in an attempt to alleviate dental pain, and the resultant continuous contact produces injury.

Clinical features

Most caustic agents cause characteristic damage to the mucosa. This may appear initially as just an erythematous zone. With greater concentration or longer duration of exposure to the chemical, a wrinkled white membrane that represents superficial necrosis becomes evident (Fig. 72.7)[14].

Pathology

Microscopic evaluation reveals coagulative necrosis of the epithelium. The necrosis begins on the surface and may extend partially into the epithelium, or it may involve its entire thickness.

Treatment

A chemical burn is a self-resolving condition requiring no treatment except for discontinuing or preventing exposure to the offending agent. Application of emollient pastes or topical anesthetics as a palliative measure may provide some temporary relief.

Morsicatio Buccarum

Synonyms: ■ Chronic cheek chewing ■ Chronic cheek biting

Key features

- Factitial habit
- Bilateral shaggy white lesions of the anterior buccal mucosa
- No treatment indicated

Introduction

Chronic irritation or injury to the buccal mucosa from repetitive chewing, biting or nibbling produces a characteristic appearance clinically[2]. Similar changes may also be observed on the labial mucosa.

Clinical features

Morsicatio buccarum typically presents as bilateral shaggy white lesions of the anterior buccal mucosa that approximate the area where the upper and lower teeth meet (occlusal plane). The white areas are ragged and shredded (Fig. 72.8). Foci of erythema, erosion or traumatic ulceration are rarely identified.

Pathology

Microscopic evaluation reveals marked hyperparakeratosis of the surface epithelium, which demonstrates a ragged morphology. Varying degrees of vacuolization and spongiosis are observed in the superficial portion of the epithelium. Surface colonization by bacteria is also a frequent feature. Although these findings are relatively nonspecific, in the appropriate clinical setting they are highly suggestive of this factitial habit.

Treatment

Morsicatio buccarum is a benign condition requiring no treatment.

Fig. 72.7 Aspirin burn. To relieve a toothache, this patient placed an aspirin in the mouth adjacent to the symptomatic tooth. Note the wrinkled white membrane that represents superficial epithelial necrosis.

Fig. 72.8 Cheek chewing (morsicatio buccarum). Repetitive nibbling of the superficial layers of the epithelium resulted in these changes. Note that the characteristic shaggy, white lesion approximates the area where the upper and lower teeth meet.

Traumatic Ulcer

Key features

- Acute or chronic injury to the oral mucosa may cause a traumatic ulcer
- Commonly occurs on the tongue, lips or buccal mucosa
- May mimic oral squamous cell carcinoma
- Self-limited process that heals within 3–6 days following removal of etiologic agent

Introduction

The etiology of a traumatic ulcer is related to acute or chronic injury to the oral mucosa. The injury is often mechanical in nature, such as biting the tongue or cheek accidentally, or lacerating the mucosa with sharp foods or objects (e.g. the sharp edge of a fractured tooth).

Clinical features

Traumatic ulcers are moderately painful lesions. They are characterized by mild erythema surrounding a central ulcer that is covered by a yellow fibrinopurulent membrane (Fig. 72.9). Sometimes there is a white border of hyperkeratosis surrounding the ulcer. Traumatic ulcers occur most commonly on the tongue, lips and buccal mucosa, although other sites may be involved. They are usually self-limiting, if the etiologic agent is removed, and generally heal within 3–6 days. Since traumatic ulcers can clinically mimic oral squamous cell carcinomas (SCCs), biopsy is indicated if the ulcer does not resolve within 2–3 weeks following elimination of potential causes.

Treatment

Remove any obvious causative agent. Application of a thin protective film of cellulose compound, with or without a topical anesthetic as a palliative measure, may provide some relief.

Drug-Related Gingival Enlargement (Hyperplasia)

Key features

- Enlargement of the gums noted during the first year of drug administration
- Typically associated with phenytoin, nifedipine or cyclosporine
- Severity correlated with patient susceptibility and level of oral hygiene

Fig. 72.9 Traumatic ulcer. This lesion of the lateral tongue demonstrates a yellow fibrinopurulent membrane with a white border of hyperkeratosis. Compare this to the exophytic, ulcerated mass depicted in Fig. 72.17, which represents oral squamous cell carcinoma.

Introduction

Many systemic medications have been reported to be associated with gingival enlargement (Table 72.1), but a high prevalence has been noted only with phenytoin (50%), nifedipine (25%) and cyclosporine (25%). Although it is still controversial whether the risk of developing this side effect is dose-related, there is a definite correlation with poor oral hygiene.

Clinical features

During the first year of drug administration, gingival enlargement commences in the interdental papillae of the anterior teeth on the labial side. The hyperplasia may extend over part or all of the involved teeth. Edentulous areas are usually spared, but significant hyperplasia under poorly maintained dentures has been reported. The enlarged gingiva is usually normal in color, firm, and nodular or lobulated. However, associated inflammation can lead to a red, edematous or friable appearance.

Pathology

Microscopically, redundant tissue of normal composition or an increased amount of collagen with a normal density of fibroblasts is seen. When the specimen is clinically inflamed, there is increased vascularity and a chronic inflammatory cell infiltrate.

Treatment

A rigorous regimen of oral hygiene consisting of frequent professional cleaning and home plaque control utilizing chlorhexidine rinses helps to prevent drug-associated gingival enlargement. Discontinuation of the suspected offending drug or even substitution with another drug of the same class may result in cessation or some regression of the gingival hyperplasia.

If all else fails, then extirpation of the excess gingival tissue, a procedure normally performed by a periodontist, remains the treatment of choice. Samples of excised tissue should be submitted for histopathologic evaluation as there are other causes of gingival enlargement (see Table 72.1).

CAUSES OF GINGIVAL ENLARGEMENT (HYPERPLASIA, HYPERTROPHY)	
SYSTEMIC MEDICATIONS	
Common	
Anticonvulsants (phenytoin, phenobarbital, lamotrigine, valproate, vigabatrin, ethosuximide, topiramate, primidone)	
Calcium channel blocking agents (**nifedipine**, amlodipine, diltiazem, felodipine, verapamil)	
Cyclosporine*	
Uncommon	
Antibiotics (erythromycin, cotrimoxazole)	Sertraline
Lithium	Oral contraceptives, estrogens
Amphetamines	
• Local inflammatory factors – poor oral hygiene, periodontal disease • Hormone-related – pregnancy, acromegaly • Granulomatous disorders – orofacial granulomatosis, Crohn's disease, sarcoidosis • Wegener's granulomatosis • Vitamin C deficiency (scurvy) • Gingival fibromatosis/multiple gingival fibromas – tuberous sclerosis, Cowden disease, hereditary gingival fibromatosis • Leukemia – acute monocytic leukemia, acute myelomonocytic leukemia > other types of myelogenous or lymphocytic leukemias • Other malignancies – Kaposi sarcoma • Deposits – primary systemic amyloidosis, infantile systemic hyalinosis, mucopolysaccharidoses, fucosidosis, Fabry disease	
*Consider substitution with oral tacrolimus	

Table 72.1 Causes of gingival enlargement (hyperplasia, hypertrophy).

Contact Stomatitis

Synonyms: ■ Oral mucosal cinnamon reaction ■ Lichenoid amalgam reaction ■ Contact lichenoid reaction

Key features

- Cinnamon flavoring and dental amalgam (silver-containing filling material) may cause lichenoid changes of the oral mucosa
- Red, white or mixed lesions are seen, with varying degrees of erosion, ulceration or striae formation
- Lesions may be located where the offending agent contacts the mucosa for a prolonged period of time
- Removal of the offending agent should be curative

Introduction

Numerous foods, artificial flavorings, food additives, and materials used in dentistry have been implicated as etiologic agents of allergic or irritant contact stomatitis (Table 72.2). Two of these, namely cinnamon flavoring (found in many foods, gums, candies and dentifrices) and dental amalgam ("silver" dental fillings), may lead to unique clinicopathologic features.

Epidemiology

The frequency of true allergic reactions due to contact with antigenic substances is probably not as high for the oral mucosa as for the skin. The reduced reactivity of the oral mucosa has been attributed to many factors, including the brief period of contact of agents with the mucosa, the more rapid dispersal and absorption of antigens, and the diluting and neutralizing properties of saliva.

Clinical features

The clinical features of contact stomatitis from *cinnamon flavoring* can vary; sometimes it produces localized lesions on the buccal mucosa or lateral borders of the tongue that appear as shaggy white keratotic areas[2] (Fig. 72.10). The buccal lesions may resemble oral lichen planus or morsicatio buccarum clinically, while the tongue lesions may resemble oral hairy leukoplakia or SCC. Erosion, ulceration and erythema can also be seen. Gingival involvement appears as swelling and erythema.

Contact stomatitis from *dental amalgam* occurs mainly at sites adjacent to amalgam restorations, such as the posterior buccal mucosa and ventrolateral surface of the tongue[15]. When the mucosa is relaxed, the lesion is characteristically seen to directly contact the amalgam restoration, which is often on the buccal (rather than occlusal) surface of the tooth (Fig. 72.11). The lesions may be white or erythematous, with or without peripheral striae, and they can resemble oral lichen planus. Ulceration or erosion may also be observed. With both amalgam and cinnamon reactions, pain is not a universal finding although it may be present.

POTENTIAL CAUSES OF CONTACT STOMATITIS OR CHEILITIS
ALLERGIC
• Flavorings: cinnamon, mint, menthol, vanillin • Dental metals: mercury, gold, nickel, palladium, copper, silver, cobalt, chromium, beryllium, tin, zinc • Dental adhesives: acrylate compounds, eugenol • Topical anesthetics: benzocaine • Essential oils: clove, lemon, orange
IRRITANT
• Aspirin • Dental chemicals: eugenol, peroxides, phenol, sodium hypochlorite • Chlorhexidine mouth rinse • Silver nitrate stick • Sodium lauryl sulfate (in toothpaste)

Table 72.2 Potential causes of contact stomatitis or cheilitis.

Pathology

Biopsy specimens of contact stomatitis from dental amalgam or cinnamon flavoring often demonstrate a lichenoid mucositis. The cinnamon reaction may have a psoriasiform pattern, whereas, in general, patients with contact stomatitis have spongiosis histologically. In lichenoid mucositis, the epithelium may have hyperkeratosis, basilar crowding and atypia, atrophy of the spinous layer, lymphocytic exocytosis, and, sometimes, ulceration. Immediately subjacent to the epithelium is a band of chronic inflammatory cells that, in some areas, effaces the rete ridge architecture. A perivascular infiltrate composed primarily of lymphocytes with occasional plasma cells frequently surrounds small blood vessels. Longstanding amalgam reactions are characterized by a much broader band of lichenoid inflammation compared to routine lichen planus, and it is not unusual to find well-defined germinal centers within the lymphocytic infiltrate.

Treatment

With contact stomatitis due to cinnamon flavoring, the lesions disappear within a week of discontinuing the offending product, but may

Fig. 72.10 Contact stomatitis from artificial cinnamon flavoring. Use of artificial cinnamon-flavored gum caused this shaggy, white keratotic lesion of the buccal mucosa.

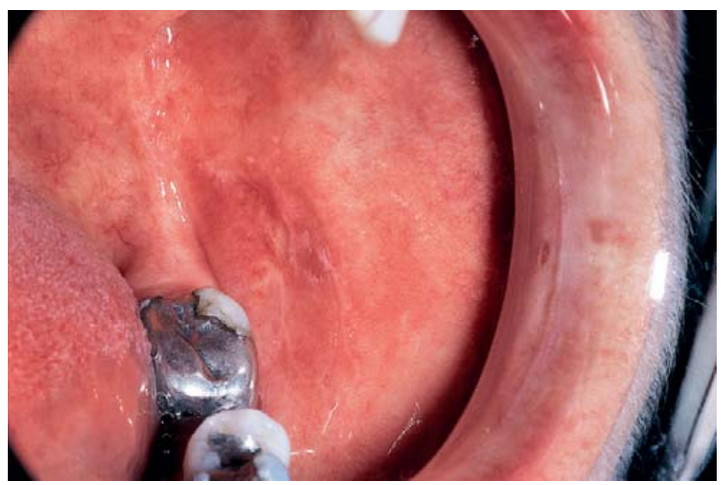

Fig. 72.11 Lichenoid stomatitis secondary to amalgam hypersensitivity. Superficial erosions with radiating white striae are localized to the buccal mucosa adjacent to a large amalgam restoration.

reappear quickly with reuse of the product or other cinnamon-containing agents, confirming the cause. When contact stomatitis secondary to amalgam is suspected, patch testing is recommended and should include organic and inorganic mercury as well as amalgam and the other dental metals. The offending restoration may be treated conservatively at first by polishing, smoothing and recontouring (in addition to cleaning the teeth to remove plaque), but if these measures fail, appropriate alternative dental materials, such as composite (a white plastic-like material), gold or porcelain fused to metal, can be used to replace the amalgam restoration[16].

Recurrent Aphthous Stomatitis

Synonyms: ■ Recurrent oral aphthae ■ Aphthous ulcers ■ Canker sores ■ Simple or complex aphthosis

Key features

- The three forms of simple recurrent aphthous stomatitis are minor, major and herpetiform
- Lesions are painful, typically less than 5 mm in diameter, round to oval, and appear creamy-white with an erythematous halo
- The pathomechanism is unknown, but immunologic factors may be involved
- Usually controlled through the use of topical corticosteroids

Introduction

Recurrent aphthous stomatitis is a relatively common ulcerative disorder of the oral cavity. While the etiology remains obscure, it is likely to be a multifactorial disorder influenced by a host of predisposing factors. Recurrent aphthous stomatitis is believed by some to be the result of a dysfunction of the immune system, resulting in immunologically mediated damage to epithelial cells[17,18]. This abnormal immune response may be triggered or influenced by trauma, hematinic (iron, folate or vitamin B_{12}) deficiencies, hormonal fluctuations, psychological stress, infectious agents, food hypersensitivities, genetic factors, and HIV infection. Complex aphthosis, the almost constant presence of more than three oral aphthae or oral and genital aphthae, requires the exclusion of Behçet's disease, inflammatory bowel disease, cyclic neutropenia, vitamin deficiencies (e.g. B_{12}, folate), HIV infection and other disorders listed in Table 72.3[18].

Epidemiology

Recurrent aphthous stomatitis is a common disorder that has been documented to affect 10–50% of certain professional student populations. A recent large retrospective series from a referral oral medicine center identified a male predilection, and the peak prevalence occurs during the second decade[18].

Clinical features

There are three categories of simple aphthae. *Minor aphthae*, the most common form, are characterized by round to ovoid, shallow, painful ulcers that are usually less than 5 mm in diameter. Individual lesions are covered by a creamy-white pseudomembrane and have a rather sharply defined border and an erythematous rim (Fig. 72.12). The ulcers are typically limited to the non-keratinized oral mucosa, with common sites of involvement including the labial and buccal mucosa, floor of the mouth, ventral surface of the tongue, soft palate and oropharyngeal mucosa. These lesions usually heal without scarring within 1–2 weeks. Most patients experience infrequent recurrences, although some may have almost continuous lesional activity.

Major aphthae are characterized by larger ulcerations, typically >1 cm and sometimes approaching 3 cm. Lesions are usually deeper, persist for up to 6 weeks, and may heal with scarring. Major aphthae are associated with considerable oral pain, and are sometimes accompanied by fever and malaise.

Herpetiform aphthae are very uncommon, consisting of multiple small, painful ulcerations that superficially resemble primary HSV infection. Up to 100 ulcers are possible at one time. Herpetiform aphthae are typically confined to non-keratinized mucosa and are recurrent, features that help distinguish the condition from primary HSV infection.

The aphthae in patients with complex aphthosis generally resemble minor aphthous ulcers except that there is a greater number of lesions, although major and/or herpetiform aphthae may occur[19,20].

RECURRENT APHTHAE – ETIOLOGIES AND DIFFERENTIAL DIAGNOSIS

ETIOLOGIES

- Idiopathic (immune-mediated)
- Related to an underlying systemic disorder: inflammatory bowel disease, systemic lupus erythematosus, HIV infection, Behçet's disease, reactive arthritis*, cyclic neutropenia, PFAPA (*p*eriodic *f*ever, *a*phthous stomatitis, *p*haryngitis and *a*denitis) syndrome, certain hereditary periodic fever syndromes (e.g. HIDS, NOMID)
- Possibly related to an underlying nutritional disorder (controversial): vitamin B_{12}, folate or iron deficiency

DIFFERENTIAL DIAGNOSIS

Recurrent erosions and ulcerations due to:

- An inflammatory disorder, e.g. erythema multiforme, fixed drug eruption, contact stomatitis – less pain at onset, less peripheral erythema
- Recurrent herpes simplex – only involves mucosa overlying bone (hard palate, attached gingiva) in immunocompetent hosts
- Trauma – less pain at onset, less peripheral erythema, more ragged edges

*Previously referred to as Reiter's disease.

Table 72.3 Recurrent aphthae – etiologies and differential diagnosis. HIDS, hyperimmunoglobulinemia D with periodic fever syndrome; HIV, human immunodeficiency virus; NOMID, neonatal-onset multisystem inflammatory disease.

Fig. 72.12 Recurrent aphthous stomatitis. Shallow, creamy-white ulceration surrounded by an intensely red halo and located on non-keratinized mucosa, representing a classic presentation.

Pathology

Histopathologic features are relatively nonspecific. Early lesions may show a neutrophilic vessel-based submucosal infiltrate. In most patients, however, the appearance and distribution of lesions allow for the diagnosis to be made clinically.

Treatment

The primary goals of therapy are promotion of healing, management of pain and nutrition, and prevention of recurrence[20]. Application several times daily of a thin film of a superpotent topical corticosteroid gel, as early as possible in the course of an outbreak, will typically reduce significantly the pain and time to healing. Topical analgesics may be included for transient relief of pain. While it is not possible to

prevent recurrences, the frequency of episodes is often reduced following topical corticosteroid therapy. Patients with complex aphthosis may require therapy with oral colchicine, dapsone or even thalidomide (Table 72.4).

Behçet's Disease

Synonym: ■ Behçet's syndrome

Key features

- Recurrent oral and genital aphthae
- Anterior or posterior uveitis and/or retinal vasculitis
- Erythema nodosum-like and papulopustular lesions

Behçet's disease is a rare chronic multisystem disorder that is more prevalent in countries located along the ancient Silk Road (see Ch. 26)[21,22]. Episodes of disease activity may be intermittent, with exacerbations and remissions of unpredictable duration and frequency. Oral aphthae are present in 99% of patients with Behçet's disease, and they frequently occur before any other signs of the disease develop. These aphthae are usually multiple, no larger than 6 mm in diameter, and last approximately 1–3 weeks, with uneventful healing and no scarring[22].

Systemic manifestations, clinical criteria for the diagnosis of Behçet's disease, and treatment options are outlined in Tables 26.11, 26.13 and 26.14, respectively.

Eosinophilic Ulcer of the Oral Mucosa

Synonyms: ■ Eosinophilic ulcer of the tongue ■ Traumatic eosinophilic granuloma ■ Riga–Fede disease (childhood variant)

Introduction

Eosinophilic ulcer of the oral mucosa represents an uncommon, self-limited ulcerative condition. Approximately half of the patients report antecedent trauma. A similar disorder, referred to as Riga–Fede disease[23], has been described on the ventral tongue of infants and toddlers with erupted mandibular incisor teeth who are nursing, as well as in children with congenital insensitivity to pain. The infiltrate is composed of numerous eosinophils admixed with large, atypical mononuclear cells that have been characterized in various studies as representing macrophages, myofibroblasts and, most recently, a clonal population of $CD30^+$ T lymphocytes. The latter observation has led some authors to speculate that a subset of eosinophilic ulcers may be an oral counterpart of cutaneous $CD30^+$ lymphoproliferative disorders (e.g. lymphomatoid papulosis)[24]. Of note, at least one recent report observed that ulcers with a clonal population of T cells did not behave any differently than polyclonal lesions[25].

Epidemiology

Eosinophilic ulcers can occur in any age group, from infants and young children to the elderly. There is no gender predominance.

Clinical features

Although the majority of eosinophilic ulcers are located on the tongue, they can also appear on the buccal, labial, alveolar or palatal mucosa. The initial lesion is a rapidly enlarging, firm nodule that develops a central ulceration with elevated borders and an indurated base; it is typically covered with a fibrinous exudate. The ulcers are usually 1–2 cm in diameter and may or may not be painful. Multiple lesions are sometimes observed.

Pathology

Histologically, eosinophilic ulcers are characterized by a dense, diffuse infiltrate of eosinophils and pleomorphic mononuclear cells that extends deeply into the submucosal tissue and underlying striated muscle. Large, atypical cells may represent $CD30^+$ T lymphocytes. The base of the ulcer is composed of poorly formed granulation tissue that may have an increased number of capillaries with prominent endothelial cells.

Treatment

Most eosinophilic ulcers resolve spontaneously within a few months, so treatment other than supportive care is not required. Because SCC can be in the differential diagnosis, a biopsy is often performed; the latter may trigger healing. Recurrences occasionally occur.

Orofacial Granulomatosis

Subtype/synonyms: ■ Granulomatous cheilitis: cheilitis granulomatosa, Miescher's cheilitis

Key features

- Persistent, non-tender swelling of the lip and/or face
- Non-caseating granulomatous inflammation

Introduction

Orofacial granulomatosis is a term introduced in 1985 by Wiesenfeld to describe non-infectious, non-necrotizing granulomatous disorders of the lips, face and oral cavity[26]. These include granulomatous cheilitis as well as orofacial manifestations of Crohn's disease and sarcoidosis[27]. The etiology of most forms of orofacial granulomatosis is unknown. Some investigators, however, have suggested that it may be an allergic response consisting of cell-mediated hypersensitivity to foods, food additives, or certain flavoring agents in common oral hygiene products[28].

Epidemiology

It occurs primarily in young adults and usually presents during the second or third decade. There is no notable sex predilection.

Clinical features

Orofacial granulomatosis is a chronic process that usually presents as diffuse enlargement of the lips or facial swelling. Oral ulceration, gingival overgrowth or mucosal tags are less commonly seen. Swelling may be intermittent initially, but eventually it persists[29]. Lip involvement is termed "granulomatous cheilitis" and usually only the upper or lower lip is affected (Fig. 72.13). Rarely, granulomatous cheilitis has been reported with facial nerve palsy and fissured tongue, resulting in the condition known as Melkersson–Rosenthal syndrome.

For most patients, the disorder is relatively asymptomatic. The differential diagnosis may include angioedema, although the swelling that

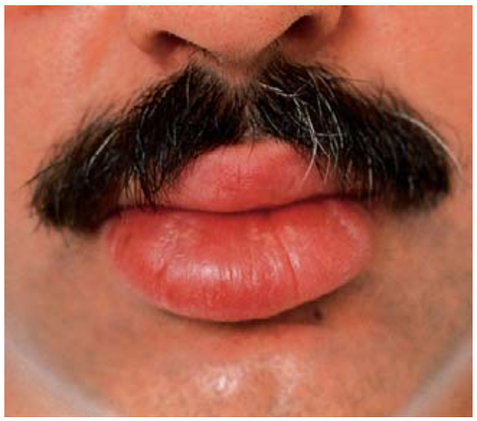

Fig. 72.13 Cheilitis granulomatosa. Slightly asymmetric swelling, predominantly of the lower lip. A biopsy specimen demonstrated non-caseating granulomas.

characterizes that condition typically resolves spontaneously within 24–48 hours.

Pathology

The most striking histopathologic feature of orofacial granulomatosis is non-necrotizing granulomatous inflammation, although in some cases the granulomas are rather sparse.

Treatment

Intralesional corticosteroids can be used to treat orofacial granulomatosis. Because of its tendency to relapse, repeated corticosteroid injections may be necessary. Systemic agents, such as dapsone, clofazimine, hydroxychloroquine, thalidomide, tumor necrosis factor (TNF)-α inhibitors (e.g. adalimumab, infliximab [approved for Crohn's disease]), or even systemic corticosteroids, have also been used. In addition, long-term courses of oral antibiotics (e.g. tetracyclines, erythromycin) have been tried.

Wegener's Granulomatosis

Key features

- Necrotizing granulomatous vasculitis of the upper and lower respiratory tract and necrotizing glomerulonephritis
- Destructive ulcerated lesions of the oral and nasal cavity
- Pathognomonic friable "strawberry gums" may be seen
- Up to 80% of patients have antineutrophil cytoplasmic antibodies (ANCA)

Introduction/clinical features

Wegener's granulomatosis (WG) is a necrotizing granulomatous disease of unknown etiology that, without treatment, is often fatal (see Ch. 24). The criteria for the diagnosis of both the classic and limited forms of WG are outlined in Figure 40.5.

While there is a superficial form of WG, characterized by involvement of the skin or oral mucosa without systemic manifestations, it is noteworthy that skin and/or mucosal involvement may represent the initial presentation of classic or limited WG.

Because WG commonly involves the nose, nasopharynx and paranasal sinuses, epistaxis, sinusitis and nasal obstruction are common complaints. Destruction of the nasal cartilage may result in perforation of the nasal septum and/or saddle nose deformity[30]. Oral manifestations can include rather destructive oropharyngeal, lingual or gingival ulcerations. The gingivae may exhibit petechial hemorrhage that is superimposed on a friable micropapular surface, an essentially pathognomonic appearance termed "strawberry gums" (Fig. 72.14)[31,32]. Gingival pain and bleeding are common.

Pathology

Biopsy specimens from pulmonary lesions of WG show vasculitis of small to medium-sized arteries with necrotizing granulomatous inflammation, while skin biopsies can demonstrate leukocytoclastic vasculitis and/or granulomatous inflammation[30]. However, such classic features are infrequently observed in oral biopsy specimens.

Fig. 72.14 Wegener's granulomatosis – strawberry gums. The affected areas of the gingiva are red–purple, micropapular and friable, with a resemblance to ripe strawberries.

Treatment

The treatment of classic WG consists of systemic corticosteroids and cyclophosphamide[33], and oral lesions typically respond to this regimen.

EPITHELIAL PATHOLOGY

Oral Leukoplakia/Erythroplakia

Key features

- Leukoplakia and erythroplakia are strictly clinical diagnoses
- Leukoplakia is the most common premalignant condition of the oral cavity
- Biopsy is mandatory in order to assess the degree of dysplasia and to exclude invasive SCC

Introduction

Oral leukoplakia is defined as a white patch or plaque that cannot be characterized clinically or pathologically as any other disease. The development of oral leukoplakia is strongly associated with the use of tobacco, primarily in the combustible form, and alcohol. It is regarded as a premalignant condition[34].

The term "erythroplakia" is used to describe an intraoral lesion that is similar in appearance to erythroplasia of Queyrat, a form of SCC *in situ* affecting the glans penis. Erythroplakia is defined as a red patch that does not represent any other recognizable condition, and biopsy specimens usually show more advanced dysplastic changes compared to leukoplakia.

Epidemiology

Oral leukoplakia is the most common premalignant oral mucosal lesion. Its prevalence in various adult populations has been reported to range from 1% to 5%, although a recent study from the US suggested a lower prevalence of approximately 0.5%. In general, there is a male predominance. Leukoplakia usually develops after the age of 30 years, with a peak incidence in those over 50 years of age. Erythroplakia is a far less common condition than oral leukoplakia. There is no apparent

Fig. 72.15 Leukoplakia. Sharply demarcated, white plaque involving the ventral surface of the tongue and floor of the mouth.

sex predilection and lesions tend to occur during the sixth or seventh decade[35].

Clinical features

Oral leukoplakia may appear as a homogeneous white or a non-homogeneous "speckled" (red and white) plaque that usually has sharply demarcated borders (Fig. 72.15). Leukoplakia should not be confused with leukoedema, which is a gray–white discoloration of the buccal mucosa and represents a normal variant; the latter becomes less apparent when stretched. Common sites of involvement include the floor of the mouth, the lateral and ventral surfaces of the tongue, and the soft palate. Non-homogeneous lesions and those of the tongue and floor of the mouth have been reported to have a higher risk for malignant transformation[34].

Erythroplakia is characterized as a flat or slightly elevated, velvety, rather sharply circumscribed plaque. The lesions are often asymptomatic. They may be clinically indistinguishable from inflammatory conditions. Sites of involvement are similar to those of oral leukoplakia.

Pathology

Lesions of leukoplakia usually demonstrate benign features, with simple hyperkeratosis seen most frequently. Epithelial dysplasia, if present, ranges from mild to severe, although carcinoma *in situ* or even invasive SCC may be encountered. Erythroplakia, on the other hand, generally shows more advanced dysplastic features, with 90% of lesions demonstrating severe epithelial dysplasia, carcinoma *in situ* or invasive carcinoma at the time of biopsy[35].

Treatment

Because both oral leukoplakia and erythroplakia are considered premalignant, biopsy is mandatory. If no dysplasia or mild dysplasia is evident, the decision to treat may depend upon the site of the lesion. Leukoplakia in low-risk sites (buccal mucosa, labial mucosa, hard palate) may warrant periodic clinical evaluation, with cessation of any potentially carcinogenic habits. Moderate or severely dysplastic lesions often require complete removal and continued monitoring.

Erythroplakic lesions typically require prompt surgical removal and careful follow-up. The methods of treatment for both leukoplakia and erythroplakia include surgical excision, cryosurgery and CO_2 laser ablation[36]. Recurrence rates of 30% or greater have been described, despite what appears clinically to be complete removal, although one report noted just a 10% recurrence rate after laser ablation and a mean follow-up period of 52 months[36]. The high recurrence rates have led to anecdotal use of adjunctive therapy with agents such as topical imiquimod. To date, there have been very few well-controlled, randomized, prospective studies concerning the management of leukoplakia and erythroplakia[37,38].

Proliferative Verrucous Leukoplakia

Key features

- Lack of association with traditional risk factors for oral cancer
- Multifocal red and white plaques, with a varying degree of verrucous change
- Lesions have often been present for decades and eventually transform into either verrucous carcinoma or SCC

Introduction

In 1985, a multifocal precancerous condition of the oral mucosa, proliferative verrucous leukoplakia (PVL), was first described[39]. Often the patients had had lesions for decades, and eventually transformation to either SCC or verrucous carcinoma was documented.

Epidemiology

In contrast to "routine" leukoplakia (see above), patients with PVL tend to be women and significantly fewer have traditional risk factors for oral cancer (e.g. smoking and/or alcohol abuse). Multiple studies have failed to link PVL to human papillomavirus (HPV) infection[40].

Clinical features

At the time of diagnosis, many of the patients with PVL have had the condition for years. Due to a prominent host response to the epithelial atypia, the early stages of PVL may resemble oral erosive lichen planus (which may account for many of the reports of so-called malignant transformation of lichen planus). Initially, there is usually a mixture of red and white patches in multiple sites. Often the lesions are discrete rather than confluent. Over time, the lesions acquire a fine papillary or verrucous surface, although this may require decades[41]. When ulceration, marked thickening or induration develops, this typically is a sign that malignant transformation to either verrucous carcinoma or SCC has occurred.

Pathology

The histopathologic features of PVL can vary tremendously, depending upon the stage at which it is biopsied and the site chosen for biopsy. In the earliest phases, the histology may appear very bland, with only hyperorthokeratosis and perhaps epithelial atrophy or basilar hyperplasia[41]. Over time, varying degrees of epithelial dysplasia develop, but these changes can be focal and may differ depending upon the site. Eventually, features of verrucous carcinoma and/or SCC can be seen.

Treatment

Treatment of PVL is problematic because surgical excision, the most commonly utilized treatment modality for routine oral leukoplakia, has not proven to be effective in controlling PVL. Prognosis is generally considered to be guarded to poor, and in one of the larger long-term studies, only 15% of the patients were alive and disease-free at a mean of 11.6 years[42].

Nicotine Stomatitis

Synonym: ■ Stomatitis nicotina

Key features

- Characterized by gray–white mucosa with umbilicated papules
- Associated with the application of heat to the palatal mucosa, usually from pipe smoking

Introduction

Nicotine stomatitis is most commonly seen in pipe smokers, and it is probably due to the heat that the pipe stem directs toward the palatal mucosa[43]. Of note, palatal lesions clinically identical to those seen in pipe smokers have also been observed in hot tea and coffee drinkers[44].

Fig. 72.16 Nicotine stomatitis. Gray–white palatal mucosa with numerous umbilicated papules representing inflamed palatal mucous glands.

Clinical features

Nicotine stomatitis presents as a gray or white discoloration of the palate due to increased keratinization (Fig. 72.16). Umbilicated papules with red central puncta, representing inflamed palatal salivary gland orifices, may be present[43]. These changes are more prominent toward the posterior hard palate and anterior soft palate.

Pathology

While the condition should not generally require biopsy, the histopathologic features include hyperkeratosis and parakeratosis, acanthosis, and mild chronic sialodochitis.

Treatment

Treatment is usually not necessary. Cessation of smoking will typically result in complete resolution within 1–2 weeks.

Actinic Cheilitis

Synonym: ■ Actinic cheilosis

Key features

- Primarily affects the vermilion zone of the lower lip in fair-skinned individuals
- Scaling, roughness and/or erosions
- Characterized by some degree of epithelial dysplasia histologically

Introduction

Actinic cheilitis is a common condition similar to actinic keratosis and is typically confined to the vermilion zone of the lower lip.

Epidemiology

Actinic cheilitis is seen most commonly in white, fair-skinned men over 40 years of age[45]. As with actinic keratoses, the condition is predominantly observed in people who have had significant amounts of exposure to ultraviolet irradiation[46].

Clinical features

Early features of actinic damage to the lower vermilion zone include loss of normal dermatoglyphics, atrophy, and blurring of the margin between the vermilion zone and the skin. Evolution to precancerous actinic cheilitis is heralded by the development of scaling and roughness. Initially this may be localized, but multifocal areas of involvement are not unusual. Fissuring and erosions are eventually seen as the condition progresses.

Pathology

The basic microscopic features of actinic cheilitis consist of thickening of the epithelium and hyperkeratosis. It is important to note that different areas within the same lesion may show different degrees of epithelial dysplasia. Examination of multiple sections is often indicated to identify areas of severe dysplasia, carcinoma *in situ*, or invasive SCC.

Treatment

Actinic cheilitis frequently represents a "field change", and while only focal areas may appear worrisome, the widespread nature must be considered in treating the patient[47]. In some patients, it can be difficult to distinguish epithelial dysplasia from *in situ* or even invasive SCC[46].

Treatment options for typical actinic cheilitis consist of cryosurgery, topical agents such as 5-fluorouracil or imiquimod, and photodynamic therapy. Treatment of severe actinic cheilitis consists of vermilionectomy with submission of the tissue for histopathologic examination. CO_2 laser ablation has also been used to treat this condition, usually after the presence of invasive SCC has been excluded.

Oral Squamous Cell Carcinoma

Key features

- The most common malignancy of the oral cavity
- Develops primarily in middle-aged or elderly men
- Significant association with the use of tobacco and alcohol
- Most common intraoral sites are the lateral and ventral surfaces of the tongue and floor of the mouth

Introduction

SCC is the most common malignancy of the oral cavity, and it is strongly associated with the use of tobacco and the consumption of alcohol[48]. Other etiological factors include betel nut chewing, primarily in the Indian subcontinent and Southeast Asia, and HPV infection, especially types 16 and 18[49]. Carcinomas of the vermilion zone of the lower lip are associated with actinic damage secondary to chronic sun exposure. Lastly, a recent study suggested that a slightly increased risk for oral SCC might be inherited[50].

Epidemiology

SCC accounts for more than 90% of all malignant neoplasms of the mouth and oropharynx. In the US, over 30 000 new cancers of the oral cavity are diagnosed annually. While typically a disease of middle-aged or elderly men, and accounting for 4% of all cancers within this group, there is some evidence that suggests an increasing incidence of oral SCC among women and younger patients. In fact, in some series, up to 16% of newly diagnosed cases were in individuals between the ages of 18 and 45 years[51]. Although very few SCCs in the oral cavity proper (anterior to the tonsillar pillars) are HPV-positive, in the oropharynx (behind the anterior tonsillar pillar), HPV status has been shown to influence prognosis, with HPV-positive tumors having a better prognosis[51a].

Clinical features

While any intraoral site may be affected, the most common sites are the lateral and ventral surfaces of the tongue and the floor of the mouth.

Clinically, oral SCC may present as an ulcer, an exophytic mass, or an endophytic process with varying degrees of induration (Fig. 72.17). The surface is typically irregular, rough or granular. These lesions are often painless early on in their disease course. Patients may present with dysphagia or dysphonia[52].

Pathology

Oral SCCs are histologically similar to those occurring elsewhere (see Ch. 108).

Treatment

Treatment of oral SCC consists of various combinations of surgery, radiotherapy and chemotherapy. Radiation therapy plus chemotherapy allows for organ preservation and decreases the risk of metastases. Ninety percent of recurrences occur within 2 years of initial treatment.

Fig. 72.17 Squamous cell carcinoma. Ulcerated, indurated, exophytic mass involving the right lateral border of the tongue, a typical presentation and site for this tumor.

In comparison to SCC of the skin, intraoral lesions are characterized by significantly more aggressive behavior. In addition, oral cancers are often diagnosed at a relatively advanced stage. Therefore, the prognosis is less favorable. Five-year survival rates for stage I or II disease approach 80%, while the 5-year survival rate for stages III and IV is 30% or less. In addition, oral cancer patients have a 2–3% annual risk of developing a second primary SCC of the upper aerodigestive tract after treatment of their original tumor.

Verrucous Carcinoma

Subtype/synonyms: ■ Oral verrucous carcinoma: oral florid papillomatosis, Ackerman tumor

Key features

- Uncommon, low-grade variant of SCC
- White and exophytic, with a papillary or warty (verrucous) topography
- Characterized by slow, persistent growth

Introduction

Verrucous carcinoma is often considered a low-grade variant of SCC. In addition to the oral mucosa, similar lesions occur in the anogenital region, plantar surface of the foot, and laryngeal mucosa.

Epidemiology

Verrucous carcinoma is a rare variant of SCC, with an incidence of 1–3 per 1 million population[53]. The disease usually affects men over 50 years of age. While HPV, particularly HPV-6 and HPV-11, may be detected in some of these tumors, its precise etiologic role is still unclear.

Clinical features

The most common site of involvement for verrucous carcinoma is the oral mucosa, particularly the palate, buccal mucosa and alveolar processes. Clinically, lesions present as slowly growing, white, exophytic, papillomatous or warty proliferations with well-demarcated borders. Ulceration is uncommon.

Pathology

Histopathologically, verrucous carcinoma is characterized by hyperkeratosis and an extremely acanthotic epithelium with a papillary or verrucous surface[54]. The epithelium is well differentiated, with minimal atypia and rare mitotic figures. A dense infiltrate of chronic inflammatory cells is frequently present in the superficial connective tissue. Excised lesions should be examined with multiple sections because as many as 25% of verrucous carcinomas show foci of typical SCC.

Treatment

The treatment of choice for verrucous carcinoma is wide surgical excision[55]. Adjunctive therapy with imiquimod and/or oral retinoids has been anecdotally reported to be useful. Traditionally, radiation therapy is not employed because of concern regarding anaplastic transformation; however, there are case reports of successfully combining chemotherapy plus radiation therapy.

SALIVARY GLAND DISEASES

Mucocele

Synonyms: ■ Mucous cyst of oral mucosa ■ Ranula (when located on the floor of the mouth)

Key features

- Common condition caused by disruption of a minor salivary gland duct with resultant spillage of mucus into the submucosal tissue
- Affects a wide age range
- Most commonly seen on the lower labial mucosa
- Often has to be surgically excised to provide complete resolution

Introduction

A mucocele is one of the more commonly encountered disorders of the oral mucosa. Mucoceles develop when a minor salivary duct is disrupted, resulting in the escape of mucus into the adjacent submucosal connective tissue (see Ch. 110).

Epidemiology

While the majority of mucoceles are detected in younger individuals (second through fourth decade), the lesion can be seen at any age.

Clinical features

The patient will typically report the sudden onset of a painless, soft submucosal swelling. Any color change is dependent on how deep the swelling is relative to the surface mucosa, with very superficial lesions often appearing vesicular, slightly deeper mucoceles having a bluish tinge (Fig. 72.18), and the deepest lesions having no discernible color change. Patients often describe the lesion as having multiple cycles of swelling, rupturing and refilling. While the lower labial mucosa is the most common site of involvement, any oral mucosal area that contains minor salivary glands can potentially develop a mucocele[56]. In particular, they sometimes develop on the ventral tongue, buccal mucosa and posterior hard palate, but the upper labial mucosa is a rare site. A lesion that appears to be a mucocele in the retromolar region (behind the last molar tooth in the mandible) should be examined histologically, as mucoepidermoid carcinoma is seen with some frequency in this location.

Pathology

Histopathologically, a collection of mucus is surrounded by chronic inflammatory cells (consisting primarily of macrophages) as well as granulation tissue. Lobules of inflamed minor salivary glands are often included in the tissue sample.

Treatment

While some very superficial mucoceles may undergo rupture followed by reconnection of the duct to the surface, most mucoceles require surgical excision of the mucus deposit plus the adjacent minor salivary glands in order to resolve the process. Occasionally, a mucocele will

Fig. 72.18 Mucocele. Soft nodule with bluish hue in a typical location: lower lateral labial mucosa.

Fig. 72.19 Cheilitis glandularis. Erythematous mucosal macules on the lower lip at sites of inflamed salivary gland ducts. There is also evidence of actinic cheilitis.

recur after surgery, but this is not common. Other therapeutic modalities are outlined in Chapter 110.

Cheilitis Glandularis

Key features

- Rare condition characterized by inflammatory hyperplasia of the lower labial salivary glands
- Primarily affects adult men
- Possibly associated with chronic sun exposure or irritation
- Dysplasia is often present in the overlying epithelium

Introduction

Cheilitis glandularis is a rare anomaly of the lips, consisting of an inflammatory hyperplasia of the lower labial salivary glands, which may result from chronic irritation[57].

Epidemiology

It is seen primarily in adult men. The lower lip is most commonly involved, and the condition has been associated with an increased risk for the development of SCC.

Clinical features

The clinical presentation of cheilitis glandularis may vary from slight hypertrophy of the lower lip to nodular enlargement that results in its eversion[58]. The secretory ducts become dilated and inflamed, appearing as pinpoint red mucosal macules (Fig. 72.19).

Pathology

Histopathologically, there are focal dense accumulations of inflammatory cells within and around the mucous glands. The vermilion zone often displays actinic cheilitis.

Treatment

The treatment of cheilitis glandularis consists of vermilionectomy of the lower lip, with or without cosmetic debulking.

Necrotizing Sialometaplasia

Key features

- Uncommon ulcerative process of the posterior hard palate thought to be due to ischemia
- Frequently misdiagnosed as a malignancy, both clinically and histologically

Introduction

Necrotizing sialometaplasia is an uncommon disorder that is most likely due to an interruption of the blood supply to salivary gland tissue, typically in the region of the posterior hard palate or anterior soft palate, leading to ischemic necrosis[59]. While such a disruption in blood supply can follow surgical procedures in the area, in most patients the cause of the ischemic injury is unknown. Very infrequently, a submucosal malignancy may occlude the palatal blood vessels[60,61].

Epidemiology

The condition is almost always seen in adult patients, with a slight male predominance in most series.

Clinical features

The patient will usually complain of the sudden onset of swelling of the palate, in addition to pain, paresthesia or anesthesia of the area. Within 1–2 weeks, the ischemic tissue sloughs, and the patient will often state that "part of the roof of my mouth fell out". This leads to a well-demarcated ulcer with a border that is minimally elevated or flush with the surrounding intact mucosa. By palpation, the ulcer has no underlying induration or mass.

Pathology

Because ulcerated oral malignancy is often the leading diagnosis clinically, this may influence the histopathologic interpretation, especially if the pathologist is not familiar with the disorder. A misdiagnosis of mucoepidermoid carcinoma or SCC is not unusual, as the benign squamous metaplasia of the ductal epithelium can mimic a malignancy. Confinement of the metaplastic and ischemic changes to the original boundaries of the salivary gland lobules is the key diagnostic feature[62].

Treatment

Once the diagnosis of necrotizing sialometaplasia is established, additional treatment is not required. Depending upon the size of the defect, it may take several weeks to heal.

Sjögren's Syndrome

Key features

- Autoimmune disorder characterized by keratoconjunctivitis sicca and xerostomia
- Primarily affects women

Introduction/clinical features

Sjögren's syndrome (SjS) is the second most common autoimmune connective tissue disease, exceeded only by rheumatoid arthritis (see

Ch. 45). While the etiology and pathogenesis remain unclear, patients are known to produce a number of autoantibodies, including IgG antibodies against SS-A (Ro) and SS-B (La) (see Ch. 40). Patients with SjS have a 40-fold increased risk of lymphoma, predominantly the non-Hodgkin B-cell type[63].

SjS is a systemic disorder that presents primarily as dry eyes (keratoconjunctivitis sicca)[64] and dry mouth (xerostomia). Primary SjS is characterized by these features alone (sicca syndrome), whereas secondary SjS consists of sicca syndrome in association with another autoimmune disorder, such as systemic lupus erythematosus or rheumatoid arthritis.

Symptoms of SjS are the result of decreased glandular function secondary to lymphocytic infiltration, primarily by $CD4^+$ T cells. Both the major and minor salivary glands may be affected, leading to reduced salivary production. Major gland involvement is clinically evident in fewer than half of affected patients, presenting as firm, diffuse, nontender or slightly tender enlargement that is usually bilateral.

Patients express variable degrees of ocular and oral dryness[65], with a gradual onset of symptoms in most cases. Oral pain may be present, along with dysphagia and difficulty wearing prostheses[66]. Xerostomia frequently leads to increased dental caries, in particular along the gum line. There is an increased susceptibility to oral candidiasis as well[65]. Systemic manifestations are discussed in Chapter 45.

Pathology

The diagnosis of SjS may be difficult to appreciate initially, due to the often insidious onset of the disease. Salivary gland biopsy is frequently used to support the diagnosis of SjS and there are two pathologic appearances. In the parotid gland, benign lymphoepithelial lesions consist of a proliferation and infiltration of lymphocytes in the glandular tissue in association with hyperplasia and metaplasia of salivary duct epithelium, forming the characteristic epimyoepithelial islands. Minor salivary gland involvement by SjS is characterized by focal aggregates of 50 or more lymphocytes (constituting one "focus") adjacent to normal-appearing acini[65]. A minimum of five glands must be harvested from the lower labial mucosa, and a focus score of one or greater in a 4 mm^2 area of glandular tissue is generally considered to be consistent with the disease[67]. However, given the lack of international consensus, criteria do vary slightly with some pathologists requiring two or more foci.

Although harvesting these minor salivary glands is a relatively simple surgical procedure[68], some clinicians reserve it for patients whose clinical and serologic findings are equivocal[69]. Review by an oral pathologist may improve detection of the diagnostic histologic features[67]

Treatment

The treatment for SjS consists of symptomatic care and management of the associated complications. Sugarless gum and candy may be used to stimulate salivary flow. Artificial salivary substitutes can also be beneficial. Pilocarpine or cevimeline may be prescribed to stimulate glandular function for those patients with functioning residual salivary tissue. Treatment of systemic features is discussed in Chapter 45.

THE DIFFERENTIAL DIAGNOSIS OF INTRAORAL TUMORS AND TUMOR-LIKE LESIONS
DEVELOPMENTAL LESIONS
• Congenital inclusion cysts – Bohn nodules (alveolar ridge) – Epstein pearls (palate) • Torus • Lingual thyroid • Dermoid cyst • Enteric duplication cyst • Nasoalveolar cyst • Lymphatic malformation
REACTIVE/INFLAMMATORY CONDITIONS
• Mucocele • Fibroma* • Melanoacanthoma • Eosinophilic ulcer • Pyogenic granuloma • Peripheral giant cell granuloma • Necrotizing sialometaplasia • Nodular fasciitis
BENIGN SALIVARY GLAND NEOPLASMS
• Pleomorphic adenoma • Monomorphic adenoma • Papillary cystadenoma
OTHER BENIGN NEOPLASMS
• Squamous papilloma • Infantile hemangioma • Angiomyoma • Myofibroma, hemangiopericytoma • Granular cell tumor† • Neurofibroma • Schwannoma • Palisaded encapsulated neuroma • Melanotic neuroectodermal tumor of infancy • Ameloblastoma • Lipoma
MALIGNANT SALIVARY GLAND NEOPLASMS
• Adenoid cystic carcinoma • Mucoepidermoid carcinoma • Adenocarcinoma
OTHER MALIGNANT NEOPLASMS
• Squamous cell carcinoma • Melanoma • Lymphoma • Kaposi sarcoma • Rhabdomyosarcoma • Osteosarcoma • Fibrosarcoma • Liposarcoma
*Ossification may occur. †A congenital epulis represents a granular cell tumor of the alveolar ridge.

Table 72.5 The differential diagnosis of intraoral tumors and tumor-like lesions.

Salivary Gland Tumors

Key features

- Usually seen on the palate
- In general, benign tumors are diagnosed more often than malignant tumors
- Slight female predominance

Introduction/epidemiology

Tumors of the minor salivary glands are uncommon, constituting approximately 15% of all salivary gland neoplasms. However, whenever an intraoral submucosal mass is detected, the diagnosis of a salivary gland neoplasm should be considered.

Clinical features/pathology

Most salivary gland tumors present as a painless, rubbery, firm swelling. Pain may be noted, however, in malignant tumors. Occasionally, ulceration is present, clinically mimicking SCC. The posterior hard palate/anterior soft palate is the most frequently affected site, followed by the upper lip and buccal mucosa. Pleomorphic adenoma and mucoepidermoid carcinoma represent the most common benign and malignant tumors, respectively (Table 72.5)[70,71].

Treatment

The treatment of benign salivary gland tumors consists of conservative surgical excision. Malignant tumors usually require more extensive removal. Radiotherapy is generally used as a postsurgical adjunct.

ORAL MANIFESTATIONS OF HEMATOLOGIC/ONCOLOGIC DISEASE

Chemotherapy- and Radiotherapy-Induced Oral Mucositis

Key features

- Chemotherapy-induced oral mucositis usually develops in patients who have been treated with cytotoxic drugs and subsequently develop neutropenia
- Radiotherapy-induced oral mucositis most commonly occurs in patients treated for head and neck malignancies
- Erosions, ulcerations and hemorrhagic crusting of the oral mucosa are seen
- Self-healing, but recurrent, in patients receiving multiple cycles of chemotherapy

Introduction

Drug-induced direct cytotoxic effects on oral epithelial cells, in combination with neutropenia (which also predisposes patients to superimposed infections), often leads to the development of ulcers of the oral mucosa. The ulcers usually develop 4–7 days after administration of the chemotherapeutic agent(s) and tend to be less severe in those who have received recombinant human granulocyte colony-stimulating factor (G-CSF). For those individuals undergoing hematopoietic stem cell transplantation who have received high-dose chemotherapy plus radiotherapy, treatment with recombinant human keratinocyte growth factor (palifermin) also reduces the severity of mucositis[72].

Radiotherapy for head and neck malignancies can cause direct cytotoxic damage to the oral epithelium as well, with painful mucositis usually appearing after the third week of treatment[73].

Clinical features

Characteristically, a single or multiple round, oval or irregularly shaped ulcers are seen, usually on the gingivae or other mucosal sites that are frequently traumatized (lateral tongue, buccal mucosa). Pain may or may not be present. Diagnosis is based upon clinical features as well as the temporal relationship to chemotherapy administration or initiation of radiotherapy.

The differential diagnosis includes infections (e.g. viral or candidal) and, for more longstanding lesions, oral SCC. Of note, the association of neutropenia and oral ulcers is also seen in patients with cyclic neutropenia, with crops of lesions coinciding with the nadir of the neutropenia.

Treatment

Resolution typically occurs within 2 to 3 weeks of completing the chemotherapy cycle or radiotherapy[74]. Although palifermin can reduce the severity of oral mucositis (see above), it also leads to a markedly thickened layer of keratin on the dorsum of the tongue and a resultant whitish discoloration. Maintenance of oral hygiene (e.g. use of soft toothbrushes and rinses), topical anesthetics, non-narcotic or narcotic analgesics[73], and antimicrobial agents can also be helpful.

Leukemia

Key features

- Associated intraoral findings include infections and gingival hemorrhage
- Gingival enlargement occurs most commonly with monocytic and myelomonocytic leukemias

Introduction

While oral infections related to neutropenia and immunosuppression from chemotherapy are common, direct involvement of the oral mucosa by leukemic cells is rather unusual.

Clinical features

There are numerous oral manifestations associated with leukemia and its treatment[75]. Most common is bruising or spontaneous and persistent hemorrhage due to thrombocytopenia. Leukopenia results in poor healing and an increased prevalence of viral, fungal and bacterial infections. The tissues may exhibit an overall pallor of anemia or ulcerative gingivitis. Diffuse, firm, non-tender gingival enlargement can result from infiltration of the gingival connective tissue by leukemic cells, primarily in patients with monocytic or myelomonocytic forms of leukemia[76].

Treatment

Multi-agent chemotherapy and allogeneic hematopoietic stem cell transplantation are most commonly used to treat acute leukemias. Management of oral complications requires establishment of a definitive diagnosis for the particular complaint and treating it accordingly.

Lymphoma

Key features

- Non-Hodgkin lymphomas typically account for over 80% of lymphomas
- Relatively uncommon within the oral cavity, where it presents as an extranodal proliferation

Introduction/epidemiology

Non-Hodgkin lymphoma comprises a heterogeneous group of lymphoid neoplasms whose biologic behavior ranges from relatively indolent to highly aggressive[77]. Unlike Hodgkin disease, up to 40% of non-Hodgkin lymphomas may arise in extranodal sites, including the oral cavity.

In general, non-Hodgkin lymphoma is a disease of older adults and increases in incidence with age. HIV-infected individuals appear to have a greater risk of developing *oral* non-Hodgkin lymphoma[78].

Clinical features

The head and neck region is the second most common extranodal site for non-Hodgkin lymphoma, after the gastrointestinal tract[79]. The most common intraoral locations are the palate and the buccal vestibule. Lymphoma in these areas presents as a soft to rubbery-firm, slowly growing, mucosa-colored to purplish swelling. Ulceration may be present, mimicking SCC. Overlying telangiectasias may also be evident. Pain is usually not a prominent feature.

Pathology

Non-Hodgkin lymphomas of the oral cavity are primarily of the B-cell type.

Treatment

Treatment for non-Hodgkin lymphoma consists of chemotherapy and/or monoclonal antibodies (e.g. rituximab). The survival rates for non-Hodgkin lymphomas are highly variable, depending upon tumor classification and stage.

Melanoma

Key features

- Oral mucosal melanomas are rare, constituting less than 1% of all melanomas
- Approximately one oral melanoma is detected annually per 10 million individuals in the US
- Predominantly affects men, with an average age of 55 years

Introduction/epidemiology

Oral melanomas account for far less than 1% of all oral malignancies, and occur in the US at an annual rate of 1.2 per 10 million population[80]. Men are affected more often than women, with most cases diagnosed between 40 and 70 years of age (mean age of 55 years)[81].

Fig. 72.20 Amalgam tattoo. Foreign body tattoos are the most common cause of acquired oral pigmentation, and most of them are due to iatrogenic implantation of dental amalgam. In this case, the amalgam was used to seal the apices of endodontically treated teeth, resulting in tattooing of the maxillary vestibule. Histologically, darkly staining deposits are seen within the dermis.

Clinical features

Clinically, oral melanomas exhibit virtually all of the features of their cutaneous counterparts. The preferred site for oral melanomas is the hard palate, followed by the maxillary attached gingiva[82]. The differential diagnosis includes foreign body tattoo (Fig. 72.20), blue nevus, oral melanotic macule, physiologic pigmentation, and melanoacanthoma. Melanomas are usually painless. Uncommonly, they may be amelanotic, resembling erythroplakia, a pyogenic granuloma, or an invasive SCC.

Pathology

Histopathologically, oral melanomas feature infiltration of the connective tissue by atypical melanocytes (as well as proliferation within the epithelium), with or without melanin production (see Ch. 113). For those lesions devoid of melanin, the diagnosis may be confirmed by immunohistochemistry using antibodies directed against S100 protein, HMB45, MART-1/Melan-A or MITF.

Unlike cutaneous melanomas, mucosal melanomas of the head and neck are usually in a vertical growth phase at the time of diagnosis. While the majority of these mucosal melanomas apparently have a minimal associated radial growth phase[83], it is possible that they are simply discovered at a more advanced stage due to their location[80].

Treatment

The treatment of choice for oral melanoma is wide surgical excision with adequate negative margins[84]. Sentinel lymph node biopsy also provides useful prognostic information[85]. While standard chemotherapy and radiotherapy appear to have little impact on the course of the disease, targeted therapies (e.g. tyrosine kinase inhibitors) may improve survival.

Whereas the overall 5-year survival rate for cutaneous melanoma is at least 90%, that of oral mucosal melanoma is only about 15%, with a median survival post-diagnosis of less than 2 years.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASE

Amyloidosis

Key features

- Systemic or localized deposition of fibrillar proteins
- May be primary or secondary
- Most commonly affects the kidney and heart
- Amyloid deposits within the tongue can occur and may produce macroglossia

Introduction

Amyloidosis is a term for diseases sharing the common feature of extracellular deposition of pathologic insoluble fibrillar proteins within organs and tissues (see Ch. 47). Systemic amyloidosis occurs as a primary disease in association with plasma cell disorders such as multiple myeloma or secondary to chronic inflammatory diseases. It can also be inherited or occur as part of the aging process[86].

Clinical features

Macroglossia, a classic feature that occurs in about 20% of patients with primary systemic amyloidosis, is characterized by firm enlargement of the tongue[87,88]. Scalloping of its edge can develop and sometimes the macroglossia is accompanied by secondary ulceration. Hemorrhagic papules and plaques may also appear on the tongue or in other oral mucosal sites. Taste disturbances have been noted with or without macroglossia, and xerostomia can result from involvement of the salivary glands[86]. Cutaneous and systemic features are discussed in Chapter 47.

Pernicious Anemia

Key features

- Most common cause of vitamin B_{12} deficiency
- Affects up to 2% of the population over the age of 60 years
- Immunologically mediated condition with antibodies directed against intrinsic factor and parietal cells of the stomach
- Tongue may appear smooth and beefy red

Introduction

Pernicious anemia is an autoimmune disorder characterized by megaloblastic hematopoiesis and/or neuropathy due to vitamin B_{12} deficiency[89]. It is the most common underlying cause of this vitamin deficiency and is associated with chronic atrophic gastritis. Of note, B_{12} deficiency is also seen in vegetarians, post-gastrectomy and individuals with tapeworm infections.

Patients with pernicious anemia produce antibodies directed against intrinsic factor and parietal cells of the fundus and body of the stomach. The malabsorption of vitamin B_{12} is due to intrinsic factor deficiency.

Epidemiology

Pernicious anemia is a relatively common disorder, and is present in up to 2% of individuals over 60 years of age. There is a slight female predilection. In addition, there may be a genetic predisposition, as the disease occurs 20 times more frequently in close relatives[89].

Clinical features

Pernicious anemia typically has an insidious onset, with patients eventually presenting with symptoms of anemia. Peripheral neuropathies are frequently reported, along with CNS involvement that ranges from demyelination to axonal degeneration.

Oral manifestations consist primarily of glossitis and stomatitis[90,91]. These changes may occur in the absence of symptomatic anemia. Atrophic glossitis manifests as a smooth, "beefy-red" tongue, with patchy, ill-defined areas of erythema gradually evolving to more diffuse dorsal tongue involvement (Fig. 72.21). Some patients experience a generalized sore mouth or burning sensation. Taste disturbances have also been reported. The differential diagnosis of atrophic glossitis includes other nutritional deficiencies (e.g. folate, iron, niacin and riboflavin) and candidiasis.

Treatment

Injection of vitamin B_{12} often leads to rapid improvement of oral signs and symptoms.

Crohn's Disease

Synonym: ■ Regional enteritis

Fig. 72.21 Pernicious anemia/candidiasis. Erythematous, atrophic tongue as a manifestation of pernicious anemia with a superimposed candidal infection.

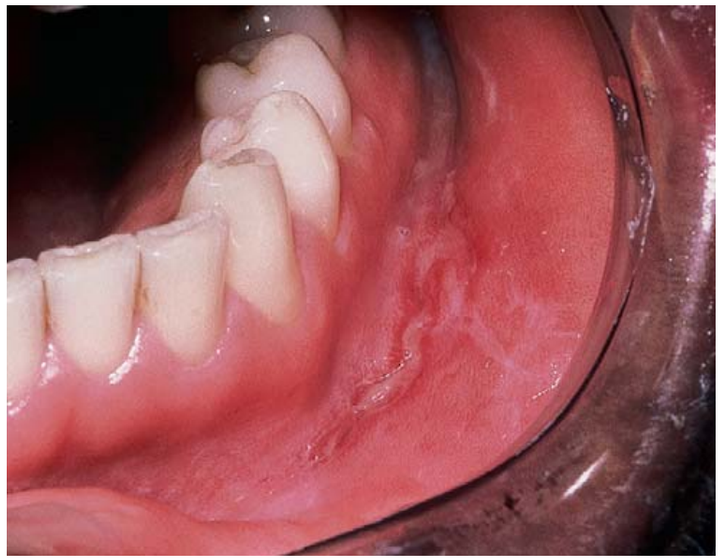

Fig. 72.22 Crohn's disease. Linear ulceration of the mandibular vestibule: the classic oral manifestation of this disease.

Key features

- Chronic granulomatous disorder affecting any segment of the gastrointestinal tract from the oral cavity to the anus
- Most commonly affects the distal ileum and/or proximal colon
- Oral involvement is uncommon and usually presents as linear ulceration of the buccal vestibule, although persistent swelling of the labial or buccal mucosa may be seen

Introduction/epidemiology

Crohn's disease represents an idiopathic chronic granulomatous disorder of the gastrointestinal tract. The condition has also been termed "regional enteritis", due to the alternating of affected areas with unaffected areas.

Crohn's disease is usually diagnosed before the age of 30 years, with peak prevalence in the second and third decades. The disease affects men and women approximately equally, but Caucasians are affected more frequently than other ethnic groups[92].

Clinical features

Oral signs and symptoms reportedly occur in 5–15% of patients with Crohn's disease. Linear fissures and/or ulcers of the vestibule are the most common clinical presentation (Fig. 72.22). Patients may also present with persistent, firm, painless swelling of the labial, buccal or facial tissues[92]. This may resemble granulomatous cheilitis both clinically and histologically[93] (see above). Cobblestone lesions of the buccal mucosa and vestibule may also be seen. Fibrosis and adhesions can occur as sequelae of these lesions. Additional manifestations include oral aphthae and pyostomatitis vegetans[94].

Pathology

Histopathologically, the oral lesions of Crohn's disease show non-necrotizing granulomatous inflammation. Sarcoidosis, a foreign body reaction, and infection should be excluded.

Treatment

Oral lesions typically respond to therapy for bowel lesions, but topical or intralesional corticosteroids are also effective[95]. Treatment of the gastrointestinal involvement may include systemic corticosteroids, often with sulfasalazine. Azathioprine, 6-mercaptopurine, methotrexate, TNF-α inhibitors (e.g. adalimumab, infliximab, certolizumab) and natalizumab (an integrin receptor antagonist) are also used to treat Crohn's disease[96].

Pyostomatitis Vegetans

Key features

- Typically associated with inflammatory bowel disease
- Multiple "snail-track" pustules superimposed upon diffuse mucosal erythema

Introduction

Pyostomatitis vegetans is a rare mucocutaneous disorder that is often associated with an underlying gastrointestinal disorder such as ulcerative colitis or, less commonly, Crohn's disease[97]. Pyostomatitis vegetans may represent an oral mucosal variant of pyoderma gangrenosum.

Epidemiology

Most cases of pyoderma vegetans are diagnosed in individuals 20 to 60 years of age. Men are affected more commonly than women.

Clinical features

Pyostomatitis vegetans is characterized by multiple tiny, creamy-yellow pustules set against a diffuse, intensely erythematous background. The pustules are often arranged in a linear serpentine fashion, and are often described as having a "snail-track" appearance. The pustules are easily ruptured, leading to shallow erosions and ulcerations. While any area of the oral cavity may be affected, the labial, gingival and buccal mucosa are most commonly involved. The dorsum of the tongue is usually spared[97]. The differential diagnosis includes herpetiform aphthae and oral pemphigus vulgaris.

Pathology

Intraepithelial and/or subepithelial microabscesses containing numerous eosinophils as well as neutrophils are seen.

Treatment

Treatment of pyostomatitis vegetans is focused on controlling the underlying gastrointestinal disease if it is identified. In patients without inflammatory bowel disease, therapy most often consists of moderate to high doses of systemic corticosteroids, sometimes in combination with azathioprine. Management of the associated gastrointestinal disease often results in improvement in the oral lesions.

ORAL MANIFESTIONS OF HIV INFECTION

INTRODUCTION

The diagnosis and management of skin diseases in the anogenital region may be complex. The juxtaposition of urinary, genital and alimentary tracts (Fig. 73.1) gives rise to special considerations at this site, and disease of any of these major systems may present with cutaneous manifestations. Many systemic diseases preferentially affect the genital area. Local factors, including warmth, moisture, irritants, friction and the effects of body fluids, are important in this region, contributing to skin problems.

Skin conditions may be more difficult to diagnose in the anogenital region than at other cutaneous sites, as typical appearances may be lost and there may be hesitation to perform biopsies. Examination of the scalp, nails and oral cavity frequently assists in diagnosis. Special considerations apply to treatment, as the natural occlusion of this area may increase the percutaneous absorption of topical corticosteroids, with the potential for cutaneous atrophy and/or hypothalamic–pituitary–adrenal axis suppression. Warmth and moisture may also increase the risk of bacterial and yeast infections.

Only a limited number of symptoms in the anogenital area are possible, and pruritus and genital pain may be the presenting feature of a wide variety of diseases.

LICHEN SCLEROSUS

Synonyms: ■ Lichen sclerosus et atrophicus ■ Balanitis xerotica obliterans (men) ■ Kraurosis vulvae (women)

Key features

- Chronic inflammatory disease with a predilection for the anogenital region
- Pruritus is the most frequent symptom
- Major clinical signs are pallor, atrophy, fissures and foci of hyperkeratosis
- Scarring may cause loss of the normal architecture of the vulva in women and phimosis in men

Introduction

Lichen sclerosus is a chronic inflammatory disease that preferentially affects the anogenital region, although any cutaneous site may be affected; 15–20% of patients with genital lichen sclerosus will have extragenital disease[1]. Symptoms may be longstanding as there is frequently a delay in diagnosis. Patients require long-term evaluation due to the risk of scarring and the risk of developing squamous cell carcinoma.

History

The initial clinical description of lichen sclerosus was by Hallopeau in 1889 and the characteristic histologic features were described by Darier in 1892. Over the years there has been much confusion over nomenclature, with the use of terms such as leukoplakia, lichen albus, kraurosis vulvae, and lichen sclerosus et atrophicus. The International Society for the Study of Vulvovaginal Disease (ISSVD) favors "lichen sclerosus".

Epidemiology

Lichen sclerosus is 6–10 times more prevalent in women than in men. The disorder may occur at any age, but the two peaks of onset are during childhood and either after menopause or in the 4th or 5th decade (in men). Although most studies have centered on white European patients, there are reports of lichen sclerosus occurring in Africans and Asians. Powell et al.[2] calculated a prevalence of 1 in 660 women and an annual incidence of 51.9/100 000 in postmenopausal women. The incidence of lichen sclerosus in boys may be underestimated; when foreskins of circumcised boys were examined, 14% were found to have the characteristic features of lichen sclerosus[3].

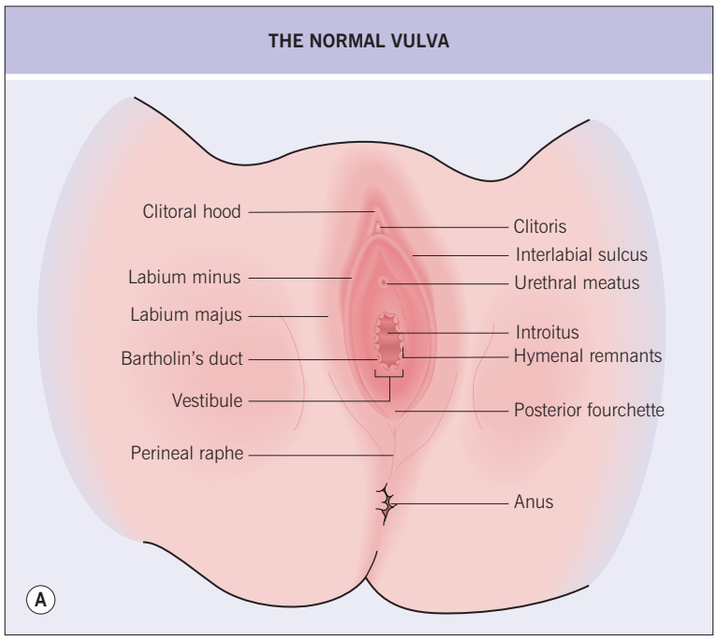
Etiology

The cause of lichen sclerosus remains unknown. An inherited tendency is suggested by the occurrence of familial cases, the association with HLA-DRB1*12 (and the related haplotype DRB1*12/DQB1*0301/04/09/010)[4] and the association with other autoimmune disorders such as thyroid disease, vitiligo and morphea[5]. An infectious etiology has been proposed, but *Borrelia* or other spirochetal infection has not been confirmed in large studies. Anti-extracellular matrix protein and anti-basement membrane zone antibodies have been reported in lichen sclerosus sera, but the pathogenicity of these antibodies remains to be determined[6,7]. Local friction or rubbing may induce lesions of lichen sclerosus via the Koebner phenomenon, and some cases of early-onset lichen sclerosus may be associated with the antiandrogenic oral contraceptive pill. In uncircumcised males, chronic exposure of susceptible epithelium to urine due to naviculomeatal dysfunction has been proposed as causative[7a].

Clinical features

Both male and female patients may present with pruritus or soreness, but rarely may be entirely asymptomatic[8]. Dyspareunia is frequently reported. Children with lichen sclerosus are more likely to present with urinary or bowel symptoms (e.g. constipation) or hemorrhagic bullae, which may lead to a misdiagnosis of child abuse[9].

In women, the characteristic clinical findings are vulvar hypopigmentation and thin, wrinkled, atrophic skin in a figure-of-eight distribution encircling the vulvar and perianal region (Fig. 73.2). Focal areas of hyperkeratosis, erosions and fissures are frequently seen. Additional cutaneous features that are helpful in identification are purpura (Fig. 73.3), telangiectasias, and rarely, hemorrhagic blisters. Lichen sclerosus is a scarring disease and therefore some architectural change



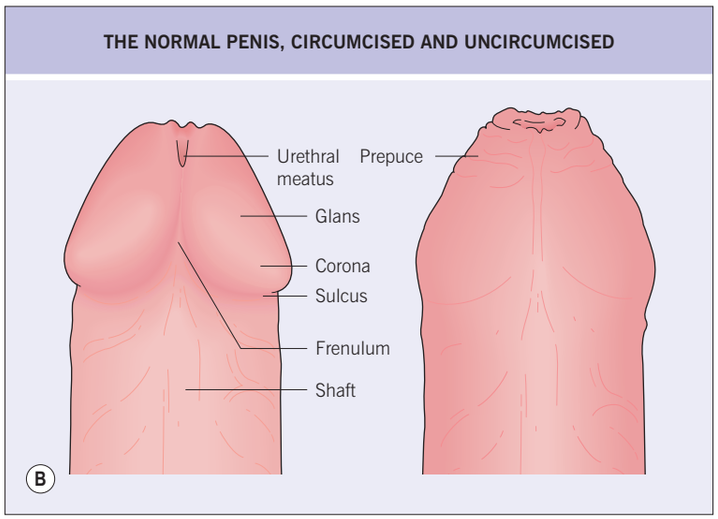


Fig. 73.1 Genital anatomy. A The normal vulva. **B** The normal penis, circumcised and uncircumcised.

Fig. 73.2 Lichen sclerosus of the perianal region.

Fig. 73.3 Lichen sclerosus of the vulva with characteristic purpura. *Courtesy, Kalman Watsky, MD.*

is common (Fig. 73.4). Burying of the clitoris secondary to midline fusion or fusion of the labia minora to the labia majora may occur. In untreated or severe disease, there may be total loss of the labia minora and narrowing of the introitus. Lichen sclerosus affects the glans penis and foreskin of men (Fig. 73.5) and, in contrast to in women, involvement of the perianal region is uncommon. The disease usually presents with pruritus, pain and dyspareunia. Affected boys may have recurrent balanitis and a poor urinary stream, and some may require circumcision.

Extragenital lichen sclerosus favors the submammary region, as well as the shoulders, neck and wrists, presenting as asymptomatic, hypopigmented, wrinkled patches with follicular plugging (see Ch. 44); occasionally, there are multiple guttate lesions. The diagnosis is established by a combination of the characteristic clinical and histologic findings.

Pathology

The principal histologic findings are compact orthokeratosis, follicular plugging (in non-mucosal sites), a thinned epidermis, vacuolization of the basal layer, and hyalinization of the papillary dermis. A deep band-like lymphocytic infiltrate is often observed. Squamous hyperplasia may be present and may be associated with an increased risk of squamous cell carcinoma. In bullous lichen sclerosus there is extensive vacuolar degeneration of the basal layer with clefting. Early on, the papillary dermis may be edematous and homogenous, but, with time, hyalinization and sclerosis are observed. Histologic examination of the skin is imperative as it can be difficult to distinguish lichen sclerosus from mucous membrane (cicatricial) pemphigoid or erosive lichen planus on the basis of clinical appearance alone. Occasionally, despite marked clinical changes, the disease cannot be confirmed histologically and repeat biopsies over time may be needed to establish the diagnosis. In lesions that have been treated with potent topical corticosteroids, ascertaining the diagnosis histologically may prove challenging.

Differential diagnosis

Very mild or early disease may be confused with dermatitis. The presence of vulvar scarring necessitates the exclusion of other scarring disorders such as erosive lichen planus and mucous membrane pemphigoid. The absence of oral or vaginal mucosal involvement helps to distinguish lichen sclerosus from erosive lichen planus. In children, sexual abuse must be considered; however, the diagnoses of lichen sclerosus and sexual abuse are not mutually exclusive.

The principal differential diagnoses are:

- erosive lichen planus
- mucous membrane pemphigoid
- lichen simplex chronicus
- morphea

Fig. 73.4 Lichen sclerosus of the vulva. There is marked architectural change with loss of the labia minora and marked midline fusion.

Fig. 73.5 Lichen sclerosus of the penis. Erythematous and white plaque on the glans. *Courtesy, Ronald P Rapini, MD.*

- vulvar eczema
- child sexual abuse.

Treatment

The main aim of therapy is to bring the disease under control as quickly as possible with the fewest side effects. For initial treatment (after the diagnosis is established), a potent topical corticosteroid such as clobetasol propionate 0.05% ointment is prescribed. One possible regimen is daily application of clobetasol propionate 0.05% ointment to the affected area for 3 months[8–10]. This alleviates symptoms in the majority of patients, often within weeks. Subsequently, the corticosteroid is tapered down over 2 weeks and the clinical remission maintained by occasional application of a corticosteroid, using less than 30 g in any 6-month period. In some patients there is complete resolution of signs as well as symptoms, with the exception of the scarring, which is irreversible[8].

There is no longer any role for vulvectomy in the management of lichen sclerosus unassociated with malignancy. Similarly, testosterone creams are less effective and have the potential to cause virilization. In longstanding disease where narrowing of the introitus has resulted in dyspareunia, surgical refashioning may be helpful. Dilators may also be needed, in addition to psychosexual counseling.

Longitudinal evaluation is essential for patients with lichen sclerosus because both men and women[8,11] are at increased risk of developing genital squamous cell carcinomas (estimates of the risk are approximately 2–5%). Women with lichen sclerosus may develop differentiated vulvar intraepithelial neoplasia (VIN) which has a high risk of becoming squamous cell carcinoma as compared to undifferentiated VIN (HPV-associated disease). Men are also at risk of penile intraepithelial neoplasia. Non-healing fissures, ulcers or nodules must be examined histologically. Written educational material and patient support groups are very helpful (e.g. www.lichensclerosus.org). It is essential that patients who notice any of the features of malignancy have ready access to medical care to allow prompt assessment.

The first- and second-line therapies for anogenital lichen sclerosus are outlined in Table 73.1. There have been several case series demonstrating success with topical calcineurin inhibitors; however, given the risk of malignant transformation in this condition, the authors caution against chronic maintenance therapy until long-term safety data are available.

THERAPIES FOR ANOGENITAL LICHEN SCLEROSUS
FIRST-LINE
Soap substitutes and emollients (3) Superpotent topical corticosteroids (3-month course) (2) Circumcision in men, if phimosis (2)
SECOND-LINE
In some patients, longer-term maintenance with potent topical corticosteroids (2) Surgery to correct narrowing of introitus and reverse clitoral burying (3) Topical calcineurin inhibitors (2) Circumcision in men, if unresponsive to medical treatment (3)

Table 73.1 Therapies for anogenital lichen sclerosus. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

LICHEN PLANUS

Synonyms: ■ Vulvovaginal gingival syndrome (erosive lichen planus in women) ■ Peno-gingival syndrome in men ■ Mucosal lichen planus

Key features

- Four distinct forms of genital lichen planus are observed: (1) papules or plaques in the setting of generalized cutaneous lichen planus; (2) erosive disease; (3) hypertrophic disease; and (4) lichen planopilaris
- Although cutaneous disease is often self-limiting, mucous membrane disease is more persistent
- The classic findings in cutaneous disease are violaceous, flat-topped papules and plaques; lacy white streaks typically occur on the genitalia as well as the oral mucosa
- Erosive lichen planus often involves multiple mucous membrane sites – in particular, the vulva, vagina and oral mucosa

Introduction

Approximately 50% of women and 25% of men with cutaneous lichen planus have genital involvement. The classic violaceous papules and plaques typically affect the labia minora and majora or the mons pubis in women and the glans or shaft of the penis in men. Erosive lichen planus is a distinct subtype of the disease, characterized by severe, scarring erosive disease of the vestibule, introitus, vagina and oral cavity[12,13]. Hypertrophic genital lichen planus and lichen planopilaris are the least frequent forms.

History

Erasmus Wilson reported a patient with vulvar lichen planus in 1867, but the first histologic description of lichen planus was by Darier in 1909. Isolated case reports of vaginal involvement with vaginal discharge and hyperemic vaginal mucosa appeared in the 1950s, and the term "desquamative inflammatory vaginitis" was introduced in 1968.

Fourteen years later, Pelisse recognized erosive lichen planus as a distinct subtype of lichen planus and gave it the name "vulvo-vaginal-gingival syndrome"[13].

Epidemiology

Lichen planus is more prevalent in women, generally presenting in the sixth decade. The exact prevalence is unknown, but, in the UK, lichen planus accounts for approximately 1% of referrals to dermatologists. In the vulvar clinic, genital lichen planus is less frequently encountered than lichen sclerosus, but it is likely that some cases of genital involvement in cutaneous lichen planus may be missed.

Etiology

Lichen planus probably represents T cell-mediated damage to epidermal cells that express altered self or foreign antigens on their surface, but the exact etiology is unknown (see Ch. 11). Some cases of lichen planus may be drug-induced, but whether this is true for genital disease is uncertain. Chronic liver disease, particularly that due to hepatitis C infection, may be associated with lichen planus in certain parts of the world such as the Mediterranean basin and Japan, but not in the UK[14]. There is an association of erosive lichen planus of the vulva with autoimmune disease[5].

Clinical features

There are four distinct presentations of genital lichen planus, as follows.

- In classic lichen planus, the genital lesions are similar to those in other cutaneous sites but lacy reticulation may be very prominent. Genital involvement is usually limited to the mons pubis and the labia majora and minora in women versus the glans penis and shaft in men (see Ch. 11). Penile plaques are frequently annular (Fig. 73.6A). Scarring is not a feature of classic lichen planus. Severe cutaneous pruritus is the usual presenting symptom, but sometimes genital lesions are asymptomatic. The lesions are usually self-limiting.
- Erosive lichen planus occurs much more frequently in women than in men. Pain and dyspareunia are the most common complaints. In female patients, extensive erosions occur around the vaginal orifice, edged by lacy white reticulations; similar lesions may also occur on the labia (Fig. 73.6B). Erosive lichen planus frequently leads to scarring, resulting in distortion of the vulvar architecture. In severe cases, there may be complete obliteration of the vaginal canal and urinary retention. Vaginal involvement can present as a discharge, erythema and contact bleeding of the vaginal mucosa, and scarring with adhesions. Oral involvement is frequently observed, usually in the form of a desquamative gingivitis, but lacy white reticulations and erosions may also occur. Erosions limited to the perianal area alone have been described.
- In the hypertrophic form of lichen planus, hyperkeratotic white plaques on the vulva or shaft of the penis may be seen.
- In lichen planopilaris, follicular keratotic papules are limited to the hair-bearing labia majora and the mons pubis, but may also occur on the scalp, trunk, axillae and extremities.

Pathology

The typical histologic findings are irregular epidermal acanthosis, accentuation of the granular layer, liquefactive degeneration of the basal layer, and a band-like dermal infiltrate of lymphocytes. It is more difficult to interpret biopsy specimens of mucous membranes, where these findings are more variable. In erosive disease, as there is loss of the epithelium, the specimen should include the edge of the erosion as well as the surrounding lacy reticulated pattern. Despite this, it is often impossible to unequivocally confirm the disease, but histologic evaluation can aid in excluding other disorders in the differential diagnosis.

Differential diagnosis

The main differential diagnoses are lichen sclerosus and mucous membrane pemphigoid. Direct immunofluorescence may be necessary to exclude pemphigoid. Orogenital ulceration raises the possibility of Behçet's disease (see Ch. 26); however, simple aphthous stomatitis and HSV infection are more likely causes of oral and genital ulcers, respectively. Lichenoid drug eruptions and graft-versus-host disease may give lichen planus-like changes. Early lichen planus may be confused with vulvar eczema, and in the setting of significant pruritus, there may be superimposed lichen simplex chronicus. For hypertrophic disease, vulvar intraepithelial neoplasia, squamous cell carcinoma and lichen simplex chronicus are the major differential diagnoses.

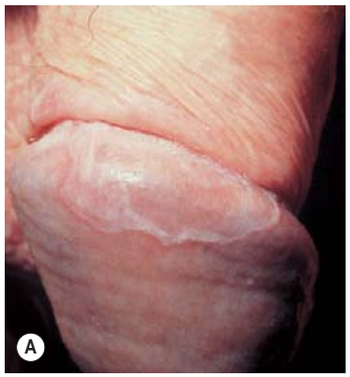

Fig. 73.6 Lichen planus. A An annular band is seen on the glans of the penis. This is a typical finding. **B** Erosive lichen planus of the vulva with fissures and an extensive white lacy pattern. *A, Courtesy, R Turner, MD.*

Treatment

The treatment of genital lichen planus is outlined in Table 73.2. Potent or moderately potent corticosteroid ointments will control most symptoms of classic genital lichen planus, as the disease is usually self-limiting. Hypertrophic disease may require intralesional corticosteroids.

The management of erosive lichen planus is more difficult, as the disease is often more persistent. The majority of patients will respond to a 3-month course of topical clobetasol propionate 0.05% (as described for lichen sclerosus) and thereafter can be maintained on moderately potent corticosteroids[15]. A combination of a moderately potent corticosteroid with a topical antifungal cream (e.g. econazole) may be as effective as more potent corticosteroids, particularly for maintenance therapy. For more resistant disease, there are anecdotal case reports of benefit from topical tacrolimus, systemic immunosuppressants (e.g. mycophenolate mofetil), and oral hydroxychloroquine. Low-dose weekly methotrexate, as for oral erosive lichen planus, may be helpful for severe disease[16]. Tricyclic antidepressants can be used to treat an associated vulvar pain syndrome. Erosive vaginal disease may require surgery to lyse adhesions, and the regular use of vaginal dilators with a corticosteroid ointment may help prevent recurrence.

Long-term evaluation of these patients is advised because of the risk of malignant transformation. In our study of a cohort of women with erosive lichen planus (and a mean follow-up period of 72 months), a 2.4% incidence of squamous cell carcinoma development was observed[15]. For further details on the treatment of lichen

THERAPIES FOR ANOGENITAL LICHEN PLANUS
FIRST-LINE
Soap substitutes and emollients (3) Superpotent topical corticosteroids (2) For vaginal disease, corticosteroid foams*, enemas*, suppositories* or ointments (± dilators) (2)
SECOND-LINE
Longer-term maintenance with superpotent topical corticosteroids or combined moderately potent corticosteroid/antifungal/antibacterial preparations (2) Surgery to correct narrowing of introitus and reverse clitoral burying in women or circumcision in men (3) Topical calcineurin inhibitors (3) Intralesional corticosteroid (hypertrophic disease) (3) Systemic immunosuppressants (3) Systemic antibiotics (minocycline ± nicotinamide) (3)
*Available for the treatment of inflammatory bowel disease.

planus, including systemic agents for severe, refractory disease, see Chapter 11.

ZOON'S BALANITIS/VULVITIS

Synonyms: ■ Plasma cell balanitis/vulvitis ■ Vulvitis/balanitis circumscripta plasmacellularis ■ Zoon's erythroplasia

Key features

- Male predominance
- Erythematous, moist, speckled, discrete plaques
- Involvement of adjacent surfaces produces "kissing" lesions in men
- In men, cured by circumcision

Introduction

There is no doubt that this condition occurs in men, but its existence as a separate entity in women has been questioned. Many of the clinical features in women are indistinguishable from those of erosive lichen planus, mucous membrane pemphigoid or lupus erythematosus, and the lichenoid features histologically overlap with erosive lichen planus. Moreover, in many of the reported cases in women, it is not possible to exclude these three diagnoses.

Epidemiology

Zoon's balanitis may occur at any age but is usually seen from the third decade onwards in uncircumcised men.

Etiology

The etiology is unknown, but poor penile hygiene or chronic irritation from warmth or rubbing has been suggested. The condition does not occur in circumcised men.

Clinical features

In men, the lesions on the glans penis may be asymptomatic or give rise to pruritus or dysuria. The lesions are erythematous, discrete, moist plaques with a "cayenne pepper" speckled appearance and an orange hue. "Kissing" lesions are typical with involvement of adjacent, touching areas, e.g. around the urethral meatus (Fig. 73.7). Shallow erosions may resolve slowly, leaving a rusty stain[17].

In women, erythematous plaques similar to those in men may be seen anywhere on the vulva. Lesions may be asymptomatic or cause dyspareunia, dysuria, pruritus or pain.

Fig. 73.7 Zoon's balanitis. There are moist "kissing" lesions on adjacent surfaces of the glans and prepuce.

Pathology

The typical histologic picture is a dense lichenoid infiltrate in the upper and mid dermis with an abundance of plasma cells. Additional features include "lozenge-shaped" keratinocytes, vascular proliferation, hemosiderin deposition and erythrocyte extravasation.

Differential diagnosis

In order to establish the diagnosis, a biopsy is usually performed. The major disorder in the differential diagnosis is erosive lichen planus, but when the plaques are well demarcated, the possibility of cutaneous malignancy (e.g. squamous cell carcinoma *in situ* and extramammary Paget's disease) must be considered.

Treatment

In men, a circumcision will almost always cure the disease. Potent topical corticosteroids may provide some symptomatic relief, but medical measures are generally ineffective.

EPITHELIAL DISORDERS OF THE ANOGENITAL REGION

Dermatitis

Key features

- Appearance ranges from mild erythema to gross lichenification
- Pruritus and soreness are the main complaints
- A mixed etiology is common
- Exogenous irritants and allergens must be sought

Introduction

Although anogenital dermatitis has traditionally been subdivided into endogenous dermatitis (e.g. seborrheic dermatitis and atopic dermatitis), lichen simplex chronicus, and exogenous dermatitis (e.g. allergic or irritant contact dermatitis), in practice it is often difficult to distinguish between these subtypes. A mixed picture, in which endogenous dermatitis is worsened by exogenous irritants or allergens, is commonly observed. Lichen simplex chronicus may develop secondarily to other anogenital diseases such as candidiasis, psoriasis and lichen sclerosus.

Pathogenesis

In an Oxford study, 97% of patients with vulvar dermatitis had an endogenous predisposition, having either an atopic background or

seborrheic dermatitis[18]. The anogenital area is susceptible to irritants, and allergic contact dermatitis is very prevalent in this site; the latter is usually due to topical medications. Psychological issues and local environmental problems such as heat, sweating and over-cleansing may be contributing factors.

Clinical features

The cutaneous features are varied, ranging from mild, usually poorly demarcated erythema to gross lichenification (Fig. 73.8). Symptoms include pruritus (Figs 73.9 & 73.10), soreness and superficial dyspareunia in women. In lichen simplex chronicus, there is unremitting itching plus scratching or rubbing. Fissuring is common, especially perianally. The typical anogenital sites affected are the labia majora and the mons pubis in women, the crura and scrotum in men, and the perianal area in both sexes. Lichenification is most often seen on the scrotum in men and the labia majora in women. Signs of seborrheic dermatitis, e.g. a scaly scalp and greasy scaling and erythema of nasolabial folds and eyebrows as well as erythema at other flexural sites (inframammary, intergluteal fold and axillae), should be sought. Atopic dermatitis at other sites will usually be obvious from the history or examination.

Differential diagnosis

The key to making the diagnosis is a thorough dermatologic examination. The diagnosis is usually made on the basis of clinical appearance, but a skin biopsy can be helpful in excluding other diagnoses. Plaques of psoriasis are often more well defined than those of dermatitis. Extramammary Paget's disease should also be considered, but these lesions are also sharply demarcated. It is important to identify irritants and possible allergens through a careful history and possibly patch testing. In addition, bacterial and *Candida* cultures should be performed to exclude superimposed infection, which is common in the anogenital region. Early lesions of lichen sclerosus may be indistinguishable from dermatitis.

Treatment

Treatment is directed at reducing pruritus and soreness. If the area is acutely inflamed, potent topical corticosteroids, often in combination with topical antifungal agents, topical antibacterial agents and/or topical immunomodulators, are helpful. Over a period of a few weeks, the topical corticosteroid can be tapered to one that is moderately potent.

Fig. 73.8 Vulvar dermatitis. Lichenification is prominent. The underlying diagnosis was atopic dermatitis.

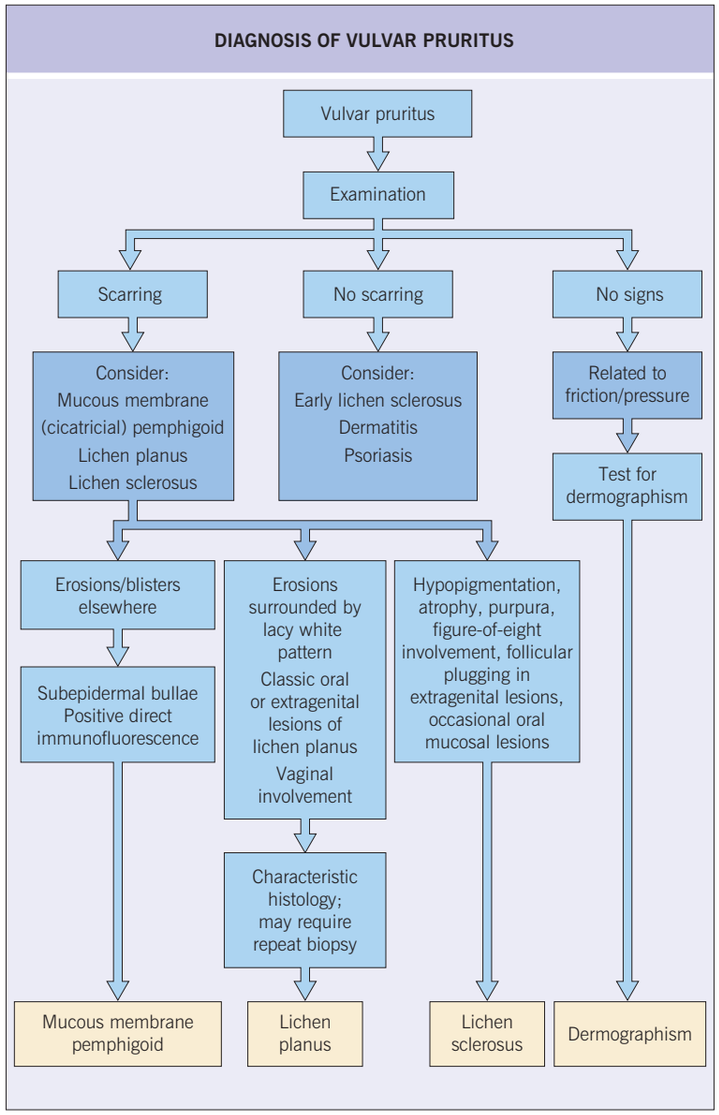

Fig. 73.9 Diagnosis of vulvar pruritus.

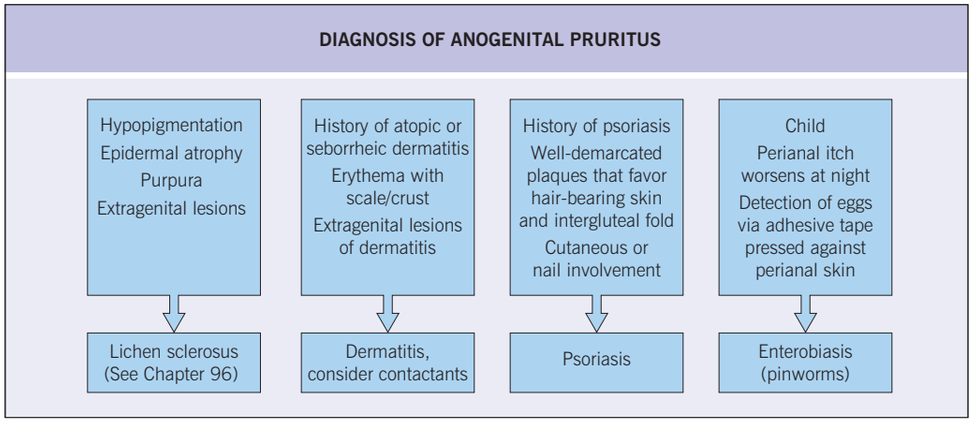

Fig. 73.10 Diagnosis of anogenital pruritus. Histologic evaluation may be required to confirm the clinical diagnosis (e.g. lichen sclerosus) or to exclude more unusual etiologies (e.g. extramammary Paget's disease). Systemic contact dermatitis reactions in this region may also be very pruritic.

The regular use of bland emollients and the substitution of an emollient for soap should be advised in all cases. Irritants, e.g. fragranced bath products, soap and medicated wipes, must be avoided. Exacerbating factors, including stress, heat, excessive washing and candidiasis, should be identified. When lichenification is present, it is especially important to break the itch–scratch cycle. Additional therapies include sedative antihistamines or tricyclic antidepressants, usually doxepin, at bedtime (see Ch. 6).

Contact Dermatitis

It is important to consider the possibility of contact dermatitis in any patient with dermatitis, a history of reactions to topical medications, or treatment-resistant disease. Contact dermatitis of the anogenital region may be irritant or allergic (see Chs 14 & 15)[19]. Irritant contact dermatitis is seen in infants as diaper dermatitis and in older patients as a consequence of overzealous cleanliness, urinary or fecal incontinence, chronic diarrhea, or bowel disease including tumors or inflammatory bowel disease.

Allergic contact dermatitis of the anogenital region occurs in men and women[20]. Relevant allergens include topical anesthetics, corticosteroids, fragrances, preservatives, rubber chemicals and spermicides. Type I immediate hypersensitivity reactions may occur to latex and seminal fluid, and there is the possibility of consort contact dermatitis. Allergic contact dermatitis must be considered in all patients with perianal dermatitis, because medications (topical, per anum) are frequently used by both sexes. Hemorrhoid creams and medicated toilet paper are common culprits.

Psoriasis

Key features

- Erythematous well-defined plaques
- Evidence of psoriasis elsewhere on total-body skin examination
- Intergluteal cleft frequently affected
- Poor response to treatment

Psoriasis of the anogenital region may look quite different from psoriasis at other sites (see Ch. 8). The typical silvery scale is lost, as in other flexural sites such as the axillae and submammary region.

Clinical features

In women, erythematous, smooth, clearly demarcated plaques typically affect the labia majora and the mons pubis. Psoriasis is usually confined to the hair-bearing areas, so the labia minora are unaffected. Men may have circumscribed plaques on the glans penis and shaft of the penis (Fig. 73.11). Persistent, painful fissuring of the perianal area and the intergluteal cleft can be a severe problem in both sexes.

Differential diagnosis

Often the diagnosis is very straightforward, established from a combination of the clinical appearance in the genital region plus typical lesions elsewhere on the body or classic nail changes. Seborrheic dermatitis may be difficult to distinguish from psoriasis, and, sometimes, clear features of both psoriasis and seborrheic dermatitis are seen in the same patient, when the term "sebopsoriasis" seems appropriate. The differential diagnosis includes tinea cruris (especially if there are pustules, an active border, extension of lesions onto the buttock or upper inner thigh, and/or concomitant tinea pedis or unguium) and erythrasma. On the glans penis, reactive arthritis (formerly Reiter's disease) may provoke lesions identical to those of psoriasis.

Treatment

Unfortunately, topical therapy for anogenital psoriasis is not entirely satisfactory. Many topical agents suitable for use on the body, such as coal tar, anthralin, vitamin D derivatives or retinoids, may be too irritating in flexural sites. Moderately potent topical corticosteroid–antibiotic combinations remain the most useful therapy; however, in intertriginous sites, corticosteroid-induced atrophy remains a concern. Topical tacrolimus or pimecrolimus may also be helpful in such occluded sites. Some patients will improve when a systemic agent is used (e.g. methotrexate, cyclosporine, TNF inhibitors), usually for widespread disease.

Fig. 73.11 Psoriasis of the penile shaft. Well-demarcated erythematous plaque with slight scale. Similar lesions can be seen in patients with reactive arthritis (formerly Reiter's disease). *Courtesy, Jean L Bolognia, MD.*

PREMALIGNANT AND MALIGNANT LESIONS

Intraepithelial Neoplasia (Vulvar, Penile, Anal)

Synonyms: ■ Bowen's disease ■ Bowenoid papulosis ■ Erythroplasia of Queyrat ■ Squamous cell carcinoma *in situ*

Key features

- Premalignant condition
- Human papillomaviruses are a common association

Introduction

The term "intraepithelial neoplasia" defines an intraepithelial change within anogenital epithelium that is premalignant. On the vulva it is termed VIN (vulvar or vulval intraepithelial neoplasia); on the penis, PIN (penile intraepithelial neoplasia); and on or around the anus, AIN (anal intraepithelial neoplasia). The terminology has been very confusing and it is now recommended that the terms Bowen's disease, erythroplasia of Queyrat, and bowenoid papulosis should not be used for lesions in the anogenital area. However, dermatologists still recognize a distinct clinical variant, bowenoid papulosis, characterized by discrete papules in a younger age group and a tendency for spontaneous regression. Additionally, some authorities believe that erythroplasia of Queyrat and Bowen's disease remain useful terms in men[21].

Epidemiology

It may occur at any age. The incidence in young women is rising.

Pathogenesis

Oncogenic human papillomaviruses are implicated in many cases of intraepithelial neoplasia (chiefly HPV types 16, 18, 31 and 33). There is an association with smoking and immunosuppression, including HIV infection. Lichen sclerosus and lichen planus are also predisposing factors.

Pathology

Intraepithelial neoplasia is characterized by nuclear hyperchromasia, disorderly maturation of keratinocytes, and coarse nuclear chromatin. Multiple mitotic figures are usually visible above the basal layer. VIN

Fig. 73.12 Penile intraepithelial neoplasia. Persistent erythema not responding to topical corticosteroids. *Courtesy, R Turner, MD*

Fig 73.13 Bowenoid papulosis variant of intraepithelial neoplasia. A Multiple red–brown to brown papules on the shaft of the penis. **B** Coalescence of red–brown to brown papules on the upper inner thigh. *B, Courtesy, Robert Hartman, MD.*

was originally graded 1–3 depending on the degree of abnormalities within the epidermis. More recently, VIN was reclassified into *usual type* VIN associated with HPV infection and a *differentiated type* that arises in the setting of lichen sclerosus or lichen planus[22].

Clinical features

The clinical presentation is varied. Erythematous well-demarcated plaques that look similar to plaques of Bowen's disease in extragenital sites may occur on the vulva, or the keratinized epithelium of the penis in men. Alternatively, warty white plaques, erosions or hyperpigmented patches may be seen. Shiny erythematous plaques may occur on the glans and prepuce of the uncircumcised male (erythroplasia of Queyrat; Fig. 73.12). In patients with bowenoid papulosis-type lesions, distinct red–brown papules are seen on the genitalia (Fig. 73.13A), which may extend to the inner thighs (Fig. 73.13B). Differentiated VIN usually presents as small ulcers or keratotic plaques.

Differential diagnosis

Intraepithelial neoplasia must be distinguished from inflammatory conditions such as lichen sclerosus, as well as condyloma acuminatum, Zoon's balanitis/vulvitis, and cutaneous malignancies, in particular, invasive squamous cell carcinoma.

Treatment

Treatment options depend on the site, the extent of disease, the age of the patient, and the type of intraepithelial neoplasia (see above). In localized disease, a biopsy to establish the diagnosis, followed by local excision, is preferred, so long as the surgery is not too mutilating. Recurrence is a problem with all treatment modalities. In men, circumcision is offered, as this may reduce the risk of progression to invasion[21]. Observation may be an option in selected cases if treatment is not feasible; however, if progression is observed, then surgical excision is necessary. Differentiated VIN associated with lichen sclerosus or lichen planus has a high risk of progression to invasive disease and must be excised. Cryosurgery is rarely indicated in the opinion of the authors, as recurrence rates are very high; laser therapy also has a high recurrence rate. Medical treatments such as topical fluorouracil or imiquimod may be helpful in some cases although local side effects may be severe. In some, but not all, patients, imiquimod can lead to histologic regression of disease and viral clearance[23]. In widespread disease, simple vulvectomy has been performed, but only after exhaustion of all other options.

Long-term evaluation is recommended and should include serial examinations and cervical and anal cytology, especially in the setting of HIV infection. Examination of sexual partners should be advised.

Invasive Squamous Cell Carcinomas

Key features

- Most common tumor in the anogenital region
- Etiology is different from squamous cell carcinomas arising in actinically damaged skin

Epidemiology

Squamous cell carcinomas (SCCs; see Ch. 108) most frequently occur in the elderly, although they may occur in younger adults. The incidence of genital SCC in women is rising.

Pathogenesis

HPV infection and lichen sclerosus account for the majority of SCCs of the anogenital region. HPV-associated tumors tend to arise in the younger adult, while lichen sclerosus-related tumors occur in postmenopausal women or older men[24,25]. Smoking and immunosuppression are also risk factors. SCC is very rare in circumcised men, and the presence of a foreskin, which can lead to trapping of smegma and low-grade inflammation, may predispose one to the development of carcinoma. SCC of the genital region is rarely due to cumulative UV light exposure[24], although there have been reports of SCC of the penis and scrotum developing in men who had received multiple PUVA treatments. Tar, chimney soot, asbestos and petroleum products are known carcinogens in the case of scrotal SCC.

Clinical features

In men, the majority of lesions present on the glans, the coronal sulcus or the prepuce as ulcers or plaques. The ulcers often have a heaped-up

edge (Fig. 73.14). In the uncircumcised man, delay in diagnosis may occur because of an associated phimosis masking the tumor. Although any area on the vulva may be involved, the labia are the most frequent sites. The clinical presentation varies from non-healing ulcers or fissures to nodules and plaques. Invasive anal carcinoma may arise from the anal margin or from within the lower anal canal.

Differential diagnosis

SCC must be distinguished from other tumors such as amelanotic melanomas or basal cell carcinomas. It is important to biopsy any suspicious lesion that develops in the anogenital area, particularly in the context of predisposing diseases such as lichen sclerosus, HPV infection and HIV infection.

Treatment

Treatment is usually surgical, with the extent of surgery dependent on both the size and depth of invasion. Consultation with a gynecologist or urologist with expertise in oncology is usually indicated. In addition to excision of the primary tumor, histologic examination of regional lymph nodes may be necessary, depending on the clinical stage. Microscopically controlled surgery can be utilized in an attempt to avoid mutilating surgery.

Anogenital Melanoma (see Ch. 113)

Key features

- Rare tumor not related to UV exposure
- Usually arises *de novo*, i.e. in the absence of a pre-existing benign melanocytic neoplasm
- Poor prognosis, due primarily to depth of invasion at time of diagnosis
- Mucosal lentiginous melanoma is the most common histologic type

Introduction

Although anogenital melanoma is a rare tumor, melanoma is the second most common primary tumor of the vulva in women.

Epidemiology

The incidence of vulvar melanoma has been estimated at 0.19 per 100 000 in a Swedish population[26], but similar figures are not available for men. Vulvar melanomas account for 0.3% of all melanomas in women. Compared with melanomas elsewhere, vulvar and penile melanomas occur in an older population, typically in the seventh decade, although they may appear at any age.

Pathogenesis

Melanoma is a multifactorial disease, but two of the major factors – sun exposure and melanocytic nevi – play a minimal (nevi) or no known (UV) role in anogenital melanoma. The latter may explain why the number of new cases of vulvar melanoma is falling while the incidence of cutaneous melanomas in the Western world is rising.

Fig. 73.14 Invasive squamous cell carcinoma of the foreskin. This patient with psoriasis had received PUVA therapy without genital protection.

Clinical features

In women, melanomas may present with bleeding, a "lump" or pruritus. Amelanotic melanomas account for approximately one-quarter of cases. Melanoma can arise throughout the genital tract, including the cervix and the vagina, as well as any site on the vulva. The labia majora and the clitoris are the most common tumor sites. In men, a crusted nodule is the most frequent presentation[27]. Most tumors arise on the glans penis, although they may occur at any site, including the scrotum.

The prognosis for anogenital melanoma is significantly worse than for the more common cutaneous melanomas. Reported 5-year survival rates vary from 35% to 60% for vulvar melanomas, less than 30% for penile melanomas, and less than 10% for anorectal melanomas. A key factor is the greater Breslow thickness due to delay in diagnosis, but it remains to be determined whether anogenital melanomas are fundamentally more aggressive.

Pathology

On genital skin, mucosal lentiginous melanoma is the most frequent histologic type of melanoma. Nodular and superficial spreading melanomas occur less frequently. Mucosal lentiginous melanomas show many histologic similarities to acral lentiginous melanomas. As with cutaneous melanoma, prognosis is determined by tumor thickness at presentation.

Differential diagnosis

For macular lesions, the major differential is a genital lentigo. Palpable pigmented melanomas must be distinguished from atypical-appearing seborrheic keratoses, melanocytic nevi and bowenoid papulosis. Melanocytic nevi that are superimposed on lichen sclerosus may have an atypical clinical appearance and the histologic features of a persistent nevus. Anal amelanotic melanoma may initially be misdiagnosed as hemorrhoids.

Treatment

Due to the rarity of the tumor, there have been no randomized therapeutic trials. Vulvar and penile melanomas are therefore treated similarly to cutaneous melanoma. Radical vulvectomy with bilateral lymph node dissection was the historical practice, but less aggressive treatment has gained favor over the past 25 years. Although the surgical margins for cutaneous melanoma have been reduced significantly, the exact surgical margins for anogenital melanomas are still debated. The role of prophylactic inguinal node dissection and sentinel lymph node biopsy is also controversial. Palliative radiotherapy has been tried for very extensive local disease. Immunotherapy (e.g. ipilimumab) may improve survival rates and depending upon the presence of specific mutations, targeted therapies such as tyrosine kinase inhibitors could be considered.

Basal Cell Carcinoma (see Ch. 108)

Basal cell carcinoma may occur in the anogenital area and is usually diagnosed as a squamous cell carcinoma prior to biopsy or excision. Rarely, it has been reported to metastasize.

Extramammary Paget's Disease

Key features

- Rare intraepithelial adenocarcinoma
- May be primary or secondary to an underlying malignancy
- Associated with an underlying visceral malignancy in 10–20% of patients

Introduction

Extramammary Paget's disease can be *primary*, arising as an intraepithelial adenocarcinoma, or *secondary*, due to pagetoid spread of an adjacent or contiguous *in situ* or invasive neoplasm. Extramammary Paget's disease may become invasive and metastasize via the lymphatic system.

Epidemiology

Elderly Caucasian women most commonly develop this malignancy, but in Japan there is a male predominance.

Etiology

The histogenesis of primary Paget's disease has been long debated but Toker cells have been proposed as the cell of origin[28]. Secondary Paget's disease represents a cutaneous extension of an underlying adnexal adenocarcinoma (see Ch. 111) or an underlying visceral malignancy (most commonly colorectal or urothelial, but it may also be cervical, prostatic, ovarian or endometrial).

Clinical features

The vulva in women and the perianal region in men are the most commonly affected sites[29,30]. There may be associated pruritus or burning or the lesions may be asymptomatic. A slowly expanding erythematous plaque is typical, with a sharp demarcation between normal and involved skin (Fig. 73.15A,B). Scattered areas of white scale and erosion can give rise to a "strawberries and cream" appearance.

Pathology

The diagnosis must be confirmed by histologic examination. Vacuolated Paget cells in the epidermis are distinctive (Fig. 73.15C), but immunohistochemical staining is necessary to exclude the important differential diagnoses of pagetoid melanoma and intraepithelial neoplasia (Fig. 73.16), as well as to help differentiate between primary and secondary disease[31]. An underlying adnexal tumor must be sought.

Differential diagnosis

Extramammary Paget's disease may be misdiagnosed as dermatitis or lichen simplex chronicus, leading to a delay in diagnosis. Psoriasis, erosive lichen planus and candidiasis are additional entities that might be confused with this neoplasm.

Treatment

A thorough search for internal malignancies associated with extramammary Paget's disease should be performed, especially when suggested by the immunocytochemical findings and location (e.g. an internal malignancy is approximately five times more likely when there is perianal as opposed to vulvar or penoscrotal involvement). The evaluation should include a full cutaneous and lymph node examination, colonoscopy, cystoscopy, and, in women, a complete pelvic and breast examination, plus imaging of the pelvis and a mammogram. In men, a prostate-specific antigen (PSA) level and prostate examination are also required.

In the anogenital region, treatment is by Mohs micrographic surgery or wide local excision; however, the multifocal nature of extramammary Paget's disease and the fact that clinically inapparent extensions of the disease may be present make recurrences very frequent. Other treatment options include topical imiquimod, radiotherapy, photodynamic therapy, CO_2 laser ablation, and topical 5-fluorouracil. Combination therapy is often employed.

Long-term follow-up is recommended for these patients.

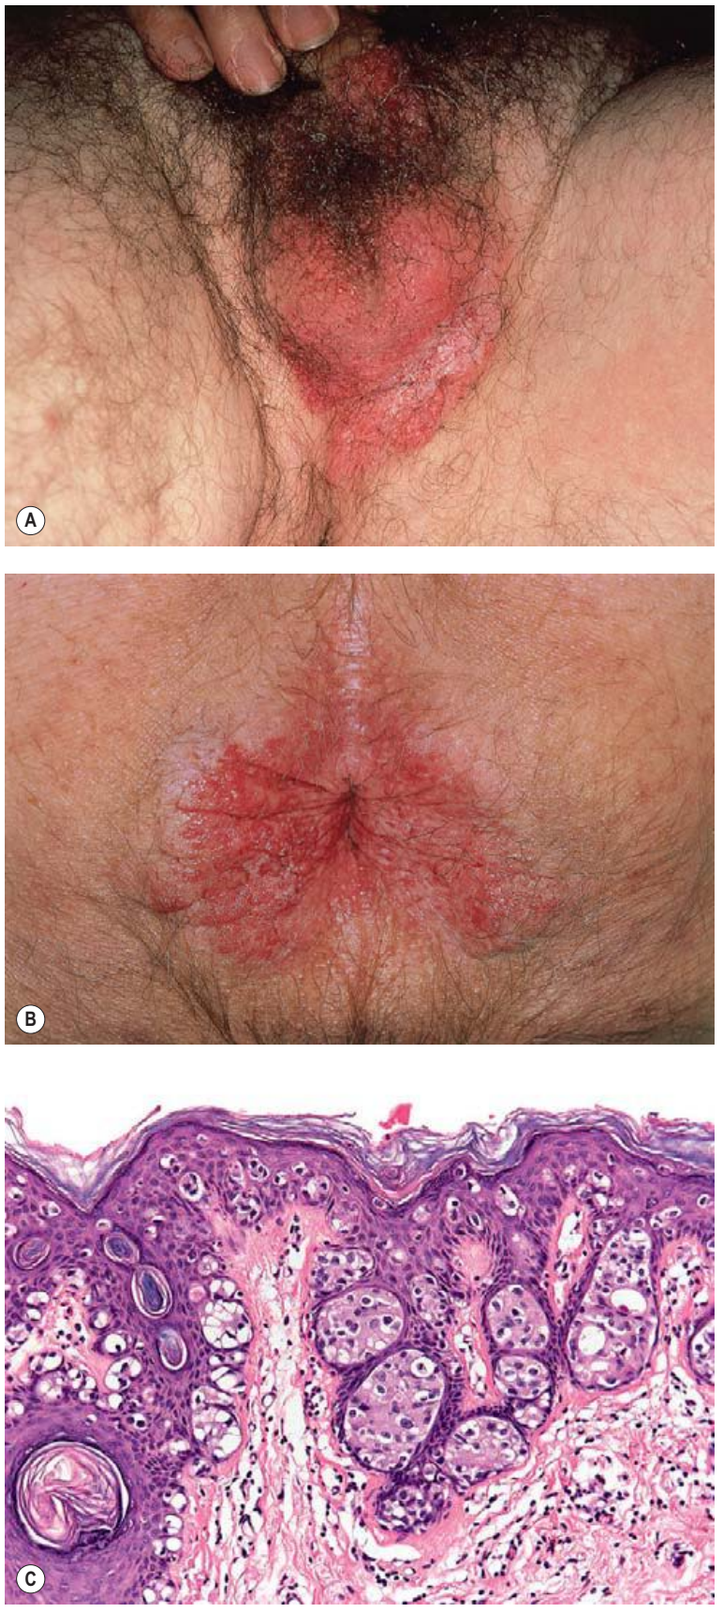

Fig. 73.15 Extramammary Paget's disease. A Erythematous plaque with hydrated scale at the base of the scrotum. **B** Well-demarcated perianal plaque with both erosions and scale, giving rise to a "strawberries and cream" appearance. **C** Photomicrograph demonstrating pagetoid cells within the epidermis, both as single cells and in nests. *B, Courtesy, Kalman Watsky, MD. DYSESTHETIC GENITAL PAIN SYNDROMES

The term "dysesthetic genital pain syndrome" encompasses a number of disorders in which the clinical appearance is normal despite the patient's experience of severe disabling pain (notably in the absence of a clinically identifiable neurologic disorder; Fig. 73.17). Although still a matter of debate, these disorders are usually considered to be regional pain syndromes. Unmedullated C fibers transmit pain and touch, and it is now recognized that these nerve fibers can be remodeled after a stimulus has passed, explaining why perception of subsequent stimuli may be altered. Relatively minor inflammation or trauma, often unrecalled, may precipitate the onset of pain. Vulvar pain has been recently reclassified by the International Society for the Study of Vulvovaginal Disease (ISSVD; Table 73.3)[32].

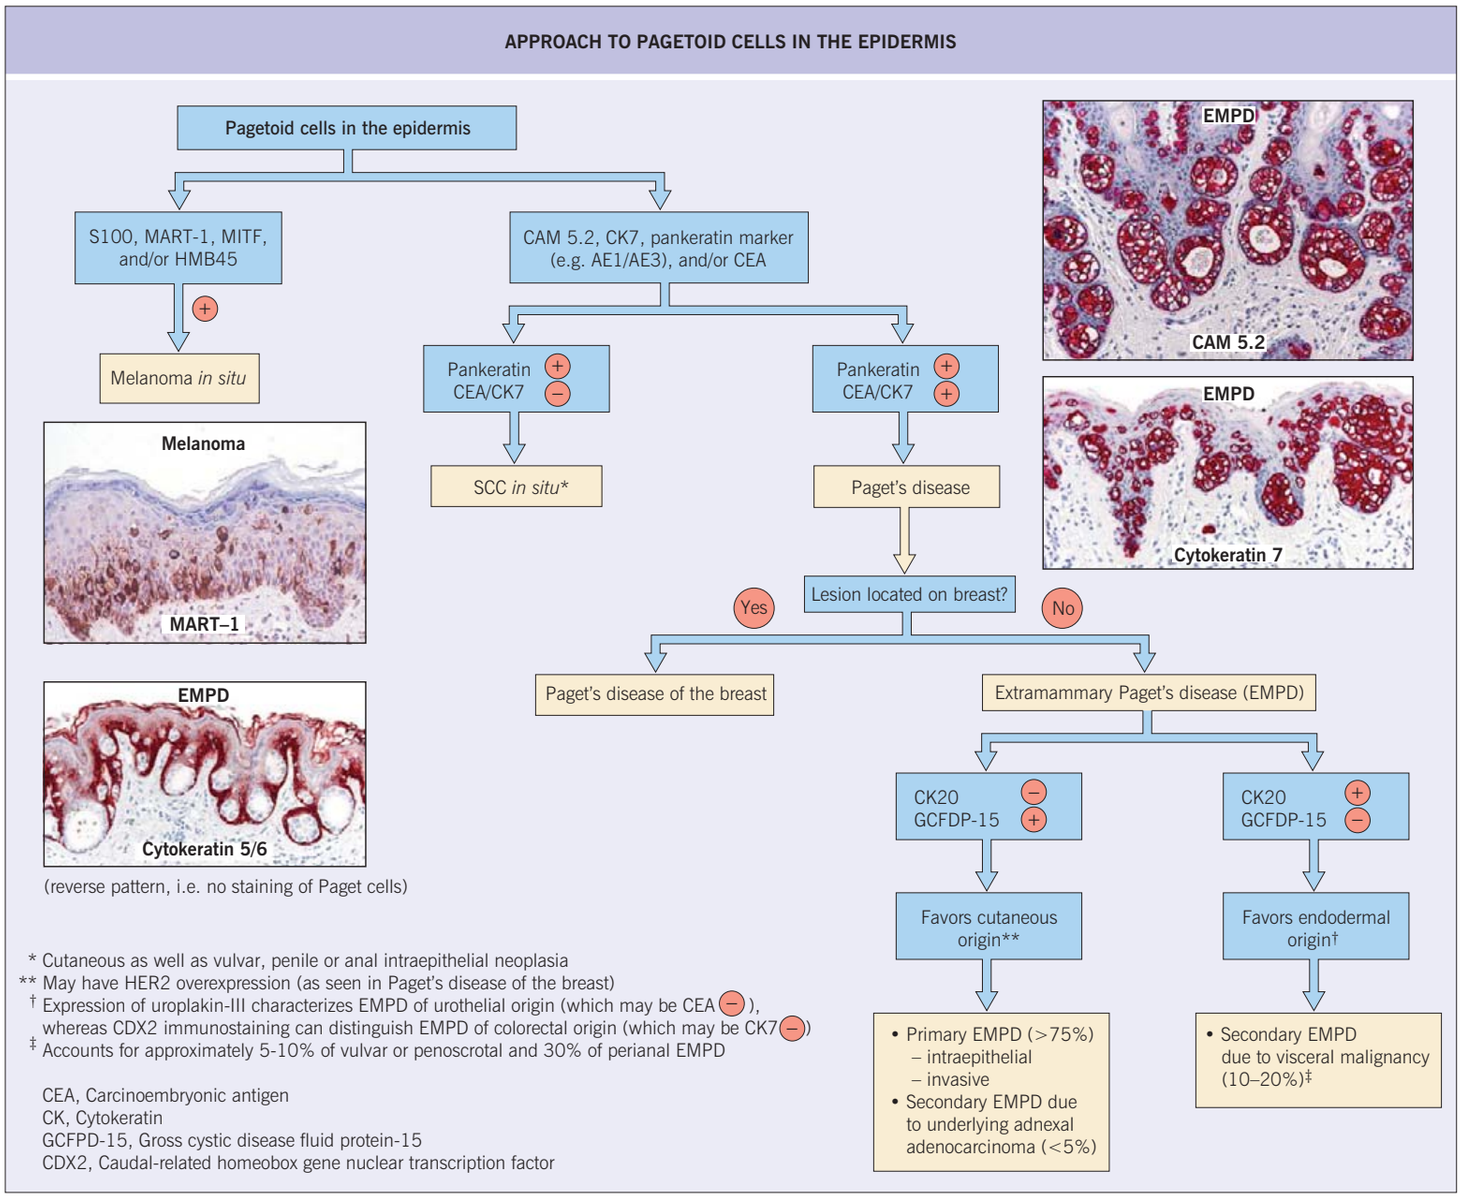

Fig. 73.16 Algorithm for the approach to Paget cells in the epidermis. The CAM 5.2 immunohistochemical stain is positive in >95% of Paget's disease (mammary and extramammary) and approximately one-third of Bowen's disease; it stains low-molecular-weight keratins. AE1 stains most subfamily A keratins (but not 12, 17 and 18) while AE3 stains subfamily B keratins.

Localized Vulvodynia (Vestibulodynia)

Key features

- Superficial dyspareunia
- Tenderness on localized pressure within the vulvar vestibule
- Occurs in young, sexually active women

Introduction

"Localized vulvodynia" is now the preferred term for this specific subtype of the vulvar pain syndrome, characterized by superficial dyspareunia and point tenderness within the vestibule, often at 5 and 7 o'clock[33].

Clinical features

This particular localized pain syndrome occurs in the young premenopausal sexually active woman whose main complaint is one of dyspareunia on penetration. Insertion of tampons may be impossible. The vulva looks entirely normal but there is pain when the vestibular area is pressed by a cotton-tipped applicator.

Differential diagnosis

Localized vulvodynia must be differentiated from other causes of vulvar pain (see Table 73.3). Hymenal and posterior vestibule fissures and herpes simplex must be excluded. A fungal culture should be obtained to exclude *Candida* infection.

Treatment

It is important to explain the diagnosis in detail to the patient, providing written information and patient support group information where possible. Regular application of bland emollients and avoidance of irritants such as detergents and fragranced products are helpful. Local desensitization by applying emollients with increasing pressure over weeks is helpful in our experience but there are very few treatments for this condition that have been supported by clinical trials. Topical local anesthetic agents (e.g. 5% lidocaine) applied before intercourse may be helpful. Tricyclic antidepressants, starting with small doses (e.g. 10 mg)

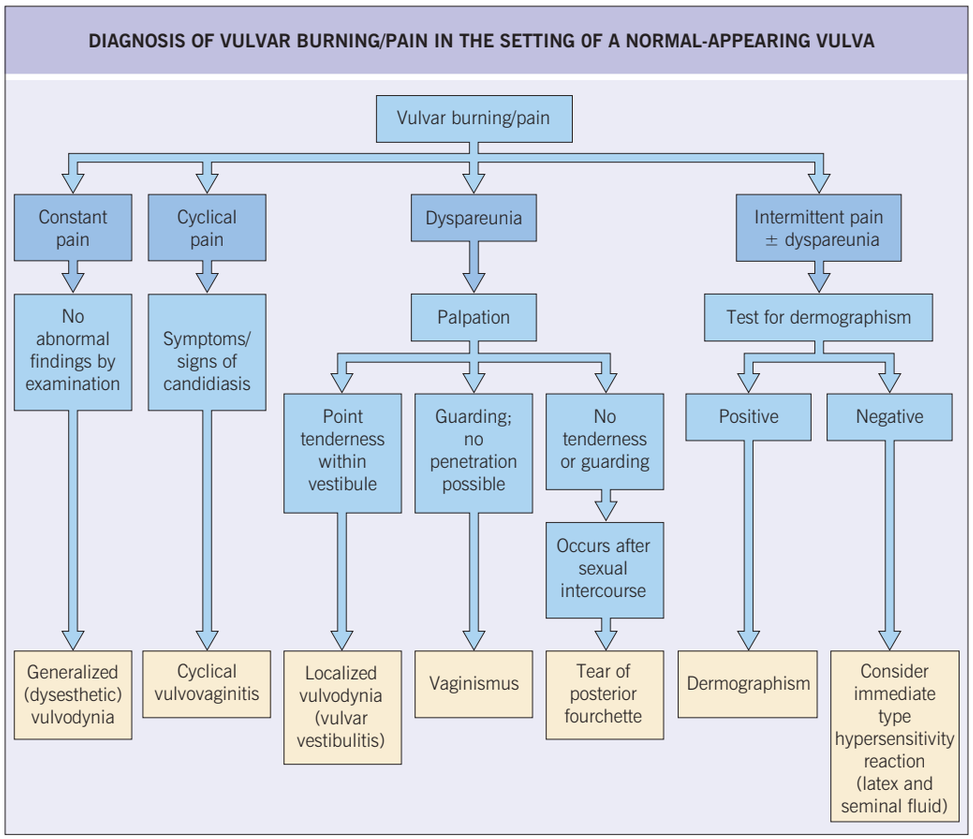

Fig. 73.17 Diagnosis of vulvar burning/pain in the setting of a normal-appearing vulva.

ISSVD TERMINOLOGY AND CLASSIFICATION OF VULVAR PAIN
VULVAR PAIN RELATED TO A SPECIFIC DISORDER
• Infectious (e.g. candidiasis, HSV infection, herpes zoster) • Inflammatory (e.g. lichen planus, immunobullous disorders) • Neoplastic (e.g. Paget's disease, squamous cell carcinoma) • Neurologic (e.g. herpes neuralgia, spinal nerve compression)
VULVODYNIA
Localized (vestibulodynia, clitorodynia, hemivulvodynia, etc.)
• Provoked (sexual, non-sexual, or both) • Unprovoked • Mixed (provoked and unprovoked)
Generalized (dysesthetic vulvodynia)
• Provoked (sexual, non-sexual, or both) • Unprovoked • Mixed (provoked and unprovoked)

Table 73.3 ISSVD terminology and classification of vulvar pain (2003).

of amitriptyline nightly and increasing slowly (over several weeks) to 100 mg nightly if necessary, are often used; nortriptyline is a less sedating alternative. Topical corticosteroid/antifungal ointments or oral gabapentin have been effective in some patients. There is increasing evidence for the role of surgery in selected cases[34]. Some evidence exists for the efficacy of pelvic floor electromyography and biofeedback, and there are anecdotal reports of the benefits of a low oxalate diet and oral calcium citrate.

Generalized Vulvodynia/Scrotodynia (Dysesthetic Vulvodynia/Scrotodynia)

Key features

- Burning and/or pain
- Clinical examination of vulva or scrotum is normal

Introduction

Persistent burning pain is characteristic and patients have often consulted many doctors before the correct diagnosis is made. Depression may be a feature of any chronic pain syndrome. There is an association with fibromyalgia and the irritable bowel syndrome.

Scrotodynia is probably analogous to vulvodynia; however, there is less published on the subject[35]. Precipitating events include sexual activity, exercise, friction and heat. Pain may also affect the penis.

Clinical features

Pain, often accompanied by a burning sensation, is felt over the entire vulva, scrotum or penis, and may extend down the thighs. The genital area may hurt even when nothing is touching it. Often, symptoms are worse on sitting or walking up stairs. Wearing of underwear may be impossible. On inspection, the scrotum or vulva looks entirely normal.

Differential diagnosis

Other causes of genital pain, e.g. infection (bacterial, viral or fungal), lichen sclerosus or lichen planus, must be excluded by examination before the diagnosis can be made. A potassium hydroxide (KOH) preparation and/or fungal culture to exclude candidiasis is essential. It is important to test for dermographism, as treatment with antihistamines may greatly benefit these patients.

Treatment

Treatment strategies are very similar to those for localized vulvodynia or scrotodynia (see above)[33]. In addition, acupuncture may be helpful. Referral to a pain clinic, with management by a special team of anesthesiologists and psychologists, is often useful. Some authors consider that early diagnosis and treatment may shorten the duration of symptoms. Despite a variety of treatments, there remains a group that fails to respond.

Cyclical Vulvovaginitis

Some women experience premenstrual exacerbation of their pain, and *Candida* infection has been implicated (see below). Fisher et al.[36] suggested that estrogen sensitivity may be an important factor.

BENIGN LESIONS OF THE GENITALIA
COMMON
• Epidermoid cysts • Pearly penile papules • Vestibular papillomatosis • Angiokeratomas • Urethral caruncle
LESS COMMON
• Fox–Fordyce disease • Syringomas • Idiopathic calcinosis of the scrotum • Hidradenoma papilliferum

Table 73.4 Benign lesions of the genitalia.

Anal Pain

Anal pain may occur in both men and women and it shares many features with vulvodynia and scrotodynia. Associated depression is frequent.

BENIGN LESIONS

A wide variety of benign lesions can be found in the anogenital area (Table 73.4). Some of the more important lesions are discussed below.

Epidermoid Cysts

Epidermoid cysts are frequently encountered on the glabrous labia majora and scrotum, and may be multiple. They are yellow, vary in size, and may become inflamed. Treatment is by excision, but this is only necessary if the cyst is symptomatic.

Vestibular Papillomatosis

Papillomas within the vestibule are found in approximately 45% of premenopausal women and 10% of postmenopausal women. They are pink, asymptomatic, fine projections. Women should be reassured that the finding is normal.

THE ANOGENITAL REGION AND SYSTEMIC DISEASE

Inflammatory Bowel Disease

Crohn's disease must be suspected in patients with recurrent abscesses, sinuses or fistulas in the perineal region. Often, multiple firm perianal skin tags are seen. Perianal disease may precede bowel symptoms by a number of years. Marked, firm, granulomatous labial swelling is rarely the initial presentation (see Ch. 93). A lesional biopsy will reveal non-caseating granulomas.

Zinc Deficiency

Zinc deficiency may be genetic, as in the autosomal recessively inherited condition acrodermatitis enteropathica, or acquired, as in premature babies or full-term infants who are breastfed. An extensive periorificial eruption is typical.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (see Ch. 91) may present with erythema, papulonodules or ulcers in the perineal area.

Behçet's Disease

Behçet's disease is a rare multisystem inflammatory disorder in which recurrent oral aphthae combine with some of the following clinical features: genital erosions or ulcers, arthritis, uveitis, neurologic disorders such as cranial nerve palsies and mono- and hemiparesis, arterial and venous thromboses, and pathergy (see Ch. 26). The disease is more prevalent in men and in those from the Mediterranean basin and Japan; it typically presents in young adults in their third or fourth decade of life. Recurrent flares and remissions are to be expected. Treatment is with a variety of immunosuppressive drugs or thalidomide.

INFECTIONS

Sexually transmitted infections (see Chs 78 & 81) and condylomata acuminata (see Ch. 79) are described elsewhere, but some miscellaneous infections that favor the anogenital region are discussed below.

Perianal Streptococcal Disease

The typical presentation is that of a 3- or 4-year-old boy with erythema and sometimes crusting of the perianal area[37] (see Ch. 74). Constipation is frequent because of the discomfort. The disease can be associated with guttate psoriasis and is frequently misdiagnosed as irritant dermatitis or candidiasis. Specimens for bacterial culture must be obtained. The group A β-hemolytic streptococcus is responsible. Treatment is with oral penicillin or erythromycin.

Recurrent Toxin-Mediated Perineal Erythema

Recurrent toxin-mediated perineal erythema is an unusual condition that presents 2–3 days after a throat infection as a fine diffuse macular erythema of the perineal region[38]. Marked local edema may be present and the hands may be similarly affected. Desquamation follows the erythema and the condition can be recurrent. Streptococcal or staphylococcal pharyngitis is the most common cause and the erythema is toxin-mediated. Long-term prophylactic penicillin may be beneficial in some patients.

Kawasaki Disease

Kawasaki disease is thought to be mediated by bacterial toxins, but the exact cause has not been elucidated. It is a disease of children. In up to two-thirds of cases, perineal erythema may be a presenting feature (see Ch. 81); additional findings include a strawberry tongue, fissured lips, fever and lymphadenopathy, followed by desquamation of the hands and feet. Coronary artery aneurysms may be life-threatening. Treatment is with aspirin and IVIg.

Fournier's Gangrene

Fournier's gangrene is a severe necrotizing infection of the external genitalia, perineum or perianal area that occurs in patients with an underlying predisposition such as diabetes or immunosuppression[39]. The infection is polymicrobial. Extensive surgical debridement with a prolonged course of systemic antibiotics is necessary.

Erythrasma

Pigmented patches or thin plaques with fine scale tend to occur in flexural areas, including the groin. Coral pink fluorescence under Wood's lamp examination is diagnostic. Distinction from dermatophytosis is usually possible clinically, as scaling is diffuse in erythrasma and there is no tendency toward central clearing.

Dermatophytosis

Chronic, slowly advancing, scaly erythematous lesions may be seen in the groin (tinea cruris) or the medial buttocks in addition to the upper thighs. Central clearing is often present and pustules may be seen; there is usually (if not always) concomitant tinea pedis and/or unguium. The diagnosis is made by microscopy and culture of skin scrapings.

Cutaneous Candidiasis

Key features

- *Candida* spp. are normal commensals of the gastrointestinal tract
- Precipitating factors must be sought, e.g. diabetes, systemic corticosteroids, systemic antibiotics

Introduction

Candidiasis is one of the most common infections of the genital and perianal skin. It is important to confirm the infection by microscopy (KOH preparation) and culture because many genital skin problems in men and women are erroneously attributed to candidiasis.

Epidemiology

Candida spp. are normal commensals in the gastrointestinal tract. In addition, approximately 15–30% of asymptomatic women are vaginal carriers of *Candida* spp.; during pregnancy, this rises to 40%[40].

Etiology

It seems likely that the development of candidiasis represents failure of a host response to the yeast[41]. Candidiasis is more commonly seen in uncontrolled diabetics, the immunosuppressed, and during treatment with broad-spectrum antibiotics, high-dose estrogen or topical corticosteroids. Copper-containing intrauterine devices may predispose to infection. Candidiasis can be sexually transmitted and this is probably most important in recurrent infections.

Clinical features

In men, balanitis, balanoposthitis, or a more widespread involvement of the perianal area, perineum and groin is seen. Balanitis is more common in the uncircumcised man. The skin is erythematous and glazed with yellow pustules and erosions. In severe infections, edema may prevent retraction of the foreskin.

Women complain of severe pruritus and vaginal discharge. Creamy white curds are visible on the vaginal walls, and there is vulvar erythema, but pustules are seen only rarely. In the postmenopausal woman, the atrophic mucosa may become dry, sore and erythematous as a result of a candidal infection.

In both men and women, candidiasis may affect the perianal area. In this site, sheet-like erythema is seen and fissuring is common. The inguinal-scrotal fold in men is a frequent site of involvement, and here, in addition to the erythema, the skin focally may appear white due to overhydration of the accompanying scale. Satellite lesions, including pustules, are frequently seen.

In babies, candidiasis is a common cause of diaper dermatitis. There may be rapid spread of erythema and pustules that typically affect the skin creases, unlike the more common irritant dermatitis. Rarely, a nodular ulcerated variant may occur.

Differential diagnosis

It is very important to establish the diagnosis because many inflammatory conditions of the genitalia such as lichen sclerosus and contact dermatitis are treated initially as a "yeast" infection. The presence of the pseudohyphae of *Candida* is not sufficient to make the diagnosis; the appropriate clinical signs must also be present. Subcorneal pustules and erosions are also seen in impetigo, but this is easily excluded by a bacterial culture. In women, other causes of a vaginal discharge include bacterial vaginosis and *Trichomonas*.

Treatment

It is essential to determine whether there are any underlying causes, for example, uncontrolled diabetes. Topical polyene or imidazole antifungals may suffice in localized balanitis or intertrigo. If there is severe pruritus, the addition of a mild topical corticosteroid may be helpful. In vaginal candidiasis, vaginal suppositories containing nystatin or an imidazole can be used. Single-dose oral treatment is an alternative, e.g. fluconazole 150 mg, for vaginal disease. In difficult infections, in the immunocompromised patient and in vulvar disease, more prolonged systemic treatment is necessary, e.g. fluconazole 50–100 mg daily for 14 days (level of evidence, 3). Antimicrobial therapies are discussed in more detail in Chapter 127.

Recurrent Candidiasis

Recurrent candidiasis can be defined as more than three episodes of candidiasis per year. Precipitating factors must be identified. Advice should be given on foreskin hygiene and keeping the perineal area cool with cotton underwear. Sexual transmission may be an important factor in recurrent candidiasis and, therefore, treatment of both partners may be justified. Three possible regimens are oral fluconazole 150 mg weekly for 6 months, clotrimazole 500 mg vaginal tablet weekly for 6 months, or itraconazole 200 mg BID orally once monthly for 6 months.

Cyclical Vulvovaginitis

Cyclical vulvovaginitis is recurrent vulvovaginitis with or without the typical candidal discharge. Pain is cyclical, corresponding to a particular phase of the menstrual cycle, and is associated with superficial dyspareunia. Although *Candida* cannot always be cultured, the vulvovaginitis is usually responsive to prolonged courses of oral antifungal medication.

EROSIVE GENITAL DISEASE

Erosions and ulcerations are seen in a wide variety of conditions (Table 73.5). Genital aphthae and HSV are common. Erosions may occur after scratching or rubbing or as a result of blister formation. To determine the cause of the erosions, it is essential to take a careful history and perform a full examination of the skin, including the mucosal surfaces. For example, a white lacy pattern on the buccal mucosa may suggest a diagnosis of lichen planus. Further investigations will be determined by the clinical appearance, but swabs for bacterial and fungal culture are often necessary. Biopsies of lesional skin for light microscopy and perilesional skin for direct immunofluorescence are indicated if an autoimmune blistering disorder is suspected.

Acquired Autoimmune Blistering Disorders

Introduction

Immunofluorescence (direct and indirect) is an essential investigation in suspected blistering conditions as it may be very difficult to

CAUSES OF GENITAL EROSIONS
Lichen sclerosus
Erosive lichen planus
Genital aphthae
Infection • Candidiasis • Impetigo (*Staphylococcus/Streptococcus*) • Herpes simplex viral infection or herpes zoster • Primary syphilis, chancroid • Cytomegalovirus, Epstein-Barr virus*, *Mycoplasma* • Tuberculosis
Squamous cell carcinoma and other malignancies
Intraepithelial neoplasia
Zoon's plasma cell balanitis/vulvitis
Acquired bullous diseases • Pemphigus vulgaris • Bullous pemphigoid • Mucous membrane (cicatricial) pemphigoid • Linear IgA bullous dermatosis • Epidermolysis bullosa acquisita • Erythema multiforme, Stevens–Johnson syndrome • Fixed drug eruption
Inherited bullous disease • Hailey–Hailey disease • Epidermolysis bullosa
Complex aphthosis – Behçet's disease, inflammatory bowel disease
Crohn's disease
Extramammary Paget's disease
Langerhans cell histiocytosis
Necrolytic migratory erythema, acrodermatitis enteropathica
Papular acantholytic dyskeratosis
Toxic erythema of chemotherapy
*Diagnosed via EBV IgM antibodies or PCR; favors female children and adolescents.

Table 73.5 Causes of genital erosions.

distinguish between the different blistering disorders on clinical grounds alone[42]. This is particularly true in the anogenital region.

Bullous pemphigoid (see Ch. 30)

Bullous pemphigoid is the most common blistering disorder of the elderly, although it may occur at any age: for example, localized vulvar pemphigoid has been described in children[43]. Bullous pemphigoid has a propensity to develop in flexural sites, therefore the genital region is frequently affected; scarring is not a feature of genital involvement. Tense blisters are seen arising from urticarial plaques or from normal skin. Mucosal involvement occurs in 50% of patients. A prodromal phase of pruritic urticarial plaques without blisters may be present for months or years.

Mucous membrane (cicatricial) pemphigoid (see Ch. 30)

Mucous membrane pemphigoid is a scarring blistering disorder. In the genital region, it is clinically indistinguishable from erosive lichen planus unless blisters are seen or described; thus, histology and immunofluorescence are essential (Fig. 73.18). Men report penile lesions, dysuria, difficulty in retracting the foreskin due to phimosis, and change in urinary stream due to meatal stenosis. Women report pain, pruritus and dysuria. The associated scarring frequently causes marked architectural change of the vulvar area, with labial fusion, introital narrowing and, less frequently, urethral stenosis.

Fig. 73.18 Mucous membrane pemphigoid of the vulva. Ulcerations and scarring of the perianal area and perineum (positive direct immunofluorescence distinguished this from erosive lichen planus).

Linear IgA bullous dermatosis (see Ch. 31)

Linear IgA bullous dermatosis is a rare disease that can affect both adults and children. Involvement of the genital and perioral regions is frequently seen, especially in children. Annular polycyclic lesions are characteristic, with multiple blisters at the peripheral margins.

Pemphigus vulgaris (see Ch. 29)

Pemphigus vulgaris has a predilection for mucosal sites. Fragile blisters may be seen elsewhere on the skin, but on the genitalia widespread erosions are observed. Vulvovaginal involvement may occur.

Principles of treatment for the bullous disorders

The extent and severity of the disease determine the specific treatment. The aim is to control symptoms with the fewest possible medication-associated side effects. Treatment usually consists of a mixture of topical and systemic anti-inflammatory and immunosuppressive agents. Great symptomatic relief can be gained from the use of potent topical corticosteroids, either as sole treatment in localized disease or as an adjunct to systemic treatment in widespread or more severe disease. Secondary infection, including candidiasis, is a particular problem in the genital region.

Acquired Reactive Bullous Disease

Erythema multiforme and Stevens–Johnson syndrome

Erythema multiforme (EM) and Stevens–Johnson syndrome (SJS) may present as a bullous eruption, particularly in the genital region. In recurrent EM, an associated HSV infection should be sought, remembering that there may be a delay of up to 2 weeks from infection to appearance of the lesions. In recurrent cases, a trial of prophylactic oral antiviral therapy may be indicated. Involvement of two or more mucosal sites points to SJS, in which drugs are the most common etiology (see Ch. 20).

Fixed drug eruption (see Ch. 21)

Recurrent erythematous, blistered or eroded plaques may occur on both skin and mucous membranes[44]. Often, cutaneous lesions are strikingly round, but this may not hold true in mucous membrane sites. The lesions reoccur in exactly the same site with each exposure to the drug. Genital lesions frequently appear as erosions rather than blisters. Many drugs are capable of causing a fixed drug eruption, but common culprits are acetaminophen (paracetamol), tetracyclines, trimethoprim–sulfamethoxazole, and nonsteroidal anti-inflammatory drugs.

Inherited Bullous Disease

Hailey–Hailey disease (see Ch. 59)

Patients with autosomal dominant Hailey–Hailey disease have recurrent involvement of flexural areas. Expanding erythematous plaques with superimposed erosions and sometimes vesicles and pustules are seen. In the inguinal creases, there is a particular tendency to form hypertrophic plaques. Secondary infection with bacteria, fungi and HSV is a frequent problem and must be excluded in any exacerbation. Topical corticosteroids in combination with antifungal/antibacterial agents can ease symptoms. CO_2 laser ablation can also prove helpful.

Leptospirosis 1217
Bacteria previously classified as fungi 1217

Key features

- Roughly 20% of outpatient dermatology visits are for bacterial skin infections
- Staphylococci and streptococci cause the majority of bacterial skin conditions, which range from common infections (e.g. impetigo) to rare multisystem disorders (e.g. toxic shock syndrome)
- An increase in the prevalence of community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) is a growing concern
- Various systemic diseases and immunodeficiency states predispose patients to bacterial skin infections that can be severe and refractory to treatment

NORMAL SKIN FLORA

The cutaneous flora (microbiome) is relatively simple compared to the diverse communities of microorganisms that inhabit the mouth, digestive tract, and vagina. Skin flora is composed of aerobic cocci, aerobic and anaerobic coryneform bacteria, Gram-negative bacteria, and yeast. These organisms help to prevent skin infections by providing ecological competition for pathogenic microorganisms and by hydrolyzing lipids of sebum to produce free fatty acids, which are toxic to many bacteria. The ecology of particular areas of the skin is determined by the availability of moisture, presence of sebaceous lipids, and gaseous environment. Table 74.1 lists the organisms that commonly inhabit normal skin[1].

NORMAL SKIN FLORA

Class	Organisms	Location on body
Aerobic cocci	*Staphylococcus aureus**, *S. saprophyticus, S. epidermidis*†, *Micrococcus luteus, M. roseus, M. varians*	All body sites, especially intertriginous areas
Aerobic coryneform bacteria	*Corynebacterium minutissimum, C. lipophilicus, C. xerosis, C. jeikeium, Brevibacterium epidermidis*	Intertriginous areas (e.g. axillae, groin, toe webs)
Anaerobic coryneform bacteria	*Propionibacterium acnes, P. granulosum, P. avidum*	Sebaceous glands and follicles
Gram-negative bacteria	*Acinetobacter* spp.	Axillae, perineum, antecubital fossae
Yeast	*Malassezia furfur*	Skin rich in sebaceous glands (e.g. scalp)

*Whether or not *S. aureus* is a true resident or contaminant of the skin is a matter of controversy. However, it is commonly found in the anterior nares (35% of population), perineum (20%), and axillae and toe webs (5–10%).
†*S. epidermidis* is the most common coccus on human skin.

Table 74.1 Normal skin flora. *Adapted from Leyden J. Pathophysiology of certain bacterial diseases. In: Soter N, Baden H (eds). Pathophysiology of Dermatologic Diseases. New York: McGraw-Hill, 1991:427–51.*

GRAM-POSITIVE BACTERIA

STAPHYLOCOCCAL AND STREPTOCOCCAL SKIN INFECTIONS

Impetigo

Synonyms: ■ Bullous impetigo: pemphigus neonatorum ■ Impetigo contagiosa ■ Non-bullous impetigo: crusted impetigo ■ Staphylococcal impetigo ■ Streptococcal impetigo

Key features

- *Staphylococcus aureus* and, to a lesser degree, group A β-hemolytic *Streptococcus* spp. are the major causes of impetigo
- Represents the most common bacterial skin infection in children
- Nasal carriers of *S. aureus* are at particular risk of developing impetigo
- Treatment decisions should consider resistance patterns of *S. aureus*

Introduction

Impetigo is a common, contagious, superficial skin infection that can present in non-bullous and bullous forms (Fig. 74.1; see Fig. 34.2A). The most common pathogen in both non-bullous and bullous impetigo is *Staphylococcus aureus*, and group A β-hemolytic *Streptococcus*

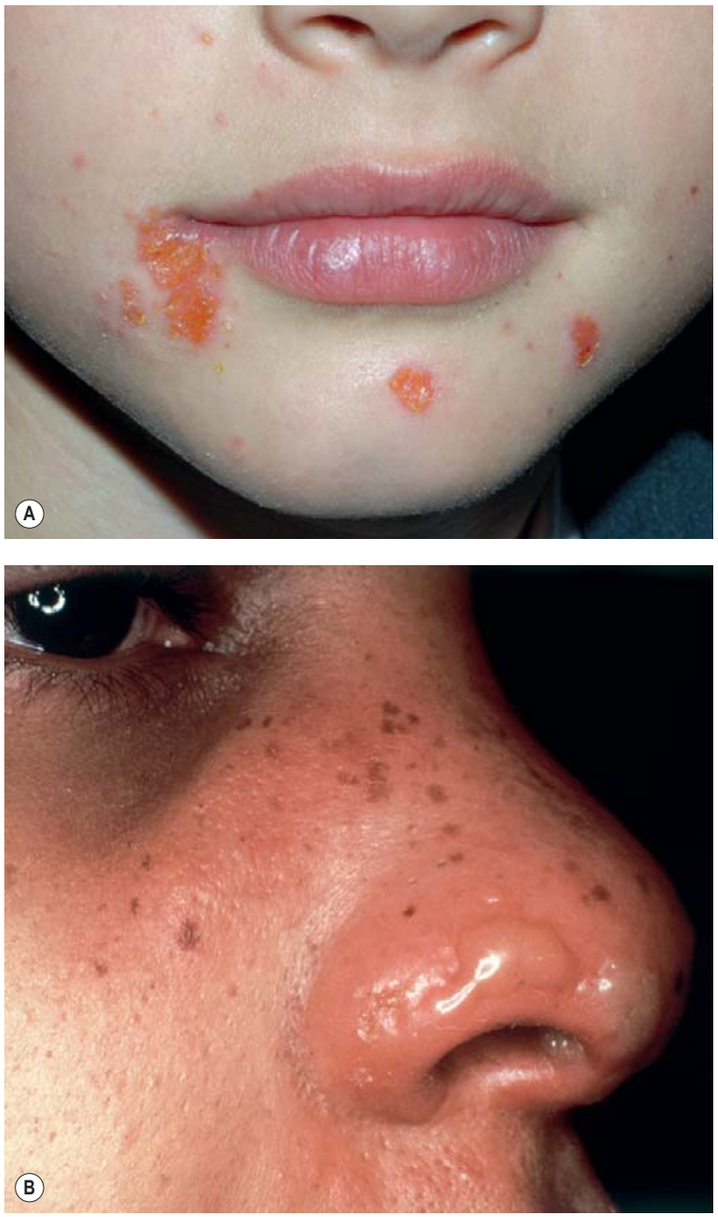

Fig. 74.1 Staphylococcal impetigo. A Honey-colored crusts on the chin of a child with non-bullous impetigo. **B** Superficial bullae and dry erosion on the nose due to bullous impetigo. *A, Courtesy, Julie V Schaffer, MD.*

(*Streptococcus pyogenes*) represents another important cause of non-bullous impetigo. Overall, non-bullous impetigo accounts for approximately 70% of cases. Table 74.2 compares the clinical characteristics and complications of bullous and non-bullous impetigo.

Epidemiology

Impetigo frequently occurs in children (especially those <6 years of age), and worldwide it represents the most common bacterial skin infection in this group. Adults most commonly acquire impetigo through contact with infected children. Impetigo is extremely contagious, spreading rapidly via direct person-to-person contact or through fomites. In temperate climates, peak incidence is in the summer months. Predisposing factors include a warm ambient temperature, high humidity, poor hygiene, an atopic diathesis, skin trauma, and participation in contact sports (e.g. wrestling, football). Nasal, pharyngeal, axillary and/or perineal colonization with *S. aureus* imparts an increased risk for developing impetigo and other staphylococcal infections.

Pathogenesis

Non-bullous impetigo is usually caused by *S. aureus* or (less often in temperate climates) *Str. pyogenes*. Infection typically occurs at sites of scratching (e.g. insect bites, atopic dermatitis), minor trauma (e.g. an abrasion, laceration or burn) or other skin infections (e.g. varicella). Disruption of the skin barrier allows the bacteria to adhere, invade and establish infection.

Bullous impetigo results from the local production of exfoliative toxins (ETA, ETB) by phage group II *S. aureus* at site(s) of cutaneous infection; systemic elaboration of the same toxins is the cause of staphylococcal scalded skin syndrome (SSSS; see below). In both diseases, blister formation is mediated by exfoliative toxin binding to the desmosomal protein desmoglein 1 and cleaving its extracellular domain, thus leading to acantholysis within the epidermal granular layer. *S. aureus* can be cultured from fluid within the blisters of bullous impetigo, but not those of SSSS. Bullous impetigo is more likely to develop on clinically intact skin (especially in intertriginous sites) than is non-bullous impetigo.

Clinical features

The clinical features of impetigo are outlined in Table 74.2[2,3].

Pathology

In *non-bullous impetigo*, small neutrophilic vesiculopustules are present within the epidermis. Spongiosis frequently underlies the pustule. The upper dermis contains an intense infiltrate of neutrophils and lymphocytes. Gram-positive cocci are present in the lesions.

In *bullous impetigo*, there is cleavage of the upper epidermis, typically within the granular layer. Acantholysis mimicking pemphigus foliaceus may be observed. Relatively few inflammatory cells are present within the blister cavity, and a neutrophilic infiltrate is often found in the upper dermis. Gram-positive cocci may be evident.

Diagnosis and differential diagnosis

The diagnosis of impetigo is usually made clinically; exudate from beneath the crust or fluid from intact bullae can be sent for culture to confirm the diagnosis and (especially for more extensive cases requiring systemic therapy) determine susceptibility to antibiotics. Leukocytosis is seen in approximately half of patients with impetigo. The differential diagnosis of non-bullous and bullous impetigo is presented in Table 74.3.

Treatment

For healthy patients with a few superficial lesions and no systemic symptoms, either mupirocin 2% ointment or retapamulin 1% ointment can be prescribed. These topical medications are often equally (if not more) effective than oral antibiotics for limited disease. Treatment should also include cleansing the affected area and removing crusts (which can be facilitated by wet dressings).

Table 74.4 outlines treatment options for impetigo. The extent of skin involvement, the presence of complications (e.g. cellulitis, lymphangitis), comorbid conditions (e.g. atopic dermatitis, varicella), the patient's immune status, and local drug-resistance patterns (e.g. the prevalence of community-associated methicillin-resistant *S. aureus* [CA-MRSA]) should be taken into account when deciding whether topical, oral or intravenous therapy is most appropriate[4,5]. The efficacy of antimicrobial treatment of streptococcal impetigo in preventing acute post-streptococcal glomerulonephritis is not known; in contrast to pharyngitis, a link between streptococcal pyoderma and acute rheumatic fever has not been established. Methods for "decolonizing" the nares and skin of patients with recurrent staphylococcal impetigo are discussed in the folliculitis section below.

Bacterial Folliculitis

Introduction

Bacterial folliculitis is a superficial or deep infection of the hair follicle. A furuncle develops when the entire follicle and surrounding tissue are involved (see below)[6].

Epidemiology and pathogenesis

S. aureus is the most common infectious cause of folliculitis (see Ch. 38). Gram-negative folliculitis occasionally develops in acne vulgaris patients treated with long courses of oral antibiotics. In addition, pseudomonal folliculitis can result from the use of improperly chlorinated

CHARACTERISTIC FEATURES OF BULLOUS AND NON-BULLOUS IMPETIGO		
	Non-bullous impetigo	**Bullous impetigo**
Epidemiology	• ~70% of all cases of impetigo • Children most often affected	• Less common • Often occurs in the neonatal period (see Ch. 34), but children also affected
Clinical lesions	• Early: single 2–4 mm erythematous macule that rapidly evolves into a short-lived vesicle or pustule • Late: superficial erosion with a typical "honey-colored" yellow crust and rapid direct extension of infection to surrounding skin	• Early: small vesicles enlarge into 1–2 cm superficial bullae • Late: flaccid, transparent bullae measuring up to 5 cm in diameter; after rupture there is a collarette of scale, but no thick crust; usually little surrounding erythema
Distribution	• Face (around the nose and mouth) and extremities	• Face, trunk, buttocks, perineum, axillae and extremities
Associated findings	• Mild lymphadenopathy may be present	• Usually no systemic symptoms but can be associated with weakness, fever and diarrhea
Clinical course	• Usually a benign, self-limited process • Usually resolves within 2 weeks without scarring if untreated	• Usually resolves in 3–6 weeks without scarring if not treated
Complications	• In 5% of cases, non-bullous impetigo caused by *S. pyogenes* (serotypes 1, 4, 12, 25 and 49) results in acute post-streptococcal glomerulonephritis (APSG)* • Risk of APSG is not altered by treatment with antibiotics • Impetigo has not been linked to a risk of rheumatic fever	• In infants/young children and adults with immunodeficiency or renal failure, exfoliative toxin may disseminate and cause staphylococcal scalded skin syndrome
*Associated with anti-DNase B and antistreptolysin O (ASO) antibodies.		

Table 74.2 Characteristic features of bullous and non-bullous impetigo[2,3].

DIFFERENTIAL DIAGNOSIS OF NON-BULLOUS AND BULLOUS IMPETIGO		
	Most common	**Less common**
Non-bullous impetigo	Insect bites Eczematous dermatoses Herpes simplex viral infection Candidiasis	Inflammatory tinea corporis/faciei Varicella Scabies Pediculosis Pemphigus foliaceus
Bullous impetigo	Bullous insect bite reactions Thermal burns Herpes simplex viral infection	Autoimmune bullous dermatoses (e.g. linear IgA bullous dermatosis, bullous pemphigoid) Bullous erythema multiforme Stevens–Johnson syndrome Bullous mastocytosis

Table 74.3 Differential diagnosis of non-bullous and bullous impetigo.

TREATMENT OPTIONS FOR IMPETIGO AND ECTHYMA*				
	Uncomplicated		**Complicated**	
	First-line	**Second-line**	**First-line**	**Second-line**
Impetigo	Mupirocin 2% ointment - or - retapamulin 1% ointment - or - fusidic acid 2% cream†	β-lactamase-resistant penicillin - or - first-generation cephalosporin - or - clindamycin - or - macrolide‡	IV ceftriaxone (daily dosing)	IV ampicillin/sulbactam - or - IV cefuroxime
Ecthyma	β-lactamase-resistant penicillin (e.g. dicloxacillin) - or - first-generation cephalosporin (e.g. cephalexin)			
*See Table 74.5 for treatment recommendations for community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA). †Not available in the US; increasing rates of *S. aureus* resistance have been reported. ‡In communities with low levels of resistance.				

Table 74.4 Treatment options for impetigo and ecthyma. See Chapter 127 for specific antibiotics within each class.

hot tubs and whirlpools. Predisposing factors for staphylococcal folliculitis include occlusion, maceration and hyperhydration of the skin; shaving, plucking or waxing hair; use of topical corticosteroids; hot and humid weather; atopic dermatitis; and diabetes mellitus.

Clinical features

Staphylococcal folliculitis most frequently involves the face (especially the beard area), scalp, chest, back, axillae and buttocks (see Ch. 38). The appearance depends on the depth of follicular involvement. Superficial folliculitis (Bockhart's impetigo) presents with small (1–4 mm) pustules or crusted papules on an erythematous base. The lesions are frequently clustered and heal without scarring. Sycosis barbae, a type of deep folliculitis, appears as large erythematous papules, often with a central pustule and sometimes coalescing to form plaques studded with pustules and crusts. Bacterial folliculitis may be pruritic or (especially with deeper involvement) tender[7].

Diagnosis and differential diagnosis

The diagnosis of bacterial folliculitis is usually made based on clinical inspection. Gram staining and bacterial cultures can help to identify the causative organisms, which is especially useful in severe, recurrent or treatment-resistant cases. The differential diagnosis includes other forms of folliculitis (see Ch. 38) as well as acne vulgaris, rosacea, chloracne, pseudofolliculitis barbae, and keratosis pilaris.

Treatment

Superficial staphylococcal folliculitis can be treated with antibacterial washes that contain chlorhexidine or triclosan. Topical antibiotics such as mupirocin or clindamycin may also be used for 7–10 days to treat localized lesions. When staphylococcal folliculitis is widespread or recurrent, oral β-lactam antibiotics (e.g. a β-lactamase-resistant penicillin or first-generation cephalosporin), tetracyclines or (depending on local resistance patterns) macrolides can be prescribed. Although pseudomonal folliculitis is often self-limited, ciprofloxacin is an option for more severe cases.

In patients with recurrent staphylococcal folliculitis and their close contacts, application of mupirocin 2% ointment twice daily to the nares for 5–10 days can be used to eradicate nasal carriage of *S. aureus*; methods to decolonize the skin (e.g. axillae, perineum/groin, submammary area) include topical mupirocin, washes containing chlorhexidine or triclosan, and dilute sodium hypochlorite baths (e.g. 0.5 cup household bleach [6% sodium hypochlorite] in a full standard bathtub). Elimination of bacterial contamination of potential fomites such as keyboards, toys and sports equipment (e.g. shoulder pads, wrestling mats) should also be considered (e.g. using ethanol- or sodium hypochlorite-based disinfectants).

Abscesses, Furuncles and Carbuncles

Introduction

Abscesses and furuncles (boils) are collections of pus that are "walled-off" from the surrounding tissues. Whereas an abscess can occur anywhere in or on the body, a furuncle, by definition, involves a hair follicle. A contiguous collection of furuncles is termed a carbuncle.

Epidemiology and pathogenesis

Furuncles most often occur in adolescents and young adults. *S. aureus* is usually the causative organism, although anaerobic bacteria are occasionally cultured from recurrent furuncles in the anogenital region. Predisposing factors include chronic *S. aureus* carriage, diabetes mellitus, obesity, poor hygiene, and immunodeficiency states (e.g. chronic granulomatous disease, hyperimmunoglobulin E syndrome)[8].

Clinical features

Abscesses are localized collections of pus that are usually inflamed. They can arise in any cutaneous site. Furuncles are acute, inflammatory abscesses of hair follicles and surrounding tissue, and, as such, occur only in hair-bearing skin. The most common locations are the face, neck, axillae, buttocks, thighs and perineum. Sites prone to friction or minor trauma, such as the area under a belt, are also susceptible. Furuncles usually begin as firm, tender, red nodules that progressively enlarge and become painful and fluctuant (Fig. 74.2); rupture results in decreased pain. Systemic symptoms are usually absent, although regional lymphadenopathy may develop. Furunculosis (multiple or recurrent furuncles) can be associated with chronic *S. aureus* carriage.

Carbuncles are collections of furuncles that extend deep into the subcutaneous tissue. The surface usually displays multiple draining sinus tracts and occasionally ulcerates. They usually occur in areas with thicker skin (e.g. nape of neck, back, thigh). Systemic symptoms are usually present. Carbuncles are slow to heal and lead to scarring.

Pathology

Biopsy specimens reveal a dense neutrophilic infiltrate in the subcutaneous tissue. Furuncles are characterized by an acute, suppurative reaction involving the follicle below the infundibulum, as well as perifollicular necrosis with fibrinoid debris.

Fig. 74.2 Furuncle secondary to methicillin-resistant *Staphylococcus aureus*. Fluctuant erythematous nodule with a central pustule. *Courtesy, Julie V Schaffer, MD.*

Diagnosis and differential diagnosis

Diagnosis is based primarily on clinical appearance. Gram stains and cultures from the lesion support the diagnosis. Extensive furuncles and carbuncles can be associated with leukocytosis. A ruptured epidermoid or pilar cyst, hidradenitis suppurativa ("acne inversa") and cystic acne should be considered in the differential diagnosis.

Treatment

For simple furuncles, warm compresses may promote maturation, drainage and resolution. Larger or deeper fluctuant lesions typically require incision and drainage. Systemic antibiotic therapy is recommended (in conjunction with incision and drainage if possible) in the following situations: (1) furuncles around the nose, in the external auditory canal or in other locations where drainage is difficult (e.g. elsewhere on the face, hands, genitalia); (2) severe or extensive disease (e.g. multiple sites); (3) lesions with surrounding cellulitis/phlebitis or associated with signs/symptoms of systemic illness; (4) lesions not responding to local care; and (5) patients with concerning comorbidities or immunosuppression[9,10]. Given the high proportion of furuncles that are caused by MRSA, empiric coverage with antibiotics such as doxycycline, trimethoprim–sulfamethoxazole (TMP-SMX) or (depending on local resistance patterns) clindamycin should be considered (see below). Patients with recurrent furunculosis may benefit from eradication of *S. aureus* from the nares, axilla and perineum (see Bacterial Folliculitis above).

Methicillin-Resistant *Staphylococcus aureus*

Introduction

Methicillin resistance was first noted in isolates of *S. aureus* in 1961. Although initially associated with nosocomial infection (healthcare-associated [HA]-MRSA), in recent years CA-MRSA has become a growing problem among young, otherwise healthy individuals[11]. Although there is considerable regional variation, overall, MRSA represents the most common cause of purulent skin and soft tissue infections presenting to emergency departments in the US[12,13].

Clinical features

Furunculosis is the most frequent manifestation of CA-MRSA infection (see Fig. 74.2). These lesions can evolve into large abscesses, cellulitis or necrotic plaques (which may be misdiagnosed as spider bites). Less often, impetigo (bullous or non-bullous), SSSS and folliculitis are seen, and life-threatening complications such as septic shock, toxic shock syndrome and necrotizing fasciitis occasionally develop.

Pathogenesis

The cause of methicillin resistance is the production of an altered penicillin-binding protein (PBP), called PBP2a, with decreased affinity

for β-lactam antibiotics (which interfere with bacterial cell wall synthesis by binding to PBPs). PBP2a is the protein product of the *mecA* gene, which is located within a specific mobile genetic element called the staphylococcal cassette chromosome *mec* (SCC*mec*). Acquisition of different SCC*mec* elements by *S. aureus* led to the emergence of HA-MRSA (usually SCC*mec* types I–III) and CA-MRSA (usually SCC*mec* types IV and V) strains; methicillin-resistant coagulase-negative staphylococci are thought to represent a reservoir of SCC*mec* for CA-MRSA. Many CA-MRSA strains also encode virulence factors such as Panton-Valentine leukocidin (PVL), a pore-forming cytotoxin that can cause destruction of leukocytes and tissue necrosis.

As a reflection of their distinct SCC*mec* elements, CA-MRSA and HA-MRSA have different patterns of antibiotic resistance. CA-MRSA is typically susceptible to multiple non-β-lactam antibiotics, whereas HA-MRSA is usually resistant to several antimicrobial classes, including aminoglycosides, macrolides and clindamycin. However, some isolates of the USA300 clone, which currently causes most CA-MRSA skin infections in the US[13], have developed resistance to macrolides, clindamycin, tetracycline (less often doxycycline), quinolones and mupirocin.

Resistance to macrolides (e.g. erythromycin) in staphylococci may result from: (1) active drug efflux via a pump encoded by the *msrA/msrB* gene (frequent in MRSA isolates); or (2) modification of the bacterial ribosome by the erythromycin ribosomal methylase encoded by *erm* genes, which produces cross-resistance to clindamycin[14]. Erythromycin stimulates expression of *erm*, which leads to clinically relevant resistance. If initial sensitivity testing shows resistance to erythromycin and susceptibility to clindamycin, resistance to clindamycin will still develop if *erm* is present, since bacterial variants with constitutive expression of this gene commonly arise and are selected for during clindamycin therapy. This "inducible resistance" can be assessed with the D-test (double-disk diffusion) (Fig. 74.3).

Diagnosis and treatment

When an *S. aureus* infection is suspected, culture and susceptibility testing should be performed, whenever feasible, to guide antibiotic selection. Prior to obtaining these results, empiric antibiotic therapy (Table 74.5) can be chosen based on the prevalence of MRSA and resistance patterns in a given community as well as the severity of the infection[10]. Vancomycin should be considered for patients with severe infections, especially in geographic regions where CA-MRSA is prevalent and in individuals with a history of MRSA colonization or intravenous drug use[15].

Blistering Distal Dactylitis

Blistering distal dactylitis is a localized infection of the volar fat pad of a finger or, less often, a toe, with occasional involvement of the nail fold or more proximal portion of the digit. Darkening of the skin is often observed for several days to a week before blister formation. The infection most commonly occurs in children aged 2–16 years.

Group A *Streptococcus* spp. or *S. aureus* are usually the causative organisms. Inoculation may follow local skin trauma or autoinoculation from nose picking[16]. The differential diagnosis includes herpetic whitlow, a thermal or chemical burn, acute paronychia, bullous impetigo and frictional bullae.

Drainage and a 10-day course of an oral antistaphylococcal antibiotic are recommended. Although topical therapy with mupirocin has been described, systemic therapy can prevent development of new sites of infection as well as local extension.

Ecthyma

Ecthyma is a deep form of non-bullous impetigo characterized by extension into the dermis to produce a shallow ulcer (Fig. 74.4). It can be caused by a primary infection with *Str. pyogenes* or streptococcal superinfection of a pre-existing ulceration or excoriated insect bite. Tables 74.4 and 74.6 summarize the clinical aspects and treatment of ecthyma[17].

Staphylococcal Scalded Skin Syndrome

Synonyms: ■ Ritter's disease ■ Pemphigus neonatorum

Introduction

Staphylococcal scalded skin syndrome (SSSS) is caused by hematogenous dissemination of the same exfoliative toxins that lead to bullous

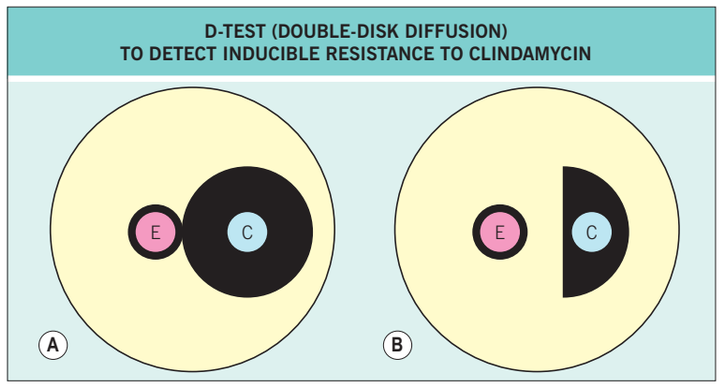

Fig. 74.3 D-test (double-disk diffusion) to detect inducible resistance to clindamycin. Erythromycin (E) and clindamycin (C) disks are placed 15–17 mm apart on an agar plate inoculated with the organism. Following incubation, the zones of inhibition around the disks are evaluated. If the zone around the clindamycin disk is circular in shape and of sufficient size (**A**), the organism is negative for inducible resistance. However, if the portion of the zone adjacent to the erythromycin disk is "flattened", producing a "D" shape (**B**), the organism is positive for inducible resistance to clindamycin.

EMPIRIC THERAPY FOR SKIN INFECTIONS SUSPECTED TO BE CAUSED BY COMMUNITY-ASSOCIATED METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* (CA-MRSA)

Minor infections*		Severe infections		
First-line	**Second-line**	**First-line**	**Second-line**	**Third-line**
Trimethoprim–sulfamethoxazole† Minocycline† Doxycycline† Clindamycin	Linezolid	Vancomycin	Linezolid Daptomycin Telavancin	Quinupristin-dalfopristin Tigecycline

*E.g. furuncles/abscesses (if antibiotic treatment is indicated; see text), purulent cellulitis, and infections that failed to respond clinically to treatment with an antistaphylococcal β-lactam; for non-purulent cellulitis or when oral therapy is needed for impetigo (see Table 74.4), first-line treatment is a β-lactamase-resistant penicillin (e.g. dicloxacillin) or a first-generation cephalosporin (e.g. cephalexin, cefadroxil).

†Do not provide coverage of group A streptococci; if coverage of the latter and CA-MRSA is desired, can be combined with a β-lactam.

Table 74.5 Empiric therapy for skin infections suspected to be caused by community-associated methicillin-resistant Staphylococcus aureus (CA-MRSA). If present, wound exudate should be sent for culture/sensitivity prior to beginning therapy. Quinolones and macrolides are not optimal for treatment of CA-MRSA because resistance is common and may develop rapidly. *Based on Liu C, Bayer A, Cosgrove SE, et al. Clinical practice guidelines by the Infectious Diseases Society of America for the treatment of methicillin-resistant Staphylococcus aureus infections in adults and children: executive summary. Clin Infect Dis. 2011;52:285–92.*

Fig. 74.4 Ecthyma. Ulceration with hemorrhagic crust on the wrist due to infection with group A streptococci. *Courtesy, Kalman Watsky, MD.*

CLINICAL FEATURES OF ECTHYMA	
Clinical findings	• Fewer than 10 lesions are typically seen, most commonly on the lower extremities • An initial vesiculopustule enlarges (0.5–3 cm in diameter) over the course of several days, and develops a hemorrhagic crust • The ulcer has a "punched-out" appearance and a purulent, necrotic base • Lesions are slow to heal and produce scarring
Risk factors	• Young age (children), lymphedematous limbs, poor hygiene, neglect (including the elderly), immunosuppression, scratching (e.g. of insect bites), trauma
Complications	• Lesions are often contaminated with staphylococci • Systemic symptoms and bacteremia are rarely seen • Cellulitis and osteomyelitis are extremely infrequent
Diagnosis	• Clinical appearance • Culture of moist, purulent base; skin biopsy with deep-tissue Gram stain and culture occasionally required
Differential diagnosis	• Ecthyma gangrenosum • Ulcers due to vasculitis, vasculopathies, other causes (see Ch. 105)

Table 74.6 Clinical features of ecthyma.

Fig. 74.5 Staphylococcal scalded skin syndrome. **A** Diffuse erythema with an early superficial erosion in the antecubital fossa. **B** More extensive involvement on the neck with a wrinkled appearance of the erythematous skin in addition to peeling and multiple erosions. *Courtesy, Julie V Schaffer, MD.*

impetigo when produced locally. Cleavage of the epidermis through the granular layer results in the formation of tender, flaccid bullae[18].

Epidemiology

SSSS is primarily a disease of infants and young children, who have decreased renal toxin clearance (especially neonates) and/or a lack of toxin-neutralizing antibodies. Occasionally, adults with chronic renal insufficiency or immune suppression are affected. Outbreaks occurring in neonatal nurseries are usually secondary to asymptomatic carriage of a toxigenic strain of *S. aureus* by healthcare workers or parents. A male predominance exists (2:1 male:female ratio in sporadic cases, 4:1 in epidemics)[19].

Pathogenesis

Most cases of SSSS are caused by phage group II strains (e.g. types 55, 71) of *S. aureus* (which can be methicillin-sensitive or resistant) that produce exfoliative (also know as epidermolytic) toxins (ETs). ETA (chromosomally encoded) and ETB (plasmid encoded) are serine proteases that bind and cleave desmoglein 1 (Dsg1). This causes splitting of the desmosomes, which leads to disruption of the epidermal granular layer and bulla formation. Desmoglein 1 is targeted by autoantibodies in pemphigus foliaceus, which has identical histological features to SSSS.

In contrast to bullous impetigo, where the effects of the ETs are limited to the site(s) of infection, in SSSS the toxin diffuses from a focus of infection and (in the absence of specific antitoxin antibody) spreads hematogenously to produce widespread effects. In children, the infectious focus is usually in the nasopharynx or conjunctivae, whereas staphylococcal pneumonia or bacteremia may be present in adults[20].

Clinical features

There is often a prodrome of malaise, fever, irritability and severe tenderness of the skin. The patient may have purulent rhinorrhea or conjunctivitis as a manifestation of the underlying staphylococcal infection. Erythema typically first appears on the head (accompanied by variable facial edema) and in intertriginous sites, often with generalization within 48 hours. The skin subsequently develops a wrinkled appearance owing to the formation of flaccid, sterile bullae within the superficial epidermis (Fig. 74.5). The Nikolsky sign is positive. Classically, the flexural areas are the first to exfoliate, leaving behind moist skin and thin, varnish-like crusting. Patients demonstrate characteristic periorificial (e.g. perioral, periocular) crusting and radial fissuring (see Figs 34.14 & 81.17). Intraoral lesions do not occur.

COMPARISON OF TOXIC EPIDERMAL NECROLYSIS AND STAPHYLOCOCCAL SCALDED SKIN SYNDROME		
	TEN	**SSSS**
Cause	Usually drug-induced	Infection with toxin-producing *S. aureus*
Age	Primarily adults	Primarily infants and young children
Histology	Dermal–epidermal separation with epidermal necrosis; dermis has a variable inflammatory infiltrate	Granular layer split in epidermis; dermis lacks inflammatory infiltrate
Distribution of rash	Areas of sparing often present	Generalized with flexural accentuation
Mucous membranes	Involved, erosions	Uninvolved
Nikolsky's sign	In some areas, difficult to elicit	Present in seemingly uninvolved skin
Face	Vermilion lip erosions and crusting	Perioral and periocular crusting and radial fissuring with mild facial swelling
Treatment	IVIg, corticosteroids (controversial) and supportive care (similar to a burn victim)	Antibiotics (β-lactamase-resistant) and supportive care

Table 74.7 Comparison of toxic epidermal necrolysis (TEN) and staphylococcal scalded skin syndrome (SSSS). Also see Fig. 81.17. *Adapted from Habif T. Clinical Dermatology: A Color Guide to Diagnosis and Therapy. New York: Mosby-Year Book, 1996:256–7, 570–4.*

Scaling and desquamation continue for the next 3–5 days, followed by re-epithelialization without scarring. With proper treatment, SSSS resolves in 1–2 weeks, usually without sequelae. The mortality rate is 3% for children but >50% in adults[21].

Pathology

Histologic examination shows a sharply demarcated zone of cleavage at or below the stratum granulosum. There are usually no inflammatory cells in the bullae. The upper dermis also lacks an inflammatory infiltrate, and no organisms are seen on Gram stain of biopsy specimens.

Diagnosis and differential diagnosis

SSSS is generally a clinical diagnosis. Although cultures taken from intact bullae are negative, *S. aureus* may be cultured from the conjunctiva, nasopharynx, feces or pyogenic foci on the skin. Blood cultures are almost always negative in children but may be positive in adults. The leukocyte count can be elevated or normal. Examination of frozen sections is occasionally helpful in confirming the level of the split in the bullae. Slide latex agglutination, double immunodiffusion or enzyme-linked immunosorbent assay (ELISA) tests can identify the toxins responsible for SSSS.

The differential diagnosis may include sunburn, a drug reaction, Kawasaki disease, extensive bullous impetigo, a viral exanthem, toxic shock syndrome, GVHD and pemphigus foliaceus. Differentiation from toxic epidermal necrolysis (TEN) is outlined in Table 74.7 and Fig. 81.17.

Treatment

Patients with severe, generalized forms of SSSS require hospitalization and parenteral antibiotics. Oral treatment with a β-lactamase-resistant antibiotic (e.g. dicloxacillin, cephalexin) for a minimum of 1 week is usually sufficient for milder disease. Identification and decolonization of *S. aureus* carriers (see Folliculitis section above) are important, especially in hospital-acquired cases[22].

Toxic Shock Syndrome

Introduction

Toxic shock syndrome (TSS) is an acute multisystem disease caused by a *S. aureus* exotoxin (Table 74.8).

CASE DEFINITIONS FOR THE TOXIC SHOCK SYNDROMES
TOXIC SHOCK SYNDROME
• Fever: temperature >102°F (or >38.9°C) • Rash: diffuse macular erythroderma • Desquamation: 1–2 weeks after the onset of illness (especially palms and soles) • Hypotension: systolic blood pressure <90 mmHg for adults (<5th percentile for children) • Involvement of three or more of the following organ systems: – Gastrointestinal – Muscular – Central nervous – Renal – Hepatic – Mucous membranes (erythema) – Hematologic (platelets <100 000/mm^3) • Negative results for the following tests (if done): – Blood and cerebrospinal fluid cultures (blood culture may be positive for *Staphylococcus aureus*) – Serologic tests for Rocky Mountain spotted fever, leptospirosis, measles
STREPTOCOCCAL TOXIC SHOCK SYNDROME
• Isolation of group A streptococci from a normally sterile site* (e.g. blood, cerebrospinal fluid, tissue biopsy, surgical wound) or • Isolation of group A streptococci from a non-sterile site† (e.g. throat, sputum, vagina, superficial skin lesion) and • Hypotension: systolic blood pressure <90 mmHg for adults (<5th percentile for children) and • Two or more of the following signs: – Renal impairment – Coagulopathy (platelets <100 000/mm^3 or disseminated intravascular coagulation) – Liver impairment – Acute respiratory distress syndrome – Generalized erythematous macular rash ± desquamation – Soft tissue necrosis (e.g. necrotizing fasciitis, myositis, gangrene)
*Defined as a definite case. †Defined as a probable case, excluding any other possible etiology.

Table 74.8 Case definitions for the toxic shock syndromes. See www.cdc.gov/osels/ph_surveillance/nndss/print/toxic_shock_syndrome_current.htm for details on the current case definitions.

Epidemiology and pathogenesis

In the early 1980s, there was an outbreak of TSS in young women using highly absorbent tampons ("menstrual" TSS). The incidence of menstrual TSS then declined substantially following changes in tampon manufacturing and use, and in a recent population-based study it accounted for approximately half of TSS cases[23a]. TSS can also occur in patients who have undergone surgical procedures. In addition, it may develop in association with cutaneous pyodermas, postpartum infections, abscesses, burns, and infections associated with nasal packing or insulin pump infusion sites. Non-menstrual TSS affects both sexes equally.

TSS is due to infection or colonization with strains of *S. aureus* that produce toxic shock syndrome toxin-1 (TSST-1). The absence of

THE TOXIC SHOCK SYNDROMES		
	Staphylococcal	**Streptococcal**
Typical patient	Young (15–35 years) and healthy	Young (20–50 years) and healthy
Diffuse macular erythroderma	Very common	Less common
Vesicles and bullae	Rare	Uncommon (5%)
Localized extremity pain	Rare	Common
Soft tissue infection	Rare	Common
Hypotension	100%	100%
Renal impairment	Common	Common
Predisposing factors	Surgical packing, surgical meshes, abscesses, contraceptive sponge, tampon	Lacerations, bites, bruises, varicella
Positive blood cultures	<15%	>50%
Mortality	<3%	30–60%

Table 74.9 The toxic shock syndromes (staphylococcal versus streptococcal).

antibodies against TSST-1 represents a risk factor for the development of TSS. This toxin is thought to act as a "superantigen" that binds to major histocompatibility complex (MHC) class II molecules of antigen-presenting cells (APCs) and the Vβ region of T-cell receptors in a non-antigen-specific manner, which leads to massive release of cytokines and chemokines as well as clonal T-cell expansion (see section on Streptococcal TSS)[23]. Of note, the *neonatal TSS-like exanthematous disease* (see Ch. 10) occurs during the first week of life due to colonization with TSST-1-producing *S. aureus* (usually methicillin-resistant) and has a relatively mild course due to the immature, relatively anergic state of T cells in newborns.

Clinical features

TSS is characterized by the sudden onset of high fever with myalgias, vomiting, diarrhea, headache and pharyngitis. Rapid progression to hypotensive shock can occur, but the clinical spectrum ranges from relatively mild to fulminant fatal disease. The dermatologic manifestations are more extensive and predictable in staphylococcal TSS than in streptococcal TSS (Table 74.9). Patients usually develop diffuse erythema or a scarlatiniform exanthem that starts on the trunk and spreads to the extremities (Fig. 74.6). Additional findings include erythema and edema of the palms, soles and oral mucosa as well as a strawberry tongue, hyperemia of the conjunctivae, and (with disease progression) generalized non-pitting edema. Desquamation of the hands and feet occurs 1–3 weeks after the onset of symptoms.

After recovery, Beau's lines and nail shedding can be seen. In severe cases, telogen effluvium may occur. With proper treatment, the majority of patients completely recover. However, complications include decreased renal function, prolonged weakness and fatigue, protracted myalgias, vocal cord paralysis, upper extremity paresthesias, carpal tunnel syndrome, arthralgias, amenorrhea and gangrene[24].

Pathology

Biopsy specimens of the eruption show an infiltrate of neutrophils and lymphocytes in the superficial dermis. Papillary dermal edema as well as epidermal spongiosis and exocytosis may be noted. Hair follicles and eccrine sweat glands display similar findings.

Diagnosis and differential diagnosis

A high index of suspicion is required in order to make a timely diagnosis. Table 74.8 outlines the case definition of TSS. The possibility of streptococcal TSS (see Table 74.9 and below) should also be considered. TSS can have clinical overlap with Kawasaki disease, scarlet fever, SSSS, early TEN, Rocky Mountain spotted fever and leptospirosis[25].

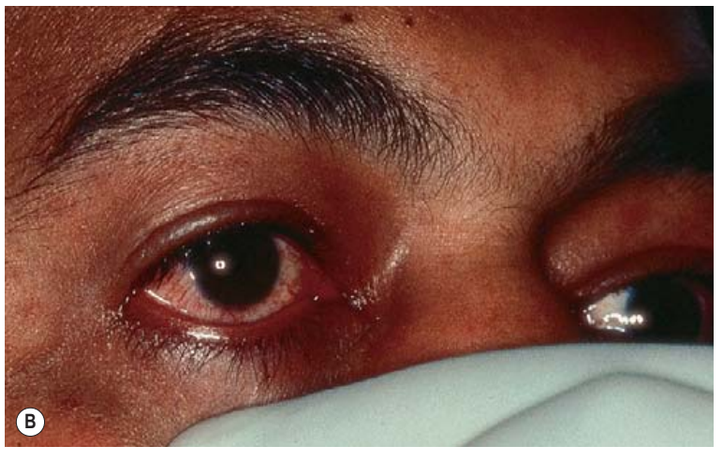

Fig. 74.6 Toxic shock syndrome due to *Staphylococcus aureus* infection. **A** Blotchy erythema is evident on the thigh. **B** Hyperemia of the conjunctiva is seen.

Treatment

Severe cases of TSS require intensive monitoring and supportive therapy. Hypotension can be treated with intravenous fluids and vasopressor agents. Foreign bodies (e.g. surgical mesh, nasal packing, tampons) should be removed and abscesses drained. Beta-lactamase-resistant antibiotics are used to eradicate the toxin-producing staphylococci; MRSA is responsible for only a small proportion of TSS cases[23a]. Some advocate using antibiotics that suppress protein (and thereby toxin) production, such as clindamycin, and administration of intravenous immunoglobulin (IVIg) may help to neutralize the toxin[26]. In severe cases of shock unresponsive to antibiotics, low-dose corticosteroids have been used[27].

Scarlet Fever

Synonym: ▪ Scarlatina

Introduction

Primarily a disease of children, scarlet fever was often fatal in the pre-antibiotic era. The erythematous exanthem and enanthem are due to toxins produced by group A β-hemolytic streptococci.

Epidemiology and pathogenesis

Scarlet fever is caused by streptococcal pyrogenic exotoxins (SPEs) types A, B and C (also referred to as erythrogenic toxins), which are produced by group A streptococci and lead to immune activation. The majority of cases occur between 1 and 10 years of age; by the age of 10 years, 80% of the population has developed anti-SPE antibodies that prevent development of the eruption. Scarlet fever usually follows tonsillitis or pharyngitis and is most common during the late fall, winter and spring in temperate climates. However, it occasionally develops as a complication of wound ("surgical scarlet fever"), post-burn, pelvic or puerperal infections[28].

Clinical features

Scarlet fever is typically preceded by the sudden onset of a sore throat, headache, malaise, chills, anorexia, nausea and high fevers. Patients, especially young children, may experience vomiting, abdominal pain and seizures. The eruption begins 12–48 hours later as blanchable erythema on the neck, chest and axillae. There is subsequent generalization (usually within 12 hours) and development of tiny superimposed papules with a sandpaper-like texture ("sunburn with goose pimples"). Pastia's lines (linear petechial streaks) are seen in the axillary, antecubital and inguinal areas. The cheeks are flushed with circumoral pallor. The throat is red and edematous, developing an exudate after 3–4 days; palatal petechiae and tender cervical adenopathy are often evident. The tongue is initially white with bright red papillae, but later becomes beefy red ("strawberry tongue"). Desquamation occurs after 7–10 days, most prominently on the hands and feet (see Fig. 74.8A&B), and can last for 2–6 weeks. Possible complications of scarlet fever and the underlying streptococcal infection include otitis, mastoiditis, sinusitis, pneumonia, myocarditis, meningitis, arthritis, hepatitis, acute glomerulonephritis and rheumatic fever[20].

Pathology

Biopsy specimens reveal engorged capillaries and dilated lymphatics, most prominent around hair follicles. Dermal edema, perivascular neutrophilic infiltrates and small areas of hemorrhage represent additional findings. Spongiosis and parakeratosis are seen during the desquamative stage.

Diagnosis and differential diagnosis

Clinical diagnosis is usually not difficult. There is almost always an elevated leukocyte count with a left shift. Eosinophilia of 10–20% is often seen after 2–3 weeks of convalescence. Hemolytic anemia can occur, and mild albuminuria and hematuria may be present early in the disease. Nasal and/or throat cultures grow group A streptococci. Detection of antistreptolysin O (ASO), antihyaluronidase, antifibrinolysin and anti-DNase B antibodies can also be useful in confirming the streptococcal infection.

The differential diagnosis of scarlet fever may include a drug eruption, a viral exanthem, toxic shock syndrome, early SSSS, Kawasaki disease and recurrent toxin-mediated perineal erythema. Infection with *Arcanobacterium haemolyticum*, a Gram-positive rod, can result in pharyngitis and a scarlatiniform exanthem in adolescents and young adults.

Treatment

As with other group A streptococcal infections, penicillin (or amoxicillin) is the drug of choice; a 10–14-day course is usually sufficient. A clinical response can be expected within 24–48 hours. Antibiotic treatment as long as 10 days after the onset of symptoms will prevent the development of rheumatic fever. In penicillin-allergic patients, a first-generation cephalosporin (if no history of an immediate-type reaction), clindamycin or a macrolide can be used (although some strains of group A streptococci are resistant to macrolides).

Streptococcal Toxic Shock Syndrome

Synonyms: ▪ Streptococcal toxic shock-like syndrome ▪ Toxic streptococcal syndrome

Introduction

Streptococcal TSS is a rapidly progressive, life-threatening illness caused by infection with toxin-producing group A streptococci.

Epidemiology and pathogenesis

Streptococcal TSS mainly affects healthy individuals between 20 and 50 years of age. A disruption of the cutaneous barrier usually serves as the portal of bacterial entry. In contrast to the occult infections that predominate in staphylococcal TSS, many cases are associated with invasive soft tissue infections (e.g. necrotizing fasciitis) with virulent (e.g. M types 1 and 3) strains of group A streptococci, and the majority of patients are bacteremic[29]. Toxins that have been implicated include SPEs A, B and C as well as the more potent streptococcal mitogenic exotoxin Z (SMEZ). Streptolysin O may also act synergistically with SPE-A.

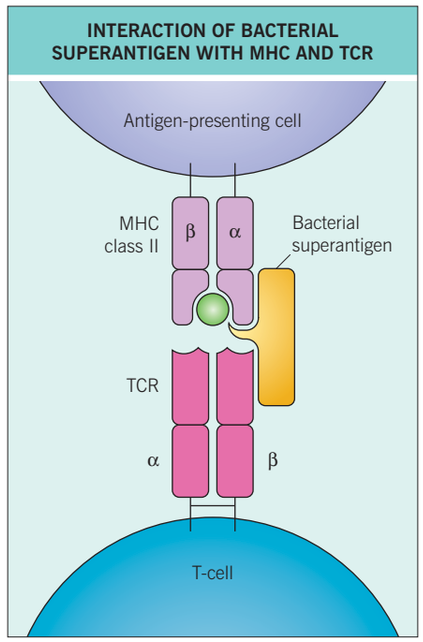

Fig. 74.7 Interaction of bacterial superantigen with the major histocompatibility complex (MHC) and the T-cell receptor (TCR). *Adapted from Janeway CA, Travers P, Walport M, Shlomchik M. Immunobiology: the Immune System in Health and Disease, 6th edn. New York: Garland Science, 2004.*

Similar to staphylococcal TSS, the clinical manifestations of streptococcal TSS result from massive cytokine release due to superantigen activity of bacterial exotoxins. Superantigens bind directly (without intracellular processing) to MHC class II molecules on APCs (outside the antigen-presenting groove) and the Vβ region of the T-cell receptor (Fig. 74.7), thereby stimulating T cells in a relatively nonspecific manner. A given superantigen–T-cell interaction may lead to the activation of 5–30% of the entire circulating T-cell population, compared to ~0.01% for conventional antigens. This leads to production of huge amounts of cytokines, especially tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1) and IL-6; there is also upregulation of Toll-like receptors (TLRs) 2 and 4, which augments deleterious effects of endotoxin from Gram-negative bacteria (e.g. those colonizing the gut) as well as streptococci, resulting in further elaboration of proinflammatory mediators. As a consequence, patients develop clinical manifestations such as fever, erythematous eruptions, vomiting, hypotension, and tissue injury in multiple organ systems[20]. The use of nonsteroidal anti-inflammatory drugs (NSAIDs), which lessen fever and other signs of infection, might delay the diagnosis and treatment of a streptococcal soft tissue infection, allowing TSS to occur[30].

Clinical features

Streptococcal TSS is defined as a group A streptococcal infection with an early onset of shock and organ failure (see Table 74.8). The most common initial symptom is severe local pain in an extremity. Although 50% of patients display signs of a soft tissue infection (e.g. swelling, tenderness, erythema), some present with only pain and no obvious physical findings. The development of a violaceous hue, bullae or necrosis points to a deeper infection, such as necrotizing fasciitis or myositis, and portends a worse outcome.

The disease may begin insidiously with nonspecific flu-like symptoms, such as fever, chills, myalgias and diarrhea. CNS symptoms (e.g. confusion, altered consciousness) are commonly seen. A generalized blanching macular erythema is observed much less often than in staphylococcal TSS, but blistering is more likely to occur. Desquamation on the hands and feet eventually appears in 20% of patients. Shock and multiorgan failure usually develop 48–72 hours after the onset of symptoms. Complications of streptococcal TSS can include renal failure, disseminated intravascular coagulation, and acute respiratory distress syndrome. The mortality rate for streptococcal TSS ranges from 30% to 60%.

Pathology

Biopsy specimens from skin lesions may show spongiosis, necrotic keratinocytes, subepidermal blister formation, and a neutrophilic and/or lymphocytic perivascular infiltrate in the dermis[31].

Diagnosis and differential diagnosis

Published criteria require isolation of group A streptococci from a sterile site for a "definite" diagnosis, combined with hypotension and clinical or laboratory abnormalities in two or more organ systems (see Table 74.8). Serum creatinine often rises early in the course, and creatine phosphokinase is elevated in the setting of necrotizing fasciitis or myonecrosis. The white blood cell count may be increased or normal with a substantial left shift[32]. Although staphylococcal and streptococcal TSSs share some common features, major differences exist (see Table 74.9).

Treatment

Most cases require intensive supportive therapy. Hypotension should be treated with aggressive intravenous fluid and vasopressors. Clindamycin inhibits the production of bacterial toxins and is a component of first-line antimicrobial treatment (together with penicillin); linezolid also blocks toxin production, and administration of IVIg to neutralize toxins may be of benefit. Early surgical intervention (e.g. drainage, debridement, fasciotomy, amputation) is crucial for necrotizing soft tissue infections and can be life-saving[33].

Erysipelas

Synonym: ■ St Anthony's fire

Introduction

Erysipelas is a superficial variant of cellulitis caused primarily by group A streptococci that affects the dermis with prominent lymphatic involvement; in contrast, classic cellulitis is centered in the deep dermis and subcutaneous tissues[34].

History

In the Middle Ages, erysipelas was thought to be caused by ingestion of the fungus *Claviceps purpurea*, which produces ergot alkaloids and is found in contaminated rye. The eponymous distinction refers to St Anthony, an Egyptian monk and healer who was believed to be the only person able to provide relief from erysipelas. An eleventh century hospital, the French House of St Anthony, had "fiery red" interior walls and was strictly devoted to the care of patients with erysipelas.

Epidemiology and pathogenesis

Erysipelas is a disease of the very young, the aged, the debilitated, and those with lymphedema or chronic cutaneous ulcers. Women outnumber men, but boys are more commonly affected than girls in the pediatric age group. There is an increased frequency during the summer months. The incidence of erysipelas has increased since the late 1980s.

Erysipelas is usually caused by group A streptococci; groups G, B, C and D streptococci are occasionally implicated. *S. aureus*, *Pneumococcus* spp., *Klebsiella pneumoniae*, *Yersinia enterocolitica* and *Haemophilus influenzae* type b can also cause an erysipelas-like infection.

Clinical features

Although erysipelas classically affects the face (Fig. 74.8C), the lower extremity is now the most common location. After an incubation period of 2 to 5 days, there is an abrupt onset of fever, chills, malaise and nausea. A few hours to a day later, a sharply marginated erythematous plaque with a ridge-like border develops and progressively enlarges. It is clearly demarcated from the surrounding skin (Fig. 74.8D), hot, tense and indurated with non-pitting edema. The affected area is painful to palpation and may burn. Regional lymphadenopathy is usually present, with or without lymphangitis. Pustules, vesicles, bullae and small areas of hemorrhagic necrosis may also form. Complications of erysipelas are uncommon and usually occur in patients with underlying disease. When the infection resolves, desquamation and postinflammatory pigmentary changes may ensue[35].

Pathology

Biopsy specimens reveal diffuse edema and a neutrophilic infiltrate in the dermis. Dilation of the lymphatics, foci of suppurative necrosis, and dermal–epidermal separation are often seen. There is no primary necrotizing vasculitis, thrombosis or leukocytoclasis.

Diagnosis and differential diagnosis

Diagnosis is based primarily on clinical findings. Laboratory evaluation shows an elevated leukocyte count with a left shift. Blood cultures are positive in only ~5% of cases. Although cultures from pustules or bullae may be helpful, the sensitivity of cultures of skin biopsy specimens is low, especially in immunocompetent hosts. Anti-DNase B and ASO titers are useful indicators of the streptococcal etiology. Direct immunofluorescence and latex agglutination tests can be used to detect streptococci within skin specimens.

The differential diagnosis of erysipelas includes other forms of cellulitis and soft tissue infections (e.g. erysipeloid, necrotizing fasciitis) as well as inflammatory causes of "pseudocellulitis" (Table 74.10).

Treatment

A 10- to 14-day course of penicillin is the treatment of choice for erysipelas caused by streptococci. Although macrolides such as erythromycin may be used in penicillin-allergic patients, some strains of *Str. pyogenes* are macrolide-resistant. Erysipelas may recur in patients with abnormal local circulation (e.g. lymphedema), and penicillin prophylaxis is occasionally required[36]. The future development of an effective vaccine against *Streptococcus* spp. could dramatically change the epidemiology of the infections caused by this microorganism[37].

Streptococcal Intertrigo

Intertrigo caused by group A streptococci is an under-recognized entity that usually affects young children. Infants are particularly vulnerable due to irritation and friction in moist, deep skin folds of the neck,

CAUSES OF "PSEUDOCELLULITIS"

Infections and bites
- Arthropod bite reactions (e.g. insect, spider)
- Erythema migrans
- Herpes zoster
- Toxin-mediated erythema (e.g. recurrent toxin-mediated perineal erythema)

Neutrophilic dermatoses
- Sweet's syndrome, neutrophilic panniculitis
- Familial Mediterranean fever, other periodic fever syndromes

Drug reactions
- Fixed drug eruptions (especially non-pigmenting)
- Vaccine/injection site reactions
- Toxic erythema of chemotherapy (e.g. due to gemcitabine)

Other inflammatory disorders
- Allergic contact dermatitis (including airborne and dermal)
- Phytophotodermatitis
- Well's syndrome
- Panniculitis, e.g. lipodermatosclerosis, erythema nodosum
- Thrombophlebitis
- Angioedema
- Interstitial granulomatous dermatitis, inflammatory granuloma annulare
- Inflammatory morphea

Metabolic disorders
- Gout

Malignancy
- Erysipeloid skin metastases (especially breast carcinoma)

Table 74.10 Causes of "pseudocellulitis".

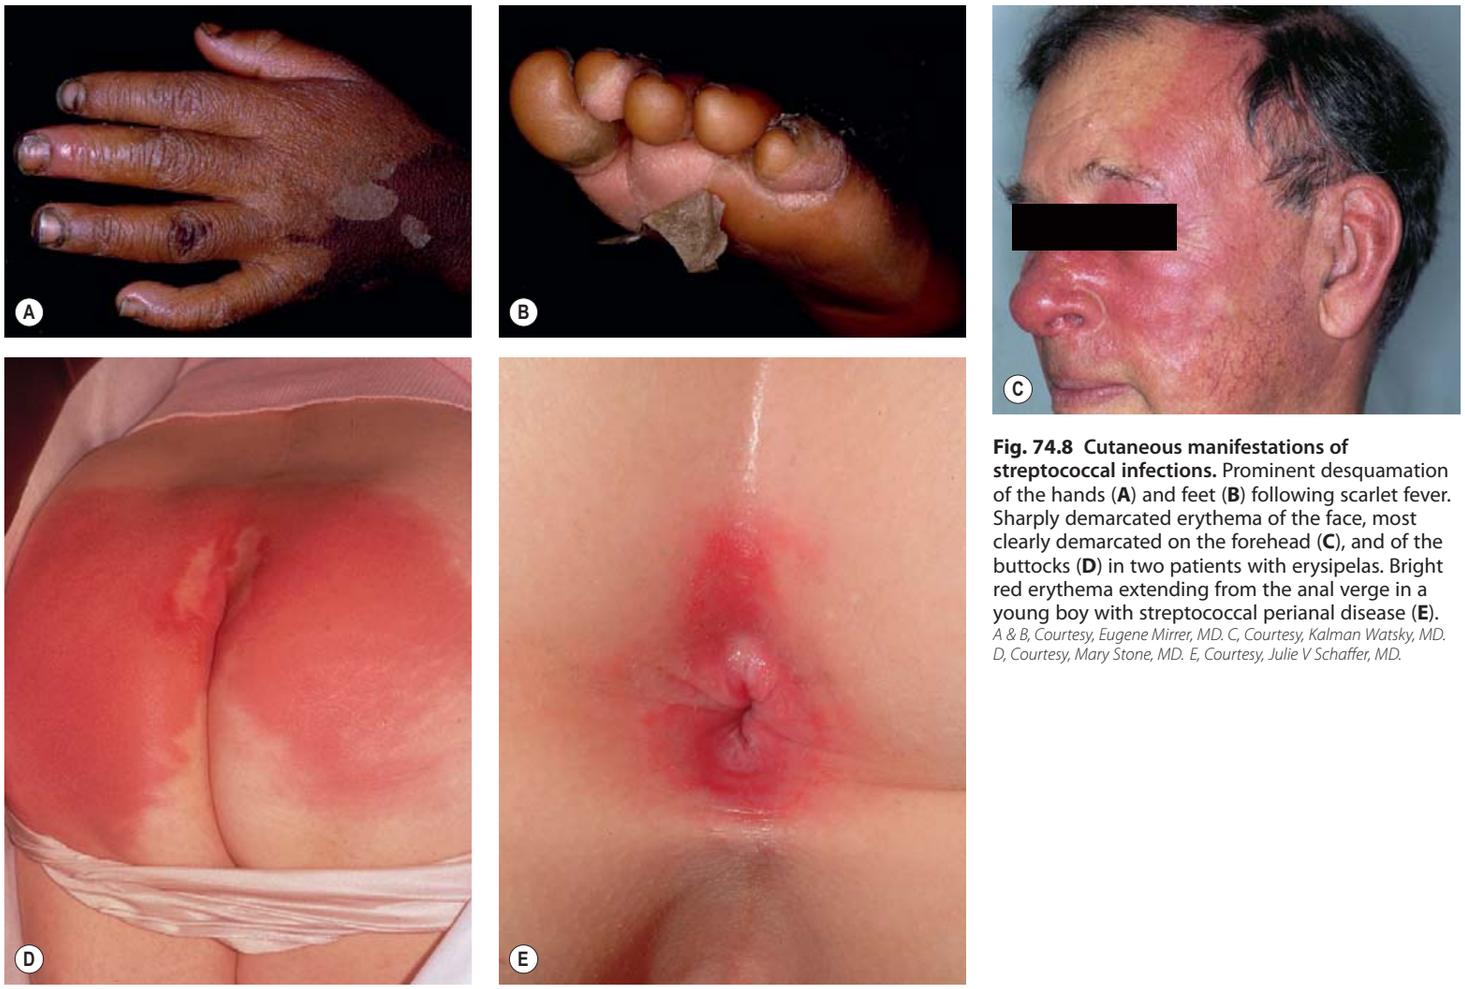

Fig. 74.8 Cutaneous manifestations of streptococcal infections. Prominent desquamation of the hands (**A**) and feet (**B**) following scarlet fever. Sharply demarcated erythema of the face, most clearly demarcated on the forehead (**C**), and of the buttocks (**D**) in two patients with erysipelas. Bright red erythema extending from the anal verge in a young boy with streptococcal perianal disease (**E**).
A & B, Courtesy, Eugene Mirrer, MD. C, Courtesy, Kalman Watsky, MD. D, Courtesy, Mary Stone, MD. E, Courtesy, Julie V Schaffer, MD.

axillae, antecubital and popliteal fossae, and inguinal region. Sharply demarcated, intensely erythematous patches or thin plaques are observed in an intertriginous site, often accompanied by a foul odor. In contrast to intertriginous candidiasis, satellite lesions are uncommon. Affected children occasionally exhibit irritability and low-grade fevers. Bacterial culture can confirm the diagnosis, which should be considered when simple intertrigo fails to respond to barrier creams and other measures to reduce friction and minimize moisture. A 10-day course of oral penicillin is usually effective[38].

Perianal Streptococcal Disease

Synonym: ▪ Perianal cellulitis ▪ Perianal streptococcal dermatitis

Perianal disease caused by infection with group A streptococci presents as sharply demarcated, bright red erythema extending 2–3 cm around the anal verge (Fig. 74.8E). Patients may complain of perianal pruritus or irritation, painful defecation, blood-streaked stools, or soiling of undergarments due to anal leakage. Systemic symptoms are absent. Children, especially boys under the age of 4 years, are most commonly affected. Perianal infection may be preceded by pharyngitis and should be considered in patients with an outbreak of guttate psoriasis.

Other causes of perianal erythema or pruritus include a *S. aureus* infection[38a], candidiasis, seborrheic dermatitis, pinworm infection, inflammatory bowel disease, child abuse, and the early phase of Kawasaki disease. Perianal streptococcal disease can be diagnosed with skin culture. In a recent randomized controlled study, a 7-day course of cefuroxime was found to be more effective than a 10-day course of penicillin in the treatment of perianal streptococcal disease[39].

Cellulitis

Introduction

Cellulitis is an infection of the deep dermis and subcutaneous tissue that manifests as areas of erythema, swelling, warmth and tenderness[40].

Epidemiology and pathogenesis

Cellulitis in immunocompetent adults is most often caused by group A streptococci or *S. aureus*, and the latter organism is the most frequent etiology in children. Although *H. influenzae* was once a common cause of cellulitis in pediatric patients, it is now rare due to routine vaccination against *H. influenzae* type b. A mixture of Gram-positive cocci and Gram-negative aerobes and anaerobes is often implicated in cellulitis surrounding diabetic and decubitus ulcers. Bacteria typically gain access to the dermis via a break in the skin barrier in immunocompetent individuals, but a bloodborne route is common in immunocompromised patients. Lymphedema, alcoholism, diabetes mellitus, intravenous drug abuse, and peripheral vascular disease are all risk factors for cellulitis. Recurrent bouts of cellulitis may result from damage to the lymphatic system (e.g. from a lymph node dissection, saphenous vein harvest or prior episode of cellulitis)[41,42].

Clinical features

Cellulitis is often preceded by systemic symptoms such as fever, chills and malaise. The affected area displays all four of the cardinal signs of inflammation: rubor (erythema), calor (warmth), dolor (pain), and tumor (swelling). The borders are usually ill-defined and non-palpable. In severe infections, vesicles, bullae (Fig. 74.9), pustules or necrotic tissue may be present. Ascending lymphangitis and regional lymph node involvement may occur. In children, cellulitis most often affects the head and neck, whereas in adults it tends to involve

Fig. 74.9 Bullous cellulitis. Extensive soft tissue infection of the lower extremity due to group A streptococcal infection.

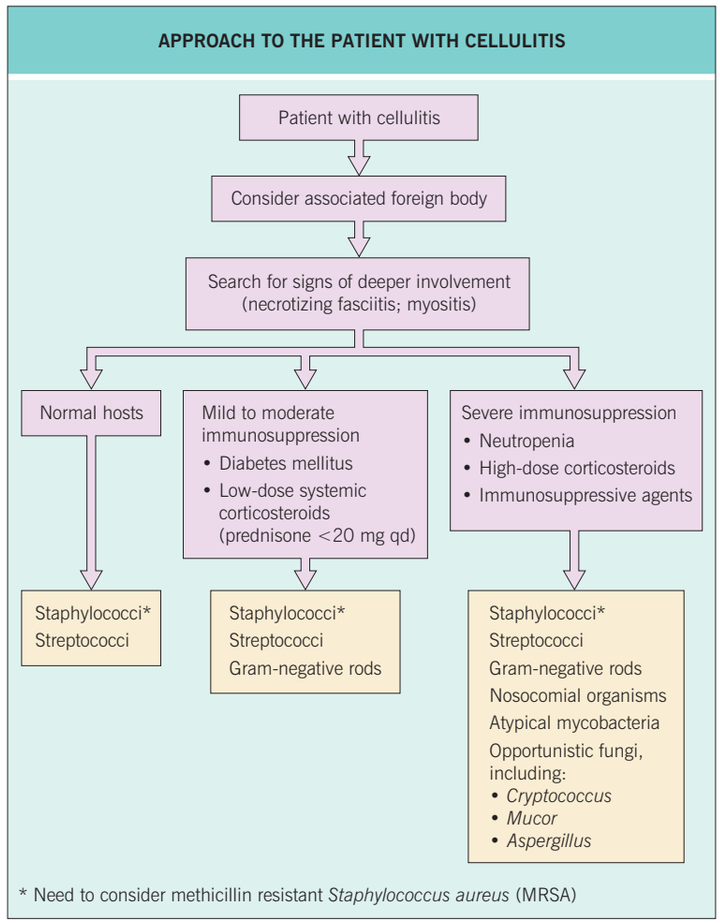

Fig. 74.10 Approach to the patient with cellulitis.

the extremities. Intravenous drug users typically develop cellulitis of the upper extremities (the usual sites of drug injection). Complications are uncommon, potentially including acute glomerulonephritis (if caused by a nephritogenic strain of streptococcus), lymphadenitis, subacute bacterial endocarditis, and recurrences related to abnormal lymphatic damage[42].

Pathology

A mild or moderate inflammatory infiltrate composed of lymphocytes and neutrophils can be seen throughout the dermis, often extending into the subcutaneous fat. Edema (occasionally leading to subepidermal bullae) and dilation of lymphatics and small blood vessels are also evident. With special stains, the causative organism may be identified.

Diagnosis and differential diagnosis

The diagnosis of cellulitis is usually clinical (Fig. 74.10). The leukocyte count is often normal or only slightly elevated. Blood cultures are almost always negative in immunocompetent hosts. An exception is *H. influenzae* cellulitis, where there is usually an increased leukocyte count with a left shift and positive blood cultures. Atypical organisms are more common in children and immunocompromised patients, and needle aspiration or skin biopsy may help to identify the infectious etiology. The differential diagnosis of lower extremity cellulitis includes deep vein thrombosis and inflammatory diseases such as stasis dermatitis, superficial thrombophlebitis and panniculitis (especially lipodermatosclerosis). While superficial thrombophlebitis often presents with redness and tenderness, the absence of a fever and the presence of a palpable cord aid in the diagnosis. Misdiagnosis of lipodermatosclerosis as cellulitis often leads to unnecessary hospitalizations. Additional causes of "pseudocellulitis" are listed in Table 74.10.

Treatment

Treatment of cellulitis is typically targeted against group A streptococci and *S. aureus*. For uncomplicated cases, a 10-day course of an oral antibiotic that covers these organisms (e.g. dicloxacillin, cephalexin or clindamycin) is appropriate. Hospitalization and parenteral antibiotics may be necessary for patients who are seriously ill, have facial involvement or fail to respond to oral therapy. If MRSA is suspected (e.g. cellulitis in association with an abscess), agents such as clindamycin, TMP-SMX or doxycycline should be used (see Table 74.5); if group A streptococcal infection is also a possibility, the latter agents should be combined with a β-lactam. Diabetic or decubitus ulcers complicated by cellulitis require broad-spectrum coverage (e.g. piperacillin/tazobactam or, in penicillin-allergic patients, metronidazole plus ciprofloxacin). Adjunctive measures include immobilization and elevation of an affected extremity and the application of wet dressings to areas with bullae or exudate. If signs and symptoms do not improve after 36–48 hours of treatment, cultures and susceptibilities should be obtained and antibiotics adjusted accordingly. NSAIDs may mask the signs and symptoms of deeper necrotizing infections and should be avoided when treating cellulitis. The clinical features and treatment of other types of cellulitis (e.g. *Erysipelothrix rhusiopathiae*, *Vibrio vulnificus*) are discussed below[43].

Pyomyositis

Pyomyositis is a primary bacterial infection of the skeletal muscles, most commonly caused by *S. aureus*[36]. Once referred to as tropical myositis, it is becoming more prevalent in temperate climates. Predisposing factors include trauma, diabetes mellitus, HIV infection, intravenous drug use and other forms of immunosuppression. Patients often present with a 1–2-week history of low-grade fevers, myalgias, and progressive firmness, pain and enlargement of a deep soft tissue mass. Palpation of the affected area reveals "woody" induration. Muscle abscess formation occurs during the second stage of disease, and septicemia may follow.

MRI is the diagnostic modality of choice for the first stage of the disease; ultrasound-guided aspiration may be helpful later in the course. Treatment includes incision and drainage as well as appropriate intravenous antibiotics until clinical improvement is noted, followed by oral antibiotics for a total of 3 weeks[36].

Botryomycosis

Synonyms: ■ Granular bacteriosis ■ Bacterial pseudomycosis

Introduction

Botryomycosis (named for its characteristic groups of granules that resemble grapes) is a rare, chronic, purulent and granulomatous bacterial infection that primarily affects the skin and is most often caused by *S. aureus*.

Epidemiology and pathogenesis

Botryomycosis is found worldwide, and over two-thirds of patients have only skin involvement. The disease affects all ages and has a slight male predominance (male : female ratio, 3 : 2). Although most cases are due to infection with *S. aureus*, it has also been caused by *Pseudomonas*, *Proteus*, *Moraxella*, *Serratia* and *Corynebacteria* spp. Defects of cellular immunity, particularly low T-lymphocyte counts, have been associated with the development of botryomycosis[44].

Clinical features

Botryomycosis presents as cutaneous and subcutaneous nodules, ulcers or verrucous plaques. Multiple sinuses and fistulas may discharge purulent fluid or yellow granules composed of bacterial masses. Most patients have localized disease on the extremities, and it may be preceded by trauma. The lesions may be pruritic, tender, or involve the underlying muscle or bone. Systemic symptoms are infrequent. Visceral botryomycosis most often affects the lungs and is extremely rare, occurring primarily in immunocompromised patients or following surgery[45].

Pathology

Biopsy specimens reveal a chronic inflammatory reaction with fibrosis and foreign body giant cells. The most distinctive feature is 1–3 mm granular bodies (grains) that represent bacteria, cells and debris. Grains have basophilic centers and a homogeneous, eosinophilic, hyaline periphery thought to be secondary to a host immunoglobulin response (Splendore–Hoeppli phenomenon). The granules stain with PAS, Gram and Giemsa.

Diagnosis and differential diagnosis

When botryomycosis is suspected, both bacterial and fungal cultures should be obtained and a skin biopsy performed for histopathologic examination (as well as culture). Microscopic examination (fresh mount or 20% KOH) shows coarsely lobulated granules with club-like projections. Gram staining of crushed granules usually displays masses of staphylococci. The differential diagnosis of cutaneous botryomycosis includes mycetoma, actinomycosis, a ruptured epidermoid cyst, a staphylococcal abscess, orf, tuberculosis, and dimorphic fungal or atypical mycobacterial infections.

Treatment

Botryomycosis is typically treated surgically with debridement or excision in conjunction with antibiotic therapy. The CO_2 laser has also been used successfully.

Necrotizing Fasciitis

Synonyms: ■ Type 1 – polymicrobial necrotizing fasciitis ■ Type 2 – group A streptococcal necrotizing fasciitis ■ "Flesh-eating bacteria" syndrome ■ Fournier's gangrene ■ Synergistic necrotizing cellulitis

Introduction

Necrotizing fasciitis is characterized by rapidly progressive necrosis of subcutaneous fat and fascia, which can be life-threatening without prompt recognition, aggressive surgical intervention and immediate antibiotic therapy.

Epidemiology and pathogenesis

Approximately 500–1500 cases of necrotizing fasciitis are reported each year in the US. Risk factors include diabetes mellitus, immunosuppression, cardiac or peripheral vascular disease, and renal failure, but it can also occur in young, previously healthy individuals. Necrotizing fasciitis may follow penetrating or blunt injury or develop in the absence of preceding trauma. Other predisposing factors include intravenous drug use, recent surgery, varicella, and decubitus or ischemic ulcers.

Mortality rates range from 20% to 40%. Higher mortality is associated with female sex, older age, greater extent of infection, delay to first debridement, an elevated serum creatinine or lactic acid level, disease due to group A streptococci, and a greater degree of organ dysfunction at the time of admission to hospital. Diabetes mellitus can also result in higher mortality, particularly if renal dysfunction or peripheral vascular disease is also present[46,47].

In children, necrotizing fasciitis is most commonly caused by group A streptococci. In adults, it frequently results from a polymicrobial infection (typically following trauma or surgery) with anaerobic and aerobic bacteria, including streptococci, *S. aureus*, *Escherichia coli*, *Bacteroides* and *Clostridium* spp. Uncommon pathogens include *V. vulnificus*, *Aeromonas hydrophila*, *Pseudomonas aeruginosa* and *H. influenzae* type b[48]. Opportunistic fungal infections, such as zygomycosis, can cause necrotizing fasciitis in immunocompromised patients[49].

Clinical features

Infection begins with an area of exquisite tenderness, erythema, warmth and swelling that does not respond to antibiotics. The skin appears shiny and tense. Initially, severe pain may be out of proportion to skin findings. The disease progresses at an alarming rate, with the skin changing from red and purple to a characteristic gray–blue color in ill-defined patches within 36 hours of onset. Violaceous and/or hemorrhagic bullae may develop. Necrosis of the superficial fascia and fat produces a thin, watery, malodorous fluid (Fig. 74.11). The area may later become anesthetic as cutaneous nerves are destroyed. The subcutaneous tissues may feel hard and "woody" on palpation. Patients can become extremely toxic, with fever, chills, malaise, leukocytosis, tachycardia and shock. The most common site of involvement is the extremities, although the trunk is often affected in children. When necrotizing fasciitis involves the perineum and genitalia, it is referred to as Fournier's gangrene[50].

Pathology

Gangrene of the subcutaneous tissues, with spread along fascial planes, is followed by involvement of the overlying skin. Fibrinoid necrosis is present in the media of vessels passing through the destroyed fascia, and fibrin thrombi are evident. The epidermis, dermis and skin appendages in the area of gangrene undergo coagulation necrosis. Infiltration with neutrophils and mononuclear cells as well as numerous bacteria occurs in upper layers of the dermis.

Diagnosis and differential diagnosis

Early in the disease course, it is often difficult to differentiate necrotizing fasciitis from cellulitis. The presence of severe pain or anesthesia suggests a deeper component, and an MRI can delineate the depth of tissue involvement. Other clues that suggest necrotizing fasciitis rather

Fig. 74.11 Necrotizing fasciitis. Necrosis of the subcutaneous fat and fascia of the inner aspect of the upper arm in an elderly patient with diabetes mellitus. Note the watery discharge. *Courtesy, Jean L Bolognia, MD.*

than cellulitis include rapidly spreading tense edema, hemorrhagic bulla formation, grayish discoloration, foul-smelling discharge and an elevated creatine phosphokinase level. Figure 74.12 outlines an algorithm for assessing and treating suspected necrotizing fasciitis. Conditions that can mimic necrotizing fasciitis include trauma with hematoma formation, clostridial myonecrosis, pyomyositis, phlebitis, bursitis and arthritis.

Treatment

Extensive surgical debridement (fasciotomy) is the mainstay of effective treatment. On occasion, amputation is necessary. Therapy (which can be directed by results of a Gram stain of exudate) should be initiated with a β-lactam/β-lactamase inhibitor with broad-spectrum coverage against streptococci, staphylococci, Gram-negative bacilli and anaerobes (e.g. ampicillin/sulbactam or piperacillin/tazobactam, often administered together with clindamycin and ciprofloxacin); an alternative is a carbapenem. In a patient with true penicillin allergy, empiric therapy with ciprofloxacin plus metronidazole or clindamycin can be used. Coverage of *Pseudomonas* spp. is particularly important for neutropenic patients. Hyperbaric oxygen therapy remains controversial, though it may be beneficial for a subset of patients with anaerobic Gram-negative necrotizing fasciitis; however, surgery and antimicrobial therapy should never be postponed. IVIg may be useful for patients with severe group A streptococcal infection. Nutritional support is crucial for enhancing postoperative wound healing, and, eventually, reconstructive surgery is often necessary[51].

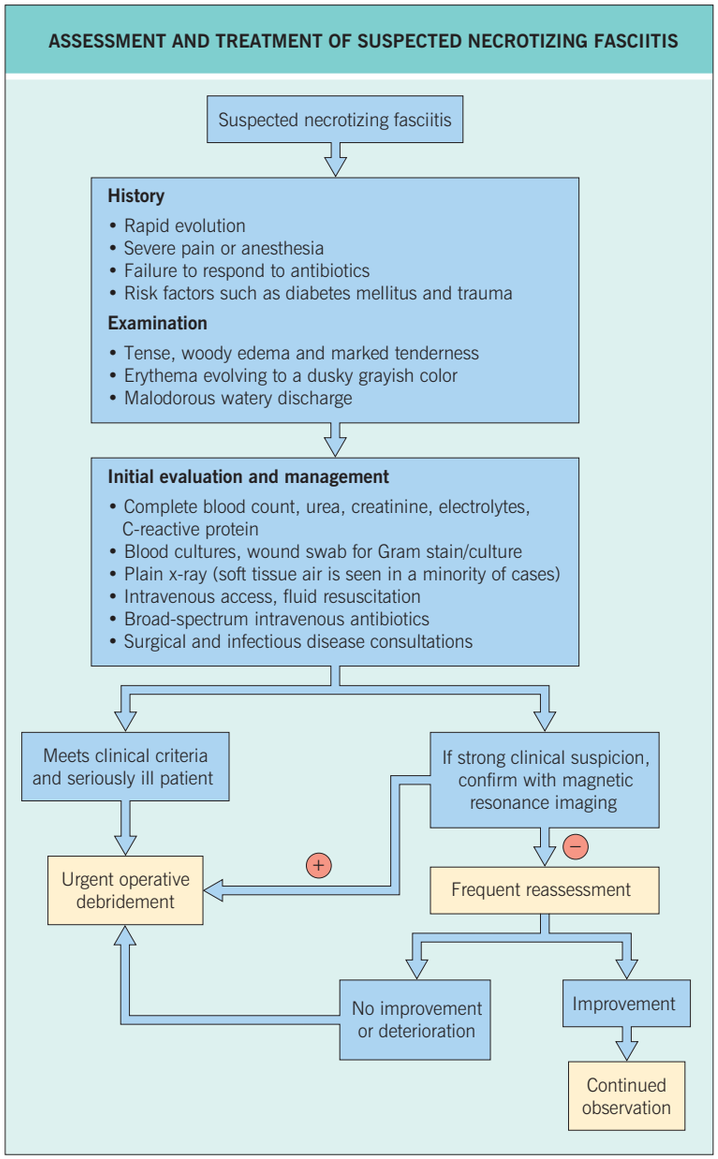

Fig. 74.12 Algorithm for assessment and treatment of suspected necrotizing fasciitis.

Bacteremia/Septicemia

Staphylococcal septicemia may occur in the absence of any cutaneous or internal focus of infection. Immunocompromised states, erythroderma (especially secondary to Sézary syndrome), central venous catheters, abnormal or prosthetic heart valves, and intravenous drug use are all risk factors for Gram-positive bacteremia. A large percentage of patients with late-stage cutaneous T-cell lymphoma eventually succumb to septicemia, especially staphylococcal. The skin lesions of *S. aureus* septicemia are classically pustular petechiae, purulent purpura, and subcutaneous abscesses that probably represent hematogenous spread of the infection to the skin. Biopsy specimens show nonspecific inflammation, often with a positive Gram stain, and cultures grow *S. aureus*. When *S. aureus* bacteremia leads to endocarditis, a number of other characteristic skin signs may appear, including petechiae, splinter hemorrhages, Osler's nodes (resulting from immune complex deposition and small vessel vasculitis) and Janeway lesions (septic emboli forming microabscesses). Clinically, Osler's nodes are tender, erythematous papules and nodules with white centers that favor the finger pads and thenar/hypothenar eminences, whereas Janeway lesions are painless, small hemorrhagic macules or papules on the palms and soles. Both staphylococcal bacteremia and endocarditis are treated with prolonged courses of intravenous antibiotics.

CLOSTRIDIAL SKIN INFECTIONS

Clostridia are spore-forming Gram-positive rods that are ubiquitous soil saprophytes and part of the normal intestinal flora. While *Clostridium perfringens* is an obligate anaerobe and thus proliferates in hypoxic or ischemic tissue, *C. septicum* is much more aerotolerant and requires a smaller infective dose.

C. perfringens produces two membrane-active toxins, α-toxin and perfringolysin, which have synergistic effects. Alpha-toxin possesses biologic activity akin to phospholipase C and sphingomyelinase, while perfringolysin disrupts endothelial cell integrity, impairs recruitment of phagocytes and induces intravascular platelet aggregation, leading to reduced arteriolar blood flow. Impaired oxygen delivery then results in tissue hypoxia and anaerobic glycolysis of muscle tissues. Production of hydrogen sulfide and CO_2 accounts for the characteristic "gas" gangrene visualized on radiographic imaging. Local progression results in myonecrosis, whereas shock and multiorgan failure can occur when the toxins enter the systemic circulation.

The majority of cases of anaerobic cellulitis (a necrotizing subcutaneous infection) and myonecrosis (gas gangrene) are caused by clostridia. These diseases are compared and their treatment outlined in Table 74.11. Soft tissue crepitus, evidence of gas on plain films, or a foul-smelling brownish discharge ("dirty dishwater") should prompt the clinician to suspect a clostridial infection, especially following trauma or surgery in patients with diabetes mellitus and peripheral vascular disease[52,53].

CORYNEBACTERIAL SKIN INFECTIONS

Corynebacteria are Gram-positive rods that account for nearly half of the cutaneous flora. A warm, moist local environment represents a risk factor for infection of the skin with non-diphtherial corynebacteria[54].

Erythrasma

Erythrasma is a superficial and often chronic skin infection caused by excessive proliferation of *Corynebacterium minutissimum* within the stratum corneum. The organism's growth is favored by moist, occluded intertriginous areas, including the groin, axillae, intergluteal fold, inframammary region, umbilicus, and web spaces between the toes. Other predisposing factors include a warm humid climate, poor hygiene, hyperhidrosis, obesity, diabetes mellitus, advanced age and immunosuppression[55]. Whether the associated scale precedes and promotes development of erythrasma or results from bacterial overgrowth is a matter of debate.

CLOSTRIDIAL ANAEROBIC CELLULITIS AND MYONECROSIS		
	Anaerobic cellulitis*	**Myonecrosis (gas gangrene)**
Risk factors (for both conditions)	Trauma (penetrating, "crush" injuries) or surgery, with improper/incomplete debridement or contamination of the wound Diabetes mellitus, peripheral vascular disease Injection drug use (e.g. black tar heroin) Colonic disease or malignancy (*C. septicum* myonecrosis)	
Organism†	*C. perfringens* > other anaerobic bacteria (e.g. *Bacteroides, Peptostreptococcus*, *Prevotella* spp.)	*C. perfringens* (~80%) > *C. novyi*, *C. septicum*
Incubation period	>3 days	12–24 hours
Course	Rapid	Very rapid
Exudate	Thin, dark gray–brown, foul-smelling ("dirty dishwater")	Thin, dark gray–brown, foul-smelling ("dirty dishwater")
Overlying skin changes	Minimal	Dark yellow to bronze discoloration, necrosis, bullae
Swelling	Minimal	Severe
Crepitus	Usually present (with abundant gas in subcutaneous tissues and along fascial planes)	Sometimes present
Pain	Absent or mild	Severe
Fever	Low-grade	Low-grade
Toxemia	Absent or mild	Present (e.g. tachycardia, hypotension, oliguria)
Bacteremia/laboratory findings	Typically absent/minimal	Bacteremia in ~15%; marked leukocytosis, hemolytic anemia
Treatment (for both conditions)	• Early, aggressive surgical debridement (repeated every 24–48 hours until clinical resolution) • The causative clostridial organisms are typically sensitive to penicillin; however, because the infections may be polymicrobial, broad-spectrum coverage (e.g. with clindamycin plus a third-generation cephalosporin) is indicated until culture results are available • Adjunctive hyperbaric oxygen therapy	

*Can progress to myonecrosis.
†Infections may be polymicrobial, which can lead to overlap with necrotizing fasciitis.

Table 74.11 Clostridial anaerobic cellulitis and myonecrosis.

Lesions are pink to red, well-defined patches that are covered with fine scales and have associated wrinkling. With time, the red color fades to brown (Fig. 74.13A,C). The condition is asymptomatic or mildly pruritic. A "disciform" variant can occur in a more widespread distribution outside the usual intertriginous locations (Fig. 74.13D); this is occasionally the presenting manifestation of type 2 diabetes mellitus. Interdigital erythrasma is the most common bacterial infection of the foot and the most frequent form of erythrasma. It presents as asymptomatic, chronic maceration with fissuring or scaling of interspaces[56]. Progression of erythrasma to cellulitis or bacteremia in immunocompromised patients has occasionally been reported.

When lesions are illuminated with a Wood's lamp, bright coral-red fluorescence appears as a result of porphyrin produced by the bacteria (Fig. 74.13B). Gram staining of the scale demonstrates Gram-positive filaments and rods, and corynebacteria can be cultured on Tissue Culture Medium 199. The differential diagnosis of intertriginous erythrasma includes tinea, seborrheic dermatitis and cutaneous candidiasis, while interdigital erythrasma needs to be distinguished from tinea and complex toe web infections[57].

Topical therapies include 20% aluminum chloride, clindamycin, erythromycin, azole antifungals, and Whitfield ointment (salicylic and benzoic acids). Oral erythromycin or tetracyclines can be used for widespread or recalcitrant cases. Use of antibacterial soaps may help to prevent recurrences.

Pitted Keratolysis

Synonyms: ▪ Keratolysis plantare sulcatum ▪ Ringed keratolysis

Introduction

Pitted keratolysis is a non-inflammatory bacterial infection of palmoplantar skin.

Epidemiology and pathogenesis

Pitted keratolysis occurs worldwide in temperate and tropical climates. Hyperhidrosis, prolonged occlusion, and increased skin surface pH are predisposing factors. Most infections are caused by *Kytococcus sedentarius* (formerly *Micrococcus sedentarius*), but other bacteria such as *Dermatophilus congolensis*, *Corynebacterium* and *Actinomyces* spp. have been implicated. *K. sedentarius* produces two serine proteases (K1 and K2) that degrade keratin in the stratum corneum[58]. Sulfur-containing compounds released by the bacteria lead to a characteristic associated malodor.

Clinical features

Small (1–7 mm), crater-like depressions are present within the stratum corneum on weight-bearing regions of the soles (Fig. 74.14) and (rarely) the palms. These pits may coalesce into large craters or rings of craters. There is usually no associated erythema, and the condition often goes unnoticed by the patient. Hyperhidrosis and malodor are common associated findings.

Pathology

Well-defined "pits" extend approximately two-thirds of the way into the stratum corneum. Gram, PAS and Gomori methenamine silver stains reveal bacteria in the walls and at the bottom of the craters. No inflammation is observed.

Diagnosis and differential diagnosis

The diagnosis of pitted keratolysis is usually clinical. There is no fluorescence on examination with a Wood's light. The differential diagnosis includes plantar warts, tinea pedis, palmoplantar punctate keratoderma, pits of nevoid basal cell carcinoma syndrome, Darier disease and circumscribed palmoplantar hypokeratosis.

Treatment

Topical erythromycin, clindamycin, mupirocin, tetracycline and azole antifungals have all been reported to lead to a rapid resolution of pitted keratolysis[54]. Oral erythromycin is occasionally indicated for extensive involvement. Aluminum chloride 20% solution or (in recalcitrant cases) botulinum toxin can be used to treat the associated hyperhidrosis.

Fig. 74.13 Erythrasma. Trichomycosis Axillaris

Trichomycosis axillaris is a superficial corynebacterial infection that results in concretions on the shafts of axillary and (less often) pubic hairs. The hair shafts develop adherent yellow, red or black nodules or cylindrical sheaths that can be seen with the naked eye (Fig. 74.15). There is a characteristic odor, and the sweat occasionally takes on a red color and stains clothing. However, like pitted keratolysis, the condition frequently goes unnoticed. Wood's lamp examination reveals a pale yellow fluorescence, and Gram staining of the concretions shows Gram-positive rods. The differential diagnosis includes white piedra, black piedra and hair casts (see Ch. 77). Shaving the affected hair provides an instant cure, and use of antimicrobial cleansers can prevent recurrences. Additional treatment options include topical erythromycin or clindamycin[54].

Cutaneous Diphtheria

Cutaneous infection with *Corynebacterium diphtheriae* is endemic in several tropical countries and some urban poor populations (e.g. recent reports of a nontoxigenic but invasive strain in Vancouver[58a]), where it is spread by person-to-person contact in a highly contagious manner. However, it is very rare in most parts of the world. For children living in endemic regions, cutaneous diphtheria represents a form of immunization, as toxin is absorbed slowly from skin lesions and induces high levels of antibodies. In addition to children, elderly and immunocompromised individuals are most commonly affected, with predisposing factors including poor hygiene, injection drug use and skin trauma. Vaccination against diphtheria does not necessarily prevent cutaneous disease.

Cutaneous diphtheria most commonly presents as an ulcer (ecthyma diphthericum) with a punched-out appearance and variable gray

Fig. 74.15 Trichomycosis axillaris. Cylindrical sheaths and beading of the axillary hairs. A yellow color is seen most commonly.

Fig. 74.16 Ecthyma diphthericum. Punched-out ulcer with a black eschar on the upper lip.

"pseudomembranous" eschar (Fig. 74.16). Acral sites are favored, and a pustule or crusted dermatitis may also be observed. Lesions are commonly co-infected with *S. aureus* or *Str. pyogenes*. Local lymphadenopathy and toxin-mediated complications, such as myocarditis and polyneuritis, are rare.

Gram stain and culture of the exudate can establish the diagnosis. Treatment includes a 10-day course of oral antibiotics (penicillin or erythromycin are first-line), thorough cleansing of the wound site, a topical antibiotic and (for toxigenic strains) intravenous diphtheria antitoxin[59].

OTHER GRAM-POSITIVE SKIN INFECTIONS

Cutaneous Anthrax

Key features

- *Bacillus anthracis* causes pulmonary, gastrointestinal and cutaneous disease
- Cutaneous anthrax has traditionally been considered an occupation-related condition
- In this century, *B. anthracis* re-emerged as a potential agent of biological warfare and terrorism

Introduction and epidemiology

The name *Bacillus anthracis* is derived from the Greek word for coal, *anthrakis*, reflecting the black, coal-like eschars. *B. anthracis* is an aerobic, sporulating, Gram-positive rod measuring 1–1.5 × 3–5 microns. The bacterium causes disease in humans via three routes: inhalation, ingestion and cutaneous inoculation; the last-mentioned produces the least severe form of anthrax and accounts for ~95% of infections. Anthrax is primarily a disease of animals (e.g. sheep, cows, horses, goats) that is endemic in parts of western Asia and Africa. Most human cases are due to occupational exposure to infected animals or their carcasses (including hides and wool; "woolsorter's disease")[60]. Two thousand cases are reported annually worldwide, with <10 per year in the US.

History

The fifth and sixth plagues of Egypt that are described in the book of Exodus are thought to have been anthrax. *B. anthracis* was the first bacterium proven to be the etiologic agent of a specific disease, independently demonstrated by Dr Robert Koch and Dr Louis Pasteur. Anthrax was first used as a biological weapon during World War I. Release of anthrax from a biological weapons complex in the Soviet Union in 1979 resulted in 66 fatalities. In 2001, anthrax spores were sent through the US mail as a terrorist weapon, resulting in 11 cases of inhalational anthrax and 5 fatalities[61].

Pathogenesis

Anthrax spores are environmentally hardy and can survive for decades in the soil. Full virulence requires the presence of both an antiphagocytic capsule and three toxin components (protective antigen, lethal factor and edema factor) that combine to form two toxins: lethal toxin and edema toxin. Edema toxin impairs neutrophil function and affects water homeostasis, leading to edema; lethal toxin causes release of TNF-α and IL-1β[62].

Clinical features

The clinical features of cutaneous anthrax are outlined in Table 74.12[63]. Additional key points include the following:

- The lack of pain despite a necrotic eschar helps to differentiate cutaneous anthrax from the bite of a brown recluse spider.
- A pustular primary lesion is unlikely to be cutaneous anthrax, although "cloudy" vesicles may be seen. The term "malignant pustule", which is often attributed to anthrax, is a misnomer.
- Vesicles may discharge serosanguineous fluid containing numerous organisms, which are evident on Gram stain.
- Lymphangitis and painful lymphadenopathy with systemic symptoms (fever, malaise, headache) occur rarely.
- Antibiotic therapy does not alter the progression from vesicle to ulcer to eschar, as the process is toxin-mediated.
- Multiple lesions, when present, tend to cluster in the same area of the body.

Pathology

Spongiosis, papillary dermal edema, and a superficial and deep inflammatory infiltrate with abundant neutrophils are observed. Substantial

CUTANEOUS ANTHRAX – CLINICAL CHARACTERISTICS
• Incubation period averages 7 days (range 1–12 days) • A purpuric macule or papule develops in an exposed area (e.g. forearm, neck, chest, finger); the papule may resemble an insect bite and can be pruritic • Within 48 hours of the lesion's appearance, a vesicle (1–3 mm) forms with surrounding non-pitting edema • The central vesicle ulcerates and small vesicles may form around the ulcer • The lesion becomes hemorrhagic and depressed, and a *painless,* black necrotic eschar forms centrally with an increase in the surrounding erythema and edema • The eschar dries, loosens and sloughs over the next 1–2 weeks, with no permanent scar

Table 74.12 Cutaneous anthrax – clinical characteristics. *Adapted from Carucci JA, McGovern TW, Norton SA, et al. Cutaneous anthrax management algorithm. J Am Acad Dermatol. 2002;47:766–9.*

hemorrhage is often evident, and the inflammatory infiltrate may involve nerves. Extensive ulceration and coagulative necrosis can be seen in older lesions. Elongated Gram-positive bacilli are present, often in small clusters. Spores grow readily on all routine culture media at 37°C, with a "jointed bamboo-rod" cellular appearance and a unique "curled-hair" colonial morphology.

Diagnosis and differential diagnosis

Gram staining of exudate or touch preparations can aid in rapid diagnosis. The organism grows in culture within 6–24 hours; however, antibiotic administration for more than 24 hours prevents the recovery of pathogens in culture.

Laboratory personnel must be alerted to the possibility of anthrax to ensure that the *Bacillus* isolate is not assumed to be *B. cereus* and that further speciation is performed. Definitive diagnosis requires specific testing such as phage gamma lysis and detection of capsule and wall antigens. Serologic assays can become positive as early as 10 days after onset of symptoms, with peak titers at 40 days.

The differential diagnosis includes cutaneous infection with *Bacillus megaterium*[63a], a brown recluse spider bite, the eschar of several rickettsial diseases, soft tissue infections (e.g. cellulitis), orf, milker's nodule, opportunistic bacterial and fungal infections, and entities in the ulceroglandular category (e.g. tularemia; see below).

Treatment

Without antibiotic treatment, mortality from cutaneous anthrax may be as high as 20% (usually from septicemia), but that number falls to almost zero with proper antimicrobial therapy. Although antibiotics do not alter the evolution of the cutaneous lesions (which are toxin-mediated), the likelihood of systemic illness is reduced. In the US, cutaneous anthrax is assumed to potentially be associated with a concomitant inhalational exposure; as a result, the Centers for Disease Control and Prevention (CDC) recommend antibiotic therapy for at least 60 days (rather than 7–10 days). Quinolones (e.g. ciprofloxacin 500 mg orally twice daily) are first-line agents, with doxycycline as an alternative therapy[64].

An anthrax vaccine, consisting of an inactivated cell-free filtrate of a non-encapsulated, attenuated strain of *B. anthracis*, is available. It is approved for use as postexposure prophylaxis and can be administered in conjunction with antimicrobials in cases of bioterrorism. Following the initial dose, the vaccine is administered at 4 weeks and 6, 12 and 18 months, followed by yearly boosters.

Bacillus cereus Infection

Bacillus cereus is a large Gram-positive rod best known for causing mild food poisoning. However, it can also produce primary cutaneous disease as well as life-threatening pneumonia, meningitis or necrotizing fasciitis in immunocompromised patients. Skin infection typically presents as a single necrotic bulla, and *B. cereus* infection should be considered in neutropenic patients with such a lesion. These individuals typically present with high fevers and negative blood cultures. Vancomycin is considered the drug of choice, but quinolones and imipenem may also be used[65].

Erysipeloid

Synonyms: ■ Diamond skin disease ■ Erysipeloid of Rosenbach (localized cutaneous form) ■ Pseudoerysipelas

Erysipeloid is an acute cutaneous infection caused by *Erysipelothrix rhusiopathiae*, a Gram-positive, non-motile, smooth or curved bacillus. It is caused by traumatic inoculation of the organism into the skin, which most often occurs in fishermen or persons who prepare meat, poultry or fish. There are two types of erysipeloid, localized and generalized, and they usually occur within 1 week of inoculation. The *localized form* is characterized by an erythematous to violaceous area of non-suppurative cellulitis (Fig. 74.17), which can be pruritic or painful. Hemorrhagic vesicles may develop. Although the classic finding is involvement of the finger webs with sparing of the terminal phalanges, other sites may be affected. Constitutional symptoms are unusual in localized erysipeloid, which is typically a self-limited condition. However, the *generalized form* presents with fever and arthralgias in addition to widespread cutaneous lesions. The latter range from perifollicular papules to erythematous plaques to macular purpura and necrosis. Complications can include endocarditis, septic arthritis, and cerebral and other visceral abscesses. The organism is often difficult to culture, and PCR-based assays can help to establish the diagnosis[66]. Erysipelas, cellulitis, spider bites and fixed drug eruptions may simulate localized erysipeloid (see Table 74.10). Most patients with untreated localized disease recover spontaneously. Penicillin is the drug of choice; erythromycin, cephalosporins and tetracyclines are alternatives. The best means of prevention is using gloves when preparing fish or meat[67].

Fig. 74.17 Erysipeloid. Erythema and edema with vesicle formation on the hand and fifth digit.

Listeriosis

Listeria monocytogenes is a motile Gram-positive bacillus that is ubiquitous in the environment (e.g. soil, water, vegetation) and represents a common veterinary pathogen (especially in sheep and cattle). In humans, infection is usually acquired by eating contaminated food and primarily affects the elderly, pregnant women and immunocompromised individuals (e.g. those with HIV infection or receiving immunosuppressive medications). These patients most often develop a gastrointestinal illness (accompanied by fever, myalgias and bacteremia) or meningitis. Neonatal septicemia and meningitis due to vertical transmission can also occur and may be associated with disseminated skin lesions ranging from pustules (or occasionally vesicles) to petechiae and purpura to granulomatous papules and nodules. In addition, veterinarians and farmers who assist animals in parturition may acquire primary cutaneous listeriosis, which typically presents with pustular or papular lesions on the arms and hands. The first-line treatment for listeriosis is ampicillin, and TMP-SMX represents an alternative; *L. monocytogenes* is resistant to cephalosporins.

GRAM-NEGATIVE BACTERIA

NEISSERIA MENINGITIDIS

Acute and Chronic Meningococcemia

Introduction

Meningococcemia is characterized by fever and a petechial eruption, and it has acute and chronic forms. The causative organism, *Neisseria meningitidis*, is an aerobic Gram-negative diplococcus.

Epidemiology and pathogenesis

Meningococcal infections occur worldwide and affect primarily infants (6 months to 1 year), adolescents and young adults. There is a male predominance, with a male:female ratio of 3–4 : 1. Most cases develop in the winter and spring. Individuals with asplenia or deficiency (congenital or acquired) in a terminal complement component (C5–C9),

properdin, factor D or immunoglobulins are at increased risk of infection (see Ch. 60). In addition, there is evidence that patients with low TNF-α production, high IL-10 production, or homozygosity of certain alleles at the IL-1 locus are at increased risk of a fatal outcome[68].

At least 13 strains of *N. meningitidis* are known, of which strains A, B, C, Y and W-135 are most often implicated in human disease. *N. meningitidis* owes its virulence to its polysaccharide capsule. Proliferation of *N. meningitidis* in contact with host cells increases the production of a bacterial transferase that adds phosphoglycerol onto its type IV pili; this modification results in bacterial detachment and migration across the epithelium, a prerequisite for dissemination and invasive disease[69]. The bacteria elaborate an endotoxin that triggers inflammatory processes leading to shock, multiorgan failure and purpura fulminans.

The only known reservoir is the human nasopharynx. Rates of carriage in the US range from 5% to 15%. Transmission is by the respiratory route, with an incubation period of 2–10 days. Active or passive exposure to tobacco smoke, as well as concurrent viral infection of the upper respiratory tract, disrupts the integrity of the respiratory mucosa and thereby increases the risk of invasive meningococcal disease.

Clinical features

Infection with *N. meningitidis* most often results in an asymptomatic carrier state, which leads to lifelong immunity against that subgroup. Upper respiratory symptoms as well as bacteremia without sepsis may also occur. When acute meningococcemia develops, one-third to one-half of patients present with a petechial eruption, typically in association with a fever, chills, myalgias and headache. Retiform purpura (Fig. 74.18) and ischemic necrosis may follow. Bullous hemorrhagic lesions occasionally arise, most commonly on the trunk and lower extremities. In a minority of patients, only a transient, blanchable morbilliform eruption is seen. Hypotension, meningitis, meningoencephalitis, pneumonia, arthritis, pericarditis, myocarditis and progression to disseminated intravascular coagulation (DIC) can occur in association with the petechial and purpuric eruption of acute meningococcemia.

Chronic meningococcemia is a rare disease that is characterized by recurrent episodes of fever, arthralgias, and the development of erythematous macules and papules 12–24 hours after the onset of fevers (Fig. 74.19). The skin lesions may develop into tender nodules with indistinct borders. Petechiae, retiform purpura, pustules and erythema multiforme-like lesions have also been described. The fever and rash of chronic meningococcemia tend to resolve concurrently and then recur within 2–10 days.

Pathology

Biopsy specimens from patients with acute meningococcemia show leukocytoclastic vasculitis and thrombosis; organisms can be visualized with Gram stain in 70% of cases. In chronic meningococcemia, a perivascular infiltrate composed of lymphocytes and a few neutrophils can be appreciated; leukocytoclastic vasculitis may be seen in petechial lesions.

Diagnosis and differential diagnosis

The initial diagnosis is often clinical. Time is of the essence in diagnosing patients with meningococcemia and initiating treatment, as rapid decompensation occurs in acute infections. Cultures for *N. meningitidis* from blood and skin as well as cerebrospinal, synovial and pericardial fluid may have a low sensitivity, especially after administration of antibiotics. Latex agglutination tests that detect group A, B, C, Y and W-135 antigens in the CSF and urine have good specificity but low sensitivity. PCR-based assays have better sensitivity (which may be higher in skin biopsy specimens than blood or CSF samples[70]) and specificity, and their use is increasing (where available). The diagnosis of chronic meningococcemia can be confirmed via blood cultures obtained during a febrile episode.

Acute meningococcemia must be differentiated from enteroviral infections (which can present with meningitis and a petechial exanthem), Rocky Mountain spotted fever, septic vasculitis due to acute bacteremia and endocarditis, TSS, purpura fulminans, leptospirosis and various non-infectious vasculitides. The differential diagnosis of chronic meningococcemia includes bacterial endocarditis, Sweet's syndrome, Henoch–Schönlein purpura, rat-bite fever, erythema multiforme and chronic gonococcemia. The arthralgias associated with chronic meningococcemia must not be confused with rheumatic disease, as administration of corticosteroids could provoke progression of the infection[71].

Treatment

The treatment of choice for acute meningococcemia is high-dose intravenous penicillin; chloramphenicol and quinolones are alternatives in patients with a history of immediate-type hypersensitivity to penicillins (although some strains are resistant to the latter agents). In areas of high penicillin resistance or when other forms of bacterial meningitis are considerations, a third-generation cephalosporin can be utilized. Chronic meningococcemia is treated with similar antibiotics. All close contacts should receive prophylactic treatment with ciprofloxacin, rifampin, azithromycin or ceftriaxone. Experimental therapies that have been tried in small numbers of patients include activated protein C, anti-endotoxin monoclonal antibodies, tissue plasminogen activator, antithrombin III infusion, topical nitroglycerin, plasmapheresis and extracorporeal membrane oxygenation[72]. To date, these interventions have not proven to be effective in decreasing mortality.

A quadrivalent vaccine that protects against serogroups A, C, Y and W-135 is available in the US and is routinely given to children at the age of 11–12 years (with a booster at age 16 years) and to other individuals

Fig. 74.18 Acute meningococcemia. Purpura with irregular outline and central gunmetal grey color. *Courtesy, Kalman Watsky, MD.*

Fig. 74.19 Chronic meningococcemia. Multiple erythematous crusted papules and nodules on the arm.

at high risk for infection, such as college students who live in dormitories and military recruits. The duration of immunity is 3–5 years, and the vaccine it not effective in children less than 2 years of age[73],

PSEUDOMONAS AERUGINOSA

Pseudomonas aeruginosa is a ubiquitous Gram-negative, strictly aerobic, motile bacillus. It is widely distributed in the soil and on plants, growing especially well in aqueous environments. This organism has relatively low virulence and usually requires a local anatomic or immunologic defect to cause disease. Primary cutaneous infection with *P. aeruginosa* can occur in otherwise healthy individuals in areas exposed to high levels of moisture in conjunction with skin barrier disruption; these infections have a very good prognosis. In contrast, cutaneous manifestations of *Pseudomonas* sepsis in immunocompromised individuals are associated with a grave prognosis[74].

Green Nail Syndrome

In green nail syndrome, the nail develops green–black to green–blue discoloration due to pyocyanin, a blue–green pigment produced by *P. aeruginosa* (Fig. 74.20). Predisposing factors include frequent or prolonged exposure to water, excessive use of detergents and soaps, nail trauma, and other causes of onycholysis. The diagnosis of green nail syndrome is usually clinical; if necessary, it can be confirmed by Gram stain and culture of exudate and nail fragments. The differential diagnosis includes a subungual hematoma, melanocytic nevus, melanoma and *Aspergillus* infection. Treatment involves avoidance of predisposing factors, clipping the nail, and topical application of a quinolone or aminoglycoside (e.g. tobramycin) solution for 1–4 months. In refractory cases, removal of the affected nail can be considered.

Pseudomonal Pyoderma and Blastomycosis-like Pyoderma

Pseudomonal pyoderma is a superficial infection of the skin with *P. aeruginosa*. Features include a blue–green purulence, a "grape juice-like" or "mousy" odor, and a moth-eaten appearance of the skin. The borders are often macerated and eroded (Fig. 74.21). Pseudomonal pyoderma can complicate burns, decubitus ulcers and other chronic cutaneous ulcers. Pseudomonal pyoderma often plays a role in Gram-negative toe web infections and in "infectious eczematoid dermatitis" on the hands and feet or in the anogenital region.

Blastomycosis-like pyoderma is a rare condition that presents as large verrucous plaques with multiple pustules and elevated borders. Histologic examination reveals pseudoepitheliomatous hyperplasia with intraepidermal abscesses; fungi are not seen, and fungal cultures are negative. This condition usually occurs in immunocompromised patients, and other bacteria (e.g. *S. aureus*) have also been implicated.

Treatment of these conditions includes systemic antipseudomonal antibiotics, topical antimicrobial and drying agents, and debridement (e.g. of the hyperkeratotic rim in web space infections). Additional treatment options for blastomycosis-like pyoderma include surgical excision, electrodesiccation and curettage, and ablative laser therapy.

Otitis Externa and Malignant Otitis Externa

P. aeruginosa colonizes 1–2% of normal ear canals. However, acute pseudomonal infection can result in otitis externa ("swimmer's ear"). In this condition, the external auditory canal is swollen and macerated with a green, purulent discharge. The tympanic membrane is uninvolved, and manipulation of the pinna results in extreme pain. An exudative dermatitis of the external ear and retroauricular area may also be present. Treatment includes removal of canal debris, antibiotic eardrops (preferably those that also cover *S. aureus*, since co-infection is common), and possibly the instillation of a cotton wick. Oral therapy is only occasionally required.

Malignant otitis externa is a severe variant that is seen most often in elderly diabetic patients and those with HIV infection or other immunodeficiencies. Manifestations include severe pain, persistent drainage, and the development of granulation tissue at the junction of the osseous and cartilaginous portions of the auditory canal. Local lymphadenopathy and parotid swelling may be present. Deeper invasion can result in osteomyelitis of the skull, nerve palsies, mastoiditis, sepsis and sigmoid sinus thrombosis. Treatment includes extended courses of intravenous antipseudomonal penicillins or cephalosporins as well as oral ciprofloxacin, and surgical intervention may be required[75].

Auricular chondritis secondary to *Pseudomonas* spp. has also been associated with piercing of the cartilaginous portion of the pinna[76].

Pseudomonal Folliculitis

Pseudomonal folliculitis ("hot tub folliculitis") is associated with the use of whirlpools, hot tubs and (less often) swimming pools with low chlorine levels[77]. Erythematous, edematous perifollicular papules and papulopustules arise 8–48 hours after exposure and resolve spontaneously in 7–14 days (see Ch. 38). The lesions frequently occur in sites covered by bathing suits, and the face and neck are usually spared. Associated symptoms (which do not reflect systemic spread of *P. aeruginosa*) may include pruritus, painful eyes, earaches, a sore throat, headache, fever, painful swollen breasts, malaise, rhinorrhea, nausea, vomiting and abdominal pain.

The diagnosis can be confirmed by isolation of *P. aeruginosa*, especially serotype O-11, from lesions. The differential diagnosis includes other forms of folliculitis (e.g. due to *S. aureus*) and papular urticaria.

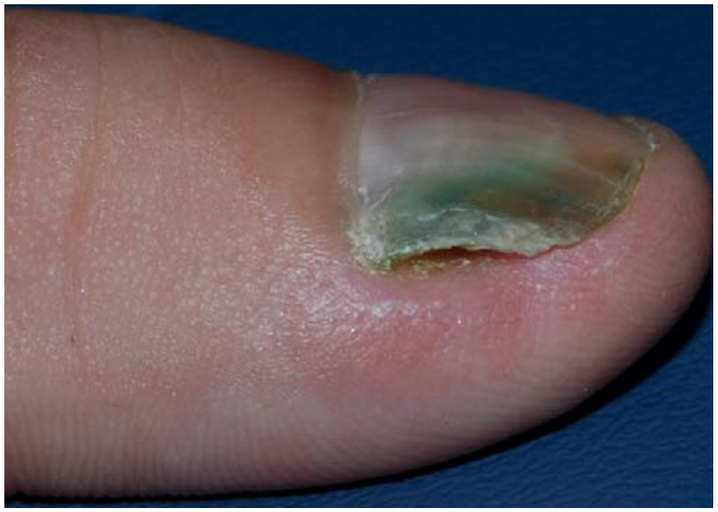

Fig. 74.20 Green nail syndrome. Blue–green discoloration of the nail due to pyocyanin produced by *Pseudomonas aeruginosa*. Note the associated onycholysis. *Courtesy, Julie V Schaffer, MD.*

Fig. 74.21 Superficial infection of the skin with *Pseudomonas*. Note the maceration, erosions and moth-eaten appearance of the skin. *Courtesy, Kalman Watsky, MD.*

Fig. 74.22 Pseudomonas hot-foot syndrome. Tender erythematous nodules on the heel. *Courtesy, Justin J Green, MD.*

Treatment is generally not indicated in immunocompetent hosts, as it is usually a self-limited process. In the case of widespread eruptions, recurrences, immunosuppression or associated systemic symptoms, an oral quinolone or topical gentamicin can be used.

Pseudomonas Hot-Foot Syndrome

Pseudomonas hot-foot syndrome occurs after swimming or wading in pool water that contains high concentrations of *P. aeruginosa*. The soles may be diffusely erythematous, and extremely painful, red-to-purple, 1–2 cm nodules develop on weight-bearing surfaces (Fig. 74.22); palmar involvement occasionally occurs. Systemic symptoms are uncommon. Histologic examination of the nodules shows perivascular and periecrine neutrophilic infiltrates with microabscess formation. The condition is self-limiting and requires only symptomatic treatment. Idiopathic palmoplantar hidradenitis (see Ch. 39) has identical clinical features and may be pathogenically related to pseudomonas hot-foot syndrome. Additional diagnostic considerations may include pernio, symmetric lividities and erythema nodosum[78].

Ecthyma Gangrenosum

P. aeruginosa septicemia occurs primarily in patients who are immunocompromised, with severe neutropenia representing a major predisposing factor. Fever, hypotension and alterations in consciousness often develop, and ecthyma gangrenosum is an occasional cutaneous manifestation. Lesions are usually few in number and begin as erythematous or purpuric macules, most commonly located in the anogenital area or on the extremities. They then evolve into hemorrhagic vesicles or bullae, which rupture and become necrotic ulcers with a central black eschar. The surrounding tissue is erythematous and tender (Fig. 74.23). Of note, a localized anogenital form of ecthyma gangrenosum can also occur in immunocompromised patients (including premature infants[79]) and may not be associated with identifiable bacteremia.

Histologic examination shows a necrotizing hemorrhagic vasculitis, and Gram-negative rods can be seen in the medial and adventitial walls of deeper vessels. The intima is characteristically spared. Multiple lesions, prolonged neutropenia, and a delay in antibiotic treatment portend a poor prognosis. Once the diagnosis is suspected, biopsy and tissue culture of a skin lesion (as well as blood and urine cultures) should be performed, followed by prompt initiation of intravenous therapy with an aminoglycoside and an antipseudomonal penicillin. Nowadays, *Pseudomonas* sepsis is seen less frequently in oncology patients due to shorter durations of neutropenia (secondary to the use of colony-stimulating factors and peripheral blood stem cell rather than bone marrow transplants) and administration of prophylactic antibiotics.

Clinically identical lesions can result from septic emboli due to other organisms, including *E. coli, Aeromonas hydrophila, Burkholderia cepacia, Candida, Fusarium, Aspergillus* and other saprophytic fungi[80].

Fig. 74.23 Ecthyma gangrenosum. Embolic lesion of *Pseudomonas aeruginosa* on the chest. Note the necrotic center and inflammatory border.

BARTONELLA

The genus *Bartonella* encompasses species formerly designated as *Rochalimaea* and *Grahamella*. *Bartonella* are small, pleomorphic, facultative intracellular Gram-negative bacilli closely related to *Brucella* species. Although there are 21 known species of *Bartonella*, only three are known to cause human disease, namely *B. henselae* (cat scratch disease), *B. quintana* (trench fever) and *B. bacilliformis* (Carrion's disease). Both *B. henselae* and *B. quintana* also cause bacillary angiomatosis and endocarditis. One study found that two-thirds of patients with Henoch–Schönlein purpura had antibodies to *B. henselae*[81]. Depending on factors such as the immune status of the infected individual, a particular *Bartonella* species can cause either acute or chronic infection and manifestations ranging from vascular proliferation to suppuration[82].

Bartonellosis

Synonyms: ■ Carrion's disease ■ Oroya fever ■ Verruga peruana

Introduction

Bartonellosis is a potentially life-threatening biphasic infection caused by *Bartonella bacilliformis*. Two clinical forms of bartonellosis are recognized: (1) Oroya fever, an acute febrile disease with associated hemolytic anemia; and (2) verruga peruana (Peruvian wart), a chronic disease characterized by cutaneous vascular lesions.

History

The biphasic nature of bartonellosis was first described in 1540 by Miguel de Steta. In 1885, a medical student, Daniel Carrion, died of complications of Oroya fever after inoculating himself with blood derived from a lesion of verruga peruana, proving a common causality for the two disease states.

Epidemiology and pathogenesis

The disease is transmitted by the bite of a Phlebotomine sand fly (*Lutzomyia verrucarum*). It occurs in mountain valleys of Peru, Ecuador and southwestern Colombia, where the vector resides. There is no racial, gender or age predilection, but the disease tends to be milder in children than in adults. The incubation period varies between 3 and 14 weeks.

Clinical features

The onset of *Oroya fever* is often sudden, with dyspnea, weakness, pallor, tachycardia, fever, thirst, anorexia, arthralgias and headache. A precipitous drop in the erythrocyte count may occur secondary to

massive hemolysis, and hyperbilirubinemia and hemoglobinuria can result. After the initial septicemia, a variable degree of immunodeficiency ensues. During this phase, a third of patients develop secondary bacterial infections; when death occurs, it is often secondary to an enteropathic bacterial infection, especially with *Salmonella enterica*. Lymphadenopathy, splenomegaly, and megaloblastic hyperplasia of the bone marrow are seen in severe cases. Patients with Oroya fever usually require 8–10 weeks for full recovery.

Most patients who recover from Oroya fever develop cutaneous nodules during or after their convalescent period, but *verruga peruana* can also appear in previously asymptomatic individuals. Bright red papules and nodules (2 mm to several centimeters in diameter) appear within small erythematous patches. Lesions may be sessile or pedunculated and are usually located on the head and extremities. Hemorrhage, ulceration and secondary bacterial infection can occur. In the absence of complications, lesions usually heal without scarring but may recur[83].

Pathology

The histologic features of verruga peruana vary and can resemble those of a pyogenic granuloma or Kaposi sarcoma. Masses of intracytoplasmic *Bartonella* organisms (Rocha–Lima inclusions) are present within swollen endothelial cells (as well as red blood cells); the bacilli are also found extracellularly. Thrombosis and occlusion of vessels occurs.

Diagnosis and differential diagnosis

The presence of organisms within red blood cells or within the cytoplasm of endothelial cells is diagnostic. *B. bacilliformis* can be isolated from blood cultures and an ELISA is available. The differential diagnosis of verruga peruana includes multiple pyogenic granulomas, bacillary angiomatosis, warts, molluscum contagiosum and yaws.

Treatment

Table 74.13 outlines the treatment recommendations for bartonellosis.

Cat Scratch Disease

Synonyms: ■ Cat scratch fever ■ Subacute regional lymphadenitis ■ Inoculation lymphoreticulosis ■ English–Wear infection

Introduction

Cat scratch disease (CSD) is caused by infection with *Bartonella henselae*. In immunocompetent hosts, it is a benign, self-limited illness characterized by tender regional lymphadenitis that lasts for weeks to months. Over 90% of patients report a recent scratch and/or bite from a cat[84].

Epidemiology and pathogenesis

Approximately 20 000 cases of CSD are diagnosed annually in the US. CSD occurs worldwide and has a predilection for younger persons (median age 15 years). Both sexes are equally affected. In the US, CSD is most common during the fall and winter. Transmission of infection among cats occurs via a flea vector (*Ctenocephalides felis*). Although flea-vectored transmission to humans has not been documented, it could explain some cases in which there is no history of exposure to cats.

Clinical features

CSD is the most common cause of persistent lymphadenopathy (longer than 3–4 weeks) in children and adolescents. Lymphadenopathy usually presents 2–4 weeks after a scratch and can last 2–6 months (or longer if fibrosis occurs). A single, large (1–10 cm), tender, mobile lymph node, with erythema and swelling of the overlying skin, is most often noted in the axilla. Suppuration occurs in only 10–25% of patients. A skin lesion (e.g. a red papule or crusted pustule) develops at the inoculation site in two-thirds of patients.

Although most patients are otherwise well, the lymphadenopathy can be accompanied by fevers, malaise, fatigue, weakness and headaches. Additional manifestations such as encephalopathy, hepatic granulomas, osteomyelitis and pulmonary involvement develop in up to 15% of patients. The oculoglandular syndrome of Parinaud (unilateral conjunctivitis and ipsilateral preauricular lymphadenopathy) occurs in ~5% of individuals with CSD. Immunosuppressed patients (e.g. those with HIV infection) are prone to a more severe and complicated disease course.

Pathology

Affected lymph nodes display central necrosis surrounded by histiocytic and epithelioid cells with an inner palisading layer. Giant cells with a peripheral zone of lymphoid cells are also evident. The primary skin lesion can show similar changes, albeit less well developed. The Warthin–Starry silver stain demonstrates bacilli within areas of necrosis. Electron microscopic examination shows the bacteria to be extracellular and in small groups.

Diagnosis and differential diagnosis

For patients who present with regional adenopathy and a history of a recent cat scratch, the diagnosis is usually made clinically. A sensitive and specific assay for *B. henselae* antibodies is available, and antibody titers are usually high during the first few weeks after the onset of lymphadenopathy; PCR-based testing can also be performed. Other causes of lymphadenopathy such as infections (bacterial, fungal or viral), reactive hyperplasia, drug reactions or malignancy can be excluded by fine-needle aspiration histology or biopsy and culture of lymph node tissue[85].

Treatment

Table 74.13 outlines current recommendations for the treatment of CSD.

Bacillary Angiomatosis

Synonyms: ■ Epithelioid angiomatosis ■ Disseminated cat scratch disease

Introduction

Bacillary angiomatosis is caused by infection with *B. henselae* or *B. quintana*. Vascular proliferation is the predominant feature of this condition, which most often affects HIV-infected individuals.

History

The disorder was first described in 1983 as subcutaneous vascular proliferations in individuals with AIDS. Electron microscopy and Warthin–Starry-stained sections of the lesions revealed small bacilli. In 1989, LeBoit and colleagues coined the name "bacillary angiomatosis" and proposed histologic criteria for the disorder. In the early 1990s, *R. quintana* and *R. henselae* (subsequently reclassified in the genus *Bartonella*) were recognized as the causes of bacillary angiomatosis (see Table 74.13).

Epidemiology and pathogenesis

Bacillary angiomatosis is an uncommon disease that is most often seen in HIV-infected patients when their $CD4^+$ count is <200 cells/mcl (see Ch. 78). Fortunately, with the advent of effective antiretroviral therapy (ART), the prevalence of bacillary angiomatosis has decreased substantially. The associated vascular proliferation may be due to an angiogenic factor produced by *B. henselae* and *B. quintana*. Only 20% of patients with bacillary angiomatosis due to *B. henselae* report a preceding cat scratch or bite, compared to 90% of those with CSD[86].

Clinical features

Cutaneous lesions of bacillary angiomatosis may present as superficial angiomatous papules and nodules, violaceous lichenoid plaques, or deep subcutaneous nodules. The papules and nodules resemble pyogenic granulomas (Fig. 74.24A) and may be smooth-surfaced, pedunculated, or surrounded by a collarette of scale. These lesions may display central umbilication, crusting or ulceration. Subcutaneous nodules are often several centimeters in diameter and skin-colored; overlying erosions or ulcerations may develop. Less commonly, bacillary angiomatosis presents as a cellulitic erythematous plaque that can involve the underlying bone. The host immune status largely

MAJOR HUMAN DISEASES CAUSED BY BARTONELLA SPECIES AND THEIR TREATMENT								
Species	**Disease**	**Vector**	**Reservoir/ host**	**Epidemiology**	**Recommended treatment**	**First-line**	**Second-line**	**Notes**
B. bacilliformis	Bartonellosis (Carrion's disease, Oroya fever, verruga peruana)	Phlebotomine sand fly (*Lutzomyia verrucarum*)	Human	• Andean mountain valley regions of Peru, Ecuador and southwestern Columbia (altitudes of 2500–8000 feet) • More common in immunologically naive tourists and transient workers • Milder in children	• Oroya fever	Chloramphenicol* plus β-lactam antibiotic Quinolone (norfloxacin, ciprofloxacin) [>6 years of age, non-pregnant]	Trimethoprim–sulfamethoxazole Macrolide Doxycycline	• Successful treatment does not eliminate risk for developing verruga peruana • Adjunctive treatment needed with chloramphenicol, as treatment failures have been seen with monotherapy • Death occurs in ~40% of untreated individuals
					• Verruga peruana	Rifampin Streptomycin [traditional]	Ciprofloxacin Azithromycin	• Only 5% of patients recall an acute febrile illness • Disappearance of skin lesions within 1 month with treatment
B. henselae	Cat scratch disease	Cat flea (*Ctenocephalides felis*)	Cat	• Primarily seen in young people (<18 years) in the fall and winter • Immunocompetent > immunocompromised	• Mild to moderate, uncomplicated	Supportive care (analgesics) only Needle aspiration of suppurative lymph nodes	Azithromycin Doxycycline *plus* rifampin	• Azithromycin shown to decrease lymph node volume but not effective in preventing dissemination or complications
					• Severe, complicated	Doxycycline *plus* rifampin		• Severe disease includes retinitis, encephalopathy, visceral spread
	Bacillary angiomatosis			• Immunocompromised (e.g. common in HIV)	• Mild, uncomplicated bacillary angiomatosis	Erythromycin	Doycycline Azithromycin Clarithromycin	• Jarish–Herxheimer-like reaction may occur • Treatment failures seen with quinolones, trimethoprim–sulfamethoxazole, narrow-spectrum cephalosporins • Use of iv antibiotics recommended for GI intolerance or poor absorption states • Doxycycline *plus* rifampin recommended for CNS disease because of better CNS penetration
	Bacillary peliosis hepatis			• Immunocompromised				
	Bacteremia (chronic afebrile)		*(Cat exposure not a risk factor in bacteremia)*	• Immunocompetent or immunocompromised				
	Endocarditis			• Late complication of chronic bacteremia	• Severe, complicated bacillary angiomatosis	Erythromycin Doxycycline *plus* rifampin Doxycycline *plus* aminoglycoside		
B. quintana	Trench fever "Five day fever" "Urban trench fever" "Quintan fever"	Human body louse (*Pediculosis humanus*)	Human	• First reported in World War I troops, now associated with homelessness and poor hygiene ("urban trench fever")				
	Bacillary angiomatosis			• Immunocompromised (e.g. common in HIV)				
	Bacteremia (chronic afebrile)			• Immunocompetent or immunocompromised				
	Endocarditis			• Late complication of chronic bacteremia				

*Gray baby syndrome can develop in premature neonates who receive chloramphenicol.

Table 74.13 Major human diseases caused by *Bartonella* species and their treatment[82]. Fever and splenomegaly due to bacteremia with *Bartonella rochalimae* (a recently recognized species) has also been described.

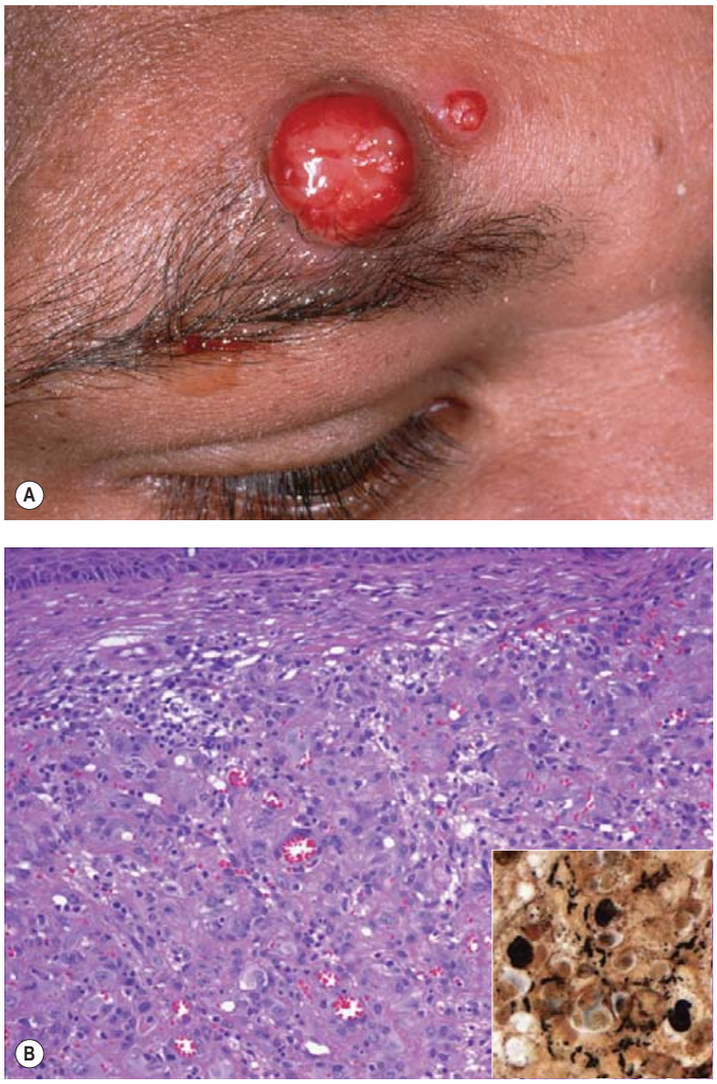

Fig. 74.24 Bacillary angiomatosis. A Bright red nodule and papule on the forehead. **B** Histologically, a dermal proliferation of vessels with plump endothelial cells is evident and scattered neutrophils are present in the accompanying infiltrate. Bacilli (in this case *Bartonella henselae*) are identified with the Warthin–Starry stain (insert). *B, Courtesy, James Patterson, MD.*

determines the number and distribution of the lesions. Immunocompetent patients may have a single lesion at the site of inoculation, whereas the entire cutaneous surface can be affected in those who are severely immunocompromised.

Extracutaneous bacillary angiomatosis may occur with or without cutaneous disease and can affect any organ. Bacillary peliosis hepatis caused by *B. henselae* (but not *B. quintana*) presents with nausea, vomiting, diarrhea, abdominal pain, hepatosplenomegaly and elevated liver enzymes. Bacillary peliosis splenis may lead to pancytopenia and require splenectomy. Patients can also present with malaise and night sweats[87].

Pathology

Biopsy specimens reveal lobular proliferations of capillaries and venules, plump and protuberant endothelial cells, and a marked neutrophilic infiltrate with evidence of leukocytoclasis throughout the interstitium (Fig. 74.24B). In H&E-stained sections, interstitial clumps of bacilli appear as purplish granular material. Bacteria can be readily identified with a Warthin–Starry stain (see Fig. 74.24B, insert).

Diagnosis and differential diagnosis

PCR-based assays are a rapid and sensitive method to identify *Bartonella* from tissue specimens. Culture of *B. henselae* or *B. quintana* on chocolate or supplemented agar may take 20 to 40 days. Testing to detect antibodies against *B. henselae* (but not *B. quintana*) is sensitive and specific.

The clinical differential diagnosis includes pyogenic granulomas, Kaposi sarcoma, cherry angiomas, angiokeratomas, verruga peruana and a disseminated atypical mycobacterial infection. Histologically, bacillary angiomatosis can be confused with verruga peruana, Kaposi sarcoma, pyogenic granuloma and angiosarcoma.

Treatment

Cutaneous lesions begin to improve within 1 week of appropriate antibiotic therapy and resolve completely within 4 weeks. At least 3 months of treatment is recommended, as therapeutic failures and relapses can occur with shorter courses. Immunosuppressed patients with disease relapses may require maintenance therapy. Surgical excision of solitary cutaneous lesions, although effective, is usually not necessary. Table 74.13 outlines treatment recommendations for bacillary angiomatosis.

OTHER GRAM-NEGATIVE SKIN INFECTIONS

Brucellosis

Synonyms: ■ Undulant fever ■ Malta fever ■ Bang's disease

Brucellosis is a chronic granulomatous disease caused by *Brucella*, a genus of Gram-negative coccobacilli[88]. Approximately 500 000 cases occur worldwide annually, the majority in the Middle East. Transmission occurs through the consumption of contaminated unpasteurized milk products (commonly raw goat's milk and cheese), direct contact with infected animal parts, or inhalation of aerosolized particles. Infection is rare in the US (100–200 cases per year) and is primarily an occupational disease of farmers, laboratory personnel, butchers and veterinarians. Children tend to have a more benign course, with fewer complications and better response to treatment.

Brucellosis demonstrates substantial clinical variability (Fig. 74.25). The acute form is characterized by nonspecific signs and symptoms (e.g. fever, malaise, headache, diaphoresis, arthralgias, myalgias, back pain, lymphadenopathy and hepatosplenomegaly). Patients with chronic brucellosis are afebrile but experience arthralgias, headaches, myalgias, diaphoresis, cyclic depression, sexual impotence, spondylitis, episcleritis and uveitis. Malodorous perspiration is highly characteristic. Skin lesions occur in <10% of patients, most often presenting as a disseminated eruption of violaceous papulonodules. Other cutaneous manifestations of brucellosis include erythema nodosum-like lesions, extensive purpura and a morbilliform eruption[89]. Endocarditis represents the major cause of death.

Acute brucellosis may mimic mononucleosis, influenza, malaria, typhoid fever, typhus, tularemia, tuberculosis or sarcoidosis. The chronic form can be confused with rheumatologic, neurologic or psychosomatic conditions. Multidrug regimens are recommended for brucellosis, with doxycycline (first-line) in various combinations with streptomycin, rifampin, quinolones, aminoglycosides and TMP-SMX. There is some concern regarding the use of rifampin in areas with a high prevalence of tuberculosis, as resistance may develop.

Glanders

Glanders is principally a disease of horses, mules and donkeys that is caused by *Burkholderia mallei* (formerly *Pseudomonas mallei*), a nonmotile, strictly aerobic, non-pigment-producing, Gram-negative bacillus. Glanders is endemic in Africa, Asia, the Middle East, and Central and South America. Human disease is rare, occurring chiefly in those with direct contact with infected animals, such as veterinarians, animal caretakers, abattoir workers and laboratory personnel. Tissue damage results from production of exotoxins, including pyocyanin (interferes with electron transfer), lecithinase (causes cell lysis), collagenase, lipase and hemolysin.

Glanders has four clinical forms (septicemic, localized, pulmonary and chronic). Acute *septicemic* glanders is characterized by malaise, anorexia, chills, fever, diarrhea, prostration and joint pains. Patients may have flushing, cyanosis, a disseminated pustular eruption, cellulitis, lymphangitis, erythroderma and/or jaundice. Multiorgan failure ensues, and the mortality rate is ~50% (>90% without treatment).

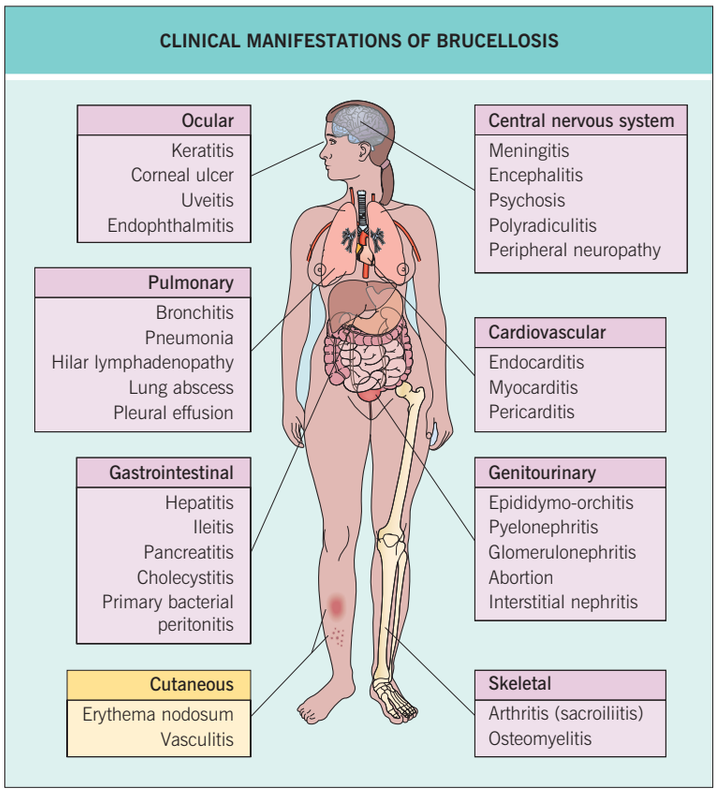

Fig. 74.25 Clinical manifestations of brucellosis. *With permission from Slack MPE. Gram-negative coccobacilli. In: Armstrong D, Powderly WG (eds). Infectious Diseases. Edinburgh: Mosby, 2004.*

In the *localized* form, a nodule, pustule or vesicle surrounded by hemorrhagic edema appears at the inoculation site after approximately 1 to 5 days. The superficial portion of the lesion sloughs, producing an ulcer with a gray–brown base. Glanders may also involve the nose and cause ulceration or perforation of the nasal septum or palate. *Chronic* glanders features malaise, myalgias and often fevers. Painful subcutaneous and intramuscular abscesses may appear at any site, and they may ulcerate, drain or extend into joints, periosteum and bone. Multiple subcutaneous and intramuscular nodules ("farcy buds") appear along the draining lymphatics, and the term "farcy pipes" refers to the firm cords that result from lymphatic involvement.

Glanders should be considered when localized cutaneous abscesses and secondary lesions appear in the path of lymphatic drainage (see Table 77.15). Accurate diagnosis can be made with serologic testing. For localized disease, a 60- to 150-day course of oral amoxicillin/clavulanate, doxycycline or TMP-SMX can be prescribed. Alternatives include ciprofloxacin, streptomycin, gentamicin, imipenem and ceftazidime[90].

Melioidosis

Synonym: ▪ Whitmore disease

Melioidosis is caused by *Burkholderia pseudomallei* (formerly *Pseudomonas pseudomallei*), a mobile, obligately aerobic, non-spore-forming bacillus found in soil and water. The name melioidosis is derived from the Greek words *melis*, meaning "donkey distemper", and *eidos*, meaning "resembles glanders". Melioidosis is endemic in Southeast Asia and northern Australia, but it also occurs in South Pacific islands, Africa, India, the Middle East, and Central and South America. Infection develops via direct contact of abraded or lacerated skin with contaminated soil or water as well as through ingestion, inhalation or sexual intercourse. It is more common in adults with underlying medical conditions (e.g. diabetes mellitus, renal insufficiency).

Acute melioidosis can produce localized cutaneous infections, pneumonia or septicemia. *Subacute* melioidosis, primarily a pulmonary disease, is frequently confused with tuberculosis. *Chronic* melioidosis is characterized by abscesses and granulomas in multiple sites. Cutaneous manifestations may include cellulitis, subcutaneous abscesses, granulomatous lesions, ecthyma gangrenosum, purpura, pustules and urticaria.

Both complement-fixing and agglutinating antibodies appear within 4 to 6 weeks after infection. PCR-based and other molecular diagnostic techniques are also available.

Treatment of melioidosis is difficult, and sensitivity studies should be performed. Current treatment guidelines favor imipenem, ceftazidime, piperacillin/tazobactam, tetracyclines or TMP-SMX; *B. pseudomallei* has shown resistance to quinolones, macrolides and aminoglycosides. Intensive supportive care lowers the mortality rate to about 20% (vs 40–50% in some areas). Melioidosis has a high relapse rate (approximately 10%), and long-term antibiotic therapy is needed, as *B. pseudomallei* can remain latent in the body for up to 25 years[91,92].

Because *B. mallei* and *B. pseudomallei* represent potential agents of bioterrorism, attempts are being made to develop vaccines for these infections[93].

Cutaneous Malacoplakia (Malakoplakia)

Cutaneous malacoplakia is a rare chronic infectious condition that is characterized by granulomatous inflamation with distinctive macrophages that are unable to phagocytose and kill bacteria effectively. It occurs primarily in immunocompromised hosts, particularly solid organ transplant recipients, and is most commonly due to *E. coli*, although *Pseudomonas, Proteus, Klebsiella, Staphylococcus* and *Mycobacterium* spp. have also been implicated.

Most cases of malacoplakia affect the genitourinary tract. Cutaneous lesions usually involve the perianal region and can present as ulcerations, abscesses with multiple draining sinuses, yellow-to-pink soft papules, and erythematous indurated nodules.

Histologic examination of involved tissue shows highly characteristic findings. *Michaelis–Gutmann bodies* are intracytoplasmic laminated concretions that represent accumulations of calcified, iron-containing phagolysosomes; they stain with PAS, von Kossa, Perls' and Giemsa stains. *von Hansemann cells* are large macrophages that contain Michaelis–Gutmann bodies and stain positively for CD68, lysozyme and α_1-antitrypsin. The histopathologic differential diagnosis may include sarcoidosis, infectious granulomas, Langerhans cell histiocytosis, granular cell tumor and fibrous histiocytoma.

The treatment of malacoplakia is difficult. Localized disease may be amenable to surgical excision. Prolonged courses of antibiotics, including quinolones, TMP-SMX and clofazimine, have been used successfully. Ascorbic acid and bethanechol chloride have been employed to increase intracellular cGMP and improve macrophage function. In severe cases, reducing the dosage of immunosuppressive therapy (if possible) may be of benefit[94,95].

Tularemia

Synonyms: ▪ Deer fly fever ▪ Rabbit fever ▪ Pahvant Valley plague

Tularemia is a bacterial infection caused by *Francisella tularensis*, a Gram-negative, non-motile coccobacillus. First described in 1911 as a plague-like illness, there are 150–200 cases per year in the US. Skin or mucous membranes are the portal of entry for infections associated with tick or deer fly bites and exposure to the organism via abrasions. Inhaled or ingested organisms rarely cause the disease. Rabbits, hares and ticks are the main reservoirs for *F. tularensis*. Although infected rabbits and their carcasses are classically described as the main sources of infection, deer flies and ticks are more significant vectors.

Tularemia occurs in six clinical forms according to the mode of transmission: ulceroglandular, glandular, oculoglandular, oropharyngeal/gastrointestinal, typhoidal/septicemic, and pneumonic (Fig. 74.26). Ulceroglandular tularemia is the most common form and is characterized by both lymphadenopathy and an erythematous, indurated, punched-out ulcer that may last for several weeks. The lymph nodes can become fluctuant and suppurate. Occasionally, ulceration or lymphadenopathy occur in isolation. Other rare cutaneous manifestations include buboes, a morbilliform eruption, erythema nodosum and erythema multiforme.

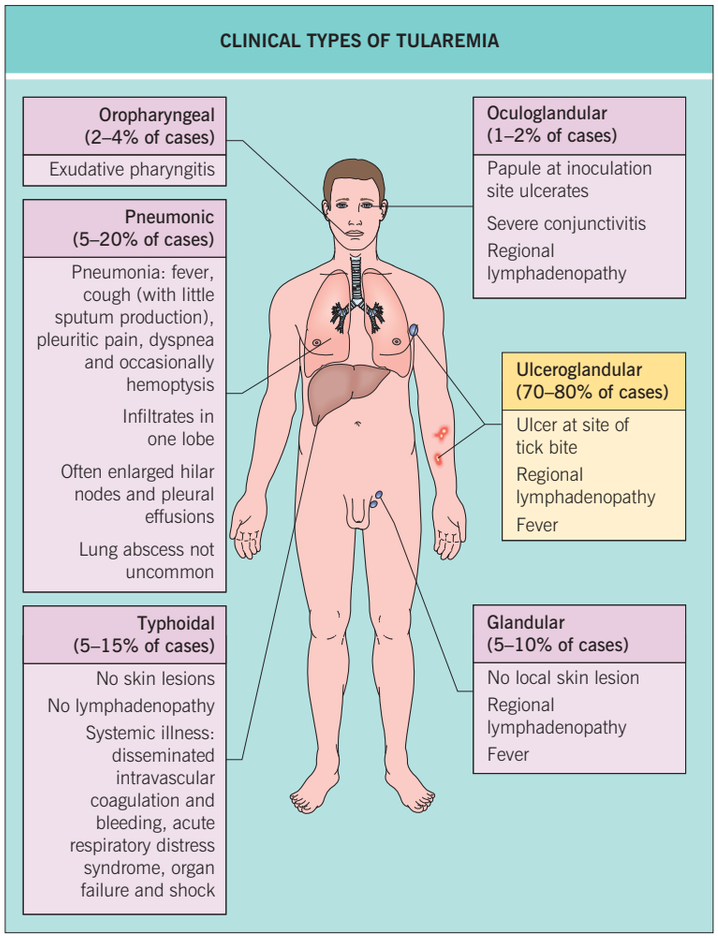

Fig. 74.26 Clinical types of tularemia. *Adapted with permission from Slack MPE. Gram-negative coccobacilli. In: Armstrong D, Powderly WG (eds). Infectious Diseases. Edinburgh: Mosby, 2004.*

Because of concern regarding the potential use of *F. tularensis* as a biologic weapon, tularemia is a reportable disease in the US[96]. Fluorescent antibody testing is rapid and reliable. Attempts to culture *F. tularensis* are usually not made due to its high infectivity, risk to laboratory workers, and inability to grow on most media. The differential diagnosis of ulceroglandular tularemia includes other ulceroglandular entities (e.g. bubonic plague, tuberculous chancre, rat-bite fever, glanders), anthrax, soft tissue infections (i.e. *Staphylococcus, Streptococcus*, *Pasteurella multocida*), and infectious causes of a sporotrichoid pattern (see Ch. 77).

Treatment options include a 10-day course of streptomycin (the classic first-line agent), gentamicin or a quinolone; alternatives include a 14–21-day course of doxycycline or chloramphenicol (longer due to a higher risk of relapse with these bacteriostatic medications)[97]. A Jarisch–Herxheimer-like reaction may occur following the initiation of therapy.

Haemophilus influenzae Cellulitis

Haemophilus influenzae is a Gram-negative coccobacillus that can cause facial cellulitis with a violaceous hue in infants and young children (usually 6–24 months of age) following an upper respiratory tract infection. It favors the buccal and periorbital areas and is often associated with high fevers, an increased leukocyte count with a left shift, and positive blood cultures. Routine vaccination of children against *H. influenzae* type b has greatly reduced the incidence of this form of cellulitis[98]. First-line therapy for severe *H. influenzae* infections is a third-generation cephalosporin; selection of empiric antibiotic therapy for cellulitis is discussed above.

Rhinoscleroma

Rhinoscleroma is a slowly progressive, chronic granulomatous infection involving the nose and upper respiratory tract. It is caused by *Klebsiella rhinoscleromatis*, a short, immotile Gram-negative bacillus that is a subspecies of *Klebsiella pneumoniae*. Endemic foci exist in Central Europe, Egypt, India, Indonesia, Mexico, Central America and tropical Africa. Deficiencies of cellular, but not humoral, immunity cause ineffective phagocytosis by macrophages, giving rise to large, vacuolated, non-lipidized histiocytes with intracellular bacteria (Mikulicz cells)[99]. Clinical features, diagnostic techniques, the differential diagnosis and treatment recommendations are outlined in Table 74.14. Histologic findings mimicking Rosai–Dorfman disease have been observed in the lymph nodes of a patient with rhinoscleroma[100].

RHINOSCLEROMA – CLINICAL FEATURES, DIFFERENTIAL DIAGNOSIS AND TREATMENT	
Risk factors	• Poor hygiene, poor nutrition and living in overcrowded conditions
Stage one: rhinitic/catarrhal/atrophic	• Nonspecific rhinitis • Purulent rhinorrhea and crusting • Nasal obstruction
Stage two: granulomatous/infiltrative/hypertrophic	• Granulomatous nodules form in the nose, pharynx and larynx • Dysphonia, anosmia and anesthesia of soft palate may occur • Epistaxis, deformity of the nose, destruction of the nasal cartilage (Hebra nose)
Stage three: sclerotic/cicatricial	• Nodules replaced by fibrous tissues with resultant extensive scarring and stenosis often requiring surgical intervention (e.g. tracheotomy, reconstruction of the airway)
Diagnosis	• Presence of Mikulicz cells and Russell bodies on routine histology – *Mikulicz cells*: large, vacuolated, non-lipidized histiocytes with intracellular bacteria – *Russell bodies*: plasma cells with aggregates of condensed immunoglobulins • PAS, Giemsa, silver and Gram stains are reliable • Immunoperoxidase studies are sensitive and specific • Cultures are positive in only ~50% of cases • "Crypt-like" irregularities of the trachea can be seen on computed tomography
Differential diagnosis (see Table 45.3)	• Mucocutaneous (New World) leishmaniasis, paracoccidioidomycosis (and other dimorphic fungal infections), rhinosporidiosis, leprosy, yaws, tertiary syphilis, nasal tuberculosis, sarcoidosis, Wegener's granulomatosis, nasal T-cell/natural killer cell lymphoma, basal cell and squamous cell carcinoma, extranodal Rosai–Dorfman disease
Treatment	• Antimicrobial therapy for 6 months or until nasal biopsy is negative; tetracycline is first-line therapy along with surgical correction of obstructed airway • Rifampin and ciprofloxacin are alternative antibiotics • Sclerotic lesions respond to ciprofloxacin • Bacterial superinfection is common, requiring treatment with clindamycin or a third-generation cephalosporin

Table 74.14 Rhinoscleroma – clinical features, differential diagnosis and treatment.

Salmonellosis

Salmonellosis refers to the spectrum of infections caused by Gram-negative aerobic bacilli in the genus *Salmonella*. Enteric fever due to *S. typhi* is known as typhoid fever[101], and a similar clinical syndrome of enteric fever produced by non-typhoidal strains such as *S. paratyphi* is referred to as paratyphoid fever. *S. typhi* is spread via direct contact with persons who have typhoid fever or are chronic carriers. In contrast, non-typhoidal *Salmonella* is most commonly acquired from inadequately cooked poultry and eggs, resulting in gastroenteritis.

Typhoid fever is characterized by fever, headache, malaise, myalgias, cough, sore throat, nausea, vomiting, diarrhea and constipation. The characteristic cutaneous sign, "rose spots", are pink, blanching, slightly elevated papules that measure 2–8 mm and are usually found on the anterior trunk in groups of 5–15 lesions. They occur in up to 50% of patients with typhoid fever and less often in non-typhoidal enteric fever. Rose spots often occur in crops during the second to fourth weeks of the illness, and *Salmonella* spp. can usually be cultured from these lesions. Other cutaneous manifestations of salmonellosis include erythema multiforme, Sweet's syndrome, hemorrhagic bullae, pustular dermatitis, and a generalized erythematous eruption known as erythema typhosum.

A history of travel to endemic areas (e.g. Southeast Asia, South America), persistence of fevers, and positive cultures aid in distinguishing salmonellosis from influenza and other viral infections. Since the late 1980s, *S. typhi* has developed resistance to all the drugs that were then used as first-line treatments (chloramphenicol, TMP-SMX and ampicillin). Currently, quinolones are first-line therapy, although resistance has begun to emerge (especially in Asia). Third-generation cephalosporins are the treatment of choice in children.

Rat-Bite Fever

Synonyms: ▪ Haverhill fever ▪ Erythema arthriticum epidemicum

Streptobacillus moniliformis infections result in an acute illness characterized by fever, arthritis and a rash. While the disorder is usually caused by a bite (rat-bite fever), it can also occur from close contact with rodents or ingestion of contaminated food, water or raw milk (Haverhill fever).

The incidence of rat-bite fever is highest in urban areas with poor sanitation where there is a large population of rats. Erythema, edema, abscess formation, ulceration and secondary infection may develop at the site of the bite. Regional lymphadenopathy is common. Paroxysms of fever interspersed with afebrile periods as well as headaches, nausea, vomiting and myalgias may occur. In infants and children, weight loss and diarrhea can be significant. One of the hallmarks of the disease is a migratory polyarthritis that occurs in 50% of cases and may mimic rheumatoid arthritis. At 2 to 4 days following the onset of fever and arthritis, most patients with rat-bite fever develop an acrally distributed eruption involving the palms and soles. Morbilliform macules and papules, petechiae, vesicles, pustules and crusts may be seen.

The triad of fever, arthritis/arthralgias and a rash can be caused by numerous infectious diseases, including viral infections (e.g. enteroviruses, EBV, parvovirus B19) Rocky Mountain spotted fever, acute or chronic meningococcemia, acute rheumatic fever and secondary syphilis. Non-infectious causes include Still's disease, systemic lupus erythematosus, serum sickness-like drug reactions, Sweet's syndrome, Schnitzler's syndrome and periodic fever syndromes.

Penicillin is the drug of choice for rat-bite fever and is usually administered for a week, although patients with septicemia may require up to 6 weeks of parenteral therapy. Tetracyclines and streptomycin are also effective. Erythromycin, clindamycin and cephalosporins have been used as well, but studies of their efficacy are lacking. Although most infections resolve spontaneously within 2 weeks, 10–15% of untreated cases are fatal[102].

Plague

Plague is an acute bacterial infection caused by *Yersinia pestis*, a Gram-negative, rounded, bipolar bacillus transmitted by fleas and rodents (Fig. 74.27). The highest incidence of *Y. pestis* infection is in Southeast Asia. In the US, most human infections occur in two regions: (1) northern New Mexico, northern Arizona and southern Colorado; and (2) California, southern Oregon and far western Nevada. Plague also occurs in Africa, South America and other regions of Asia.

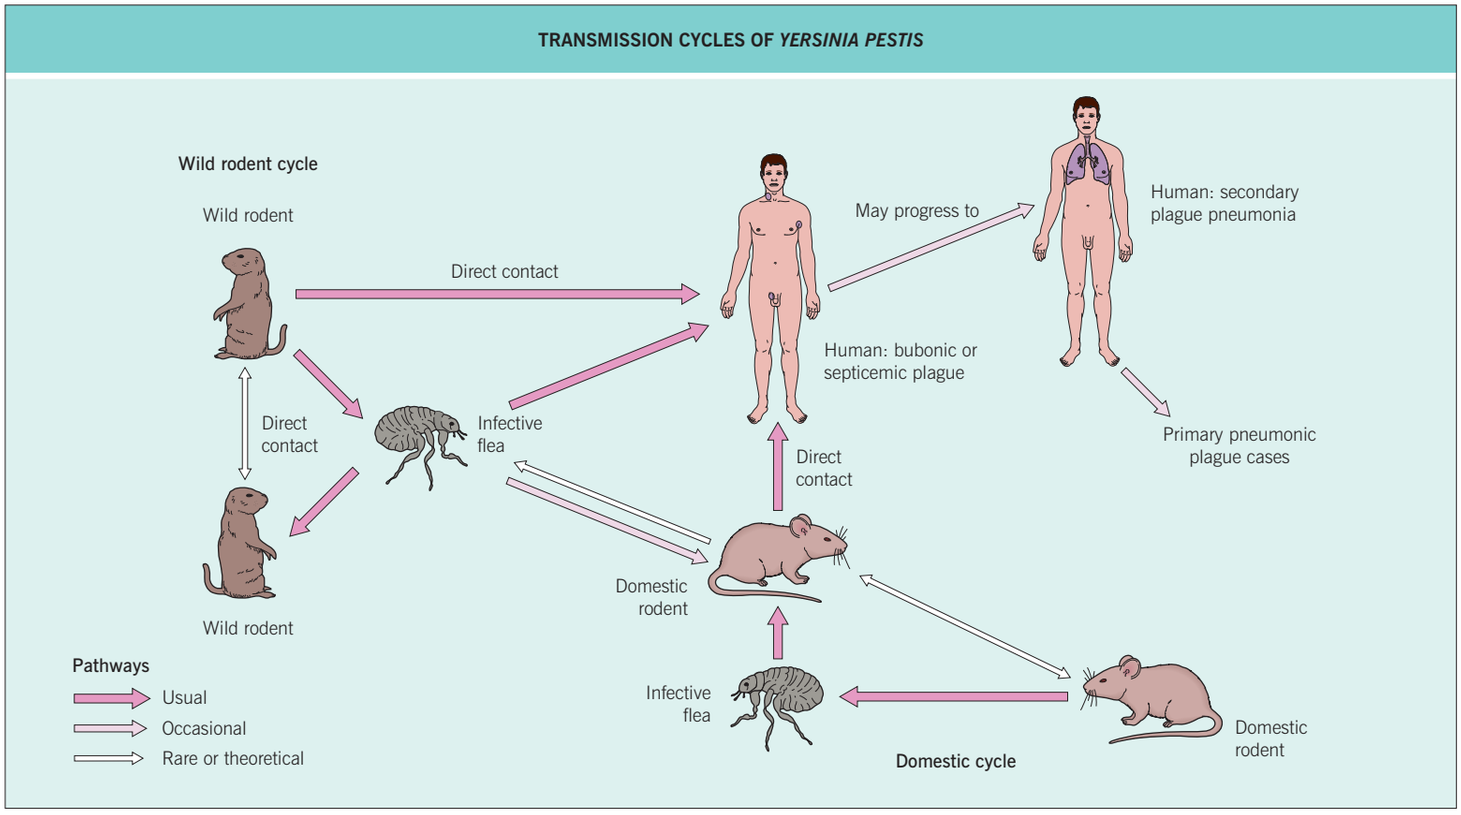

Fig. 74.27 Transmission cycles of *Yersinia pestis*. *With permission from Dennis DT, Gage KL. Plague. In: Armstrong D, Powderly WG (eds). Infectious Diseases. Edinburgh: Mosby, 2004.*

RISK FACTORS FOR *VIBRIO* INFECTION
ACQUISITION OF INFECTION
Cutaneous exposure to contaminated seawater and/or shellfish
• Exposure to warm coastal salt water (April–October in temperate climates) • Handling shellfish • New injury to the skin or a pre-existing wound predisposes to a primary cutaneous infection, which can lead to cellulitis, necrotizing fasciitis and/or septicemia in susceptible hosts (see below)
Consumption of contaminated raw/undercooked seafood
• Classically raw oysters, but also found in clams, crabs and other shellfish • Leads to an acute gastrointestinal illness in immunocompetent individuals and septicemia in susceptible hosts (see below)
UNDERLYING MEDICAL CONDITIONS THAT PREDISPOSE TO SEVERE INFECTIONS
Liver disease
• Hemochromatosis – *V. vulnificus* is ferrophilic and requires higher levels of iron than other pathogens – Patients have decreased hepcidin antibacterial activity • Alcoholic cirrhosis
Diabetes mellitus
• Peripheral neuropathy predisposes to cutaneous wounds that serve as a portal of entry
Gastrointestinal disease
• Peptic ulcer disease – Antacid use may lead to increased survival of *V. vulnificus* • Gastrointestinal surgery
Immunosuppression
• HIV infection and AIDS • Leukemia or lymphoma • Treatment with corticosteroids or chemotherapy
End-stage renal disease

Table 74.15 Risk factors for *Vibrio* infection.

Fig. 74.28 Hemorrhagic bullae of the leg secondary to *Vibrio vulnificus* infection.

Three clinical forms of plague are recognized: bubonic, septicemic and pneumonic. The symptoms of *bubonic* plague are variable. Constitutional symptoms may be lacking or severe. In approximately 10% of patients, the inoculation wound develops into a pustule or ulcer. This is followed by painful regional lymphadenopathy; suppuration and discharge from the lymph nodes may occur. In *septicemic* plague, vesicles, carbuncles, petechiae and purpura may be seen. Necrotic lesions and hemorrhage from the nasopharynx or gastrointestinal tract have also been described. In *pneumonic* plague, the patient develops acute pneumonitis. Apathy, delirium, coma and seizures occur in seriously ill patients. Bubonic plague may simulate tularemia, rat-bite fever, sporotrichosis, tuberculosis, streptococcal ecthyma, syphilis or lymphogranuloma venereum. Septicemic plague must be differentiated from typhus, typhoid fever, tularemia, malaria and other bacteremias.

Untreated bubonic plague has a 25–50% fatality rate, while untreated septicemic or pneumonic plague is nearly always fatal. Streptomycin and other aminoglycosides (e.g. gentamicin) are first-line treatments for plague. Doxycycline and quinolones may be used when oral therapy is acceptable. Chloramphenicol (which attains high concentrations in the cerebrospinal fluid) is the drug of choice for plague meningitis or endophthalmitis. Postexposure prophylaxis with doxycycline or ciprofloxacin, if taken within 7 days, is extremely effective in preventing disease[103]. The development of a vaccine against pneumonic and bubonic plague has been technically difficult to achieve.

Vibrio vulnificus Infection

The genus *Vibrio* constitutes a group of Gram-negative anaerobic bacteria, among which *V. vulnificus* is the most common cause of cutaneous disease. *V. vulnificus* infections occur most commonly in men over 40 years of age who have chronic liver disease or diabetes mellitus and a history of exposure to seawater or raw seafood[104]; additional risk factors are listed in Table 74.15. The clinical presentation of *V. vulnificus* septicemia includes fever, chills, nausea, vomiting, diarrhea, abdominal cramps and hypotension. Skin lesions develop in 75% of these patients, with progression from erythematous and purpuric macules to vesicles and hemorrhagic bullae (Fig. 74.28) to necrotic ulcers in a manner reminiscent of purpura fulminans. Wounds acquired in or contaminated by seawater can also lead to *Vibrio* cellulitis that is erythematous, edematous and painful, typically with rapid evolution to hemorrhagic bullae. Progression to necrotizing fasciitis or myositis occasionally occurs. First-line treatment is doxycycline (oral or intravenous) plus a third-generation cephalosporin (intravenous or intramuscular); alternative regimens include a quinolone or the combination of an aminoglycoside and TMP-SMX. Necrotic lesions may require surgical debridement[105].

EHRLICHIOSIS AND ANAPLASMOSIS

These infections are discussed in Chapter 76.

SPIROCHETES

BORRELIA BURGDORFERI

Lyme Disease

Synonym: ▪ Lyme borreliosis

Lyme disease is a multisystem disorder with prominent skin findings that is caused by *Borrelia* species of spirochetes. Although found worldwide, it has a particularly high incidence in North America and Europe, representing the most common tick-borne disease in the US. Lyme disease can occur year-round, but most cases present in the summer. If diagnosed in its early stages, it is a completely curable illness.

The species of *Ixodes* tick vector differs depending on the geographic region, e.g. *I. pacificus* in the western US, *I. scapularis* (also called *I. dammini*) in the eastern US and Great Lakes region, *I. ricinus* in Europe, and *I. peisulcatus* in Asia. *B. burgdorferi* is the predominant etiologic organism in the US, whereas *B. garinii* and *B. afzelii* are the predominant causes of Lyme disease in Europe[106]. This may explain the occurrence of borrelial lymphocytoma and acrodermatitis chronica atrophicans in Europe but not the US. Once the spirochete is in the midgut of the tick vector (after feeding on an infected host, e.g. white-tailed deer), it produces outer surface protein C (OspC), which enables it to traverse the midgut epithelium, enter the hemocoel, and make its way to the salivary glands. *B. burgdorferi* is ultimately transmitted to

humans via the tick's saliva. The rate of transmission is low in the first 24 hours of attachment and increases dramatically after 48 hours.

Chapter 19 describes the clinical features and treatment of Lyme disease, in particular erythema migrans (Fig. 74.29), and Table 74.16 outlines the extracutaneous manifestations of Lyme disease. The next sections discuss borrelial lymphocytoma and acrodermatitis chronica atrophicans.

Borrelial Lymphocytoma

Synonyms: ■ Lymphadenosis benigna cutis ■ Lymphocytoma cutis ■ Cutaneous lymphoid hyperplasia ■ Spiegler–Fendt lymphoid hyperplasia, pseudolymphoma of Spiegler and Fendt, sarcoidosis of Spiegler and Fendt ■ Cutaneous B- or T-cell pseudolymphoma

Lymphocytoma is a benign, reactive form of lymphoid hyperplasia that can be attributed to various stimuli, including *Borrelia* infection. Borrelial lymphocytoma usually appears during the early disseminated stage of Lyme disease (see Ch. 19). Because it is caused by *B. afzelii* and *B. garinii* (neither of which is present in North America), borrelial lymphocytoma is virtually never seen in those who have not traveled outside of the US, although it occurs in approximately 1% of patients with Lyme disease in Europe.

Fig. 74.29 Erythema migrans. Expanding erythematous plaque on the neck (**A**) and on the lateral trunk (**B**). *B, Courtesy, Dennis Cooper, MD.*

The formation of a lymphocytoma following a tick bite was first reported in 1950, but it was not until 1986 that *Borrelia* was cultured from such a lesion. A firm, bluish-red, occasionally tender nodule or plaque appears most commonly on the earlobes in children and the nipple/areola in adults, less often developing on the genitalia, trunk or extremities. It may be associated with regional lymphadenopathy.

Histologically, the epidermis is normal and separated from the dermal infiltrate by a Grenz zone. The dense dermal infiltrate of lymphocytes forms a pattern that closely resembles the architecture of a lymphoid follicle. The histologic differential diagnosis includes an arthropod bite reaction and cutaneous lymphoma, with the presence of Bcl-2 protein within follicular cells and monoclonality by PCR favoring the latter (see Ch. 119)[107]. Of note, *B. burgdorferi*-associated B-cell lymphomas have been described[108]. Borrelial lymphocytoma responds to the antibiotics used for Lyme disease (see Ch. 19) as well as to topical and intralesional corticosteroids[109].

Acrodermatitis Chronica Atrophicans

Synonym: ■ Herxheimer disease

Acrodermatitis chronica atrophicans (ACA) is a cutaneous manifestation of chronic Lyme disease. First described in Europe in 1883 by Buchwald as "idiopathic atrophy", it is most commonly due to an infection with *B. afzelii* (although it has also been associated with *B. burgdorferi* and *B. garinii*). As a result, it is extremely rare in the US but is seen in approximately 10% of patients with Lyme disease in Europe.

ACA occurs 6 months to 8 years after the initial infection, predominantly in women 40–70 years of age, and appears to be associated with long-term persistence of *Borrelia* organisms in the skin. It is a biphasic disorder consisting of an early, easily treatable, inflammatory stage and a late, treatment-resistant, atrophic stage. Initially, erythematous to violaceous plaques and nodules develop on the acral portion of the extremities, often insidiously. The skin is frequently doughy and swollen. This early stage follows a waxing and waning course for weeks to years. In the late stage, the skin has a glistening ("cigarette-paper") appearance with prominent blood vessels (Fig. 74.30). Fibrous nodules may form on extensor surfaces (ulnar or tibial bands). Hypopigmentation, hyperpigmentation, pain, pruritus, hyperesthesia, paresthesias and scaling may also be present. Rarely, the condition may be complicated by the development of basal cell or squamous cell carcinoma[110].

In biopsy specimens of early lesions, a dermal perivascular lymphocytic infiltrate with plasma cells, telangiectatic endothelial-lined spaces, and mild epidermal atrophy is seen. Histologic examination of late lesions shows an atrophic epidermis and an interstitial lymphocytic infiltrate with plasma cells and occasional histiocytes and mast cells. The dermis may be attenuated, with periadnexal fibrosis. The differential diagnosis may include eczematous dermatitis (including stasis), cold injury, atrophy secondary to chronic use of potent topical corticosteroids, severe photodamage, and, in the case of fibrotic lesions, scars, morphea and fibromatoses[111].

MAJOR EXTRACUTANEOUS FEATURES OF LYME DISEASE	
General	Fever, malaise, headache, regional lymphadenopathy, non-productive cough
Eyes	Conjunctivitis, keratitis, iritis, episcleritis, retrobulbar neuritis
Neurologic	Meningitis, encephalitis, Guillain–Barré syndrome, Bell's palsy, psychiatric syndromes, optic atrophy, ataxia
Cardiac	Heart block, arrhythmias, pericarditis, myocarditis, cardiomyopathy, congestive heart failure
Rheumatologic	Arthralgias, tendinitis, oligoarthritis, bone calcifications and cysts
Genitourinary	Orchitis, softening of the testes, proteinuria, microhematuria

Table 74.16 Major extracutaneous features of Lyme disease.

Fig. 74.30 Acrodermatitis chronica atrophicans. The acral skin is atrophic, shiny and wrinkled, with prominent superficial veins.

Fig. 74.31 Cutaneous yaws on the knee of an adolescent from Indonesia. *Courtesy, Peter Ehrnstrom, MD.*

NON-VENEREAL (ENDEMIC) TREPONEMATOSES

Yaws, pinta and endemic syphilis are caused by organisms that are morphologically and antigenically identical to the causative organism of venereal syphilis, *Treponema pallidum* (see Ch. 82). All three diseases have chronic relapsing courses with major dermatologic manifestations. The primary route of transmission is person-to-person via skin, mucous membrane or possibly fomite contact. With the exception of pinta, children are most often affected.

The diagnosis of yaws, pinta and endemic syphilis is based primarily upon clinical features. The same serologic assays used for venereal syphilis can be used to diagnose the endemic treponematoses, but a positive test does not differentiate among the four diseases. Treponemal tests (e.g. TPHA, FTA-ABS, MHA-TP) are specific for treponemal infections (see Ch. 82) and may remain positive for life, regardless of treatment. The non-treponemal tests (e.g. VDRL, RPR) may indicate a current or recent infection, or a biological false-positive result (in 1–3% of the population). The vast majority of false-positive sera have antibody titers of <1 : 4. The quantitative non-treponemal tests are particularly useful in the evaluation of patients following therapy; a fourfold decrease in antibody titers indicates successful treatment, while a fourfold rise indicates reinfection or relapse. Diagnosis can also be made through darkfield examination of exudates from lesions.

Treatment of the non-venereal treponematoses is similar to that for venereal syphilis. The World Health Organization (WHO) recommends that patients over 10 years of age with active disease be given 2 400 000 U of benzathine penicillin, while those under 10 years of age should receive 50 000 U/kg. Family members, close contacts and patients with latent disease are similarly treated. Patients allergic to penicillin can receive doxycycline as recommended for venereal syphilis[112].

Yaws

Synonyms: ■ Pian (French) ■ Frambösie (German) ■ Buba (Spanish) ■ Parangi (Malay)

Yaws is a three-stage infection caused by *T. pallidum* subspecies *pertenue*. It occurs in warm, humid, tropical climates, most often in Africa, Asia, South and Central America, and the Pacific islands. A recent resurgence of the disease has been reported[113]. Yaws most commonly involves the lower extremities of children under 15 years of age (Fig. 74.31). A "mother yaw", the main lesion of the *primary* stage, occurs at the site of inoculation within 10 days to 3 months. It begins as an erythematous, infiltrated, painless papule that over time enlarges peripherally to become 1–5 cm in diameter, then ulcerates and develops an amber-yellow crust. The lesion is rich in treponemes and eventually heals spontaneously over 3 to 6 months.

"Daughter yaws", the lesions of *secondary* yaws, are smaller and more widespread than the primary lesion. They usually occur adjacent to body orifices, such as the nose and mouth, and can expand or ulcerate. Both types of lesions are highly infectious. Only 10% of patients progress to the final stage, during which abscesses form, become necrotic and ulcerate. The ulcers may coalesce into serpiginous tracts, which heal with significant scarring and produce crippling deformities. Yaws can also cause various forms of periostitis, dactylitis and osteitis, with the latter potentially leading to curvature of the tibia ("saber shins").

Histologic examination of early yaws lesions demonstrates spongiosis, acanthosis and papillomatosis. Characteristic neutrophilic intraepidermal microabscesses and a moderate to dense dermal inflammatory infiltrate composed mostly of plasma cells and lymphocytes can be seen. Silver stains easily identify treponemes in specimens. The skin lesions of yaws can resemble venereal syphilis, eczema, psoriasis, verrucae, calluses, scabies, tungiasis, sarcoidosis and vitamin deficiencies[114].

Pinta

Pinta affects the skin exclusively and is caused by an infection with *T. carateum*. The disease is found only in the western hemisphere (Central and South America) in semiarid, warm climates. All ages are equally affected. The *primary* lesions occur 7 days to 2 months after inoculation, most often on the lower extremities. They begin as tiny macules or papules surrounded by an erythematous halo. Over a period of months, they develop into poorly defined, erythematous, infiltrated plaques that measure 10–12 cm in diameter. *Secondary* lesions ("pintids") start as small, scaly papules, subsequently enlarging and coalescing into psoriasiform plaques. They are initially red but later become slate-blue, brown, gray and black. The primary and secondary lesions are highly infectious. *Tertiary* pinta is characterized by symmetric depigmented, vitiligo-like lesions, which may be atrophic or hyperkeratotic and are not considered to be infectious.

Biopsy specimens of primary and secondary lesions reveal moderate acanthosis, slight spongiosis, and a superficial dermal inflammatory infiltrate around dilated blood vessels. Some lesions show lichenoid changes, with hyperkeratosis, hypergranulosis, and vacuolar degeneration of the basal layer. The depigmented lesions of late pinta have epidermal atrophy and a complete absence of melanin. Except for long-standing, late depigmented lesions, treponemes can be visualized in biopsy specimens with silver stains. Early pinta is difficult to differentiate from venereal syphilis, yaws and endemic syphilis. The early lesions can also be confused with eczema, psoriasis, leprosy, lichen planus, lupus erythematosus and tinea corporis. The lesions of late pinta are frequently mistaken for vitiligo[114].

Endemic Syphilis

Synonym: ■ Bejel

Endemic syphilis is caused by an infection with *T. pallidum* subspecies *endemicum*. Most cases are seen in the arid, warm climates of North Africa and the Arabian Peninsula as well as in Southeast Asia. Children under 15 years of age are most commonly affected. In contrast to yaws and pinta, a *primary* lesion is rarely noticed. It usually consists of an inconspicuous small papule or ulcer in the oropharynx or on the nipples of breastfeeding women. In *secondary* endemic syphilis, patches on mucous membranes, split papules, angular stomatitis, non-pruritic papular skin eruptions, and generalized lymphadenopathy are usually seen. Condylomata lata are also frequently present. During the secondary stage, some patients experience osteoperiostitis of the long bones, which can cause nocturnal leg pain.

Six months to several years after inoculation, some patients develop the *tertiary* stage of endemic syphilis. Gumma formation may lead to gross mutilation of the skin, mucous membranes, muscle, cartilage and bone. Without treatment, disfiguring lesions of the palate and nasal septum may occur, leading to difficulty in articulation and swallowing. The eyes and bones can also be severely affected in late-stage endemic syphilis.

The histologic picture closely resembles that of venereal syphilis. In the early stages, biopsy specimens demonstrate a perivascular dermal infiltrate of mostly plasma cells and lymphocytes. Oral lesions may resemble venereal syphilis, aphthosis, perlèche, vitamin deficiencies and primary herpes simplex viral infection. The mutilating nasopharyngeal lesions of endemic syphilis can be mistaken for tertiary venereal syphilis, leprosy, rhinoscleroma, mucocutaneous leishmaniasis, paracoccidioidomycosis and tuberculosis (see Tables 45.3 & 74.14)[114].

LEPTOSPIROSIS

Synonyms: ■ Fort Bragg fever ■ Pretibial fever ■ Weil's disease

Leptospirosis is a worldwide zoonosis caused by spirochetes in the genus *Leptospira*. It is transmitted via contact of non-intact skin or mucous membranes with urine (or other body fluids, with the exception of saliva) from infected mammals (e.g. rodents, dogs, livestock, wild animals), either directly or from drinking or swimming in contaminated water. Veterinarians, farmers, slaughterhouse or sewer workers, and recreational water sport participants are most often affected. Leptospirosis occurs in an anicteric form (~90% of cases) and a more severe icteric form (~10% of cases). After an incubation period of 7–12 days, an initial "septicemic" stage of fevers, chills and myalgias lasting 3–7 days is followed by an "immune" stage (during which serologic tests are positive) that can result in meningitis, uveitis, and renal, hepatic and/or pulmonary dysfunction. Cutaneous manifestations include erythematous macules, papules, patches and/or plaques in a widespread distribution or (especially with *L. interrogans* serovar Autumnalis) localized to the shins, as well as petechiae and purpura secondary to vascular involvement. Antibiotic treatment is most effective early in the disease course; options include oral doxycycline, amoxicillin or azithromycin and (for more severe disease) intravenous penicillin or third-generation cephalosporins.

BACTERIA PREVIOUSLY CLASSIFIED AS FUNGI

ACTINOMYCOSIS

Introduction

Actinomycosis is a subacute or chronic bacterial infection characterized by suppurating abscesses, granulomatous inflammation and sinus formation. *Actinomyces israelii*, an anaerobic or microaerophilic Gram-positive, non-acid-fast actinomycete, is the most common causative organism. Cervicofacial (accounting for two-thirds of infections), pulmonary/thoracic and gastrointestinal forms exist.

Fig. 74.32 Cervicofacial actinomycosis or "lumpy jaw". Soft tissue swelling and draining erythematous nodules are seen. The discharge contained sulfur granules.

Epidemiology and pathogenesis

Actinomycosis is seen worldwide, and men are affected three times more often than women. Humans are the only known reservoir for *Actinomyces* spp. *A. israelii* is part of the normal flora of the oral cavity and is also found in the gastrointestinal tract and female genital tract. The most important predisposing factor is trauma, especially dental procedures. *Actinomyces* spp. are not considered particularly pathogenic, and their virulence is enhanced by co-infection with other organisms. In actinomycotic mycetoma, species of *Actinomyces* other than *A. israelii* are usually responsible for the formation of sulfur granules (see Ch. 77).

Clinical features

In patients with *cervicofacial* actinomycosis ("lumpy jaw"), there is usually a history of poor dental hygiene, dental disease, or a previous orofacial injury or procedure. An initial bluish swelling in the mandibular area progresses to brawny erythematous nodules, which gradually increase in size and form fistulous abscesses (Fig. 74.32). These eventually drain purulent material with characteristic yellow "sulfur granules" that represent clumps of bacteria. Multiple sinus tracts, fever, pain and leukocytosis may develop. Lymphadenopathy is usually absent.

Pulmonary actinomycosis (15–20% of patients) occurs after bacteria gain access to the lung through the aspiration of infected oral material. Pulmonary cavities are usually seen at the bases of the lungs. Extension to the pleura and chest wall may occur, and pleurocutaneous fistulas can develop. *Gastrointestinal* actinomycosis is usually preceded by trauma or inflammatory disease but may occur spontaneously. Granulomatous lesions involving the bowel can eventually extend to the abdominal wall, producing a brawny, erythematous mass with draining sinus tracts. Actinomycosis may also involve the central nervous, musculoskeletal and other organ systems[115].

Pathology

An intense neutrophilic infiltrate is followed by the development of granulomatous inflammation with giant cells. Histiocytes, plasma cells and epithelioid cells can be seen at the periphery of the abscess, while characteristic granules representing microcolonies of *Actinomyces* are seen centrally. Histologically these "sulfur granules" have a basophilic center and acidophilic periphery; they measure up to 28 microns in diameter.

Diagnosis and differential diagnosis

Careful microscopic examination of purulent material should be performed to detect the sulfur granules that are characteristic of actinomycosis (or actinomycotic mycetoma). They are composed of

FOUR MAJOR CLINICAL FORMS OF CUTANEOUS NOCARDIOSIS	
PRIMARY	
Actinomycotic mycetoma	• Half of all cases of actinomycotic mycetoma are due to *Nocardia* species* • Traumatic inoculation causes a painless nodule that enlarges, suppurates and drains via sinus tracts • Purulent discharge contains sulfur granules • The foot is the usual site of involvement • May involve underlying muscle and bone
Lymphocutaneous	• Occurs days to weeks after trauma • Appears as a crusted pustule or abscess resistant to antibiotics • Ascending lymphatic streaks, a sporotrichoid pattern of papulonodules, and tender palpable lymph nodes may be seen
Superficial cutaneous	• Traumatic implantation of foreign objects (including soil and gravel) into the skin • The diagnosis is based on a high index of suspicion, lack of response to routine antibiotic treatment, and laboratory results
SECONDARY	
Pulmonary/systemic	• Subcutaneous abscesses of the chest wall • Pustules, nodules, cutaneous fistulae • Almost universally fatal if left untreated • Most commonly caused by *Nocardia asteroides*
*In Mexico and Central and South America, *N. brasiliensis* is the etiology of 90% of actinomycotic mycetomas, whereas in the US, most mycetomas are caused by true fungi.	

Table 74.17 Four major clinical forms of cutaneous nocardiosis.

Gram-positive, branching filaments that fragment into diphtheroid forms and coccobacilli; acid-fast staining is negative. Cervicofacial actinomycosis may resemble symbiotic anaerobic (e.g. *Eikenella corrodens*) and aerobic bacterial infections, tuberculosis (scrofuloderma), dimorphic fungal infections, dental sinus tracts and even neoplasms.

Treatment

The drug of choice for actinomycosis is penicillin G or ampicillin. Deep-seated, chronic infections should be treated with 2–6 weeks of intravenous therapy followed by 3–12 months of oral penicillin. For acute infections, 2–3 weeks of oral penicillin plus incision and drainage and surgical excision of sinus tracts is sufficient. Doxycycline, erythromycin and clindamycin are acceptable alternatives for penicillin-allergic patients. Imipenem has been shown to be effective in treatment-resistant cases. In order to avoid relapse, therapy should be extended beyond the resolution of symptoms.

NOCARDIOSIS

Introduction

Nocardiosis is caused by various species of *Nocardia*, a filamentous, Gram-positive, acid-fast organism. *Nocardia* is recognized as an opportunistic pathogen in immunocompromised individuals, causing disseminated or systemic disease; in contrast, cutaneous nocardiosis commonly occurs in immunocompetent hosts.

Epidemiology and pathogenesis

Nocardiosis has a worldwide distribution and affects all age groups. Men are affected three times more often than women, and children may be more prone to developing lymphocutaneous disease. *Nocardia* spp. are ubiquitous in the soil. Localized trauma (e.g. puncture wounds), occupational exposures (e.g. farmers, gardeners) and immunodeficiency are risk factors for contracting nocardiosis.

Clinical features

The three major forms of primary cutaneous nocardiosis are: (1) mycetoma (see Ch. 77); (2) lymphocutaneous nocardiosis; and (3) superficial cutaneous nocardiosis. In addition, approximately 10% of patients with pulmonary-systemic nocardiosis develop secondary skin lesions. In immunosuppressed patients, lesions may present as widely disseminated subcutaneous nodules[116]. Table 74.17 details the various clinical presentations of *Nocardia* infection[117].

Pathology

Histologically, an intense neutrophilic infiltrate with abscess formation is seen. Sulfur granules are observed in *Nocardia* mycetoma but are absent in other forms of cutaneous nocardiosis. Organisms are not visible in routinely stained sections but appear as branching filaments on Gram stain. *Nocardia* also stains with Grocott–Gomori methenamine silver and acid-fast stains.

Diagnosis and differential diagnosis

Nocardia grows easily on all common laboratory media. However, the laboratory should be notified if *Nocardia* is suspected, because its growth is slow and specimens must be held for up to 2 weeks. Nocardiosis should be suspected in patients with sporotrichoid lesions or trauma-associated superficial cutaneous infections that do not respond to routine treatment. It should also be considered in patients at risk for opportunistic infections.

Treatment

Sulfonamides are the drugs of choice for nocardiosis. Minocycline is an effective alternative for sulfonamide-allergic patients, and linezolid may be added in resistant cases. For subcutaneous abscesses, surgical treatment is often required. Local forms of nocardiosis should be treated for 6–12 weeks, whereas immunocompromised patients and those with disseminated disease require 3–12 months of antimicrobial therapy.

Mycobacterial Infections 75

Marcia Ramos-e-Silva and Maria Cristina Ribeiro de Castro

Chapter Contents

Leprosy 1221
Cutaneous tuberculosis 1228
Non-tuberculous mycobacterioses 1235

In 1896, the name "mycobacteria" was given to a large group of bacteria that produce filamentous pellicles similar to molds (when grown in liquid media). These organisms are thin, slightly curved to straight, non-motile and non-spore-forming, with a waxy coating that makes them resistant to most stains. Mycobacteria are also acid-fast, which means they are not readily decolorized by acid after staining[1–3]. The genus *Mycobacterium* contains more than 50 species, a number of which have been recognized during the past 30 years[1,3]. While some species may be saprophytic or pathogenic depending on the immunologic state of the host[2,4], *M. leprae* and *M. tuberculosis* are virulent and constitute an important world health problem. Research on leprosy has been greatly hampered by the inability to culture the organism (it has the longest doubling time of all known bacteria), but the discovery of the genomic sequence of *M. leprae* in 2001[5] was a significant advancement.

Although the classic mycobacterioses, leprosy and tuberculosis, have been known since antiquity, in the past few decades there has been a worldwide explosion in the incidence of mycobacterial infections. Several factors have played a role in this increase, including the emergence of resistant strains of *M. tuberculosis* and a rise in the number of immunocompromised hosts, including those with AIDS[3]. The different species of mycobacteria that are associated with cutaneous disease are outlined in Table 75.1 utilizing Runyon's classification[1,3,6].

This chapter will address the species of mycobacteria that are of greatest interest to dermatologists: *M. leprae, M. tuberculosis* and non-tuberculous mycobacteria that cause infections of the skin.

LEPROSY

Synonym: ■ Hansen's disease

Key features

- Chronic infectious disease caused by the bacillus *Mycobacterium leprae*, an intracytoplasmic parasite of macrophages and Schwann cells
- Slowly progressive disease characterized by granulomas and neurotropism, with a predilection for the skin as well as peripheral nerves
- The primary skin lesion is erythematous or hypopigmented, and it is often anesthetic
- Based upon the clinicopathologic findings (which reflect the degree/type of immunity), leprosy is divided into two major forms – lepromatous (a predominantly Th2 response) and tuberculoid (a predominantly Th1 response)
- In lepromatous leprosy, multiple organisms are present in the dermis (and in nasal secretions), whereas in tuberculoid leprosy, there are only a few organisms

MYCOBACTERIA THAT CAUSE CUTANEOUS DISEASE

Group and pigment	Rate of growth	Pathogens
Slow growers		
Photochromogens*	2–3 weeks	*M. kansasii, M. marinum, M. simiae*
Scotochromogens†	2–3 weeks	*M. scrofulaceum, M. szulgai, M. gordonae, M. xenopi*
Nonchromogens‡	2–3 weeks	*M. tuberculosis, M. avium, M. intracellulare, M. ulcerans, M. haemophilum, M. malmoense, M. terrae, M. genavense, M. bovis§, M. nonchromogenicum*
Rapid growers	3–5 days	*M. fortuitum, M. chelonae, M. smegmatis, M. abscessus, M. immunogenum, M. goodii, M. wolinskyi, M. cosmeticum, M. mucogenicum*
Non-cultured (to date)		*M. leprae*

*Capable of yellow pigment formation upon exposure to light.
†Capable of yellow pigment production without light exposure.
‡Incapable of pigment production.
§Including bacillus Calmette-Guérin.

Table 75.1 Mycobacteria that cause cutaneous disease. Modified classification of Runyon[1,3,6].

Introduction

Leprosy is a chronic infectious disease with prominent involvement of the skin and nerves that is caused by the bacillus *Mycobacterium leprae*. It is divided into two major forms that depend upon the degree and type of immunity – lepromatous (a predominantly Th2 response) and tuberculoid (a predominantly Th1 response). Leprosy is a serious health issue in a number of low-income countries. Although it seldom kills, leprosy represents a deforming, disabling and stigmatizing disease[7,8]. Once worldwide in distribution, leprosy is now seen primarily in tropical and subtropical regions of Asia, Africa, and Central and South America (Fig. 75.1). The geographic distribution is probably related more to a lower standard of living and poorer hygiene than to the warmer climate[10,11]. Early diagnosis and prompt therapy are key components in the strategy to control this chronic infectious disease[8].

History

The first written descriptions of leprosy may date back to as early as 600 BC in India, and to 200 BC in China and Japan. Many of the cases mentioned in the Bible may actually have been psoriasis, vitiligo or other skin disorders rather than leprosy. The earliest scientific evidence of leprosy has come from an Egyptian skeleton and two Coptic mummies from the second century BC and the fifth century AD, respectively.

One theory was that leprosy was brought from India to the Mediterranean basin by Alexander the Great's soldiers between 327 and 326 BC and then spread throughout the Greek and Roman Empires. Recent studies utilizing comparative genomics have shown that all extant cases of leprosy are attributable to a single clone, and the disease appears to have originated in the Near East or eastern Africa. During the Middle Ages, leprosy reached epidemic proportions in Europe and then spread to the New World via the wave of exploration in the late fifteenth and sixteenth centuries. Independent of geographic location, the afflicted have frequently been ostracized by their communities and families[9,10,12].

During the nineteenth century, Danielssen and Boeck provided the first modern description of leprosy, and in the 1870s, a third Norwegian, Gerhard Henrik Armauer Hansen, conducted landmark studies on the microbiology and epidemiology of *M. leprae*. Mitsuda created the skin test for leprosy in 1919[10,11,13], and the value of sulfones in the treatment of leprosy was reported by Faget and colleagues in 1942[14]. Rabello advanced the notion of polar forms of leprosy in 1938, with a formal presentation in 1953 at the International Congress of Leprosy. In 1966, Ridley and Jopling suggested a classification of leprosy based on the immunologic status of the patient[10,11,13] (see below).

Epidemiology

In the early 1980s, an estimated 11–15 million people worldwide were thought to have leprosy[11,15], compared to only 212 000 in 2010. The number of new cases per year has decreased from more than 500 000 in 2003 to fewer than 250 000 in 2010[9,16]. The substantial reduction in the number of affected individuals reflects the impact of multidrug therapy[17]. The goal of the World Health Organization (WHO) is a prevalence rate of less than 1 case per 10 000 persons, which has been achieved in all but a few countries[16].

In the Americas, the highest incidence is seen in Brazil, especially in western Amazonia[9,11–13] (see Fig. 75.1). Although men and women are equally affected, the lepromatous form of leprosy is seen twice as often in men as in women. Leprosy affects all races and ages; however, its peak incidence occurs in individuals between 10–15 and 30–60 years of age[7,11,18].

The three requirements for the spread of leprosy are: a contagious patient, a susceptible person, and close or intimate contact. In endemic countries, the vast majority of new cases are in children and young adults who have close relatives with contagious forms of the disease. Of note, the risk of acquiring the disease from household contacts is 25%, emphasizing the public health importance of domicile control[11]. The incubation period varies widely, from months to over 30 years, but it is usually 4–10 years[18]. The organism is spread predominantly via nasal and oral droplets from the bacilliferous patient and much less often from eroded skin. Even after 1 to 7 days, the bacillus is still viable in dried secretions. Inoculation is via the nasal mucosa or, less commonly, through breaks in the skin barrier. Transmission also depends on the infectivity of the contagious patient[12,13,19]. An unusual mode of transmission, reported from India, was via reused tattoo needles.

Although leprosy primarily affects humans, it can be found or reproduced in armadillos, monkeys and mice[8]. The same strain of *M. leprae* has been found to infect wild armadillos and humans in the southern US, suggesting that leprosy represents a zoonosis in this region[20].

Pathogenesis

The bacillus *M. leprae* is a very small, slightly curved rod that is characteristically acid-fast. It is an obligate intracellular microorganism that has a predilection for macrophages and Schwann cells. The major sites of involvement are the peripheral nerves, skin, mucous membranes, bones and viscera (e.g. testes, liver)[12]. The bacillus requires a temperature of ~35°C to grow, and thus has a preference for cooler regions of the body (e.g. the nose, testicles and ear lobes) as well as regions where the peripheral nerves are close to the skin[18,21].

The fact that the majority of exposed individuals do not develop disease implies that there is variability in susceptibility/resistance, depending upon genetic and environmental factors. For example, susceptibility and the type of immune response appear to correlate with

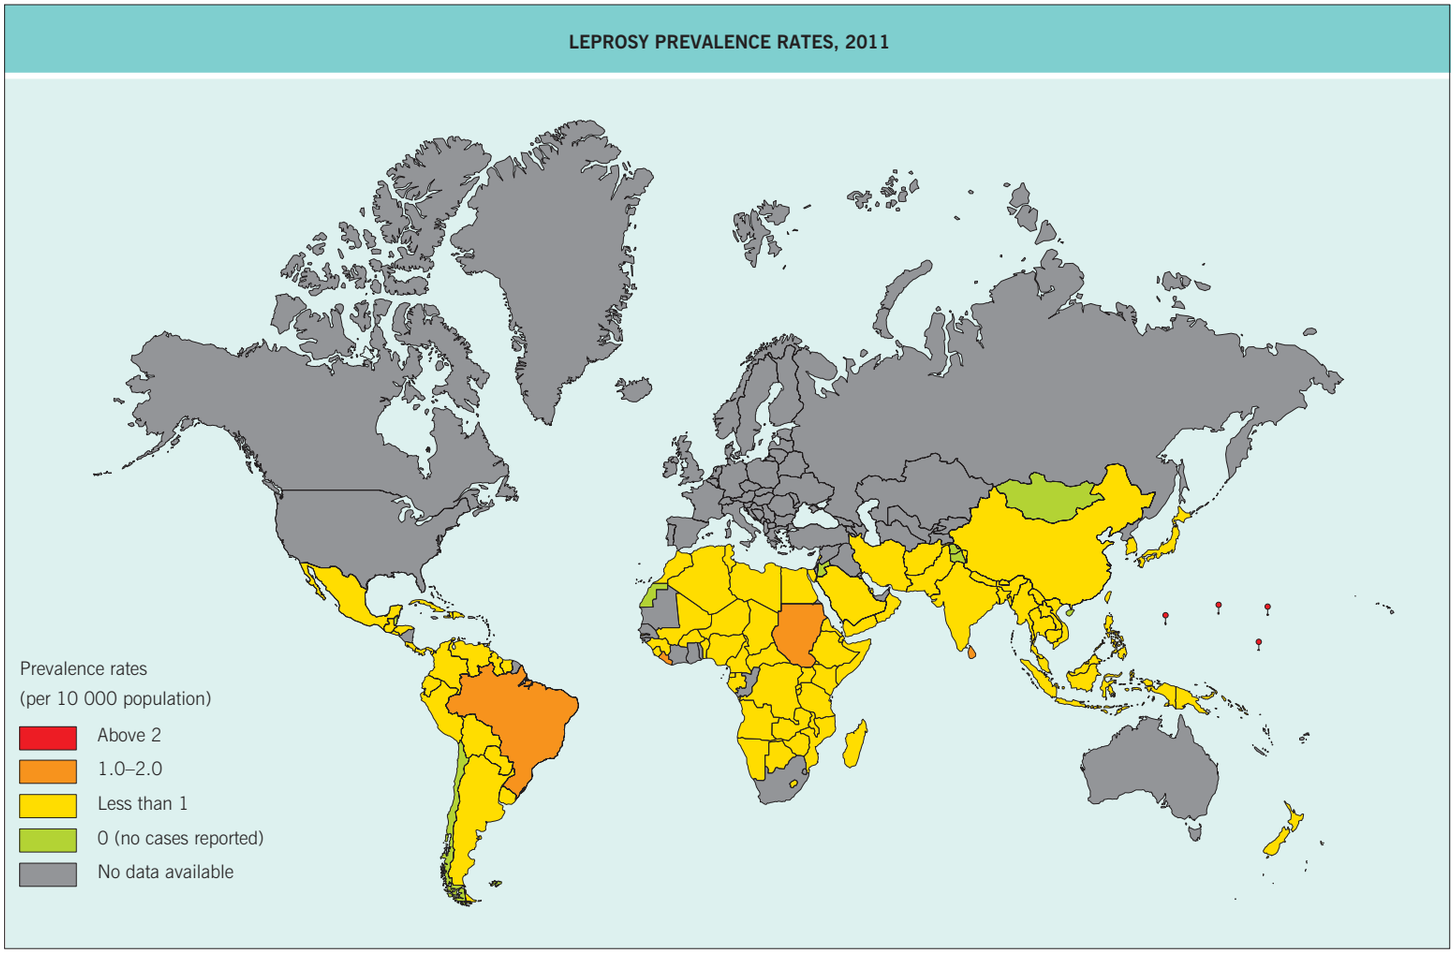

Fig. 75.1 Leprosy prevalence rates, 2011. The World Health Organization (WHO) has achieved its goal of a prevalence rate of less than 1 case per 10 000 persons in all but a few countries. *Reproduced from the World Health Organization, 2011*[9].

specific HLA types, such that individuals with HLA-DR2 and HLA-DR3 are more likely to develop the tuberculoid form and those with HLA-DQ1 the lepromatous form[11,18]. Polymorphisms in several genes, including those that encode tumor necrosis factor (TNF)-α, interleukin (IL)-10, lymphotoxin-α (a low-producing allele associated with early-onset leprosy), leukotriene A_4 hydrolase, the vitamin D receptor, and Toll-like receptor (TLR) 2, have also been shown to be related to either overall susceptibility or the particular form of leprosy that develops (although there is variability in different populations)[22–24]. In Vietnamese and Brazilian populations, a leprosy susceptibility locus on chromosome 6q25–q26 contains 17 markers in a block of approximately 80 kilobases that overlaps the 5′ regulatory region shared by the Parkinson's disease gene *PARK2* (encoding parkin, an E3 ubiquitin protein ligase) and the co-regulated gene *PACRG*[25]. In addition, genome-wide association studies in Chinese populations have linked variants in genes encoding proteins in the nucleotide-binding oligomerization domain containing-2 (NOD2) pathway (which regulates the innate immune response) with susceptibility to leprosy (especially the multibacillary form); of note, variants in some of the same genes have been associated with Crohn's disease[26].

Depending upon the level of specific cell-mediated immunity (as reflected in the lepromin test), the disease can progress without restraint, limit itself, or resolve spontaneously. Humoral immunity is increased in forms that are associated with minimal cell-mediated immunity (i.e. the lepromatous end of the spectrum; Fig. 75.2)[8,11]. For example, serum levels of antibodies against phenolic glycolipid-1 (PGL-1; an *M. leprae*-specific antigen) are highest in patients with lepromatous leprosy[27].

Macrophages play an important role in the body's attempt to eliminate *M. leprae*, producing cytokines such as IL-1, TNF-α and IL-12 when they encounter this organism. These cytokines then stimulate the number and activity of other macrophages. Studies in humans have shown that a predominantly Th1 $CD4^+$ T-cell response is seen in patients with tuberculoid leprosy. This response produces cytokines (IL-2, interferon [IFN]-γ and TNF-β) that maintain the inflammation. In patients with lepromatous leprosy, a predominantly Th2 response leads to the release of a different set of cytokines (IL-4, IL-5, IL-10 and IL-13), which suppress macrophage activity[21,28]. The cell wall of *M. leprae* contains lipid complexes, including phenolic glycolipid-1 (PGL-1), which may play a role in suppressing the T-cell response and IFN-γ production (as well as the organism's invasion of Schwann cells)[21,29,30].

More recent studies have provided additional insights into the pathogenesis of leprosy. Within lesions of tuberculoid leprosy, $CD4^+$ T cells that express the antimicrobial protein granulysin have been detected at a sixfold greater frequency when compared to lepromatous skin lesions[31]. Tuberculoid lesions also have stronger expression of TLR2 and TLR1, activation of which can induce differentiation of both macrophages and dendritic cells. $CD1b^+$ dendritic cells (which promote T-cell activation and secretion of proinflammatory cytokines) were not detected in lesions from patients with progressive lepromatous leprosy[32]; instead, these lesions had upregulation of genes belonging to the leukocyte immunoglobulin-like receptor (LIR) family. LIR-7 has been shown to suppress innate host defense by several mechanisms, including blocking antimicrobial activity triggered by TLRs[33].

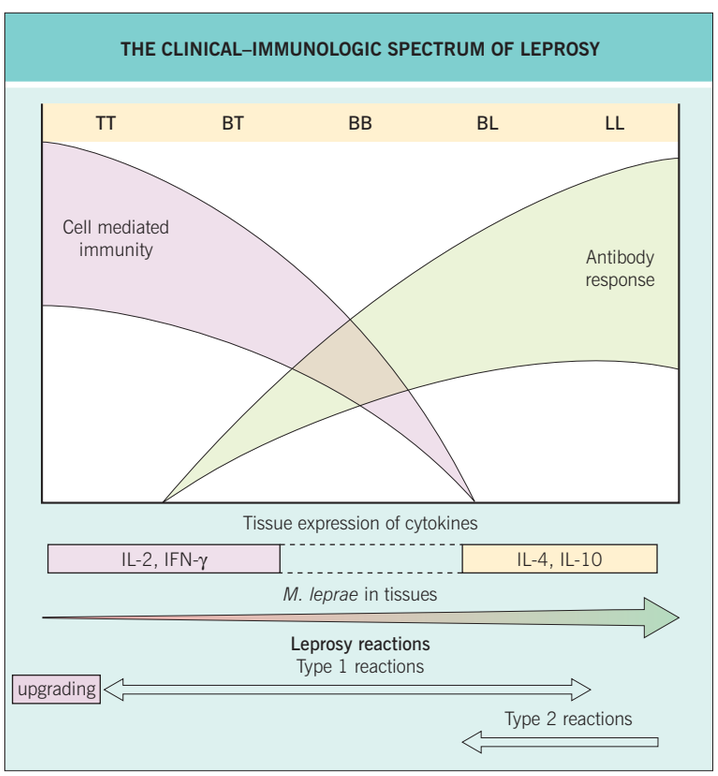

Fig. 75.2 The clinical-immunologic spectrum of leprosy. This reflects the underlying host immunity as measured by the T-lymphocyte and antibody responses to *Mycobacterium leprae*. Spontaneous and drug-induced fluctuations in the immune response are responsible for type 1 and type 2 reactions. TT, tuberculoid leprosy; BT, borderline tuberculoid leprosy; BB, mid-borderline leprosy; BL, borderline lepromatous leprosy; LL, lepromatous leprosy; IFN, interferon; IL, interleukin. *Adapted from Britton WJ. Leprosy. In Cohen J, Powderly WG (eds). Infectious Diseases. London: Mosby, 2003. With permission of Elsevier.*

Clinical Features

There is a wide spectrum of clinical findings in leprosy. After advancing the notion of polar forms of leprosy in 1938, Rabello, a Brazilian dermatologist, divided leprosy into four types: (1) lepromatous, which occurs in patients with depressed cell-mediated immunity; (2) tuberculoid, in patients with intact cell-mediated immunity; (3) dimorphous; and (4) indeterminate. The dimorphous form is "unstable" and capable of evolving into lepromatous or tuberculoid forms, depending upon whether there is improvement or worsening of cell-mediated immunity (see Fig. 75.2). In 1966, Ridley and Jopling created a classification, also based on polar forms, with lepromatous (LL) at one end, tuberculoid (TT) at the other end, and three types of borderline leprosy in between: borderline lepromatous (BL, immunodepressed end), borderline-borderline (BB, in the middle), and borderline tuberculoid (BT, immunocompetent end)[11,13,18,34].

In 1997, the WHO created an operational system in order to facilitate the classification and therapy of leprosy in endemic areas with no access to laboratory facilities. This scheme divides leprosy into three groups: (1) paucibacillary, single-lesion leprosy (one skin lesion); (2) paucibacillary leprosy (two to five skin lesions); and (3) multibacillary leprosy (more than five skin lesions). This simplified classification is based solely on the number of cutaneous lesions, independent of their size, location or histologic features. However, on a global basis, the classification scheme outlined in Table 75.2 is still the one most commonly employed[35,36].

The clinical manifestations of leprosy involve primarily the skin and the nervous system (see Table 75.2). In addition to anesthesia or hypesthesia of individual cutaneous lesions, peripheral nerves can become enlarged and palpable. Certain peripheral nerves are more commonly affected, based primarily upon their more superficial location. Palpation of these nerves is an integral component of the physical examination of a patient with leprosy (Fig. 75.3). The clinician should also determine via a neurologic examination whether there is a general decrease in sensation to pain, temperature and/or touch (e.g. on the distal extremities). This is in addition to inspection for neuropathic changes (e.g. muscle atrophy, flexion contractures of the fourth and fifth fingers), vasomotor alterations and secretory disturbances (e.g. dry eyes and nose)[13,18].

Lepromatous leprosy, the form with the least cellular immunity and greatest number of bacilli, is characterized initially by multiple, poorly defined, erythematous macules, papules, nodules and plaques. Lesions are widespread, and they are usually rather symmetric in distribution. The most common sites of involvement are the face, buttocks and lower extremities. Infiltration of the skin of the forehead can lead to a leonine facies (Fig. 75.4). Additional signs and late sequelae include madarosis, saddle nose (Fig. 75.5), infiltration of both earlobes, and acquired ichthyosis on the lower extremities (Fig. 75.6). Anesthesia in a stocking or glove distribution may develop, often together with enlarged peripheral nerves and neuropathic changes. Ocular

CLASSIFICATION OF LEPROSY						
Clinical findings	**LL**	**BL**	**BB**	**BT**	**TT**	**I**
Type of lesions	Macules, papules, nodules, diffuse infiltration	Macules, papules, plaques, infiltration	Plaques and dome-shaped, punched-out lesions	Infiltrated plaques	Infiltrated plaques, often hypopigmented	Macules, often hypopigmented
Number of lesions	Numerous	Many	Many	Single, usually with satellite lesions, to more than 5	One or few (up to 5)	One or few
Distribution	Symmetric	Tendency to symmetry	Evident asymmetry	Asymmetric	Localized, asymmetric	Variable
Definition	Vague, difficult to distinguish normal versus affected skin	Less well-defined borders	Less well-defined borders	Well-defined, sharp borders	Well-defined, sharp borders	Not always defined
Sensation	Not affected	Diminished	Diminished	Absent	Absent	Impaired
Bacilli in skin lesions	Many (globi)	Many	Many	Few (1+), if any, detected	None detected	Usually none detected

Table 75.2 Classification of leprosy. LL, lepromatous leprosy; BL, borderline LL; BB, mid-borderline leprosy; BT, borderline TT; TT, tuberculoid leprosy; I, indeterminate. *Adapted from A Guide to Leprosy Control, 2nd ed. Geneva: World Health Organization, 1988:27–28.*

manifestations such as lagophthalmos (inability to completely close the eyes) and corneal and conjunctival anesthesia due to involvement of branches of the facial and trigeminal nerves, respectively, are sometimes present in severe cases[18]. *Histoid leprosy* is a clinically distinct variant of multibacillary disease that some authors classify as a variant of lepromatous leprosy. It is characterized by the development of dermatofibroma-like papules and nodules.

Borderline leprosy, as its name implies, has features that are intermediate between the two ends of the spectrum. Cutaneous lesions (Fig. 75.7) are usually asymmetric, e.g. there may be unilateral earlobe swelling. The severity of the cutaneous and peripheral nervous system abnormalities depends upon whether the patient is "leaning" towards the lepromatous pole (BL) or the tuberculoid pole (BT; see Table 75.2). Within the cutaneous plaques, hair is usually absent.

In *tuberculoid leprosy*, only a few well-demarcated plaques are seen and sometimes only neural involvement is present. The borders of the skin lesions are often slightly elevated, and this represents the preferred site for histologic examination. In some patients, the papules or plaques are erythematous, while in others, especially in darkly pigmented individuals, they are hypopigmented (Fig. 75.8). There is typically partial, but not complete, pigment loss. The plaques should be examined for alopecia as well as anesthesia or hypesthesia. Unilateral neuropathic changes, especially of the extremities (e.g. resorption of the digits), may be seen[11,15,34].

One of the major problems faced by clinicians and patients, especially during treatment, is the development of reactions (see Fig. 75.2). These are characterized by acute inflammation (Fig. 75.9) that appears suddenly. Type 1 reactions can affect patients with any form of leprosy (except for the early indeterminate form), with a predilection for those in borderline categories, while type 2 reactions most often occur in those with lepromatous or borderline lepromatous leprosy. In addition to the administration of antimicrobial drugs, the most frequent causes of reactions are pregnancy[37], other infections and even mental distress. The immunopathogenesis, clinical manifestations and treatment of the two major types of inflammatory reactions are outlined in Table 75.3[38]. *Type 1 (reversal) reactions* are due to a change in the immunologic state of the patient and are often associated with neuritis. When there is an increase in cell-mediated immunity, this is referred to as an "upgrading" reaction.

Type 2 reactions are due to the formation of immune complexes in association with an excessive humoral reaction. They typically occur when patients with lepromatous forms of leprosy undergo treatment. A type 2 reaction represents a small vessel vasculitis (cutaneous and systemic), and the most common clinical manifestation is *erythema nodosum leprosum* (see Fig. 75.9B)[13,18,21,39]. In addition, patients (usually from Central or South America) with the diffuse form of lepromatous leprosy may develop the *Lucio phenomenon*, a reactional state characterized by thrombotic phenomena as well as necrotizing cutaneous small vessel vasculitis. On a worldwide basis, leprosy is a common cause of cutaneous vasculitis, especially in low-income countries[7,40].

Pathology and Laboratory Evaluation

There are three basic histopathologic patterns observed in leprosy: lepromatous, tuberculoid and borderline. In the *lepromatous* pattern, an infiltrate is seen in the dermis, subcutis, lymph nodes, abdominal organs (e.g. kidney and liver), testicles and bone marrow. The infiltrate contains Virchow cells, which are macrophages with numerous bacilli as well as lipid droplets in their cytoplasm. In H&E-stained sections,

A Type 1 "upgrading" reaction in a patient with borderline lepromatous disease characterized by marked inflammation of a facial plaque. **B** Erythema nodosum leprosum (type 2 reaction) with the appearance of multiple red papulonodules as a result of immune complex-mediated small vessel vasculitis in a patient with lepromatous leprosy. *B, Courtesy, Louis A Fragola, Jr, MD.*

TWO MAJOR TYPES OF LEPROSY REACTIONAL STATES		
	Type 1 – Reversal reaction with "upgrading"	**Type 2 – Vasculitis (most commonly erythema nodosum leprosum)**
Immune mechanism	Enhancement of cell-mediated immunity with a Th1 cytokine pattern	Excessive humoral immunity with a Th 2 cytokine pattern and formation of immune complexes; may be accompanied by increased cell-mediated immunity
Pathogenic process	Delayed-type hypersensitivity reaction	Cutaneous and systemic small vessel vasculitis
Leprosy category	Borderline (BT, BB, BL) or tuberculoid with immunologic recovery during or after treatment	Lepromatous and BL > BB; especially patients with a high bacterial index who are undergoing treatment
Clinical characteristics	• Increased inflammation in established skin lesions • Emergence of "new" skin lesions • Acute nerve pain or tenderness (neuritis) and loss of function • Recent (<6 month history) or progressive neurologic impairment in the absence of painful nerves	• Nodular skin lesions • Fever, myalgias, malaise • Severe joint swelling and pain • Iridocyclitis • Lymphadenitis • Hepatosplenomegaly • Orchitis • Glomerulonephritis
Treatment	Prednisone	Thalidomide

Table 75.3 Two major types of leprosy reactional states[13,18,21,38,39]. Secondary amyloidosis may occur in patients with type 2 reactional states.

these cells have a foamy appearance. With Sudan III stain, the lipid inside the Virchow cells appears orange. The bacilli in leprosy can be detected by Gram, Ziehl-Neelsen, Fite (the most commonly used) or Wade stain, all of which stain the bacilli a bright red color. Sudan III and Sudan IV (also known as scarlet red) stain the bacilli black and red, respectively. Methenamine silver stains are also useful for detecting fragmented acid-fast bacilli. For lesions where bacilli are scanty, it is recommended that at least six sections be examined before declaring them negative[13,41].

A band of normal-appearing dermis (Unna band or Grenz zone) separates the epidermis from the infiltrate, which is composed of plasma cells and lymphocytes in addition to Virchow cells (Fig. 75.10). Both isolated bacilli and globi (clumps of bacilli) are seen in the dermis; when the patient is undergoing successful therapy, the organisms fragment and become granular. Cutaneous nerves demonstrate lamination of the perineurium, giving them an onion-skin appearance. In the histoid variant, a well-circumscribed proliferation of spindle cells (which contain numerous bacilli) is seen; the bacilli typically line up along the long axis of the cell.

In the *tuberculoid* pattern of leprosy (Fig. 75.11), a dermal granulomatous infiltrate is seen that may have a linear pattern as it follows the course of a nerve. Epithelioid cells and Langhans giant cells are surrounded by lymphocytes. The cutaneous nerves are edematous, and there is an absence of organisms, even with special stains. The inflammation and fragmentation of nerve fibers in tuberculous leprosy differentiate it from sarcoidosis and other granulomatous disorders.

The *borderline* pattern contains histologic features of both the lepromatous form (e.g. Virchow cells) and tuberculoid form (e.g. granulomas). Predominance of the former versus the latter is dependent upon whether the patient has the BL, BB or BT form of borderline leprosy. There are three different histologic "scenarios" in borderline leprosy:

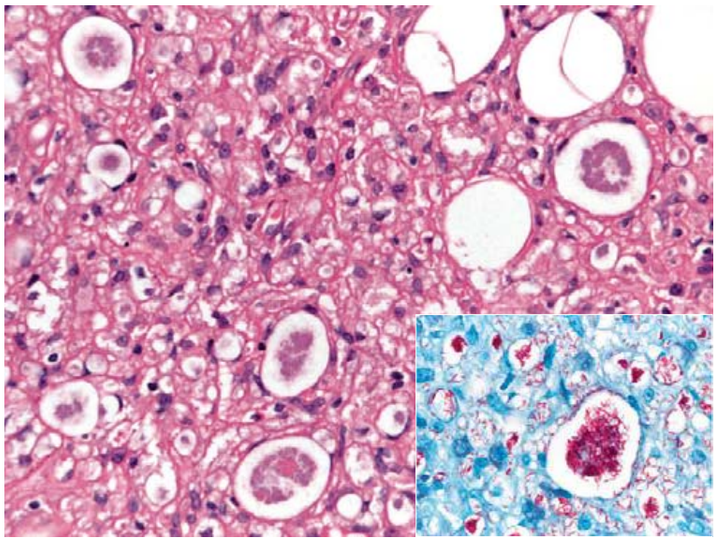

Fig. 75.10 Lepromatous leprosy. Diffuse dermal infiltrate of foamy histiocytes; note the globi which represent clumping of mycobacteria. Fite stain highlighting the numerous bacilli as well as globi (insert). *Courtesy, Lorenzo Cerroni, MD.*

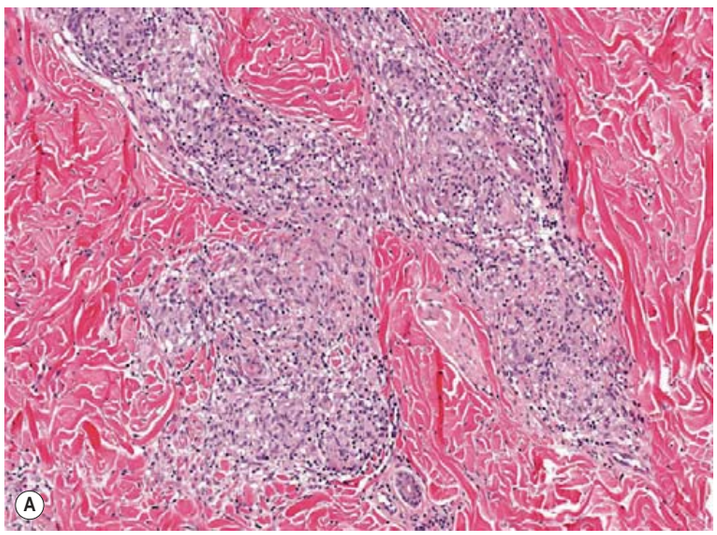

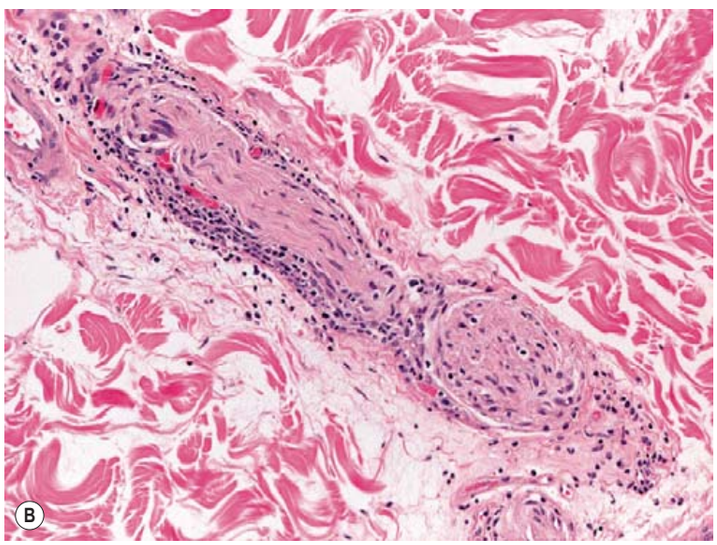

Fig. 75.11 Tuberculoid leprosy. A Granulomatous nodular infiltrate within the dermis. **B** Nerve involvement characterized by a sparse perineural infiltrate with lymphocytes, histiocytes and plasma cells. *Courtesy, Lorenzo Cerroni, MD.*

(1) the patient has some lesions with a lepromatous pattern and other lesions with a tuberculoid pattern; (2) Virchow and tuberculoid patterns are seen in the same lesion; and (3) lesions have a mixture of foamy and epithelioid cells.

Indeterminate leprosy is usually difficult to diagnose histologically. Only a patchy infiltrate of lymphocytes or histiocytes around blood vessels or appendages is seen[8,15]. There are no granulomas or Virchow cells[7,13], and organisms are usually absent.

When leprosy is suspected, the diagnosis of several forms (e.g. LL, BL) can be confirmed by finding bacilli in cutaneous scrapings, lymph nodes or nasal secretions. Samples for bacilloscopy may be obtained from the earlobes, forehead, chin, extensor forearms, and dorsal fingers, as well as the buttocks and trunk. To avoid bleeding, a fold of skin is firmly squeezed between the finger and thumb of the examiner or with forceps, and a small incision is made with a scalpel blade. The liquid obtained is smeared onto a slide and allowed to dry. The smear is usually stained by the Fite (or Ziehl-Neelsen) method and a search is made for red rods (against a blue background) at 100× with oil immersion[8]. Organisms are found in 100% of patients with lepromatous leprosy, in 75% of those with borderline leprosy, and in only 5% of those patients with tuberculoid leprosy. A biopsy specimen of the skin lesions should be obtained, especially in patients with suspected tuberculoid leprosy (see above).

The detection of *M. leprae* DNA in fresh skin samples and split skin smears by PCR has been described. In one study utilizing this technique, detection of *M. leprae*-specific repetitive sequence (RLEP) in biopsy specimens was shown to be more sensitive than detection of an 18 kDa protein gene (80% vs 57%)[42]. PCR analysis can also be performed on biopsies of nasal mucosa. In addition, immunohistochemical staining of biopsy specimens for the PGL-1 antigen may prove helpful in paucibacillary disease.

Serologic assays for anti-PGL antibodies are only sensitive for the diagnosis of leprosy in the setting of multibacillary disease. However, measurement of these antibodies can help to classify patients, monitor the response to treatment, and predict leprosy reactions[43]. Serum levels of anti-PGL-1 IgG and IgM antibodies are highest in those with lepromatous disease and lowest (or absent) in those with BT or tuberculous disease, therefore representing a marker of mycobacterial "load" in affected individuals. Elevation of anti-PGL IgM antibody levels is also associated with reactions and impairment of nerve function[27].

Three classic tests – the histamine, pilocarpine and Mitsuda tests – can be done to aid in diagnosis and determining prognosis. However, nowadays these tests are done less frequently. In the first, a drop of 0.001% histamine is placed on the suspect patch and another one on normal skin. Both areas are pricked with a needle (through the drop) and, after 10 minutes, the intensity and extent of the wheal and flare are recorded. This response is dependent upon the integrity of sympathetic nerves fibers, and, in hypopigmented lesions of leprosy (the type of lesion most commonly tested), it will be decreased, delayed or absent[8,10].

In the pilocarpine test, tincture of iodine is applied to the suspect lesion (and normal skin as a control) prior to the injection of pilocarpine into these sites. Afterwards, these areas are dusted with a starch powder that will turn blue if there is normal sweating. Because sweating depends on the integrity of parasympathetic nerve fibers, it is decreased in lesions of leprosy. Quinizarine, which turns from white to blue, can be used instead of iodine and starch[8].

The lepromin or Mitsuda test consists of an intradermal injection of 0.1 ml of a suspension of heat-killed *M. leprae*. The response is positive when a nodule forms at the site of injection 3 to 4 weeks later, indicating that the patient is able to mount a specific cell-mediated response to the bacilli. The test provides prognostic, but not diagnostic, information. It is positive in TT and BT leprosy[8].

Lastly, leprosy, especially LL and BL, is one of the causes of biologically false-positive Venereal Disease Research Laboratory (VDRL) and fluorescent treponemal antibody absorption (FTA-ABS) assays for syphilis (see Ch. 82).

Differential Diagnosis

A number of skin diseases may be confused with leprosy. Hypopigmented lesions can mimic pityriasis alba, pityriasis versicolor, mycosis fungoides or sarcoidosis. The circinate erythematous plaques may be misdiagnosed as tinea corporis, sarcoidosis, lichen planus, psoriasis or

mycosis fungoides. The differential diagnosis of the infiltrated plaques or nodules includes leishmaniasis, syphilis, sarcoidosis, lymphoma and cutaneous tuberculosis[12,15]. The neurologic findings may be confused with other types of peripheral neuropathy (e.g. due to diabetes mellitus, nutritional disorders, vasculitis, poliomyelitis or syringomyelia), while the deforming acral features may suggest Dupuytren's contractures, scleroderma, tabes dorsalis, or other diseases associated with neuropathic changes[11,12,15].

The differential diagnosis of a type 1 reaction includes acute lupus erythematosus, cellulitis and drug reactions, while in patients with type 2 reactions, the possibility of other vasculitides and panniculitides (including erythema nodosum; see Ch. 100) needs to be considered. The individual lesions of erythema nodosum leprosum appear in crops but resolve relatively rapidly and are widespread, whereas the lesions of erythema nodosum are longer-lived and favor the shins.

Treatment

The WHO recommends multidrug regimens that are safe, effective and easily administered (Table 75.4). If bacilloscopy is available, patients are considered to have paucibacillary leprosy if no bacilli are found; they are treated with rifampin monthly plus a sulfone (usually dapsone) daily for 6 months, and then observed for 2 years. For patients with paucibacillary disease and a single lesion, single-dose therapy ('ROM scheme': single dose of 600 mg *r*ifampin, 400 mg *o*floxacin and 100 mg *m*inocycline), has yielded good results. If at least one bacillus is detected via bacilloscopy, the patient should receive rifampin, clofazimine and dapsone for 1 to 2 years and then be observed for 5 years. A second option is to combine a sulfone with clofazimine[44–46]. Pediatric therapeutic schemes recommended by a WHO are also summarized in Table 75.4.

Multidrug therapy is extremely effective. Importantly, after the first dose, the patient is no longer infectious to others (i.e. transmission of leprosy is interrupted). All patients who complete the prescribed regimen are considered cured, as there are virtually no relapses. Bacilli may be found but they are non-viable. Drugs that may play a significant role in the treatment of leprosy in the future include other quinolones (e.g. moxifloxacin, sparfloxacin), clarithromycin and ansamycins[47–49]. Rifapentine (a rifampin derivative) has higher peak serum concentrations, a longer serum half-life and more bactericidal activity against *M. leprae* than does rifampin. In addition, moxifloxacin appears to be more bactericidal than ofloxacin. As a result, the combination of rifapentine, moxifloxacin and minocycline (PMM) may be superior to rifampin, ofloxacin and minocycline (ROM)[49].

For the two major inflammatory reactions, additional medications are often required. Oral prednisone (20–60 mg per day) is used for type 1 (reversal) reactions, while thalidomide (100–200 mg per day) is the principal therapy for type 2 reactions (erythema nodosum leprosum). Systemic corticosteroids are also recommended for the Lucio phenomenon. Although thalidomide remains the treatment of choice for type 2 reactions, its teratogenicity can be problematic and it is unavailable in many countries where leprosy is endemic. Lenalidomide and pomalidomide are thalidomide analogues with different side-effect profiles (e.g. less teratogenicity, more myelosuppression) that could have potential utility in the treatment of type 2 reactions. Additional drugs with possible benefit in type 2 reactions include clofazimine, cyclosporine (which has been used for corticosteroid-resistant type 1 reactions), chloroquine, pentoxifylline and phosphodiesterase type-4 inhibitors (e.g. roflumilast)[49–51].

Although leprosy is now considered a curable disease with a good prognosis and excellent survival rate, it can still be incapacitating and stigmatizing. It is very important to make the diagnosis as early as possible and to examine contacts, since treatment provided in the early stages of the disease prevents disability. Recognition of leprosy in its initial phases (in particular the cutaneous findings) by healthcare professionals as well as the general population in endemic countries is essential in order to reduce the impact of this disease[8].

CUTANEOUS TUBERCULOSIS

Key features

- Infection of the skin due to *Mycobacterium tuberculosis*, an acid- and alcohol-fast bacillus
- Increases in the incidence of tuberculosis (TB) in recent years are attributed to the HIV epidemic, emergence of resistant strains of *M. tuberculosis*, and a decline in TB control efforts
- Exogenous exposure produces primarily the tuberculous chancre and TB verrucosa cutis
- Endogenous infection can lead to scrofuloderma, miliary TB and lupus vulgaris
- Tuberculids include a papulonecrotic eruption, lichen scrofulosorum and erythema induratum

Introduction

Tuberculosis (TB) has affected humans since prehistoric times. There was, however, a worldwide explosion in its incidence in the late 1980s and early 1990s, and consequently a resurgence of cutaneous TB[2,52–54]. This phenomenon has been attributed to the HIV epidemic, the emergence of resistant strains of *Mycobacterium tuberculosis*, increased use of immunosuppressive therapies, more migration of people around the world, and a decline in TB control efforts[52,53], superimposed on the pre-existing factors of poverty and malnutrition.

MULTIDRUG THERAPY/WHO SCHEME FOR THE TREATMENT OF LEPROSY						
	Rifampin	**Clofazimine**	**Dapsone**	**Ofloxacin**	**Minocycline**	**Therapy duration**
MB (>5 lesions*)	600 mg once monthly	300 mg once monthly and 50 mg daily	100 mg daily	–	–	12 blister packs over 12 to 18 months
PB (2–5 lesions*)	600 mg once monthly	–	100 mg daily	–	–	6 blister packs over 6 to 9 months
PB (single lesion*)	600 mg × 1	–	–	400 mg × 1	100 mg × 1	Single dose
DOSE ADJUSTMENTS FOR CHILDREN						
10 to 14 years of age, MB†	450 mg once monthly	150 mg once monthly and 50 mg every other day	50 mg daily	–	–	12 blister packs over 12 to 18 months
<10 years of age, MB†	300 mg once monthly	100 mg once monthly and 50 mg twice weekly	25 mg daily	–	–	12 blister packs over 12 to 18 months
5 to 14 years of age, single lesion PB	300 mg × 1	–	–	200 mg × 1	50 mg × 1	Single dose

*WHO classification for endemic areas when no facilities for performing bacilloscopy are available.
†For PB disease (2–5 lesions), clofazimine is not required and the duration of therapy is 6 to 9 months.

Table 75.4 Multidrug therapy/WHO scheme for the treatment of leprosy. These recommendations are those currently standardized by the WHO[7,36,44–46]. MB, multibacillary; PB, paucibacillary.

History

There are paleopathologic findings suggesting *M. tuberculosis* infections as early as 3700 BC in Egypt, and 2500 to 1500 BC in Europe. Utilizing PCR, *M. tuberculosis* DNA has been demonstrated in mummified remains from ancient times. In 1826, Laennec first reported cutaneous TB in the form of a "prosector's wart". Rokitansky and Virchow subsequently described the histologic features of cutaneous TB in detail, comparing them to those of visceral TB. The discovery of *M. tuberculosis* by Koch in 1882 and the advances in descriptive pathology during the nineteenth century helped to establish cutaneous TB as part of the spectrum of this infectious disease[53,54].

Epidemiology

M. tuberculosis is not particularly virulent, as only 5% to 10% of infections lead to clinical disease. This bacterium has a worldwide distribution; it is more prevalent in regions with a cold and humid climate but can also occur in the tropics (Fig. 75.12)[55]. The incidence of cutaneous TB parallels that of pulmonary TB and is therefore seen more commonly in low-income countries and impoverished populations. HIV-infected individuals and those receiving immunosuppressive therapies (especially TNF-α inhibitors; see Ch. 128) are at particular risk for the development and reactivation of TB.

Pathogenesis

M. tuberculosis is the predominant etiologic agent in cutaneous TB. Occasionally, *M. bovis* and bacille Calmette-Guérin (BCG), an attenuated strain of *M. bovis*, may produce skin lesions[39,52].

M. tuberculosis is a slender, non-motile, aerobic, non-spore-forming, filamentous rod. It is an acid- and alcohol-fast bacillus that has a waxy coating with a high lipid content, which makes it resistant to degradation after phagocytosis[56].

M. tuberculosis disseminates primarily via inhalation of aerosolized droplets of saliva from individuals with active disease; transmission by ingestion or inoculation can also occur[56]. Intact skin provides an effective protective barrier against invasion of the organism, but a break in the mucocutaneous barrier can facilitate its entrance[57]. Untreated infected individuals who do not have underlying medical problems have a 5% to 10% lifetime risk of progression to active TB; this risk increases substantially with immunosuppression (e.g. HIV infection or treatment with medications such as TNF-α inhibitors).

Studies using a model of zebrafish infected with *Mycobacterium marinum* have demonstrated that granulomas, which are classically considered as host-protective structures formed to control infection, actually contribute to early bacterial growth and facilitate its spread[58] (Fig. 75.13). Mycobacteria induce granuloma formation by releasing the early secreted antigenic target 6 (ESAT-6) protein, which stimulates neighboring epithelial cells to produce matrix metalloproteinase-9 (MMP-9). MMP-9 enhances recruitment of macrophages that contribute to bacterial proliferation and spread as well as maturation of the nascent granuloma[59]. Increased production of other MMPs (e.g. MMP-1, MMP-3) has also been shown to drive tissue destruction in TB[60]. Eventually, development of adaptive immunity results in the curtailment (but not eradication) of bacterial growth by $CD4^+$ and $CD8^+$ effector T cells. The mature granuloma therefore represents an equilibrium between mycobacterial growth and the host immune response, and MMPs represent potential targets for antimycobacterial therapy.

The interaction of T cells and mycobacterial antigens, which are displayed on the surface of antigen-presenting cells, induces the liberation of interferons and other cytokines. These substances promote the activation and expression of MHC class II on antigen-presenting cells as well as the IL-2 receptor on T cells. During the initial sensitization, memory T cells are generated and will remain for decades in lymphoid organs and the circulation[52]. In mice, the intracellular pathogen resistance 1 gene (*Ipr1*) within the supersusceptibility to tuberculosis 1 (sst1)

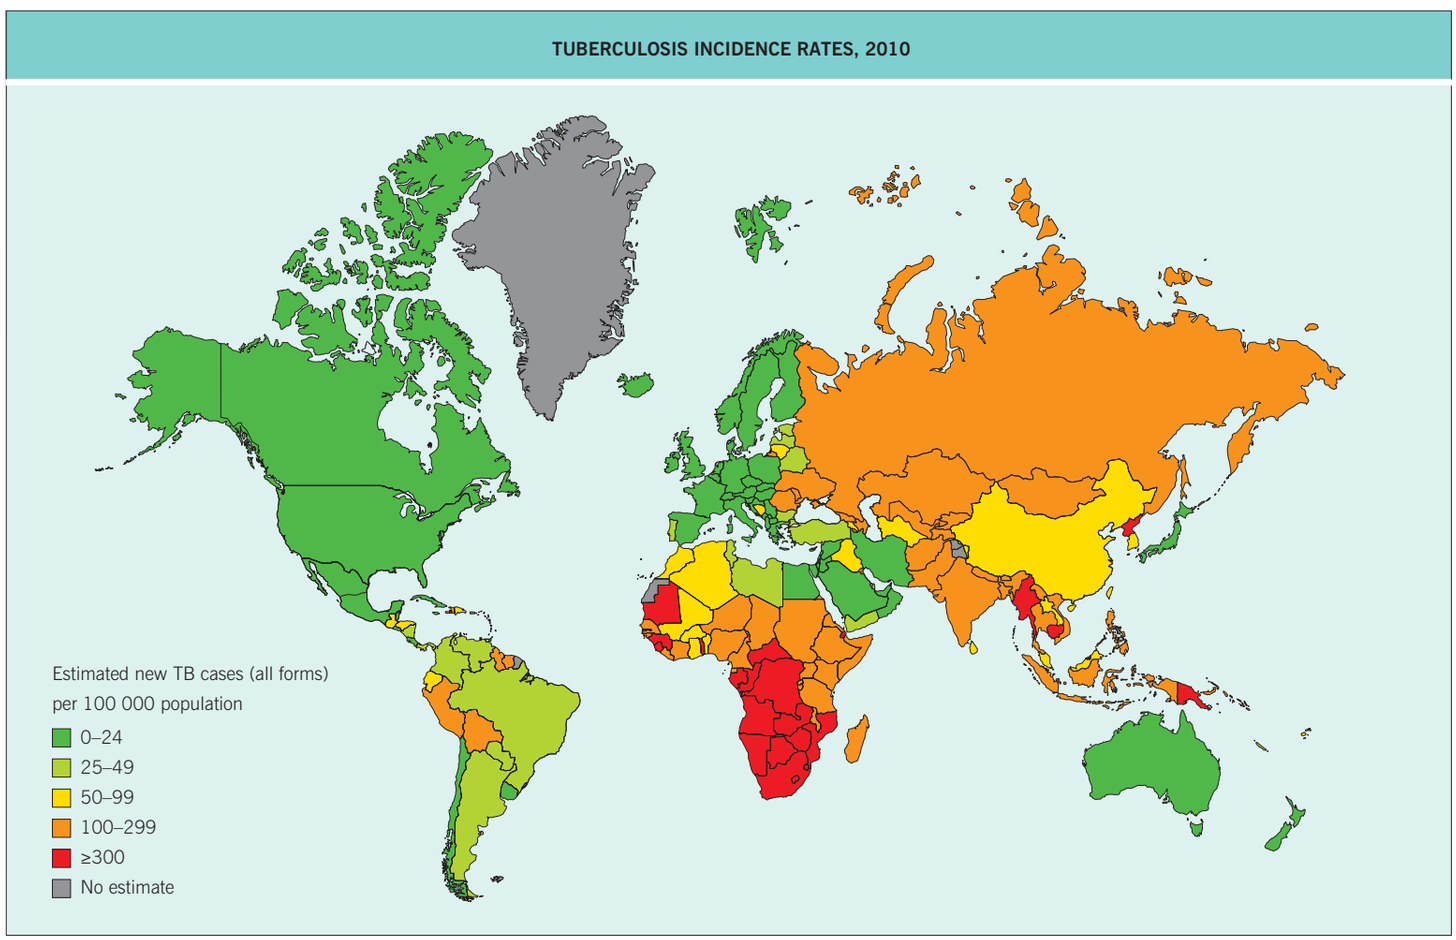

Fig. 75.12 Tuberculosis incidence rates, 2010. *Reproduced from the World Health Organization[55].*

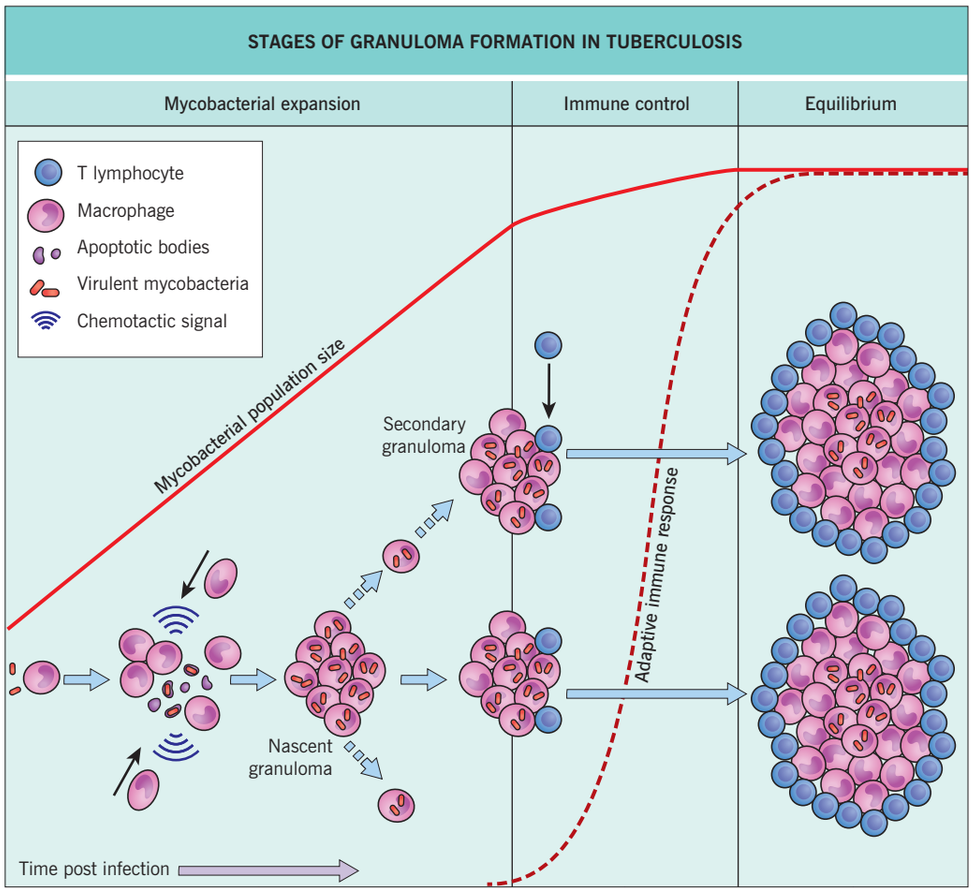

Fig. 75.13 Stages of granuloma formation in tuberculosis. The initial stage of tuberculosis is characterized by expansion of the mycobacterial population in the absence of adaptive immunity. Mycobacterial multiplication and spread are facilitated by the formation of the nascent granuloma. Infected macrophages undergo apoptosis and recruit additional macrophages, which phagocytose remnants of infected cells and their mycobacterial contents. Some of these newly infected macrophages then seed secondary granuloma formation. When adaptive immunity eventually occurs, $CD4^+$ and $CD8^+$ effector T cells curtail mycobacterial growth. Although this controls the infection, it is not eradicated. The mature granuloma therefore represents an equilibrium between mycobacterial proliferation and the host response. *Adapted with permission from Bold TB & Ernst JD. Who benefits from granulomas, mycobacteria or host? Cell. 2009;136:18–19.*

locus encodes a protein that mediates innate immunity to *M. tuberculosis* and other intracellular organisms. Ipr1 is expressed in macrophages and limits the multiplication of *M. tuberculosis* within these cells[61].

The sensitization status of the host to mycobacterial antigens (e.g. previously infected vs never exposed), the degree of cell-mediated immunity of the host, the route of infection, and the pathogenicity of the infective strain of mycobacteria determine the resulting infection (Table 75.5). In HIV-infected patients, cell-mediated immunity is impaired; as a consequence, there may be reactivation of quiescent disease[52,57].

Clinical Features

Cutaneous TB has a wide variety of clinical presentations[3,52,54,56,62]. Lesions can be due to direct inoculation of *M. tuberculosis* from an exogenous source, e.g. tuberculous chancre, TB verrucosa cutis and, occasionally, lupus vulgaris. Skin involvement due to endogenous infection may appear as scrofuloderma, acute miliary TB, a tuberculous gumma, orificial TB and lupus vulgaris (see Table 75.5). In addition, immune reaction to *M. tuberculosis* can have several cutaneous manifestations, which are called tuberculids.

Cutaneous tuberculosis

A *tuberculous chancre* develops 2 to 4 weeks after the inoculation of *M. tuberculosis* into the skin of an individual without a history of TB. It is a painless, firm, reddish-brown papulonodule that slowly enlarges, eventually eroding to form a sharply demarcated ulcer[3,52,56]. Frequently there is spread to draining lymphatics and regional lymph nodes[52]; the combination of the latter with a tuberculous chancre is analogous to the Ghon complex in the lung[52,56]. The skin lesion usually heals spontaneously within 3 to 12 months, leaving an atrophic scar and calcified regional lymph nodes. The tuberculous chancre may occasionally evolve into verrucous plaques, scrofuloderma-like lesions or lupus vulgaris[54,56].

Tuberculosis verrucosa cutis results from exogenous inoculation of *M. tuberculosis* at sites prone to trauma in previously infected individuals[3,56]. The lesion begins as a small, asymptomatic, indurated wart-like papule with a subtle inflammatory rim (Fig. 75.14). It gradually enlarges, often in a serpiginous manner, to form a firm reddish-brown verrucous plaque. The center of the lesion may become fluctuant, with pus and keratinaceous debris expressed by slight pressure[3,54,56]. After several years, the plaque can heal spontaneously[52].

Scrofuloderma begins as a firm, deep-seated, subcutaneous nodule that has accumulated inflammatory material and necrotic tissue, best characterized as a "cold abscess". The suppurative nodule later becomes fluctuant and drains, with ulceration and sinus tract formation (Fig. 75.15). Because of the drainage, the bacilli secondarily infect the overlying dermis. The borders of the ulcers are often blue, the margins are undermined, and the base is covered with soft granulation tissue. Multiple ulcers can appear. After healing, keloids and retracted tethered scars develop at the sites of infection. The original focus of TB is usually underlying lymph nodes or bones, but it may be joints or the epididymis[3,52,54,63].

Orificial tuberculosis usually results from autoinoculation of *M. tuberculosis*, although occasionally it has an exogenous origin. The affected patients typically have advanced internal TB in the setting of impaired cell-mediated immunity. The mucosal or cutaneous lesions occur within or adjacent to a natural orifice that is draining an active internal tuberculous infection, primarily pulmonary, intestinal or anogenital. The most common location is the mouth, especially the tongue. The initial lesion is an edematous red papule that ulcerates (Fig. 75.16) and develops undermined edges. The ulcers are painful, recalcitrant to treatment, and do not tend to heal spontaneously[3,56].

Lupus vulgaris (Fig. 75.17) is a form of cutaneous TB that occurs in previously sensitized individuals with a strongly positive delayed-type hypersensitivity (DTH) reaction to tuberculin (reflecting cell-mediated immunity). It can develop secondarily from TB verrucosa cutis or scrofuloderma as well as from other endogenous and exogenous sources; lupus vulgaris also occasionally arises following BCG inoculation. The typical lesion is a red–brown plaque composed of papulonodules with an "apple-jelly" color on diascopy. As the plaque expands, central scarring often develops. This can lead to substantial tissue destruction over a period of years. Lupus vulgaris has a number of clinical presentations

CLINICAL PRESENTATIONS OF CUTANEOUS TUBERCULOSIS							
	Tuberculous chancre	**Tuberculosis verrucosa cutis**	**Scrofuloderma**	**Orificial tuberculosis**	**Lupus vulgaris**	**Acute miliary tuberculosis**	**Tuberculous gumma**
Synonyms	Primary inoculation tuberculosis, cutaneous primary complex	Warty tuberculosis, prosector's wart, lupus verrucosus	Tuberculosis cutis colliquativa	Acute tuberculous ulcer, tuberculosis cutis orificialis	Tuberculosis luposa	Tuberculosis cutis disseminata, tuberculosis cutis acuta generalisata	Metastatic tuberculous ulcer, metastatic tuberculous abscess
Incidence	Rare except in Asia; 1–2% of cutaneous tuberculosis	Most common form of cutaneous tuberculosis (e.g. ~40% of cases in Hong Kong)	Common in immigrants from developing countries	Rare	Low: 10–15% of cutaneous tuberculosis; women affected 2–3 times more often than men	Rare; infants and young children, seldom adolescents or adults	Children with low socioeconomic status or immunocompromised hosts
Transmission	Inoculation into skin and/or mucosa of previously uninfected person, i.e. with no specific immunity	Inoculation into skin and/or mucosa of previously infected person with moderate or high immunity	Contiguous involvement of skin overlying a focus of tuberculosis, usually in lymph node or bone. Also reported after BCG vaccination	Autoinoculation of mucosa or skin adjacent to a natural orifice draining an active internal tuberculous infection	Direct extension; hematogenous or lymphatic spread from a tuberculous focus; reinfection; BCG vaccination	Hematogenous dissemination from primary lung focus in patient with low immunity; may follow viral infection	Acute hematogenous dissemination from a primary focus during periods of bacillemia and lowered resistance
Tuberculin skin test	Early: negative Later: positive	Positive	Usually positive	Variable, often negative	Usually positive	Usually negative	Usually negative
Histopathology	• Acute: nonspecific neutrophilic inflammation with necrosis; bacilli • Later: granulomatous inflammation with central caseation, epithelioid and Langhans giant cells; disappearance of bacilli	Acute inflammation in the epidermis, pseudoepitheliomatous hyperplasia, microabscesses in upper dermis, sparse granulomatous foci; occasionally bacilli present	Tuberculous granulation tissue and caseation necrosis in the deeper dermis; bacilli can be isolated from pus	Nonspecific inflammatory infiltrate and necrosis, some tubercles with caseation deep in dermis; bacilli easily found	Well-developed tubercles with scant caseation, nonspecific inflammatory infiltrate; no visible bacilli	Necrosis, nonspecific inflammatory infiltrate surrounded by macrophages, sometimes developing into small abscesses; abundant bacilli	Massive necrosis and abscess formation; large number of bacilli
Diagnosis	Histology and culture PCR IGRA*	Culture PCR IGRA	Culture PCR IGRA	Histology and culture PCR Presence of another focus of TB IGRA*	Histology and culture PCR IGRA	Smear, histology and culture; PCR Presence of another focus of TB IGRA*	Culture and histology PCR IGRA*
Differential diagnosis	Other pyogenic ulcers and chronic chancriform lesions, including the following: sporotrichosis, dimorphic or opportunistic fungal infections, *M. marinum* infection, nocardiosis, tularemia, syphilis, cat scratch disease	Warts, verrucous fungal infections (e.g. chromomycosis), tertiary syphilis, hypertrophic lichen planus	Dimorphic or opportunistic fungal infections, non-tuberculous mycobacterial infections, syphilitic gumma, actinomycosis, chronic bacterial osteomyelitis, adenitis with drainage, hidradenitis suppurativa, severe acne conglobata	Painful ulcerative diseases that affect orifices and periorificial skin: HSV, recurrent aphthous stomatitis, pemphigus, histoplasmosis	Sarcoidosis, discoid lupus erythematosus, dimorphic fungal infections, leishmaniasis, tertiary syphilis, squamous cell carcinoma	Varicella, enteroviral exanthems, rickettsialpox, PLEVA	Panniculitis, dimorphic or opportunistic fungal infection, syphilitic gumma, hidradenitis suppurativa
*May have an indeterminate result early in the disease course or in immunocompromised patients.							

Table 75.5 Clinical presentations of cutaneous tuberculosis. BCG, bacille Calmette-Guérin; IGRA, interferon-γ release assay (e.g. QuantiFERON® TB Gold [In-Tube], T-SPOT®.TB; see Table 75.6).

Fig. 75.14 Tuberculosis verrucosa cutis. A wart-like papule at the site of exogenous inoculation in a patient with immunity against *M. tuberculosis*.

Fig. 75.15 Scrofuloderma. Plaques and nodules with central ulceration as well as resultant scarring with retraction.

Fig. 75.16 Orificial tuberculosis. A non-healing ulcer of the nasal mucosa.

including the following: (1) plaque-type; (2) ulcerative or mutilating; (3) vegetating; (4) tumor-like; and (5) papulonodular. The head and neck region is the most commonly affected site, in particular the nose, cheeks and ear lobes[3,54,56]. Mucosa, especially oral, can also be involved.

The initial lesions of *miliary tuberculosis* are pinhead-sized, bluish-red papules capped by minute vesicles. The vesicles develop a tiny central umbilication followed by the formation of crusts. When the papules heal, they leave a residual white scar with a brownish rim[3,52,56]. The cutaneous lesions are the result of a bacteremia, and the primary focus is often in the lungs.

A *tuberculous gumma* is also due to a bacteremia with cutaneous seeding. It can present as a firm subcutaneous nodule that slowly softens or as an ill-defined fluctuant swelling. The overlying skin gradually breaks down to form an undermined ulcer, often with sinus tract formation. The extremities are more often affected than the trunk[3].

Tuberculids

The tuberculids represent a group of disorders that classically were associated with a focus of internal TB. They are considered immune reactions within the skin due to hematogenous dissemination of *M. tuberculosis* or its antigens from a primary source, in an individual with strong antituberculous cell-mediated immunity. Often beginning as an immune complex-mediated reaction, they evolve into a granulomatous inflammatory response.

Because the supporting evidence is often circumstantial, there is an ongoing debate as to the pathogenesis of tuberculids and their association with *M. tuberculosis*[3,54,62]. Arguments in favor of an association with *M. tuberculosis* include a positive tuberculin skin reaction in affected patients; the presence of *M. tuberculosis* DNA (as detected by PCR) in lesions of erythema induratum, lichen scrofulosorum and papulonecrotic tuberculid; and a positive response to antituberculous chemotherapy. In addition, many of the lesions demonstrate granulomatous inflammation. However, those who argue against an association state that there are multiple causes of granulomatous inflammation and an active focus of TB is usually not found in patients with tuberculids. Also, a positive tuberculin test simply reflects a past exposure to TB. However, the argument that corticosteroids can improve these eruptions is not a particularly strong one against an association, since other infectious diseases, e.g. viral hepatitis, can improve with such therapy and one would expect an antigen-driven inflammatory process to respond to corticosteroids. Although the positive PCR findings are not absolute proof of pathogenesis, in the setting of appropriate controls, they do provide strong evidence in favor of an association.

Papulonecrotic tuberculid presents with dusky red papules or papulopustules that are widely distributed in a somewhat symmetric pattern (Fig. 75.18). Individual lesions may have central necrosis and are usually asymptomatic; occasionally there is associated pruritus. Papulonecrotic tuberculid is seen most often in children and young adults, and lesions favor the extensor surfaces of the arms and legs and the buttocks. Usually there is spontaneous healing of individual lesions, often with scar formation. Multiple cyclic eruptions are characteristic, even after antimycobacterial therapy. PCR for mycobacterial DNA and the tuberculin test are positive[3,54]. Histologically, there is evidence of leukocytoclastic vasculitis and wedge-shaped necrosis in the dermis; later on, a perivascular mononuclear cell infiltrate and granuloma formation can be seen. The history and clinical appearance aid in the diagnosis, which is bolstered by the histologic findings. The differential diagnosis may include pityriasis lichenoides et varioliformis acuta (PLEVA) and small vessel vasculitis.

The early lesions of *lichen scrofulosorum*, a rare disorder, are firm, typically perifollicular, pink or yellow–brown, tiny flat-topped papules with variable scale. These asymptomatic papules are grouped in clusters, predominantly on the trunk. Lesions may persist for months and then disappear without scarring. Although it is seen in all age groups, children with nodal or skeletal TB are most frequently affected. This type of tuberculid has also been reported after BCG vaccination and it can be triggered by tuberculin testing in highly reactive patients. Histologic examination demonstrates superficial granulomas around hair follicles and sweat ducts, with little or no caseation necrosis. No bacilli are found; however, PCR testing has demonstrated *M. tuberculosis* DNA within lesions. The differential diagnosis includes lichen nitidus, lichen planus and other lichenoid dermatoses (see Ch. 12) as well as "id" reactions, Blau syndrome, sarcoidosis and secondary syphilis[3,54,62].

Erythema induratum (*nodular vasculitis*) is a form of lobular panniculitis that is associated with *M. tuberculosis* infection in a subset of affected individuals (especially in countries with a high prevalence of TB) (see Ch. 100). The term *erythema induratum of Bazin* is reserved for cases related to *M. tuberculosis*. Immune complex deposition (which may play a role in the vasculitic component) and a delayed-type hypersensitivity reaction to mycobacterial antigens are thought to be involved in the pathogenesis of this condition[39,62]. Women are most commonly affected (approximately 80–90% of patients), with peaks in incidence during early adolescence and around menopause.

Fig. 75.17 Lupus vulgaris. A Annular granulomatous plaque with central scarring. **B** Coalescing pink-brown papules. **C** Red-brown plaque on the neck. *C, Courtesy, Eugene Mirrer, MD.*

Fig. 75.18 Papulonecrotic tuberculid. Erythematous papules and papulopustules on the heel.

Fig. 75.19 Site of a BCG vaccination. Enlarging granulomatous plaque (BCGitis).

Symptoms often begin after exposure to low temperatures. Typically, subcutaneous nodules appear on the calves of both legs; they may involute or break down, creating irregular deep ulcers with undermined bluish borders. Healing results in atrophic hyperpigmented scars. Histologically, a lobular (or lobular plus septal) panniculitis is seen. A neutrophilic vasculitis with mural thickening of subcutaneous arteries and veins and perivascular cuffing may also be evident. Fat necrosis and granulomas can sometimes be observed. Bacilli are absent and caseation is rare[3,54].

Other entities such as erythema nodosum, lupus miliaris disseminatus faciei, granulomatous rosacea and lichenoid tuberculid were formerly considered tuberculids, but they are no longer included in this category[62].

BCG inoculation

BCG vaccination is performed with attenuated *M. bovis*. By increasing the degree of protection against *M. tuberculosis* infection, this vaccine has reduced the worldwide incidence of TB considerably. It can, however, cause complications (Fig. 75.19), which include localized or generalized tuberculids, lupus vulgaris, scrofuloderma and other nonspecific reactions such as fever, local inflammation, subcutaneous abscesses with or without ulceration, severe regional lymphadenitis, osteitis, and tuberculous foci in distant organs. Rarely, it can lead to a fatal infection[62]. Injections of methanol extraction residue (MER) of BCG have been used as adjuvant immunotherapy in patients with melanoma and can also result in nodules and subcutaneous abscesses (Fig. 75.20).

Diagnosis

In addition to the use of tuberculin skin tests, *M. tuberculosis* infection can be diagnosed with IFN-γ release assays (e.g. QuantiFERON® TB Gold [In-Tube], T-SPOT®.TB). These assays determine whether exposure to recombinant peptides from *M. tuberculosis* (ESAT-6, culture filtrate protein [CFP]-10, ±TB7.7) stimulates IFN-γ production by T cells within patient blood samples. In general, IFN-γ release assays have greater specificity and similar sensitivity compared to tuberculin skin

Fig 75.20 Complication of injection of methanol extraction residue (MER) of BCG. Nodules, some of which have ulcerated, arranged in a linear "lymphatic" pattern in a patient with a high-risk extremity melanoma who had received an injection of MER of BCG as adjuvant immunotherapy.

ADVANTAGES AND DISADVANTAGES OF IFN-γ RELEASE ASSAYS AND TUBERCULIN SKIN TESTING

	Tuberculin skin test	IFN-γ release assays
Advantages	Does not require a laboratory Relatively low cost	Requires a single patient visit Results can be available within 24 hours Prior BCG vaccination does not cause a false-positive result Does not boost responses measured by subsequent tests
Disadvantages	Requires two patient visits Results are not available for 48 hours Prior BCG vaccination can cause a false-positive result May boost responses in subsequent tests Infections with non-tuberculous mycobacteria may lead to a false-positive result	Requires laboratory processing within 16 hours (for QuantiFERON® TB Gold In-Tube) or 8–30 hours (for T-SPOT®.TB; the latter if use T-cell Xtend®) Relatively high cost Infections with some non-tuberculous mycobacteria (e.g. *M. kansasii, M. szulgai* and *M. marinum*) may lead to a false-positive result
Situations where preferable	Children <5 years of age	Patient groups that historically have low rates of returning for a second visit (e.g. homeless persons, drug users) Individuals who have received BCG

Table 75.6 Advantages and disadvantages of interferon-γ (IFN-γ) release assays and tuberculin skin testing. Both types of tests may be negative in patients with early active tuberculosis. Indeterminate IFN-γ release assay results due to failure of the internal positive control (i.e. a "low mitogen" response) are more common in immunocompromised individuals and young children. Indeterminate results due to inappropriately high IFN-γ levels in the negative control ("high nil") can also occur. Testing with a second method after an initial negative test may be useful when the risk of infection/progression is high or when there is clinical suspicion of active tuberculosis. The QuantiFERON® TB Gold (In-Tube) test directly measures IFN-γ levels, whereas the T-SPOT®.TB test determines the number of IFN-γ-producing T cells; both use a peripheral blood sample. BCG, bacille Calmette-Guérin.

tests; when QuantiFERON® TB Gold and T-SPOT®.TB are compared, the former may have slightly higher specificity and the latter marginally higher sensitivity[64]. The US Centers for Disease Control and Prevention (CDC) guidelines state that an IFN-γ release assay may be used in place of a tuberculin skin test in all situations where the latter would be employed. Advantages and disadvantages of these methods of TB detection as well as special situations where one type of test would be preferred are listed in Table 75.6.

CLASSES, ACTIVITIES AND CROSS-RESISTANCES OF THE ANTITUBERCULOUS AGENTS

Agent	Class of compound	Spectrum of activity	Cross-resistance to other antituberculous agents
FIRST-LINE AGENTS			
Rifampin	Antibiotic	Broad	Other rifamycins
Isoniazid	Synthetic	Tubercle bacilli	None
Pyrazinamide	Synthetic	Tubercle bacilli	None
Ethambutol	Synthetic	Tubercle bacilli	None
Rifapentine	Antibiotic	Broad	Other rifamycins
Rifabutin	Antibiotic	Broad	Other rifamycins
SECOND-LINE AGENTS			
Kanamycin, amikacin, streptomycin	Aminoglycoside antibiotics	Broad	Other aminoglycosides, viomycin, capreomycin
Capreomycin, viomycin	Tuberactinomycin antibiotics	Tubercle bacilli	Aminoglycosides
Levofloxacin, ofloxacin, moxifloxacin, gatifloxacin	Quinolone antibiotics	Broad	None
Ethionamide, prothionamide	Thioamides	Tubercle bacilli	Thiacetazone
Cycloserine, terizidone	Synthetic	Broad	None
para-Aminosalicylic acid	Synthetic	Tubercle bacilli	None
THIRD-LINE AGENTS			
Clofazimine	Riminophenazine antileprotic	Mycobacteria	None
Amoxicillin/clavulonate	Antibiotic	Broad	None
Linezolid	Antibiotic	Broad	None
Imipenem	Antibiotic	Broad	None
Thiacetazone	Synthetic	Tubercle bacilli	Ethionamide, prothionamide
Clarithromycin	Antibiotic	Broad	None

Table 75.7 Classes, activities and cross-resistances of the antituberculous agents. Agents that are active against *M. tuberculosis* may also show activity against some other species of mycobacteria. Strains of *M. bovis* are naturally resistant to pyrazinamide. There are only limited data on other activities of capreomycin and viomycin. *Adapted from Grange JM, Zumla A. Antituberculosis agents. In Cohen J, Powderly WG (eds). Infectious Diseases. London: Mosby, 2003. With permission from Elsevier..*

Treatment

Treatment of the cutaneous forms of TB is the same as that for systemic TB (Table 75.7 & Fig. 75.21). Administration of appropriate therapy not only provides a direct benefit to individuals with active or latent infection (the latter via a 9-month course of isoniazid to prevent disease) but also prevents bacterial resistance and reduces transmission of *M. tuberculosis*[52,56]. In addition to the increase in *multidrug-resistant TB* that accompanied the resurgence of this disease in the late 1980s and early 1990s, *extensively drug-resistant TB* strains that are even more difficult to treat have also emerged in all regions of the world (Table 75.8). The current CDC-recommended regimens for tuberculosis therapy are outlined in Table 75.9[65]. In addition to "repurposing" existing antibiotics (e.g. quinolones, amoxicillin with clavulanate, linezolid, clarithromycin) for use in patients with extensively drug-resistant TB, novel drugs currently being investigated in clinical trials include nitroimidazole/nitroimidazopyran agents (OPC-67863 and PA-824; inhibit synthesis of proteins and cell wall lipids), a

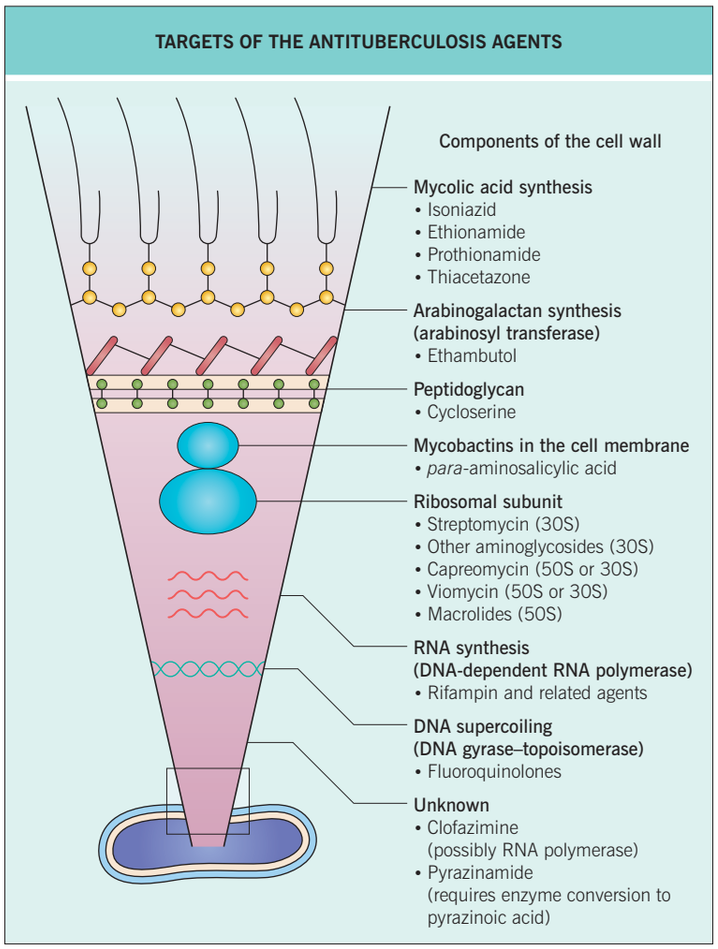

Fig. 75.21 Targets of the antituberculous agents. *Adapted from Grange JM, Zumla A. Antituberculous agents. In: Cohen J, Powderly WG (eds). Infectious Diseases. London: Mosby, 2003. With permission from Elsevier..*

MULTIDRUG-RESISTANT AND EXTENSIVELY DRUG-RESISTANT TUBERCULOSIS
MULTIDRUG-RESISTANT TUBERCULOSIS (MDR-TB)
• Resistant to isoniazid and rifampin, the two most effective first-line drugs • Estimated to account for 4% of all new TB cases worldwide in 2009
EXTENSIVELY DRUG-RESISTANT TUBERCULOSIS (XDR-TB)
• Resistant to isoniazid and rifampin • Resistant to quinolones, the most effective second-line drugs • Resistant to at least one of three injectable second-line drugs: amikacin, kanamycin or capreomycin • Estimated to account for 5% to 10% of cases of MDR-TB

Table 75.8 Multidrug-resistant and extensively drug-resistant tuberculosis.

diarylquinoline (TMC207; targets ATP synthase), an oxazolidinone (AZD5847; inhibits protein synthesis), and an ethambutol analogue (SQ109; thought to inhibit cell wall biosynthesis and have synergistic effects with other agents)[66–68]. With regard to vaccines, sequential administration of BCG and a recombinant modified vaccinia virus Ankara (MVA) expressing antigen 85A can induce robust antimycobacterial immunity[69].

Although the production of nitric oxide by macrophages is known to help control infection by *M. tuberculosis*, the organisms can persist within these cells. Proper function of the mycobacterial proteosome appears to play an important defensive role, and, in the future, inhibition of proteosome function could provide a novel therapeutic approach[70].

NON-TUBERCULOUS MYCOBACTERIOSES

Synonyms: ■ Atypical mycobacterioses ■ Mycobacteria other than tuberculosis (MOTT) ■ Environmental mycobacterioses ■ Anonymous mycobacterioses ■ Opportunistic mycobacterioses

Key features

- Over a dozen species of mycobacteria, found in the natural environment and transmitted via inoculation into the skin, can produce cutaneous disease
- Clinical presentations include pustules, keratotic plaques and nodules (with or without suppuration), a sporotrichoid (lymphocutaneous) pattern, and ulcers with draining sinuses
- Disseminated infections usually occur in immunocompromised hosts
- Although suggested by a history of exposure, the diagnosis rests on isolation or identification of the responsible organism

Introduction

Non-tuberculous ("atypical") mycobacteria were first isolated in 1931 by Pinners, who also discovered that these organisms were different from *M. tuberculosis* – they were not virulent in the guinea pig model, and they responded poorly to antituberculous therapy[71]. Their importance as human pathogens, however, was not appreciated until the 1950s[72].

These environmental mycobacteria are found in water, wet soil, house dust, dairy products, cold-blooded animals, vegetation and human feces. Non-tuberculous mycobacterioses are transmitted by inhalation, ingestion or percutaneous penetration, which can result in pulmonary, lymph node or skin disease[6,71]. The type of disease depends on the species of mycobacteria, the route and degree of exposure, and the immune status of the host[1].

Recognition of non-tuberculous mycobacterial infections is important given the increasing incidence in immunosuppressed as well as normal hosts[53,73–75]. For example, in high-income countries, disseminated non-tuberculous mycobacteriosis is one of the most common systemic bacterial opportunistic infections in AIDS patients[4,53]. Cutaneous (and systemic) non-tuberculous mycobacterial infections are frequently misdiagnosed because of their nonspecific or sometimes subtle clinical presentations, especially in patients who are immunosuppressed, combined with inadequate biopsy and culture techniques[71]. These infections should be suspected in patients with indolent ulcers, nodules or plaques, especially in the setting of immunosuppression. Therapy varies depending on the causative organism (Table 75.10)[71,76–83]; however, initial empiric treatment with clarithromycin can be considered while waiting for culture and sensitivity results in patients with clinical presentations suggestive of a cutaneous non-tuberculous mycobacterial infection[84].

In 1954, Runyon proposed the first classification system for non-tuberculous mycobacteria based upon rate of growth *in vitro* and pigment production following exposure to light (see Table 75.1). Given advances in identification (including genomic analysis), more than 100 species of mycobacteria are now recognized. Selected non-tuberculous mycobacteria of dermatologic interest will be discussed in this chapter.

Mycobacterium ulcerans

Synonyms: ■ Buruli ulcer ■ Bairnsdale ulcer ■ Searle's ulcer

Introduction and history

M. ulcerans is a slow-growing, acid-fast bacillus that characteristically infects the skin and subcutaneous tissues, producing indolent ulcers. Worldwide, after leprosy and tuberculosis, Buruli ulcer is the third most common mycobacteriosis in immunocompetent hosts[76]. The initial description of patients with huge cutaneous ulcers was made by Cook

DRUG REGIMENS FOR CULTURE-POSITIVE PULMONARY TUBERCULOSIS CAUSED BY DRUG-SUSCEPTIBLE ORGANISMS

Initial phase			Continuation phase			Range of total doses (minimal duration)	Rating‡ (evidence)§	
Regimen	Drugs	Interval and doses* (minimal duration)	Regimen	Drugs	Interval and doses*,† (minimal duration)		HIV⁻	HIV⁺
1	INH RIF	7 days per week for 56 doses (8 wk) or 5 days per week for 40 doses (8 wk)¶	1a	INH/RIF	7 days per week for 126 doses (18 wk) or 5 days per week for 90 doses (18 wk)¶	182–130 (26 wk)	A (I)	A (II)
	PZA		1b	INH/RIF	Twice weekly for 36 doses (18 wk)	92–76 (26 wk)	A (I)	A (II)**
	EMB		1c††	INH/RPT	Once weekly for 18 doses (18 wk)	74–58 (26 wk)	B (I)	E (I)
2	INH RIF PZA EMB	7 days per week for 14 doses (2 wk), then twice weekly for 12 doses (6 wk), or 5 days per week for 10 doses (2 wk)¶, then twice weekly for 12 doses (6 wk)	2a	INH/RIF	Twice weekly for 36 doses (18 wk)	62–58 (26 wk)	A (II)	B (II)**
			2b††	INH/RPT	Once weekly for 18 doses (18 wk)	44–40 (26 wk)	B (I)	E (I)
3	INH RIF PZA EMB	Three times weekly for 24 doses (8 wk)	3a	INH/RIF	Three times weekly for 54 doses (18 wk)	78 (26 wk)	B (I)	B (II)
4	INH RIF EMB	7 days per week for 56 doses (8 wk) or 5 days per week for 40 doses (8 wk)¶	4a	INH/RIF	7 days per week for 217 doses (31 wk) or 5 days per week for 155 doses (31 wk)¶	273–195 (39 wk)	C (I)	C (II)
			4b	INH/RIF	Twice weekly for 62 doses (31 wk)	118–102 (39 wk)	C (I)	C (II)

*When DOT is used, drugs may be given 5 days/week and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.

†Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive an 8-month (31-week; either 217 doses [daily] or 62 doses [twice weekly]) continuation phase.

‡Definitions of evidence ratings: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given; E = should never be given.

§Definitions of evidence ratings: I = randomized clinical trial; II = data from clinical trials that were not randomized or were conducted in other populations; III = expert opinion.

¶Five-day-a-week administration is always given by DOT. Rating for 5 day/week regimens is A(III).

**Not recommended for HIV-infected patients with $CD4^+$ cell counts <100 cells/mcl.

††Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph. For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

Table 75.9 Drug regimens for culture-positive pulmonary tuberculosis caused by drug-susceptible organisms. Among patients with extrapulmonary tuberculosis, regimen 1 is recommended as initial therapy unless the organisms are known or strongly suspected of being resistant to the first-line drugs. If PZA cannot be used in the initial phase (i.e. regimen 4), the continuation phase must be increased to 7 months. Doses of medications (maximum dose) when given *daily*: INH, isoniazid 5 mg/kg (300 mg); RIF, rifampin 10 mg/kg (600 mg); PZA, pyrazinamide 25 mg/kg (2000 mg); EMB, ethambutol 18 mg/kg (1600 mg); RPT, rifapentine, which is given once weekly at 10 mg/kg. DOT, Directly Observed Therapy. From ref. 65.

in 1897 in Uganda (Buruli is a county in Uganda). It was not until the late 1940s, in Australia, that the agent was isolated and characterized by MacCallum and colleagues[1,76].

Epidemiology

M. ulcerans infections have been reported in more than 30 countries around the world. The primary endemic foci are wetlands in tropical or subtropical countries[76]; although the exact mode of transmission is not known, exposure to water from rivers or ponds (or even exposure to mud) is thought to play a role. The organism is harbored by snails, fish and water insects, and it can be isolated from aquatic plants. In Australia, koalas and opossums are naturally infected.

Agricultural activities and consequent deforestation have contributed to recent increases in the incidence of *M. ulcerans* infections, especially in West Africa. Focal outbreaks have followed floods and human migrations. The countries most affected are in Central Africa (e.g. Uganda, the Democratic Republic of Congo) and West Africa (e.g. the Ivory Coast, Ghana, Benin). Some Southeast Asian countries and Australia have major foci of infection, and there have been a few reports from South America and Mexico[72,76].

The disease is rarely transmitted from patient to patient, and the agent is typically introduced into the skin by minor trauma. Children under 15 years of age are more commonly affected, but the infection can occur in all age groups[72,76].

Pathogenesis

After inoculation into the skin, the *M. ulcerans* organisms proliferate and form abundant clumps of extracellular acid-fast bacilli. The organisms are found at the base of the ulcer and within adjacent necrotic subcutaneous tissue as well as in surrounding normal-appearing skin. The extracellular location of the mycobacteria (i.e. lack of phagocytosis) and the unique pathology (cell death) are thought to be a reflection of a plasmid-encoded immunomodulatory macrolide toxin, mycolactone[85]. Numerous disseminated lesions may cause systemic toxic effects[76]. HIV-infected individuals do not appear to be predisposed to this infection.

Clinical features

The initial lesion is usually a single, asymptomatic, firm, non-tender, mobile subcutaneous nodule that measures 1 to 2 cm in diameter. After 1 or 2 months, the nodule becomes fluctuant and ulcerates. The resultant painless ulcer has a deep necrotic base with undermined edges, and it often expands to 15 cm or more in diameter. The vast majority of lesions are on the extremities (lower > upper). There is little or no regional lymphadenopathy or systemic manifestations. Edema can develop in adjacent tissues. Without treatment, ulcers may remain small and heal as depressed scars, or they may spread rapidly over large areas of skin (even an entire limb), causing extensive scarring and

TREATMENT OF NON-TUBERCULOUS ("ATYPICAL") MYCOBACTERIAL INFECTIONS		
Agent	**Local**	**Systemic medications: alone or combined**
M. ulcerans	For ulcers, surgical excision; local heat (40°C); hyperbaric oxygen	For early lesions (nodules, plaques), rifampin plus streptomycin (or rifampin plus clarithromycin) for at least 4 weeks*; nitrogen oxide-releasing topical creams
M. marinum		Clarithromycin, minocycline > doxycycline†, rifampin, ethambutol, trimethoprim–sulfamethoxazole; two agents for serious infections (e.g. clarithromycin + rifampin or ethambutol)
M. kansasii		Isoniazid (or clarithromycin) + rifampin + ethambutol ± pyridoxine; other options (depending on susceptibilities) include azithromycin, moxifloxacin, streptomycin and sulfamethoxazole
M. fortuitum	Surgical excision	Ciprofloxacin, ofloxacin, clarithromycin‡, trimethoprim–sulfamethoxazole, minocycline, doxycycline; at least two agents for serious infections
M. chelonae	Surgical excision	Clarithromycin; for severe infections, combine clarithromycin with linezolid, imipenem, tobramycin, amikacin, doxycycline and/or ciprofloxacin (often resistant to latter two agents)
M. abscessus	Surgical excision	Clarithromycin or azithromycin + (for serious infections) amikacin, cefoxitin or imipenem
M. avium complex		Clarithromycin or azithromycin + ethambutol ± rifampin or rifabutin
M. haemophilum	Surgical excision	Clarithromycin + rifampin ± ciprofloxacin or amikacin
M. scrofulaceum	Surgical excision	Isoniazid + rifampin, clarithromycin

*WHO recommends 8 weeks[81].
†Resistance to tetracyclines has been reported.
‡Often have inducible resistance to macrolides.

Table 75.10 Treatment of non-tuberculous ("atypical") mycobacterial infections[71,72,76–83]. Therapy for 3 to 6 months or more is often required. If clinical suspicion is high for a non-tuberculous mycobacterial infection, empiric treatment with clarithromycin can be considered while waiting for culture and sensitivity results.

deformity. Structures such as the eye, breast or genitalia are sometimes lost or severely damaged. Underlying bone can become involved, and progressive osteomyelitis may require amputation[72,76].

Pathology

Histologically, granulomatous inflammation may be seen in association with substantial necrosis, predominantly in the subcutaneous fat[1,72]. There is also contiguous coagulation necrosis of the deep dermis and destruction of nerves, appendages and blood vessels. Interstitial edema is noted. In active lesions, inflammatory cells are few in number, presumably as a result of the immunosuppressive activity of the toxin. With healing, there is a granulomatous response. Many acid-fast bacilli can be seen in characteristic clumps, particularly in the center of the lesion[72,76].

Diagnosis and differential diagnosis

Clumps of acid-fast bacilli may be seen in Ziehl-Neelsen-stained smears from the necrotic base of an ulcer or a similarly stained biopsy specimen (e.g. of the necrotic tissue at the ulcer base or undermined edge and in the subcutis). *M. ulcerans* can be cultured, but visible growth often requires 6 to 8 weeks of incubation at 32°C. Molecular techniques such as PCR prove useful in establishing the diagnosis, especially when culture and histopathology are negative[72,76]. In one series of 70 patients with Buruli ulcers, a modified PCR assay had a sensitivity of 98%, while the sensitivities of direct smear, culture and histology were 42%, 49% and 82%, respectively[86].

The differential diagnosis depends upon the stage of disease. During the initial phase, when a subcutaneous nodule is present, *M. ulcerans* infection must be differentiated from other forms of panniculitis (infectious and non-infectious; see Ch. 100), cysts, nodular fasciitis, a foreign body granuloma and other granulomatous diseases. During the ulcerative phase, considerations may include fungal infections, pyoderma gangrenosum, suppurative panniculitis and other causes of ulcers (see Ch. 105)[1].

Treatment

Surgical excision is the treatment of choice for ulcers (see Table 75.10). This is obviously easier to accomplish when the ulcers are small, and large ulcers often require skin grafts[1,72]. Continuous local heating to 40°C by circulating water jackets promotes healing, even without excision[61]. Hyperbaric oxygen can also be useful[1,3], but drug therapy for ulcers is often disappointing[3]. Unfortunately, amputation of limbs is sometimes necessary[72].

A trial of oral rifampin (10 mg/kg) plus intramuscular streptomycin (15 mg/kg) daily for at least 4 weeks may convert early lesions (nodules, plaques) from culture-positive to culture-negative (see Table 75.10). Recent studies in a mouse model suggest that treatment with an oral regimen of clarithromycin plus rifampin or rifapentine has similar efficacy[87]. Physical therapy is important when the patient is at risk for contractures. There is no effective prophylaxis, but vaccination with BCG may lead to limited, relatively short-lived protection[76].

Mycobacterium marinum

Synonyms: ■ Fish tank granuloma ■ Swimming pool granuloma ■ Infection by *M. balnei*

Introduction and history

M. marinum is a free-living organism that causes disease in freshwater and saltwater fish and sporadically in humans. The latter results from exposure to contaminated water when there are breaks in the skin barrier[78]. *M. marinum* was first isolated from saltwater fish in the Philadelphia Aquarium in 1926 by Aronso[1,3]. The first report of human disease was in 1951, when the agent was found in granulomatous skin lesions of individuals who swam in a contaminated swimming pool[3].

Epidemiology and pathogenesis

M. marinum is found in aquatic environments, including fresh, salt and brackish water. When cleaning fish tanks at home or in the workplace (e.g. restaurants, fish markets), trauma to the hands may result in exposure to *M. marinum*. The infection can also affect swimming pool bathers, as this organism seems to be rather resistant to chlorine[1].

Cutaneous infection with *M. marinum* requires a portal of entry, e.g. abraded or traumatized skin[1]. The incubation period is typically 2 to 3 weeks, but it can range from 1 week to 2 months[1]. In several case series of skin infections with non-tuberculous mycobacteria, *M. marinum* was the most common species identified[83].

Clinical features

The initial lesion is a single bluish-red inflammatory nodule or pustule at the site of inoculation, which is often on an upper extremity (Fig. 75.22A). It then forms a crusted ulcer, suppurative abscess or verrucous nodule[1,3]. Multiple lesions can develop along the course of the draining lymphatics, i.e. sporotrichoid (lymphocutaneous) spread (Fig. 75.22B; see Table 77.15). Among the non-tuberculous mycobacterioses, *M. marinum* is the most common etiology of this pattern. Occasionally, deeper infections are complicated by tenosynovitis, septic arthritis or, rarely, osteomyelitis. As with other non-tuberculous mycobacterioses, disseminated lesions can occur in immunocompromised hosts (Fig. 75.22C).

Fig. 75.22 ***Mycobacterium marinum*** **infections.** A range of presentations, including an erythematous plaque with scale-crust at the inoculation site on the lateral hand (**A**), a sporotrichoid pattern with the inoculation site on the distal third finger (**B**), and disseminated necrotic lesions on the face of an immunocompromised patient (**C**).

Pathology

The histologic features, as in other mycobacterial infections, range from acute and chronic inflammation to well-formed tuberculoid granulomas. Fibrinoid changes and caseation necrosis can occur[3]. In immunocompetent individuals, organisms are often difficult to find.

Diagnosis and differential diagnosis

The clinical features combined with a history of trauma in a wet environment or exposure to fish tanks suggests the possibility of *M. marinum* infection. The diagnosis is confirmed by culture, which is positive in 70% to 80% of cases[78]. When this infection is suspected, the laboratory should be notified in advance and care must be taken to provide proper culture conditions. *M. marinum* grows best at 31°C, in contrast to the optimal incubation temperature of 37°C for many other mycobacteria[78]; growth becomes evident after a mean of approximately 3 weeks, and identification of the species and its antimicrobial susceptibility pattern often requires 2 months[83]. PCR for detection of a 65 kDa heat shock protein gene can also be performed.

Infection due to *M. marinum* should be differentiated from sporotrichosis and the entities outlined in Table 77.15 as well as tuberculosis verrucosa cutis. It is not associated with marked regional lymphadenitis.

Treatment

M. marinum is usually sensitive to the antimicrobial drugs listed in Table 75.10[71]; however, sensitivity testing should always be requested as part of the laboratory evaluation[78]. Based on usual *in vitro* susceptibility patterns and clinical responsiveness, initial empiric treatment with clarithromycin (pending culture and sensitivity results) has been recommended when there is suspicion of an *M. marinum* infection[83].

Mycobacterium kansasii

Introduction and history

M. kansasii is a mycobacterium that is closely related antigenically to *M. tuberculosis.* There is evidence that an infection with this organism provides increased immunity against tuberculosis[72].

M. kansasii was first reported in 1953 as the "yellow bacillus". This characteristic pigmentation is due to the deposition of β-carotene crystals after exposure to light[1].

Epidemiology and pathogenesis

This organism is found throughout the world, but it is more prevalent in temperate zones such as in the US, UK, northern France and Belgium. It has been isolated from cattle and swine, but the natural reservoir may be water. Middle-class, middle-aged, white men of urban origin are most commonly affected[3,72].

The lung is the major site of infection with *M. kansasii,* and the diagnosis of pulmonary disease rests on examination and culture of sputum[3]. Cutaneous infection is usually acquired via minor trauma such as puncture wounds[62].

Clinical features

Verrucous plaques, ulcers and nodules are observed, and the lesions may be arranged in a lymphocutaneous (sporotrichoid) pattern. The majority of patients with cutaneous involvement have some alteration in immune status[1,3,72]. Papulonecrotic lesions and cellulitis are less common presentations[3]. Iijima and Sasaky[88] divided cutaneous mycobacteriosis due to *M. kansasii* into three types: (1) chronic granulomatous; (2) primary cutaneous pyogenic; and (3) disseminated acute pyogenic, which occurs primarily in immunocompromised individuals.

Pathology

Histologic features are as variable as the clinical presentations. Typical tuberculoid granulomas may be seen, or a dense neutrophilic infiltrate may be evident, with or without abscess formation and epidermal necrosis[72]. In some patients, the findings are indistinguishable from those of *M. tuberculosis* infection[1].

Diagnosis and differential diagnosis

M. kansasii can be isolated from lesional skin biopsy specimens, and the laboratory should be advised to provide appropriate culture conditions to detect slow-growing mycobacteria[1,72]. The rarity of diagnosis of primary cutaneous *M. kansasii* infections may be a reflection of the failure to grow the organisms in culture as well as difficulties in phenotyping. PCR analysis may circumvent these potential problems[89].

Table 75.5 and the *M. ulcerans* section above outline the differential diagnosis of verrucous plaques and ulcers, respectively. Sporotrichosis and other non-tuberculous mycobacterial infections need to be considered when there is a sporotrichoid pattern (see Table 77.15). A combination of histologic examination, special stains, and culture for bacteria and fungi usually distinguishes these entities.

Treatment

A combination of antituberculous medications must be used, especially when the infection is disseminated[3,72]. Resistance may occur, and although different drug regimens have been recommended (see Table 75.10), sensitivity testing should be performed to optimize therapy[1,3,72].

Fig. 75.23 Suppurative lymphadenitis due to *Mycobacterium fortuitum* infection. The inoculation chancre was on the foot. From ref. 90. *Courtesy, Rubem Azulay, MD.*

Mycobacterium fortuitum, Mycobacterium chelonae and *Mycobacterium abscessus*

Synonyms: ▪ *M. chelonei* = *M. chelonae* ▪ Turtle tubercle bacillus

Introduction and history

These three organisms are often grouped together as the fortuitum complex[71]. Although they can be distinguished on the basis of DNA and serologic analyses, they result in infections with similar clinical features[3].

In 1903, Friedmann[57] isolated *M. chelonae*. Two subspecies (*chelonae* and *abscessus*) were initially identified, but *M. abscessus* was reclassified as a separate species in 1992[1]. *M. chelonae* was once used in an attempt to develop a vaccine as immunotherapy for *M. tuberculosis* infections[71]. In 1905, Küster described *M. fortuitum* as a frog pathogen, and for this reason it was originally named *M. ranae*. Costa-Cruz used the name *M. fortuitum* in 1938 for what he believed to be a new species isolated from a skin abscess that occurred after an injection[1,90].

Epidemiology and pathogenesis

The organisms exist as saprophytes, and they are found in water, soil, dust and animals. Cutaneous infections are uncommon, and immunocompromised patients are more susceptible to severe disease caused by these species of mycobacteria[71,91].

Infections typically occur following trauma, surgery or other procedures, including contact with contaminated medical instruments (e.g. liposuction, mesotherapy), placement of implants (e.g. prosthetic breast implants) and tattooing[74,75,92]. A post-injection abscess is another frequent presentation[3], e.g. after acupuncture or botulinum toxin injection. Furunculosis of the lower extremities has also been observed following footbaths in nail salon customers[73]. Less often, cutaneous infection is the result of dissemination from an endogenous source[71].

Clinical features

This group of mycobacteria can produce a variety of clinical diseases, including non-cavitary pneumonia, keratitis, endocarditis, lymphadenitis, osteomyelitis and skin infections (Fig. 75.23). The cutaneous manifestations range from cellulitis (Fig. 75.24), abscesses and papulopustules to sinuses and ulcers with extensive subcutaneous necrosis and serosanguineous or purulent discharge[71]. However, the most common presentation is multiple erythematous subcutaneous nodules, frequently occurring on the distal limbs or in a sporotrichoid pattern[3,90,91].

Pathology

The presence of both neutrophilic microabscesses and granuloma formation with foreign body-type giant cells is characteristic[1]. Necrosis may occur[3].

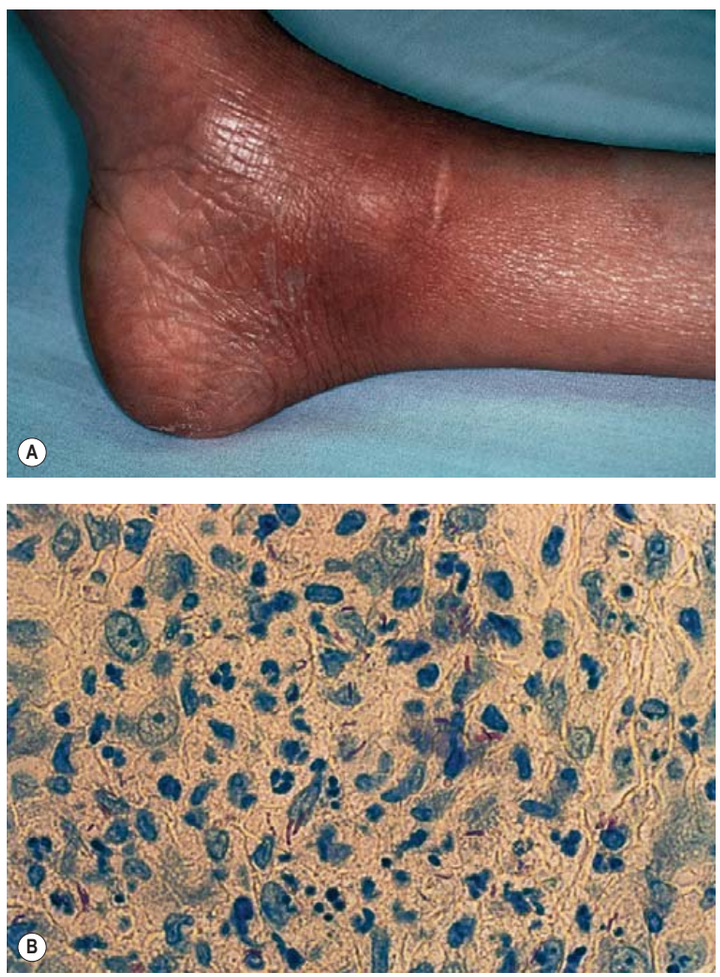

Fig. 75.24 *Mycobacterium chelonae* infection. This immunosuppressed patient presented with an area of warmth and mild erythema on the ankle (**A**). Acid-fast bacilli (stained red) in a biopsy specimen (**B**).

Diagnosis and differential diagnosis

Culture of biopsy material must be performed. When an abscess is present, a biopsy specimen that includes the wall is preferred, rather than aspiration of pus. The organisms grow on routine bacterial culture media, such as 5% sheep blood agar or chocolate agar, within 7 days. In addition, PCR detection of the 16S–23S rRNA gene internal transcribed spacer sequences can be performed.

The disease should be considered in patients with therapy-resistant or "cold" abscesses. It can also be confused with foreign body reactions, subcutaneous mycoses or osteomyelitis[3].

Treatment

Treatment is dependent on the type and extent of the lesions[1]. These organisms are resistant to antituberculous drugs, but, to date, nearly all *M. chelonae* and 80% of *M. fortuitum* isolates have been sensitive to clarithromycin. Excision and debridement may be required for abscesses and ulcers. Recommended antibiotics, prescribed either alone or in combination, are listed in Table 75.10[3,71,77]; prolonged courses may be required.

Mycobacterium avium complex

Synonyms: ■ *M. avium* ■ *M. avium intracellulare* (MAI) ■ *M. intracellulare*

Introduction

M. avium (the avian tubercle bacillus) and *M. intracellulare* are closely related and difficult to differentiate, so it is common to refer to them as *M. avium* complex (MAC) or *M. avium intracellulare* (MAI)[3,71].

MAC is a facultative mycobacterium that only occasionally produced human disease before the AIDS epidemic[1,3]. The incidence of infection then increased sharply, and MAC became one of the most common causes of opportunistic bacterial infections in patients with AIDS[3,71]. The infection often occurs during the terminal stage of AIDS and causes disseminated disease in 15–40% of such patients[71].

Epidemiology and pathogenesis

The organism is found in the environment, including fresh and salt water, soil, dairy products and domestic animals[3,71]. It may be transmitted via inhalation into the lungs, or via water and food into the gastrointestinal tract, without person-to-person transmission[1]. As many as 30% of samples of normal human feces yield isolates of MAC[1,3].

Chronic pulmonary infection is the most common clinical manifestation of MAC infection in those who are not co-infected with HIV, followed in frequency by cervical and inguinal lymphadenitis and osteomyelitis. Lymphadenitis is seen more often in children. Cutaneous lesions may be primary after a traumatic inoculation, which is rare, or secondary to a disseminated infection in an immunocompromised host[3,71].

Clinical features

In patients with AIDS, there is often disseminated disease. It is characterized by nonspecific symptoms such as fever, night sweats, weight loss, bone pain, hepatosplenomegaly and lymphadenopathy. Serum alkaline phosphatase levels may be elevated[1]. Skin involvement is unusual and most often presents with papulopustules and multiple purulent leg ulcers[1]. Nodules with abscess formation (Fig. 75.25), panniculitis, sinus tracts, folliculitis and granulomatous plaques may also be seen[3,71]. A papulonecrotic tuberculid-like eruption due to disseminated MAC has been reported in patients with AIDS[71].

Pathology

Macrophages contain large numbers of bacilli without necrosis, and spindle cell transformation of macrophages, forming a histoid-like lesion (as in leprosy) can occur[40]. The histologic features resemble those of lepromatous leprosy (see above).

Diagnosis and differential diagnosis

In disseminated disease, the diagnosis is often established by culture of the blood or specimens from bone marrow or liver biopsies[3]. Depending on the site(s) of involvement, cultures can also be performed on sputum or biopsies of skin and lymph nodes[78]; PCR analysis is also available.

The differential diagnosis includes pyoderma, folliculitis, other causes of panniculitis and ulcers, dimorphic fungal infections, lepromatous leprosy and cutaneous tuberculosis.

Fig. 75.25 ***Mycobacterium avium*** **complex cellulitis in an immunocompromised patient.** Note the sporotrichoid (lymphocutaneous) pattern of the coalescing nodules with abscess formation.

Treatment

Table 75.10 provides a list of the medications that have been used alone or in combination[1,3] to treat MAC infections. In immunocompromised patients with disseminated infection, antimicrobial therapy should be given for life[3].

Mycobacterium haemophilum

Introduction

M. haemophilum is a short, slightly curved rod that occurs singly or in a cord-like arrangement. It is a fastidious organism that requires ferric ions to grow, provided as hemin, hematin, hemoglobin or ferric ammonium citrate. In initial studies, growth was only observed with the addition of hemolyzed sheep erythrocytes; as a consequence, the organism was given the name *M. haemophilum*[72,79].

Epidemiology and pathogenesis

M. haemophilum infection occurs primarily in immunocompromised hosts. To date, more than half of the reported cases have occurred in patients with AIDS, but it can also be seen in other immunosuppressed patients, e.g. organ transplant recipients. However, this organism can also cause cervical lymphadenitis in healthy children. The majority of affected individuals are from cities located near the ocean, the Mediterranean Sea, or the Great Lakes of North America[72,79]. The natural habitat of *M. haemophilum* and the route of infection have not yet been identified[72,79].

Clinical features

This bacillus can produce several different types of cutaneous lesions[72]. Immunosuppressed adults most often present with a single bluish-red tender pustule, papulonodule or plaque, which evolves into an abscess and/or ulcer[72,79]. Lesions may also be multiple and are usually located on the extremities, often overlying joints. In addition, *M. haemophilum* can cause contiguous septic arthritis, osteomyelitis and pneumonia. Immunocompetent children infected by this organism frequently have isolated cervical, submandibular or perihilar lymphadenitis[79].

Pathology

Suppurative and granulomatous inflammation is seen, sometimes with well-formed tuberculoid granulomas, Langhans giant cells, necrosis (with or without caseation) and large numbers of acid-fast bacilli. The bacilli can be found aggregated in globi, resembling those seen in lepromatous leprosy[72,79].

Diagnosis and differential diagnosis

The diagnosis is established by culture of the bacillus from tissue or synovial fluid; in some patients, blood cultures are positive. However, this organism requires a special environment to grow, with a source of iron and a temperature between 30°C and 32°C[72,79]. Due to these stringent requirements, it may not be isolated using routine techniques[1]; PCR analysis is also available.

In immunocompetent children with cervical or submandibular lymphadenitis, the possibility of MAC infection should be considered[79], along with the more common causes of lymphadenitis (e.g. EBV, CMV). The differential diagnosis of the cutaneous lesions is similar to that for the other non-tuberculous mycobacterioses (see *M. avium* and *M. fortuitum)*.

Treatment

M. haemophilum is often resistant to antituberculous drugs, except for the rifamycins, such as rifampin and rifabutin. The combination of rifampin and clarithromycin (±amikacin) has been used successfully (see Table 75.10). The duration of therapy must be at least 6 to 9 months and even longer in immunosuppressed patients. Surgical excision is also an option when the disease is localized, e.g. adenitis in an immunocompetent child[72,79].

Mycobacterium scrofulaceum

Introduction

M. scrofulaceum was formerly grouped with MAC in a complex called MAIS (*M. avium-intracellulare-scrofulaceum*), but they were separated due to the different clinical manifestations. *M. scrofulaceum* produces self-limited disease, particularly lymphadenitis, while MAC typically causes chronic lung disease and, less often, osteomyelitis. *M. scrofulaceum* may also cause cervical lymphadenitis with sinus formation clinically indistinguishable from scrofuloderma[62].

Epidemiology and pathogenesis

This organism is most prevalent in the southeastern US. It is widely distributed and has been isolated from raw milk, other dairy products, pooled oysters, soil and water[79]. Bacilli can be found in environments with a warm temperature, low pH and dissolved oxygen, and high soluble zinc, humic acid and fulvic acid. It has also been found on the skin of healthy people and in cutaneous lesions of leprosy[80].

In general, infection by *M. scrofulaceum* affects children and seems to occur via inhalation or ingestion. Focal infection resulting from contamination during surgical procedures involving lymph nodes may also occur. Cutaneous disease in a campground worker with corticosteroid-treated systemic lupus erythematosus and no history of preceding trauma has been reported. It was suggested that the lesions resulted from a subclinical bacteremia[79,80].

Clinical features

M. scrofulaceum may cause pulmonary disease and local lymphadenitis, primarily in the submandibular and submaxillary regions. It is usually a benign self-limited disease with no systemic symptoms except for mild neck pain. The involved lymph nodes slowly enlarge over several weeks, and eventually ulceration and drainage occur with fistula formation. This organism can also produce skin lesions in a sporotrichoid pattern, but it rarely causes disseminated infection[79]. Primary cutaneous disease due to inoculation of *M. scrofulaceum* is unusual[79].

Pathology

In the lymph nodes, widespread abscess formation is the typical finding; histiocytes and granulomas may be inconspicuous. It may be difficult to differentiate *M. scrofulaceum* lymphadenitis from that due to *M. tuberculosis*[62] when there are tuberculoid granulomas with central necrosis and abscess formation. The bacilli are found within involved lymph nodes[79]. In the skin, abscess formation is typically seen.

Diagnosis and differential diagnosis

In addition to histologic examination, culture of sputum, skin or involved lymph nodes helps to confirm the diagnosis. The infection should be distinguished from other causes of cervical lymphadenopathy (see *M. haemophilum*), particularly infection with *M. tuberculosis*[79]. However, *M. tuberculosis* usually affects tonsillar and anterior cervical nodes, while *M. scrofulaceum* typically affects submandibular and submaxillary nodes. When lesions have a sporotrichoid pattern, *M. marinum* infections and other non-tuberculous mycobacterioses should be considered (see Table 77.15)[80].

Treatment

The treatment of choice is total excision of the involved lymph nodes[62,79] because, in general, antibiotic therapy is unsatisfactory. However, promising results have been reported with isoniazid plus rifampin[80]. Successful treatment with clarithromycin has also been described (see Table 75.10)[79].

Rickettsial Diseases 76

David H Walker

Chapter Contents

Spotted fever and typhus group rickettsial infections *1243*
Scrub typhus *1248*
Human ehrlichioses *1249*
Human granulocytotropic anaplasmosis *1250*
Q fever *1250*

Key features

- Rickettsiae are small, obligately intracellular, Gram-negative bacteria
- Rickettsiae reside in an arthropod host (tick, flea, louse or mite) during part of their life cycle
- The arthropod vector transmits the rickettsiae in its saliva or feces during feeding
- The major vertebrate target cells of *Rickettsia* (endothelium), *Orientia* (endothelium), *Ehrlichia* (monocytes or neutrophils), *Anaplasma* (neutrophils) and *Coxiella* (macrophages) determine to a large degree the pathogenesis of the disease
- In most spotted fever rickettsioses and scrub typhus, an eschar at the site of the vector's inoculation of organisms is an important physical sign
- A rash is the diagnostically critical clinical manifestation of Rocky Mountain spotted fever, other spotted fevers, murine typhus and louse-borne typhus
- One of the most common rickettsial diseases in travelers is African tick bite fever, which is seen in those who have been on safari or bush walking in southern Africa

INTRODUCTION

Members of the order Rickettsiales are small, obligately intracellular, Gram-negative bacteria that reside in an arthropod host for at least part of their life cycle[1]. At least 19 bacterial species belonging to four genera (*Rickettsia, Orientia, Ehrlichia* and *Anaplasma*) in this order and the related *Coxiella* genus in the order Legionellales are known agents of human diseases (Table 76.1). Cutaneous manifestations vary from nearly always present in some spotted fevers and typhus to rare in others, such as human granulocytotropic anaplasmosis and Q fever (Table 76.2). Clinical recognition of a rash is frequently the event that leads to appropriate antimicrobial treatment for life-threatening Rocky Mountain spotted fever (RMSF) and other rickettsioses.

SPOTTED FEVER AND TYPHUS GROUP RICKETTSIAL INFECTIONS

History

Epidemic typhus was described by Fracastorius in Italy in 1546; RMSF, by Maxey in Idaho in 1899; and boutonneuse fever, by Conor in Tunisia in 1910. At least ten of the diseases in this group and/or their etiologic agents were described or discovered in the last two decades. A rickettsial agent was first identified in 1906 in the Bitterroot Valley of western Montana by Howard Ricketts, who also recognized its transmission by feeding ticks. In 1916, S. Burt Wolbach visualized this agent, subsequently named *Rickettsia rickettsii*, within endothelial cells. Charles Nicolle discovered in 1909 that lice transmitted epidemic typhus, and over the next few years this disease was found to be caused by another rickettsial organism, *Rickettsia prowazekii*. Epidemic louse-borne typhus influenced the outcome of most European wars after 1500, including Napoleon's failed Russian invasion in 1812 and World War I, during and after which typhus affected 25 million persons and caused 3 million deaths in Russia. In 1934, recrudescent typhus (Brill–Zinsser disease) was determined to be caused by reactivation of latent *R. prowazekii* infection. Endemic or murine typhus was shown during the 1930s to have a rat reservoir and flea vector.

Epidemiology

Spotted fever group rickettsiae are maintained in nature principally via transmission of the bacteria in infected ova from one generation of tick, mite or flea to the next (see Table 76.1). During feeding, infected ticks instill saliva containing rickettsiae into their host's skin. Thus, the seasonal and geographic distribution of particular diseases (Fig. 76.2) depends upon the range and the host-seeking activity of the particular vector tick, mite or flea. For example, RMSF usually occurs during tick season (from late spring until the end of summer).

Typhus group rickettsiae are deposited on the host's skin in the feces of feeding human body lice (*R. prowazekii*) or fleas (*R. typhi*). The organisms are subsequently scratched into the skin, rubbed into mucous membranes, or inhaled. Humans who recover from louse-borne typhus remain latently infected and years later may develop recrudescent illness (Brill–Zinsser disease) and associated rickettsemia. Such individuals can infect feeding lice, which may then spread the disease to another person and ignite an epidemic. In addition, a zoonotic cycle of *R. prowazekii* is maintained in flying squirrels and their fleas and lice[2]. *R. typhi* is maintained in natural cycles, classically in rats and oriental rat fleas as well as in opossums and cat fleas.

Pathogenesis

After entry into the dermis, rickettsiae spread throughout the body via the bloodstream. They attach to vascular endothelial cells by outer membrane protein B and, in the case of spotted fever group rickettsiae, outer membrane protein A as well[3]. The organisms enter the cells by induced phagocytosis and then escape from the phagosome into the cytosol, where they obtain amino acids, nucleotides and other building blocks for growth from the host cell and divide by binary fission[3]. Spotted fever group rickettsiae move intracellularly and from cell to cell by stimulating propulsion via the host cell's actin, resulting in a contiguous network of infected endothelial cells that represent the source of the vascular-based disease manifestations (including skin lesions). The spotted fever rickettsiae injure the host endothelium by stimulating these cells to produce toxic reactive oxygen species, and typhus group rickettsiae replicate within the infected endothelial cell until it bursts.

The major pathophysiologic effect of rickettsial infection is increased vascular permeability, which can result in edema, hypovolemia and hypotension[4]. Although endothelial cells of the microcirculation are infected in every organ, the critical target organs in life-threatening infections are the lung and brain. A fatal outcome can result if increased vascular permeability leads to non-cardiogenic pulmonary edema, acute respiratory distress syndrome and meningoencephalitis.

As the infection progresses, macrophages and lymphocytes infiltrate the walls of affected vessels and act as effector cells, secreting cytokines

EPIDEMIOLOGY OF RICKETTSIAL INFECTIONS			
Agent	**Disease**	**Transmission**	**Geographic distribution**
Rickettsia rickettsii	Rocky Mountain spotted fever	**Bite of tick:**	
		Dermacentor variabilis (Fig. 76.1)	Eastern two-thirds and Pacific Coast of US
		D. andersoni	Rocky Mountain states
		Rhipicephalus sanguineus	Southwestern US; northern Mexico
		Amblyomma cajennense, *A. aureolatum*	Central and South America
Rickettsia akari	Rickettsialpox	**Bite of mouse mite**:	
		Liponyssoides sanguineus	North America; Eurasia
Rickettsia conorii	Boutonneuse fever (Mediterranean spotted fever)	**Bite of tick**:	
		Rhipicephalus sanguineus	Southern Europe; Africa; western and southern Asia
		Rh. pumilio	Southern Russia
Rickettsia sibirica	North Asia tick typhus, lymphangitis-associated rickettsiosis	**Bite of tick**:	
		Dermacentor nuttallii, *D. silvarum*, *Haemaphysalis concinna*, *Hyalomma asiaticum*, other species	Eurasia and Africa
Rickettsia australis	Queensland tick typhus	**Bite of tick**:	
		Ixodes holocyclus	Eastern Australia
Rickettsia honei	Flinders Island spotted fever	**Bite of tick**:	
		Bothriocroton hydrosauri, other species	Australia and southeastern Asia (Flinders Island is located between Tasmania and Australia)
Rickettsia japonica	Japanese spotted fever	**Bite of tick**:	
		vector status not established for ticks that carry the agent (*Haemaphysalis flava*, *H. longicornis*, *Ixodes ovatus*, *Dermacentor taiwanensis*)	Japan, and eastern Asia
Rickettsia felis	Flea-borne spotted fever	**By flea:**	
		e.g. *Ctenocephalides felis*	Worldwide
Rickettsia africae	African tick bite fever	**Bite of tick:**	
		Amblyomma hebraeum	Southern Africa
		A. variegatum	Central, eastern, and western Africa; Caribbean islands
Rickettsia parkeri	Maculatum disease (American tick bite fever)	**Bite of tick:**	
		Amblyomma maculatum, A. americanum	North America
		A. triste	South America
Rickettsia aeschlimannii	Unnamed disease	**Bite of tick**:	
		Hyalomma marginatum	Africa
Rickettsia slovaca	Tick-borne lymphadenopathy*	**Bite of tick**:	
		Dermacentor marginatus, *D. reticularis*	Europe
Rickettsia prowazekii	Epidemic louse-borne typhus	**Feces of human body louse** (*Pediculus humanus* var. *corporis*)	South America; Africa; Eurasia
	Brill–Zinsser disease	**None (recrudescence of latent infection)**	
	Flying squirrel typhus	**Contact with flying squirrel** (*Glaucomys volans*) and its fleas and lice	North America
Rickettsia typhi	Murine (endemic) typhus	**Feces of fleas**:	
		Xenopsylla cheopis	Worldwide
		Ctenocephalides felis	North America
Orientia tsutsugamushi	Scrub typhus	**Bite of larval trombiculid mites**:	
		L. deliense, *L. fletcheri*, *L. scutellare*, *L. arenicola*	Southern and eastern Asia; islands of the southwestern Pacific and Indian Oceans; northern Australia
		e.g. *L. pallidum*	Japan; Korea; Russian Far East
		e.g. *L. scutellare*	China; Malaysia
		e.g. *L. deliense*, *L. fletcheri*, *L. arenicola*	Tropical regions
Ehrlichia chaffeensis	Human monocytotropic ehrlichiosis	**Bite of tick**:	
		Amblyomma americanum (Fig. 76.1), *Dermacentor variabilis*	Southeastern and South Central US
Ehrlichia ewingii	*Ehrlichia ewingii* infection	**Bite of tick:**	
		Amblyomma americanum	Southeastern and South Central US
Anaplasma phagocytophilum	Human granulocytotropic anaplasmosis	**Bite of tick:**	
		Ixodes scapularis (Fig. 76.1)	Northern US
		I. pacificus	Far western US
		I. ricinus, *I. persulcatus*	Eurasia
Coxiella burnetii	Q fever	**Aerosol** of infected products of parturition of ruminants and other animals**	Worldwide

*Also reported to be caused by *Rickettsia raoultii*.
**Less common means of transmission include ingestion of contaminated dairy products and tick bites (e.g. *Dermacentor* spp.)

Table 76.1 Epidemiology of rickettsial infections. Additional potentially emerging rickettsial infections for which a small number of cases have been described include: *Rickettsia massiliae* (*Rhipicephalus* spp.; Europe, South America); *Rickettsia* species 364D (*Dermacentor occidentalis*; California); and *Rickettsia heilongjiangensis* (*Haemaphysalis* spp.; Eastern Asia – "Far East spotted fever"). A new *Ehrlichia* species transmitted by *Ixodes scapularis* was recently found to cause a febrile illness in the upper midwestern US.

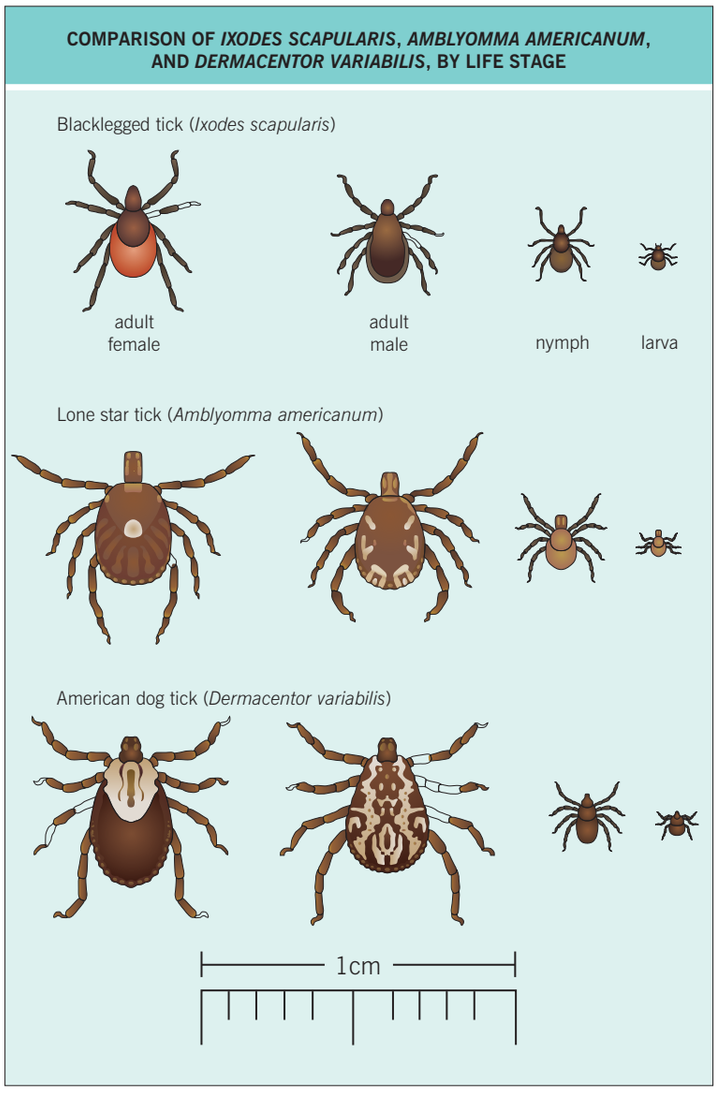

Fig. 76.1 Comparison of *Ixodes scapularis* (blacklegged tick), *Amblyomma americanum* (lone star tick) and *Dermacentor variabilis* (American dog tick), by life stage. *From Chapman AS, et al. MMWR Recomm Rep. 2006;55:1–27.*

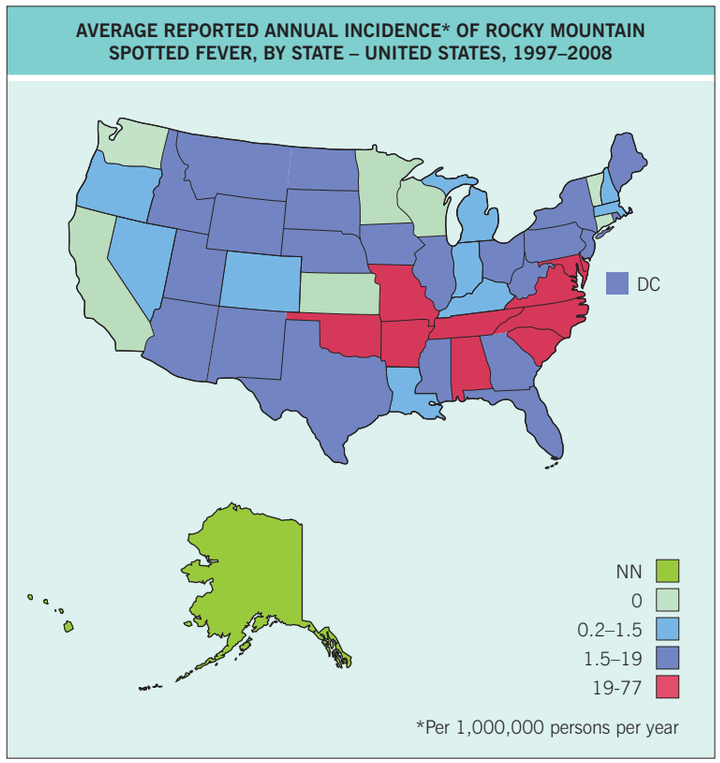

Fig. 76.2 Average reported annual incidence of Rocky Mountain spotted fever, by state – United States, 1997–2008. *From www.cdc.gov/rmsf/stats/#reportsurv.*

such as interferon-γ and tumor necrosis factor-α. Infected endothelial cells and macrophages themselves are activated by cytokines, resulting in killing of intracellular rickettsiae by mechanisms involving nitric oxide, reactive oxygen species, and tryptophan starvation (via enzymatic degradation of this amino acid). Recruited cytotoxic T cells are critical to the apoptotic elimination of infected endothelial cells, which occurs through perforin-dependent pathways. A combination of rickettsicidal mechanisms and killing of infected endothelial cells ultimately leads to clearance of the infection. Antibodies to rickettsiae play a role in the prevention of reinfection.

Clinical Features

Clinical course and systemic features

Rickettsial infections typically begin with fever (>102°F [38.9°C] in two-thirds of patients during the first 3 days of the illness and in 90% thereafter) accompanied by a severe headache and myalgias. Nausea, vomiting, abdominal pain and even abdominal tenderness are also frequent symptoms early in the disease course. When a rash develops, it usually appears on day 3 to 6 of the illness (see below and Table 76.2). Cough (related to pneumonitis and/or pulmonary edema) and confusion or lethargy (related to encephalitis) may represent additional symptoms[5]. Patients often have thrombocytopenia, although full-blown disseminated intravascular coagulation is rare[6], and hyponatremia frequently occurs secondary to increased antidiuretic hormone secretion in response to hypovolemia. Additional laboratory findings may include anemia and abnormal liver and renal function tests. As the clinical course progresses, hypotension, acute renal failure, respiratory failure and coma may develop[7].

Severe rickettsioses continue to have fatalities owing to misdiagnosis and/or initiation of *delayed* antirickettsial treatment, with mortality rates as follows: ~4% for RMSF and louse-borne typhus; ~3% for boutonneuse fever; and ~1% for murine typhus[8,9]. If *not treated* with an appropriate antimicrobial agent, approximately 25% and 15% of patients with RMSF and louse-borne typhus, respectively, will die[10]. The case fatality rate is higher with older age, male gender, and underlying diseases.

Shared cutaneous features

In many types of spotted fevers other than RMSF (see Table 76.2), an eschar consisting of a central area of dermal and epidermal necrosis (typically measuring 0.5–2 cm in diameter) surrounded by a zone of erythema appears during the incubation period (usually 4–10 days) (see Fig. 76.7A). This represents the site of inoculation of rickettsiae by the tick or mite[11,12]. The rash of rickettsial diseases typically begins as erythematous macules around the wrists and ankles (spotted fevers) (Fig. 76.3) or axillae (typhus fevers). The exanthem evolves during the course of the illness, with lesions eventually appearing on most of the body, often with relative sparing of the face. Macules and papules develop on the palms and soles (often relatively late in the disease course) in approximately half of the patients with spotted fevers (Fig. 76.4). Macules reflect vasodilation related to infection of endothelial cells in the dermal microcirculation. As perivascular edema develops secondary to leakage of fluid from damaged blood vessels, macules become papules. When endothelial cell destruction leads to more severe vascular injury, petechiae appear within the lesions (Fig. 76.5), which can coalesce and become purpuric (Fig. 76.6). Cutaneous necrosis, including gangrene of the digits, extremities, ears or prepuce, occurs in 4% of patients with RMSF and occasionally in epidemic typhus, owing to more severe infection of the microcirculation in acral sites with a cooler temperature that is more favorable for rickettsial growth.

Features of specific diseases

RMSF usually follows the classic clinical course described above. After an incubation period of 2–14 (mean, 7) days following the tick bite

DERMATOLOGIC MANIFESTATIONS OF RICKETTSIAL INFECTIONS				
Disease	**Rash incidence (%)**	**Appearance of rash after onset of illness**	**Characteristics**	**Eschar (%)**
Rocky Mountain spotted fever	90	3–5 days	Early macules, later papules; petechiae in 50% of cases	<1
Rickettsialpox	100	2–3 days	Early macules and papules; later papulovesicles and crusts	90
Boutonneuse fever	97	3–5 days	Early macules, later papules	50
North Asian tick typhus	100	4–5 days	Macules and papules	75
Queensland tick typhus	90	2–6 days	Macules, papules and vesicles	75
Flinders Island spotted fever	85	A few days	Early macules and papules, later (in some patients) petechiae	50
Japanese spotted fever	100	A few days	Early macules, later (in some patients) petechiae	90
Flea-borne spotted fever	83	A few days	Macules and papules; occasionally pustules	17
African tick bite fever	50	3–5 days	Generally relatively few lesions; macules, often vesicles	90, often multiple
Maculatum disease (American tick bite fever)	80	2–4 days	Macules, papules, often vesicles	100
R. aeschlimannii infection	50	Not known	Macules, papules	100
Tick-borne lymphadenopathy	5	Not reported	Macules, papules	100
Epidemic louse-borne typhus	50–100	4–5 days	Early macules, later papules; petechiae	None
Brill–Zinsser disease	50	4–6 days	Macules, papules	None
Flying squirrel typhus	66	2–8 days	Macules, papules	None
Murine (endemic) typhus	80	5 days	Early macules, later papules	None
Scrub typhus	50	4–6 days	Early macules, later papules	60–90
Human monocytotropic ehrlichiosis	40	Median, 5 days	Macules, papules, occasionally petechiae	None
Ehrlichiosis ewingii infection	None	NA	NA	None
Human granulocytotropic anaplasmosis	Rare	NA	NA	None
Q fever	Rare	Associated with chronic infection	Macules, papules, palpable purpura; rarely erythema nodosum	None

Table 76.2 Dermatologic manifestations of rickettsial infections. NA, not applicable.

Fig. 76.3 Rocky Mountain spotted fever. The cutaneous lesions often appear first on the wrists and ankles. *Courtesy, Philippe Berbis, MD.*

Fig. 76.4 Rocky Mountain spotted fever. Petechiae on the palms and soles often develop relatively late in the disease course. *Courtesy, Ronald P Rapini, MD.*

(which 40% of patients do not recall), affected individuals present with fever, myalgias, headache and, in >50% of patients, gastrointestinal symptoms. The rash typically appears 3–5 days after onset of the illness as subtle erythematous macules on the wrists and ankles, which is followed by centripetal spread to the trunk, formation of papular lesions, and eventual development of petechiae (~50% of patients). However, cutaneous findings are absent in 10–15% patients and may be difficult to recognize in darkly pigmented skin.

R. parkeri and *R. africae*, closely related strains of spotted fever group rickettsiae transmitted by *Amblyomma* ticks, cause two similar emerging infections, ***Maculatum disease*** (***American tick bite fever***) and ***African tick bite fever***, respectively. The former is endemic in the south central and southeastern US (the range of *A. maculatum*, the Gulf Coast tick; see Fig. 76.10) and in South America, while the latter is endemic in sub-Saharan Africa and represents the rickettsial disease with the highest incidence among travelers returning to the US[13,14].

Fig. 76.5 Rocky Mountain spotted fever. Petechiae are present within erythematous papules and plaques on the buttocks. Some of the lesions have a retiform pattern.

Fig. 76.6 Rocky Mountain spotted fever. Retiform purpura on the distal lower extremity in a patient with more severe disease.

Fig. 76.7 Rickettsialpox. **A** Eschar at the site of the mite bite. **B** Scattered papules with hemorrhagic crusts.

Patients with these conditions typically present with mild constitutional symptoms (e.g. fever, headache, myalgias), one or more eschars, and tender lymphadenopathy in the region draining the eschar(s). In 50–80% of affected individuals, usually 2–4 days after disease onset, a rash develops on the trunk and extremities (sometimes involving the palms and soles). The eruption may be relatively sparse and often features small central vesicles or pustules within erythematous macules and papules. No deaths have been reported for either type of infection. Despite the substantial difference in severity, it is likely that many *R. parkeri* infections are misdiagnosed as RMSF owing to serologic cross-reactivity with *R. rickettsii*[15].

Rickettsialpox occurs primarily in urban areas, especially cities in the northeastern US. A papulovesicle arises within 48 hours at the site of the bite of a mite that parasitizes house mice and eventuates in an eschar with surrounding erythema and induration (Fig. 76.7A). Constitutional symptoms (e.g. fever, headache, myalgias) begin 1 to 2 weeks later, followed in 2 to 3 days by a cutaneous eruption that often involves the face (Fig. 76.7B) as well as the trunk and extremities, in no particular sequence. Approximately 20 to 40 skin lesions typically develop, evolving from erythematous macules and papules to papulovesicles to hemorrhagic crusts. The palms and soles are occasionally affected, and an enanthem characterized by small erosions on the tongue, palate and pharynx may occur.

Pathology

Rickettsial infection is multifocal, which is reflected in the scattered distribution of cutaneous lesions. However, randomly obtained tissue samples are unlikely to contain the classic finding of a lymphohistiocytic vasculitis, which is present in the center of a petechial macule or papule. The early finding of perivascular edema is difficult to identify histopathologically because of formalin-associated tissue shrinkage. In more developed lesions, extravasated erythrocytes (corresponding to petechiae) are observed. Thrombosis occurs in a minuscule portion of infected blood vessels, and, when present, is usually a non-occlusive hemostatic plug in a focus of denuded endothelium. Later in the disease course, vasculitis can be detected histopathologically in the skin and other organs. The inflammatory infiltrate around and within vessel walls is composed of macrophages and lymphocytes (Fig. 76.8).

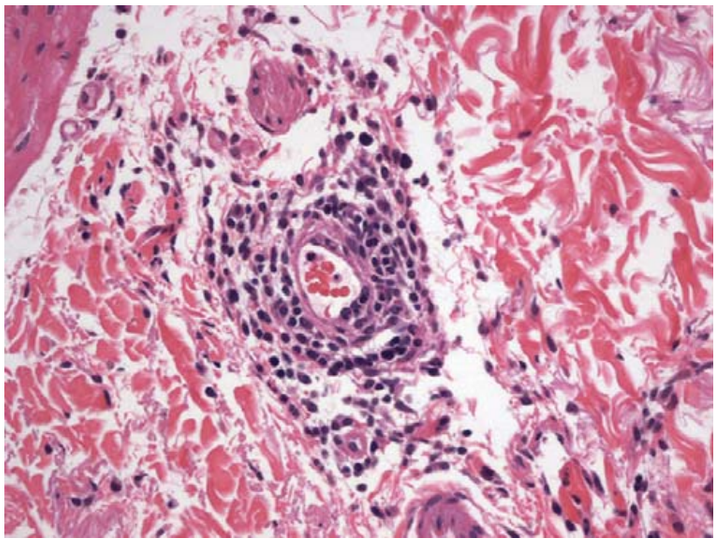

Fig. 76.8 Histologic findings in Rocky Mountain spotted fever. Typical lymphohistiocytic vasculitis involving a dermal blood vessel. *Courtesy, James W Patterson, MD.*

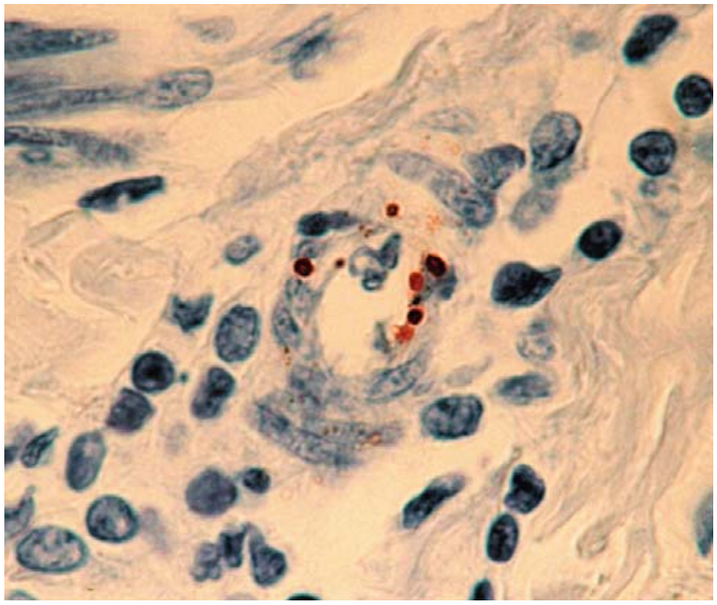

Fig. 76.9 Immunohistochemical detection of spotted fever rickettsiae. Organisms within the endothelium of a dermal blood vessel are highlighted by brown staining.

Diagnosis and Differential Diagnosis

The diagnosis of rickettsiosis is based on clinical and epidemiologic criteria such as the signs, symptoms and potential tick exposure[16]. It is essential to begin empiric treatment with effective antirickettsial agents based on clinical suspicion rather than awaiting laboratory confirmation. Indeed, serologic diagnosis is usually retrospective, because antibodies do not develop until day 7 of the illness or later[17]. Circulating rickettsiae are generally too few early in the illness to be detected by PCR-based assays, but rickettsiae can be identified by immunofluorescence or immunohistochemistry in a biopsy specimen of an eschar or a maculopapular lesion (Fig. 76.9), especially if the latter is petechial.

Prior to the onset of the rash, the differential diagnosis may include a wide variety of viral infections (which often present with similar symptoms), ehrlichiosis and typhoid fever. Patients with prominent nausea and vomiting are often suspected to have viral or bacterial enterocolitis. The abdominal pain and tenderness can suggest an acute surgical abdomen, and this has led to exploratory laparotomies. Cough and crackles on auscultation due to pulmonary edema may lead to suspicion of bacterial or viral pneumonia. Neurologic signs and cerebrospinal fluid pleocytosis can suggest viral or bacterial meningoencephalitis, while jaundice and elevated hepatic enzymes may prompt the consideration of viral hepatitis or leptospirosis.

When the cutaneous eruption initially develops, the differential diagnosis may include a viral exanthem, a drug eruption, ehrlichiosis, Kawasaki disease and early secondary syphilis. Exanthems due to enteroviruses, Epstein–Barr virus, parvovirus B19, adenovirus, dengue fever and measles can have a petechial component (see Fig. 81.2). When petechial and/or purpuric lesions become more prominent, meningococcemia, small vessel vasculitis, disseminated gonococcal infection, dengue hemorrhagic fever and other viral hemorrhagic fevers (see Table 81.7) may also be considered. In patients with thrombocytopenia, immune thrombocytopenic purpura or thrombotic thrombocytopenic purpura represent additional possibilities. The differential diagnosis for rickettsialpox and other rickettsial eruptions with a vesicular component may include vesicular viral exanthems (e.g. due to coxsackieviruses), varicella, disseminated HSV infection, pityriasis lichenoides et varioliformis acuta (PLEVA), drug eruptions, bullous insect bite reactions, and scabies. Cutaneous necrosis resembling an eschar can be seen in spider bites, ecthyma, ecthyma gangrenosum (typically in immunocompromised hosts), cutaneous anthrax, *Bacillus cereus* infection, cutaneous diptheria, tularemia, scrub typhus (see below), and primary syphilis.

Treatment

The drug of choice for rickettsial infections in nearly all patients, including young children, is doxycycline (Table 76.3)[9,16]. Chloramphenicol is a less effective alternative, having a higher rate of fatal outcomes. However, chloramphenicol is generally recommended for treatment of RMSF during pregnancy.

Mild cases of boutonneuse fever in children have been treated with azithromycin or clarithromycin with an outcome equivalent to treatment with chloramphenicol, and these macrolide antibiotics (as well as josamycin, a related agent not available in the US) may represent therapeutic options for mild rickettsioses during pregnancy. Fluoroquinolones have also been used successfully to treat patients with boutonneuse fever and murine typhus. Of note, treatment of severe rickettsial infection with macrolides or fluoroquinolones is not recommended.

SCRUB TYPHUS

Scrub typhus was described in association with red mites in China in 313 AD. *Orientia tsutsugamushi* was discovered in Japan by Nagayo and Ogata in the 1920s and early 1930s. This organism differs from *Rickettsia* spp. in its cell wall composition, having entirely unrelated proteins and a distinct ultrastructure as well as lacking lipopolysaccharide. *Orientia tsutsugamushi* is maintained in nature via transovarial transmission by its vector, trombiculid mites (see Table 76.1). Eggs laid by infected mites hatch with the emergence of infected larvae (chiggers) that feed on the rat population. Both humans and rats are dead-end hosts.

It is estimated that one million cases of scrub typhus occur annually, affecting rural populations in a large portion of Asia (from Afghanistan to Japan) and northern Australia. Infection of more than 3% of the population per month has been documented in endemic regions of southeast Asia. Immunity is strain-specific and transient, resulting in reinfections. The severity of the illness is age-dependent and varies geographically.

A cutaneous eschar forms at the site of chigger feeding in 60–90% of primary infections. This is followed by regional lymphadenopathy, fever and headache; generalized lymphadenopathy, conjunctival hyperemia and hearing loss may also develop[18]. A rash occurs in approximately half of patients, usually appearing as erythematous macules on the trunk 4 to 6 days after disease onset. Lesions then become papular, with subsequent centrifugal spread. Interstitial pneumonia frequently occurs, presenting with cough, tachypnea and radiographic infiltrates; meningoencephalitis is a less common manifestation[19]. In severe cases, acute respiratory distress syndrome, acute renal failure and hypotensive shock may develop.

TREATMENT OF RICKETTSIAL DISEASES				
	Medication	**Adult dose**	**Pediatric dose**	**Treatment duration**
• First choice for virtually all rickettsial infections in children and adults*	Doxycycline	100 mg po or iv twice daily	2.2 mg/kg (max. 100 mg) po or iv twice daily	Until ≥3 days after defervescence, for a minimum total course of 5–7 days†
• First choice for non-life-threatening RMSF in pregnant women	Chloramphenicol‡	500 mg iv every 6 hours	Not recommended	Until ≥3 days after defervescence, for a minimum total course of 5–7 days†
• First choice for non-life-threatening HME or HGA in pregnant women • Alternative for resistant scrub typhus	Rifampin	300 mg po twice daily	10 mg/kg (max. 300 mg) twice daily	Until ≥3 days after defervescence, for a minimum total course of 7–10 days
• First choice for scrub typhus in pregnant women and potentially in children • Alternative for mild rickettsioses (e.g. early boutonneuse fever) during pregnancy or in children	Azithromycin§	500 mg po daily	10 mg/kg po daily	3 days

*With the exception of infections in pregnant women, although doxycycline administration during pregnancy can be considered in life-threatening situations when the suspicion of RMSF or other severe rickettsioses is high; other tetracyclines are also effective for rickettsial infections.
†Recommended by the CDC; others recommend a 10-day course.
‡May be associated with gray baby syndrome when administered late in the third trimester of pregnancy.
§Clarithromycin may also be considered.

Table 76.3 Treatment of rickettsial diseases. Empiric treatment with an appropriate agent should be initiated immediately when a diagnosis of Rocky Mountain spotted fever (RMSF), human monocytotropic ehrlichiosis (HME), human granulocytotropic anaplasmosis (HGA) or another potentially severe rickettsiosis is suspected clinically.

Tetracyclines, particularly doxycycline, are generally the first-line treatment for scrub typhus. Chloramphenicol, another traditional therapy for this condition, is less effective than doxycycline, but azithromycin is equally effective as doxycycline and represents an option for pregnant women. Of note, resistance of *O. tsutsugamushi* to doxycycline and chloramphenicol has been documented in northern Thailand[20], and resistant infections have been treated successfully with azithromycin or rifampin.

HUMAN EHRLICHIOSES

Ehrlichial infections have been well known to veterinarians for >75 years, but human infection was not recognized until 1986, when *Ehrlichia chaffeensis* was implicated as the etiologic agent of human monocytotropic ehrlichiosis (HME)[21]. In 1999, *E. ewingii* was found to cause human infections (most often in immunosuppressed patients) with clinical manifestations similar to HME[22]. *Ehrlichia* spp. are obligately intracellular, Gram-negative bacteria that target monocytes/macrophages (*E. chaffeensis*) or neutrophils (*E. ewingii*), in which they reside as a cytoplasmic microcolony that is occasionally visible in a peripheral blood smear. Both agents are maintained in a zoonotic cycle involving persistently infected white-tailed deer as the major reservoir and lone star ticks (*Amblyomma americanum*), which are found primarily in the south central and southeastern US (with extension as far north as Illinois and Connecticut), as the primary vector (Fig. 76.10; see Table 76.1)[21]. In addition, a new *Ehrlichia* species transmitted by *Ixodes scapularis* was recently found to cause human infections clinically similar to HME in the upper midwestern US[22a].

HME is a serious infectious disease with a ~3% case fatality rate. Its incidence is likely underestimated due to the lack of specific clinical findings, and one study found that ehrlichial infection was twice as likely as RMSF among febrile patients living in North Carolina with a history of a recent tick bite[16]. Patients with HME and *Ehrlichia ewingii* infection typically present with fever, headache and myalgias; common laboratory abnormalities include thrombocytopenia, leukopenia and elevated transaminases. Progression to acute respiratory distress syndrome, meningoencephalitis and toxic shock syndrome-like manifestations can occur, even in immunocompetent individuals with HME. In addition, overwhelming ehrlichial infection may develop in immunocompromised hosts, such as those with HIV infection and organ transplant recipients[23,24].

Approximately 30–40% of patients with HME have cutaneous manifestations, which develop a median of 5 days after the onset of the illness and may be more common in children[25]. Macular, maculopapular and petechial eruptions involving the trunk and extremities are most often observed, but the morphology and distribution of skin lesions can vary considerably[25,26] (Table 76.4). *Ehrlichia ewingii* infection has not been reported to have cutaneous manifestations[22]. The differential diagnosis of ehrlichioses is similar to that of rickettsioses (see above).

PCR-based assays can identify *Ehrlichia* spp. and *Anaplasma phagocytophilum* (see below) in blood samples and assist in the rapid diagnosis of these infections; however, empiric treatment should be initiated based on clinical suspicion rather than awaiting laboratory confirmation. Doxycycline is the drug of choice for both HME and *Ehrlichia ewingii* infection. *In vitro* evidence suggests that chloramphenicol is not an effective therapy for these infections.

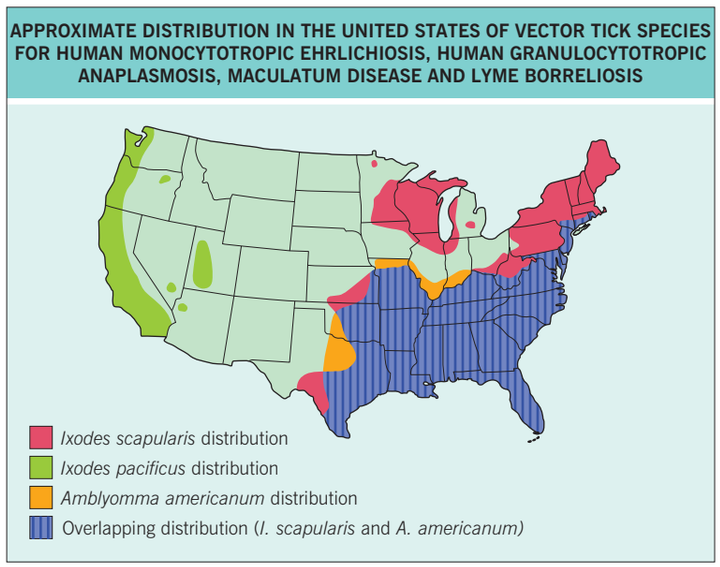

Fig. 76.10 Approximate distribution in the US of vector tick species for human monocytotropic ehrlichiosis, human granulocytotropic anaplasmosis, Maculatum disease and Lyme borreliosis. It has been postulated that *Amblyomma maculatum*, which is classically found primarily along the Atlantic and Gulf coasts, has a range as broad as that of *Amblyomma americanum*. *From Chapman AS, et al. MMWR Recomm Rep. 2006;55:1–27.*

CUTANEOUS MANIFESTATIONS OF HUMAN MONOCYTOTROPIC EHRLICHIOSIS
Macular or maculopapular exanthematous eruptions
Mottled or diffuse macular erythema (transient or persistent)
Petechiae (favor the palms, soles, trunk and palate)
Vesicles
Edema (especially of hands, feet and scrotum)
Purpuric papules (with histologic evidence of vasculitis)
Nodules secondary to polyarteritis nodosa
Ulceration (reported on the penis)

Table 76.4 Cutaneous manifestations of human monocytotropic ehrlichiosis. Several types of lesions may be present simultaneously or sequentially in an individual patient.

HUMAN GRANULOCYTOTROPIC ANAPLASMOSIS

Anaplasma phagocytophilum, previously referred to as the "human granulocytotropic ehrlichiosis (HGE) agent", is an obligately intracellular bacterium (closely related to *Ehrlichia* spp.) that causes human granulocytotropic anaplasmosis (HGA; formerly known as HGE). HGA occurs in the same geographic distribution as Lyme borreliosis (and babesiosis) owing to their transmission by the same *Ixodes* spp. tick vectors (see Table 76.1 and Fig. 76.10). The clinical features of HGA are similar to those of HME, but HGA has a lower case fatality rate (0.5–1%), often presents with peripheral neuropathy (but rarely leads to meningoencephalitis), and seldom has dermatologic manifestations (≤5% of cases)[27]. Interestingly, Sweet's syndrome has been described in association with HGA[28]. As for HME, the first-line treatment is doxycycline.

Q FEVER

Coxiella burnetii differs substantially from organisms in the order Rickettsiales, being more closely related to bacteria of the genus *Legionella*. Although *C. burnetii* are obligately intracellular bacteria found in many species of ticks, they are transmitted to humans primarily by inhalation of aerosols generated from the placenta and birth fluids of infected animals such as sheep, cattle and cats (see Table 76.1). The bacteria target macrophages, where they thrive in the acidic environment of phagolysosomes. The presence of a stable extracellular form accounts for their persistence in the environment.

The acute disease typically presents as a nonspecific febrile illness; atypical pneumonia or granulomatous hepatitis occasionally occur. Chronic Q fever most often manifests as "culture-negative" endocarditis affecting a previously damaged heart valve.

Cutaneous manifestations of Q fever are rare (see Table 76.2). A truncal maculopapular rash, an urticarial eruption, erythema nodosum, palpable purpura, palatal petechiae, and vasculitis (reported in association with mixed cryoglobulinemia) have all been described in patients with Q fever.

Fungal Diseases 77

Boni E Elewski, Lauren C Hughey, Jenny O Sobera and Roderick Hay

Key features

- Cutaneous fungal infections are broadly divided into those that are limited to the stratum corneum, hair and nails, and those that involve the dermis and subcutaneous tissues
- Superficial fungal infections of the skin are most often due to dermatophytes and *Candida* spp.
- "Subcutaneous" mycoses are often the result of implantation, while systemic or "deep" mycoses of the skin usually represent hematogenous spread or extension from underlying structures
- In the immunocompromised host, opportunistic fungi, e.g. *Aspergillus* and *Mucor* spp., can lead to both cutaneous and systemic infections

This chapter reviews common cutaneous fungal infections, and they are subdivided into three major groups: (1) "superficial"; (2) "subcutaneous"; and (3) "deep" or systemic (Table 77.1).

SUPERFICIAL MYCOSES

Introduction

The superficial mycoses are due to fungi that only invade fully keratinized tissues, i.e. stratum corneum, hair and nails. They can be further subdivided into those that induce minimal, if any, inflammatory response, e.g. pityriasis (tinea) versicolor, and those that lead to more substantial cutaneous inflammation, e.g. dermatophytoses (Table 77.2).

Non-inflammatory superficial mycoses

Synonyms: ■ Tinea nigra: tinea nigra palmaris et plantaris, superficial phaeohyphomycosis ■ Piedra: molestia de Beigel, trichomycosis nodularis ■ Pityriasis versicolor: tinea versicolor, dermatomycosis furfuracea, tinea flava

History

In 1846, Eichstedt first noted the disease known today as pityriasis (tinea) versicolor. Over the ensuing 150 years, *Malassezia furfur* (previously known as *Pityrosporum ovale* and *P. orbiculare*) came to be recognized as the causative microbe. More recently, however, studies have pointed to *M. globosa* as a causative organism[1]. In 1865, Beigel first described piedra after isolating a fungus (which was likely actually a contaminant) from a wig. Tinea nigra was first described in the 1890s by Cerqueira, who named it "keratomycosis nigricans palmaris"[2].

Epidemiology

Tinea nigra and piedra typically occur in tropical climates such as Central and South America, Africa, Asia and, occasionally, in the southeastern US. While any race, age or gender may be infected, the typical patient is a young adult. *Trichosporon beigelii* (see Table 77.2 for the revised subdivision of the *Trichosporon* genus), the cause of white piedra, is also recognized as an opportunistic pathogen.

The geographic distribution of *Malassezia* spp. is worldwide (Table 77.3). In fact, they are part of the normal flora of human skin (predominantly *M. sympodialis*). Although pityriasis versicolor occurs most frequently in tropical climates with high ambient temperatures and high humidity, it is also a common disorder in temperate climates. No racial or gender differences have been observed. The typical patient is a young adult, but people of any age may develop the disease. Interestingly, *Malassezia* requires oil to grow, accounting for the increased incidence in adolescents and preference for sebum-rich areas of the skin. *Malassezia* has been implicated in several other skin diseases, including seborrheic dermatitis and atopic dermatitis, but the latter remains controversial. Neonatal cephalic pustulosis (neonatal acne) may also be associated with *Malassezia* spp., particularly *M. sympodialis*[3] (see Ch. 34).

Pathogenesis

Hortaea werneckii (formerly *Exophiala werneckii*) and *Piedraia hortae* are both environmental pathogens. *H. werneckii* (tinea nigra) can be found in soil, sewage, and even shower stalls under humid conditions. The source of exposure to *P. hortae* (black piedra) is thought to be the soil. There is no known transmission of these organisms from human to human. *T. beigelii* (white piedra) is also acquired from the environment; however, it may occasionally be part of the normal flora of the skin and mucous membranes[4], particularly inguinal and axillary skin.

M. furfur (and other species) normally live on human skin in amounts so minute as to be undetectable on potassium hydroxide (KOH) examination of stratum corneum[5]. Pityriasis versicolor occurs when the round yeast form transforms to the mycelial form. In tropical climates, this change is a result of high temperatures and high humidity. In temperate climates, various factors have been implicated, including oily skin, excessive sweating, immunodeficiency, poor nutrition, pregnancy and corticosteroid use. Because this yeast is lipophilic, use of bath oils

ORGANIZATION OF CUTANEOUS MYCOSES	
Superficial	Involve stratum corneum, hair and nails
Subcutaneous	Involve dermis or subcutaneous tissue Often due to implantation
Systemic ("deep") "True" pathogens Opportunistic	Involve dermis or subcutaneous tissue Skin involvement usually reflects hematogenous spread or extension from underlying structures Primary or secondary skin lesions in immunocompromised hosts

Table 77.1 Organization of cutaneous mycoses.

SUPERFICIAL MYCOSES OF THE SKIN		
	Cutaneous disorder	**Pathogen(s)**
Minimal, if any, inflammation	Pityriasis (tinea) versicolor Tinea nigra Black piedra White piedra	*Malassezia furfur, M. globosa* *Hortaea werneckii* *Piedraia hortae* *Trichosporon beigelii**
Inflammatory response common	Tinea capitis, barbae, faciei, corporis, cruris, manuum, pedis Cutaneous candidiasis	*Trichophyton, Microsporum, Epidermophyton* spp. *Candida albicans*, other *Candida* spp.

**Trichosporon beigelii* has been reclassified into at least six pathogenic species: *T. asahii* (most often associated with disseminated trichosporonosis), *T. asteroides*, *T. cutaneum*, *T. inkin* (most often associated with white piedra of pubic hair), *T. mucoides* and *T. ovoides*.

Table 77.2 Superficial mycoses of the skin.

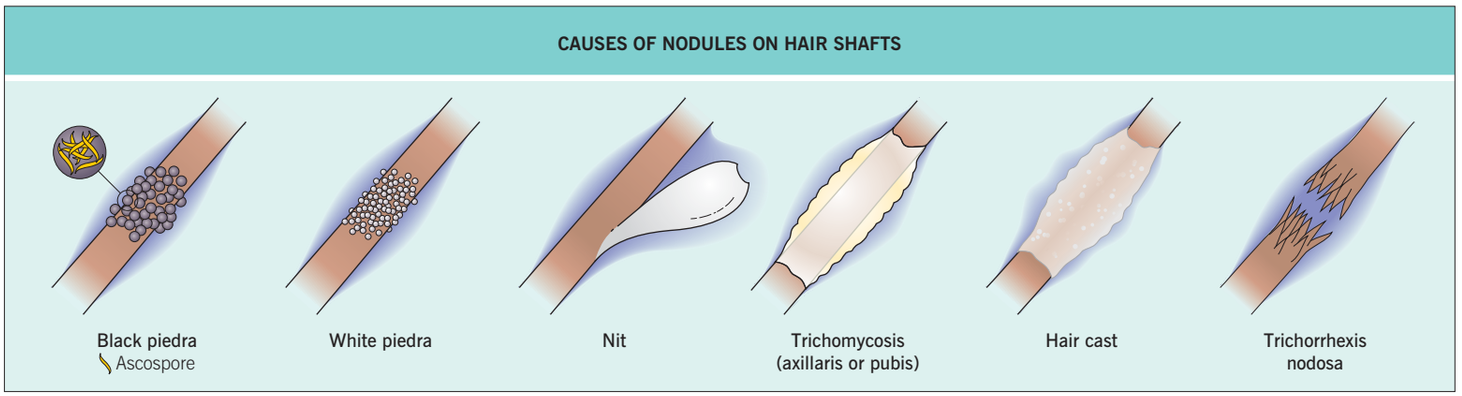

Fig. 77.1 Causes of nodules on hair shafts.

DIFFERENT SPECIES OF *MALASSEZIA* AND COMMON CLINICAL PRESENTATIONS	
Species of *Malassezia*	**Common clinical presentations**
M. furfur	Pityriasis versicolor, seborrheic dermatitis, folliculitis, neonatal cephalic pustulosis, blepharitis, and systemic infections in neonates receiving intravenous fat emulsions
M. globosa	Seborrheic dermatitis, pityriasis versicolor, folliculitis, neonatal cephalic pustulosis
M. sympodialis	Pityriasis versicolor, neonatal cephalic pustulosis*
M. pachydermatitis	Often isolated from domestic and wild animals; has occasionally been implicated in cases of systemic infection in humans; may play a role in chronic dermatitis and otitis externa
M. restricta	Seborrheic dermatitis, pityriasis versicolor
M. sloofiae	Uncommon isolate
M. obtusa	Uncommon isolate

*Most commonly isolated species in this disorder.

Table 77.3 Different species *of Malassezia* and common clinical presentations.

COMPARISON OF BLACK AND WHITE PIEDRA		
	White piedra	**Black piedra**
Nodule color	White (occasionally red, green or light brown)	Brown to black
Nodule firmness	Soft	Hard
Nodule adherence to the hair shaft	Loose	Firm
Typical anatomic location	Face, axillae and pubic region (occasionally scalp)	Scalp and face (occasionally pubic region)
Favored climate	Tropical	Tropical
Causative organism	*Trichosporon beigelii**	*Piedraia hortae*
KOH examination of "crush prep" of cut hair shafts	Non-dematiaceous hyphae with blastoconidia and arthroconidia	Dematiaceous hyphae with asci and ascospores†
Culture on Sabouraud's agar	Moist, cream-colored, yeast-like colonies‡	Slow-growing, dark green to dark brown–black colonies
Treatment	Clip affected hairs, wash affected hairs with antifungal shampoo	Clip affected hairs, wash affected hairs with antifungal shampoo

*See Table 77.2 for the revised subdivision of the *Trichosporon* genus.
†Sexual reproduction
‡Growth inhibited by cycloheximide.

Table 77.4 Comparison of black and white piedra[6].

Fig. 77.2 Tinea nigra. Single, sharply demarcated brown macule on the finger. *Courtesy, Frank Samarin, MD.*

and skin lubricants may increase the risk of disease. Risk factors for *Pityrosporum* folliculitis include chronic antibiotic use, immunosuppression and local occlusion.

Clinical features

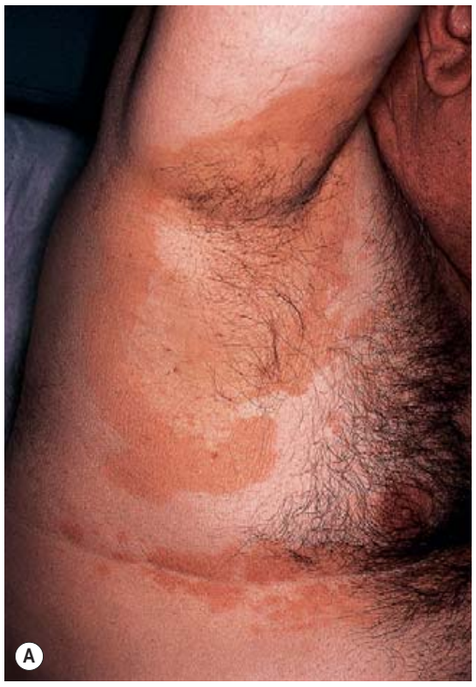
Piedra

Piedra is a superficial infection of the hair shaft. "Piedra" means "stone", reflecting the fungal elements' adherence to one another to form nodules along the hair shaft. There are two major forms – black piedra and white piedra – which are distinguished by their clinical appearance and findings on microscopic examination (Table 77.4). Patients with black piedra typically present with asymptomatic brown to black nodules along the hair shaft. Infection usually commences under the cuticle of the hair shaft and extends outward. Hair breakage may occur as a result of shaft rupture at the site of the nodules. As the nodules enlarge, they can even envelope the hair shaft (Fig. 77.1).

In white piedra, the infection also begins beneath the cuticle and grows through the hair shaft, causing weakening and breakage of the hair. The soft, less adherent nodules of white piedra are generally white but may also be red, green or light brown in color. The incidence of white piedra in the pubic region has increased since the start of the HIV pandemic. In immunosuppressed patients, *T. beigelii* can cause trichosporonosis, a serious systemic infection with fungemia, fever, pulmonary infiltrates, skin lesions (papulovesicular and purpuric, often with central necrosis) and renal disease[4].

Tinea nigra

After a 10- to 15-day incubation period, tinea nigra most commonly presents as a single, sharply marginated, brown (Fig. 77.2) to gray–green macule or patch that can be velvety or have mild scale. There are usually no associated symptoms (i.e. pruritus), and no predispositions have been identified. Although most frequently seen on the palms, tinea nigra can also appear on the soles, neck and trunk. Although palmoplantar lesions are said to resemble acquired acral melanocytic



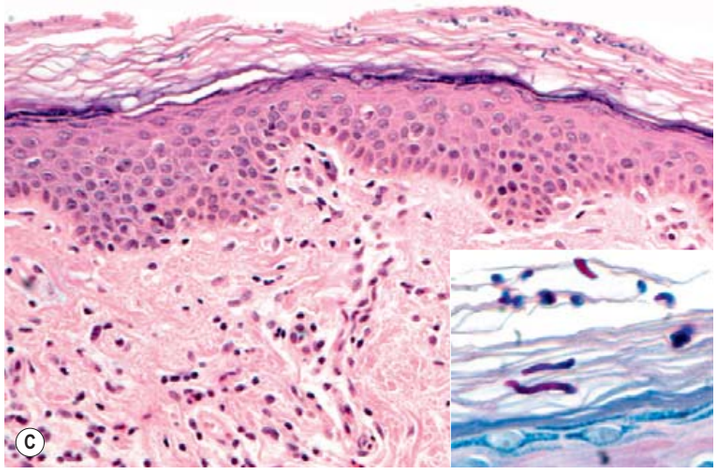


Fig. 77.3 Pityriasis (tinea) versicolor. **A** Hyperpigmented variant. **B** Hypopigmented variant on the face. **C** Yeast and short hyphae in the stratum corneum highlighted by a PAS stain (insert). *A, B, Courtesy, Kalman Watsky, MD. C, Courtesy, Lorenzo Cerroni, MD.*

nevi, the former are usually larger, lighter in color, and lack the linear striations of acral nevi. Tinea nigra can also have darker pigmentation of the advancing border as compared to the center. While the disease tends to be chronic, recurrence after effective treatment is infrequent except in the case of re-exposure.

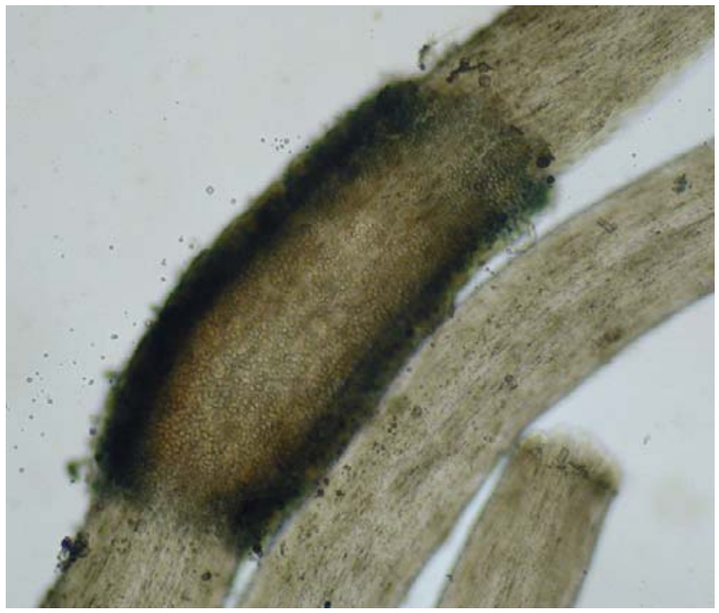

Fig. 77.4 White piedra. Potassium hydroxide preparation of a nodule on the hair shaft showing arthroconidia and blastoconidia.

Pityriasis (tinea) versicolor

Patients usually present with multiple oval to round patches or thin plaques with mild, fine scale. Demonstration of this associated scale may require scratching or stretching the skin surface. The lesions are often confluent centrally within areas of involvement, which may be extensive. Seborrheic regions, in particular the upper trunk and shoulders, are the favored sites of involvement. Less frequently, lesions are seen on the face (especially in children), scalp, antecubital fossae, submammary region and groin. Involvement of flexural areas is sometimes referred to as "inverse" pityriasis versicolor.

The most common colors are brown (hyperpigmented; Fig. 77.3A) and whitish-tan (hypopigmented; Fig. 77.3B); occasionally there is mild inflammation leading to a pink color. Decreased pigmentation may be secondary to the inhibitory effects of dicarboxylic acids on melanocytes (these acids result from metabolism of surface lipids by the yeast) or decreased tanning, due to the ability of the fungus to filter sunlight. In general, pityriasis versicolor is asymptomatic and the major concern is its appearance.

Pityrosporum folliculitis

This condition is most commonly seen in young women and is characterized by pruritic, monomorphic follicular papules and pustules on the upper trunk, arms, neck and, occasionally, the face. It is due to excessive growth of *M. furfur* and *M. globosa* within the hair follicle, with resulting inflammation (from yeast products and free fatty acids produced from fungal lipase). Only yeast forms are observed, i.e. no hyphal forms as in pityriasis versicolor.

Pathology and fungal culture

For black and white piedra, cut hair shafts are placed in KOH and a "crush preparation" is examined microscopically. In a black piedra nodule, dematiaceous hyphae are seen around an organized cluster of asci, each of which contains eight ascospores. The ascospores represent the sexual phase of *P. hortae*. *P. hortae* grows very slowly when cultured and yields a green to black colony with a velvety texture (asexual phase)[7].

KOH preparation of a crushed white piedra nodule reveals non-dematiaceous hyphae, blastoconidia and arthroconidia (Fig. 77.4), representing the asexual state. When cultured, *T. beigelii* grows rapidly, forming moist, cream-colored, yeast-like colonies that resemble "butter cream frosting". On Mycosel® agar, the organism is inhibited by the presence of cycloheximide. *T. beigelii* is often isolated from skin and nail specimens, and the significance of this must be correlated with clinical findings.

Biopsies of pityriasis versicolor and tinea nigra are usually not performed, as KOH examination of associated scale is typically

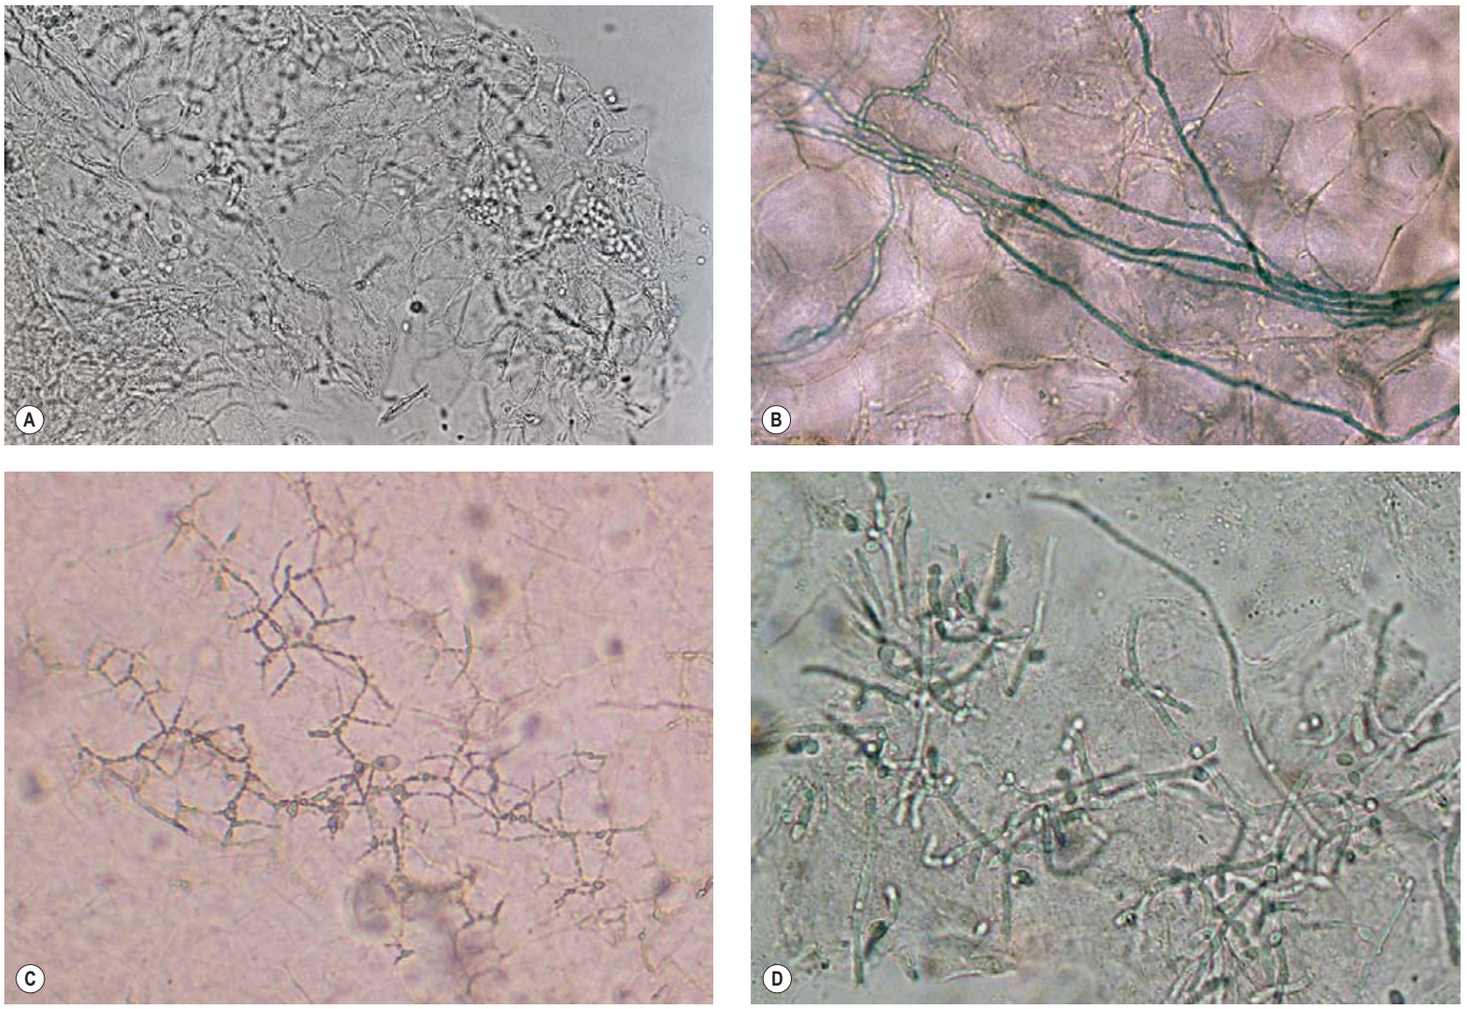

Fig. 77.5 Potassium hydroxide preparations. A Superficial skin scrapings from pityriasis (tinea) versicolor demonstrating yeast and short mycelial forms. **B** A dermatophyte, in this case *Trichophyton tonsurans*, demonstrating branching hyphae; chlorazol black stain **C** "Mosaic" pattern of cell walls that should not be misinterpreted as hyphae. **D** Yeast and pseudohyphae of candidiasis. *A, Courtesy, Ronald P Rapini, MD. diagnostic. In pityriasis versicolor, both hyphal and yeast forms are seen; although likened to "spaghetti and meatballs", the findings more closely resemble "ziti and meatballs" (Fig. 77.5A). In tinea nigra, KOH examination reveals septate pigmented hyphae. When biopsy specimens are obtained, similar findings are observed within the stratum corneum. In KOH examination of expressed follicular contents or biopsy specimens of *Pityrosporum* folliculitis, only yeast forms are seen. Cultures of *H. werneckii* first appear as pasty, green-black colonies with a yeast-like appearance, and then change after approximately 2 weeks to a fuzzy, dematiaceous (dark in color) mold. Culture of *Malassezia* is generally not required; if necessary, the plate must be overlaid with sterile oil because of the organism's lipophilic nature.

Differential diagnosis

Piedra is generally diagnosed by clinical and microscopic inspection of a hair shaft and must be distinguished from pediculosis (nits), hair casts, trichorrhexis nodosa, trichomycosis axillaris (see Ch. 74 and Fig. 77.1), and the scales of psoriasis and eczema. Unlike eczema and psoriasis, the scalp will typically appear normal in piedra.

In most patients, the diagnosis of tinea nigra is made clinically and confirmed via KOH examination and/or fungal culture. Its distinction from acral melanocytic nevi has been discussed previously (see above); occasionally, tinea nigra could be confused with a fixed drug eruption, postinflammatory hyperpigmentation, or staining from chemicals, pigments and dyes. Cutaneous melanoma has even been clinically misdiagnosed as tinea nigra.

Clinical examination is often sufficient to recognize pityriasis versicolor. However, pityriasis alba and other forms of postinflammatory hypopigmentation (see Ch. 66), vitiligo, seborrheic dermatitis, pityriasis rosea, tinea corporis and secondary syphilis may be diagnostic considerations. Progressive macular hypomelanosis, which presents as non-scaly hypopigmented macules on the trunk of young adults and may be caused by *Propionibacterium acnes,* is often misdiagnosed as residual hypopigmentation related to pityriasis versicolor. Wood's light examination (revealing bright yellow fluorescence) and then direct microscopy of scales can confirm the diagnosis of pityriasis versicolor. *Pityrosporum* folliculitis must be differentiated from other causes of folliculitis (see Table 38.1), in particular itching folliculitis, as well as acne vulgaris.

Treatment

Clipping hairs with adherent nodules as well as shampooing the affected hairs with 2% ketoconazole shampoo is usually an effective treatment for piedra (see Table 77.4). Oral terbinafine may also be of therapeutic benefit. For treatment of tinea nigra, topical keratolytic agents such as Whitfield's ointment (typically 6% benzoic acid plus 3% salicylic acid[8]) are effective, as are topical azole or allylamine antifungal medications. Several weeks of therapy may be required to prevent recurrence of disease. Systemic therapy is generally not indicated, and griseofulvin is not effective.

Patients with pityriasis versicolor usually respond to topical antimycotic treatments. Treatment of all the skin from the neck down to the knees, even if only a small area is clinically involved, may lead to higher success rates. Ketoconazole (1% or 2%) or 2.5% selenium sulfide shampoo is quite effective. Treatment can be administered twice weekly for 2 to 4 weeks; the preparation is left on the skin for 10–15 minutes before rinsing. Other topical alternatives include azole/allylamine creams and lotions, 50% propylene glycol in water, nystatin, salicylic

acid and a variety of over-the-counter dandruff shampoos. Residual pigmentary changes often require weeks to months to resolve.

Systemic therapy with ketoconazole, fluconazole or itraconazole (see Ch. 127) can also be utilized for pityriasis versicolor. In randomized controlled trials of oral ketoconazole, cure rates varied from 84% (200 mg × 5 days) to 100% (200 mg × 5 weeks), while a cure rate of 100% was observed in several randomized controlled trials following a 5-day course of oral itraconazole (200 mg daily)[9]. One open-label trial of oral fluconazole (300 mg once weekly for 2 weeks) reported a 98% cure rate; there are few comparative studies of oral antifungal medications[9]. The rate of recurrence of pityriasis versicolor is very high, especially in hot humid climates. Patients at high risk for recurrence may be helped by using ketoconazole shampoo once weekly as a body cleanser. Another preventative measure is once-monthly dosing of oral ketoconazole (400 mg), fluconazole (300 mg) or itraconazole (400 mg). The treatment of *Pityrosporum* folliculitis is reviewed in Chapter 38.

Dermatophytoses

Synonyms: ■ Tinea corporis: ringworm, tinea circinata, tinea glabrosa ■ Tinea cruris: ringworm of the groin, eczema marginatum, jock itch, gym itch ■ Tinea barbae: tinea sycosis, barber's itch, ringworm of the beard ■ Tinea capitis: ringworm of the scalp/hair, tinea tonsurans, herpes tonsurans ■ Tinea pedis: ringworm of the foot, athlete's foot ■ Tinea unguium: ringworm of the nail, dermatophytic onychomycosis

Introduction

Dermatophytoses are fungal infections caused by three genera of fungi that have the unique ability to invade and multiply within keratinized tissue (hair, skin and nails). These fungi, collectively called "dermatophytes", are alike in their physiology, morphology and pathogenicity. The three genera are *Microsporum*, *Trichophyton* and *Epidermophyton*; species within these genera that do not invade keratinized tissue in animals or humans are not considered as dermatophytes. In naming clinical infections due to dermatophytes, "tinea" precedes the Latin name for the involved body site, e.g. "tinea pedis" refers to a dermatophyte infection of the foot. Ten species of dermatophytes are commonly isolated (Table 77.5), and an additional 20 are cultured occasionally. The most common dermatophytes causing disease in humans worldwide[11] are listed in Table 77.5.

History

Dermatophyte infections have been described since ancient times. In 1910, Sabouraud published the current categorization in which dermatophytes are classified by genera.

Epidemiology

Some dermatophytes are restricted geographically, while others are found worldwide. *Trichophyton rubrum*, for example, is the most common dermatophyte and has a global distribution, while *T. concentricum* is endemic to certain parts of the South Pacific and South America. Human travel and migration, coupled with advances in antifungal therapy, have brought about changes in the geographic distribution of dermatophytes. Other important epidemiologic factors include socioeconomic status, occupation, air conditioning and the use of footwear.

Overall, dermatophytoses occur most frequently in postpubertal hosts. One major exception is tinea capitis (dermatophytosis of the scalp), which occurs primarily in children. Risk factors for the development of a dermatophyte infection during childhood include household exposure to tinea capitis or tinea pedis; environmental factors such as contaminated hats, brushes and barber instruments; and (especially for tinea unguium) Down syndrome. Individuals with chronic mucocutaneous candidiasis or common variable immunodeficiency have a propensity to develop severe, chronic or recurrent dermatophytoses (see Ch. 60). Dermatophyte infections tend to be more severe and recurrent in HIV-infected patients. Men more frequently have tinea pedis, tinea cruris and tinea unguium than women.

Pathogenesis

Transmission of dermatophytes to humans occurs via three sources, each resulting in infections with characteristic features (Table 77.6).

DERMATOPHYTES ISOLATED AROUND THE WORLD		
		Thallus (macroscopic) appearance* and/or microscopic findings
MOST COMMON		
Trichophyton	*mentagrophytes* var. *mentagrophytes*	Granular front, buff reverse; pencil-shaped macroconidia, clusters of round microconidia, spiral hyphae
	mentagrophytes var. *interdigitale*	Downy front, buff reverse; see above
	rubrum	White wooly front, venous blood reverse; pencil-shaped macroconidia, teardrop-shaped microconidia
	tonsurans	Granular front, mahogany reverse; pencil-shaped macroconidia, microconidia of varying sizes
	verrucosum	Convoluted, cream to gray, compact; chains of chlamydospores at 37°C
	violaceum	Creamy, waxy, becomes violet
Microsporum	*canis*	White wooly front, orange reverse; multi-celled, spindle-shaped macroconidia with thick walls and rough surface
	ferrugineum	Folded red–orange (rust-colored) front
	gypseum	Cinnamon–tan granular front; multi-celled, cucumber-shaped macroconidia with thin walls
Epidermophyton	*floccosum*	Khaki green, suede to granular; beaver tail-shaped macroconidia; no microconidia
LESS COMMON		
Trichophyton	*ajelloi*	Powdery surface, resembles *Microsporum* spp.
	concentricum	Glabrous colonies; antler-like hyphae
	equinum	Club-shaped macroconidia
	gourvilii	Waxy, pink to red front
	megninii	Pink, felt-like front with red reverse
	schoenleinii	Glabrous; antler- and nailhead-like hyphae; rat-tail-like macroconidia (media often fissured)
	simii	Club-shaped macroconidia in clusters
	soudanense	Yellow to apricot front with fringed border
	terrestre	Cream to yellow granular surface
	yaoundei	Glabrous, chocolate-brown front
Microsporum	*amazonicum*	Multi-celled, spindle-shaped, macroconidia with large inclusions
	audouinii	Flat, tan front with salmon reverse; pectinate (comb-like) hyphae
	cookei	Oval, thick-walled macroconidia
	equinum	One- to four-celled macroconidia resembling *M. canis*
	fulvum	Bullet-shaped macroconidia with spiral hyphae
	gallinae	Diffusable pink–red pigment
	nanum	Two-celled macroconidia
	persicolor	Pink to red front and reverse, resembles *T. mentagrophytes*
	praecox	Powdery front with yellow–orange reverse
	racemosum	Cream-colored powdery front
	vanbreuseghemii	Largest macroconidia

*On Sabouraud's agar.

Table 77.5 Dermatophytes isolated around the world[10].

While dermatophytes are not especially virulent and typically invade only the outer, cornified layers of the skin, they can be responsible for considerable morbidity. The first stage of infection involves contact with and adherence of the infectious elements of the fungus (arthroconidia) to the skin. The ability of certain fungi to adhere to a particular host arises from a variety of microbial mechanisms and host factors[2].

Dermatophytes, unlike most other fungi, produce keratinases (enzymes that break down keratin), which allow invasion of the fungi

TYPES OF DERMATOPHYTES BASED ON MODE OF TRANSMISSION		
Category	**Mode of transmission**	**Typical clinical features**
Anthropophilic	Human to human	Mild to non-inflammatory, chronic
Zoophilic	Animal to human	Intense inflammation (pustules and vesicles possible), acute
Geophilic	Soil to human or animal	Moderate inflammation

Table 77.6 Types of dermatophytes based on mode of transmission.

COMMON DERMATOPHYTES THAT CAUSE TINEA CORPORIS	
Dermatophyte	**Clinical features**
ANTHROPOPHILIC	
Trichophyton rubrum	Commonly harbored by hair follicles; may produce concentric rings; can recur; causative organism in Majocchi's granuloma (nodular folliculitis) and most common cause of tinea corporis
T. tonsurans	Commonly seen in adults who care for children with tinea capitis caused by this organism
Epidermophyton floccosum	Generally restricted to groin, feet; responsible for eczema marginatum
T. concentricum	Responsible for tinea imbricata; infections typically chronic
T. mentagrophytes var. *interdigitale*	Causes interdigital tinea pedis, tinea cruris and onychomycosis
ZOOPHILIC	
T. mentagrophytes var. *mentagrophytes*	May be associated with dermatophytid reaction; causes inflammatory tinea pedis and tinea barbae; associated with exposure to small mammals
Microsporum canis	Associated with pet exposure (cat or dog)
T. verrucosum	May mimic bacterial furunculosis; associated with exposure to cattle
GEOPHILIC	
M. gypseum	Frequently associated with outdoor/occupational exposure; lesions may be inflammatory or bullous

Table 77.7 Common dermatophytes that cause tinea corporis.

into the stratum corneum. Mannans in the cell walls of dermatophytes have immuno-inhibitory effects. In *T. rubrum*, the mannans may also decrease epidermal proliferation, thereby decreasing the likelihood of the fungus being sloughed off prior to invasion. This mechanism is thought to contribute to the chronicity of infections caused by *T. rubrum*[12]. However, host factors such as protease inhibitors may limit the extent of invasion. If invasion is successful, disease occurs.

The severity of clinical disease is also affected by several host factors. Sebum has an inhibitory effect on dermatophytes, and the degree of disease activity may be related to the number and activity of sebaceous glands in a particular body region. Breaks in the skin barrier or macerated skin encourage dermatophyte invasion, and increased susceptibility may be inherited or related to the competency of the immune system. Once dermatophytes have invaded and begun to proliferate in the skin, several mechanisms aid in limiting the infection to keratinized tissue. These include the preference of dermatophytes for the cooler temperature at the skin's surface, serum factors that inhibit dermatophyte growth (e.g. β-globulins, ferritin and other metal chelators)[2] and the host immune system. Further invasion or dissemination is extremely unusual (see below). Other conditions influencing dermatophyte infections include skin disorders such as Darier disease, Hailey–Hailey disease and ichthyoses that affect cutaneous barrier function.

Clinical features

Tinea corporis

Tinea corporis is a dermatophyte infection of the skin of the trunk and extremities, excluding the hair, nails, palms, soles and groin. The infection is generally restricted to the stratum corneum and most commonly affects exposed skin. While tinea corporis occurs worldwide, it is most common in tropical regions. Any dermatophyte can potentially cause tinea corporis, but *T. rubrum* is the most common pathogen worldwide, followed by *T. mentagrophytes* (Table 77.7).

Tinea corporis can result from human-to-human (including autoinoculation, e.g. from tinea capitis or pedis), animal-to-human (often transmitted by domestic animals) or soil-to-human spread (see Table 77.6). Other factors that can predispose an individual to tinea corporis include occupational or recreational exposure (e.g. military housing, gymnasiums, locker rooms, outdoor occupations, wrestling), contact with contaminated clothing and furniture, and immunosuppression[13].

There are multiple clinical presentations of tinea corporis, and they can mimic other dermatologic conditions (Table 77.8). As with most dermatophyte infections, the extent of inflammation depends on the causative pathogen and the immune response of the host. Also, because hair follicles serve as reservoirs for infection, areas of the body with more hair follicles may be more resistant to treatment.

The typical incubation period is 1 to 3 weeks. Infection spreads centrifugally from the point of skin invasion, with central clearing of the fungus, typically resulting in annular lesions of varying sizes

DIFFERENTIAL DIAGNOSES OF DERMATOPHYTE INFECTIONS				
Tinea corporis	**Tinea cruris**	**Tinea faciei**	**Tinea capitis**	**Tinea pedis**
Dermatitis – Nummular eczema – Atopic – Stasis – Contact – Seborrheic (petaloid) Pityriasis versicolor Pityriasis rosea Parapsoriasis Erythema annulare centrifugum Annular psoriasis Subacute lupus erythematosus Granuloma annulare Impetigo	Cutaneous candidiasis Intertrigo – Seborrheic dermatitis – Psoriasis Erythrasma Contact dermatitis Lichen simplex chronicus Parapsoriasis/mycosis fungoides Hailey–Hailey disease Langerhans cell histiocytosis	Dermatitis – Seborrheic – Perioral – Contact Rosacea Lupus erythematosus Acne vulgaris Annular psoriasis (children)	Seborrheic dermatitis Alopecia areata Trichotillomania Psoriasis If pustules: – Pyoderma – Folliculitis If scarring: – Lichen planus – Discoid lupus erthematosus – Folliculitis decalvans – Central centrifugal cicatricial alopecia	Dermatitis – Dyshidrotic – Contact Psoriasis – Vulgaris – Pustular Juvenile plantar dermatosis Secondary syphilis If interdigital: – Erythrasma – Bacterial infection, e.g. GNR

C, Courtesy, Kalman Watsky, MD.*

(Fig. 77.6A). However, lesions may assume other shapes (e.g. arcuate, circinate, oval) (Fig. 77.6B–D). Most are scaly, although scale may be lessened or absent if topical corticosteroids have been used (tinea "incognito") (Fig. 77.6E). Pustules within the active border are suggestive of tinea (see Fig. 77.6D). Lesions can also be vesicular, granulomatous or verrucous in appearance. Associated symptoms include pruritus and burning.

Clinical variants of tinea corporis include tinea profunda, Majocchi's granuloma and tinea imbricata. Tinea profunda results from an excessive inflammatory response to a dermatophyte (analogous to a kerion on the scalp). It may have a granulomatous or verrucous appearance and be mistaken for cutaneous tuberculosis, a dimorphic fungal infection or squamous cell carcinoma. Majocchi's granuloma, usually caused by *T. rubrum*, is characterized by perifollicular papulopustules or granulomatous nodules (Fig. 77.7). This variant, commonly seen in women who have tinea pedis or onychomycosis and shave their legs, represents a deep dermatophyte folliculitis in which the wall of the follicle is disrupted. The lesions may be extensive or even vegetating and can also occur in the setting of immunosuppression.

Tinea imbricata is a dermatophytosis caused by the anthropophilic dermatophyte *T. concentricum*. It causes chronic infections in an equatorial band encompassing the South Pacific, Asia, and Central and South America. The clinical presentation consists of concentric annular rings resembling erythema gyratum repens.

Tinea cruris

Tinea cruris is a dermatophyte infection of the inguinal region, in particular the inner aspects of the upper thighs (Fig. 77.8) and crural folds, with occasional extension onto the abdomen and buttocks. While tinea cruris occurs worldwide, like most other dermatophyte infections, it is more common in tropical environments. The three most common causative agents are *Epidermophyton floccosum*, *T. rubrum* and *T. mentagrophytes* (Table 77.9).

This disease is more often seen in men than in women, since the scrotum provides a warm and moist environment that encourages fungal growth and men are more likely to have tinea pedis and onychomycosis as a source of dermatophytes. Other predisposing factors include obesity and excessive perspiration. Tinea cruris is frequently

Fig. 77.7 Majocchi's granuloma. Perifollicular inflammation and pustules on the buttocks due to *Trichophyton rubrum*.

Fig. 77.8 Tinea cruris. Note the arciform erythematous border on the upper inner thigh.

TINEA CRURIS: COMMON CAUSATIVE PATHOGENS	
Dermatophyte	**Clinical features**
Trichophyton rubrum	• Most common cause of tinea cruris • Infection tends to be chronic • Fungus not viable in scale (e.g. on furniture, rugs, linens) for long periods of time • Frequent extension to buttocks, waist and thighs
Epidermophyton floccosum	• Commonly associated with "epidemics" of tinea cruris in locker rooms or dormitories • Infection is acute (rarely chronic) • Arthroconidia are viable in scale (e.g. on furniture, rugs, linens) for long periods of time • Infection rarely extends beyond groin region • Causative agent of "eczema marginatum" (well-demarcated borders with multiple small vesicles or, sometimes, vesiculopustules)
T. mentagrophytes, in particular var. *mentagrophytes*	• Infection tends to be more severe and acute, with intense inflammation and pustule formation • May rapidly spread to the trunk and lower extremities, causing a severe inflammatory condition • Often acquired from animal dander

Table 77.9 Tinea cruris: common causative pathogens.

Fig. 77.9 Tinea manuum. Diffuse scaling of the palm of one hand, with accentuation in the creases.

associated with tinea pedis because clothing that is brought over the feet is contaminated and then comes in contact with skin in the groin region.

The initial sign of infection is usually an area of erythema and pruritus in the fold between the scrotum and the inner thigh. Characteristic lesions are sharply demarcated with a raised, erythematous, scaly advancing border that may contain pustules or vesicles. The lesion may initially be circinate and then become serpiginous. The disease can remain unilateral or become bilateral.

The duration of infection depends on the causative pathogen. Infections with *T. rubrum* and many other anthropophilic species tend to be chronic (sometimes even leathery and lichenified), while the zoophilic form of *T. mentagrophytes* (var. *mentagrophytes*) and other animal-acquired strains often cause acute infections with a prominent inflammatory component (with or without pustules; see Table 77.9). The scrotum itself is generally spared in tinea cruris. If the scrotum is involved or there are erosions or satellite pustules, cutaneous candidiasis should be considered. Measures to prevent recurrences of tinea cruris include wearing loose clothing, drying thoroughly after bathing, using topical powders, weight reduction (if obese), laundering contaminated clothing and linens, and treating concomitant tinea pedis.

Tinea manuum

Dermatophyte infections on the dorsal aspect of the hand have a clinical presentation similar to tinea corporis. However, dermatophyte infection of the palm and interdigital spaces has distinct characteristics and is referred to as tinea manuum. The reason for the two different clinical pictures is thought to be related to the lack of sebaceous glands on the palms. The typical causative organisms are the same as those for tinea pedis and tinea cruris: *T. rubrum*, *T. mentagrophytes* and *E. floccosum*. Two non-dermatophyte fungi that cause "tinea manuum" are *Scytalidium dimidiatum* and *S. hyalinum*.

Moccasin-type tinea pedis is often present in patients with tinea manuum, and the two share clinical features such as chronicity and hyperkeratosis. Tinea manuum is usually non-inflammatory and often unilateral ("two feet and one hand syndrome") (Fig. 77.9); there is diffuse hyperkeratosis of the palms and digits that fails to respond to emollients[14]. An important clinical clue is tinea unguium of the involved

hand, but infection of all the fingernails is uncommon. Other presentations include exfoliative, vesicular and papular variants. The differential diagnosis may include psoriasis, irritant or allergic contact dermatitis, dyshidrosis and a "dermatophytid" reaction.

Tinea barbae

Tinea barbae is a dermatophytosis that involves the bearded areas of the face and neck in men. The causative organisms are typically zoophilic dermatophytes, namely *T. mentagrophytes* var. *mentagrophytes* and *T. verrucosum*. Infection with *Microsporum canis* or *T. rubrum* is uncommon. In certain geographic regions, other anthropophilic dermatophytes (*T. schoenleinii, T. violaceum* and *T. megninii*) are endemic and cause tinea barbae. Disease is often acquired from animals. In the past, a common cause of infection was contaminated razors in barbershops. With the increased use of disposable razors and disinfectants, however, the incidence of tinea due to this source has been dramatically reduced.

Because zoophilic organisms are the most common culprit and due to the large number of terminal hair follicles in the affected areas, the clinical presentation tends to be severe, with intense inflammation and multiple follicular pustules. Abscesses, sinus tracts, bacterial superinfection and even kerion-like boggy plaques can develop. Patients may have constitutional symptoms such as malaise as well as lymphadenopathy and even scarring alopecia. A second type of tinea barbae is superficial, less inflammatory, and similar to tinea corporis; *T. rubrum* is usually the causative agent in this variant (Fig. 77.10). Alopecia may be present in the center of the lesion, but it is reversible. Other conditions that can mimic tinea barbae include bacterial folliculitis, viral infections (herpes simplex or zoster), acne vulgaris, cervicofacial actinomycosis and a dental sinus tract. Spontaneous resolution may occur if all of the infected hairs fall out.

Fig. 77.10 Tinea barbae. More superficial form due to *Trichophyton rubrum*. Several follicular pustules are seen. *Courtesy, Jean L Bolognia, MD.*

Tinea faciei

While some dermatophyte infections of the face have classic features, e.g. scale, annular configuration, pustules in the border (Fig. 77.11), others can be more difficult to diagnose clinically ("tinea incognito"; see Table 77.8) and require a high index of suspicion.

Tinea capitis

Tinea capitis (Fig. 77.12) is a common dermatophyte infection of the scalp in children, whereas adult infection occurs infrequently. The causative pathogens are members of only two genera: *Trichophyton* and *Microsporum*. *T. tonsurans* is currently the most common cause of tinea capitis in the US (accounting for ≥90% of cases), with a predilection for individuals of African descent[15], and *M. canis* is the second most frequent etiology. The incidence of tinea capitis due to *T. violaceum* (which is endemic in Africa) has recently increased in some areas of the US, likely reflecting immigration patterns. Worldwide, there is a great deal of variation in the epidemiology of tinea capitis, but *T. tonsurans* (as well as *M. canis*) has become a major cause of tinea capitis in Europe and elsewhere. The anthropophilic dermatophyte *M. audouinii*, which was once common and then subsequently diminished secondary to social and therapeutic advances, has recently reappeared in Europe and may potentially re-emerge in the US as well.

Different clinical presentations arise from the various causative organisms. For example, *T. tonsurans* causes an endothrix infection (see below), which classically results in "black dot" tinea capitis due to hair breakage near the scalp. In contrast, *M. audouinii* is an ectothrix form of tinea capitis that typically presents with dry, scaly patches of alopecia ("gray patch" tinea capitis). The pathogenicity of the culprit organism is not the only factor in determining the severity of disease; the host immune response to the organism plays an important role as well. Tinea capitis can range from a non-inflammatory scaling that resembles seborrheic dermatitis (especially *T. tonsurans*; Fig. 77.12A) to a severe pustular eruption with alopecia, known as a kerion. Alopecia with or without scale is the most common presentation of tinea capitis (Fig. 77.12B–D). The alopecia may occur in discrete patches or involve the entire scalp. Use of dermoscopy can highlight "comma", "corkscrew" and dystrophic broken hairs that represent clues to the diagnosis of tinea capitis (see Ch. 69)[16]. Many patients have posterior cervical and posterior auricular lymphadenopathy, which is helpful in differentiating tinea capitis from less inflammatory scalp disorders that cause alopecia, such as alopecia areata.

A kerion results from advanced disease coupled with an exaggerated host response that leads to boggy, purulent plaques with abscess formation and associated alopecia (Fig. 77.12E). Some patients may even

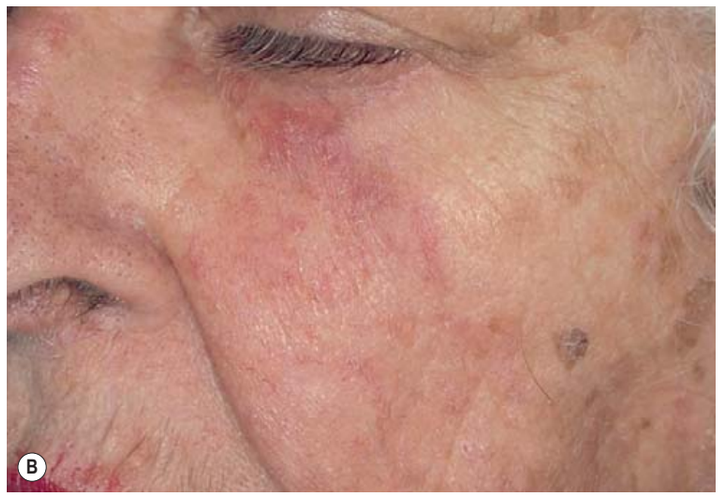

Fig. 77.11 Tinea faciei. A Area of erythema and scale on the nose and philtrum of a young child. **B** Serpiginous lesion with minimal scale on the upper cheek of an older woman. *A, Courtesy, Julie V Schaffer, MD. B, Courtesy, Jean L Bolognia, MD.*

become systemically ill with extensive lymphadenopathy. The hair in the affected area usually returns, but the longer the infection persists, the more likely the alopecia will be permanent. If a kerion is misdiagnosed as a bacterial abscess or other condition and treated (after incision and drainage or partial excision) with antibiotics, the infection will likely worsen, thereby increasing the likelihood of scarring alopecia.

The "carrier state" of *T. tonsurans* tinea capitis refers to a clinical situation in which there are no obvious signs or symptoms of a scalp infection, yet a positive fungal culture is obtained. Although also seen in children, this typically occurs in adults who have been exposed to infected children. The carriers shed the fungus and are considered contagious[17]. Consequently, some experts advocate treating all carriers with oral or topical antimycotics.

For those dermatophytes that invade hair, three patterns of invasion exist: endothrix, ectothrix and favus (Fig. 77.13):

- The *endothrix pattern* results from infection with anthropophilic fungi in the genus *Trichophyton* and is characterized by non-fluorescent arthroconidia within the hair shaft (see Fig. 77.12F). The clinical presentation varies from scaling to "black dots" with patchy alopecia to kerion formation. *T. tonsurans* and *T. violaceum* are important causes of endothrix infection.
- The *ectothrix pattern* occurs when arthroconidia are formed from fragmented hyphae outside the hair shaft (see Fig. 77.13). Cuticle destruction ensues. Ectothrix infection can be fluorescent (*Microsporum*) or non-fluorescent (*Microsporum* and *Trichophyton*), as determined by Wood's lamp examination. Clinical features vary from patchy, scaly alopecia with little inflammation (that may mimic alopecia areata) to kerion formation.
- *Favus* is the most severe form of dermatophyte hair infection and is most frequently caused by *T. schoenleinii*. Hyphae and air spaces are observed within the hair shaft, and a bluish-white fluorescence by Wood's light examination is typically seen. Favus presents as thick, yellow crusts composed of hyphae and skin debris ("scutula"). Scarring alopecia may develop in chronic infections (Fig. 77.14).

There are many scalp and hair disorders that lead to scaling or alopecia (scarring and non-scarring) that are not due to fungal infections (see Table 77.8). However, one should always consider and exclude a fungal infection (especially in children), because the treatment is typically quite simple and effective, and chronic untreated tinea capitis can lead to

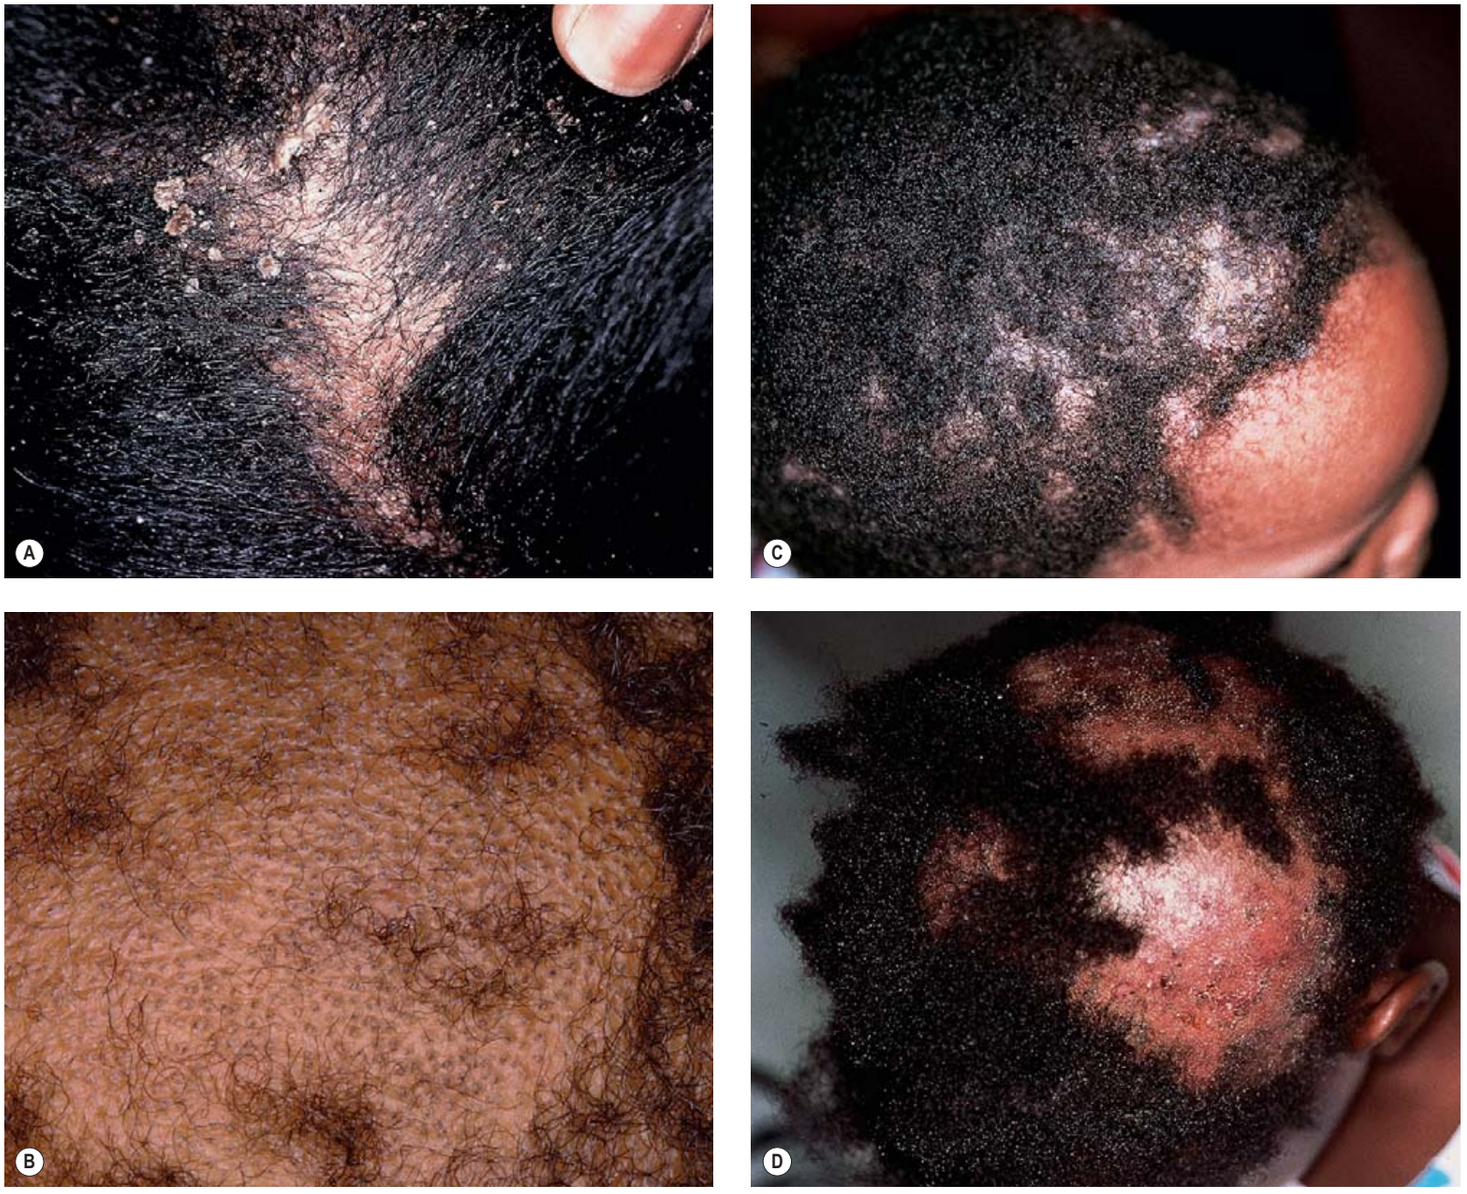

Fig. 77.12 Tinea capitis. The range of clinical presentations of tinea capitis due to *Trichophyton tonsurans*, from mild scalp scaling (**A**) to patchy alopecia with black dots (**B**) or scale (**C**) to large areas of alopecia with pustules and scale-crust (**D**). *B, Courtesy, Louis A Fragola, Jr, MD.*

scarring alopecia. Oral therapy is required, as the drug must penetrate the hair follicle to be effective. Also important in the management of tinea capitis are preventive measures. Because the disease is contagious, all individuals residing with the infected patient should be examined for signs of tinea capitis and appropriately treated. Chronicity may develop if a child is continually re-exposed from untreated family members. Appropriate adjunctive treatment for household contacts (as well as the patient) includes regular (e.g. every other day) use of an antifungal shampoo, such as 2% ketoconazole or 2.5% selenium sulfide, until the patient is free of disease. Although routine screening in schools is difficult, screening children who have two or more infected classmates may be beneficial[18]. Also, combs, brushes and headwear used by the patient should be disinfected or (preferably) discarded.

Tinea pedis

Tinea pedis is a dermatophyte infection of the soles and interdigital web spaces of the feet. Infection of the dorsal aspect of the foot is considered tinea corporis. The feet are the most common location for dermatophyte infections, and the majority of the US adult population has experienced tinea pedis. This condition is more common in adults than children and is found around the world, affecting both sexes. The lack of sebaceous glands and the moist environment created by occlusive shoes are important factors in the development of tinea pedis[19]. In fact, tinea pedis is uncommon in populations that do not wear shoes. However, the fungus may be acquired from going barefoot (locker rooms, gyms, public facilities). Host factors that contribute to the pathogenesis of tinea pedis have yet to be identified.

The dermatophytes that are typically responsible for tinea pedis are *T. rubrum*, *T. mentagrophytes*, *E. floccosum* and *T. tonsurans* (in children). Non-dermatophyte pathogens that produce clinical findings identical with tinea pedis include *S. dimidiatum* and *S. hyalinum* (moccasin and interdigital types) and, occasionally, *Candida* spp. (interdigital type). There are four major clinical types of tinea pedis, as outlined in Table 77.10: moccasin (Fig. 77.15A), interdigital (Fig. 77.15B), inflammatory (Fig. 77.15C) and ulcerative. Each type has different associated morbidities and complications that can affect diagnostic considerations and therapeutic options. These include bacterial superinfection (the "dermatophytosis complex"), dermatophytid reactions, cellulitis (especially in patients who have venous hypertension, harvested saphenous veins and chronic edema), and even osteomyelitis leading to amputation in diabetics. Other conditions that can mimic tinea pedis are listed in Table 77.8. KOH examination and culture easily differentiate the moccasin and inflammatory forms of tinea pedis from these entities[20]. Erythrasma can be diagnosed with Wood's light examination because of its "coral red" fluorescence. The use of oral antifungals should be considered in diabetics, immunocompromised patients, and those with moccasin-type tinea pedis. Finally, other dermatophyte infections often occur together with tinea pedis – in particular, tinea cruris, onychomycosis and tinea manuum – and these sites should be examined.

Tinea unguium (dermatophytic onychomycosis)

Onychomycosis is a term used to encompass all fungal infections of the nail and includes those due to dermatophytes as well as non-dermatophytes. It is divided into three patterns based upon the point of fungal entry into the nail unit:

- *distal/lateral subungual,* with invasion via the hyponychium (most common; Fig. 77.16A–C)
- *superficial white,* with direct penetration into (and usually confinement to) the dorsal surface of the nail plate (often due to *T. mentagrophytes* [var. *interdigitale*]; see Fig. 77.16D,E)
- *proximal subungual,* with invasion under the proximal nail fold (frequently in immunocompromised hosts).

Onychomycosis can be challenging to manage due to difficulties in diagnosis, the requirement for long treatment periods, potential side effects of systemic medications, and frequent recurrences. Although many consider onychomycosis solely as an annoyance, patients with the condition often complain of discomfort and pain associated with trimming the nails, running, and other activities such as dancing. In addition, serious complications such as cellulitis can result from onychomycosis, especially in patients who are diabetic or

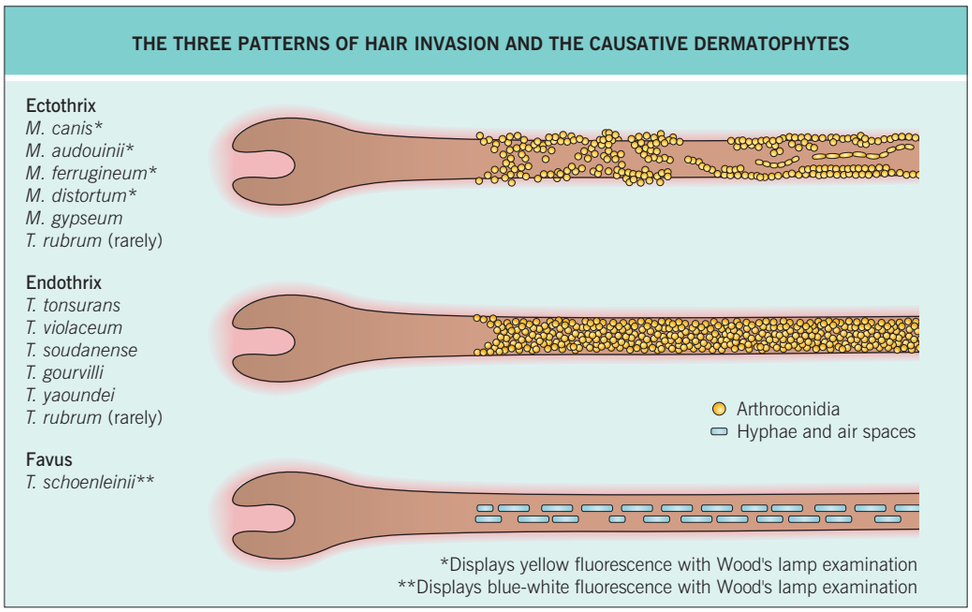

Fig. 77.13 The three patterns of hair invasion and the causative dermatophytes.

Fig. 77.14 Favus due to *Trichophyton schoenleinii*. Scarring alopecia with erosions and several scutula on the occipital scalp. The latter represent masses of keratin plus fungi.
Courtesy, Israel Dvoretzky, MD.

immunocompromised. Infections with non-dermatophytes such as *Fusarium* spp. (see below) are of particular concern in the latter group.

Tinea unguium refers specifically to dermatophyte infection of the nail unit. It occurs worldwide, affects men more often than women, and is frequently associated with chronic tinea pedis. Trauma and other nail disorders represent predisposing factors. All dermatophytes can cause tinea unguium, but the most common causative pathogens are *T. rubrum*, *T. mentagrophytes* and *E. floccosum* (and, rarely, *Microsporum* spp.).

Toenail infections are considerably more common than fingernail infections, and only rarely does fingernail onychomycosis occur without concurrent toenail infection. A single nail may be involved, but more commonly, multiple nails on one or both hands or feet are affected. In the distal/lateral subungual type, invasion of the hyponychial region leads to hyperkeratosis of the nail bed. With further progression of infection, there is yellowing and thickening of the distal nail plate as well as onycholysis (Fig. 77.16A,B), which provides an ideal environment for further proximal invasion and growth of the dermatophyte. Eventually, the entire nail bed and plate may become involved (total dystrophic pattern).

The clinical appearance of the superficial white type of onychomycosis can vary based on host factors (e.g. immunosuppression) and the causative organism. Discrete white patches (Fig. 77.16D) are seen in the classic form due to *T. mentagrophytes* (var. *interdigitale*). However, transverse striate bands (Fig. 77.16E), origination from the proximal nail fold (which may overlap with the proximal subungual type if there is also invasion under the nail fold), and deeper invasion of the nail plate can also occur. These variants are more likely be caused by *T. rubrum* (with more invasive forms observed in healthy children as well as individuals with HIV infection) or (with deep invasion of the nail plate) non-dermatophyte molds such as *Fusarium* spp.[21]

Although nail dystrophy can be the result of a number of insults and conditions (e.g. trauma, psoriasis and inherited disorders; see Ch. 71; Fig. 77.17), an estimated 50% or more of cases are due to fungal infection (onychomycosis). Dermatophytes account for ~90% of cases of onychomycosis, and the remainder are due to yeasts or non-dermatophyte molds (Table 77.11). *Candida* spp. are often found in association with chronic paronychia (see Ch. 71), and infection of the nail may occur in this setting. The fingernails are usually affected, with ridging, yellow discoloration and onycholysis. *Candida* spp. are a relatively common cause of onychomycosis in children less than 3 years of age, and nail involvement also represents a manifestation of chronic mucocutaneous candidiasis (see Ch. 60).

Pathology

Tinea pedis, manuum, faciei, cruris and corporis are usually diagnosed via KOH examination (see Fig. 77.5B,C) and occasionally with fungal cultures. The chlorazol black E stain can help to highlight fungal elements in KOH preparations. Use of calcofluor, a fluorescent stain specific for the chitin in the fungal cell wall, and examination with a fluorescent microscope can also demonstrate fungi (apple-green fluorescence).

If biopsies are performed of cutaneous dermatophyte infections, hyphae are seen within the stratum corneum; the fungi are made more apparent by PAS or silver stains. In dermatophytoses affecting glabrous skin, spongiosis, parakeratosis and pustules are often seen. In onychomycosis, hyphae and arthroconidia may be visible in the nail plate and nail bed with PAS staining, and little to no inflammation is generally present[2]. Histologic examination of formalin-fixed, PAS-stained nail plates is a quick and reliable method for diagnosing onychomycosis (see Fig. 77.16F), with a sensitivity of 80% to >95% (compared to 35–60% for culture alone)[22]. Biopsy specimens of tinea capitis, Majocchi's granuloma and tinea barbae can demonstrate hyphae or arthroconidia within hair shafts and are usually done if the diagnosis is suspected but KOH examination and culture are negative. However, false-negative results are a potential problem and tissue should also be sent for culture.

Table 77.10 The four major types of "tinea pedis" caused by dermatophytes and non-dermatophytes. CMI, cell-mediated immunity.

THE FOUR MAJOR TYPES OF "TINEA PEDIS" CAUSED BY DERMATOPHYTES AND NON-DERMATOPHYTES			
Type	**Causative organism**	**Clinical features**	**Treatment considerations**
Moccasin	*Trichophyton rubrum* *Epidermophyton floccosum*	Diffuse hyperkeratosis, erythema, scaling and fissures on one or both plantar surfaces; frequently chronic and difficult to cure*; may be associated with fungal CMI deficiency	Topical antifungal plus product with urea or lactic acid; may require oral antifungal therapy
	Scytalidium hyalinum *S. dimidiatum*		
Interdigital	*T. mentagrophytes* (var. *interdigitale*) *T. rubrum* *E. floccosum*	Most common type; erythema, scaling, fissures and maceration in the web spaces; the two lateral web spaces are most commonly affected; "dermatophytosis complex" (fungal infection followed by bacterial invasion†) can develop; pruritus common; may extend to dorsum and sole of foot	Topical antifungal; may require topical or oral antibiotic if superimposed bacterial infection
	S. hyalinum *S. dimidiatum* *Candida* spp. *Fusarium* spp.		
Inflammatory (vesicular)	*T. mentagrophytes* (var. *mentagrophytes*)	Vesicles and bullae on the medial foot; often associated with the dermatophytid reaction‡	Topical antifungal usually sufficient
Ulcerative	*T. rubrum* *T. mentagrophytes* *E. floccosum*	Typically an exacerbation of interdigital tinea pedis; ulcers and erosions in the web spaces; commonly secondarily infected with bacteria; seen in immunocompromised and diabetic patients	Topical antifungal; may require topical or oral antibiotics if secondary bacterial infection (common)

Dermatophytes Non-dermatophytes

*Because of the thickness of stratum corneum on plantar surfaces and the inability of *T. rubrum* to elicit an immune response sufficient to eliminate the fungus[20].

†Often *Pseudomonas, Proteus* spp.or *Staphylococcus aureus.*

‡Reaction to fungal elements presenting as a dyshidrotic-like eruption on the ÿngers and palms (culture negative for fungus).

Fig. 77.15 Tinea pedis. Diffuse scaling in the moccasin type (**A**), maceration between the third and fourth toes in the interdigital form (**B**), and erythema, scale-crust and bullae in the inflammatory form (**C**). The patient in A also has involvement of the right hand, i.e. one hand–two feet tinea. *B, Courtesy, Jean L Bolognia, MD.*

Differential diagnosis

Careful clinical examination is the first and most important step in diagnosing dermatophyte infections. Because many other conditions can mimic dermatophytoses (see Table 77.8 and Fig. 77.17), KOH examination and/or culture are often necessary to confirm the diagnosis. Guidelines for proper specimen collection are outlined in Figure 77.18. Because all dermatophytes have hyaline hyphae, they essentially look the same in KOH preparations (see Fig. 77.5B). When identification of the particular species will provide helpful information or culture is needed to confirm the diagnosis, the specimen is cultured at 25–30°C (and in some instances also at 37°C) for 2 to 4 weeks.

Colonial morphology, microscopic examination of conidia (the asexual propagules formed *de novo* by the fungus), noting the growth rate/requirements, and biochemical tests allow precise identification of the dermatophyte. The presence or absence of microconidia (usually small and unicellular) and macroconidia (usually larger and multicellular) and the typical features of each (such as shape and cell wall texture) remain fairly consistent among genera (Fig. 77.19). Other distinguishing microscopic features include the identification of arthroconidia (infective fungal elements) and chlamydoconidia. Sometimes, conidia may not be present in culture ("sterile" organism), and the hyphal patterns (spiral, pectinate, antler, racquet, and nodular bodies)

Fig. 77.16 Tinea unguium. Onycholysis, yellowing, crumbling and thickening of the fingernails (**A**), thumb nails (**B**) and toenails (**C**) in the distal/lateral subungual variant. Diffuse (**D**) and striate (**E**) white discoloration of the toenail in the superficial white variant. Hyphae within a formalin-fixed, PAS-stained nail plate (**F**). *A, C, D, Courtesy, Jean L Bolognia, MD. B, Courtesy, Louis A Fragola, Jr, MD. F, Courtesy, Mary Stone, MD.*

may be important in identification of the organism. The color, texture and topography of the colony are features that are typical of, or even unique to, a particular species (see Table 77.5).

Dermatophytes are able to grow on media containing cycloheximide (e.g. Mycosel®, DTM [dermatophyte test medium]). However, some clinically relevant non-dermatophyte fungi do not (e.g. *Scopulariopsis brevicaulis*, *Aspergillus* spp., *Cryptococcus neoformans*, *Candida tropicalis*, *Pseudallescheria boydii*, *Trichosporon beigelii*). These can potentially be missed if specimens, in particular from nails, are grown only on cycloheximide-containing media[23].

Treatment

Topical antifungals (see Ch. 127) are the first-line treatment for many patients with uncomplicated, localized cutaneous dermatophyte infections such as tinea corporis, tinea cruris and tinea pedis. The major potential adverse reaction is irritant (or, occasionally, allergic) contact dermatitis, usually from the alcohols or other components in the vehicle[24]. Systemic antifungal therapy, although associated with a higher incidence of side effects (including potentially severe adverse reactions; see Ch. 127), is required to cure certain infections, including tinea manuum, capitis and unguium. Suggested regimens are presented

in Table 77.12. In general, oral treatment is also needed for infections involving extensive areas of skin, in hairy sites other than the scalp (e.g. tinea barbae), or associated with excessive inflammatory reactions. The adjunctive use of topical products containing glycolic acid, lactic acid or urea may help to reduce the amount of hyperkeratosis in infections such as tinea manuum and tinea pedis.

Treatment of tinea unguium deserves special consideration. Oral antifungal therapy is generally required (see Table 77.12), with the occasional exception of classic superficial white onychomycosis, and removal of dermatophytomas (subungual pockets of densely packed hyphae) is recommended. Although "cure" rates of up to 80% (or higher with prolonged therapy) have been reported[7] with newer antifungal drugs (itraconazole, fluconazole and terbinafine), recurrent disease, especially in toenails, is common. Preventive measures include breathable footwear and cotton socks, antifungal or absorbent powders, frequent nail clipping and avoiding re-exposure (e.g. not going barefoot in locker rooms). Old shoes often harbor large numbers of infectious organisms and should be discarded or treated with disinfectants or antifungal powders.

Combination therapy consisting of a topical corticosteroid plus a topical antifungal has been advocated by some clinicians for the treatment of dermatophyte infections. While a reduction in inflammation can be seen, the negative effects of high-potency corticosteroids on immune defenses coupled with restrictions on treatment duration to avoid side effects such as striae lead to an unacceptable failure rate[25]. Low-potency corticosteroids are a safer option when anti-inflammatory activity is needed.

Invasive dermatophytosis

Rarely, dermatophytes proliferate within the dermis. Invasion or dissemination of dermatophytes is most often seen in the setting of a chronic dermatophyte infection (most commonly *T. rubrum*) in an

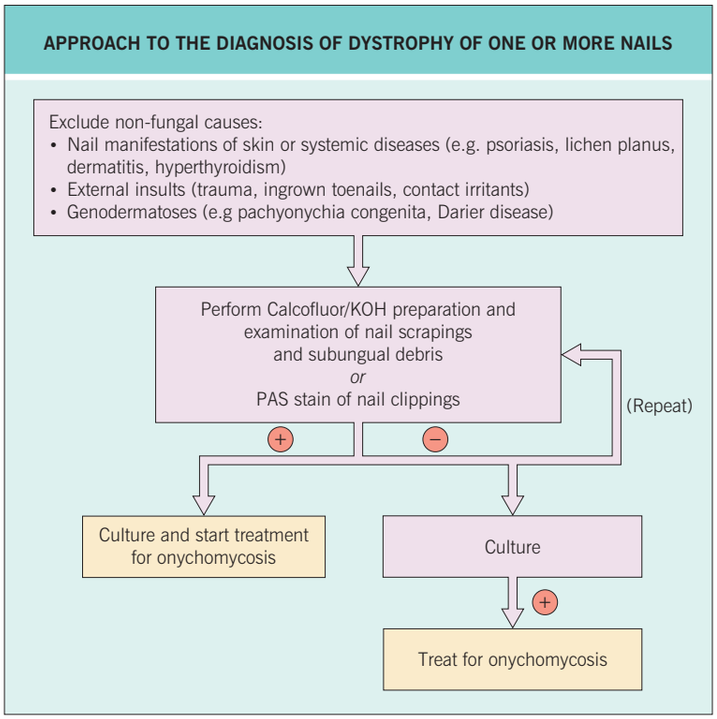

Fig. 77.17 Approach to the diagnosis of dystrophy of one or more nails. An organized approach is essential in correctly and efficiently diagnosing onychomycosis.

NON-DERMATOPHYTE MOLDS THAT CAN CAUSE ONYCHOMYCOSIS

Fungus	Key features
Fusarium spp.	Superficial white pattern*
Aspergillus spp.	Superficial white pattern*
Acremonium	Superficial white pattern*
Scopulariopsis brevicaulis	Lateral yellow–brown discoloration KOH of nail reveals lemon-shaped conidia and atypical hyphae
Scytalidium hyalinum	Whitish discoloration of the nail†
Scytalidium dimidiatum	Black discoloration of the nail†

*Deeper invasion of the nail plate can also occur.
†May also be associated with paronychia or tinea pedis.

Table 77.11 Non-dermatophyte molds that can cause onychomycosis.

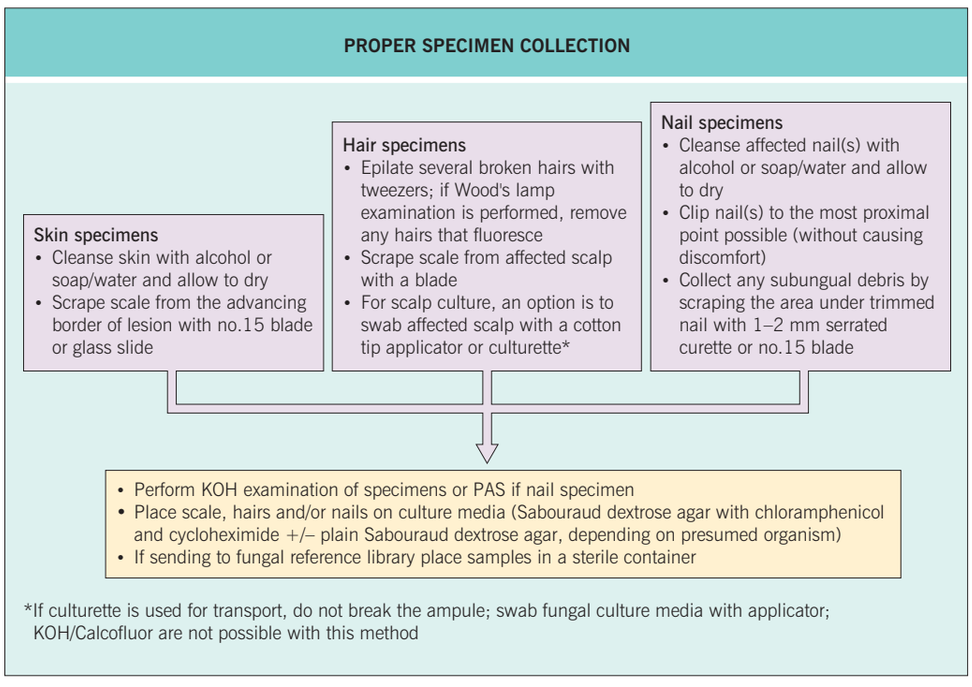

Fig. 77.18 Proper specimen collection. Proper collection of skin, hair and nails is important. Following these simple guidelines will help the clinician to achieve the most accurate diagnosis. *Courtesy, Judy Warner.*

immunosuppressed individual. Hematogenous spread can lead to an acute onset of ulcerating or draining dermal and subcutaneous nodules. A more indolent process can also occur and most often presents as tender nodules on the extremities. Currently, the recommended treatment is surgical excision (if localized) and systemic itraconazole or terbinafine[26,27], but amphotericin B, griseofulvin and ketoconazole have also been used successfully.

Mucocutaneous Candida *infections*

Mucocutaneous candidiasis has a wide spectrum of clinical presentations. Early descriptions of oral candidiasis (thrush) were made by Hippocrates. In the 1940s, the association between oral antibiotics and candidal infections was recognized. Oral infection often presents as thrush (white exudate resembling cottage cheese; pseudomembranous form) (Fig. 77.20A,B) or as a patch of erythema (chronic atrophic form); it can also produce adherent white plaques (chronic hyperplastic form) as well as glossitis (painful atrophy of the dorsal tongue). Other presentations include denture stomatitis, angular cheilitis (perlèche) (Fig. 77.20C), vulvovaginitis and balanitis (see Ch. 73). Predisposing factors for mucocutaneous candidiasis include diabetes mellitus, xerostomia, occlusion, hyperhidrosis, the use of corticosteroids and broad-spectrum antibiotics, and immunosuppression, including HIV infection[28]. In the case of angular cheilitis, overlap of the skin at the angles of the mouth, which is common in edentulous and elderly patients, is a key contributing factor, along with use of orthodontic appliances, drooling, atopic dermatitis, and (occasionally) iron or vitamin deficiencies (e.g. B_2).

Cutaneous *Candida* infections present with markedly erythematous, sometimes erosive, patches that are often accompanied by satellite papules and pustules (Fig. 77.20D–F). The most common sites of involvement are intertriginous zones (e.g. submammary, beneath pannus, inguinal creases, intergluteal fold) and the scrotum, as well as the diaper area in infants. Candidiasis is sometimes superimposed on intertriginous seborrheic dermatitis or psoriasis. *Candida* can also infect the periungual areas (e.g. in the setting of chronic paronychia), nails (see Onychomycosis above) and web space between the third and fourth fingers (erosio interdigitalis blastomycetica; Fig. 77.20G), especially in individuals whose hands are frequently exposed to water.

Mucocutaneous candidiasis is most commonly due to *C. albicans*, followed by *C. tropicalis*. The diagnosis is established by the presence of budding yeast and pseudohyphae on KOH examination (see Fig. 77.5D) and by a positive fungal culture. *C. albicans* and *C. stellatoidea* can be distinguished by their ability to form chlamydocondidia on cornmeal-Tween 80 agar. Identifying and removing predisposing factors is very important in the management of mucocutaneous candidiasis. Topical nystatin and azole antifungals are generally effective therapy[29,30]. When oral therapy is required, options include fluconazole and itraconazole (see Ch. 127). Treatment options for various forms of mucocutaneous candidiasis are outlined in Table 77.13.

Chronic mucocutaneous candidiasis

This is discussed in detail in Chapter 60. Chronic mucocutaneous candidiasis is not a single entity but rather a clinical manifestation of a number of disorders, including primary immunodeficiencies. Patients have defects in cellular immunity that prevent effective handling of *Candida* organisms, leading to chronic, sometimes therapy-resistant, infections of the skin (including granulomatous lesions), nails and mucosae. Some patients have associated autoimmune endocrinopathies as well as alopecia areata and vitiligo. Therapy involves oral fluconazole and itraconazole (see Table 77.13).

Granuloma gluteale infantum/adultorum and perianal pseudoverrucous papules/nodules

Granuloma gluteale infantum/adultorum is a reactive condition that occurs in the setting of chronic, severe irritant contact dermatitis in the anogenital region of either infants with chronic diarrhea or children and adults with encopresis or urinary incontinence[31]. It exists on a spectrum with perianal pseudoverrucous papules/nodules, and the term *Jacquet's erosive dermatitis* has been used for a variant with prominent punched-out erosions[32]. Erythematous to violaceous nodules and plaques, often ovoid in shape and sometimes eroded, develop on the vulva (Fig. 77.21), lower buttocks, perianal region and occasionally the scrotum. Similar to *Candida* infections, satellite pustules may also be seen. In addition to chronic irritation (e.g. from frequent loose stools), predisposing factors may include occlusion, topical corticosteroid use and candidal infection. Histologically, epidermal hyperplasia, a variably dense mixed inflammatory infiltrate in the dermis and vascular proliferation are typically observed. Although barrier creams and topical antifungal agents may have some benefit, the condition tends to persist until the irritant trigger is eliminated.

SUBCUTANEOUS MYCOSES

The "subcutaneous" mycoses are due to a large and diverse group of organisms that cause disease when implanted or otherwise introduced into the dermis or subcutis. Chromoblastomycosis, mycetoma, sporotrichosis and lobomycosis are discussed in detail in this section.

Another chronic subcutaneous fungal infection is basidiobolomycosis, which is caused by *Basidiobolus ranarum*. Although this organism is an environmental saprophyte that is found worldwide, the associated infection occurs most commonly in children living in tropical and subtropical climates. The most common portal of entry is the skin, typically after arthropod bites or minor trauma. Clinically, the disease manifests as a solitary, painless, indurated subcutaneous nodule or swelling of the thigh or buttock. The classic treatment is saturated solution of potassium iodide (SSKI; see Ch. 100), although successful results have been reported with ketoconazole and trimethoprim–sulfamethoxazole. Surgical excision is not recommended. A related organism, *Conidiobolus coronatus*, causes an infection that has similar clinical features but typically affects the face (especially the nasal region).

Although not a true fungal disease, protothecosis is treated with antifungal agents and is due to implantation. *Prototheca* (usually *P. wickerhamii*) is a genus of achlorophyllic algae that can be introduced

SUGGESTED SYSTEMIC REGIMENS FOR DERMATOPHYTOSES				
	Fluconazole	**Griseofulvin**	**Itraconazole***	**Terbinafine**
Tinea pedis (moccasin type)/ tinea manuum (adults)	150–200 mg/week × 4–6 weeks	750–1000 mg/day (microsize) or 500–750 mg/day (ultramicrosize) × 4 weeks	200–400 mg/day × 1 week	250 mg/day × 2 weeks
Tinea pedis (moccasin type)/ tinea manuum (children)	6 mg/kg/week × 4–6 weeks	15–20 mg/kg/day (microsize suspension) × 4 weeks	3–5 mg/kg/day (maximum 400 mg) × 1 week	Daily dosing as for tinea capitis (see below) × 2 weeks
Tinea unguium (adults)	Toenail ± fingernail involvement: 150–200 mg/week × 9 months	1–2 g/day (microsize) or 750 mg/day (ultramicrosize) until nails are normal†	200 mg/day × 12 weeks or 200 mg bid × 1 week/month for 3–4 consecutive months	250 mg/day × 12 weeks
	Fingernail involvement only: 150–200 mg/week × 6 months	1–2 g/day (microsize) or 750 mg/day (ultramicrosize) until nails are normal†	200 mg/day × 6 weeks or 200 mg bid × 1 week/month for 2 consecutive months	250 mg/day × 6 weeks
Tinea unguium (children)	6 mg/kg/week × 3–4 months (fingernails) or 5–7 months (toenails)	20 mg/kg/day (microsize suspension) until nails are normal†	5 mg/kg/day (<20 kg), 100 mg/day (20–40 kg), 200 mg/day (40–50 kg), or 200 mg bid (>50 kg) × 1 week/ month for 2 (fingernails) or 3 (toenails) consecutive months	62.5 mg/day (<20 kg), 125 mg/day (20–40 kg) or 250 mg/day (>40 kg) × 6 weeks (fingernails) or 12 weeks (toenails)
Tinea corporis (extensive, adults)	150–200 mg/week × 2–4 weeks	500–1000 mg/day (microsize) or 375–500 mg/day (ultramicrosize) × 2–4 weeks	200 mg/day × 1 week	250 mg/day × 1 week
Tinea corporis (extensive, children)	6 mg/kg/week × 2–4 weeks	15–20 mg/kg/day (microsize suspension) × 2–4 weeks	3–5 mg/kg/day (maximum 200 mg) × 1 week	Daily dosing as for tinea capitis (see below) × 1 week
Tinea capitis (adults)‡	6 mg/kg/day × 3–6 weeks	10–15 mg/kg/day (ultramicrosize; usually maximum 750 mg/day) × 6–8 weeks	5 mg/kg/day (maximum 400 mg) × 4–8 weeks	250 mg/day × 3–4 weeks§
Tinea capitis (children)‡	6 mg/kg/day × 3–6 weeks	20–25 mg/kg/day (microsize suspension) × 6–8 weeks	5 mg/kg/day (maximum 500 mg) × 4–8 weeks	Granules: 125 mg (<25 kg), 187.5 mg (25–35 kg) or 250 mg (>35 kg) × 3–4 weeks§

*Not approved in US for use in children.
†No longer commonly used for this indication.
‡Combined with 2.5% selenium sulfide shampoo or ketoconazole 2% shampoo; "id" reaction should not be confused with a medication allergy.
§Not recommended for *Microsporum canis*, unless given at double-dose.

Table 77.12 Suggested systemic regimens for dermatophytoses. bid, twice daily.

into the skin via trauma, often in the setting of exposure to contaminated water. Common clinical presentations include solitary cutaneous plaques (sometimes eczematous), nodules or ulcers, as well as olecranon bursitis. The extremities are the most frequent sites of involvement. Although immunocompetent patients typically have chronic, stable disease, patients who are immunocompromised can have widespread disease, including algemia. Protothecosis is difficult to treat; surgical excision and systemic antifungals (e.g. amphotericin B) are more effective in immunocompetent hosts.

Chromoblastomycosis

Synonyms: ■ Chromomycosis ■ Cladosporiosis ■ Verrucous dermatitis ■ Phaeosporotrichosis ■ Pedroso's disease ■ Fonseca's disease

Introduction

Chromoblastomycosis presents as a "verrucous dermatosis" and is caused by several genera of dematiaceous (pigmented) fungi. Typically chronic in nature, an expanding verrucous plaque on the lower, or occasionally upper, extremity is the classic presentation. There are six fungi that are responsible for the vast majority of cases: *Fonsecaea pedrosoi*, *Fonsecaea compacta*, *Fonsecaea monophora*, *Phialophora verrucosa*, *Cladophialophora carrionii (formerly Cladosporium carrionii)* and *Rhinocladiella aquaspera*. The clinical presentation and colonial morphologies of each of these fungi are very similar, and differentiation is based on microscopic and conidial characteristics.

History

Pedroso first recognized chromoblastomycosis in 1911. Four years later, Medlar and Lane reported the first case in the US (in Boston)[33]. There has been some confusion over the proper naming of this condition. At one point, chromoblastomycosis was thought to be closely related to blastomycosis; however, cellular division does not occur via budding ("blasto-") but rather via internal septation, hence the preference for the term "chromomycosis". Nonetheless, some authors have argued that the latter is also confusing, because it has the same meaning as phaeohyphomycosis (see below), and so they prefer the term "chromoblastomycosis".

Epidemiology and pathogenesis

Chromoblastomycosis is most commonly found in tropical and subtropical climates and occasionally in temperate zones such as the US, Europe and Canada. Farmers, miners and others working in rural areas are at higher risk than the general population. Men 20 to 60 years of age are more often affected, probably due to increased occupational exposure, which accounts for up to 90% of cases[34].

The fungi responsible for causing chromoblastomycosis are found in the soil and in decaying plants and wood. The disease is typically

TREATMENT OF MUCOCUTANEOUS *CANDIDA* INFECTIONS	
Type of infection	**Treatment regimen (adult doses unless otherwise indicated)**
Oropharyngeal candidiasis	**Nystatin*** 100 000 units/ml suspension: • Children and adults – 4–6 ml swish and swallow qid • Infants – 2 ml (1 ml inside each cheek) qid **Clotrimazole*** 10 mg troche five times daily **Fluconazole**† 200 mg po on day 1, then 100–200 mg po daily *Continue treatment for 7–14 days after clinical resolution*
Esophageal candidiasis	**Fluconazole*** 200–400 mg po on day 1, then 100–400 mg daily **Itraconazole** 200 mg po daily **Voriconazole** 200 mg po or iv bid **Posaconazole** 400 mg po bid **Caspofungin** 50 mg po iv daily *Continue treatment for 7–14 days following resolution of symptoms, for a minimum of 21 days total*
Candidal vulvovaginitis‖	**Fluconazole*** 150 mg po single dose or (for severe disease or an immunosuppressed patient) three doses at 3-day intervals **Butoconazole** 2% vaginal cream, 5 g daily for 1–3 days **Clotrimazole***,‡ • 1% vaginal cream (or other topical formulation), 5 g daily for 7–14 days • Vaginal suppositories: 100 mg daily for 7 days or 200 mg daily for 3 days **Miconazole***,‡ • 2% cream, 5 g daily for 7 days • Vaginal suppositories: 100 mg daily for 7 days, 200 mg daily for 3 days, or 1200 mg single dose **Tioconazole*** 6.5% cream, 5 g single dose **Terconazole*** • 0.4% or 0.8% cream, 5 g daily for 7 or 3 days, respectively • 80 mg vaginal suppository daily for 3 days **Nystatin** 100 000 units vaginal suppository daily for 14 days *For suppression in patients with recurrent infections:* **Fluconazole** 150 mg weekly for 6 months **Clotrimazole** vaginal suppository, 200 mg twice weekly or 500 mg weekly for 6 months
Chronic mucocutaneous candidiasis	**Fluconazole** • *Eradication:* 400–800 mg po daily for 4–6 months • *Suppressive therapy*§: 200 mg po daily
Candidal intertrigo or balanitis‖	Topical **imidazole** (see Table 127.15) or **ciclopirox** cream or lotion twice daily for 1–2 weeks or until resolved¶ *Systemic agents for recalcitrant or severe cases*§*:* **Fluconazole** • 50 to 100 mg po daily for 14 days • 150 mg po weekly for 2–4 weeks **Itraconazole** 200 mg po twice daily for 14 days

*Recommended as first-line treatment for immunocompetent individuals.
†Recommended as first-line treatment for HIV-infected patients (or other immunosuppressed individuals) with moderate to severe disease, recurrent infection or a CD4 count of <200 cells/mcl.
‡Preferred treatments (with 7-day regimens) for pregnant patients.
§Outside the setting of chronic mucocutaneous candidiasis, chronic systemic suppressive therapy in immunosuppressed individuals is discouraged due to the risk of colonization with resistant organisms.
‖In cases of recurrent vulvovaginitis, treatment of the patient's sexual partner is controversial; in contrast, for recurrent balanitis, eradication of *Candida* from the sexual partner's genital tract is generally recommended.
¶After clinical resolution, topical treatments may be continued twice weekly to prevent recurrence.

Table 77.13 Treatment of mucocutaneous *Candida* infections. Candidal onychomycosis can be treated with the oral fluconazole or itraconazole regimens described for tinea unguium in Table 77.12. See Table 127.20 for pediatric dosing of fluconazole. bid, twice daily; iv, intravenously; po, orally; qid, four times daily.

contracted from trauma to the lower extremities, particularly as a result of not wearing shoes. The organism is introduced into the dermis or subcutis via implantation.

Clinical features

The disease usually presents as a papule or nodule on the leg, which progresses to form a verrucous (Fig. 77.22A) or granulomatous (Fig. 77.22B) plaque. The lesion may appear annular as the central portion resolves with scarring. Several lesions may coalesce to form a multi-nodular mass, or multiple lesions may exist as discrete islands scattered within unaffected skin. It is thought that autoinoculation from scratching may be responsible for the spread of infection. Typically, only one extremity is affected. Sometimes, a subcutaneous nodule or mass is the presenting lesion. There are usually no constitutional symptoms.

Pathology

Pseudoepitheliomatous hyperplasia, intraepidermal abscesses, and suppurative and granulomatous inflammation within the dermis are the typical histologic findings. Round, pigmented bodies, which are said to resemble "copper pennies" (6 to 12 microns; Fig. 77.22C), are present in the dermis, both extracellularly and within giant cells. These are unique to chromoblastomycosis and are also known as "Medlar bodies" or sclerotic bodies[2]. Detection of organisms via PCR of tissue samples has been reported for the more common species.

Differential diagnosis

After a thorough clinical examination, a biopsy is indicated to exclude other infectious diseases characterized by granulomatous lesions associated with scarring, such as cutaneous tuberculosis, tertiary syphilis, blastomycosis and leishmaniasis. Mycetoma is another implantation mycosis that commonly affects the lower extremity, but edema, draining sinuses and grains point to this diagnosis. If a biopsy is not feasible, a KOH examination of scrapings from a pigmented portion of the lesion can be performed. The presence of Medlar bodies is diagnostic (excluding other entities such as blastomycosis), but hyphae may also be seen. Culture growth (at 25–30°C) is slow and the different genera produce similar colonial morphologies. The major differences between genera

Fig. 77.21 Granuloma gluteale infantum. **A** Multiple dark red papules and nodules in the anogenital region of an infant. **B** Coalescing moist, pink papules on the vulva and suprapubic area of another infant. *A, Courtesy, Robert Hartman, MD. B, Courtesy, Julie V Schaffer, MD.*

are the microscopic features, in particular the type of conidia produced in culture. The three major types are:

- Cladophialophora-like (long branching side chains with shield cells at branch points)
- Phialophora-like (conidia resemble overflowing buds in a vase)
- Rhinocladiella-like (overall configuration similar to a mascara brush).

Treatment

Therapeutic options are limited. Some authors have advocated heat therapy based on evidence that the causative organisms will not grow at high temperatures. For small lesions, surgical excision can be attempted together with systemic antifungal treatment. 5-Flucytosine combined with either oral thiabendazole, intravenous amphotericin B or an oral triazole has been reported to be efficacious. Itraconazole alone (200–400 mg/day) administered for at least 6 months may have cure rates of up to 80–90%[35]. Successful treatment with voriconazole or posaconazole has also been described. In a small series, oral terbinafine (500 mg/day) given for at least 7 months was described as effective[36]. Other treatment considerations include cryosurgery and the addition of antibiotics if the lesion is secondarily infected.

Mycetoma

Synonyms: ■ Madura foot ■ Maduromycosis

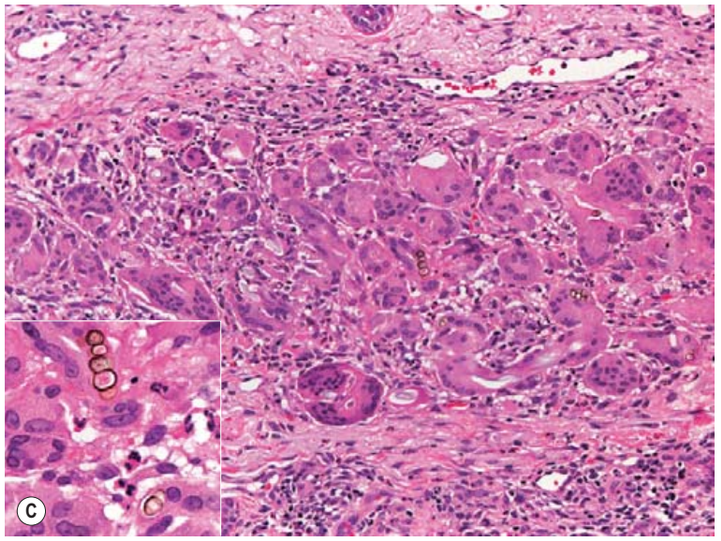

Fig. 77.22 Chromoblastomycosis. Annular and figurate plaques due to central clearing and scarring with a verrucous surface on the arm (**A**) and a more granulomatous appearance on the leg (**B**). **C** Brown-colored sclerotic body (see insert) within a mixed granulomatous and neutrophilic dermal infiltrate. *C, Courtesy, C Massone, MD.*

Introduction

Mycetoma (often referred to as "Madura foot") is a Greek term for "fungal tumor". It is a granulomatous infection of dermal and subcutaneous tissue that may extend to muscle or even bone and is due to implantation. Mycetoma is differentiated from other mycoses by its characteristic draining sinuses containing grains (sclerotia, sulfur granules) and local edema. Three different subtypes exist: actinomycotic mycetoma (caused by filamentous aerobic and anaerobic organisms, e.g. *Nocardia brasiliensis* [see Ch. 74], *Actinomadura madurae*),

eumycotic mycetoma (caused by true fungi) and botryomycosis (caused by true bacteria, e.g. *Staphylococcus aureus, Pseudomonas* spp.; see Ch. 74).

History and epidemiology

Dr John Gill provided the first formal description of mycetoma in 1842, in Madura (India), hence the name "Madura foot"[37]. Mycetoma is endemic to tropical and subtropical climates. Actinomycotic mycetoma is more prevalent in Central and South America, while eumycotic mycetoma is more common in Africa. The typical patient is a man between 20 and 50 years of age.

Pathogenesis

In most cases, causative organisms are acquired from the soil via direct inoculation into the skin, leading to a dermal and subcutaneous fungal infection. Deeper invasion can subsequently occur, i.e. to muscle and bone. This process may occur rapidly or over many years. Sometimes, multiple sites of involvement appear in the vicinity of the original lesion, likely due to multiple injuries rather than contiguous spread of disease. Lack of protective footwear, malnutrition, and exposed cuts and abrasions are risk factors for infection.

Clinical features

The foot is the most common site of infection, followed by the hand, trunk and scalp. Involvement is typically unilateral and begins as a painless papule. Once the subcutaneous tissues are infected, the surrounding soft tissue swells and eventually forms purulent draining sinuses (Fig. 77.23A). The drainage contains the characteristic grains (sclerotia), which represent compact masses of fungal colonies and vary in size from minute to almost a centimeter in diameter. Invasion of deeper tissues then ensues, and sometimes cavities are formed within involved bone. Surprisingly, this disease is generally asymptomatic. All three subtypes can have a similar clinical presentation.

Pathology

Pseudoepitheliomatous hyperplasia is a common histologic finding that accompanies suppurative and granulomatous inflammation of the dermis and subcutis as well as fibrosis. The characteristic grains represent tightly packed colonies of organisms (Fig. 77.23B). Estimation of the diameter of the filaments comprising the grain (as compared to the size of the nuclei of surrounding inflammatory cells) allows a distinction between eumycotic (thicker filaments) and actinomycotic (thin, fine filaments) mycetomas. Special stains, e.g. silver (Grocott) and Brown–Brenn can aid in distinguishing the subtype (see Ch. 0).

Differential diagnosis

To establish the diagnosis of mycetoma, both the history and clinical appearance are important considerations. However, differentiating mycetoma from conditions with similar presentations (e.g. actinomycosis, coccidioidomycosis) requires laboratory evaluation. In addition to noting the color of the grains (Table 77.14), KOH examination, Gram stain and culture (bacterial and fungal) of exudate from a sinus tract and/or tissue should be performed.

Fig. 77.23 Madura foot. A Note the soft tissue swelling of the foot as well as multiple nodules with pustular discharge. **B** Histology of a grain, which represents tightly packed colonies of fungal organisms. *B, Courtesy, Lorenzo Cerroni, MD.*

COLORS OF GRAINS AND GEOGRAPHIC DISTRIBUTION OF EUMYCOTIC AND ACTINOMYCOTIC MYCETOMAS

Pathogen		Grain color	Geographic distribution
Eumycotic	*Madurella mycetomatis*	Black	North, Central and South America; Caribbean, Africa, Europe, Middle East, Asia
	Madurella grisea	Black	North, Central and South America; Africa, Asia
	Leptosphaeria senegalensis	Black	Africa, Asia
	*Pseudallescheria boydii**	White	North, Central and South America; Africa, Oceania, Asia, Europe
	Acremonium spp.	White	North, Central and South America; Asia, Europe, Oceania
Actinomycotic	*Nocardia brasiliensis*†	White	Worldwide (all *Nocardia* spp.)
	Nocardia asteroides‡	White	
	Nocardia caviae	Yellow–white	
	Actinomyces israelii§	Yellow–white	Worldwide
	Actinomadura madurae	Pink or white	Worldwide
	Actinomadura pelletieri	Red	North and South America, Africa, India
	Streptomyces somaliensis	Brown or yellow	Africa (arid regions)

*Most common cause in the US.
†Most common cause in Mexico.
‡Rare.
§Very rare cause of mycetoma; usually causes actinomycosis (e.g. cervicofacial, thoracic and abdominal), which also has draining sinuses and grains.

Table 77.14 Colors of grains and geographic distribution of eumycotic and actinomycotic mycetomas.

Treatment

For the best outcome, eumycotic mycetoma must be diagnosed early and surgically excised (including a large margin of normal surrounding tissue) before the underlying bone becomes involved. Once the lesion has been excised, systemic antifungal therapy is administered. Amphotericin B is not very effective. Depending upon the particular fungus, ketoconazole, itraconazole, fluconazole, voriconazole, posaconazole and terbinafine have been used to treat eumycotic mycetomas[38]. The medical treatment of actinomycotic mycetoma consists primarily of streptomycin or amikacin plus either trimethoprim–sulfamethoxazole or dapsone; therapy is continued for months to years.

Sporotrichosis

Synonym: ▪ Rose gardener's disease

Introduction

Sporotrichosis is a subcutaneous mycosis that is caused by the dimorphic organism *Sporothrix schenckii*. A gardener being pricked by a contaminated rose thorn is a classic vignette for the acquisition of sporotrichosis. Although various clinical presentations are possible, the most common one is a lymphocutaneous or "sporotrichoid" pattern, which refers to the primary inoculation site plus spread of the infection along the lymphatics in a nodular pattern.

Epidemiology

S. schenckii is present in the soil throughout the world. However, sporotrichosis is endemic to Mexico, Central America and South America as well as other areas such as South Africa. In these locations, exposure to the organism typically occurs in individuals who work outdoors. In temperate climates, such as in the US and Canada, the disease most often develops in gardeners, especially those growing orchids and roses. Sphagnum moss is often implicated as the source of *S. schenckii*. All age groups are affected, but it is more common in adults. In the past decade, the incidence of sporotrichosis in the Rio de Janeiro region of Brazil has increased >100-fold due to transmission by infected cats, which (in contrast to humans) harbor large numbers of organisms in cutaneous ulcers[39].

Pathogenesis

Sporotrichosis is most commonly acquired from cutaneous inoculation, especially by vegetation such as thorns and wood. With the exception of cats in Brazil, animal-to-human transmission is rare. Multiple inoculations may occur simultaneously, not to be confused with spread of a single primary lesion. The presentation and course of sporotrichosis depends on the host immune response as well as the size and virulence of the inoculum. In naive hosts, involvement of regional lymphatics ensues. In those with a prior history of exposure to *S. schenckii*, no lymphatic spread occurs, and a "fixed" ulcer[40] or granulomatous plaque develops at the site of inoculation; the latter is often seen on the face (especially in children living in endemic areas).

Extensive cutaneous disease with or without systemic involvement is also possible, especially in an immunocompromised host. Cases of inhaled sporotrichosis have been reported with systemic and cutaneous dissemination, similar to disseminated histoplasmosis and other dimorphic fungal infections.

Clinical features

The initial presentation of sporotrichosis is a single papule at a site of injury, most commonly on the hand, appearing several weeks after inoculation. The lesion then becomes eroded or ulcerated with purulent drainage, but it is generally not painful. Additional lesions appear weeks later, typically developing as dermal and subcutaneous nodules and ulcers along the path of lymphatic drainage (often up the arm; Fig. 77.24A). This is the well-known "sporotrichoid" pattern. The involved lymphatic vessels may become fibrosed[41]. Lesions of "fixed cutaneous sporotrichosis" can have a granulomatous appearance, often with ulceration, and disseminated lesions typically present as subcutaneous nodules.

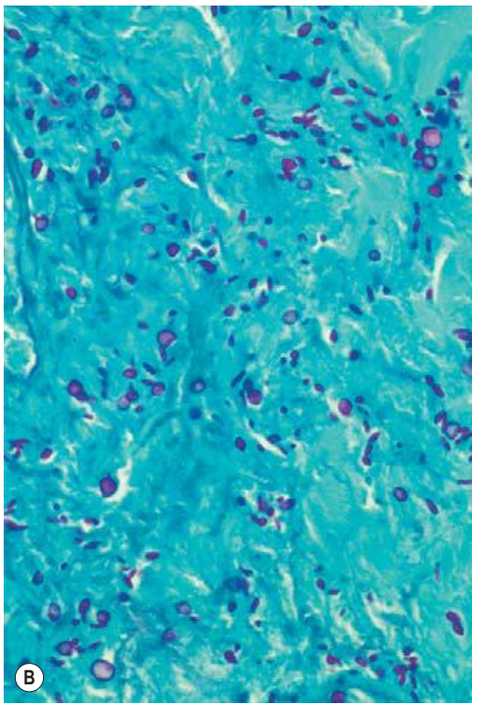

Fig. 77.24 Lymphocutaneous (sporotrichoid) pattern. **A** An eroded nodule on the thumb representing the primary lesion with a secondary lesion along the lymphatics due to sporotrichosis. **B** Multiple yeast forms of *Sporothrix schenckii* in the dermis; note that many of the organisms have the characteristic cigar shape. **C** Ulcerated nodule on the extensor forearm with multiple more proximal nodules due to nocardiosis in a patient with lymphoma who was receiving systemic corticosteroids. *B, Courtesy, Ronald P Rapini, MD. C, Courtesy, Jean L Bolognia, MD.*

Pathology

Histologically, suppurative and granulomatous inflammation is found in the dermis and subcutis. The causative organisms are rarely evident; staining with fluorescent-labeled antibodies may aid in recognition of the cigar-shaped yeast forms, which are difficult to identify. Asteroid bodies are often seen. When numerous fungi are present (e.g. in an

immunocompromised host), budding yeast and cigar-shaped organisms can often be visualized with PAS (Fig. 77.24B) or silver stains.

Differential diagnosis

When there is a sporotrichoid pattern, the major entity to be excluded is an atypical mycobacterial infection, in particular with *M. marinum*; less common causes are outlined in Table 77.15. As organisms are not typically seen by KOH or histopathologic examination, culture (of pus or tissue) is often required to definitively diagnose sporotrichosis; a nested PCR assay can also be used to detect organisms in clinical samples[42]. *S. schenckii* is a member of the dimorphic family of fungi (see below), and whether a hyphal or yeast form develops depends on the temperature. Growth is rapid at 25°C, revealing a glabrous white to brown mold that becomes firm, wrinkled and more darkly pigmented over time. Microscopically, delicate conidia are clustered at the ends of conidiophores (specialized hyphae); single, thick-walled pigmented conidia can also arise from hyphae. At 37°C, on enriched glucose-containing media, there are slow-growing, whitish, pasty, yeast-like colonies. On microscopic examination of the latter, cigar-shaped budding yeasts are seen. The differential diagnosis of fixed plaque sporotrichosis and disseminated lesions is broad and includes other granulomatous disorders, both infectious and inflammatory.

Treatment

Topical therapy is not effective. Oral saturated solution of potassium iodide (SSKI) has been used with success. Although neither fungistatic nor fungicidal, SSKI is thought to affect the host's immune reaction to the organism. Its cost is low, but it has a bitter taste as well as potential side effects (e.g. iododerma, gastrointestinal upset and thyroid suppression; see Ch. 100). Based upon multicenter, non-randomized trials and case series, the Mycoses Study Group of the Infectious Disease Society of America has recommended itraconazole (100–200 mg/day) for 3–6 months as the treatment of choice for lymphocutaneous or fixed cutaneous sporotrichosis[43]. The drug is generally safe and well tolerated, and the relapse rate is low. Amphotericin B may be indicated in severe or disseminated disease.

Lobomycosis

Synonyms: ■ Keloidal blastomycosis ■ Lacaziosis ■ Lobo's disease

Lobomycosis is a chronic fungal infection characterized by cutaneous nodules that resemble keloids. The causative organism, *Lacazia loboi* (previously known as *Loboa loboi*), is closely related to *Paracoccidioides brasiliensis* and has never been cultured *in vitro*[44]. Lobomycosis occurs in Central and South America and has been linked to contact with dolphins and the marine environment as well as soil and vegetation in rural areas. Infection typically occurs after minor trauma and most often affects men[45].

Lobomycosis presents as asymptomatic, firm, keloid-like nodules that favor the distal extremities, ears (especially the helices) and face but can also affect the trunk (Fig. 77.25A,B). The lesions enlarge slowly over years, forming broad, multinodular plaques that may have a smooth surface or (occasionally) a verrucous appearance and ulceration. Histologic evaluation shows highly characteristic chains of thick-walled, yeast-like cells (known as "brass knuckles") with intercellular bridges (Fig. 77.25C); PAS or silver stains highlight these organisms, which can also be identified in scrapings from the surface of skin lesions[46]. Additional findings include a dermal granulomatous infiltrate and either atrophy or pseudoepitheliomatous hyperplasia of the epidermis. Treatment with surgical excision or cryosurgery is employed if feasible, since antifungal medications are typically ineffective. However, clofazamine and itraconzole may be of some benefit for patients with widespread disease[47].

SYSTEMIC MYCOSES

This section reviews systemic infections caused by opportunistic as well as true fungal pathogens. The true pathogens are generally dimorphic and cause infection in hosts with normal immune status, while opportunistic pathogens, which are generally less virulent, take advantage of the immunocompromised state.

True Pathogens

Introduction

The systemic mycoses due to true pathogens include histoplasmosis, blastomycosis, coccidioidomycosis and paracoccidioidomycosis. They are caused by dimorphic fungi, meaning the organisms can exist in two forms – as molds (with septate hyphae and conidia) in nature and as other forms (usually yeasts) in living tissue and (with the exception of *Coccidioides immitis*) at 37°C. Each pathogen has certain geographic preferences (Fig. 77.26; see below). Acquisition of disease is typically through inhalation of the causative fungi, leading to pulmonary symptoms and pneumonitis. The vast majority of infections resolve spontaneously, and patients are left with strong, specific immunity. Disseminated histoplasmosis and coccidioidomycosis may occur in HIV-infected persons, as can disseminated infections with *S. schenckii* (dimorphic) and *Penicillium marneffei* (dimorphic and opportunistic).

Histoplasmosis

Synonyms: ■ Darling's disease ■ Cave disease ■ Ohio valley disease ■ Reticuloendotheliosis

Introduction

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum* var. *capsulatum*[48].

Epidemiology

H. capsulatum is found in the soil in warm, moist climates, particularly the Mississippi, Ohio, and St. Lawrence river valleys in the US and Canada. Between 80% and 90% of persons from endemic areas may exhibit positive histoplasmin skin testing[49]. Birds, fowl and even bats are significant reservoirs for histoplasmosis. Because the feces of these animals contain the organisms, the areas in which they live can harbor infectious fungal spores. Caves, schoolyards, construction sites, unoccupied buildings, and chicken coops tend to be high-risk areas.

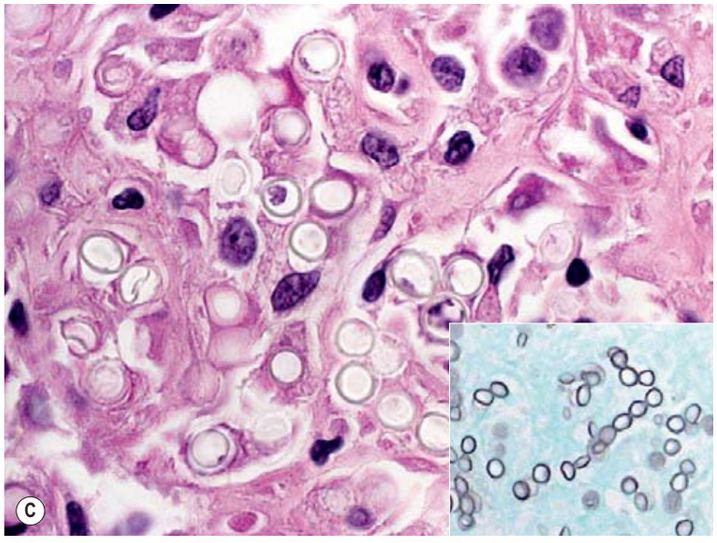

Fig. 77.25 Lobomycosis. A, B Multinodular pinkish-brown plaques with a keloid-like appearance on the helix and back. **C** Spherical organisms with doubly refractile walls are seen within the dermis. Chain formation is commonly observed (insert; Grocott methenamine silver stain). *A, B Courtesy, Regina Carneiro, MD, and Caroline Brandao, MD. C, Courtesy, C Massone, MD.*

Pathogenesis
Histoplasmosis is caused either by inhalation of *H. capsulatum* or, rarely, by direct cutaneous inoculation of the fungus. Immunocompetent hosts can acquire the disease, but immunocompromised hosts have a higher risk of dissemination. Clinical presentations include acute and chronic pulmonary histoplasmosis, disseminated histoplasmosis, and primary cutaneous histoplasmosis. In disseminated histoplasmosis, the most common sites of involvement (after the lung) are the spleen, lymph nodes, bone marrow and liver; calcifications within the lymph nodes, lungs and spleen can serve as evidence of prior infection. Cutaneous manifestations most commonly result from disseminated disease.

Clinical features
The skin lesions of histoplasmosis are nonspecific, making the diagnosis virtually impossible with physical examination alone. When chronic disseminated histoplasmosis occurs in immunocompetent hosts, oral ulcers are the most common mucocutaneous finding; nodules and vegetative plaques are occasionally seen in these individuals. Disseminated histoplasmosis in immunocompromised hosts (including those with HIV infection) can present with mucocutaneous erosions or ulcers as well as multiple erythematous papules or nodules with scale or crust (Fig. 77.27A,B). In African histoplasmosis, a variant caused by *H. capsulatum* var. *duboisii*, most patients present with mucocutaneous, subcutaneous and bone lesions.

Pathology
Microscopic examination of biopsy specimens demonstrates characteristic intracellular yeast forms surrounded by a rim of clearing (Fig. 77.27C). Histiocytes and giant cells are the host cells in histoplasmosis, which is in the differential diagnosis of "parasitized macrophages" (Table 77.16). For easier identification of the fungi, tissue may be stained with PAS or Gomori methenamine silver.

Differential diagnosis
Because cutaneous histoplasmosis has a wide spectrum of clinical presentations, the diagnosis usually rests on histologic examination and culture of involved skin tissue. To evaluate for disseminated disease, bone marrow (sensitivity 70–90%) and blood should be cultured at 25°C and 37°C, with plates held for up to a month. At 25°C, characteristic tuberculate macroconidia develop. Additional diagnostic tests include cultures of sputum and body fluids, polysaccharide antigen testing of blood and urine (useful in detecting disseminated disease), histoplasmin skin testing (indicated only in non-endemic areas), and serologic assays to measure antibody responses (complement fixation, immunodiffusion). Highly sensitive and specific PCR-based assays can be used to identify histoplasmosis in blood and tissue[50,51]. Diseases in the differential diagnosis include other dimorphic fungal infections (e.g. paracoccidioidomycosis), mucocutaneous tuberculosis, major aphthae, and oral squamous cell carcinoma. For primary cutaneous histoplasmosis, entities in Table 77.15 should be considered.

Treatment
In primary, self-limited, asymptomatic histoplasmosis, treatment may not be necessary. However, in symptomatic or disseminated disease, systemic antifungal therapy is required. Amphotericin B, given intravenously and titrated up to 1 mg/kg/day, is currently the most effective therapy and should be used initially for severe disease, followed by itraconazole. In immunocompetent hosts with mild to moderate, stable disease, itraconazole (200–400 mg/day) is the treatment of choice[52]; ketoconazole can also be used. HIV-infected patients with disseminated histoplasmosis require lifelong maintenance therapy with itraconazole after initial treatment with amphotericin B (if required for severe disease). Successful treatment with voriconazole and posaconazole have also been described[53].

Blastomycosis

Synonyms: ▪ North American blastomycosis ▪ Gilchrist's disease

Introduction
Blastomyces dermatitidis is a dimorphic fungus and the causative agent of blastomycosis.

Epidemiology
This disease is endemic to North America, particularly the Mississippi and Ohio river valleys, Great Lakes region and the southeastern states. While all ages and genders can be affected, adult men are most likely to develop systemic infection, and children are more likely to develop acute pulmonary blastomycosis rather than chronic or cutaneous

disease. The soil is probably the most important source of infection, making those who have occupations with frequent outdoor exposure at higher risk than the remainder of the population. Blastomycosis has also been observed in other countries, including Africa and India.

Pathogenesis
The lungs are typically the first site of infection, via inhalation of organisms. In contrast to infections with other dimorphic fungi, secondary cutaneous dissemination is a common occurrence and may even be the first sign of disease. Cutaneous manifestations are sometimes seen in the absence of overt pulmonary disease. Primary cutaneous blastomycosis is uncommon and results from direct inoculation of the skin from trauma, such as in the laboratory.

Clinical features
The most common cutaneous findings are papulopustules and well-demarcated verrucous plaques with scale-crust (Fig. 77.28A,B) and pustules within their borders. Central ulceration can occur, and more advanced disease may have an appearance similar to pyoderma gangrenosum. The number of lesions can vary from one to several, and they tend to occur on exposed skin. Healing begins centrally and is followed by cribriform scarring. Mucous membrane involvement is occasionally observed.

Pulmonary infection is subclinical in up to 50% of patients with inhalation blastomycosis. Bone involvement may occur and presents as osteomyelitis with rare extension to muscle; genitourinary disease is uncommon.

Pathology
Histologic examination of skin lesions demonstrates pseudoepitheliomatous hyperplasia, suppurative and granulomatous inflammation, and round yeast forms with characteristic broad-based budding and thick, double-contoured walls. This budding pattern helps to differentiate blastomycosis from other fungal infections. Methenamine silver and PAS staining (Fig. 77.28C) allow better visualization of the fungi within giant cells and neutrophilic abscesses. Similar budding yeast forms can be seen in sputum samples.

Differential diagnosis
Cutaneous blastomycosis must be differentiated from other cutaneous infections (e.g. verrucae, folliculitis, nocardiosis, tuberculosis and chromoblastomycosis as well as those due to other dimorphic fungi), inflammatory dermatoses (e.g. pyoderma gangrenosum, halogenoderma, sarcoidosis) and neoplasms (e.g. squamous cell carcinoma). Lesions of blastomycosis-like pyoderma, an exaggerated vegetative response to a prolonged primary or secondary bacterial infection, can also resemble cutaneous blastomycosis. Current or past residence in an area in which blastomycosis is endemic is a helpful clue.

Identification of characteristic broad-based budding yeast forms in pus by KOH or calcofluor examination is diagnostic of blastomycosis. Either skin tissue or pus should be cultured at both 37°C and 25°C. The former temperature allows identification of the budding yeast form, while the characteristic colonial morphology with white spikes (coremia) is observed at 25°C. Other tests such as blastomycin skin testing and complement fixation testing are not usually helpful. PCR-based assays are also available[54].

Treatment

Blastomycosis, like histoplasmosis, requires systemic treatment with amphotericin B (given at the same doses) when severe or progressive. In mild to moderate non-CNS disease, itraconazole (200–400 mg/day) is the treatment of choice[55]. Ketoconazole (400–800 mg/day) and fluconazole (400–800 mg/day) are alternative medications. Voriconazole has shown promising activity against *Blastomyces* both *in vitro* and in animal models[53,56]. In case reports and small series, it has been used successfully to treat blastomycosis, either alone or in combination with liposomal amphotericin B[57]. Occasionally, surgical treatment is indicated.

Coccidioidomycosis

Synonyms: ■ Valley fever ■ Desert rheumatism ■ San Joaquin valley fever ■ California disease

Introduction

Coccidioidomycosis is caused by the dimorphic, highly virulent pathogen *Coccidioides immitis*.

Epidemiology

Coccidioidomycosis occurs predominantly in the summer and fall in the southwestern US, northern Mexico, and Central and South America. The arthroconidia of *C. immitis* are inhaled via dust particles. Primary infection of the respiratory tract shows no gender or age preference, but disseminated disease is more common in Mexicans (5×), African-Americans (25×) and Filipinos (175×). Immunosuppressed states (e.g. HIV infection) and pregnancy also predispose to dissemination; Caucasian women are most likely to have more limited disease.

Pathogenesis

C. immitis is thought to be the most virulent of all fungi. Infectious arthroconidia are inhaled and cause pulmonary infection in the vast majority of people living in endemic areas. The infection is asymptomatic in approximately 60% of affected individuals, while the remainder develop flu-like symptoms several weeks after exposure[58]. Dissemination to the skin and other organs can occur and depends on host factors (see above). Rarely, primary cutaneous coccidioidomycosis results from direct inoculation of the organism into the skin.

Clinical features

Symptomatic primary inhalation coccidioidomycosis typically presents as a flu-like syndrome with fatigue, anorexia, fever, cough and pleuritic chest pain. The cutaneous manifestations can occur alone or in combination with the above symptoms and are grouped into four patterns:

- papules, pustules, plaques, abscesses and sinus tracts, with the face being the most common site of involvement (Fig. 77.29A,B)
- ulcerations
- toxic erythema in the form of a diffuse macular eruption seen early in the disease and sometimes mimicking contact dermatitis
- hypersensitivity reactions such as erythema multiforme and erythema nodosum.

In HIV-infected patients, the papules may resemble molluscum contagiosum. Bone and meningeal involvement can also occur, presenting as osteomyelitis and meningitis, respectively.

Pathology

Biopsy specimens of specific lesions (types 1 and 2 above) reveal characteristic endospore-containing spherules that measure 30–60 microns when mature (Fig. 77.29C). PAS and silver methenamine stains are helpful in identifying immature spherules. A suppurative granulomatous reaction with histiocytes, lymphocytes and giant cells typically surrounds the spherules and released endospores.

Differential diagnosis

Coccidioidomycosis can be diagnosed via direct examination (with KOH or calcofluor) and culture of infected tissue, pus or body fluids. Histologically, sporangia (up to 300 microns in diameter) containing numerous endospores can also be seen in mucosal polyps due to *Rhinosporidium seeberi*. When cultured at 25°C or 37°C, *C. immitis* proliferates quickly (within days) and yields a white to tan to brown colony with varying morphology. Microscopically, septate hyphae that form thick-walled, barrel-shaped arthroconidia are seen at both temperatures. These arthroconidia alternate with thin-walled, vacant cells, which rupture and release the infectious arthroconidia when mature (Fig. 77.30). The infectious hyphal forms produced in culture should be examined with extreme caution, as the examiner is at risk for contracting the disease.

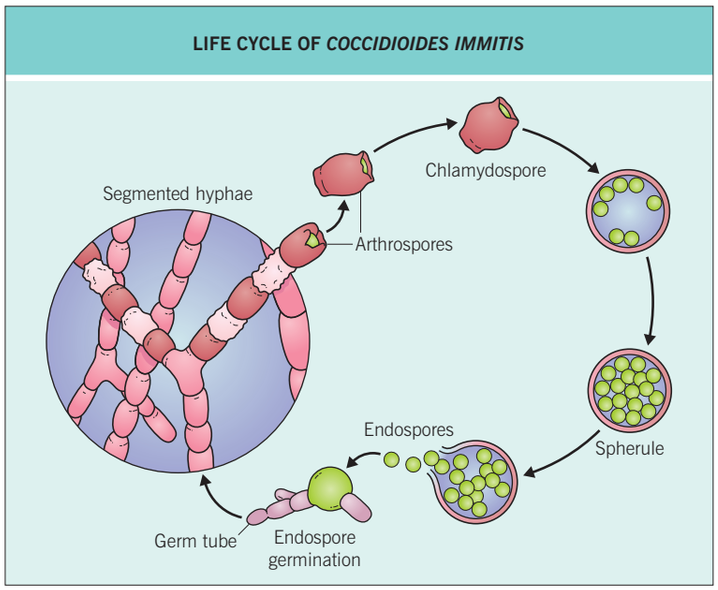

Fig. 77.30 Life cycle of *Coccidioides immitis*.

Serologic testing and exoantigen testing are useful in making the diagnosis of coccidioidomycosis. PCR-based assays are also available, and *in situ* hybridization has been described[54,59].

Treatment

As in the other dimorphic fungal infections, systemic antifungal therapy is required for severe or disseminated disease. Amphotericin B is the most effective medication, and the intravenous dose for severe disease is 1.0–1.5 mg/kg/day (higher dose for patients with AIDS). The chronic nature of disseminated disease requires prolonged therapy with ketoconazole (at least 400 mg/day)[60] or itraconazole (400 mg/day), and, in the case of meningitis, fluconazole. Voriconazole and posaconazole, which have *in vitro* activity against coccidioidomycosis equal or superior to that of itraconazole[53], have been used successfully (alone or in combination with liposomal amphotericin B) to treat disseminated disease.

Paracoccidioidomycosis

Synonyms: ■ South American blastomycosis ■ Brazilian blastomycosis

Introduction and epidemiology

Paracoccidioidomycosis is caused by the dimorphic fungus *Paracoccidioides brasiliensis*. It is endemic to the Central and South American countries of Brazil, Argentina, Venezuela, Ecuador and Colombia.

Pathogenesis

P. brasiliensis is a dimorphic saprophyte that is found in the soil. In most cases, infection occurs via inhalation of the conidia from the environment. Pulmonary disease ensues and can be followed by dissemination to the skin, mucous membranes, gastrointestinal tract, spleen, adrenal glands and lymph nodes.

Clinical features

Paracoccidioidomycosis has several different clinical presentations with varying prognoses. In many patients, the primary pulmonary disease is subclinical to mild. When progressive disseminated disease occurs, mucocutaneous involvement is commonly seen. Lesions are often painful and ulcerative or verrucous; they are typically found on the face and in the nasal and oral mucosae (Fig. 77.31A,B). The ulcerations are referred to as "moriform stomatitis". Lymphangitic spread may occur, resulting in cervical lymphadenopathy.

Another clinical presentation is that of primary mucocutaneous paracoccidioidomycosis. This frequently has an intraoral and perioral distribution due to trauma from chewing contaminated sticks and leaves.

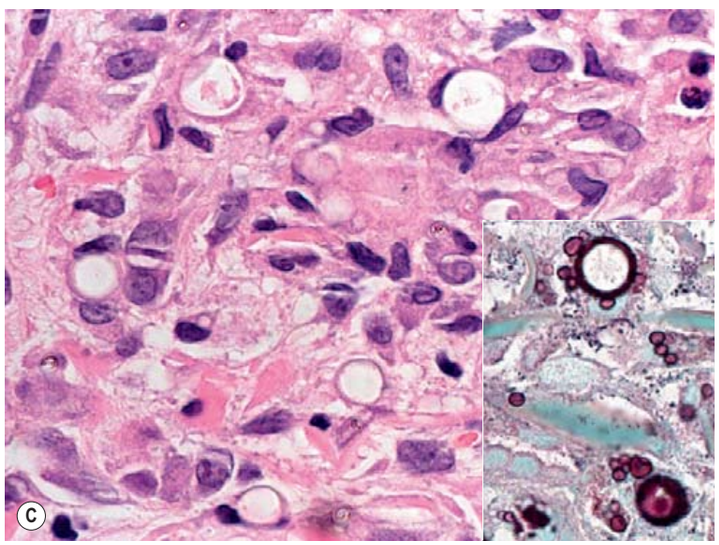

Fig. 77.31 Paracoccidioidomycosis. Ulcerated plaques on the palate (**A**) and verrucous granulomatous red–brown plaques with crusting involving the perioral region and upper lip (**B**). **C** Dermal histiocytic infiltrate and yeast forms with multiple small, narrow-based buds. The organisms are highlighted with a Grocott methenamine silver stain (insert). *A, B, Courtesy, Marcia Ramos-e-Silva, MD PhD. C, Courtesy, C Massone, MD.*

Granulomatous lesions are typically seen. Primary cutaneous paracoccidioidomycosis can also occur via direct inoculation of the skin, resulting in the development of a verrucous papule or plaque or cutaneous ulceration.

Pathology

The histologic features of paracoccidioidomycosis resemble those of blastomycosis (see above). Pseudoepitheliomatous hyperplasia is accompanied by suppurative and granulomatous inflammation. Yeast forms are found within and outside of giant cells. Large, thick-walled organisms with multiple narrow-based buds may be seen, leading to an outline that resembles a "mariner's wheel" (Fig. 77.31C).

Differential diagnosis

The differential diagnosis includes mucocutaneous leishmaniasis, Wegener's granulomatosis, NK-cell lymphoma, and syphilis (endemic and epidemic) (see Table 45.3). Microscopic examination and culture

of the organism are essential for diagnosing paracoccidioidomycosis. KOH or calcofluor examination of an appropriate specimen (sputum, dermal scraping, or pus) may reveal round to ovoid cells with narrow-based buds, which are also seen when the organism is cultured at 37°C.

Treatment

There are several effective treatment options for paracoccidioidomycosis, including amphotericin B, systemic azoles and sulfonamides. Prolonged therapy is generally required. In disseminated disease, systemic therapy with amphotericin B or an azole antifungal is indicated. Itraconazole is a preferred treatment because it provides reasonable efficacy and side-effect profile, as well as low potential for recurrent disease. Treatment with voriconazole can also be effective. Attempts to modulate the immune system via peptides derived from the *P. brasiliensis* 43 kDa glycoprotein have been described[61].

Opportunistic Pathogens

Introduction

Opportunistic mycotic infections may occur in individuals with primary or secondary immunodeficiencies. Worldwide, disseminated candidiasis and aspergillosis are the two most common systemic mycoses in neutropenic patients. Less commonly, zygomycosis, phaeohyphomycosis (due to pigmented fungi; see below) and hyalohyphomycosis (due to non-pigmented [hyaline] fungi; most often fusariosis) are seen (Fig. 77.32). Disseminated histoplasmosis, coccidioidomycosis, penicilliosis and cryptococcosis are the systemic mycoses seen most commonly in the setting of HIV infection. Opportunistic pathogens are less virulent (compared to true pathogens) and impart no specific protective immunity to those infected.

History

Aspergillosis was among the first mycoses recognized, with the initial report of a human case by Sluyter in 1847. In 1855, Kurchenmeister isolated *Mucor* from the lung and described zygomycosis. Benham distinguished cryptococcosis from blastomycosis in the 1930s. *Fusarium* emerged as an opportunistic pathogen in neutropenic oncology patients in the 1990s.

Epidemiology

With the exception of several dimorphic fungi, opportunistic fungal infections occur worldwide and have no geographic predilection. The causative pathogens are commonly found in the environment. For example, *Aspergillus* spp., Zygomycetes and *Fusarium* spp. are soil saprophytes found in decaying vegetation. *Cryptococcus neoformans* can be isolated from avian (especially pigeon) droppings. *Penicillium marneffei* is endemic to Southeast Asia and China, where the reservoir is thought to be in bamboo rats, but infection has been reported in the US. Lastly, *Candida* spp. commonly colonize the skin and gastrointestinal tract[1].

CUTANEOUS FEATURES OF COMMON OPPORTUNISTIC MYCOSES

Mycosis	Common cutaneous presentations	Microscopic appearance
Systemic candidiasis† • *Candida albicans* • *C. tropicalis* (frequent skin lesions) • *C. glabrata, C. krusei* (intrinsic fluconazole resistance)	Firm erythematous papules and nodules, often with a pale center (but possibly hemorrhagic); ecthyma gangrenosum-like lesions	
Aspergillosis† • *Aspergillus flavus* and *fumigatus*	Necrotic papulonodules, subcutaneous nodules (secondary cutaneous); may be associated with an intravenous catheter site (primary cutaneous); disseminated disease usually results from primary pulmonary involvement; galactomannan (more specific, lower sensitivity) and 1,3β-D-glucan (less specific for aspergillosis) serum assays can be used to screen high-risk patients	Zygomycosis† • *Mucor* • *Rhizopus* • *Absidia*	Ecthyma gangrenosum-like lesions, cellulitis, facial edema (commonly unilateral due to contiguous spread of sino-orbital disease), necrotic papulonodules, plaques, large hemorrhagic crusts on the face; may be associated with an intravenous catheter site (primary cutaneous)	
Cryptococcosis** • *Cryptococcus*	Ulceration, cellulitis, molluscum contagiosum-like lesions; assays to detect cryptococcal antigens in blood or CSF are available	Phaeohyphomycosis* • *Alternaria* • *Exophiala* • *Phialophora*	Subcutaneous cysts, ulcerated plaques, hemorrhagic pustules, necrotic papulonodules	Hyalohyphomycosis*† • *Fusarium* • *Penicillium* • *Paecilomyces*	Umbilicated or necrotic papules, pustules, abscesses, cellulitis, subcutaneous nodules; *Fusarium* infection is often associated with a periungual focus	Trichosporonosis • *Trichosporon* spp.	Papulovesicles, purpuric papules, necrotic papulonodules	
* Less common
**Especially in the setting of AIDS
†With use of prophylactic fluconazole and (more recently) voriconazole in high-risk oncology patients, incidences of systemic candidiasis and (with voriconazole use) aspergillosis have decreased, but incidences of zygomycosis and (with fluconazole use) fusariosis and other hyalohyphomycoses have increased

Fig. 77.32 Cutaneous features of common opportunistic mycoses. While the lesions of opportunistic fungal infections seem nonspecific, certain presentations may be more likely associated with a particular species.

Overall, the incidence of opportunistic mycoses has increased in conjunction with the HIV pandemic and greater use of immunosuppressive therapy. In fact, some opportunistic mycoses are considered to be AIDS-defining diseases (see Ch. 78). In contrast, the incidence of disseminated candidiasis has fallen with the use of prophylactic fluconazole in high-risk oncology patients (e.g. neutropenic patients with hematologic malignancies, hematopoietic stem cell transplant recipients). In the future, the same may happen with aspergillosis and fusariosis with the use of voriconazole. However, these agents lack activity against the organisms that cause zygomycosis, which may continue to increase in incidence unless the use of prophylactic antifungals that cover Zygomycetes (e.g. posaconazole) becomes routine.

Pathogenesis

Aspergillosis is an opportunistic mycosis that is caused by fungi in the genus *Aspergillus*, most often *A. fumigatus* and *A. flavus*. Burns, sites of trauma, surgical wounds, intravenous catheters (Fig. 77.33A) and macerated skin underlying occlusive dressings typically serve as portals of entry in primary cutaneous aspergillosis[62]. The risk of dissemination is significant in immunocompromised individuals. In *secondary* cutaneous aspergillosis (a more common form), the conidia are inhaled, producing a primary lung infection that is followed by dissemination to the skin. Immunosuppression – particularly neutropenia plus chronic use of corticosteroids and sometimes late-stage AIDS – is a major risk factor for the development of invasive or disseminated aspergillosis.

Fungi in the class Zygomycetes and order Mucorales cause zygomycosis, which is also called mucormycosis. The genera most commonly responsible are *Rhizopus, Mucor* and *Absidia*. Risk factors include poorly controlled diabetes mellitus as well as other forms of immunosuppression, especially when associated with neutropenia. *Primary* infections can be rhino-orbito-cerebral, pulmonary, gastrointestinal or cutaneous (via direct inoculation of the skin in settings similar to those of primary cutaneous aspergillosis), and hematogenous dissemination may occur in immunocompromised hosts. Skin lesions that arise from contiguous spread (e.g. from the sinuses) or dissemination are referred to as *secondary* cutaneous zygomycosis. Aspergillosis and zygomycosis are both characterized by necrotic skin lesions due to the angioinvasive nature of these organisms.

Cryptococcus neoformans is the causative pathogen in cryptococcosis. This organism (which can be acquired from pigeons) is inhaled, resulting in a primary pulmonary infection with subsequent dissemination to the CNS, bone and skin. The latter is referred to as *secondary* cutaneous cryptococcosis. *Primary* cutaneous cryptococcosis can also occur, but the diagnosis is made after a systemic evaluation has been performed. Immunocompetent hosts may acquire this infection, but they have a low risk for dissemination, while immunocompromised hosts, particularly those with AIDS, often develop disseminated disease. The use of antiretroviral therapy (ART; formerly referred to as highly active antiretroviral therapy [HAART]) in HIV-infected individuals has led to a dramatic decrease in the incidence of cryptococcosis.

Yeasts belonging to the genus *Candida* are responsible for candidiasis, which can present as a mucocutaneous condition (see above) or (in immunocompromised hosts) a disseminated infection that often originates from the gastrointestinal tract. The ability of *Candida* to exist in the form of pseudohyphae in tissue and blastoconidia in the bloodstream allows for adaptation and evasion of host defenses[63]. *C. albicans* is the most common species, but *C. tropicalis* is often implicated as the causative agent of fungemia in patients with leukemia. Neutropenia, especially in patients who have received prolonged courses of corticosteroids, sets the stage for disseminated candidiasis; patients are usually also receiving broad-spectrum antibiotics.

Hyalohyphomycosis includes infections with *Penicillium, Paecilomyces* and *Fusarium* spp. (see Fig. 77.32). These molds are found in the soil and throughout the environment and can cause disseminated infections in immunocompromised hosts. Disseminated infections with *Fusarium*, an angioinvasive organism, most often affect neutropenic oncology patients and may originate from a periungual focus (e.g. paronychia, onychomycosis). *Penicillium marneffei* is a dimorphic fungus, and HIV patients are particularly at risk.

Clinical features

All of the opportunistic mycoses can present with several different types of cutaneous lesions (see Fig. 77.32). Skin findings range from firm papules (Fig. 77.33B) and necrotic papulonodules (Fig. 77.33C) to hemorrhagic bullae (Fig. 77.33D) and ulcers. Subcutaneous nodules and cellulitis (Fig. 77.33E,F) can also be seen.

In disseminated aspergillosis, the CNS, kidneys and heart (in addition to the lungs) are often involved in severe widespread disease. The prognosis is poor but improves when the patient is no longer neutropenic or corticosteroids are discontinued. Secondary cutaneous zygomycosis due to an underlying sinus infection may initially present with subtle unilateral facial swelling and mild erythema, while advanced disease is characterized by large areas of necrosis covered by a thick hemorrhagic crust.

Secondary cutaneous cryptococcosis is associated with a poor overall prognosis, with a mortality rate of up to 80% if left untreated[64]. Findings range from papulonodules to ulcers and abscesses, and they may resemble lesions of herpes viral infections or molluscum contagiosum (Fig. 77.33G). Approximately 15% of patients with systemic cryptococcosis have skin lesions, and no predictable body distribution has been identified[65].

Cutaneous lesions of disseminated candidiasis frequently present as firm pink papules or nodules (see Fig. 77.33B) on the trunk and extremities. The lesions often have a pale center but may be purpuric in patients with thrombocytopenia. Other presentations include ecthyma gangrenosum-like lesions (hemorrhagic bulla followed by necrotic eschar), pustules, abscesses and purpura (in thrombocytopenic patients). While *C. albicans* is the most commonly associated species, *C. tropicalis* is more likely to produce cutaneous lesions[56]. Systemic sites of involvement include the liver, spleen, muscle, kidney, retina and heart valves. A sepsis-like syndrome may occur, with tachycardia, hypotension, dyspnea and high fevers.

Like histoplasmosis, *P. marneffei* typically infects the liver, spleen and lymph nodes. The skin may be involved with umbilicated papules that resemble molluscum contagiosum, necrotic nodules and acneiform lesions. The most common sites are the face (particularly the forehead), arms and trunk. When mucosal surfaces are involved, ulcers and papules are seen; prominent lymphadenopathy is often present.

Skin lesions develop in approximately 75% of patients with disseminated fusariosis, typically presenting as targetoid erythematous, ecthyma gangrenosum-like or purpuric nodular lesions in a widespread, scattered distribution. Affected individuals often have high fevers and severe myalgias.

Pathology

Histologic examination of lesions of cutaneous aspergillosis demonstrates 45° dichotomous branching of hyaline, septate hyphae (Fig. 77.34A) that are best demonstrated with silver or PAS staining. Suppurative and granulomatous inflammation and/or necrosis may be observed.

In zygomycosis, there are highly characteristic broad, non-septate hyphae that have 90° branching and have been likened to ribbons (Fig. 77.34B). PAS staining may be helpful. Suppuration and necrosis, as well as blood vessel invasion by the fungi, are often seen.

Histologic findings in cryptococcosis are described as either gelatinous (numerous organisms with little inflammation) or granulomatous (fewer organisms with more inflammation and little necrosis). While a PAS stain highlights the central yeast forms (Fig. 77.34C), mucicarmine or Alcian blue is used to visualize the characteristic capsule. India ink preparations, e.g. of CSF or dermal scrapings, also demonstrate the presence of the capsule. The wider the capsule and the more severe the immunocompromise, the less the inflammation.

In disseminated candidiasis, budding yeast and pseudohyphae are seen in the dermis, rather than in the stratum corneum as in mucocutaneous candidiasis.

P. marneffei has microscopic characteristics similar to histoplasmosis. The small organisms are numerous and found within macrophages and giant cells (see Table 77.16). The histologic findings of fusariosis are similar to those of aspergillosis, with acute-branching, septate hyphae, angioinvasion, necrosis and a variable granulomatous infiltrate.

Fig. 77.33 Clinical findings of opportunistic fungal infections in immunocompromised hosts. Primary cutaneous aspergillosis characterized by hyperpigmented plaques with brown–black scale-crusts at the site of intravenous catheters on the arm (**A**); firm pink papulonodule due to disseminated candidiasis (**B**); erythematous papulonodule with central necrosis due to embolus of *Mucor circinelloides* (**C**); necrotic hemorrhagic bulla due to embolus of *Aspergillus flavus* (**D**); cellulitis with area(s) of necrosis due to *Rhizopus* (**E**) and *Cryptococcus neoformans* (**F**); and crusted molluscum contagiosum-like lesions due to disseminated cryptococcosis (**G**). *C, Courtesy, Julie V Schaffer, MD. F, Courtesy, Kalman Watsky, MD. G, Courtesy, Athanasia Syrengelas, MD PhD.*

B, Courtesy, Jean L Bolognia, MD. C, Courtesy, Athanasia Syrengelas, MD PhD.*

Differential diagnosis

Microscopic examination of dermal scrapings (using KOH or calcofluor), histologic analysis, and culture of skin tissue are used to diagnose opportunistic fungal infections. The former studies are important considering that many of these organisms can also represent culture contaminants[66]. The clinical differential diagnosis ranges from folliculitis and molluscum contagiosum to cellulitis and ecthyma gangrenosum due to a disseminated bacterial infection. When there are necrotic eschars, the possibility of herpes zoster or vasculitis may be raised (see Fig. 77.32).

Macroscopically, cultures of *Aspergillus flavus* and *A. fumigatus* have been likened to "south sea islands" because the central portion is khaki green (*flavus*) or blue–green (*fumigatus*) with a rim of white to yellow color. Microscopically, spherical "heads" with conidia forming on the exterior are seen. In zygomycoses, culture reveals fast-growing "woolly" colonies in most instances. Microscopically, rhizoids, round sporangia and sporangiospores (asexual spores formed within sporangia) are seen (see Fig. 77.32)[67]. Culture of *Cryptococcus neoformans* yields a cream-colored colony that is similar in appearance to *Candida* colonies. On birdseed agar, the *C. neoformans* colony becomes brown. Because *P. marneffei* is a dimorphic fungus, at 25°C the mold form is seen with a diffusible red pigment, and at 37°C the colony appears as a yeast.

Antibodies against the capsule can be detected in cryptococcosis, and high titers herald a poor prognosis. Serum assays for components of the fungal cell wall, such as 1,3 β-D-glucan (detects a variety of fungi, including *Aspergillus* and *Fusarium*) and galactomannan (relatively specific for *Aspergillus* but somewhat less sensitive), have been used to screen high-risk patients for early evidence of an invasive fungal infection. PCR-based assays have also become available for detection of many opportunistic fungi (especially *Aspergillus*)[68,69].

Treatment

Prevention of opportunistic mycoses in high-risk patients can be aided by reduced exposure to environments such as construction sites and the use of ventilation systems. Prophylaxis with systemic antifungals (e.g. fluconazole, posaconazole, voriconazole) is commonly administered to patients receiving myelosuppressive chemotherapy and hematopoietic stem cell transplant recipients, both before and during periods of neutropenia. Even in the absence of neutropenia, individuals on chronic high-dose systemic corticosteroids (e.g. with chronic GVHD) are at significant risk for opportunistic fungal infections and represent another group now receiving prophylaxis. In the past, a febrile neutropenic patient unresponsive to systemic broad-spectrum antibiotics was empirically begun on amphotericin B. Nowadays, that patient might receive voriconazole, posaconazole or one of the echinocandins (e.g. caspofungin; Table 77.17; see Ch. 127). Of note, voriconazole is a triazole that has activity against *Aspergillus* and *Fusarium* as well as *Candida* (but not Zygomycetes); it causes photosensitivity (and increased risk of squamous cell carcinoma and melanoma) and, like itraconazole, drug–drug interactions due to inhibition of cytochrome P450. Posaconazole, another triazole with a similar range of activity (but also covering Zygomycetes), is used for both treatment and prophylaxis of opportunistic fungal infections.

Once an opportunistic mycosis is diagnosed, prompt treatment is essential. Primary cutaneous infections with opportunistic molds, if localized, can be surgically excised, followed by administration of oral antifungals. Disseminated infections carry a poor prognosis and are frequently fatal, particularly when treatment is delayed or ineffective. Amphotericin B (including lipid formulations) has been the standard treatment for several decades. However, voriconazole has proven superior for invasive fungal infections due to *Aspergillus*, and, in the case of disseminated candidiasis, caspofungin is now administered[70] (see Ch. 127). For systemic infections due to other opportunistic fungi, amphotericin B is still employed, but voriconazole does have activity against *Fusarium* and posaconazole has activity against both *Fusarium* and Zygomycetes.

In addition to amphotericin B and several triazoles, terbinafine may have activity against *P. marneffei*, which has a high mortality rate if inadequately treated. Unfortunately, recurrence is likely unless treatment is continued indefinitely[71].

TREATMENT OF OPPORTUNISTIC MYCOSES							
	Aspergillosis	Zygomycosis	Cryptococcosis	Candidiasis	Penicilliosis	Fusariosis	Forms of administration
Amphotericin B	+	+	+	+	+	+	iv
Itraconazole (200–400 mg/day)	+	–	+	+	+	–	po, iv
Fluconazole	–	–	+	+	–	–	po, iv
Voriconazole	+	–	+	+	+	+	po, iv
Posaconazole	+	+	+	+	+	+	po
Caspofungin	+	–	–	+	–	–	iv
Micafungin	+	–	–	+	–	–	iv
Anidulafungin	+	–	–	+	–	–	iv

Table 77.17 Treatment of opportunistic mycoses. Appropriate selection of therapy for opportunistic infections is essential, given the likelihood of rapid, widespread dissemination and high mortality rates[51]. iv, intravenously; po, orally.

Phaeohyphomycosis

Introduction and history

Phaeohyphomycosis refers to infections with a group of dematiaceous fungi (i.e. pigmented due to melanin in the cell wall) that produce distinct brown to black hyphae in tissue rather than Medlar bodies or grains (see chromoblastomycosis and eumycotic mycetoma above). Although systemic disease can occur, particularly spread to the CNS from a primary lung source, this section will focus on the other three forms of phaeohyphomycosis – superficial, cutaneous and subcutaneous.

Ajello and colleagues coined the term "phaeohyphomycosis" in 1974. Initially, the list of causative pathogens was limited, but presently it is extensive and continues to lengthen[72].

Epidemiology

Because phaeohyphomycosis encompasses infections caused by many fungi, the epidemiology is complex. All age groups and both genders may be affected. There may be a slightly higher incidence in men due to increased environmental and occupational exposure. The culprit fungi in phaeohyphomycosis are found in plants and soil, making individuals with certain occupations, activities and cultural habits (such as not wearing protective footwear) at higher risk of developing the infection.

Pathogenesis

Superficial phaeohyphomycosis includes tinea nigra and black piedra (see above), while cutaneous phaeohyphomycosis includes infections of the hands, feet and nails that mimic tinea infections in the same locations (e.g. *S. hyalinum*, *S. dimidiatum*; see Table 77.10). Trauma is typically the cause of subcutaneous phaeohyphomycosis. Both immunocompetent and immunocompromised hosts may acquire this disease. The immune status of the patient has a significant effect on the severity and the likelihood for disseminated disease; *Cladosporium trichoides (Cladophialophora bantiana)* is most commonly associated with CNS disease[64]. Secondary cutaneous phaeohyphomycosis occurs when dematiaceous fungi spread from other sites to the skin.

Clinical features

The clinical presentation of cutaneous phaeohyphomycosis is similar to that of dermatophyte infections of the hands, feet or nails. Subcutaneous phaeohyphomycosis most commonly presents as a nodule or plaque in regions of the body that are prone to trauma. The course is usually chronic, with slowly progressive disease. Clinical manifestations of disseminated disease include nonspecific skin lesions (papules, plaques, nodules) and signs of cerebral involvement.

Pathology

Histologic examination of cutaneous and subcutaneous phaeohyphomycosis reveals pigmented hyphae in the stratum corneum and dermis/subcutis, respectively (Fig. 77.35). In the latter, cyst-like abscesses (possibly surrounded by a fibrous capsule) can be seen, hence the term phaeomycotic cysts. Occasionally, implanted material (e.g. a splinter) may also be observed.

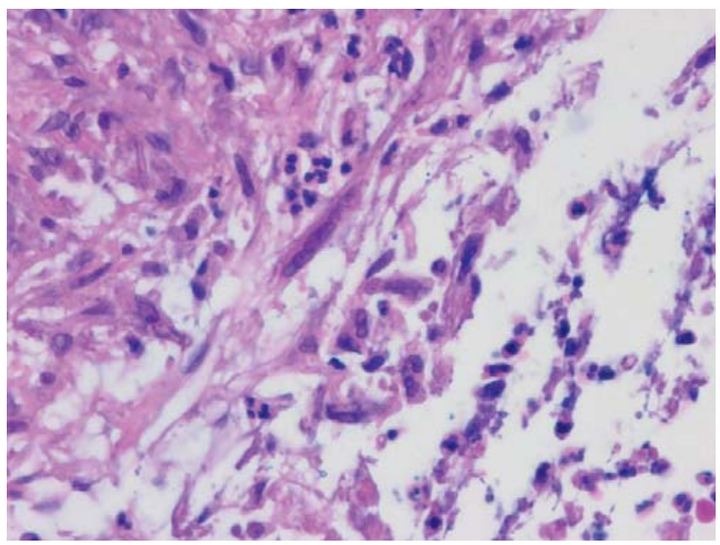

Fig. 77.35 Hyphae within a phaeohyphomycotic cyst.

Differential diagnosis

For the subcutaneous and systemic forms, the differential diagnosis may include a foreign body granuloma, cutaneous leishmaniasis, chromoblastomycosis and dimorphic fungal infections. KOH examination (superficial and cutaneous types), culture (all types) and histopathology (usually just subcutaneous and systemic types) allow the diagnosis to be made. Determination of genera and species requires fungal culture, but histopathology is useful in determining the extent of invasion and in differentiating causative pathogens from contaminants in culture specimens. *Exophiala jeanselmei* and *E. dermatitidis* are the organisms most commonly isolated from subcutaneous phaeohyphomycosis.

Treatment

Subcutaneous disease is surgically excised[73], if possible; complete surgical excision is usually curative. Systemic disease due to dematiaceous fungi continues to be a therapeutic dilemma, as it is difficult to eliminate with oral antifungals alone. Nevertheless, itraconazole, given at a dose of 200 mg twice daily for a prolonged course (>12 months), has some efficacy for the non-surgical treatment of phaeohyphomycosis. Close follow-up is required and includes repeat cultures and histologic analyses of affected sites. Additional treatments for systemic disease include voriconazole, posaconazole, amphotericin B and flucytosine.

Pneumocystis

In the past, *Pneumocystis jiroveci* (formerly referred to as *Pneumocystis carinii*) was classified as a protozoan. Currently, it is considered to be a fungus, based on genetic and biochemical analyses. This opportunistic infection occurs in individuals who are immunocompromised, including those with AIDS. The lungs are the most common site of infection (pneumonia), but, on occasion (<3% of patients), there is dissemination to other sites such as the liver, spleen and lymph nodes.

Cutaneous involvement is rare and is characterized by erythematous or skin-colored, non-tender papules or nodules[74]; there may be associated ulceration. The external ear (including the auditory canal) represents the most commonly reported site of involvement. Histologically, a diffuse infiltrate of foamy cells is seen within the dermis. Special stains (e.g. Grocott methenamine silver, Giemsa, Steiner) can be used to highlight the organisms, as can monoclonal antibodies; detection of *P. jiroveci* is also possible via PCR.

The most common treatment for pneumocystosis is trimethoprim–sulfamethoxazole (TMP-SMZ). Additional therapies include parenteral pentamidine and oral atovaquone. Prophylaxis in the setting of immunosuppression usually consists of oral TMP-SMZ or, less often, aerosolized pentamidine, oral dapsone or oral atovaquone. Prophylaxis is important for dermatologic patients receiving systemic corticosteroids combined with immunosuppressive agents such as azathioprine and cyclophosphamide.

Cutaneous Manifestations of HIV Infection

78

Armin Rieger, T Minsue Chen and Clay J Cockerell

Key features

- Cutaneous disorders in the setting of HIV infection represent a vast spectrum of diseases. As immunity deteriorates, variable presentations, opportunistic infections, mixed infections and adverse drug reactions are increasingly likely
- Because the cutaneous findings often correlate with immune status, a more focused differential diagnosis may be generated if the viral load and $CD4^+$ cell count are known. For example, seborrheic dermatitis and oral hairy leukoplakia first appear in patients with $CD4^+$counts >500 cells/mm^3, whereas giant mollusca and large non-healing perirectal ulcers due to herpes simplex virus are typically seen in patients with counts of less than 50 cells/mm^3
- With the advent of antiretroviral therapy (ART; formerly referred to as highly active antiretroviral therapy [HAART]), skin disorders such as herpes zoster and *Mycobacterium avium* complex infection may become clinically apparent or worsen when the immune status improves, a phenomenon known as the immune reconstitution inflammatory syndrome (IRIS)
- Unusual skin eruptions, skin diseases with exaggerated presentations (e.g. seborrheic dermatitis, molluscum contagiosum), sudden acute exacerbations (e.g. psoriasis), and treatment failures (e.g. refractory dermatophyte infection) should alert the clinician to the possibility of underlying HIV infection
- Several of the medications employed in ART lead to frequent drug reactions and significant drug–drug interactions

INTRODUCTION

Since the onset of the human immunodeficiency virus (HIV) pandemic in the 1980s, cutaneous disorders have been recognized as important clues to both the diagnosis of HIV infection and the existence of an associated systemic disease (including other infections).

The epidemiology of HIV infection and its complications has changed in many regions of the world with the advent of antiretroviral therapy (ART; formerly referred to as highly active antiretroviral therapy [HAART]). Although eradication of HIV infection is not possible with current medications, HIV infection/AIDS in the ART era has become a chronic, manageable disorder. As a consequence, many of the skin disorders associated with HIV disease (e.g. Kaposi sarcoma) as well as serious opportunistic infections are observed less frequently than in the past. However, with longer survival, medical problems that previously were less common have emerged (e.g. anal intraepithelial neoplasia), and ART itself has created new dermatologic challenges, including drug reactions, lipodystrophy and immune reconstitution inflammatory syndrome (IRIS). While the incidence of opportunistic infections has fallen in high-income countries, resurgence of risky behavior along with the mistaken belief that ART can "rescue and cure" infected patients may lead to a future increase in HIV infection. Unfortunately, in low-income countries where ART is not readily available, opportunistic infections are still common and are often the source of morbidity and mortality.

HISTORY

June 2011 marked the thirtieth anniversary of the identification of the acquired immunodeficiency syndrome (AIDS). The first description was officially made by Dr Michael S Gottlieb, who reported five cases of *Pneumocystis jiroveci (carinii)* pneumonia in healthy young men from Los Angeles, California[1–3]. Subsequently, the major causative agent was identified and named human immunodeficiency virus type 1 (HIV-1; hereafter referred to has HIV), and homology to an African zoonosis was demonstrated. Both blood-related and sexual transmission were identified, and recognition of mother-to-child transmission led to specific measures for delivery and breastfeeding. Universal precautions have been adopted for the handling of blood and body fluids, and ART was introduced in 1996.

EPIDEMIOLOGY

HIV infection/AIDS is a pandemic that still poses one of the greatest challenges in global public health. It has disproportionately affected resource-poor countries and disadvantaged persons, such as commercial sex workers, intravenous drug users and those living in poverty, as well as men who have sex with men.

Approximately 34 million people in the world are currently living with HIV infection (~22 million of whom reside in sub-Saharan Africa) and nearly 32 million have died since 1981[4]. It is estimated that there are currently over 2.5 million children living with HIV infection and 18 million children who have been orphaned because of AIDS. In 2009, there were approximately 2.7 million new HIV infections (including 390 000 children) and 1.8 million AIDS-related deaths worldwide. HIV has had an especially disastrous effect in sub-Saharan Africa (Fig. 78.1). However, in this region as well as several other areas with a high prevalence of HIV infection (e.g. India, Thailand and Caribbean countries), the HIV incidence rate has decreased or stabilized over the past 5–10 years[4]. In contrast, the HIV infection rates in Central Asia and Eastern Europe (particularly in the Russian Federation and Ukraine) have risen substantially during the past decade, especially in high-risk groups (i.e. intravenous drug users and sex workers); as a result, the prevalence of HIV infection has more than doubled in this region.

Currently, AIDS is the leading cause of death in Africa and the fourth leading cause of death in low-income countries worldwide[5]. On a global basis, access to antiretroviral drugs is still limited, although in the last few years it has improved in low- and middle-income countries. Prevention and treatment efforts require political leadership, national programs and adequate funding, as well as societal awareness and response[6,7].

PATHOGENESIS

HIV (including HIV-2, which is discussed separately below, as well as HIV-1) is an enveloped, single-stranded RNA virus belonging to the genus *Lentivirus* within the family Retroviridae. HIV has substantial genetic variability due to the high error rate and recombinogenicity of its reverse transcriptase as well as the very rapid turnover of the virus in infected individuals. The incubation period ranges from 3 to 6 weeks, but it may be shorter when it is transmitted hematogenously and/or when the viral inoculum is large. Upon initial infection, the virion binds to $CD4^+$ T lymphocytes, monocyte-macrophages and dendritic cells. Changes in conformation induce fusion of the viral envelope with the plasma membrane. Next, its outer coat is removed and the virus particle is internalized (Fig. 78.2). The RNA genome is released into the cytoplasm and transcribed by a reverse transcriptase enzyme that produces a DNA copy of the HIV RNA. The DNA copy is then integrated into the host DNA and can be expressed as a cellular gene. As

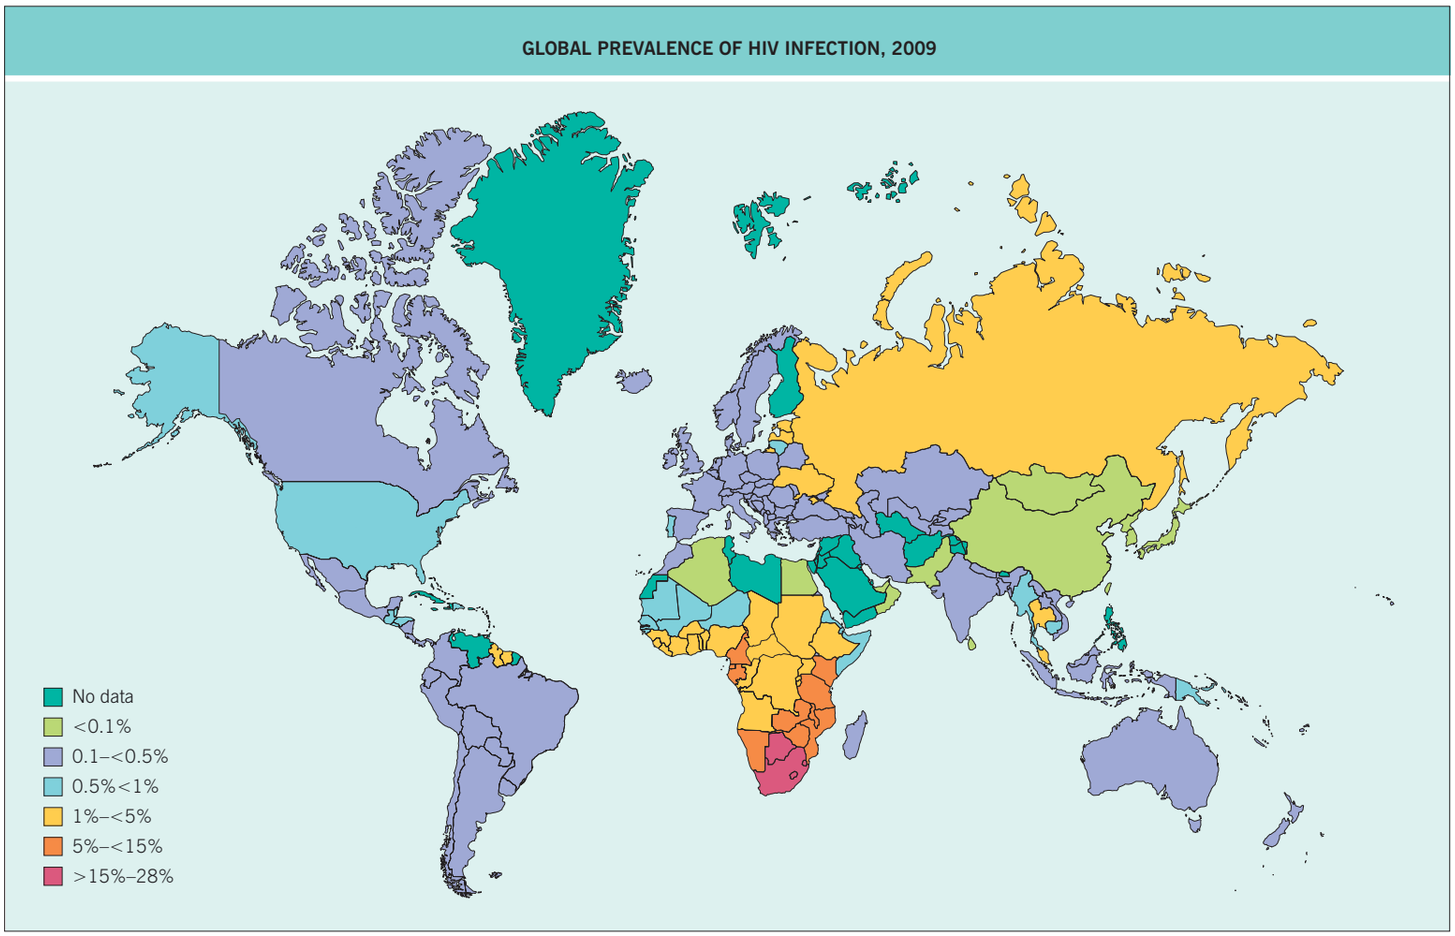

Fig. 78.1 Global prevalence of HIV infection, 2009. The estimated percentage of the adult population living with HIV infection in each country is indicated. The worldwide estimate of the number of persons living with HIV is 34 million. *From the Joint United Nations Programmes on HIV/AIDS.*

a result, there is transcription of viral DNA into RNA, which either becomes the genome of new viral particles or is translated into viral proteins. Cleavage of the latter into structural components of the virus is accomplished by proteases. Intact viruses are then produced and host cells are destroyed. $CD4^+$ cells are affected primarily, significantly impairing the host's immune system, especially the cellular component. On average, over one billion HIV particles are produced daily, leading to a decline in the infected individual's $CD4^+$ cell count[8].

In the humoral response to HIV, antibodies (IgG, IgM, IgA) directed against viral proteins are typically detectable within 12 weeks of infection. In the cellular response, $CD8^+$ cytotoxic T lymphocytes (CTLs) directed against HIV begin to function within 10 days of exposure to viral antigens and are therefore present before seroconversion or development of peak levels of viral RNA. The development of a CTL response correlates with the reduction in viremia during the acute retroviral syndrome and is an important factor in controlling HIV infection throughout the disease course. In addition to their effects on viral replication, CTL activity (including cytokine production) has implications for the infectious, inflammatory and neoplastic complications of HIV infection. Although $CD4^+$ helper T lymphocytes have a role in the initial response to HIV infection, they become dysfunctional early in the disease course (even before their numbers decline). The decreased ability of infected helper T lymphocytes to proliferate and produce IL-2 is central to the pathogenesis of HIV infection. Of note, infection of Langerhans cells by HIV can also affect the immune response. Despite vigorous anti-HIV immune responses, HIV-infected individuals are not capable of clearing the infection. However, occasional patients (known as "long-term non-progressors") tolerate the virus without developing significant clinical disease[8,9].

The earliest cutaneous manifestation of HIV infection is an acute morbilliform exanthem that is often accompanied by fever and lymphadenopathy (see below). During this phase, the virus disseminates widely, seeding lymphoid organs and other internal sites such as the CNS. Over time, an immunodeficient state referred to as AIDS ensues, complicated by opportunistic infections and neoplasms, many of which have mucocutaneous manifestations[10]. In a person infected with HIV, AIDS is defined by a $CD4^+$ cell count of <200 cells/mm^3 (or $CD4^+$ T-cell percentage of <14) and/or the presence of an AIDS-defining condition (Table 78.1).

The natural history of HIV infection varies considerably. There is evidence that additional acute infections (viral or non-viral) increase HIV viral load, but the significance of this phenomenon to the patient's overall course has not been established[11]. Some patients develop AIDS within 2–3 years, ("rapid progressors"), whereas others remain free from AIDS for more than 10–15 years ("long-term non-progressors" or "long-term survivors"). For untreated disease, the median time of progression to AIDS is approximately 10 years. However, institution of ART has an immense impact on the disease course. ART's profound effect on HIV replication enables reconstitution of $CD4^+$ T cells. This immune reactivation can result in a variety of inflammatory sequelae, referred to as the immune reconstitution inflammatory syndrome (IRIS), ranging from unmasking or paradoxically "worsening" infections or neoplasms to exacerbations of inflammatory disorders (see below).

HIV-2 is another human retrovirus that causes immune deficiency due to depletion of $CD4^+$ cells. The viral structure, modes of transmission, and immune deficiency syndrome it produces are virtually identical to those of HIV-1, and patients are commonly co-infected with HIV-1[12]. Compared to HIV-1, HIV-2 has several distinct features, including genetic differences, five- to eightfold less transmissibility, rare vertical transmission, a longer period of latency, and a slower rate of $CD4^+$ cell count decline and clinical progression. The outcome among HIV-2-infected patients may be slightly better, as the degree of immunodeficiency may be less. Most infections are diagnosed in endemic

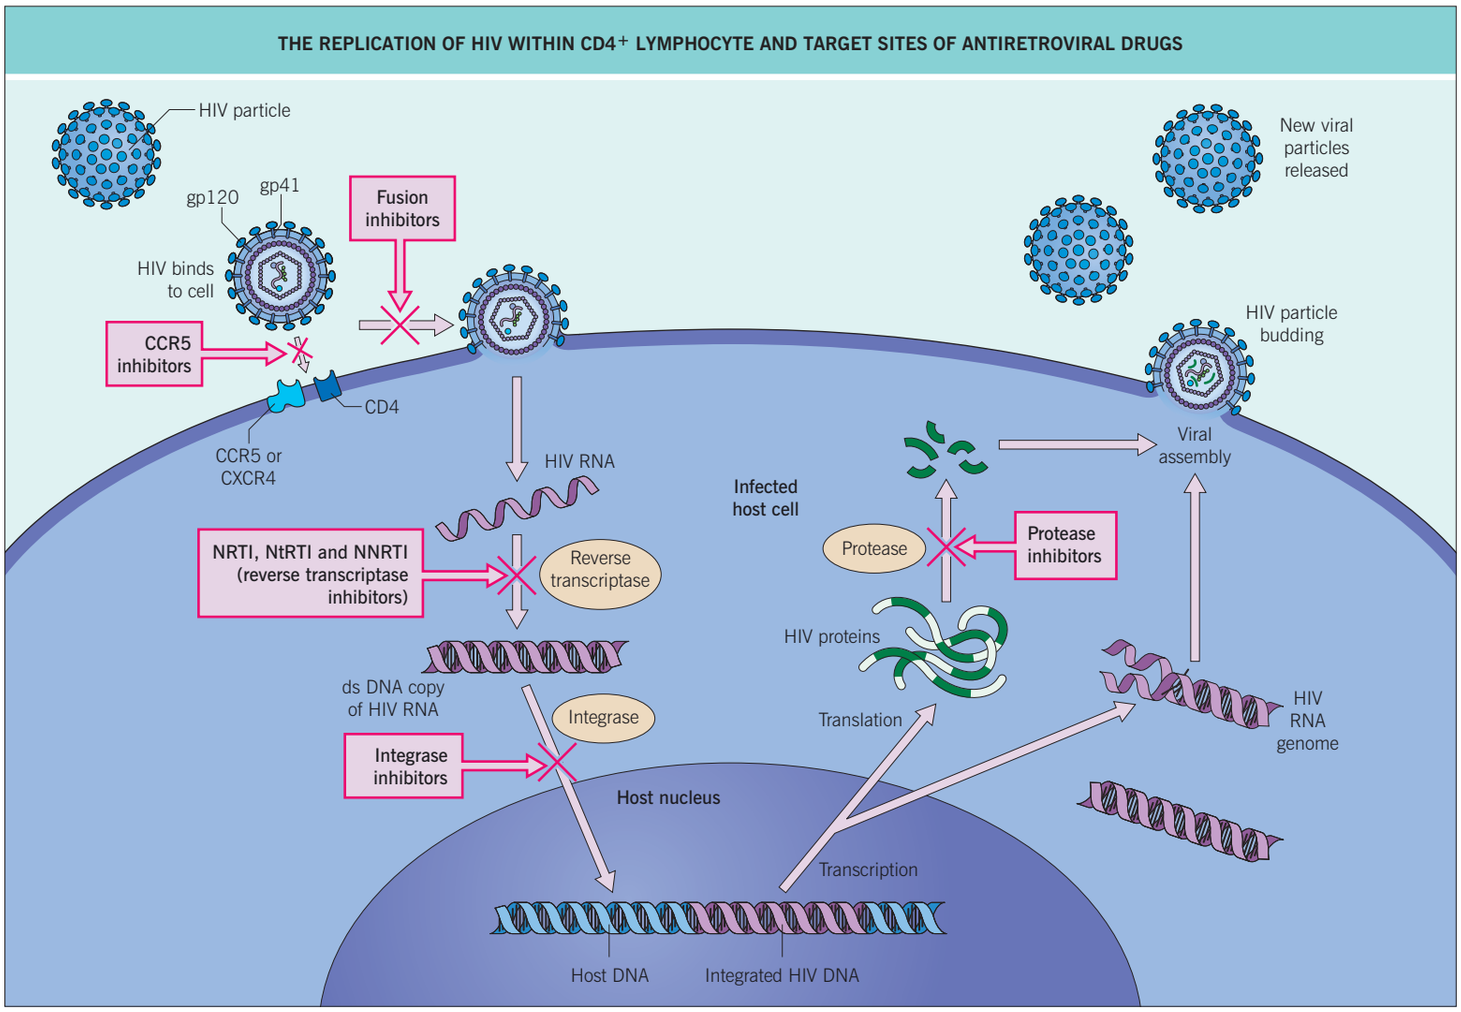

Fig. 78.2 Replication of HIV within CD4+ lymphocyte and target sites of antiretroviral drugs. CCR5, CC-chemokine receptor 5; NRTI, nucleoside reverse transcriptase inhibitor; NtRTI, nucleotide reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor.

areas (primarily West Africa); however, HIV-2 serology should not only be tested in individuals who are native to an endemic area, but also in those who have had sex with or shared a needle with an individual from an endemic area.

INFECTIOUS HIV-RELATED CUTANEOUS DISORDERS

Cutaneous infections associated with HIV seropositivity can be divided into five major categories: viral, bacterial, fungal, parasitic and ectoparasitic (the latter representing infestations rather than true infections). Patients with HIV acquired via sexual contact are at increased risk of (and should be tested for) other sexually transmitted diseases, which are discussed in Chapter 82; the converse is also true. In addition, the presence of erosions and ulcerations in the anogenital region due to diseases such as syphilis and herpes simplex infections can increase the risk of HIV transmission.

Viral Infections

Exanthem of primary HIV infection (acute retroviral syndrome)

The earliest cutaneous manifestation of HIV infection may be an exanthem occurring as a manifestation of the primary infection (Table 78.2). The latter is defined as the presence of HIV-1 in the plasma (based on detection of viral RNA or DNA by PCR and/or p24 antigen) *prior* to the development of HIV-1 antibodies (as determined by ELISA or Western blot). Primary HIV infection can be asymptomatic, but up to 80% of newly infected individuals report a history of a "viral illness" (Fig. 78.3). Also referred to as "acute retroviral syndrome", this usually occurs 2–4 weeks after HIV exposure and lasts from a few days to over 10 weeks. Reminiscent of acute mononucleosis, the most common signs and symptoms include fever, lymphadenopathy, pharyngitis and a morbilliform exanthem. The cutaneous eruption lasts 4–5 days and is typically generalized, with most pronounced involvement on the face and trunk (and often sparing the distal extremities). Additional manifestations, which can include oral or anogenital ulcers, are outlined in Figure 78.3. Due to an initial burst of HIV replication, a decline in $CD4^+$ T cells can be observed (see Fig. 78.3), only occasionally to levels that allow the development of opportunistic infections[13,14]. There is some evidence that a more severe acute retroviral syndrome portends a more aggressive disease course. The acute retroviral syndrome may be confused with a drug reaction or other infections (e.g. EBV, hepatitis B virus, enteroviruses, cytomegalovirus, secondary syphilis). The diagnosis therefore requires a high degree of clinical suspicion (not just in high-risk groups) and is confirmed by specific laboratory tests for HIV RNA/DNA and/or p24 antigen.

Herpes simplex virus (HSV)

Oral, labial and genital HSV infections in relatively immunocompetent HIV-infected individuals are typical in appearance and severity, with recurrence rates similar to those observed in the general population[15]. However, once significant immune suppression develops, lesions may progress to chronic, non-healing, deep ulcerations that favor the

AIDS-DEFINING CONDITIONS IN PATIENTS INFECTED WITH HIV

*CDC criteria define children as less than 13 years of age.
†Serious bacterial infections include: septicemia, pneumonia, meningitis, bone or joint infection, and an abscess of an internal organ or body cavity (excluding otitis media, superficial skin infections, mucosal abscesses, and indwelling catheter-related infections).

Table 78.1 AIDS-defining conditions in patients infected with HIV. *Data from: 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR Recomm Rep. 1992;41(RR-17).*

perianal region (Fig. 78.4), genitalia and tongue. More frequent recurrences are also observed when the CD4⁺ count falls to <100 cells per cubic millimeter[16,17].

Orofacial lesions associated with nasogastric tube use[18] and herpes simplex folliculitis have been described[19]. Untreated ulcerative lesions usually slowly enlarge and occasionally become verrucous. In suspected cases, scrapings of the ulcer edge for Tzanck smear (low sensitivity in this setting), direct fluorescent antibody (DFA) assay, HSV PCR and viral culture should be performed and, if negative, a skin biopsy performed[20–22]. In the setting of treatment failure, viral isolates should be tested for resistance against acyclovir and related antivirals. In most instances of resistance, reduced thymidine kinase activity is detected[23], and alternative drugs (e.g. foscarnet, cidofovir) that do not require thymidine kinase activity have to be prescribed.

Varicella zoster virus (VZV)

In HIV-infected individuals, the spectrum of primary varicella ranges from a typical course to fatal pulmonary involvement. HIV-infected patients have a 7–15 times greater relative risk of developing herpes zoster, with reactivation of latent virus occurring as cell-mediated immunity declines. The development of zoster in an HIV-infected individual is predictive of progression to more severe immune suppression, especially if associated with fever[20,24,25]. Although the classic dermatomal eruption may be seen, HIV-associated zoster can also be multidermatomal, ulcerative, chronic, verrucous and/or widely disseminated with systemic involvement (see Ch. 80). Bacterial superinfection, acyclovir resistance, therapeutic failure, and multiple recurrences are not uncommon[25]. Vasculitis with bone necrosis and exfoliation of teeth may develop if the blood supply to the mandible and maxilla are compromised[26].

Development of herpes zoster with an unusual presentation (e.g. multidermatomal, verrucous, disseminated) should prompt HIV testing. HIV-infected patients at risk for varicella who are exposed to individuals who either have varicella or are recent vaccinees may require prophylaxis with varicella zoster immune globulin (VZIG) or acyclovir[25]. Of note, herpes zoster is one of the conditions that may occur in the immune recovery syndrome, i.e. a paradoxical worsening of clinical status due to an increased ability to mount an inflammatory response (see Table 78.5), and it often appears when CD4⁺ cell counts rise to a level of approximately 250 per cubic millimeter[27]. Treatment options are outlined in Chapter 80, but in HIV-infected patients, antiviral therapy should be extended until there is clinical resolution.

Poxvirus

Molluscum contagiosum commonly affects patients with HIV infection who have significantly reduced CD4⁺ cell counts[28]. They may develop classic dome-shaped umbilicated papules as well as larger (>1 cm), coalescent and disfiguring lesions that are often resistant to treatment (Fig. 78.5). Although any part of the body can be affected, the lesions favor the face, neck and intertriginous areas.

The clinical differential diagnosis includes basal cell carcinoma and cutaneous involvement of infections with *Cryptococcus* spp., *Histoplasma capsulatum* and other dimorphic fungi. Shaving in affected areas should be avoided to prevent spread via autoinoculation. Although spontaneous regression may occur with antiretroviral therapy[20,24,29], the overall incidence of molluscum contagiosum infections remains high[30]. In addition to destructive modalities (e.g. curettage), imiquimod and topical cidofovir[31] have been used successfully to treat molluscum contagiosum in HIV-infected patients.

Vaccinia is an extremely uncommon skin disorder. Because the vaccinia virus vaccine is live and not attenuated, persons with impaired cell-mediated immunity may develop progressive vaccinia by vaccination or by inoculation from skin lesions in a vaccinee. Currently, virtually all individuals who receive the vaccinia vaccine are military recruits. Generalized vaccinia with fever and toxic symptoms typically develops 6–9 days after vaccination or other exposure to the virus. Skin lesions appear as loculated umbilicated vesicles that progress to pustules and heal with a pitted scar[29].

Human papillomavirus (HPV)

HPV is transmitted by direct person-to-person contact (which can be sexual in nature) or via fomites[32]. HPV-induced lesions are common in the general population but even more prevalent in HIV-infected individuals, and it has been demonstrated that HIV Tat protein upregulates the expression of HPV[20]. Lesions may be extensive, with multiple verrucae on the face, limbs and genitalia that coalesce into large plaques; bowenoid papulosis can also develop (see Ch. 79). In addition, "acquired epidermodysplasia verruciformis" (AEDV) presenting with widespread flat warts and pityriasis versicolor-like macules due to infection with HPV types in the genus beta can occur (see Ch. 80). HIV-infected individuals may develop squamous cell carcinomas (SCCs) in association with AEDV and other cutaneous (e.g. digital related to high-risk HPV types) as well as anogenital warts[32,33]. Institution of ART does not appear to result in clearance of warts and may be associated with the eruptive appearance of new lesions, sometimes in association with a

clinically evident inflammatory response (i.e. a form of IRIS; see below)[34,35].

Furthermore, HIV-infected patients have a higher risk of developing cervical intraepithelial neoplasia (CIN) and anal intraepithelial neoplasia (AIN), with the latter affecting approximately three-quarters of HIV-infected men who have sex with men (MSM)[36]. Immunosuppression, as evidenced by depressed $CD4^+$ cell counts, is associated with more rapid progression from low-grade to high-grade premalignant lesions. ART-induced immune reconstitution does not appear to prevent high-grade CIN or AIN from progressing to cancer, and longer survival due to ART has been associated with an increase in the incidence of anal cancer in HIV-infected individuals[37,38]. Anal cancer developed in 3% of HIV-infected MSM over a 5-year period in one prospective study[36], and the overall rate is >50-fold higher than in the general population[39]; a ~5-fold increased risk of penile cancer has also been documented. Monitoring should include serial physical examinations of the anogenital area, colposcopy/proctoscopy, cervical and anal HPV determination and cytology (utilizing the Papanicolaou [Pap] smear), followed by histologic confirmation when indicated; sensitivity can be increased by repetitive examinations[40]. Of note, recurrence rates of cervical cancer following standard therapy are significantly higher in HIV-infected women than in HIV-negative women.

Treatment decisions for cutaneous and anogenital warts in the setting of HIV infection depend upon the size and location of the lesions as well as the presence or absence of histologic atypia; the threshold for biopsy should be low, and several sites may need to be sampled to exclude SCC. Therapeutic options for warts include standard cytotoxic/destructive and immunomodulatory (e.g. topical imiquimod) approaches as well as alternative modalities such as topical or intralesional cidofovir. However, treatment is often challenging and relapse rates are high. Of note, the quadrivalent HPV vaccine (Gardasil™) was recently found to be safe and immunogenic in HIV-infected children; hopefully, use of HPV vaccines in young HIV-infected individuals will help to prevent (and even stimulate immune responses against existing) genital warts, dysplasias and cancer.

Epstein–Barr virus (EBV)

Oral hairy leukoplakia is an EBV-associated mucosal condition that represents an early sign of HIV infection. It develops in up to 25% of HIV-infected individuals[24] but can also occur in patients with other forms of immunosuppression (e.g. in organ transplant recipients). Development of oral hairy leukoplakia predicts disease progression if ART is not administered[41]. Lesions are usually asymptomatic and appear as corrugated white plaques with hair-like projections along the lateral aspect of the tongue (Fig. 78.6). There is no association with malignant degeneration. Although treatment is usually not necessary, topical or oral antiviral agents, podophyllin resin or gentian violet can be of benefit. Antiretroviral therapy may also lead to regression of the plaques[41].

Cytomegalovirus (CMV)

Despite ART, CMV remains an important cause of serious opportunistic infections in patients with advanced AIDS. Common clinical manifestations include retinitis, esophagitis and colitis. Despite the high frequency of CMV viremia, cutaneous disease is relatively uncommon; presentations include ulcers (especially in the anogenital area), verrucous or hyperpigmented plaques, purpuric papules, vesicles and morbilliform eruptions[20,42]. Ulcers may develop on any mucosal surface and are usually a sign of disseminated disease. Demonstration of intranuclear CMV inclusions within dermal endothelial cells usually proves to be a more sensitive assay than viral cultures (see Fig. 80.23). Of note, because many of the ulcerative lesions are co-infected with HSV or VZV, and CMV can also be detected in non-lesional skin, a primary role for CMV in the pathogenesis of these lesions has been questioned[43].

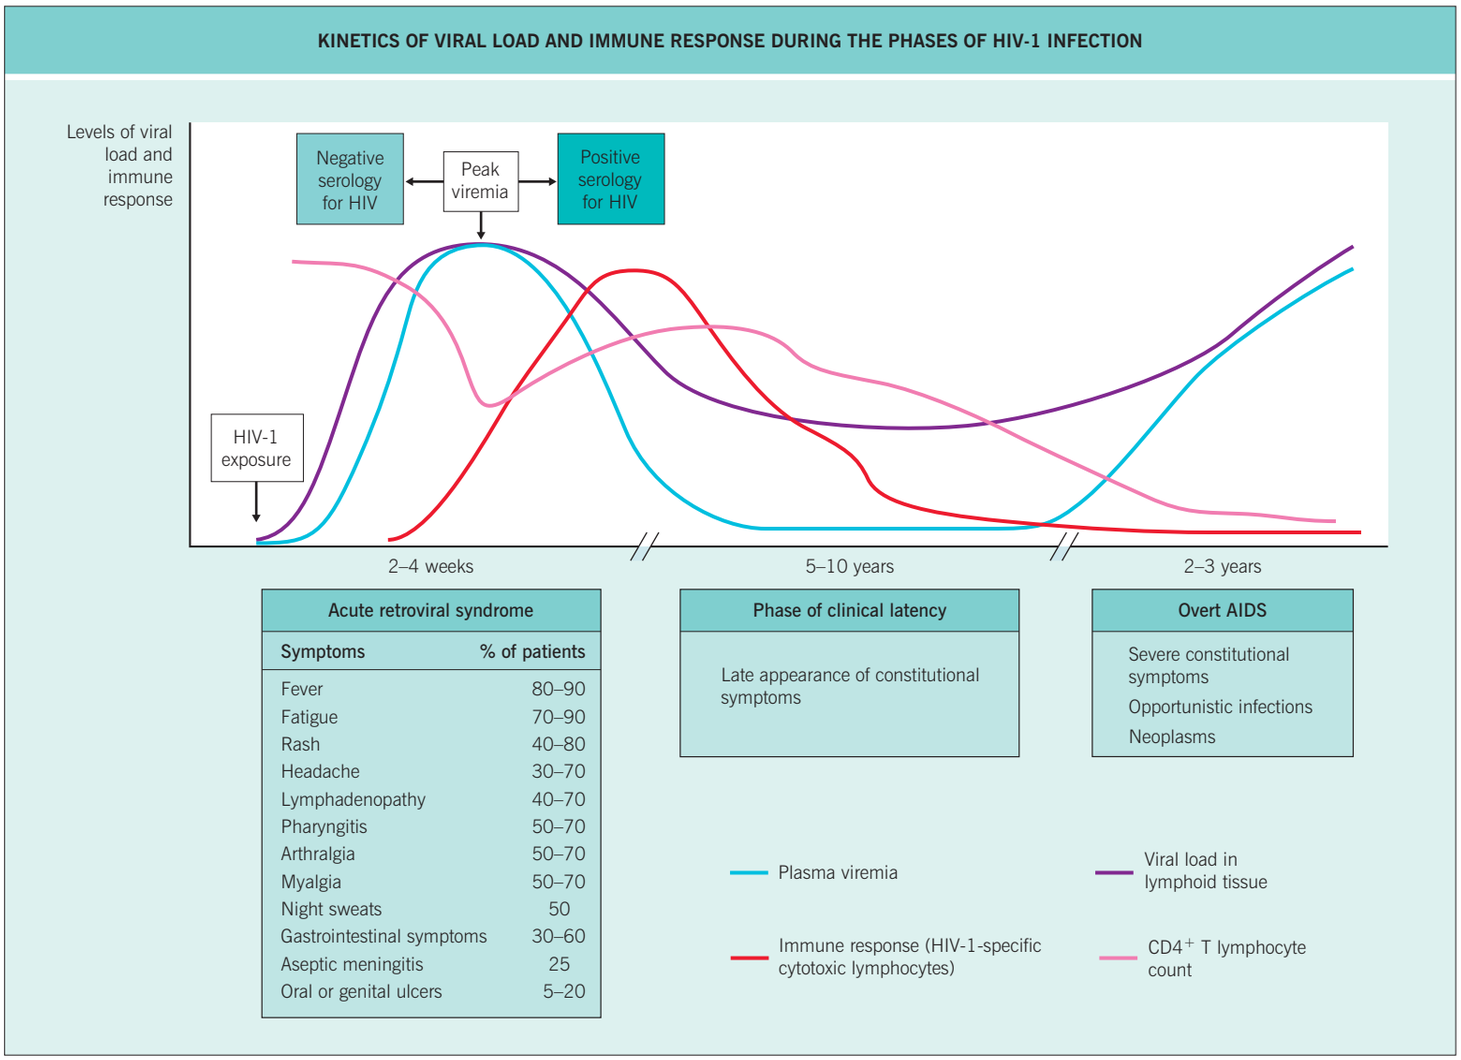

Fig. 78.3 Kinetics of viral load and immune response during the phases of HIV-1 infection. After HIV-1 exposure, initial virus replication and spread occur in the lymphoid organs, and systemic dissemination of HIV-1 is reflected by the peak of plasma viremia. A clinical syndrome of varying severity is associated with this phase of primary HIV-1 infection in up to 80% of HIV-1-infected persons. Down-regulation of viremia during the transition from the primary to the early chronic phase coincides with the appearance of HIV-1-specific cytotoxic T lymphocytes and with the progressive resolution of the clinical syndrome. The long phase of clinical latency is associated with active virus replication, particularly in the lymphoid tissue. During the clinically latent period, $CD4^+$ T-lymphocyte counts slowly decrease, as does the HIV-1-specific immune response. When $CD4^+$ T-lymphocyte counts decrease below 200 cells/ml (i.e. when overt AIDS occurs), the clinical picture is characterized by severe constitutional symptoms and by the possible development of opportunistic infections and/or neoplasms. *Adapted with permission of Elsevier from Bart PA, Pantaleo G. The immunopathogenesis of HIV-1 infection. In: Cohen J, Powderly WG (eds). Infectious Diseases. Edinburgh: Mosby, 2004.*

Bacterial Infections

The immunosuppression of HIV infection predisposes affected individuals to recurrent and potentially severe cutaneous bacterial infections, which can be localized or widespread and sometimes have unusual clinical appearances. Indwelling venous catheters, excoriations and ulcers with non-bacterial etiologies in HIV-infected individuals impair cutaneous barrier function and further increase the risk of bacterial infections. In addition to the entities discussed below, cutaneous bacterial infections that can occur in association with HIV infection include necrotizing fasciitis, nocardiosis, malacoplakia and pseudomonal "hot tub" folliculitis, "malignant" otitis externa and ecthyma gangrenosum.

Staphylococcus aureus

Staphylococcus aureus is the most common bacterial pathogen in patients infected with HIV, with common presentations including impetigo, folliculitis, furunculosis and cellulitis. The incidence of soft tissue infections with methicillin-resistant *S. aureus* (MRSA) is over sixfold higher in HIV-infected individuals that in those without HIV-infection. Pyogenic bacterial infections generally respond to treatment with antibiotics to which they are susceptible and/or (for furunculosis) incision and drainage, but unusual presentations (e.g. botryomycosis) may be refractory to therapy. Use of intranasal mupirocin and skin cleansers containing chlorhexidine gluconate can temporarily eradicate bacterial colonization (which is especially common among HIV-infected individuals), but it usually recurs.

Bacillary angiomatosis

Bacillary angiomatosis is a bacterial infection that can affect virtually any body site, but it favors the skin and subcutaneous tissue. Lesions of variable size and shape may be seen, including red to purple "vascular-appearing" papules or nodules and ulcers (see Ch. 74). The number of lesions ranges from one to more than hundreds. It has been postulated that a vasoproliferative factor may lead to their formation.

Gram-negative bacilli in the genus *Bartonella* are responsible for this disease, specifically *B. henselae* (associated with cat scratches/bites and exposure to cat fleas) and *B. quintana* (associated with poverty and poor hygiene)[44]. *B. quintana* may be transmitted from human to human by the body louse, *Pediculus humanus* var. *corporis*, although other as yet unidentified vectors may be also involved. Cutaneous lesions induced by *B. henselae* and *B. quintana* are indistinguishable, but the extracutaneous manifestations differ. Subcutaneous and osseous involvement is associated with *B. quintana* infections, whereas visceral disease is seen more often with *B. henselae* infections. Diagnosis is usually based on histologic features, i.e. characteristic vascular proliferation and numerous bacilli visualized by Warthin–Starry staining. Culture of *Bartonella* spp. and detection via PCR of the blood and/or tissue may also be helpful[45].

Resolution usually occurs with institution of appropriate antibiotic therapy (e.g. macrolides or tetracyclines)[20,46]. Optimal duration of antimicrobial treatment has yet to be defined, but a minimum of 2 months is recommended. If left untreated, death may ensue from pulmonary or hepatic failure[42].

Mycobacteria

Cutaneous tuberculosis can develop during advanced stages of HIV infection. Other mycobacteria such as *Mycobacterium avium* complex, *M. kansasii, M. haemophilum* and *M. fortuitum* may also produce skin lesions. Erythematous papules and nodules, ulcers, verrucous plaques and deep nodules can all be observed. Pruritus is generally absent and patients may be febrile. The common practice of prophylaxis with antimycobacterial medications as well as the use of ART has led to a decrease in the frequency of this complication[20].

Syphilis

Syphilis is caused by *Treponema pallidum* (see Ch. 82). Although classic papulosquamous secondary lesions are often seen, unusual presentations may be observed in hosts with HIV infection, including a noduloulcerative form, papular eruptions that mimic molluscum contagiosum, syphilitic palmoplantar keratoderma and lues maligna[42]. Lues maligna is an aggressive, widespread variant of secondary syphilis with a prodrome of fever, headaches and myalgia followed by an eruption of papulopustular or necrotic lesions[47]. CNS involvement occurs more frequently and with greater severity in individuals with HIV infection, and neurosyphilis should be considered in HIV-infected patients with neurologic symptoms. All patients with HIV infection should be tested for syphilis, and vice versa.

Fungal Infections

Cutaneous presentations of fungal infections in HIV-infected individuals range from localized superficial skin lesions to a manifestation of disseminated multiple-organ disease, and clinical morphologies may be atypical. Implementation of ART has significantly decreased the incidence of cutaneous fungal infections in this patient population[48].

Candidiasis

Candidiasis is the fungal infection most frequently encountered in association with HIV infection, and its incidence correlates with lower $CD4^+$ cell counts[49]. Ninety percent of patients with AIDS develop candidiasis of the oropharynx[41]. Perlèche with painful fissures at the oral commissures and persistent candidal infections of intertriginous zones are also commonly seen in HIV-infected individuals[42]. Other signs suggesting immune suppression include chronic paronychia, onychodystrophy and refractory vaginal candidiasis. Disseminated candidiasis has been reported and may be fatal in those with HIV infection[20].

Antiretroviral therapy has a beneficial effect on candidiasis, decreasing the prevalence of oral lesions and reducing the oral candidal load[50]. Conventional therapy (e.g. oral fluconazole) is indicated when the patient is symptomatic[42]; however, persons with $CD4^+$ counts <50 cells/mm^3 should be advised that excessive antifungal use can promote resistance.

Dermatophytoses

The severity of dermatophyte infections is increased in immunosuppressed hosts (see Ch. 77). In such patients, even minor infections can serve as a source of morbidity by providing portals of entry for serious bacterial pathogens. Cutaneous involvement can be atypical in appearance, and lesions may be more widespread and resistant to therapy. Spread of interdigital tinea pedis onto the dorsal foot, Majocchi's granuloma (a deep folliculitis with rupture of the follicle wall) and proximal white onychomycosis have all been associated with HIV infection[21,24]. The goals are to eradicate the infection as well as to prevent recurrence. The latter includes local measures such as absorbent powders[24].

Systemic fungal infections

Cryptococcosis and any of the dimorphic fungal infections (including histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, sporotrichosis and penicilliosis) can lead to disseminated disease in HIV-infected patients. Disseminated cryptococcosis (Fig. 78.7) and histoplasmosis are seen most commonly, followed by coccidioidomycosis and sporotrichosis[51]. In affected individuals, the $CD4^+$

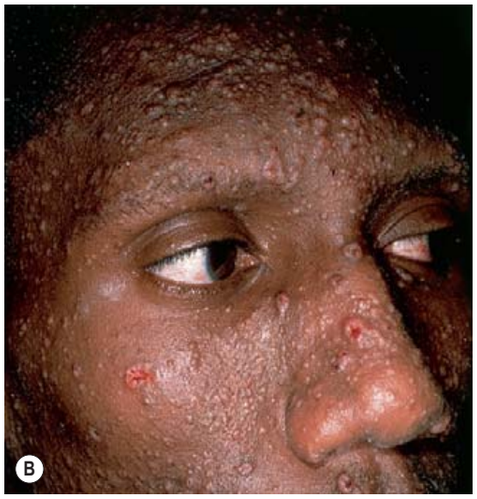

Fig. 78.7 Disseminated cryptococcosis in the setting of AIDS. **A** Several ulcers with rolled borders. **B** Numerous molluscum contagiosum-like lesions. Microscopic examination and culture of either dermal scrapings or a biopsy specimen confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS OF ORAL EROSIONS AND ULCERS IN HIV-INFECTED PATIENTS
INFLAMMATORY
Aphthae, major and minor (Fig. 78.8)
Stevens–Johnson syndrome, toxic epidermal necrolysis
INFECTIOUS
Herpes simplex and herpes zoster viral infections, acute and chronic
Cytomegalovirus (often component of co-infection with above)
Dimorphic or opportunistic fungal infections, e.g. histoplasmosis, cryptococcosis
Extragenital chancre
Mucous patches of secondary syphilis
Mycobacterial infections (tuberculosis and mycobacteria other than tuberculosis)
Necrotizing ulcerative gingivitis/periodontitis
NEOPLASTIC
Squamous cell carcinoma
Kaposi sarcoma
Lymphoma

Table 78.3 Differential diagnosis of oral erosions and ulcers in HIV-infected patients.

Fig 78.8 Major aphthae in a patient with AIDS. Resolution of these lesions may require thalidomide.

counts are usually <250 cells/mm^3 (see Table 78.2). These infections present with a wide range of morphologies, including pustules, crusted papules, papulonodules, verrucous plaques and mucocutaneous ulcerations[51].

In addition to signs of CNS involvement (e.g. meningitis), disseminated cryptococcosis may be associated with translucent dome-shaped papules with central umbilication (often on the face) that resemble mollusca contagiosa (see Fig. 78.7B)[52]. Cutaneous lesions of histoplasmosis and coccidioidomycosis can also appear on the face, and oral ulcerations are commonly seen in disseminated histoplasmosis (Table 78.3)[24]. Widely distributed crusted cutaneous ulcers have been reported in sporotrichosis[42]. Skin biopsy and culture of dermal tissue should be performed for any new, unexplained or unusual lesion where the differential diagnosis includes a disseminated bacterial, mycobacterial or fungal infection. Detection of cryptococcal antigen in the serum or cerebrospinal fluid (CSF) may be helpful in the diagnosis of systemic disease. Although intravenous amphotericin B remains a primary form of therapy, other antifungal agents (e.g. itraconazole, fluconazole, voriconazole, posaconazole, caspofungin) may prove useful (see Ch. 76). Unfortunately, these fungal infections are difficult to eradicate and relapses are common.

Pneumocystis jiroveci

P. jiroveci (formerly *P. carinii*) is now categorized as fungal organism rather than a protozoan (see Ch. 77). *Pneumocystis* pneumonia (referred to as PCP) is by far the most frequent form of infection. Disseminated cutaneous *P. jiroveci* infection is extremely rare and may appear as molluscum contagiosum-like papules, bluish cellulitic plaques, and/or deeply seated abscesses in the external auditory canal or nares[53]. It is theorized that aerosolized pentamidine administered for pulmonary infection may produce an unfavorable environment in the lung, leading to retrograde spread of the organism through the eustachian tubes. Standard therapy such as intravenous trimethoprim–sulfamethoxazole (TMP-SMX) or pentamidine is given for disseminated *Pneumocystis* infection in the setting of HIV infection[20,42]. Pulmonary prophylaxis with oral TMP-SMX or aerosolized pentamidine is recommended when the CD4$^+$ count is <200 cells/mm^3. Prophylactic treatment can be discontinued when, in the course of ART, CD4$^+$ counts have risen to >200 cells/mm^3 for >3 months[54].

Other fungal infections

In addition to those described above, a number of other fungal infections have occasionally been reported in patients with HIV disease. These include disseminated infections with *Scedosporium/Pseudallescheria* spp. and primary cutaneous (e.g. associated with an intravenous catheter site) as well as disseminated zygomycosis or aspergillosis[20]. *Prototheca* are achlorophyllic algae that occasionally cause cutaneous lesions (e.g. plaques, nodules, ulcers) in individuals with HIV, usually following skin trauma and/or exposure to contaminated water.

Parasitic Infections

Leishmaniasis

Leishmaniasis is a protozoal infection transmitted primarily by sand flies and is due to organisms of the genus *Leishmania* (see Ch. 83). HIV-associated leishmaniasis may occur in both endemic and non-endemic regions of the world. Endemic areas include the Mediterranean basin, India, east Africa, Sudan and Brazil. Individuals who were born in or once traveled to endemic areas may also develop disease, pointing

to recrudescence of a previously controlled latent infection. A decrease in the incidence of visceral leishmaniasis after the introduction of ART has been observed in several Mediterranean countries.

Multiple organs may be parasitized, and, when the skin is involved, the lesions typically present as ulcerated nodules or plaques (up to 2 cm in diameter) that favor the extremities. Atypical presentations in HIV-infected patients include disseminated lesions, diffuse erythema and induration, and large necrotic ulcerations[55]. Erosions and ulcerations of the lips, palate and nasal mucosa can be seen in mucocutaneous forms. If left untreated, destruction of cartilaginous structures may result in disfigurement. Fever, hepatosplenomegaly and varying degrees of pancytopenia may also be present.

The diagnosis of cutaneous leishmaniasis is established via microscopy, *in vitro* culture or PCR of lesional tissue. In HIV-infected patients, amphotericin B (which acts by T-cell-independent mechanisms) typically has better efficacy than pentavalent antimonials[42,56]. In a randomized open-label study, oral miltefosine (phosphocholine hexyl ester) and amphotericin B had similar cure rates[57].

Strongyloidiasis

Strongyloides stercoralis is an intestinal helminth endemic to tropical and subtropical regions. In the US, it is endemic in the rural Southeast and Appalachia. HIV-associated cutaneous strongyloidiasis may be caused by larval penetration of the skin and superficial veins giving rise to the migrating serpiginous urticarial eruption known as larva currens. Dissemination (i.e. hyperinfection) may occur in immunosuppressed individuals[58], and, when the skin is affected, lesions can mimic a number of other conditions such as urticaria and livedo reticularis; on the lower trunk, they may resemble purpuric "thumbprints" (see Ch. 83). Eosinophil counts are commonly elevated. Identification of larvae in biopsy specimens as well as sputum, duodenal or gastric contents, or CSF confirms the diagnosis, as does identification of eggs in stool specimens. *S. stercoralis* hyperinfection is almost universally fatal, with poor response to treatment with ivermectin or thiabendazole[20,59].

Acanthamebiasis

In acanthamebiasis, dissemination to the skin and CNS can occur in profoundly immunocompromised patients[60]; the usual cause is *Acanthamoeba castellani*, a microorganism that is part of the normal oral flora. Necrotic nodules and painful ulcerations on the trunk and extremities develop in these patients. Careful inspection on tissue sections will reveal amebic cysts, trophozoites and histiocyte-like cells with erythrophagocytosis. The infection is reported to respond to metronidazole[20].

Ectoparasitic Infestations

Scabies

Scabies, an infestation with the mite *Sarcoptes scabiei* var. *hominis*, is the most common ectoparasitic skin infestation in HIV-infected patients (see Ch. 84). Severe infestation may develop as a consequence of diminished cell-mediated immunity. Cutaneous lesions vary from the "classic" crusted papules to pruritic dermatitis to keratotic and crusted plaques[61] (Fig. 78.9); the latter may or may not be pruritic. Burrows, commonly found on the hands, wrists, ankles and interdigital areas, are less apparent in HIV-infected patients[62]. Also, the ears, face and scalp (sites not usually affected in immunocompetent adults) are commonly involved in immunosuppressed patients. In crusted (Norwegian) scabies, hyperkeratotic lesions may be generalized with subungual debris and marked nail thickening due to an extraordinary mite load; thousands to millions may be present on a single patient. Secondary infection with bacteremia and fatal septicemia has been reported in HIV-infected patients with scabies[62].

Crusted scabies, in particular, is extremely contagious. In any itchy HIV-infected patient, there should be a high index of suspicion for scabies. Persistent scaly or crusted eruptions should be scraped and examined for mites, and dermoscopic evaluation may also be useful in identifying mites. The hyponychium is a protected area, and, if scraped, can be a high-yield site for mites[62].

Therapy for scabies is aimed at eliminating the causative ectoparasite and providing symptomatic relief with topical and systemic antipruritics[21]. HIV-infected individuals with scabies are usually treated initially with standard therapies (e.g. topical permethrin; see Ch. 84), but they may require multiple courses. Treatment with oral ivermectin is also highly effective and is generally used in those who do not respond to standard regimens. Mites under the nails, failure to treat contacts and failure to dry laundered bed linens and clothing at high temperatures are common causes of reinfestation. Scale-crusts often serve as reservoirs for mites, and keratolytic agents such as 6% salicylic acid ointment can facilitate exfoliation as well as penetration of topical medications.

Fig. 78.9 Crusted (Norwegian) scabies in the setting of HIV infection. Crusted and keratotic plaque on the elbow that is teeming with mites.

Demodicosis

Demodicosis is caused by the mites *Demodex folliculorum* and *D. brevis* and has been reported in association with HIV infection. Rosacea-like demodicosis may be more frequent in HIV-positive patients. These eruptions, usually affecting the head and neck region, are similar in morphology to, and must be differentiated from, other pruritic papular eruptions (see below)[63]. Microscopic examination of skin scrapings placed in mineral oil demonstrates multiple mites. *Demodex* infection usually responds to treatment with topical permethrin, gamma benzene hexachloride or metronidazole, or with oral metronidazole[20,24,42]; refractory cases may require ivermectin.

Insect bite reactions

Insect bite reactions can be severe in HIV-infected patients and should be differentiated from other causes of pruritus, including non-infectious papular pruritic disorders associated with HIV infection.

NON-INFECTIOUS HIV-RELATED CUTANEOUS DISORDERS

A number of non-infectious dermatoses have been described in association with HIV infection. The development of inflammatory disorders that are characteristic of HIV infection or unusual presentations (e.g. increased severity, eruptive onset or atypical morphology) of other inflammatory conditions should alert the clinician to consider HIV infection as a possible underlying factor.

Papulosquamous Disorders

Seborrheic dermatitis

Seborrheic dermatitis is the most common skin disorder to affect HIV-infected individuals (up to 85%) and is seen in all stages of the disease (see Table 78.2)[20]. Clinical findings may be similar to those seen in the general population, i.e. erythema and yellowish, greasy scale on the scalp and face as well as involvement of other locations such as the central chest and inguinal creases. However, exaggerated presentations with exuberant facial plaques can also occur and should raise

the possibility of HIV infection, as should a sudden onset or acute worsening of seborrheic dermatitis. The disease may be more difficult to control with conventional therapy, including that aimed against *Malassezia* spp. (see Ch. 13).

Psoriasis

The overall incidence of psoriasis is probably not increased in the setting of HIV infection, although its clinical presentation tends to be more severe. It may develop at any stage of HIV infection[64]; as with seborrheic dermatitis, a rapid onset of "eruptive" psoriasis can serve as a clue to an underlying HIV infection, and psoriasis tends to worsen with declining immune status. Two clinical subgroups have been described: (1) patients with a personal and/or family history of psoriasis, in whom chronic plaque psoriasis is the most common clinical presentation; and (2) those who develop psoriasis after becoming infected with HIV and more commonly have palmoplantar involvement and psoriatic arthritis. An "inverse" distribution involving inguinal creases and genitalia may also occur[22]. The psoriasis is often extensive (Fig. 78.10) or erythrodermic, and exudative crusting or exacerbation with staphylococcal or streptococcal infections may be observed[65]. It can be associated with significant nail dystrophy, arthritis and reactive arthritis (formerly Reiter's disease)[65].

For HIV-associated psoriasis that is refractory to topical therapies, phototherapy and systemic retinoids represent first- and second-line treatments, respectively[65–67]. Immunosuppressive agents such as methotrexate, cyclosporine and tumor necrosis factor-α (TNF-α) inhibitors should be used with caution in HIV-infected patients. A beneficial effect of zidovudine on HIV-associated psoriasis (independent of $CD4^+$ cell counts) has been described[65]. However, worsening of psoriasis following ART-associated elevation in $CD4^+$ counts has been reported.

Reactive arthritis (formerly Reiter's disease)

All patients with newly diagnosed reactive arthritis should undergo HIV testing, as the association between the two conditions is strong[21]. In HIV-infected patients with HLA-B27, reactive arthritis commonly occurs after genitourinary or gastrointestinal infections. Treatment of cutaneous lesions is similar to that for psoriasis[24].

Other papulosquamous dermatoses

Generalized xerosis can be seen in HIV-infected patients and may be associated with refractory pruritus. When the $CD4^+$ count drops below 50 cells/mm^3, acquired ichthyosis with large plate-like scales may develop, beginning on the legs and often becoming widespread. Atopic dermatitis is a frequent problem in children with AIDS and is often difficult to control with conventional therapy[24,68] (see Ch. 12). Pityriasis rubra pilaris (PRP) can develop in conjunction with HIV infection (referred to as type VI PRP; see Ch. 9). In this setting, PRP is typically generalized and may occur together with follicular spines, acne conglobata and hidradenitis suppurativa (HIV-associated follicular syndrome).

Fig. 78.10 Severe psoriasis in a patient with AIDS. Both sudden acute exacerbations and treatment resistance can be observed.

Non-infectious papular pruritic disorders

Papular pruritic disorders are common in HIV infection, and the extreme itch can be debilitating. The pathogenesis of these pruritic dermatoses is not entirely clear[20]. Hypersensitivity reactions to drugs or parasites, peripheral eosinophilia with increased levels of IgE, "hyperreactive" basophils and mast cells, and circulating pruritogens associated with systemic disorders (e.g. hepatobiliary disease, renal disease, lymphoma) can contribute to the development of these conditions. Neural irritation related to HIV infection as well as autonomic dysfunction with diminished sweating and sebaceous gland secretion may also contribute to the pruritus.

The differential diagnosis of itchy papules is extensive. Underlying infections/infestations and systemic etiologies must be excluded, particularly scabies and adverse drug reactions. In some instances, primary lesions are absent, and prurigo nodularis or lichen simplex chronicus may be the only finding. Knowledge of the patient's medications, exposures, travel history and prior treatments can aid in diagnosis, and histologic evaluation may also be helpful.

Papular pruritic eruption of AIDS

Papular pruritic eruption (PPE) of AIDS is characterized by marked pruritus and greater involvement of the extremities than the trunk or face. It is more prevalent in Africa than in North America or Europe. Some authors believe that PPE represents a spectrum of pruritic disorders, including eosinophilic folliculitis[64], while others have suggested that it is an exaggerated response to arthropod antigens[69]. Clinically, the lesions are symmetrically distributed, non-follicular papules, often with secondary changes (e.g. excoriations, formation of prurigo nodularis).

Eosinophilic folliculitis

Eosinophilic folliculitis (see Ch. 38) is one of the most characteristic and common pruritic dermatoses associated with HIV disease, usually occurring in patients with $CD4^+$ counts <200 cells/mm^3. One theory is that it results from an exaggerated reaction to *Malassezia* yeast or other organisms normally present within the follicular infundibula and is a reflection of immune dysregulation leading to a Th2-predominant immune response. Excoriated follicular papules and rare intact pustules are found primarily on the face and upper trunk[64] (Fig. 78.11). Cultures are negative and peripheral eosinophilia may be present[24].

Eosinophilic folliculitis associated with HIV infection differs from Ofuji's disease in its intense pruritus but lack of circinate or palmoplantar lesions. In addition to infectious causes of folliculitis (e.g.

Fig. 78.11 Eosinophilic folliculitis. Due to associated pruritus, follicular papules are often excoriated; lesions favor the head and upper torso.

Pityrosporum, *Demodex*) , acne vulgaris, rosacea and drug reactions should be excluded[70]. Although topical corticosteroids, topical tacrolimus, topical permethrin, UVB phototherapy, systemic antibiotics, itraconazole, dapsone and oral retinoids (e.g. isotretinoin) have each shown some efficacy[24,71], HIV-associated eosinophilic folliculitis may prove recalcitrant to therapy. The impact of ART varies, with anecdotal reports of beneficial effects[72] as well as flares shortly after its institution[73,74].

Hair and Nail Disorders

A variety of disorders of the hair and nails have been recognized in HIV-infected individuals. Alopecia can occur due to infectious etiologies such as severe tinea capitis or secondary syphilis, and serious systemic infections can trigger telogen effluvium. Although alopecia in association with nucleoside analogue treatment has been reported (see Table 78.4), hair regrowth has also been observed after initiating zidovudine therapy[75].

The hair of HIV-infected patients may spontaneously straighten and become softer and more silky, or it can become lusterless and dull[75]. Sudden graying of the hair has been observed with HIV infection, and it may develop via mechanisms similar to those of alopecia areata or AIDS-related vitiligo[75]. Trichomegaly of the eyelashes, a sign of prolonged anagen phase, has also been noted in AIDS patients, including those receiving interferon-α and zidovudine[20,76]. The causes of these phenomena remain unknown and may be related to HIV infection of the hair follicle or concomitant nutritional deficiencies.

Nail disorders also commonly develop in HIV-positive patients. Proximal subungual onychomycosis, the least common of the three forms of onychomycosis, is often a reflection of immunosuppression, including HIV infection (see Ch. 77). Chronic candidiasis with paronychia and nail ridging can be seen, as can nail infections with *Scopulariopsis brevicaulis* and *Alternaria* spp. Patients receiving zidovudine may develop hyperpigmentation of the nail plates as a reflection of increased melanin within melanocytes and dermal melanophages (Fig. 78.12). Protease inhibitors, especially indinavir, have been associated with paronychia and ingrown toenails[77]. Beau's lines (transverse ridging 2–3 months after serious physiologic stress), psoriatic nail pitting and onycholysis may also be seen[75].

Vasculitis

Systemic vasculitis should be considered if an HIV-infected patient has fever of unknown origin or unexplained multisystem disease. Causes of vasculitis in the setting of HIV infection range from systemic infections to drug reactions to inflammatory disease. Arteries and veins of all sizes can be involved and any organ, including the brain, skin and neuromuscular tissues, may be affected. The pathogenesis includes immune complex-mediated disease as well as direct vessel wall damage by infectious agents. Treatable infectious causes should always be sought, e.g. hepatitis C and hepatitis B viruses, HSV, CMV, *Toxoplasma*, *Pneumocystis*, *Salmonella*, *M. tuberculosis* and *Mycobacterium leprae*.

Polyarteritis nodosa-like vasculitis with peripheral neuropathy or digital ischemia occasionally occurs in HIV-infected individuals. Unlike classic polyarteritis nodosa, multisystem involvement is often absent. Usually there is no evidence of hepatitis B viral infection. As expected, cutaneous small vessel vasculitis usually presents as palpable purpura[78,79]. Erythema elevatum diutinum, a chronic form of cutaneous leukocytoclastic vasculitis, has also been reported when $CD4^+$ counts are <200 cells per cubic millimeter[80]. Clinically, the skin lesions are similar to those seen in non-HIV-infected individuals and appear as persistent erythematous papules and nodules that favor extensor surfaces; failure to respond to dapsone has been reported in some patients.

Fig. 78.12 Zidovudine-associated melanonychia. Patients receiving zidovudine may develop longitudinal streaks, horizontal bands and diffuse hyperpigmentation.

Photosensitivity Reactions

UV light hypersensitivity

UV light "hypersensitivity" may be a presentation of HIV disease or related to photosensitizing medications such as sulfonamides. Cutaneous lesions are characteristically pruritic, lichenoid, violaceous plaques in sun-exposed areas[24], i.e. a photolichenoid reaction.

Porphyria cutanea tarda

The acquired form of porphyria cutanea tarda (see Ch. 49) is not uncommonly observed in the setting of HIV infection. When phlebotomy proves difficult because of coexistent anemia, low-dose antimalarial therapy (e.g. hydroxychloroquine three times weekly) should be considered. Avoidance of triggering factors such as alcohol and sunlight can be helpful, and serum ferritin levels and hepatitis C serologies should be obtained[81,82].

Chronic actinic dermatitis

Chronic actinic dermatitis (see Ch. 87) may also be associated with HIV infection, presenting as chronic, scaly, erythematous plaques[24]. There is usually evidence of photosensitivity, which often extends into the visible light range. Sometimes it may represent evolution of a persistent photodrug eruption.

Metabolic Changes

HIV/ART-associated lipodystrophy

Changes in body fat distribution are commonly observed in HIV-infected patients receiving ART, and this is referred to as HIV/ART-associated lipodystrophy or fat redistribution syndrome[83]. Patients may present with various constellations of findings, including lipoatrophy of the face, limbs and buttocks (see Ch. 101); central obesity ("protease pouch", "crix belly"); dorsocervical lipomatosis ("buffalo hump"); and breast hypertrophy. Hypertriglyceridemia and insulin resistance are also commonly observed. On the face, the lipoatrophy occurs predominantly on the cheek, temples and periorbitally. The resultant clinical appearance is highly characteristic and stigmatizing, potentially causing not only psychosocial stress but also decreased adherence to the antiretroviral medication regimen.

Proposed mechanisms for the lipoatrophy component include the following effects of antiretroviral drugs: (1) impaired differentiation and increased apoptosis of adipocytes; (2) increased lipolysis and decreased lipogenesis; and (3) mitochondrial toxicity[84,85]. While lipoatrophy and visceral obesity do share several risk factors (e.g. age, viral load, duration of therapy, $CD4^+$ count), lipoatrophy is associated with being Caucasian and exposure to and duration of treatment with nucleoside reverse transcriptase inhibitors (especially stavudine)[86], whereas visceral obesity/abnormal fat accumulation is associated with female sex and protease inhibitor use. Thus, the possibility has been raised that these two findings reflect separate pathophysiologic processes.

Although substituting non-nucleoside reverse transcriptase inhibitors for the protease inhibitor in a given regimen does not change the likelihood of lipodystrophy, substitution of non-thymidine analogues for stavudine (a thymidine analogue) can lead to a gradual improvement of peripheral lipoatrophy as well as dyslipidemia[87]. Other pharmacological interventions, such as administration of pravastatin, pioglitazone

and uridine, can result in fat gain in areas of peripheral lipoatrophy[88]. In contrast to the small and gradual benefits of pharmacologic treatments for lipoatrophy, surgical interventions are often successful and can provide almost immediate improvement in appearance. Surgical approaches for lipoatrophy include autologous fat transplants[89] and injection of degradable or non-degradable synthetic fillers, such as poly-L-lactic acid[90] or silicone.

Tesamorelin, an injectable growth hormone-releasing factor analogue, was recently approved by the US Food and Drug Administration (FDA) as a treatment to reduce excess visceral abdominal fat in patients with HIV/ART-associated lipodystrophy[91]. Lifestyle modification and other pharmacologic interventions, such as the use of metformin[92], may also help to decrease truncal and visceral fat. Cosmetic surgery (e.g. liposuction) is an option for the management of large dorsocervical lipomatosis, although the risk of recurrence exists.

Malnutrition

Decreased appetite and reduced intake of food along with nausea and malabsorption are common in HIV-infected patients, and they often suffer from gastrointestinal side effects of medications and infectious diarrhea. Cutaneous manifestations of malnutrition may be encountered, including those associated with kwashiorkor and deficiencies of vitamins B_{12} and A[93,94] (see Ch. 51). Nutritional replacement should be initiated once the deficiency is recognized, as severe malnutrition can be life-threatening[93,95].

Miscellaneous Conditions

Primary cutaneous mucinoses have been linked to HIV infection (see Ch. 46). Most commonly, localized lichen myxedematosus or acral persistent papular mucinosis occurs in an individual with a relatively advanced stage of HIV infection. *Granuloma annulare* is also occasionally observed in HIV-infected patients, and the lesions may be widely disseminated or have an atypical distribution pattern. *Major aphthae* (especially oral lesions; see Ch. 72) can represent a therapeutic challenge in HIV-infected individuals. After excluding infectious etiologies (see Table 78.3), systemic therapy (e.g. thalidomide) is often required. Additional findings that are occasionally observed in individuals with HIV infection include *hyperpigmentation* (in addition to that related to photosensitivity, systemic drugs or adrenal insufficiency), especially of the face, and *linear telangiectasias* on the chest.

NEOPLASTIC HIV-RELATED CUTANEOUS DISORDERS

A number of different cutaneous neoplasms may develop in patients with HIV infection. Diagnosis is established primarily by clinical assessment and histologic examination. Aggressive treatment and heightened awareness are imperative for improving prognosis.

Squamous and Basal Cell Carcinomas

As in immunocompetent individuals, fair skin and sun exposure (cumulative and intense intermittent) are risk factors for the development of basal cell carcinoma (BCC) and SCC[96]. Compared with the general population, HIV-infected individuals have a three- to fivefold higher risk of developing these non-melanoma skin cancers, which tend to appear at a younger age and are more often multifocal and located on the trunk and extremities[20,96–98]. Cutaneous SCCs in HIV-infected individuals have a high risk of recurrence and metastasis. Although BCC metastases have been reported, overall, BCCs do not behave more aggressively in patients with HIV infection[20]. As discussed above, HPV infection (in particular, high-risk genital and genus beta types) increases the risk of anogenital, oral, digital and EDV-associated cutaneous SCCs in HIV-infected individuals[37–39], and aggressive treatment is often required to prevent recurrences and metastases[20]. Monitoring strategies for HPV-associated AIN, CIN and SCC are outlined in the section on HPV (see above).

Lymphomas

Cutaneous lymphomas of B- or T-cell lineage may develop in HIV-infected adults and children[98,99], often in the setting of significant immune suppression with $CD4^+$ counts <200 cells/mm^3. Clinically, pink to violaceous papules and nodules are usually seen; the lesions often ulcerate and sometimes simulate panniculitis[20]. HIV infection-associated lymphomas are most often non-Hodgkin B-cell type and high or intermediate grade. Additional differences from lymphomas in the general population include a younger age of onset, more advanced stages and extranodal involvement (especially of the CNS, intestine and skin) at presentation[24]. Approximately one-half of non-Hodgkin lymphomas in HIV-infected patients are associated with EBV infection.

A decrease in the incidence of all types of lymphoma in HIV-infected individuals has been noted since the introduction of ART. Antiretroviral therapy also significantly improves the clinical outcome and overall survival of patients with AIDS-related lymphoma. A prior diagnosis of AIDS (see Table 78.1) and bone marrow involvement are associated with an unfavorable prognosis[100].

Cutaneous T-cell lymphoma, in particular the mycosis fungoides variant, and T-cell lymphoproliferative disorders (which can mimic mycosis fungoides clinically) can occur in patients with HIV infection[20,24,42,98], albeit much less frequently than B-cell lymphomas. The possibility of adult T-cell leukemia and lymphoma caused by human T-cell leukemia/lymphotropic virus type I (HTLV-1) needs to be considered and excluded.

Kaposi Sarcoma

The neoplasm most closely associated with HIV infection is Kaposi sarcoma (KS)[101]. With the widespread use of ART, the incidence of HIV-related KS has declined significantly in high-income countries. However, elsewhere it remains a significant source of morbidity, especially in sub-Saharan Africa. The etiologic agent, human herpesvirus type 8 (HHV-8), can be transmitted via exposure to the semen or saliva of infected individuals[24,99] (see Ch. 80). It is estimated that KS comprises 20% of childhood malignancies in African countries.

Clinically, skin lesions vary from small violaceous papules to large plaques to ulcerated nodules[42] (Fig. 78.13). The upper body is typically involved, often along skin lines in a pityriasis rosea-like pattern and at sites of local trauma[20,24]. Lesions also develop on the face, in particular the nose, and on oral mucosal surfaces, including the gingiva and hard palate[20]. Internal involvement is common in HIV-related KS, most often affecting the lymph nodes (potentially leading to lymphedema), gastrointestinal tract and lungs.

Several treatment options exist and should be selected according to the stage of HIV disease, the extent of KS involvement, comorbidities, and the likelihood of receiving effective ART. Regression may be observed with reversal of immune suppression by ART, and for patients with less extensive disease, it may be reasonable to start ART alone and monitor the response. However, flares of KS can also occur as a manifestation of immune reconstitution following initiation of ART.

HIV-associated KS responds fairly well to local destruction, e.g. cryotherapy, topical alitretinoin (9-*cis*-retinoic acid) gel, superficial radiotherapy, intralesional vinblastine or interferon, and intravenous liposomally encapsulated doxorubicin, daunorubicin or paclitaxel[24,102,103]. Radiotherapy is contraindicated for oral lesions, as AIDS patients are more likely to develop severe radiation-associated mucosal ulcers and stomatitis.

Other Cutaneous Neoplasms

Eruptive atypical nevi have been described in HIV-positive patients[42]. Melanoma has been reported in association with HIV infection, but the prognosis (based on AJCC staging) is similar to that seen in immunocompetent hosts[21]. Cutaneous smooth muscle tumors, including leiomyomas and leiomyosarcoma, occur more frequently in HIV-infected pediatric patients and may be associated with EBV infection[24,104].

DIFFERENTIAL DIAGNOSIS AND DIAGNOSIS

Differential Diagnosis of HIV-associated Skin Conditions

As noted above, HIV-infected individuals can develop a wide variety of infectious, inflammatory and neoplastic disorders of the skin, many of which have overlapping clinical features. Cutaneous eruptions range

Fig. 78.13 Kaposi sarcoma in the setting of HIV infection. Violaceous papules and plaques on the face (**A**), palate (**B**), trunk (**C**) and extremity (**D**). Oral candidiasis is also seen (**B**). Some of the lesions on the back follow cleavage lines (**C**). *D, Courtesy, Thomas Horn, MD.*

from "textbook" classic forms to bizarre variants that present a diagnostic challenge. Serious and potentially fatal diseases must be considered and distinguished first and foremost. In particular, disseminated fungal infections and adverse drug reactions (see below) may be life-threatening and require early intervention with systemic antifungal agents or withdrawal of the offending medication, respectively.

The spectrum of cutaneous diseases tends to correlate with the immune status of the HIV-infected patient. Although HIV-1 RNA (copies/ml plasma) is a marker for disease progression, levels vary during acute infection and no defined relationship between viral load and opportunistic infections exists. However, an association between HIV-related disease incidence and the $CD4^+$ cell count has been established[105] (see Table 78.2), and this allows for a more focused differential diagnosis. In general, disseminated and extensive disease presentations occur with increasing frequency at lower $CD4^+$ cell counts.

Although it does not induce an immunodeficiency syndrome, HTLV-1 primarily infects $CD4^+$ lymphocytes in a mechanism similar to that of HIV-1 and HIV-2. HTLV-1 is endemic primarily in the Caribbean basin, southern Japan, northern Iran, Papua New Guinea and some parts of Africa and also exhibits vertical (mother-to-child) transmission. Co-infections with HIV and HTLV-1 have generated substantial interest. The incidence ranges from 3% to 25% of HIV-infected individuals. It has been postulated that an HTLV-1 protein acts indirectly on the long terminal repeat (LTR) region of both HTLV-1 and HIV-1, inducing interleukin-2 (IL-2) and IL-2 receptors that accelerate HIV-1 proliferation and subsequent T-cell death. Interestingly, co-infection is associated with higher $CD4^+$ cell counts (by 75–80%). However, the lymphocyte proliferation is nonspecific and does not appear to provide immunologic benefit. Thus, in patients co-infected with HIV-1 and HTLV-1, the absolute $CD4^+$ cell count may not be as reliable as in others with regard to immune status[11]. The HTVL-1-related diseases infective dermatitis and adult T-cell leukemia/lymphoma are discussed in Chapters 13 and 120, respectively.

Diagnosis of HIV-associated Skin Conditions and HIV Infection

In HIV-infected patients, the diagnosis of cutaneous disorders is established based on the clinical appearance coupled with confirmatory studies such as scrapings, cultures, biopsies and serologic assays. Given their immunocompromised state, patients often have mixed infections (Fig. 78.14) or combination infectious–neoplastic or inflammatory–neoplastic lesions. Other factors such as age, sex and anatomic distribution assist in narrowing the differential diagnosis.

Virtually any cutaneous lesion in an HIV-infected patient may be caused by a potentially treatable infectious agent. Histologic examination and culture of biopsy specimens may be required for diagnosis. Additional evaluation with special stains and serologic or molecular tests may be necessary. Special growth requirements for fastidious opportunistic organisms need to be anticipated. It should be remembered that mixed infections may also be present[12].

HIV serologic testing should be performed in any patient who requests it. Testing is recommended for individuals in high-risk groups (e.g. men who have sex with men, intravenous drug users, commercial sex workers) and those who have sexually transmitted infections, active tuberculosis or are pregnant. Atypical herpes zoster (especially in a young person), chronic HSV infection, refractory mucocutaneous candidiasis, generalized lymphadenopathy, extranodal lymphoma or the

Fig. 78.14 Oral herpes simplex viral infection and oral candidiasis. This combined infection was in an otherwise healthy young man who proved to be HIV-positive.

Fig. 78.15 Exacerbation of leprosy due to immune reconstitution inflammatory syndrome following institution of ART therapy. *Courtesy, Beatriz Trope, MD PhD.*

occurrence of generalized pruritus, dementia, aseptic meningitis, peripheral neuropathy, fever, diarrhea or weight loss with unknown etiology should prompt testing for HIV.

HIV seroconversion usually occurs 6 weeks after initial infection. Criteria for HIV seropositivity include positive ELISA results confirmed by a positive Western blot study (usually requiring reactivity against at least two of the viral protein markers p24, gp41 or gp120/160). Non-reactive results are obtained during a seronegative "window" that can last up to 3 months after the initial infection. Thus, if HIV infection is strongly suspected, methods for detection of viral antigens or nucleic acid rather than anti-HIV antibodies need to be employed. Fourth-generation HIV screening assays have been developed that attempt to shorten the seronegative window by simultaneous detection of anti-HIV antibodies and p24 antigen.

Early (i.e. in the process of seroconversion) or advanced HIV disease, HIV-2 infection, the presence of alloantibodies (seen with pregnancy, blood transfusions or organ transplantation) or autoantibodies (seen in autoimmune connective tissue diseases, other autoimmune diseases or malignancy) may lead to an indeterminate test result in which both the ELISA and Western blot studies are positive but with reactivity against only one protein marker present. Repeat tests should be performed in 2–6 months for confirmation. Individuals with an indeterminate test result who are in the process of seroconverting will usually become seropositive within 1 month.

If necessary, HIV RNA or DNA PCR and/or isolation of the virus by culture can be used to confirm the diagnosis in questionable cases. However, the specificity of a single plasma viral load test is only about 97% and false-positive results, particularly in the range of <5000 copies/ml, have been described[106]. Importantly, HIV postexposure prophylaxis may hamper detection of the virus by culture or PCR and delay seroconversion.

TREATMENT

Antiretroviral Therapy (ART)

Fifteen years ago, the treatment of HIV infection was revolutionized by the development of combination ART regimens (previously known as HAART). The different classes of antiretroviral agents target various aspects of the HIV life cycle (see Fig. 78.2): (1) *nucleoside* (including zidovudine [AZT], the first agent developed [in 1987]), *nucleotide* and *non-nucleoside reverse transcriptase inhibitors* (*NRTIs, NtRTIs and NNRTIs,* respectively) terminate viral DNA chain synthesis; (2) the *integrase inhibitor* prevents integration of viral DNA into the host genome; (3) *protease inhibitors* abrogate viral processing and assembly; (4) the *CC-chemokine receptor 5 (CCR5) inhibitor* blocks binding of viral particles to the CCR5 co-receptor on host cells (with a host rather than viral target); and (5) the *fusion inhibitor* disrupts fusion of the viral envelope with the cell membrane (Table 78.4). ART can profoundly suppress viral propagation, leading to the reconstitution of $CD4^+$ lymphocyte counts and a dramatic decrease in disease-related morbidity and mortality. As a consequence, the annual mortality from AIDS has declined by >75% since 1995 in high-income countries.

Currently, first-line initial ART includes two N(t)RTIs (typically tenofovir and emtricitabine) and one NNRTI (usually efavirenz). The International AIDS Society–USA 2010 guidelines for adults with HIV infection recommend introduction of ART for symptomatic patients and asymptomatic patients with a $CD4^+$ cell count ≤500 cells/mm^3 or certain conditions/comorbidities (e.g. HIV RNA >100 000 copies/ml, decline in the $CD4^+$ cell count of >100 cells/mm^3/year, pregnancy, active hepatitis B or C viral infection, cardiovascular disease, a serodiscordant partner)[107]. Important factors to consider include viral resistance, patient adherence, potential adverse effects and drug interactions.

Response to therapy is monitored by quantitative HIV RNA PCR (as plasma viremia is a strong prognostic indicator of HIV disease progression)[108]. Suppression of HIV replication to below the limit of quantification for as long as possible is therefore a critical goal of ART. When HIV replication is adequately suppressed (i.e. below 50 copies/ml plasma), evolution of viral resistance to antiretroviral drugs is minimal. However, continuous replication in the presence of antiretroviral drugs, whether due to patient non-adherence, pre-existent drug resistance and/or low drug levels, can rapidly exhaust currently available treatment options.

In addition to increasing life expectancy in those with HIV infection, ART has resulted in a significant decrease in the incidence of several of its cutaneous manifestations, including candidiasis, KS, eosinophilic folliculitis, opportunistic mycoses/mycobacterioses, and oral hairy leukoplakia. However, the prevalence of HPV and poxvirus infections and incidence of anal cancer have actually increased[30]. It is possible that other cutaneous neoplasms will be seen with greater frequency as patients survive longer. While in developed countries the spectrum of concerns related to HIV has shifted from opportunistic infections to long-term complications (e.g. cancer, co-infection with other viruses such as hepatitis C, and the metabolic effects of ART), patients in developing countries continue to be ravaged by HIV infection, with high treatment costs and underdeveloped infrastructure continuing to be major obstacles.

Immune Reconstitution Inflammatory Syndrome (IRIS)

Paradoxically, exacerbations of the clinical manifestations of infectious and neoplastic (due to inflammatory immune reactions) as well as inflammatory diseases have been observed following institution of ART, especially when $CD4^+$ cell counts rise at least twofold from depressed levels (usually <50 cells/mm^3). Examples include herpes zoster, leprosy (Fig. 78.15), and disseminated *Mycobacterium avium* complex and CMV infections. This phenomenon has been referred to by various names, including IRIS, immune reconstitution-associated disease (IRAD) and immune reconstitution/recovery/restoration disease/syndrome. Distinguishing IRIS-associated flares of inflammation from active opportunistic infections or drug reactions may be difficult[27,109]. The majority of patients with IRIS have cutaneous

ADVERSE REACTIONS TO DRUGS USED TO TREAT HIV INFECTION		
Drug (abbreviation, trade name)	**Important adverse reactions/interactions**	
	Mucocutaneous	**Other**
NUCLEOSIDE/NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS		
Abacavir (ABC, Ziagen®)	• Hypersensitivity syndrome*, Sweet's syndrome (rare)	• Hypersensitivity syndrome*,†
Didanosine (ddI, Videx®)	• Xerostomia, alopecia • Lipodystrophy • Small vessel vasculitis (rare)	• Pancreatitis, optic neuritis, peripheral neuropathy, lactic acidosis, hepatic steatosis
Emtricitabine (FTC, Emtriva®)	• Xerosis, "rash" (morbilliform, pustular, urticaria), palmoplantar hyperpigmentation	†
Lamivudine (3TC, Epivir®)	• Paronychia, alopecia, "rash", pruritus	• Pancreatitis (pediatric patients)†
Stavudine (d4T, Zerit®)	• Lipodystrophy • Peripheral edema	• Peripheral neuropathy, pancreatitis, muscle weakness, lactic acidosis, hepatic steatosis
Tenofovir (TDF, Viread®)	• Morbilliform, vesicular and urticarial eruptions	• Renal impairment, hypophosphatemia
Zalcitabine (ddC, Hivid®)‡	• Macular eruption, urticaria, oral/esophageal ulcers	• Pancreatitis, peripheral neuropathy†
Zidovudine (AZT, Retrovir®)	• Blue–brown pigmentation of nails and mucosae, cutaneous hyperpigmentation • Urticaria, morbilliform eruption, small vessel vasculitis, anaphylaxis • Lipodystrophy • Acral/periarticular reticulate erythema	• Bone marrow suppression, increased MCV, thrombocytopenia, nausea, dilated cardiomyopathy, myopathy, lactic acidosis, hepatic steatosis
NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS		
Delavirdine (DLV, Rescriptor®) Efavirenz (EFV, Sustiva®) Etravirine (ETR, Intelence®) Nevirapine (NVP, Viramune®) Rilpivirine (RPV, Edurant®)	• Morbilliform eruption (usually within first 3–6 weeks), SJS, TEN, DRESS • In the case of nevirapine, higher incidence (especially in women), which may be reduced by dose escalation; also oral ulcers	• Hepatotoxicity • CNS symptoms • Delaviridine inhibits CYP450 3A4, nevirapine induces CYP450 3A4
INTEGRASE INHIBITOR		
Raltegravir (RAL, Isentress®)	• "Rash", SJS, TEN, DRESS	• Myopathy, rhabdomyolysis
PROTEASE INHIBITORS		
Amprenavir (APV, Agenerase®)‡ Atazanavir (ATV, Reyataz®) Darunavir (Prezista®) Fosamprenavir (FPV, Lexiva®) Indinavir (IDV, Crixivan®) Lopinavir/Ritonavir (Kaletra®) Nelfinavir (NFV, Viracept®) Ritonavir (RTV, Norvir®) Saquinavir (SQV, Invirase®) Tipranavir (TPV, Aptivus®)	• Morbilliform eruption, generalized erythema, SJS • Lipodystrophy syndrome, striae formation • Paronychia, ingrown toenails • Pruritus, xerosis • Desquamative cheilitis, oral numbness • Icterus, esp. atazanavir	• Hyperlipidemia, insulin resistance • Increased risk of cardiovascular disease with long-term exposure • Spontaneous bleeding in hemophiliacs • Avascular necrosis of the hip • Hepatotoxicity • Metallic taste, esp. indinavir • Inhibit CYP450 3A4, esp. ritonavir
CC-CHEMOKINE RECEPTOR 5 (CCR5) INHIBITOR		
Maraviroc (MVC, Selzentry®)§	• "Rash"	• Hepatotoxicity with allergic features • May increase risk of myocardial ischemia • Postural hypotension
FUSION INHIBITOR		
Enfuvirtide (T-20, Fuzeon®)	• Injection site reactions (granulomatous inflammation) • Morbilliform eruption	• Frequency of painful injection site reactions and high cost limit use
COMBINATIONS		
Abacavir/Lamivudine (ABC/3TC, Epzicom®) Efavirenz/Emtricitabine/Tenofovir (EFV/FTC/TDF, Atripla®) Emtricitabine/Tenofovir (FTC/TDF, Truvada®) Emtricitabine/rilpivirine/tenofovir DF (FTC/RPV/TDF, Complera®) Lamivudine/Zidovudine (3TC/AZT, Combivir®) Abacavir/Lamivudine/Zidovudine (ABC/3TC/AZT, Trizivir®)	See above	See above

*Includes fever, malaise, gastrointestinal symptoms and sometimes a cutaneous eruption; occurs in 5–8% of patients within the first 8 weeks of receiving abacavir and is an absolute contraindication for repeat administration; associated with HLA-B*5701 allele, screening for which is commercially available and recommended prior to initiating/reinitiating therapy.
†Uncommonly lactic acidosis and hepatic steatosis.
‡No longer available in the US.
§Requires an assay to screen for co-receptor tropism, since this drug is only active in patients who do not have virions that use CXCR4 for cell entry; has an immunomodulatory effect that is independent of its effect on HIV replication.

Table 78.4 Adverse reactions to drugs used to treat HIV infection. CY, cytochrome; DRESS, drug rash with eosinophilia and systemic symptoms; MCV, mean corpuscular volume; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

CUTANEOUS DISEASES THAT CAN "FLARE" DUE TO THE IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME
INFECTIONS
Mycobacterium tuberculosis
Mycobacterium leprae
Mycobacterium avium complex and other species
Herpes simplex virus 1 and 2
Varicella–zoster virus
EBV (e.g. oral hairy leukoplakia)
Cytomegalovirus
Human papillomavirus
Molluscum contagiosum virus
Candida spp.
Dermatophytes
Cryptococcus spp.
Histoplasma capsulatum, *Penicillium marneffei*
Demodex, *Malassezia* spp. (e.g. folliculitis)
Leishmania spp.
INFLAMMATORY DISORDERS
Psoriasis, seborrheic dermatitis
Sarcoidosis
Foreign body reactions (granulomatous)
Eosinophilic folliculitis
Acne vulgaris, rosacea
Papular pruritic eruption
Lupus erythematosus (systemic, discoid, tumid), relapsing polychondritis
Alopecia areata
Dyshidrotic eczema
NEOPLASMS
Kaposi sarcoma
Non-Hodgkin lymphoma
Multiple eruptive dermatofibromas

Table 78.5 Cutaneous diseases that can "flare" due to the immune reconstitution inflammatory syndrome (IRIS).

manifestations, and skin diseases that can be exacerbated by IRIS are listed in Table 78.5[110].

Drug–Drug Interactions

Knowledge of potential drug interactions is necessary to prevent adverse reactions and therapeutic failures. The human cytochrome P450 system metabolizes a number of drugs used to treat HIV infection and associated complications. Cytochrome P450 3A4 inhibitors, which include most of the protease inhibitors and delavirdine, impair drug metabolism, leading to accumulation of drugs that share the same metabolic pathway (see Ch. 131). Cytochrome P450 3A4 mixed inducers/inhibitors and inducers (e.g. efavirenz and nevirapine, respectively) may accelerate clearance of other medications and may necessitate dose adjustments. Cytochrome P450-independent interactions include: (1) an increase in intracellular drug levels and toxicity of didanosine when used in combination with ribavirin and/or tenofovir[111]; and (2) a decrease in atazanavir concentration when coadministered with tenofovir[112].

Drug Eruptions

Adverse cutaneous reactions to drugs can range from extremely mild to life-threatening, and they may be caused by either a single drug or drug combinations[110,113,114]. Unfortunately, drug eruptions are common in HIV-infected individuals, likely reflecting underlying immune dysregulation, and represent a frequent source of morbidity. Because these patients typically take multiple medications, identification of the causal agent or combination of agents is often a complex and frustrating process (see Ch. 21).

Morbilliform drug eruptions are the most common presentation of drug hypersensitivity, and the incidence is significantly higher in HIV-infected patients than in the general population. Patients may also present with urticaria, pruritus, vasculitis, exfoliative erythroderma, photodermatitis, Stevens–Johnson syndrome and toxic epidermal necrolysis. An adverse drug reaction should be high on the differential diagnosis list when a patient taking several medications develops a cutaneous eruption.

Protease inhibitors may cause retinoid-like effects, including paronychia, ingrown toenails, desquamative cheilitis and xerosis[77]. Lipodystrophy syndrome, as described previously, may also develop. Oral numbness has been observed, especially with therapeutic doses of ritonavir[115]. The major cutaneous and extracutaneous side effects of the other classes of antiretroviral drugs are outlined in Table 78.4.

Trimethoprim–sulfamethoxazole (TMP-SMX) is the most common drug to cause a cutaneous reaction in HIV-infected patients[20]. Often taken for prophylaxis or treatment of *Pneumocystis jiroveci* pneumonia or toxoplasmosis, TMP-SMX leads to an exanthematous eruption and fever in 50–60% of HIV-infected patients treated intravenously with this agent (typically 8–12 days after initiating therapy). This occurrence is 10 times more frequent than in the general population[66]. Stevens–Johnson syndrome and toxic epidermal necrolysis can also occur secondary to TMP-SMX.

Although close observation and documentation is often adequate as most cutaneous drug eruptions regress (especially the morbilliform type), if systemic signs such as fever develop or epidermal detachment is observed, the suspected offending agent(s) should be withdrawn immediately as this may herald a more serious, possibly life-threatening, complication. With some drugs such as zidovudine, sulfonamides and dapsone, patients may be successfully desensitized after an adverse drug reaction[66]. Drug rechallenge should be done under controlled circumstances. Rechallenge is contraindicated for abacavir and is not recommended for NNRTIs.

CONCLUSIONS

The number and variety of cutaneous manifestations of HIV infection are greater than those in any other organ. These complications are a source of significant morbidity and, in some cases, mortality. Although ART has decreased the incidence of many opportunistic infections, other adverse sequelae such as IRIS, drug reactions, metabolic disturbances, HPV infections and SCCs remain common and may even be increasing in incidence due to longer survival of HIV-infected individuals. By recognizing the spectrum of skin conditions associated with HIV infection and performing appropriate diagnostic tests, treatment can be administered in a timely fashion and outcomes optimized.

79 Human Papillomaviruses

Reinhard Kirnbauer and Petra Lenz

Synonyms: ■ Verrucae vulgares (singular: verruca vulgaris) – common warts ■ Verrucae palmares et plantares – hand and foot warts ■ Verrucae planae – flat warts, plane warts ■ Condylomata acuminata (singular: condyloma acuminatum) – genital warts ■ Condylomata plana – flat cervical condylomas, plane condylomas ■ Squamous intraepithelial lesion (SIL) – cervical intraepithelial neoplasia (CIN); vulvar (VIN); vaginal (VaIN); penile (PIN); anal (AIN) ■ Buschke–Löwenstein tumor – giant condylomata acuminata, condylomata acuminata gigantea ■ Florid oral papillomatosis – Ackerman tumor ■ Papillomatosis cutis carcinoides – Gottron tumor ■ Focal epithelial hyperplasia – Heck's disease

Key features

- Human papillomaviruses (HPVs) comprise a large group of approximately 120 genotypes that infect the epithelia of skin or mucosa and most commonly cause benign papillomas or warts
- Epidermodysplasia verruciformis (EV) is an inherited disease characterized by generalized flat warts or pityriasis versicolor-like macules, caused by chronic infection with HPV types in the genus β
- EV-associated HPV types are also detected in skin cancers and normal skin. These viruses are activated by UV exposure, immunosuppression, and specific host genetic background (EV)
- Anogenital HPV is a highly prevalent, sexually transmitted infection (STI) seen predominantly in young adults. Condylomata acuminata or benign anogenital warts are typically caused by HPV-6 or -11, which are considered to be low-risk types
- Persistent infection with high-risk HPV types, predominantly HPV-16 and -18, is the major cause of cervical cancers and a subset of vaginal, vulvar, penile, anal, oropharyngeal, and digital neoplasias
- Patients with cellular immunodeficiencies are at higher risk for persistent HPV infection and progressive disease
- No effective antiviral treatment for warts exists, and most therapies focus on destruction of visible lesions or induction of a cellular immune response
- Highly effective prophylactic HPV vaccines based on virus-like particles (VLPs) have been licensed for the prevention of genital warts and/or associated vulvar, vaginal and cervical cancer

INTRODUCTION

Papillomaviruses are a large group of DNA viruses that are widely distributed in animals and humans, most commonly inducing benign papillomas or warts[1]. Recurrent skin and anogenital warts may be disfiguring, impose a considerable psychological burden, and are a frequent cause of medical office visits. A subset of human papillomaviruses (HPVs) designated as high-risk types, most often HPV-16 and -18, is now recognized as the primary etiologic agent for: cervical cancer and its precursor lesions; a subset of the malignancies at other anogenital sites and in the upper aerodigestive tract; and, rarely, squamous cell cancer of the digits. In contrast, infection with the common cutaneous HPV types 1, 2, 4, 27, etc. is not thought to have any oncogenic potential[1]. In immunocompromised patients, HPV infections tend to persist and result in an increased risk of developing anogenital neoplasias. The high prevalence of genital HPV infection in sexually active young adults is a major concern, as effective antiviral treatments do not exist. More than a decade ago, prophylactic vaccines based on virus-like particles (VLPs) that prevent transmission in animal models of papillomavirus infection were developed[2]. Human vaccine studies subsequently demonstrated safety and nearly complete (>90%) efficacy for the prevention of type-specific genital HPV infection and the development of associated dysplasias[3–5].

History

The infectious etiology of human warts had long been suspected[1], and experimental transmission of common warts with a cell-free extract was demonstrated over 100 years ago[6]. The descriptions of cottontail rabbit papillomavirus (CRPV) in 1933 and of the rare genodermatosis *epidermodysplasia verruciformis* (EV) demonstrated the oncogenic potential of papillomaviruses. Following the cloning of the first papillomavirus genome in the late 1970s, the plurality of human and animal papillomaviruses became evident[7]. Based on genome sequencing, HPV types can be grouped into phylogenetic trees with a remarkable relationship to biologic data, e.g. mucosal and cutaneous types, high-risk and low-risk genital HPV, EV-associated HPV[7]. Today, the genomes of 120 HPV types have been fully characterized and additional partial DNA sequences have been obtained, indicating the existence of at least 200 HPV genotypes[8]. In 1976, zur Hausen proposed an association between papillomaviruses and cervical cancer[9], and subsequent molecular studies led to the recognition of a subset of HPV types in a high proportion of cervical carcinomas. The identification of biologic differences between "high-risk" and "low-risk" mucosal HPV confirmed infection with oncogenic HPV as the main cause of cervical cancer and its precursor lesions[10].

EPIDEMIOLOGY

Genital infection with HPV occurs most commonly by intimate contact, while infection of non-genital skin may occur via direct skin-to-skin contact or indirectly through contaminated surfaces and objects (e.g. swimming pool, gymnasium). Basal keratinocytes, which serve as the primary targets for HPV infection, are exposed to the virus through minor abrasions, and infection is promoted by maceration. Autoinoculation of virus from the lesion to adjacent skin is observed frequently, especially for digital or flat warts. Using sensitive polymerase chain reaction (PCR)-based detection, normal-appearing skin surrounding HPV-associated lesions and even skin of healthy volunteers may contain HPV DNA. These observations help to explain the high recurrence rate of warts (e.g. 20–50% for genital condylomata) and the observation that treatment may not prevent further transmission of the virus. Papillomaviruses are resistant to heat and desiccation due to the absence of a viral envelope, and even laser fumes may contain infectious virions[11].

Cutaneous warts are caused by a small group of specific HPV types, with an overall prevalence of 20% in schoolchildren and a decline thereafter with increasing age[12,13]. Patients living in larger households often report an infected cohabitant, supporting the concept of person-to-person transmission. The majority of warts will regress spontaneously within 1–2 years. Reinfection with the same HPV type appears uncommon after clearance, suggesting that protective type-specific immunity may develop[14].

Genital warts in prepubertal children are uncommon and produce special concern in healthcare providers. Although viral transmission

may occur during delivery, from close family contacts, or by autoinoculation from skin warts, the possibility that these lesions may have been caused by sexual abuse should always be carefully considered[15].

Infection of the lower anogenital tract with HPV is one of the most common sexually transmitted infections (STIs). The prevalence of cervical HPV infection varies greatly in different countries and by age; it is particularly high in young women, ranging from 20% to 45%. In a study of 608 sexually active female college students, 26% were diagnosed with genital HPV infection at study entry and another 43% acquired HPV infections of the cervix over the next 3 years[16]. A 60% incidence of new genital HPV infections over a 2-year period in sexually active male college students has also been reported[17]. In the US, an estimated 20 million people have genital HPV infections at any one time. Behavioral risk factors include sexual intercourse at an early age and the number of lifetime sexual partners[7]. Circumcised men are less likely to carry and transmit HPV infection. In men who have sex with men (MSM), anal HPV infection is very prevalent (up to 75%).

The public health impact of genital HPV infection is evident by the high number of initial visits to physicians' offices for treatment of genital warts (e.g. 360 000 in 2008 in the US) and the frequency of consequences such as abnormal Pap smears and cervical neoplasia (Fig. 79.1). The annual cost burden of genital HPV infection is estimated to be $6 billion in the US, making it the second most costly STI after HIV infection[18].

Most genital papillomavirus infections resolve spontaneously, whereupon HPV DNA becomes undetectable by PCR. The median duration of high-risk HPV infections in women is 8 months and persistence is found in 30% after 1 year and in 9% after 2 years[7]. Persistent cervical infection with high-risk HPV types represents the most important risk factor for the development of cervical pathology, including carcinoma. HPV-16 is detected in approximately 50% of cervical cancers and high-grade dysplasias. Together, HPV-16, -18, -31 and -45 are found in approximately 80% of cervical cancers[7].

Worldwide, an estimated 525 000 cases of cervical cancer are diagnosed annually, resulting in approximately 275 000 deaths[19]. The disease occurs predominantly in low-income countries that lack effective cervical screening programs. In the US, prevention and early detection programs have reduced the incidence rate of cervical cancer by approximately 75%, to 8 per 100 000 women per year. In 2010, 12 200 new cases of cervical cancer were diagnosed in the US, resulting in 4200 deaths. High-risk oncogenic HPV types account for most of the observed risk for developing cervical cancer, although smoking, cervical inflammation, parity and oral contraceptive use have been proposed as cofactors[7]. Although there is little evidence for hematogenous spread of HPV, approximately 60% of patients with anogenital infections develop low-titer, type-specific antibodies during the course of infection[20]. Titers tend to decrease slowly and may persist for years after viral clearance.

Immune suppression in HIV-infected patients and organ transplant recipients results in HPV infections that are more frequent, persistent, and likely to progress to intraepithelial neoplasias, with $CD4^+$ T-cell depletion and HIV viral load being important risk factors. In studies analyzing anal swabs, up to 93% of HIV-seropositive MSM were positive for HPV DNA, compared to 60% of HIV-negative MSM[21]. HPV-associated anal intraepithelial neoplasia (AIN), a likely anal cancer precursor, is found in up to 36% of HIV-infected MSM, compared to 20% of HIV-negative MSM. Antiretroviral therapy has shown no or only a modest beneficial effect on the incidence and progression of AIN or cervical intraepithelial neoplasia (CIN). Similarly, organ transplant recipients are at an increased risk for developing warts and genital neoplasias[22]. They also have a higher incidence of premalignant and malignant skin neoplasias, e.g. actinic keratoses, Bowen's disease or squamous cell carcinomas (SCCs), especially in sun-exposed areas.

Not only cutaneous tumors from organ transplant recipients, but also tumors, "healthy skin" and plucked hairs from immunocompetent patients often contain DNA of β HPV types (see below)[7,22]. These forms of HPV only result in highly active viral replication leading to cytopathic effects and clinical lesions in patients with EV or other forms of immunosuppression[22]. In skin swab samples, children from 1 month to 4 years of age have a high prevalence (from 50% to 70%) of HPV DNA[23], indicating that normal-appearing human skin is colonized with a multiplicity of HPV types very early in life, most likely through close skin-to-skin contact. HPV DNA has also been detected in psoriatic lesions[24] and skin cancers from PUVA-treated patients; however, highly sensitive PCR-based methods were required to amplify the HPV DNA and viral gene transcription has not been reported.

Recurrent respiratory papillomatosis (RRP) is characterized by exophytic lesions of the airways. It occurs in juvenile- and adult-onset forms and is caused by HPV-6 and -11. Despite its low incidence of 0.4–1.2 per 100 000[16], RRP is the most common benign tumor of the larynx. It is believed that in childhood-onset RRP, vertical HPV transmission from mother to child occurs by aspiration during delivery through an infected birth canal[25]. Although treatment should be considered in pregnant women with condylomata in order to reduce viral load, there is insufficient evidence to support cesarean section to prevent development of RRP in the offspring. Adult-onset RRP more likely results from genital-to-oral transmission.

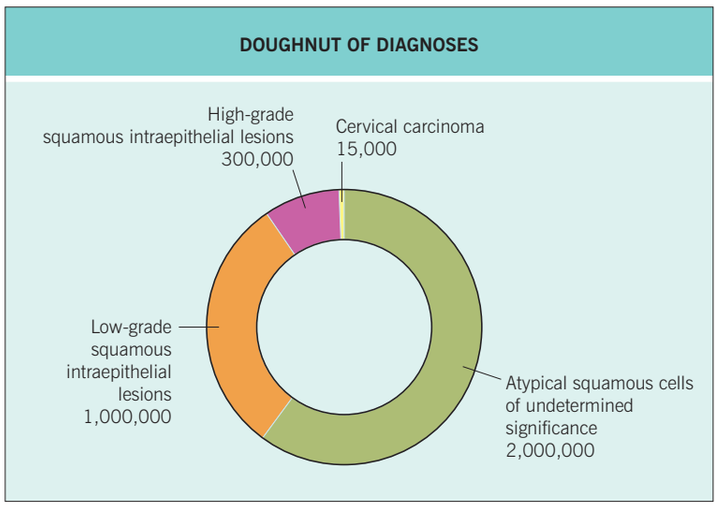

Fig. 79.1 Doughnut of diagnoses. The annual incidence of HPV-associated cervical pathologies in the US is given. The number of patients diagnosed with entities in this spectrum declines dramatically from atypical squamous cells of undetermined significance (ASCUS) to low-grade squamous intraepithelial lesions (LSIL) to high-grade squamous intraepithelial lesions (HSIL) to cervical carcinoma. *Adapted from Division of STD Prevention; Prevention of Gential HPV Infection and Sequelae: Report of an External Consultants' Meeting. Atlanta, GA: Centers for Disease Control and Prevention, 1999.*

PATHOGENESIS

Papillomavirus Evolution

Historically, the papillomaviruses have been grouped together with the polyomaviruses, but their fundamentally different biology and genetic organization resulted in their reclassification as individual families in 2000[8]. The National Center for Biotechnology Information (NCBI) nucleotide sequence database (www.ncbi.nlm.nih.gov) currently lists 120 different HPV types as well as numerous incompletely characterized putative new HPV types. By definition, a novel type has more than 10% dissimilarity from any previously characterized type in the DNA sequences of three HPV genes (E6, E7 and L1). A dissimilaritity of 2–10% is defined as a subtype, and <2% as a variant[8].

By comparing DNA sequences in conserved portions of the papillomavirus genomes across different types, a phylogenetic tree establishing the degree of relatedness among these types has been generated[8]. Two genera, the α- and β-papillomaviruses, encompass almost all known HPV types, with the genus α-papillomavirus containing mucosal and cutaneous HPV types that are pathogenic in normal hosts and the genus β containing the types associated with EV; γ, μ and ν genera contain additional cutaneous types. Within each genus, HPV types are grouped according to sequence homology into species, which often share similar biologic and pathologic properties (e.g. HPV-16 and -31). Present models postulate that HPVs co-evolved with our human ancestors and novel HPV types or variants were generated through either genetic drift or natural selection via adoption of specialized ecologic niches. Genetic recombination between HPV types does not occur.

Virology

Papillomaviruses are non-enveloped, double-stranded DNA viruses approximately 55 nm in diameter[7]. The spherical capsid is composed of two virally encoded proteins: (1) L1, the major structural protein; and (2) L2, a minor structural protein. During virion assembly within cells, L1 proteins form pentamers called capsomeres, and 72 capsomeres multimerize to form the viral capsid with an icosahedral symmetry arranged on a $T = 7$ surface lattice. The capsid surrounds the viral DNA, thereby protecting it from degradation, and it also enables the virus to bind efficiently to target cells. Packaged viral DNA is associated with cellular histones, forming a mini chromosome. In contrast, the early (E) viral proteins are not incorporated into infectious virions.

When expressed in cell culture, the L1 major capsid proteins of papillomaviruses self-assemble into virus-like particles (VLPs) that are morphologically similar to native virions (Fig. 79.2)[26]. Papillomavirus VLPs display type-specific and neutralization epitopes that are used to detect serum antibodies and as the basis for prophylactic vaccines (see below)[27,28].

The HPV genome, approximately 8 kilobases (kb) in length, is composed of three domains: the upstream regulatory region (URR), the early region, and the late region (Fig. 79.3). The URR, approximately 1 kb in length, lacks open reading frames (ORFs) and contains the origin of replication and many of the control elements for transcription and replication. The early region, approximately 4 kb in length, contains the ORFs for genes expressed early in the papillomavirus life cycle. The late region, approximately 3 kb in length, encodes the capsid proteins (see above)[7].

Papillomavirus Life Cycle

The papillomaviruses are highly species-specific, and productive infection has never been observed outside natural host tissue. The papillomavirus life cycle is completed only in fully differentiated squamous epithelia. This has impeded its study in monolayer tissue culture cells, where late gene expression and virion production do not occur. Only a small number of HPV types have been successfully propagated in mouse xenograft or raft culture systems, and limited amounts of infectious virions have been generated[7].

Productive infection and induction of hyperproliferation are initiated when the virus enters proliferating basal epithelial cells (Fig. 79.4). This layer of cells is not normally accessible to the virus because of the mechanical barrier provided by the overlying differentiated cell layers. Therefore, it is likely that infection requires an abrasion or other trauma to the epithelium to expose the basal cells to the virus. Our knowledge about early steps of infection such as viral entry and uncoating is limited. The receptor(s) that mediate virus binding to epithelial cells have not been definitively identified, but binding appears to depend on the L1 major capsid protein, and cell surface and/or basement membrane heparan sulfate is necessary for efficient infection *in vitro*[29,30]. The amino terminus of the L2 minor capsid protein is then cleaved by furin (a proprotein convertase), which exposes both a cross-neutralization epitope on L2 and a binding site (thought to be on L1) that facilitates viral entry via a putative secondary receptor on keratinocytes[30,31]. Upon infection, the covalently closed circular DNA genome becomes established as a low-copy autonomous replicon in the nuclei of basal cells, thereby creating a long-term reservoir of viral DNA.

The program of viral gene expression is intimately linked to the differentiation state of the infected cells. The E genes are transcribed at low levels in the basal cell layer and stratum malpighii. The first genes to be expressed following infection are the E1 and E2 genes, which are responsible for controlling the transcription of other viral genes and replication of the viral genome. HPVs do not encode the enzymes required for transcription or replication of viral DNA. Consequently, HPV is entirely dependent on the co-opting of cellular machinery for these functions. One major effect of HPV proteins E5, E6 and E7 is that the epidermal cell cycle, which is normally blocked for cells that are suprabasal, continues so that HPV genome copy number can be amplified to high levels during vegetative viral replication for assembly into virions (see Fig. 79.4). The E6 and E7 proteins of the high-risk mucosal HPV types act as viral oncoproteins, but no such functions are associated with the corresponding proteins of the low-risk mucosal and EV types[7]. There is limited understanding of possible differences between oncogenic (e.g. HPV-5, -8) and the non-oncogenic β HPV types.

In combination with other cellular proteins, E6 from high-risk mucosal HPV causes the ubiquitin-mediated degradation of the cellular protein p53. Elevated levels of p53 arrest cells in the G1 phase of the cell cycle or induce apoptotic cell death, so that E6-facilitated destruction of p53 removes a brake on suprabasal cell cycling. One of the principal effects of high-risk mucosal HPV E7 is to bind to the underphosphorylated form of RB (the retinoblastoma tumor suppressor protein). A physiologic role of underphosphorylated RB is to bind to and inhibit the function of the E2F transcription factor (see Ch. 107). When HPV E7 binds RB, E2F is liberated from this inhibition and is thereby able to induce the expression of genes required for DNA replication. Both E6 and E7 are multifunctional proteins, and while their effects on p53 and RB are critical ones, they do have additional targets

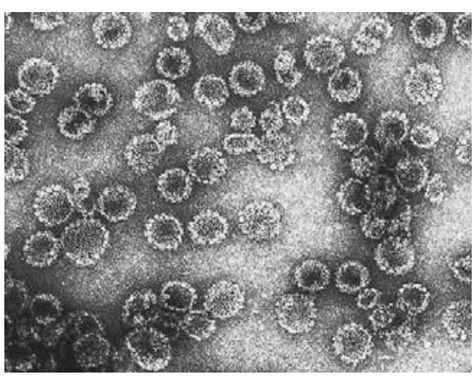

Fig. 79.2 Transmission electron photomicrograph of purified HPV-16 virus-like particles (VLPs). A prophylactic vaccine that contains HPV-6, -11, -16, -18 VLPs has been approved for the prevention of anogenital warts and cancers. Following expression in cell culture, the L1 capsid protein self-assembles into VLPs (empty capsids approximately 50 nm in diameter devoid of HPV DNA) that display type-specific and neutralization surface epitopes similar to native virions. *Courtesy, Saeed Shafti-Keramat, MD.*

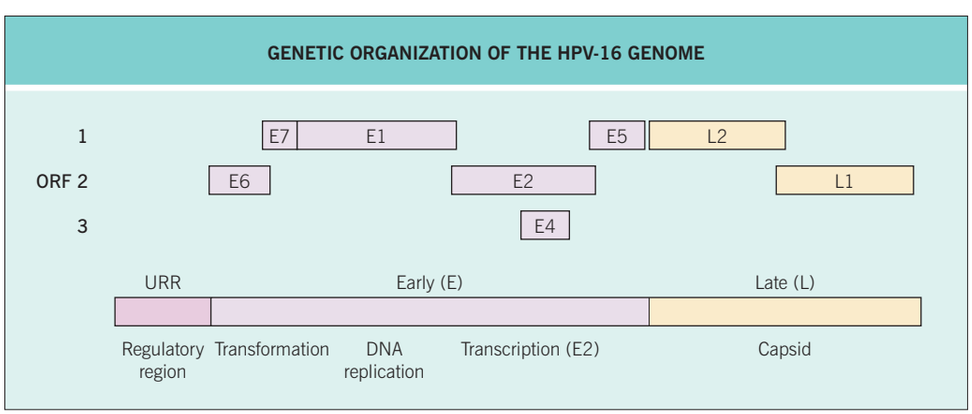

Fig. 79.3 Genetic organization of the HPV-16 genome. This is a linearized map of the 7.9 kb circular double-stranded genome. All open reading frames (ORFs) reside on one strand. Early (E) and late (L) regions are indicated. The upstream regulatory region (URR) contains the origin of replication and control elements for transcription and replication.

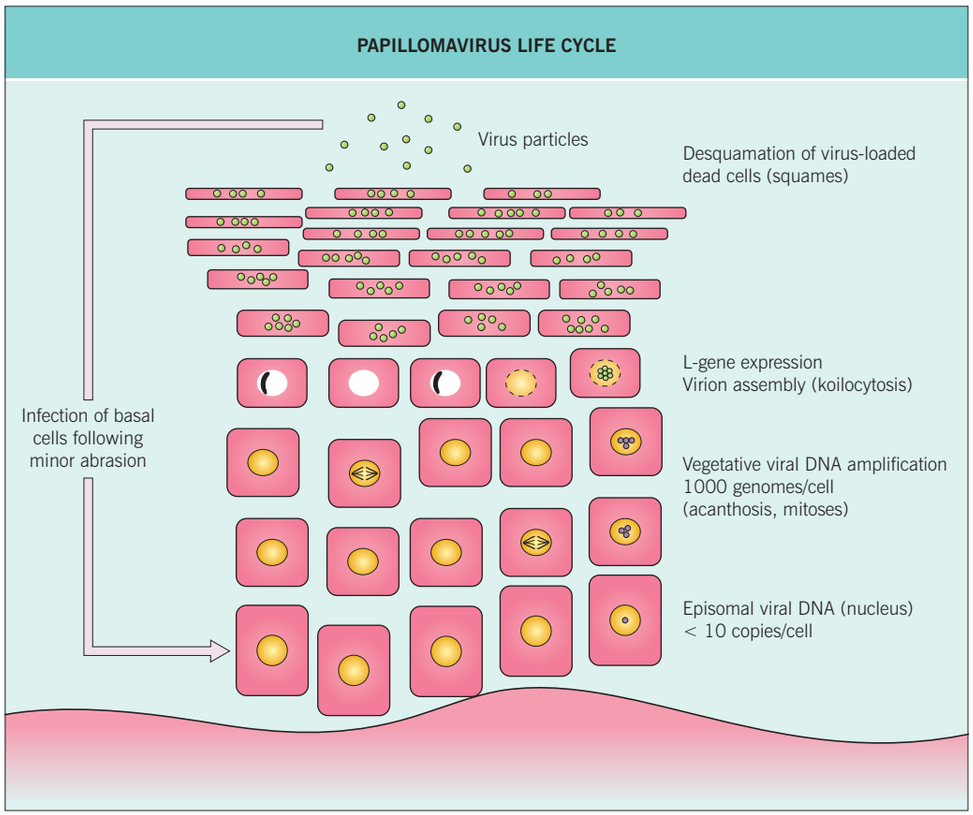

Fig. 79.4 The papillomavirus life cycle. The figure depicts a productive (virion-producing) benign wart. *Adapted from Orth G. Epidermodysplasia verruciformis. In: Salzman NP, Howley PM (eds). The Papovaviridae: Volume 2 The Papillomaviruses. New York: Plenum Press; 1987:199–243.*

important to the oncogenic potential of the virus. These include activation of telomerase by E6, binding of histone deacetylases by E7, and synergistic effects of both proteins that lead to centrosome abnormalities and chromosomal instability[7].

The genes for the virion structural proteins, i.e. the late (or L) genes, are expressed in the terminally differentiated superficial layers of the epithelium. The more superficial epithelial layers also have higher levels of expression of E1 and E2 and amplification of viral DNA. The amplified genomes are encapsulated by the L1 and L2 capsid proteins to generate infectious virions, and virus particles are observed in the granular layer of the epithelium and above. Virus assembly is not believed to lyse the cells; instead, the virus is shed with the cornified layer as cells slough from the epithelial surface (see Fig. 79.4). E4 proteins are hypothesized to disrupt the intracellular filamentous network of keratinocytes, which may facilitate virus release from the corneocytes[7].

Host Immune Response

Persistent papillomavirus infections are common, indicating that HPVs have evolved mechanisms to evade immune surveillance. There is no viremic phase during the life cycle, so a systemic immune response is avoided. In addition, low levels of viral proteins are expressed in the basal cell layer and stratum malpighii of the epidermis, where they would be most likely to be recognized by Langerhans cells and infiltrating lymphocytes. Only in the more immunologically privileged terminally differentiated layers is there extensive production of virion proteins, with shedding of infectious virus exclusively from the external epithelial surface[7]. Despite the relative success of papillomaviruses in evading immune responses, up to two-thirds of cutaneous warts spontaneously regress within 2 years, and lesions of multifocal infections often regress concomitantly. There is also an increased prevalence of warts in patients with suppressed cell-mediated immunity. In contrast, patients with underlying defects in humoral immunity do not seem to be predisposed to HPV infections, suggesting a primary role of cell-mediated responses.

Although low amounts of virion capsid proteins are produced in the lower epidermal cell layers, serum antibodies specific to conformational virion epitopes of high-risk HPV-16 can be detected in more than half of women with low-grade or asymptomatic genital HPV-16 infections[32]. It is unknown if these antibodies play a role in limiting reinfection with the same type from autoinoculation or from an infected sexual partner.

Latent HPV infections are defined as persistence of HPV DNA in clinically and cytologically normal epithelium. It is difficult to distinguish true viral latency from persistent infection with a low level of DNA replication. The mechanisms by which HPV enters into and is activated out of latency are unknown[7].

Oncogenic Potential of HPV

Different HPV types have markedly different oncogenic potentials. The vast majority of cervical cancers, for example, contain the sequences of one of five HPV types: 16, 18, 31, 33 or 45[33]. In contrast, infection with HPV-6 or -11 occurs commonly in benign or low-grade intraepithelial lesions but is very rarely associated with the development of anogenital malignancies. HPV-5 and -8 DNA sequences are frequently detected in SCCs associated with EV.

Progression of HPV-associated cervical lesions to invasive cancer typically requires several decades. Both persistent HPV infection and the accumulation of additional genetic mutations are required in the current model of multistage carcinogenesis[7]. Integration of the viral genome randomly into the host DNA is a common event, invariably leading to loss of E1 and E2 expression. In HPV-16 and -18, E2 functions to repress the transcription of E6 and E7 genes. Therefore, integration is thought to increase expression of E6 and E7, which are selectively retained and expressed at elevated levels in carcinomas, suggesting a critical role for oncogenic progression (see above)[7].

Differences in the activities of E6 and E7 genes between oncogenic and non-oncogenic HPV types principally account for the different risk of progression. E6 and E7 proteins derived from high-risk HPV types (e.g. 16 and 18) degrade p53 and interact with RB (respectively) with greater efficiency than do E6 and E7 proteins from low-risk types (e.g. 6 and 11)[7]. Degradation of p53 by E6, which eliminates from infected cells the principal "guardian of the genome" (the protein responsible for cell cycle arrest in the presence of damage to cellular DNA), can lead to the accumulation of genetic mutations in infected cells. Thus, carcinogenic progression appears to be promoted or facilitated by increased E6 and E7 expression as well as the activity of external carcinogens, resulting in genomic instability[7].

CLINICAL FEATURES

Cutaneous and mucosal HPV types form two distinct groups that infect either skin or mucosa. However, viral tropism is not absolute, as DNA of skin types may be found in genital or oral warts, and, in rare cases, mucosal types may be associated with skin lesions. Clinical manifestations depend on the HPV type involved, the anatomic location, and the immune status of the host (Table 79.1).

Cutaneous Infections

Cutaneous HPV types comprise a small group of viruses that infect the skin and induce common warts (Latin *verrucae vulgares*; singular *verruca vulgaris*), palmar and plantar warts (*verrucae palmares et plantares*), mosaic warts, flat warts (*verrucae planae*) and butcher's warts (see Table 79.1). In general, classification of warts is based on morphology, histology and anatomic location.

Common warts are hyperkeratotic, exophytic, dome-shaped papules or plaques that are typically associated with HPV-1, -2, -4, -27 or -57. These warts are most frequently located on the fingers and dorsal surfaces of the hands (Figs 79.5 & 79.6) or in other sites prone to trauma such as the knees or elbows, but they may occur anywhere on the skin surface. Involvement of the proximal nail fold and/or ablative therapy at that location may destroy the matrix, resulting in onychodystrophy (see Fig. 79.6). Characteristic features of common warts are punctate black dots representing thrombosed capillaries and bleeding after shaving of the hyperkeratotic surface (Fig. 79.7). Autoinoculation by scratching may cause a linear arrangement of warts. Slender, exophytic filiform warts can also develop, especially in periorificial locations on the face.

Palmar and plantar warts appear as thick, endophytic papules on the palms, soles, and lateral aspects of the hands and feet, with gently sloping sides and a central depression resembling an anthill (hence the term *myrmecia*, meaning anthill). On the soles, these are often painful

CLINICAL MANIFESTATIONS AND ASSOCIATED HUMAN PAPILLOMAVIRUS (HPV) TYPES

	Frequently detected	Less frequently detected
SKIN LESIONS		
• Common, palmar, plantar, myrmecial and mosaic warts	1, 2, 27, 57	4, 29, 41, 60, 63, 65
• Flat warts	3, 10	28, 29
• Butcher's warts	7	1, 2, 3, 4, 10, 28
• Digital squamous cell carcinoma and Bowen's disease	16	26, 31, 33, 34, 35, 51, 52, 56, 73
• Epidermodysplasia verruciformis (EV)	3, **5**, **8**	**9**, **12**, **14**, **15**, **17**, **19–25**, **36–38**, **47**, **49**, 50, etc.
• EV – squamous cell carcinoma	**5**, **8**	**14**, **17**, **20**, **47**
MUCOSAL LESIONS		
• Condylomata acuminata	6, 11	40, 42–44, 54, 61, 70, 72, 81
• High-grade intraepithelial neoplasias (including cervical condylomata plana, bowenoid papulosis, erythroplasia of Queyrat) and invasive cancer	16	18, 26*, 31, 33, 35, 39, 45, 51, 52, 53*, 56, 58, 59, 62, 66*, 68, 73, 82
• Buschke–Löwenstein tumor	6, 11	
• Recurrent respiratory papillomatosis, conjunctival papillomas	6, 11	
• Heck's disease (focal epithelial hyperplasia)	13, 32	

*Probably carcinogenic[33].

Table 79.1 Clinical manifestations and associated human papillomavirus (HPV) types. HPV types in the genus β are in bold.

Fig. 79.5 Verrucae vulgares (common warts). *Courtesy, A Geusau, MD.*

Fig. 79.6 Periungual common warts. Destruction of the nail matrix and bed can lead to partial (**A**) or complete (**B**) absence of the nail plate. Bowen's disease may be considered in the differential diagnosis, especially for a single, recalcitrant digital wart.

Fig. 79.7 Verrucae plantares (plantar warts). The photo was taken after shaving of the hyperkeratotic surface; the black dots represent thrombosed capillaries.

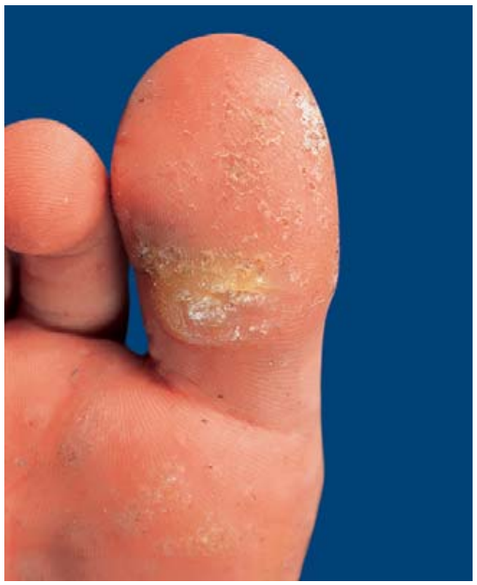

Fig. 79.8 Myrmecial wart. The wart at the base of the distal phalanx of the hallux is painful due to deep endophytic growth; in addition, there are confluent plaques of superficial warts (mosaic warts).

Fig. 79.9 Extensive and chronic verrucosis of the sole causing pain when walking. HPV-2a was isolated from the lesions of this otherwise immunocompetent and healthy patient.

Fig. 79.10 Verrucae planae (flat warts). Multiple skin-colored or pink (**A**) to brown (**B**) smooth-surfaced, flat-topped papules. These lesions are typically caused by HPV-3 or -10. *B, Courtesy, Julie V Schaffer, MD.*

from pressure when walking, due to their deep inward growth (Fig. 79.8). Plantar warts that coalesce into large plaques are referred to as *mosaic warts* (see Fig. 79.8). Extensive chronic verrucosis that is notoriously resistant to therapy has been observed in immunocompromised individuals and, at times, in patients with no apparent immune dysfunction (Fig. 79.9). Inclusion warts of the sole are plantar cysts from which HPV types 4, 60, 63 and 65 have been isolated[34]. In studies from Europe, the closely related HPV types 1, 2, 27 and 57 caused the majority of palmoplantar warts, and they occurred most commonly in patients 6–10 years of age[35,36]. Although a higher incidence of HPV-2-related warts was reported in atopic children, other investigators have failed to find such an association.

Flat warts are skin-colored or pinkish to brown, relatively smooth-surfaced, slightly elevated, flat-topped papules that are most commonly located on the dorsal hands, arms or face, often in a linear array (Fig. 79.10). They are usually caused by HPV types 3 or 10, and less often by 28 and 29.

Butcher's warts, which earn their name from their occurrence in meat- (or fish-) processing professionals, appear as extensive verrucous papules or cauliflower-like lesions on the dorsal, palmar or periungual aspects of the hands and fingers. These warts are associated with HPV-7, not animal papillomavirus types.

Epidermodysplasia verruciformis (EV), first described in 1922 by Lewandowski and Lutz, is a rare genetic disease. It is characterized by a particular susceptibility to cutaneous infections with HPV types in the genus β (see above), which do not produce clinical lesions in immunocompetent individuals[37]. The disease usually manifests in childhood with highly polymorphic, widespread lesions. About two-dozen specific HPV types have been described in EV patients, a subset of which (mainly types 5 and 8) is also detected in EV-associated skin cancers. EV typically has an autosomal recessive pattern of inheritance and is caused by truncating mutations in two genes, *TMC6 (EVER1)* and *TMC8 (EVER2)*, that encode transmembrane proteins localized to the endoplasmic reticulum[38]. These proteins form a complex that interacts with the zinc transporter 1 (ZnT1) and affects intracellular zinc distribution, downregulating zinc-associated transcription factors[39]. Inhibition of ZnT1-TMC6/8 function by the HPV E5 protein is thought to facilitate viral infection; β HPV types lack E5, but they become pathogenic in EV patients with TMC6/8 defects[39].

Patients with EV present with widespread, discrete or confluent papules that resemble flat warts (Fig. 79.11); scaly, pinkish (Fig. 79.12) or hypopigmented guttate macules and thin plaques that resemble pityriasis versicolor represent another characteristic finding. In an individual patient, warts that appear clinically distinct often contain different HPV types, and each skin lesion usually contains several HPV types. Actinic keratoses usually arise after the age of 30 years and slowly transform into invasive SCCs in approximately half of EV patients. These tumors have low metastatic potential and develop primarily in sun-exposed areas such as the forehead, ears and hands, implicating UV irradiation as an important co-carcinogen. Patients with EV should be educated about the importance of minimizing sun exposure, and family members should be screened for the presence of similar lesions.

Fig. 79.11 Epidermodysplasia verruciformis. Confluent scaly papules and plaques resembling flat warts.

Fig. 79.12 Epidermodysplasia verruciformis. Generalized erythematous macules and plaques are seen in the same patient as shown in Fig. 79.11. Lesions tested positive for HPV-8 and -36.

It may be difficult to differentiate flat warts from EV-associated lesions based on histology alone (see below), and the presence of lesional β HPV DNA (e.g. HPV-5, -8, etc.) can establish the diagnosis in an otherwise healthy individual. Beta HPV types can also induce a sporadic EV-like eruption in immunosuppressed patients, including transplant recipients and those with AIDS or a lymphoma. In addition, β HPV sequences have been isolated from the normal skin of healthy individuals by highly sensitive DNA detection methods, indicating that the general population acts as the reservoir for these HPV types.

WHIM syndrome is a rare, autosomal dominant primary immunodeficiency disorder characterized by HPV-induced *w*arts (cutaneous and genital), *h*ypogammaglobulinemia, recurrent bacterial *i*nfections and neutropenia due to *m*yelokathexis (retention of mature neutrophils in the bone marrow) (see Ch. 60). It is caused by mutations in the gene encoding the chemokine CXC receptor 4 (CXCR4), which result in impaired leukocyte trafficking and homing[40].

Fig. 79.13 Penile condylomata acuminata (genital warts). Both sessile and exophytic warts are present.

WILD syndrome is a recently characterized disorder that features *w*arts, cellular *i*mmunodeficiency, primary *l*ymphedema and multifocal anogenital *d*ysplasia. The patient reported had extensive warts, including condylomata acuminata and lesions that clinically (but not histologically) resembled those in EV. A variety of α HPV types were detected in the cutaneous and genital lesions[41].

Mucosal Infections

More than 40 HPV types preferentially infect the mucosa of the anogenital and upper aerodigestive tracts. Subclinical infections are much more common than visible warts. Application of 5% acetic acid (aceto-whitening) may aid in the identification of subclinical lesions as white areas.

Condylomata acuminata (singular: *condyloma acuminatum*), or anogenital warts, are found on the external genitalia and the perineum, perianally, or in adjacent areas such as the inguinal fold and mons pubis. Lesions may extend into the vagina, urethra, or anal canal (but rarely beyond the dentate line). Condylomata are typically discrete, sessile, smooth-surfaced exophytic papillomas or acuminate warts and may be skin-colored, brown or whitish (especially when macerated in moist areas) (Fig. 79.13). They lack the thick cuirass of horny scale present on cutaneous warts and frequently measure one to several millimeters in diameter. Condylomata may also present as pedunculated or broad-based papillomas up to several centimeters in diameter or as large confluent plaques (Fig. 79.14). *Condylomata plana*, or flat cervical warts, may be difficult to recognize without aceto-whitening and the use of a (magnifying) colposcope. High-grade intraepithelial neoplasias are usually caused by high-risk types, mainly HPV-16, -18 and -31, whereas low-grade lesions may contain low-risk as well as high-risk HPV types.

Bowenoid papulosis manifests as multiple red–brown papules or confluent plaques on the external genitalia, on the perineum, or perianally (Figs 79.15 & 79.16; see Fig. 73.13). These lesions primarily affect young adults and may clinically resemble genital warts, but histologically represent a high-grade squamous intraepithelial lesion (HSIL) or SCC *in situ*[42]. *Erythroplasia of Queyrat* is a distinct entity, presenting clinically as a well-demarcated, velvety erythematous plaque on the glabrous skin of the penis or vulva that histologically is an HSIL (Fig. 79.17). A biopsy is warranted for pigmented, erosive, bleeding and/or therapy-resistant genital lesions to exclude malignancy. Bowenoid papulosis and erythroplasia contain high-risk HPV types, predominantly HPV-16, and thus may represent a precursor lesion of vulvar, penile or perianal cancer.

Fig. 79.14 Condylomata acuminata. A Perianal papillomas that are macerated due to moisture from occlusion. **B** Confluent lesions forming hyperpigmented plaques in the perineal region and along the inguinal fold. A depigmented scar is seen at the site of treatment with liquid nitrogen.

Fig. 79.15 Bowenoid papulosis of the vulva (histologically vulvar intraepithelial neoplasia, VIN). Extensive red–brown or whitish papules and plaques containing high-risk mucosal HPV in an HIV-positive patient. Analogous high-grade squamous intraepithelial lesions (HSIL) were present perianally (AIN) and on the cervix (CIN).

Fig. 79.16 Bowenoid papulosis of the anus positive for high-risk mucosal HPV in a homosexual man. Histology revealed high-grade anal intraepithelial neoplasia (AIN).

Buschke–Löwenstein tumor (giant condylomata acuminata), *oral florid papillomatosis*, *epithelioma cuniculatum* of the sole, and *papillomatosis cutis carcinoides* of the skin comprise a group of "semi-malignant" verrucous carcinomas that are locally invasive and destructive but rarely metastasize[43] (see Ch. 108). Buschke–Löwenstein is a rare tumor of the anorectal area and external genitalia associated with the low-risk HPV types 6 or 11 that usually cause condylomata acuminata. The basis for the difference in biologic behavior between these two entities has not been established. In rare cases, pre-existing anogenital condylomata may progress into large exophytic cauliflower-like tumor masses that infiltrate deeply into underlying tissues and form fistulas and abscesses (Fig. 79.18). The histology of the Buschke–Löwenstein tumor may appear remarkably benign and resemble that of condylomata acuminata (Fig. 79.19), although focal frank malignant transformation can occur spontaneously or following X-irradiation. High-resolution imaging and a large biopsy are essential for identifying the extent of the infiltration and foci of SCC. Radical surgery may cure the disease, but recurrences are frequent, resulting in a high morbidity rate.

Oral warts appear as small, soft, pink or white, slightly elevated papules and plaques on the buccal, gingival or labial mucosa (Fig. 79.20), the tongue or the hard palate. Oral condylomata are associated with HPV types 6 and 11 and may result from digital or oral-genital sexual transmissions. In HIV-positive patients, oral papillomas are frequently detected and may contain unusual HPV types such as 7, 71, 72 and 73. In *focal epithelial hyperplasia*, or Heck's disease, multiple circumscribed papules resembling flat warts or condylomata are found on the gingival, buccal or labial mucosa. This disorder is rare in Caucasians but relatively common in children who are native South Americans, native Greenlanders, or from South African communities. It is associated exclusively with HPV-13 or -32.

HPV (especially type 16) is a causative agent in about 25% of oropharyngeal cancers, particularly those affecting the lingual and palatine tonsils. HPV-associated oropharyngeal cancers are relatively frequent in non-smokers and have a predilection for younger patients

Fig. 79.17 Erythroplasia of Queyrat. A well-demarcated velvety plaque of the prepuce positive for high-risk HPV; histology detected a high-grade penile intraepithelial neoplasia (PIN).

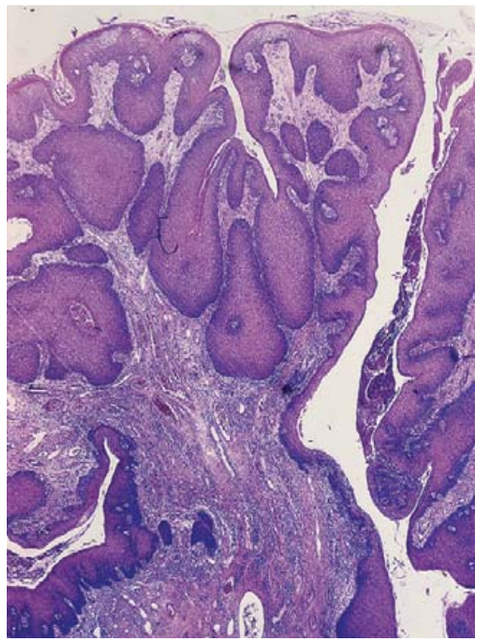

Fig. 79.19 Histology of a Buschke–Löwenstein tumor. There is downward extension of bulbous rete ridges without penetration of the basement membrane plus a lack of cellular atypia.

Fig. 79.20 Oral warts. Papillomas of the labial mucosa in a 6-year-old child.

with high-risk sexual behavior[44]. Although poorly differentiated histopathologically, they appear to have a better prognosis than HPV-negative oropharyngeal cancers[45].

In *oral florid papillomatosis*, multiple, confluent warty lesions associated with HPV-6 or -11 are found in the oral cavity or the nasal sinuses. The development of these lesions is believed to be promoted by smoking, X-irradiation and chronic inflammation. Patients with oral papillomas need frequent examinations and repeated biopsies for early diagnosis of progression to verrucous carcinoma.

Recurrent respiratory papillomatosis (RRP) features benign exophytic laryngeal papillomas caused by HPV-6 and -11[25]. Patients classically present with a triad of hoarseness, stridor and respiratory distress. Papillomas arise most often at the transition zones between the squamous and cilia-bearing epithelia of the larynx and subglottis, but they may rarely extend to the distal trachea, the bronchi or even the bronchoalveoli. Malignant transformation of laryngeal papillomas into SCCs in patients with long-lasting disease has been reported, and exogenous factors such as X-irradiation, smoking, chemical toxins or chemotherapy have been implicated as co-carcinogens.

PATHOLOGY

The histopathologic changes induced by HPV infection are variable, reflecting the myriad of clinical presentations and different anatomic sites. In productive HPV infections, a common motif in epithelial cells is the presence of cytoplasmic vacuoles isolating the nucleus from the cytoplasmic membrane. Cells with this distinctive vacuolization are referred to as koilocytotic (hollow) cells, and the presence of koilocytosis is a useful feature distinguishing verrucae from other types of papillomas[46].

Common and Deep Palmoplantar Warts

Common warts are well circumscribed from the surrounding skin and characteristically have steeply sloping "church spire" papillomatosis heaped with ortho- and parakeratosis (Fig. 79.21). Parakeratosis is most commonly observed directly overlying the summits of the papillomatosis; there is marked acanthosis and the rete ridges are elongated. In palmoplantar warts, the lateral edges of the wart bow inward to create a cup-shaped invagination below the papillomatosis. Higher-power

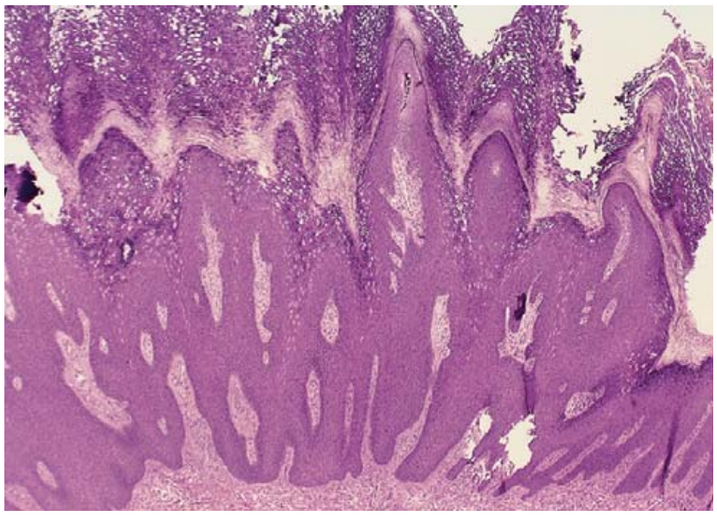

Fig. 79.21 Histology of verruca vulgaris. Note the characteristic features of "church spire" papillomatosis heaped with ortho- and parakeratosis, acanthosis, hypergranulosis and koilocytosis. *Courtesy, R Tyler, MD.*

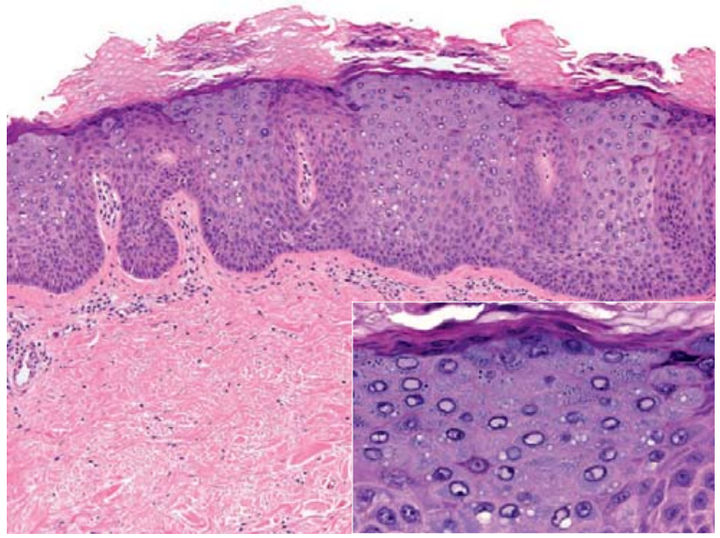

Fig. 79.22 Histology of epidermodysplasia verruciformis. Note the cells with perinuclear halos and blue–gray, granular cytoplasm in the mid to upper epidermis (insert). *Courtesy, Lorenzo Cerroni, MD.*

examination reveals hypergranulosis and condensed coarse cytoplasmic keratohyalin-like granules of variable size and shape within the granular layer, along with vacuolization of cells on top of, or sometimes between, the papillae. Koilocytosis is typically observed in or immediately below the granular layer. The papillary dermis underlying the elongated rete ridges shows increased vascularity, with some vessels being thrombosed. These thromboses correspond to the "black dots" that can be detected on clinical examination, especially of pared warts.

Flat Warts

The characteristic features of flat warts include orthokeratosis alternating with parakeratosis, acanthosis, no or minimal papillomatosis, a uniformly thickened granular layer, and vacuolization of cells in the granular and upper malpighian layers (termed "bird's eyes")[46].

Some patients with flat warts develop clinically evident inflammation around these warts, which may precede their spontaneous involution. Characteristic histologic features of regressing flat warts include parakeratosis, spongiosis, exocytosis of mononuclear cells into the lower epidermis, and (occasionally) satellite cell necrosis. By immunohistochemistry, helper T cells predominate and HLA-DR antigen, a marker of immune activation, is detected on the surface of the infiltrating lymphocytes and on some keratinocytes. Many of these changes can also be observed in regressing condylomata, suggesting that wart regression is mediated, at least in part, by a delayed-type hypersensitivity-like cellular immune response directed against keratinocytes expressing wart antigens[47].

Epidermodysplasia Verruciformis

In patients with EV, the flat warts and pityriasis versicolor-like lesions exhibit orthokeratosis with a basket-weave appearance, parakeratosis and acanthosis. Under higher power, some cells within the hyperplastic stratum malpighii have characteristic cytopathic changes. These cells are large with perinuclear halos and a cytoplasm that has a blue–gray pallor and contains keratohyaline granules of various sizes and shapes (Fig. 79.22). Keratinocytic dysplasia and actinic keratoses may be evident, especially in biopsies of lesions in sun-exposed areas[46]. Because the histologic picture is nonspecific, it may be difficult to differentiate typical flat warts from EV-associated lesions based on histology alone.

Anogenital Warts

The most consistent histologic features seen in condylomata include epidermal hyperplasia, parakeratosis, koilocytosis and papillomatosis. The papillomatosis is more gently rounded than is seen in common warts. The upper portions of the epithelia of mucosal surfaces normally have some degree of cytoplasmic vacuolization, so its detection is specific for condylomata acuminata only if present within the deeper portions of the stratum malpighii[46]. Mitotic figures may be evident, and prior treatment with podophyllotoxin (which interferes with microtubule formation in cells undergoing mitosis) can induce the appearance of aberrant mitoses that could potentially lead to misdiagnosis as SCC.

Giant Condylomata of Buschke–Löwenstein

The histology of the Buschke–Löwenstein tumor shares many features with condylomata acuminata, but there is marked downward extension of characteristically bulbous rete ridges and less vacuolization of epidermal cells (see Fig. 79.19). Mitotic figures are rarely detectable, and, when present, are normal. While customarily associated only with extension into and destruction of local tissue, metastases to local lymph nodes from foci of SCC arising in these tumors have been reported[43].

Squamous Intraepithelial Neoplasias

Persistent infection with high-risk HPV types can lead to intraepithelial neoplasia that may progress to invasive carcinoma. The precancerous lesions represent a continuum of morphologic changes with indistinct boundaries. In CIN grade I, nuclear enlargement and hyperchromasia is observed in the lower epithelial layers; these changes may be accompanied by cytoplasmic halos (koilocytotic atypia). The next stage (CIN II) shows progressive atypia in all layers of the epithelium, with abnormal differentiation of the keratinizing cell layers. The atypical cells have an increased nuclear–cytoplasmic ratio, variability of nuclear size, and an increased number of mitotic figures, including abnormal mitoses and hyperchromasia. In CIN III, the epithelium is totally replaced by immature, atypical cells with a lack of surface differentiation. The analogous lesions of the vulva, vagina, penis and anus are termed VIN (vulvar intraepithelial neoplasia; Fig. 79.23), VaIN (vaginal intraepithelial neoplasia), PIN (penile intraepithelial neoplasia) and AIN (anal intraepithelial neoplasia), respectively. Clinically, these may appear as erythematous or whitish plaques (erythroplasia, leukoplakia) or red–brown papules (bowenoid papulosis) (see Figs 73.12, 73.13, 79.15, 79.16 & 79.17).

DIFFERENTIAL DIAGNOSIS

The diagnosis of cutaneous and genital warts is straightforward if typical clinical features are present. Occasionally, various other diagnoses have to be considered and a biopsy may be required for confirmation and to identify dysplastic lesions. Immunohistochemistry with antibodies directed against cross-reacting epitopes of papillomavirus capsid proteins allows the detection of virions in palmoplantar warts, which are highly productive infections, but has limited sensitivity in genital warts and dysplasias. There is no routine infectivity assay

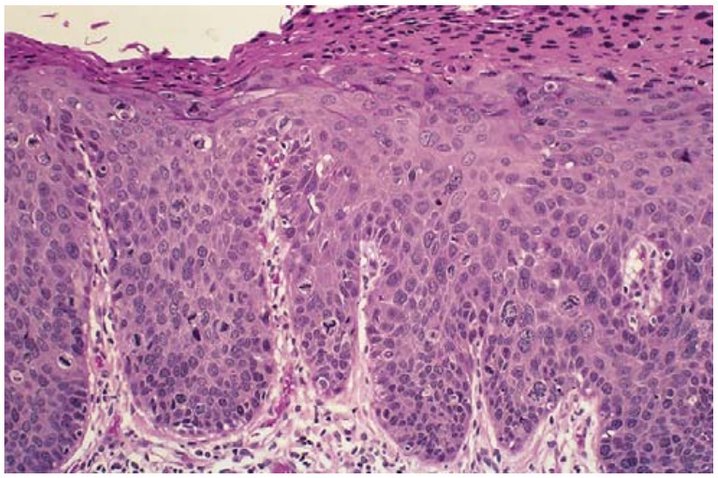

Fig. 79.23 Histology of vulvar intraepithelial neoplasia (VIN). Note the characteristic features of abnormal keratinocyte maturation, nuclear pleomorphism, and dyskeratosis. *Courtesy, R Tyler, MD.*

Fig. 79.24 Extensive and treatment-resistant penile warts in a renal transplant recipient.

available to detect virions in clinical samples, and diagnostic tests are therefore based on the molecular detection of papillomavirus DNA. Commercially available tests that utilize *in situ* hybridization (e.g. Hybrid Capture® II, Digene [available in the US]; Amplicor HPV® and Linear Array HPV Genotyping®, Roche [not available in the US]) can identify low-risk versus high-risk mucosal HPV types in clinical samples with high sensitivity and specificity. PCR-based techniques can also detect a broad range of genital and skin HPV types[48,49]. Development of circulating antibodies against the L1 major capsid protein is common following infection with genital HPV types, and ELISAs using L1 VLPs as the antigen have been useful in epidemiologic studies[32]. However, due to low antibody titers and variable intervals between infection and seroconversion, this assay is not used for diagnosis in individual patients.

Common Warts

Seborrheic keratoses (SKs), actinic keratoses (AKs), cutaneous horns (which can arise from warts as well as AKs, SCCs, SKs and other neoplasms; see Ch. 109), keratoacanthomas, other SCCs, trichilemmomas, Spitz nevi, and amelanotic melanomas may resemble common warts, and even tuberculosis verrucosa cutis or a plaque of psoriasis or hypertrophic lichen planus can have a warty clinical appearance. A wart-like periungual plaque on the finger may occasionally represent Bowen's disease and harbor high-risk HPV types 16 or 18. Similarly, amelanotic melanoma can masquerade as a persistent periungual wart and should be clinically suspected if erosion or subtle pigmentation is present. The differential diagnosis of flat warts may include acrokeratosis verruciformis, Gottron's papules of dermatomyositis (distinguished by their localization over the knuckles), lichen nitidus and lichen planus. Although both lesions of lichen planus and flat warts can develop in a linear array, the presence of Wickham's striae points to the former diagnosis. Plantar clavi (corns) are often misdiagnosed as warts, although verruca typically can be differentiated by the presence of punctate black dots representing thrombosed capillaries; in addition, shaving of the keratotic wart surface leads to capillary bleeding from the superficially located dermal papillae. Punctate palmoplantar keratoderma, punctate porokeratosis, arsenical keratoses and poromas can mimic plantar warts.

In patients with cellular immunodeficiencies, including organ transplant recipients and those with AIDS or hematologic malignancies, the number as well as incidence of cutaneous and genital warts is increased (Fig. 79.24). Warts that appear at less common sites such as the face and the neck need to be differentiated from mollusca contagiosa. In immunosuppressed patients, macular and flat warts may resemble EV, but the clinical setting and absence of a family history can aid in establishing the correct diagnosis. Other heritable immunodeficiencies that predispose affected individuals to the development of warts include WHIM syndrome (see above), idiopathic $CD4^+$ lymphopenia, DOCK8 deficiency, and severe combined immunodeficiencies (see Ch. 60).

Anogenital Lesions

Condylomata acuminata are rarely confused with condylomata lata of secondary syphilis, but serologic testing for syphilis (and, as indicated, other sexually transmitted diseases) is recommended in patients with genital warts, and dark-field examination for spirochetes may be required. Mollusca contagiosa preferentially involve the mons pubis and can be distinguished by their umbilication, with dermoscopy revealing a multilobular, yellow–white central structure surrounded by a "crown" of vessels. In men, pearly penile papules are normal anatomic structures consisting of several rows of discrete, monomorphic, dome-shaped, 1 to 2 mm papules circumferentially around the corona and/or sulcus of the glans penis (see Ch. 116). An analogous picture exists in women, called vestibular papillomatosis, with tiny, uniformly shaped, finger-like projections at the introitus and on the labia minora. Sebaceous glands of the prepuce and labia majora appear as white–gray to yellow, small papules with a regular array. Epidermoid cysts, steatocystomas or angiokeratomas of the scrotum seldom pose diagnostic problems.

Detection of subclinical genital HPV infection requires soaking with 5% acetic acid for 3 to 5 minutes; this leads to whitening ("aceto-whitening") of lesions, and the use of a colposcope for magnification will further increase diagnostic accuracy. However, aceto-whitening is not specific for HPV-induced lesions and is also observed in infectious or inflammatory conditions such as *Candida* vulvitis or balanoposthitis, psoriasis, lichen planus or eczematous dermatitis.

Bowenoid papulosis consists of red–brown papules or confluent, sometimes leukoplakia-like plaques that may be difficult to distinguish from condylomata (see Figs 79.15 & 79.16). Erythroplasia of Queyrat is a well-defined, velvety erythematous plaque of the glans or vulva that must be differentiated from erosive lichen planus and Zoon's balanitis (see Fig. 79.17 and Ch. 73). Bowen's disease can present as a solitary patch or plaque, sometimes scaly, of the vulva or penis, most often in older individuals. Extramammary Paget's disease appears as a well-defined red plaque in the groin or pubic region or on the vulva, penile root or perianal skin, with distinctive histopathologic features (see Ch. 73).

Vulvar carcinomas are etiologically heterogeneous. Carcinomas with basaloid or warty histology are related to HPV infection, whereas keratinizing squamous carcinomas are not[50]. Basaloid and warty vulvar carcinomas typically arise in younger women, are found adjacent to vulvar intraepithelial neoplasia (VIN), and are associated with risk factors related to sexual practices. Close to 90% of high-grade VIN (see Fig. 79.15) and basaloid and warty vulvar carcinomas contain high-risk HPV DNA (most often HPV-16, -31 and -33), suggesting a common etiology. In contrast, the more common keratinizing vulvar carcinoma in older women, which typically arises adjacent to lichen sclerosus and

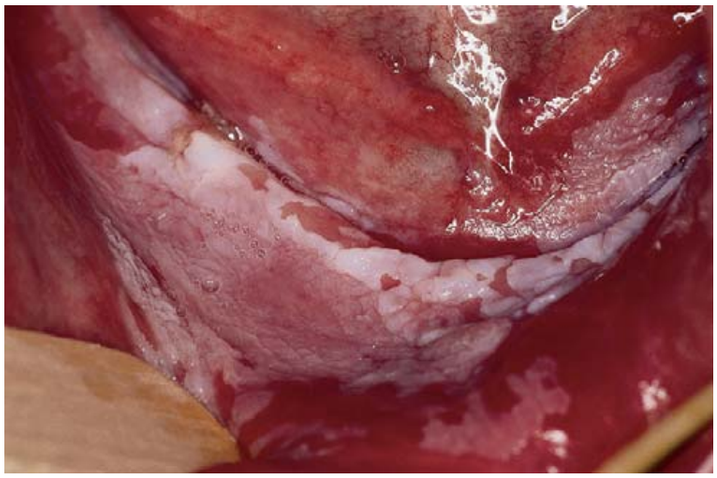

Fig. 79.25 Verrucous proliferative leukoplakia of the oral cavity. The lesions have focally progressed to invasive squamous cell carcinoma; HPV DNA was not detectable by PCR.

epidermal hyperplasia, infrequently contains HPV DNA and thus is regarded as a distinct entity[51].

Heterogeneity in etiology has also been described for anal SCC[51,52]. In both genders, the majority of anal cancers are attributable to HPV infection. Cancers of the anal canal that are positive for high-risk HPV (16, 18, 31, 33) tend to occur in younger men and women with high-risk sexual behaviors (especially MSM), have basaloid histology, and arise adjacent to AIN. In contrast, HPV-negative anal cancers usually affect older men, are well keratinized, and arise from perianal skin without AIN. Heterogeneous etiology has also been described for penile cancer, analogous to that observed for vulvar and anal squamous cell cancers[51]. Immunosuppression and a history of HPV-associated malignancy are notable risk factors for the development of a (second) anogenital cancer attributable to HPV.

Anogenital warts in children may give rise to suspicion of sexual abuse (see Ch. 90). In the majority of cases, however, the presence of several criteria will argue for a non-abusive transmission of HPV. These include an age less than 3 years, wart location somewhat distant from the anus or vulva, detection of HPV-2 or other skin-specific HPV types, genital condylomata in the mother, and an absence of signs of physical abuse or of other sexually transmitted diseases[15].

Giant condyloma acuminatum, or Buschke–Löwenstein tumor, is clinically suspected by its size and the presence of fistulas or abscesses (see Fig. 79.18). Histologic findings may be remarkably banal, and distinction from large benign genital warts can therefore be difficult at an early stage (see Fig. 79.19)[43,53]. However, high-resolution imaging reveals the extent of infiltration, and a large biopsy with serial sectioning may detect locally destructive growth and, rarely, transformed foci of SCC.

Oral Warts

Oral warts (see Fig. 79.20) or condylomata may resemble the papules of focal epithelial hyperplasia (Heck's disease); the latter is very rare in Caucasians. A distinct oral condition with the descriptive name "verrucous proliferative leukoplakia" is clinically similar to oral florid papillomatosis but does not contain HPV DNA and has a high risk of progression to metastatic squamous cell cancer (Fig. 79.25)[54]. Additional diagnostic considerations may include leukoedema (grayish-white translucent plaques, sometimes with a "moth-eaten" appearance, that favor the buccal mucosa and may become less evident upon stretching), a white sponge nevus and hereditary benign epithelial dyskeratosis.

THERAPY

General Considerations

There is currently no specific antiviral therapy available to cure HPV infection. Existing modalities focus primarily on the destruction or removal of visible lesions or induction of cytotoxicity against infected cells (Table 79.2). Because of the benign and self-limited nature of warts, treatments that cause scarring should be avoided. There is no evidence that aggressive treatment results in a better long-term outcome, and temporary interruption of therapy is an option. Common warts often regress spontaneously in children and therefore may not require treatment. A simplified algorithm for the approach to treatment of common warts is presented in Figure 79.26.

Genital warts may be disfiguring and pose a significant psychological burden. HPV infection is typically widespread and multifocal throughout the anogenital tract, and subclinical lesions are often present. Thus, regardless of the applied therapeutic modality, reported recurrence rates are high (25–65%) and it is unproven whether treatment reduces transmission rates to new sexual partners. Limiting the number of partners remains the mainstay of decreasing transmission. Condom use may also be helpful, and it has promoted regression of flat penile lesions and CIN as well as clearance of HPV in couples infected with the same HPV type[55]. Treatment is time-consuming, uncomfortable and limited to visible warts and intraepithelial neoplasias with a high risk of progression. A simplified treatment algorithm is shown in Figure 79.27. Current therapies for genital warts are summarized in Table 79.2 and include destructive, antiproliferative and immunomodulatory modalities[56].

MANAGEMENT OF ANOGENITAL WARTS WITH GRADING OF RECOMMENDATIONS
CYTOTOXIC OR ANTIVIRAL AGENT
• Podophyllotoxin 0.5% solution, 0.15% cream (1) • Cidofovir 1% gel (1), intralesional injection (3)
PHYSICAL DESTRUCTION
• Cryotherapy (liquid nitrogen, cryoprobe) (1) • Trichloroacetic acid (TCA) 70–90% solution (1) • Potassium hydroxide 5% solution (2) • Electrosurgery (1) • Scissors excision (1) • Laser vaporization (2) • Photodynamic therapy with topical aminolevulinic acid (1)
IMMUNOMODULATORY
• Imiquimod 5% cream (1) • Sinecatechins (green tea catechins) 15% ointment (1) • Topical immunotherapy with squaric acid dibutyl ester (3) • Intralesional immunotherapy with skin test antigens (2) • Intralesional interferons (1, but inconsistent results)
OTHER
• Oral isotretinoin (1)

Table 79.2 Management of anogenital warts with grading of recommendations. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports[56].

Local Destructive Therapy

Destructive or ablative therapies for *genital warts* include cryotherapy, trichloroacetic acid (TCA), electrosurgery, curettage, scalpel or scissors excision, laser vaporization and photodynamic therapy with topical aminolevulinic acid. When anesthesia is required, topical application or injection of a local agent (see Ch. 143) is usually sufficient, although general anesthesia may be indicated for surgical debulking of large lesions and occasionally in children. Ablative laser therapy is also useful for vaginal, vulvar or anal intraepithelial neoplasias. Precautions should be taken to avoid inhalation of virus particles in the aerosol plume when laser or electrosurgical procedures are performed. Application of TCA 70–90% solution is a commonly utilized office-applied therapy that results in local tissue destruction. Although scarring may occur following dermal injury, TCA has the advantage of a complete lack of systemic toxicity and it can be used during pregnancy. Cryotherapy is inexpensive, effective and does not require anesthesia; as a result, it is often used as a first-line therapy followed by patient-applied podophyllotoxin. Liquid nitrogen is applied with a cotton swab, spray gun or

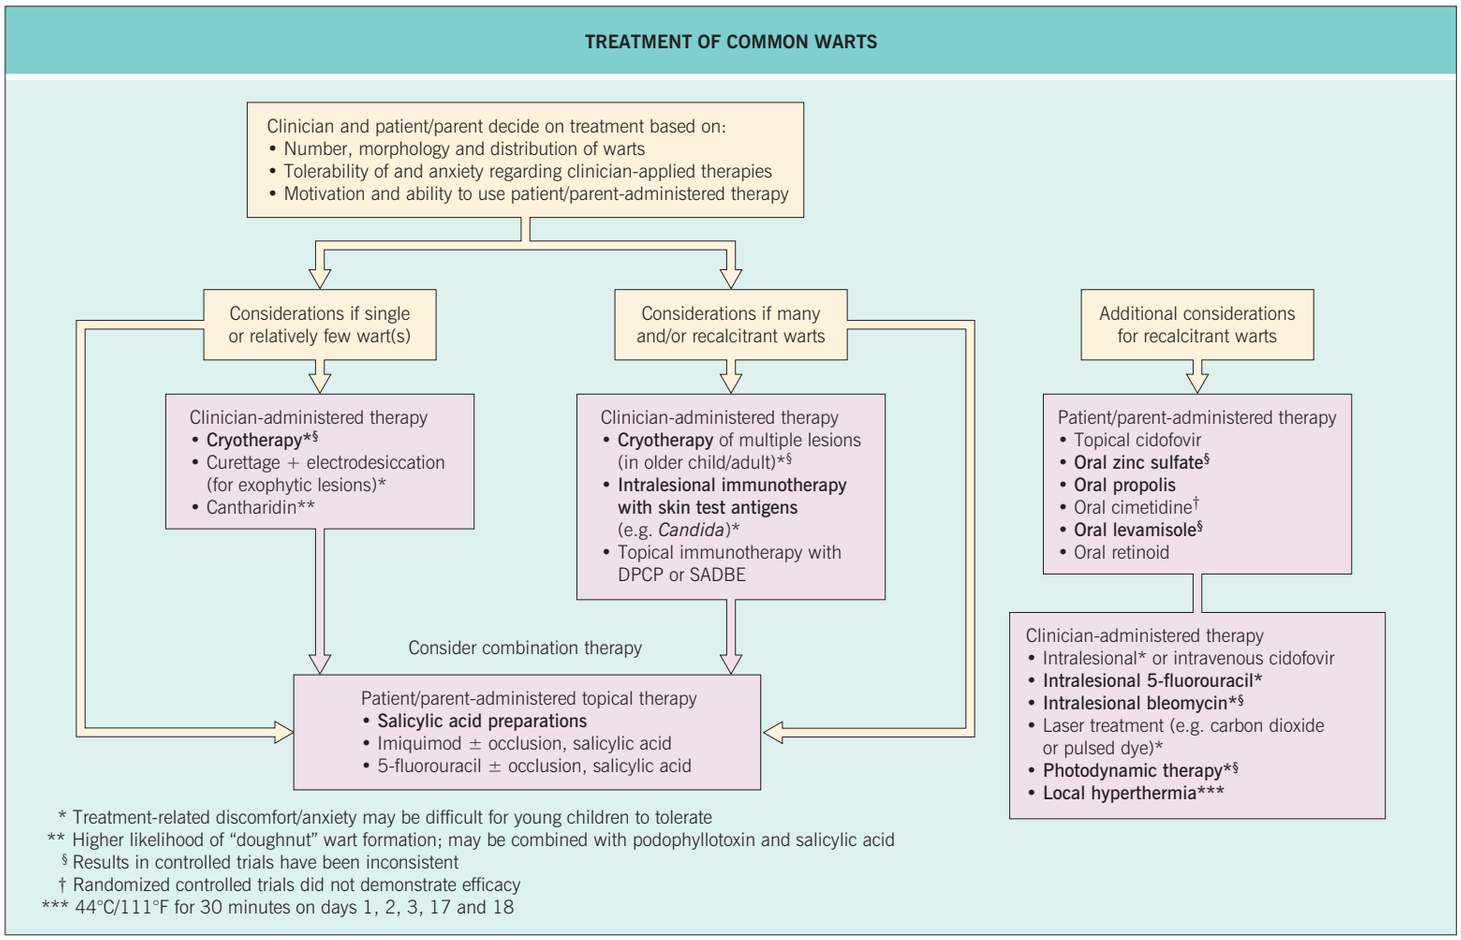

Fig. 79.26 Treatment of common warts. Therapies found to be effective in controlled trials are in bold. DPCP, diphenylcyclopropenone; SADBE, squaric acid dibutyl ester.

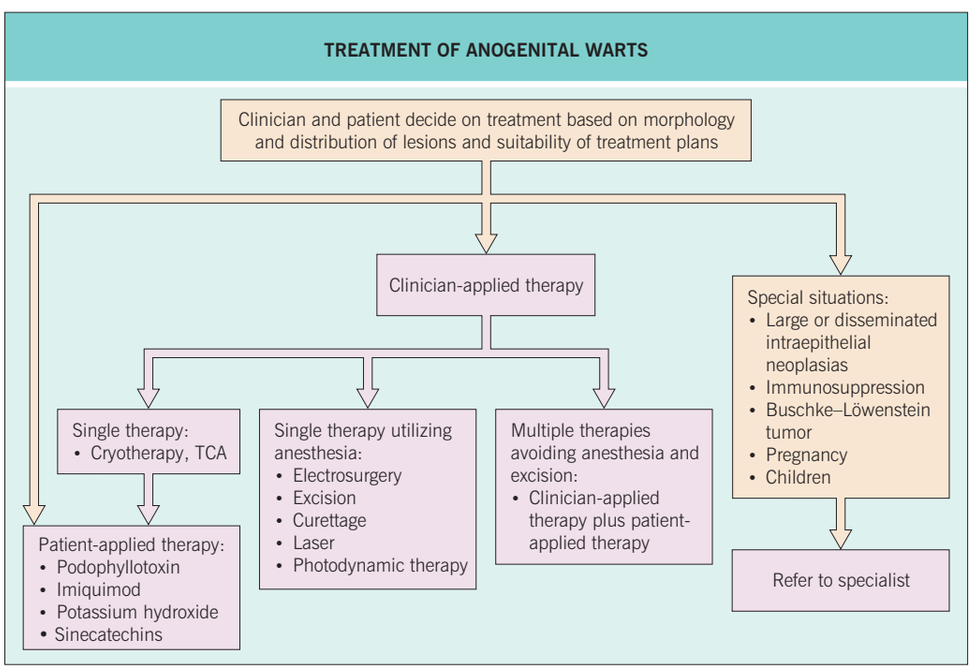

Fig. 79.27 Treatment of anogenital warts. TCA, trichloroacetic acid.

closed system cryoprobe (see Ch. 138). Two freeze–thaw cycles, the extent of which is visually controlled, lead to wart necrosis, and multiple treatments result in remission rates of 78% to 88%, with recurrences in 20–40% of patients[57]. At-home application of potassium hydroxide (KOH) 5% solution has induced regression of genital warts in men[58].

Cutaneous warts may be treated by daily application of salicylic acid/lactic acid/collodion (1:1:4) or other salicylic acid preparations for up to 12 weeks, which results in regression in two-thirds of patients. Application of petrolatum to the surrounding normal skin protects against the corrosive effect of the concentrated acid. Weight pressure causes deep inward growth of plantar warts (myrmecia), and the

resulting pain can be reduced by repeated shaving of the hyperkeratotic surface to a level at which capillary bleeding occurs. Cryotherapy with liquid nitrogen (see above) may be utilized for persistent or recurrent verrucae, including periungual lesions, with cure rates similar to or better than salicylic acid preparations in randomized controlled studies[58a–c]. Other in-office or at-home freezing products (e.g. those containing dimethyl ether and propane) are less effective. Cryotherapy that does not include a rim of surrounding skin or topical application of the blistering agent cantharidin (see Ch. 85) may produce a "doughnut wart" due to clearance in the center but not at the periphery of the lesion. Additional destructive modalities include curettage or scissor excision (especially for filiform warts and other exophytic lesions), electrosurgery (see Ch. 140), laser treatment (e.g. with CO_2 or pulsed dye lasers) and photodynamic therapy. Combination therapy with the application of topical agents following destruction may reduce the rate of recurrence.

Topical and Intralesional Cytotoxic Therapy

Podophyllin is a crude resin extract from the roots of the May apple *Podophyllum peltatum* (North America) or *Podophyllum emodi* (Far East) that has been used since 1942 for the treatment of genital warts. Systemic toxicity can occur when applied in large volumes, and death, intrauterine demise and teratogenicity have been reported. Because of low efficacy and potential toxicity, podophyllin use is no longer recommended[55]. Podophyllotoxin has been identified as the most active constituent of podophyllin. A regimen of patient self-applied podophyllotoxin 0.5% solution twice a day for 3 days repeated in weekly cycles was shown to be effective and without evidence of systemic absorption and toxicity. In a controlled randomized trial, podophyllotoxin 0.5% solution or 0.15% cream was superior to podophyllin 25% solution for the treatment of genital warts[57]. Erythema and erosions are the most common side effects. Both podophyllin and podophyllotoxin are contraindicated during pregnancy.

Warts of the urethral meatus and urethra are difficult to manage, and stenosis and stricture due to therapy are potentially serious complications. 5-Fluorouracil (5-FU) 5% cream can be applied twice a week to treat intraurethral condylomata or, as an alternative to destructive treatments, intraepithelial neoplasias of the external genitalia. However, its use in the genital area is limited by inflammatory side effects. Successful treatment of cutaneous warts with 5-FU 5% cream applied daily under occlusion or together with salicylic acid has also been described in children and adults[59], and effective therapy with intralesional 5-FU has been reported.

Intralesional bleomycin is occasionally used to treat recalcitrant cutaneous warts, but injections are painful and may result in excessive cutaneous necrosis.

Topical Immunomodifiers

Imiquimod is an imidazoquinoline compound with immunomodulatory activities that has been approved by the US Food and Drug Administration (FDA) for the topical treatment of condylomata acuminata. Imiquimod has been shown to interact with Toll-like receptors 7 and (to a lesser degree) 8, resulting in activation of cytokine secretion from monocytes/macrophages (including interferon-α, interleukin-12 and tumor necrosis factor-α) as well as stimulation of antigen-presenting dendritic cells (see Ch. 128).

In an initial randomized, double-blind, placebo-controlled clinical trial, complete clearance of genital warts occurred in 50% of patients treated with imiquimod 5% cream compared to 11% of those treated with vehicle control; recurrence rates were low (<15%) in both groups[60]. Response rates were higher for warts on mucosal sites (i.e. female and uncircumcised male patients) than for lesions on the penile shaft or suprapubic area, suggesting the importance of crossing the stratum corneum barrier for effective treatment. Later studies confirmed the therapeutic effect of imiquimod for anogenital warts and documented that this treatment resulted in a reduction of viral load, presumably due to activation of cellular immune responses. A direct comparison of imiquimod and cryotherapy for genital warts found an earlier response with imiquimod, slightly higher efficacy with cryotherapy, and similar recurrence rates[61]. In clinical practice, destruction of genital warts by the physician followed by patient-applied imiquimod (often requiring several cycles) is favorable over either modality alone[62]. Imiquimod has also been applied via suppositories (anal tampons) to prevent recurrence of anal condylomata following surgical ablation, or as primary treatment for anal condylomata and AIN in order to avoid the risk of scarring and stenosis of the anal canal associated with surgical procedures[63].

Therapeutic efficacy of imiquimod 5% cream has also been described for persistent cutaneous warts. In a controlled study (right versus left comparison) involving 14 immunosuppressed patients with recalcitrant warts on their hands and/or feet, a 36% response rate was observed for warts treated with imiquimod (three times weekly for 8 weeks, daily for 8 weeks, then daily with occlusion for 8 weeks) compared to 7% for untreated warts[64]. Improvement of common and flat warts with imiquimod therapy (daily application; ± occlusion for common warts) has also been reported in uncontrolled studies in immunocompetent patients[65]. Occlusion and/or concurrent use of salicylic acid or cryotherapy may increase imiquimod's penetration through the stratum corneum, which is especially important in acral sites.

Side effects of imiquimod include application site reactions (inflammation, erosion) that may require treatment-free periods. Imiquimod therapy is often more costly than other treatment options.

Sinecatechins 15% ointment, which contains green tea leaf-derived catechins thought to have immunostimulatory and antiproliferative properties, is FDA-approved as a topical treatment for anogenital warts. In randomized double-blind clinical studies, application of this product three times daily for up to 16 weeks led to complete clearance of anogenital warts in approximately 55% of patients (with frequent local irritation), compared to 35% of those treated with a vehicle control[65a].

Systemic Immunomodifiers

Interferons have been used topically, intralesionally and systemically for genital warts in controlled trials and have failed to demonstrate consistent efficacy. Systemic therapy, which is expensive and causes dose-related toxic side effects, is thus not recommended for routine clinical use. However, interferons may be helpful as an adjunct or salvage therapy in selected patients[53,57].

Anecdotal reports have described the successful treatment of recalcitrant common or flat warts as well as EV lesions with oral cimetidine (30–40 mg/kg daily divided into two to three doses; maximum of 2400 mg daily), which may stimulate production of interferon-γ and interleukin-2. However, three double-blind, placebo-controlled studies failed to confirm efficacy of cimetidine therapy for recalcitrant common warts. Two recent randomized controlled trials of oral zinc sulfate therapy (10 mg/kg to a maximum dose of 600 mg daily for 2 months) for treatment-resistant cutaneous warts had disparate results, with complete clearance rates in zinc-treated patients of 78% (27/32) in one study and 16% (4/25) in the other, compared with 12–13% in both placebo groups[66,67].

Immunotherapy

Increasing evidence that cellular immune responses play a critical role in wart clearance has inspired the development of topical and intralesional immunotherapy regimens for patients with multiple and/or recalcitrant warts. In a large uncontrolled study[68], 154 children and adults with recalcitrant palmoplantar warts underwent successful topical sensitization with 2% diphenylcyclopropenone (DPCP) followed by at least six applications of 0.5–4% DPCP to their warts at 3-week intervals. An 88% complete clearance rate was observed after an average of 6 months, with only local side effects (pruritus, blistering, eczematous reactions). Similar clearance rates have been reported for other contact sensitizers such as squaric acid dibutyl ester (SADBE), with application frequencies ranging from daily to monthly (often twice weekly), and regression of distant untreated warts has also been described.

Intralesional injection of *Candida*, *Trichophyton* and/or mumps skin test antigens represents another approach to immunotherapy for warts in immunocompetent adults and children. In a randomized controlled clinical trial, a significantly higher clearance rate for treated as well as distant untreated common warts was observed in patients receiving intralesional antigen as compared to placebo at 3-week intervals for a total of up to five treatments (60% versus 22%, and 41% versus 19%,

respectively)[69]. Effective treatment of flat warts and anogenital warts with topical and intralesional immunotherapy has also been described.

Antiviral Agents

Cidofovir is an acyclic nucleoside phosphonate with broad-spectrum activity against DNA viruses, including HSV and molluscum contagiosum, and it is approved for the systemic treatment of cytomegalovirus retinitis in AIDS patients. Although limited by the potential for renal toxicity, systemic treatment with cidofovir has shown efficacy in patients with HPV-associated lesions, including extensive cutaneous warts and severe RRP with pulmonary involvement. Intralesional injection of cidofovir and topical application of 1–3% cidofovir incorporated into an ointment, cream or gel base have been successfully used in a limited number of immunocompetent or immunosuppressed (e.g. HIV-infected) patients with cutaneous warts, condylomata acuminata, intraepithelial neoplasias or RRP[70,71].

Retinoids

The effects of retinoids on keratinocyte differentiation and proliferation may lead to inhibition of HPV replication and assembly. Eradication of extensive cutaneous or genital warts with oral retinoid therapy (e.g. acitretin or isotretinoin) has been reported in immunocompetent and immunosuppressed patients[72,73]. Successful treatment of flat warts with topical tretinoin or tazarotene has also been described.

Special Considerations

Early diagnosis of Buschke–Löwenstein tumor and other verrucous carcinomas is important to allow wide excision with clear resection margins. Surgery is the only established treatment that may cure the disease, although recurrence rates are high and the tumor can ultimately result in death. Cytotoxic chemotherapy and injections of interferon-α have led to remissions or cure in individual patients[43,53].

In transplant recipients and HIV-infected patients, skin and genital warts tend to resist standard treatment modalities. A surgical approach followed by non-invasive treatment of recurrent warts may be appropriate. In placebo-controlled studies, local application of imiquimod reduced genital wart area by more than 50% in 38% of HIV-infected patients. Imiquimod cream has also been used in individual cases of AIN and VIN[57], supporting a role for cellular immune enhancement for treatment of HPV-induced neoplasia.

During pregnancy, genital warts can increase in size and destructive procedures including surgery, cryotherapy, TCA application and laser treatments are appropriate to remove lesions, which may theoretically reduce the risk for the newborn to acquire RRP[25]. However, this assumption is not proven and the presence of condylomata is not an indication for delivery by cesarean section. Podophyllin and podophyllotoxin are teratogenic and thus must not be used in pregnant women.

The treatment of intraepithelial neoplasias (bowenoid papulosis, erythroplasia of Queyrat, Bowen's disease) is generally more aggressive than that of benign condylomata[56]. Prior to therapy, an aiming biopsy (e.g. colposcopically directed) is always required to exclude (micro) invasion histologically. For patients with bowenoid papulosis and erythroplasia who are younger than 45 years of age, superficial destruction (e.g. with cryotherapy or laser vaporization) of lesions may be appropriate to avoid mutilation[74]. In immunocompetent patients less than 35 years of age, bowenoid papulosis is regarded as a benign and self-limited disease[75]. Nevertheless, prolonged observation appears mandatory to detect recurrences.

HPV Vaccines

More than a decade ago, recombinant DNA technology was used to generate a prophylactic vaccine that consists of the L1 major capsid protein, which self-assembles into empty capsids designated virus-like particles (VLPs) (see Fig. 79.3)[26]. VLPs resemble native virions morphologically and immunologically, and they carry neutralization epitopes on their surface. However, as a safety advantage, they do not contain the potentially oncogenic viral DNA. Systemic immunizations with VLPs induce high-titer, long-lasting and type-specific neutralizing antibodies[27,76].

Prophylactic vaccinations in several animal models of papillomavirus infection were spectacularly successful in preventing natural or experimental infection of skin and mucosa[2,77]. In phase I/II human trials, systemic immunizations with VLP-based vaccines were nontoxic and highly immunogenic, inducing robust neutralizing antibody responses[76]. Based on these promising results, large-scale prophylactic vaccination trials were conducted to evaluate the safety and efficacy of two agents in preventing genital HPV infection and associated lesions in young women: (1) a quadrivalent vaccine of HPV-6, -11, -16, -18 VLPs (Gardasil™; Merck); and (2) a bivalent vaccine of HPV-16, -18 VLPs (Cervarix™; GlaxoSmithKline). Study endpoints were detection of HPV DNA and the development of dysplasias (squamous intraepithelial lesions) or (for the quadrivalent vaccine) anogenital warts. These studies showed near-complete protection (>90% vaccine efficacy) against vaccine-type HPV infection as well as 100% protection in the prevention of genital warts, low-grade dysplasias and high-grade dysplasias associated with the vaccine HPV types (for at least 5 years)[3–5,78,79]. The quadrivalent vaccine was also found to be nearly 90% effective in preventing genital warts caused by HPV types 6 and 11 in young men. While post-marketing evaluation of the duration of efficacy of the vaccines is ongoing, trial results have demonstrated stabilized antibody titers 5 years after vaccination, suggesting induction of a strong B-cell memory response. Also, in studies where girls and boys between the ages of 10 and 15 years were vaccinated, more than 99% have seroconverted, and they developed antibody titers that were even higher than those in women 16 to 23 years of age[80].

Two HPV vaccines are now commercially available (see above), with a primary goal of universally vaccinating children and adolescents prior to the onset of sexual activity (ideally before 12 years of age). Gardasil™ is FDA-approved for use in individuals (female and male) 9 to 26 years of age to prevent anogenital warts, dysplasias and cancer. Cervarix™ is FDA-approved for use in girls and women ages 9 to 25 years to prevent cervical dysplasia and cancer. Information gained from ongoing studies will aid in answering additional questions, including: cross-protection against related HPV types; benefits of including additional HPV types; the effects of vaccination on the incidences of cervical, vulvar, vaginal and anal cancers and genital warts in the general population; whether vaccination will reduce the carriage rate of oropharyngeal HPV-16 and the incidence of HPV-16-associated head and neck squamous cell cancer; duration of protection (when to boost); utility of surrogate assays for neutralizing antibodies; and correlates of protection.

At present, high-risk HPV types 16, 18, 31 and/or 45 are detected in about 80% of cervical cancers worldwide. A second-generation nonavalent VLP vaccine that targets seven oncogenic and two low-risk HPV types is currently being evaluated in clinical trials. As high-risk HPV-associated penile and anal cancer are relatively rare in men, vaccines that include low-risk HPV-6 and -11 VLPs to prevent genital warts might encourage male vaccination, which is likely to increase vaccine efficiency in the population as a whole due to herd immunity[27,76]. As an alternative approach to generate a broader-spectrum vaccine, genetic engineering has been employed to develop L1 VLPs that also express type-common epitopes of the minor capsid protein L2, which can induce cross-protective immunity to a variety of mucosal and even cutaneous HPV types[81–83]. Oral vaccination with attenuated *Salmonella typhimurium* expressing L1 may become a cost-effective alternative strategy for implementing HPV vaccination in developing countries. Such countries cannot afford HPV VLP vaccination programs or cytology (Pap) screening, yet they carry >80% of the worldwide burden of cervical cancer[19,84].

Successful experiments in animals have encouraged efforts to develop therapeutic vaccines against HPV infections. Most papillomavirus infections are self-limited, and it is generally agreed that a cellular immune response (albeit poorly understood) is required for clearance of infection. Cell-mediated immunity to L1 or L2 is unlikely to exhibit therapeutic efficacy, as capsid proteins are expressed neither in basal cells that harbor HPV DNA nor in progressed lesions that do not produce virions. Candidate rejection antigens are the E6 and E7 oncoproteins, which are selectively retained and expressed in cervical dysplasia and cancer, and E1 or E2 proteins, which are required to maintain the viral genome as an episome. Multiple strategies have been employed, including vaccinations with papillomavirus proteins fused to or combined with immunostimulants or dendritic cells in addition to attenuated viral or DNA expression vectors (for review, see ref. 85).

Chimeric VLPs have been engineered to incorporate an early protein such as E7 into an L1 or L1/L2 capsid. The induction of cytotoxic T-lymphocyte responses to the E7 oncoprotein, in addition to antibodies directed against the L1 capsid protein, provides both therapeutic and prophylactic benefit in mouse tumor models[86]. These strategies may prove effective in low-grade dysplasia or condylomata that have a high likelihood of spontaneous regression. However, mechanisms of immune evasion such as downregulation of MHC type I expression may diminish the success of therapeutic vaccines and, thus, favor their application as an adjunct to established ablative therapies. Also, safety issues associated with live attenuated or DNA vectors and with vaccines containing E6 or E7 oncoproteins are complex[76,87].

Human Herpesviruses 80

Natalia Mendoza, Vandana Madkan, Karan Sra, Beau Willison, L Katie Morrison and Stephen K Tyring

Chapter Contents

Herpes simplex viruses (HSV-1 and HSV-2) 1321
Varicella–zoster virus (HHV-3) 1328
Epstein–Barr virus (HHV-4) 1334
Cytomegalovirus (HHV-5) 1336
Human herpesvirus type 6 (HHV-6) 1338
Human herpesvirus type 7 (HHV-7) 1339
Human herpesvirus type 8 (HHV-8) 1340

The human herpesviruses (HHVs) are categorized into three groups: alpha, beta and gamma herpesvirinae (Table 80.1). Each virus contains a core of linear double-stranded DNA, an icosahedral capsid 100–110 nm in diameter, and an envelope with glycoprotein spikes on its surface. The pathogenesis of herpesvirus infections follows the sequence of primary infection, latency and reactivation. The eight human herpesviruses are discussed at length in this chapter and include the following: herpes simplex virus types 1 and 2 (HSV-1, HSV-2), varicella–zoster virus (VZV), Epstein–Barr virus (EBV), cytomegalovirus (CMV), human herpesvirus type 6 (HHV-6), human herpesvirus type 7 (HHV-7) and human herpesvirus type 8 (HHV-8).

HERPES SIMPLEX VIRUSES (HSV-1 AND HSV-2)

Synonyms/clinical variants: ■ Herpes – herpes simplex ■ Cold sore – fever blister, herpes febrilis, herpes labialis ■ Herpes gladiatorum – scrum pox ■ Herpetic whitlow ■ Genital herpes – herpes progenitalis

Key features

- Herpes simplex viruses produce primary and recurrent vesicular eruptions that favor the orolabial and genital regions
- The use of sensitive and specific serologic markers has provided insights into the epidemiology of HSV infections
- Antiviral therapy has significantly influenced the course and spectrum of HSV disease

Introduction

HSV-1 and HSV-2 are ubiquitous pathogens that produce primarily orolabial and genital herpes infections. Genital herpes is one of the most common sexually transmitted infections worldwide. Enhanced knowledge of the clinical manifestations, pathogenesis and histopathology of HSV infections has been paralleled by advances in the development of diagnostic markers that differentiate between the two HSV types and treatments for HSV infections. The use of sensitive and specific serologic markers has enabled the epidemiology of HSV infections to be deciphered, while antiviral therapy has allowed clinicians to control the course and extent of HSV disease. Prevention of HSV infections via molecularly derived vaccines remains an important goal.

History

Herpetic lesions have been described since antiquity, including by the noted physicians Hippocrates and Galen. The word "herpes" was first defined by Greek scholars as "to creep or crawl" in reference to the spreading nature of the skin lesions. The association between orolabial herpetic lesions and genital infection was first recognized during the late eighteenth century. However, better understanding of the pathogenesis of herpes infections did not occur until the twentieth century. Lipschitz was the first to suggest antigenic differences between the two HSV types, but it was not until 1968 that Nahmias and Dowdle demonstrated that HSV-1 was more frequently associated with orolabial and HSV-2 with genital infections[1]. In the past several decades, there have been critical insights into the pathogenesis of HSV infections as well as advances in their diagnosis, treatment and prevention.

Epidemiology

Herpes simplex viruses have a worldwide distribution. Their interaction with human hosts has the following components: (1) *primary infection* (first HSV infection, without pre-existing antibodies to HSV-1 or HSV-2) and *non-primary initial infection* (infection with one HSV type in an individual with pre-existing antibodies to the other HSV type), both of which may be symptomatic or asymptomatic; (2) *latency* in sensory ganglia; and (3) *reactivation* resulting in *recurrent infection* with asymptomatic viral shedding or clinical manifestations (recrudescence). It is estimated that approximately one-third of the world's population has experienced a symptomatic HSV infection.

In children less than 10 years of age, most herpetic infections are caused by HSV-1 (>80–90%). Analyses performed on a global basis have demonstrated HSV-1 antibodies in 50–90% of individuals 20 to 40 years old, with lower seroprevalences in higher-income countries (e.g. ~60% in the US)[2]. Although HSV-2 remains the cause of most genital herpes infections (70–90% overall)[3], recent studies have shown an increasing proportion due to HSV-1 in the US, Canada and the UK. In these countries, HSV-1 now accounts for the majority of genital herpes infections in young adults (especially college students)[4,5].

In the Centers for Disease Control and Prevention's (CDC's) 2005–2008 National Health and Nutrition Examination Survey (NHANES)[6], the seroprevalence of HSV-2 among individuals 14–49 years of age in the US was 16% overall, with higher rates in women (21%, versus 11.5% in men) and blacks (39%). Of note, 80% of those with positive serology had never had clinical symptoms or a previous diagnosis of genital HSV infection. Other factors associated with acquisition of genital herpes include an age of 15–30 years (period of greatest sexual activity), an increased number of sexual partners, lower levels of income and education, homosexuality and HIV-positivity; conversely, genital HSV-2 infection also increases the risk of acquiring and transmitting HIV infection[4].

Pathogenesis

Transmission of HSV can occur even during asymptomatic periods of viral shedding. HSV-1 is spread primarily through direct contact with contaminated saliva or other infected secretions, while HSV-2 is spread primarily by sexual contact. Virus replicates at the mucocutaneous site of infection and then travels by retrograde axonal flow to the dorsal root ganglia, where it establishes latency until reactivation. Latency enables the virus to exist in a relatively non-infectious state for varying periods of time in its host. HSV-1 can induce intracellular accumulation of CD1d molecules in antigen-presenting cells, providing a possible explanation for how this virus evades detection and establishes latency. Normally, CD1d molecules are transported to the cell surface, where

THE EIGHT HUMAN HERPESVIRUSES, THEIR CLASSIFICATION AND DIFFERENTIAL DIAGNOSES				
Human herpesvirus	**Classification**	**Predominant cell type infected**		**Differential diagnosis**
		Lytic infection	**Latent infection**	
Herpes simplex virus type 1 (HSV-1) (HHV-1)	Alphaherpesvirinae	Epithelial cells	Neurons	Orolabial herpes: aphthous stomatitis, erythema multiforme major, Stevens–Johnson syndrome, herpangina, pharyngitis (e.g. due to EBV), oral candidiasis, mucositis secondary to chemotherapy
Herpes simplex virus type 2 (HSV-2) (HHV-2)	Alphaherpesvirinae	Epithelial cells	Neurons	Genital herpes: trauma, chancre (primary syphilis), aphthae, EBV-related ulcers, CMV-related ulcers (AIDS), chancroid, granuloma inguinale, lymphogranuloma venereum
Varicella–zoster virus (VZV) (HHV-3)	Alphaherpesvirinae	Epithelial cells	Neurons	Varicella: vesicular viral exanthem (e.g. coxsackieviruses), PLEVA, rickettsialpox, disseminated HSV, insect bites, drug eruption, scabies, smallpox
				Herpes zoster: zosteriform HSV, contact dermatitis, phytophotodermatitis, bullous impetigo, cellulitis
Epstein–Barr virus (EBV) (HHV-4)	Gammaherpesvirinae	B cells, epithelial cells	B cells	Group A streptococcal infection, acute viral hepatitis, drug reaction with eosinophilia and systemic symptoms (DRESS)*, toxoplasmosis, lymphoma, and primary CMV, HHV-6 and HIV infections
				For genital ulcers: see genital herpes
Cytomegalovirus (CMV) (HHV-5)	Betaherpesvirinae	Lymphocytes, macrophages, endothelial cells	Lymphocytes, macrophages	EBV-induced infectious mononucleosis, toxoplasmosis, viral hepatitis, lymphoma
				For genital ulcers: see genital herpes
Human herpesvirus 6 (HHV-6)	Betaherpesvirinae	$CD4^+$ T cells	Lymphocytes, monocytes	Viral exanthems (e.g. measles, rubella and enterovirus, adenovirus, EBV and parvovirus infections), scarlet fever, Rocky Mountain spotted fever, Kawasaki disease
Human herpesvirus 7 (HHV-7)	Betaherpesvirinae	T cells	T cells	Similar to HHV-6
Human herpesvirus 8 (HHV-8)	Gammaherpesvirinae	Lymphocytes	Lymphocytes, endothelial cells	Acroangiodermatitis (pseudo-KS), bacillary angiomatosis, ecchymosis, hemangioma, angiosarcoma, pyogenic granuloma, pseudolymphoma/lymphoma

*Also referred to as drug-induced hypersensitivity syndrome (DIHS).

Table 80.1 The eight human herpesviruses, their classification and differential diagnoses. KS, Kaposi sarcoma; PLEVA, pityriasis lichenoides et varioliformis acuta.

they present lipids and stimulate natural killer T cells, thus promoting an immune response[7]. HSV's mechanisms to evade the immune system also include down-regulation of various immunologic cells and cytokines (Table 80.2).

The goals of the early host immune response against HSV are to limit viral replication and recruit other inflammatory cells. Toll-like receptors are critical to the first line of innate immune defense against HSV, and their functions include priming $CD8^+$ T cells. HSV-specific memory $CD8^+$ T cells, which are selectively activated and retained in latently infected sensory ganglia, have important roles in controlling the infection and preventing symptomatic recurrences (see Table 80.2).

HSV can be reactivated either spontaneously or by a trigger such as emotional stress, ultraviolet light, fever, local tissue damage, or immunosuppression. Typically, reactivation will produce vesicular lesions localized to the skin. However, viremia followed by widespread internal organ involvement can occur in immunocompromised hosts.

Clinical Features

HSV infections have a wide range of clinical presentations, and asymptomatic infection is very common. In primary infections, symptoms typically occur within 3 to 7 days after exposure. A prodrome of tender lymphadenopathy, malaise, anorexia and fever often occurs before the onset of mucocutaneous lesions, which may be preceded by localized pain, tenderness, burning or tingling. Painful, grouped vesicles appear on an erythematous base and may become umbilicated, followed by progression to pustules, erosions and/or ulcerations with a characteristic scalloped border. Crusting of lesions and resolution of symptoms typically occurs within 2 to 6 weeks. A similar prodrome can precede recurrent lesions, but these are often fewer in number, with decreased severity and duration compared to those of a primary infection.

The majority of primary orolabial infections are asymptomatic. Symptomatic infections often present as gingivostomatitis in children or as pharyngitis and a mononucleosis-like syndrome in young adults. The mouth and lips are the most common sites of involvement (Fig. 80.1), with lesions typically appearing on the buccal mucosa and gingivae. Edema and painful oropharyngeal ulcerations can lead to dysphagia and drooling. Recurrent lesions appear most often on the vermilion border of the lip. Less common sites are the perioral skin, nasal mucosa, oral mucosa overlying bone (e.g. hard palate) and the cheek (Fig. 80.2). In immunocompromised hosts, recurrent herpes infections can involve intraoral "soft" mucosa (i.e. mucosa that does not overlie bone).

Primary and non-primary initial genital herpes infections are frequently asymptomatic but (especially with the former) can also present as an excruciatingly painful, erosive balanitis, vulvitis or vaginitis. In women, lesions often also involve the cervix, buttocks and perineum and are associated with inguinal adenopathy and dysuria (Fig. 80.3). Genital lesions in men typically occur on the glans or shaft of the penis, and the buttocks are occasionally affected. Systemic complaints and complications are more common in women. Extragenital lesions, urinary retention and aseptic meningitis occur in 20%, 10–15% and 10% of affected women, respectively[8]. In contrast, aseptic meningitis is a rare complication of primary genital herpes infection in men. The presence of more extensive local involvement, regional lymphadenopathy and fever generally distinguishes primary herpes infection from recurrent disease.

Genital HSV infections can result in subclinical viral shedding or clinically evident recurrences (more frequent with HSV-2 than HSV-1), which are often relatively mild. Usually, a limited number of vesicles reappears on the genitalia or buttocks (especially in women) (Fig. 80.4),

INTERACTION OF HERPES SIMPLEX VIRUSES WITH THE IMMUNE SYSTEM: HOST RESPONSES AND VIRAL EVASION MECHANISMS

HOST IMMUNE RESPONSES TO HSV INFECTION

Innate immunity

- HSV is detected by Toll-like receptors (TLRs; see Ch. 4) on epithelial cells, antigen-presenting cells (APCs), plasmacytoid dendritic cells (DCs) and NK cells
  - TLR2 on the cell surface interacts with a viral surface glycoprotein* and leads to proinflammatory cytokine production (via NF-κB activation), including IL-1β, IL-6, IL-8, IL-12, TNF-α and MCP-1
  - TLR3 on endosomes interacts with double-stranded RNA (which accumulates in HSV-infected cells) and leads to IFN-β and -λ production**
  - TLR9 on endosomes interacts with viral genomic DNA (unmethylated CpG sequences) and leads to IFN-α production (via NF-κB activation)
- HSV is also recognized by intracellular nucleic acid sensors (e.g. IFN-γ-inducible protein 16) that detect HSV DNA and stimulate type I IFN (IFN-α and -β) production
- Type I IFNs increase expression of IFN-stimulated genes; their effects include inhibiting translation/promoting degradation of viral mRNA, inducing DC maturation, and (in part through stimulation of IL-15 production) promoting NK cell survival and proliferation
- NK cells release IFN-γ and destroy virus-infected cells (e.g. via release of perforin and granzyme B)
- $CD8^+$ T cells are primed in a process that requires TLR3 signaling by $CD8\alpha^+$ DCs
- Collectively, these responses limit HSV replication, promote host cell apoptosis, and recruit and activate DCs, other APCs, neutrophils, and other leukocytes of both innate and adaptive lineages
- Evidence is emerging that innate immune defenses also have roles in the control of latent HSV infections

Adaptive immunity

- $CD4^+$ T cells are recruited to the site of infection and activated by DCs
- $CD4^+$ T cells release IFN-γ, which induces secretion of chemokines (e.g. CXCL9 and CXCL10 by epithelial cells) that recruit cytotoxic $CD8^+$ T cells
- $CD8^+$ T cells (which also release IFN-γ) kill infected cells through perforin and Fas-mediated pathways, clearing the active infection
- Following the priming and contraction phases of the T-cell response, virus-specific $CD8^+$ T cells accumulate (referred to as memory inflation) and provide immunosurveillance; viral latency and periodic restimulation by subclinical HSV reactivation maintain this pool of cells
- B cells are recruited to the site of infection and activated by $CD4^+$ T cells to produce antibodies
- Regulatory T cells are present, but their exact role (e.g. preventing excessive immune responses versus diminishing the efficiency of viral clearance) has not been determined

HSV'S MECHANISMS OF IMMUNE EVASION

- HSV inhibits signaling through TLRs, e.g. the HSV-1 ICP0 protein reduces TLR2 signaling
- The HSV virion host shut-off (VHS) protein degrades mRNA; it prevents DC activation by a TLR-independent pathway
- HSV decreases cell surface expression of CD1d by APCs; this prevents presentation of lipid antigens that stimulate NK cells
- HSV decreases langerin expression by and increases apoptosis of Langerhans cells
- The HSV ICP47 protein binds to TAP and blocks loading of peptides onto MHC class I molecules, and "empty" MHC class I molecules are degraded by the proteasome
- The HSV-1 glycoprotein B manipulates the MHC class II processing pathway by hijacking HLA-DR from its normal transport route to the cell surface
- The HSV-1 glycoprotein C blocks complement activation, and glycoprotein E functions as an IgG Fc receptor that can block host responses such as antibody-dependent cellular cytotoxicity
- The HSV protein tristetraprolin destabilizes mRNA and can target proinflammatory cytokines such as TNF-α
- HSV can block cytokine effects by other mechanisms, e.g. inducing expression of suppressor of cytokine signaling-1 (SOCS-1) in keratinocytes and thereby abrogating the effects of IFN-γ
- HSV can induce expression of Fas ligand on the surface of monocytes/macrophages, causing apoptosis of interacting T cells and NK cells

*Not yet identified; viral envelope fusion with the host cell membrane during entry leaves viral proteins on the cell surface.
**Mutations in the genes encoding TLR3 or proteins required for TLR3 signaling (e.g. UNC-93B, TRAF3) lead to particular susceptibility to HSV encephalitis.

with resolution within 1 week. Complications are uncommon. The frequency of recurrences correlates directly with the severity of the primary infection and tends to decrease over the next several years. The time interval between recurrences varies greatly, with individuals having an average of four to seven outbreaks annually. Surprisingly, although the majority of individuals with HSV-2 seropositivity report no history of genital herpes infection, symptomatic infection is eventually diagnosed in 50% of this group of patients.

Other Clinical Presentations of HSV Infection

HSV infection can occur anywhere on the skin or mucous membranes. The clinical settings and manifestations of other cutaneous and extracutaneous presentations of HSV infection, including those in immunocompromised individuals and neonates[9–13], are summarized in Table 80.3 (Figs 80.5 to 80.9).

Diagnosis and Pathology

Multiple laboratory tests are available to diagnose HSV infection, including viral culture, direct fluorescent antibody assays (DFA; Fig. 80.10), molecular techniques and serology. In addition to a Tzanck smear (see below), DFA is frequently performed as an initial diagnostic

test due to its greater sensitivity, ability to distinguish between HSV and VZV, and rapid turnaround time. Identification of HSV by viral culture usually requires 2–5 days. In addition to being the preferred method for identifying HSV in the cerebrospinal fluid, polymerase chain reaction (PCR) is increasingly being used as a rapid, sensitive and specific method to detect HSV DNA in specimens from the skin and other organs.

For prevalence or incidence studies and to establish serostatus, the Western blot represents the gold standard for serologic assays; it is 99% sensitive and specific for HSV antibodies. In addition, several commercially available serologic tests can reliably identify patients who have been infected with HSV and can distinguish between HSV-1 and HSV-2 antibodies based on type-specific glycoproteins G-1 from HSV-1 and G-2 from HSV-2. The sensitivity and specificity of each of these assays varies depending on the test and the setting; of note, the mean time to seroconversion following initial infection is 3–4 weeks[14].

A Tzanck smear of scrapings from early lesions (e.g. the base/edges of a freshly unroofed vesicle) reveals multinucleated epithelial giant cells in the majority of HSV outbreaks (~60–75%; Fig. 80.11). In routinely stained biopsy specimens as well as Tzanck smears, HSV-1 cannot be differentiated from HSV-2. Enlarged, slate-gray keratinocyte nuclei with margination of chromatin represent an early histologic finding, which is followed by intraepidermal vesiculation associated with ballooning degeneration of keratinocytes (most prominent at the base of the vesicle) (Fig. 80.12). These swollen, pale keratinocytes often fuse to form multinucleated giant cells and may contain eosinophilic intranuclear inclusion bodies surrounded by an artifactual cleft (Cowdry type A inclusions). Ballooning degeneration can affect adnexal structures as well as the interfollicular epidermis. A variably dense dermal

OTHER CLINICAL PRESENTATIONS OF HERPES SIMPLEX VIRUS INFECTIONS		
Form of infection	**Clinical settings and HSV type(s)**	**Cutaneous and/or extracutaneous findings**
	PREDOMINANTLY MUCOCUTANEOUS	
Eczema herpeticum (Kaposi's varicelliform eruption)	• Most often in infants/children > adults with atopic dermatitis (Fig. 80.5); risk is associated with mutations in the gene encoding filaggrin • Can also occur in patients with an impaired skin barrier due to other conditions such as burns, pemphigus (foliaceus, vulgaris), Darier disease, Hailey–Hailey disease, mycosis fungoides, Sézary syndrome and ichthyoses • Usually due to HSV-1	• Rapid, widespread cutaneous dissemination of HSV infection in areas of dermatitis/skin barrier disruption • Monomorphic, discrete, 2–3 mm punched-out erosions with hemorrhagic crusts (see Fig. 80.5) are evident more often than intact vesicles • May have fevers, malaise and lymphadenopathy • Occasionally complicated by bacterial superinfections (e.g. with *Staphylococcus aureus* and/or group A streptococci) or systemic dissemination of HSV infection
Herpetic whitlow	• Often in young children (usually due to HSV-1; Fig. 80.6A) • Increasing frequency in adolescents/adults (Fig. 80.6B, C) secondary to digital–genital contact (usually due to HSV-2) • Historically in dental and medical personnel who did not use gloves	• HSV infection of the digits presenting with pain, swelling and vesicular lesions (see Fig. 80.6); appearance of vesicles may be delayed • Recurrences in the same location can be a clue to the diagnosis • Often misdiagnosed as blistering dactylitis or paronychia
Herpes gladiatorum	• Participation in contact sports such as wrestling (Fig. 80.7) • Usually due to HSV-1	• Distribution of cutaneous HSV infection (sometimes widespread), reflecting sites of contact with another athlete's skin lesions
Herpes simplex folliculitis	• Shaving with a blade razor (e.g. *herpetic sycosis* in a man's beard area) • Usually due to HSV-1 • HIV-positive or otherwise immunocompromised individuals	• Rapid development of follicular vesicles and pustules • See Table 38.1
Severe/chronic HSV infections	• Immunocompromised patients, e.g. hematopoietic stem cell or solid organ transplant recipients and individuals with HIV infection or leukemia/lymphoma	• Most common presentation is chronic, enlarging ulcerations (Fig. 80.8A,B) • Cutaneous lesions may affect multiple sites or be disseminated • Skin findings are often atypical, e.g. verrucous, exophytic and pustular lesions • Recurrences can involve oral mucosa, including the tongue (Fig. 80.8C) and areas that do not overlie bone • Involvement of the respiratory tract, esophagus and remainder of the gastrointestinal tract may also occur
	PREDOMINANTLY EXTRACUTANEOUS	
Ocular HSV infection	• Newborns (often due to HSV-2; see below) • Usually due to HSV-1 in children and adults	• Primary infection: unilateral or bilateral keratoconjunctivitis with eyelid edema, tearing, photophobia, chemosis and preauricular lymphadenopathy • Branching dendritic lesions of the cornea represent a pathognomonic finding • Recurrent episodes (typically unilateral) are common • Complications include corneal ulceration and scarring, globe rupture and blindness
Herpes encephalitis	• Most common cause of fatal sporadic viral encephalitis in the US • Associated with mutations in the genes encoding Toll-like receptor 3 or UNC-93B, which impair interferon-based cellular antiviral responses (see Table 80.2) • Usually due to HSV-1	• Manifestations can include fever, altered mental status, bizarre behavior and localized neurologic findings • The temporal lobe is often involved • Mortality ≥70% without treatment; residual neurologic defects in most survivors • Herpes labialis is a coincidental finding
	CUTANEOUS AND EXTRACUTANEOUS	
Neonatal HSV infection[9]	• Occurs in approximately 1:10 000 newborns in the US[9,10], usually resulting from exposure to HSV during a vaginal delivery • Risk of transmission is highest (30–50%) for women who acquire a genital HSV infection (which is often asymptomatic) near the time of delivery • Risk of transmission is low (<1–3%) for women with recurrent genital herpes • Due to HSV-2 or HSV-1 (latter accounts for 30–50% of cases)	• Onset from birth to 2 weeks of age, but usually ≥5 days of age • Localized (favoring the scalp and trunk) (Fig. 80.9) or disseminated cutaneous lesions; involvement of the oral mucosa, eye, CNS and multiple internal organs can occur • Vesicles may progress to bullae and erosions (see Ch. 34) • Encephalitis can present with lethargy, irritability, poor feeding, temperature instability, seizures and a bulging fontanelle • For CNS or disseminated disease, mortality is >50% without treatment and ~15% with treatment; many survivors have neurologic deficits

Table 80.3 Other clinical presentations of herpes simplex virus (HSV) infections.

infiltrate of lymphocytes, neutrophils and eosinophils is observed, with a tendency to be milder in recurrent disease. Vascular changes may include areas of hemorrhagic necrosis and perivascular cuffing. Epidermal necrosis is sometimes extensive, especially in the setting of disseminated skin lesions.

Differential Diagnosis

Orolabial herpes can sometimes be confused with aphthous stomatitis, erythema multiforme major or Stevens–Johnson syndrome, herpangina, pharyngitis (e.g. due to EBV), oral candidiasis, and chemotherapy-induced mucositis (see Table 80.1). Oral aphthae typically present as a single or few lesion(s) on the buccal mucosa without associated vesicles. Erythema multiforme major (which is most often triggered by HSV) and Stevens–Johnson syndrome can usually be distinguished from HSV by the presence of characteristic cutaneous as well as mucosal lesions. In herpangina, the posterior pharynx is more commonly involved, unlike in HSV infection, which favors the anterior portion of the mouth. Exudative tonsillitis, diffuse hyperemia of the oropharynx, and petechiae on the hard and soft palate are common manifestations of EBV-induced mononucleosis. Although a white, curd-like coating of the tongue, buccal mucosa and pharynx is the most common presentation of oral candidiasis, there is also an erythematous form of the disease. Of note, in immunocompromised hosts, the possibility of coexisting infections must be considered.

Fig. 80.6 Herpetic whitlow. On the finger of a child (**A**) and on the finger (**B**) and toe (**C**) in adults. Herpetic whitlow is sometimes misdiagnosed as cellulitis or blistering distal dactylitis, or, depending on the distribution, paronychia. *B, Courtesy, Eugene Mirrer, MD. C, Courtesy, Louis A Fragola, Jr, MD.*

Trauma, syphilitic chancres, chancroid and lymphogranuloma venereum are included in the differential diagnosis of genital herpes (see Ch. 82). The syphilitic chancre is usually a single lesion that is neither painful nor recurrent. Chancroid often manifests as several tender ulcers with a yellowish-gray exudate overlying a base of granulation tissue, while lymphogranuloma venereum presents with a transient papule, herpetiform vesicle, erosion or ulcer; both conditions typically result in tender inguinal lymphadenopathy. Genital aphthae and EBV-related genital ulcers can be difficult to distinguish from herpetic lesions without viral culture, DFA or PCR. Additional entities in the differential diagnosis of genital erosions are listed in Table 73.5.

Treatment and Prevention

FDA-approved antiviral agents for treatment of recurrent episodes of orolabial herpes in immunocompetent persons include oral valacyclovir (2 g twice daily for 1 day), oral famciclovir (single dose of 1.5 g) and topical 1% penciclovir (Table 80.4), which result in a decreased duration of mucocutaneous lesions, viral shedding and pain (especially if started at the first symptom or sign of a recurrence). Topical acyclovir 5% ointment is approved for limited mucocutaneous HSV infections in immunocompromised individuals. Both valacyclovir and famciclovir have been shown to reduce the frequency of orofacial herpes outbreaks after laser resurfacing[15].

For the treatment of primary and recurrent genital herpes, oral antivirals are the agents of choice (see Table 80.4). With early initiation (e.g. within 24–48 hours of onset), acyclovir, famciclovir and valacyclovir reduce the duration of viral shedding, pain and time to healing for first-episode and recurrent genital herpes. Intravenous acyclovir is indicated for neonatal HSV infection, severe infections in immunocompromised hosts, severe eczema herpeticum and patients with systemic complications. In immunocompromised patients, it is important to treat with oral or intravenous antivirals until the cutaneous lesions are completely healed.

Chronic suppressive therapy with the above oral antiviral agents (see Table 80.4) is usually reserved for patients with six or more outbreaks per year, although clinicians often exercise more lenient criteria for initiation of therapy for individuals with physically or emotionally severe outbreaks, an insufficient prodrome to benefit from episodic therapy, or immunosuppression. In addition to decreasing the frequency of (or even eliminating) symptomatic outbreaks, suppressive therapy reduces asymptomatic viral shedding by 95% and can prevent transmission of genital herpes to a susceptible partner[16]. Daily suppressive therapy (together with consistent condom use and avoidance of sexual activity during recurrences) is therefore also recommended for individuals with genital herpes who have a seronegative partner. Resiquimod 0.01% gel, a topically active immune response modifier, has been investigated for the treatment of recurrent genital herpes and was found to delay the time to the first recurrence, decrease the total number of recurrences, and reduce asymptomatic viral shedding[17].

The emergence of acyclovir-resistant HSV is an increasing concern for immunocompromised individuals. Foscarnet is the only antiviral drug approved by the FDA for treatment of acyclovir-resistant HSV. Cidofovir is another antiviral agent that has shown efficacy in the

treatment of acyclovir-resistant HSV. The use of foscarnet or *systemic* cidofovir is limited by potentially severe side effects (particularly renal toxicity) and the requirement for intravenous administration. Although not FDA-approved, *topical* cidofovir has been advocated by the CDC as a "user-friendly", albeit expensive, alternative treatment[18].

Individuals co-infected with HIV and HSV have more severe outbreaks and more frequent viral shedding than those without HIV infection. When added to the medical regimen of HIV-infected patients, antiherpetic suppressive therapy appears to allow the co-infected person to respond better to antiretroviral therapy and to reduce genital and plasma HIV-1 RNA levels, but it does not seem to decrease the risk of HIV-1 transmission[19,20]. Oral acyclovir, famciclovir and valacyclovir can be used for genital and orolabial HSV in the setting of HIV infection as long as there is no evidence of acyclovir resistance.

There is significant interest in prevention of HSV disease. Between 70% and 80% of HSV is transmitted during periods of asymptomatic viral shedding. Sexual abstinence is the only method for absolute prevention of genital herpes, which can be transmitted even with the use of condoms[21]. In addition to antiviral therapy, patient education regarding prevention of genital herpes transmission is essential. There is

currently no licensed vaccine available for HSV, although several vaccines are under development and evaluation for prevention of HSV infection and recurrences.

VARICELLA–ZOSTER VIRUS (HHV-3)

Synonyms/clinical forms: ■ Varicella – chickenpox ■ Herpes zoster – shingles

Key features

- VZV is the etiologic agent of varicella (chickenpox) and herpes zoster (shingles)
- VZV has a high morbidity and mortality rate in immunocompromised hosts
- Antiviral treatment as well as vaccination can reduce or eliminate serious disease-associated sequelae and decrease the incidence of VZV infection

Introduction

VZV is the etiology of varicella (chickenpox) and herpes zoster (shingles). Varicella is usually symptomatic, and before the advent of the varicella vaccine, it occurred in 90% of children in the US by the time they reached 10 years of age. Herpes zoster represents reactivation of latent VZV infection and develops in approximately 20% of healthy adults and 50% of immunocompromised persons. VZV infection in immunocompromised hosts has substantial morbidity and mortality, which must be considered in the clinical management of these patients. Early initiation of antiviral treatment can reduce or eliminate serious sequelae of VZV infections.

History

Heberden first distinguished chickenpox from smallpox in 1767[22]. The term "chickenpox" is thought to come from either the French word "chiche-pois" for chickpea (referring to the size of the vesicles) or the Old English word "gigan" meaning "to itch". The relationship between varicella and herpes zoster was first recognized in 1888, when von Bokay described the development of varicella in children following exposure to those with herpes zoster infection. Kundratiz (1922) and Bruusgarrd (1932) more convincingly demonstrated the association between the two diseases by the development of varicella in susceptible children who had been inoculated with vesicle fluid from patients with herpes zoster. This was followed by the identification of the same virus in both diseases, confirming that their etiologies were identical.

Epidemiology

VZV has a worldwide distribution and 98% of the adult population is seropositive. In the pre-vaccine era, varicella affected 90% of children <10 years of age and approximately 4 million cases occurred annually in the US[23], with large outbreaks during the winter and spring. Since the introduction of the varicella vaccine in 1995, the overall incidence of varicella has decreased by ~85%, with evidence of herd immunity. The age of peak incidence also shifted from 5–9 years to 10–14 years, and a higher rate of breakthrough varicella among immunized children in the latter age group led to the addition of a second varicella vaccine dose to the routine childhood immunization schedule in 2006[24].

Although the incidence and severity of herpes zoster increase substantially in middle to late adulthood, it can occur at any age and is more common in younger persons who had a varicella infection within the first year of life. Overall, individuals with a history of varicella have a 20% lifetime chance of developing zoster. The annual incidence of herpes zoster in the US and Europe is classically 2.5/1000 persons between ages 20 and 50 years, 5/1000 between ages 51 and 79 years, and 10/1000 in those older than 80 years of age[25]. However, there is evidence that exposure to varicella can protect seropositive adults from the development of zoster, and it has been postulated that widespread vaccination against varicella could reduce this immune boosting effect and increase the incidence of zoster. Whether this hypothetical increase will be counterbalanced by the zoster vaccine remains to be determined. Other risk factors for herpes zoster include mental and physical stress, immunocompromise (especially that due to HIV infection, allogeneic hematopoietic stem cell transplantation, and bortezomib therapy for multiple myeloma[26]), and a family history of zoster[27].

Pathogenesis

Airborne droplets are the usual route of transmission of varicella, although direct contact with vesicular fluid is another mode of spread. The incubation period ranges from 11 to 20 days. Varicella is extremely contagious, and 80–90% of susceptible household contacts develop a clinically evident infection[23]. The affected individual is infectious from 1 to 2 days before skin lesions appear until all of the vesicles have crusted.

During varicella infection, primary viremia occurs after an initial 2 to 4 days of viral replication within regional lymph nodes. A cycle of viral replication in the liver, spleen and other organs is then followed by secondary viremia, which seeds the entire body 14 to 16 days post-exposure. During this period, the virus travels to the epidermis by invading capillary endothelial cells. VZV subsequently travels from mucocutaneous lesions to dorsal root ganglion cells, where it remains latent until reactivation at a later date.

Herpes zoster appears upon reactivation of VZV, which may occur spontaneously or be induced by stress, fever, radiation therapy, local trauma or immunosuppression. During a herpes zoster outbreak, the virus continues to replicate in the affected dorsal root ganglion and produces a painful ganglionitis. Neuronal inflammation and necrosis can result in a severe neuralgia that intensifies as the virus spreads down the sensory nerve. Fluid from herpes zoster vesicles can transmit VZV to seronegative individuals, leading to varicella (not herpes zoster, which reflects reactivation of latent VZV from a prior infection). The transmission rate to susceptible household contacts is ~15% for zoster, compared to >70% for varicella.

Clinical Features

Varicella

Varicella may begin (in adults > children) as a prodrome of mild fever, malaise and myalgia. This is followed by an eruption of pruritic, erythematous macules and papules, starting on the scalp and face, then spreading to the trunk and extremities (Fig. 80.13). Lesions rapidly evolve over 12 to 14 hours into 1–3 mm clear vesicles surrounded by narrow red halos ("dew drops on a rose petal"). The number of vesicles varies from only a few to several hundred, and there is often

ANTIVIRAL THERAPY FOR HERPES SIMPLEX VIRUS AND VARICELLA–ZOSTER VIRUS	
Disease context	**Drug and dosage**
HERPES SIMPLEX INFECTIONS	
Orolabial herpes* (recurrence)	Penciclovir: 1% cream applied q2 h × 4 days Acyclovir + hydrocortisone: 5%/1% cream applied 5×/d × 5 days Famciclovir: 1.5 g po × 1 dose Valacyclovir: 2 g po bid × 1 day
Genital herpes (first episode)	Acyclovir: 200 mg po 5×/d × 10 days or 400 mg po tid × 10 days Famciclovir: 250 mg po tid × 10 days Valacyclovir: 1 g po bid × 10 days
Genital herpes (recurrence)	Acyclovir: 400 mg po tid × 5 days or 800 mg po bid × 5 days or 800 mg po tid × 2 days Famciclovir: 1 g po bid × 1 day or 500 mg po × 1 dose then 250 mg po bid × 2 days or 125 mg po bid × 5 days Valacyclovir: 500 mg po bid × 3 days or 1 g po qd x 5 days
Chronic suppression	Acyclovir: 400 mg po bid Famciclovir: 250 mg po bid Valacyclovir: 500 mg po qd for <10 outbreaks/year or 1 g po qd for ≥10 outbreaks/year
Neonatal	Acyclovir: 20 mg/kg iv q8 h × 14–21 days
Immunocompromised	*Recommend use until all mucocutaneous lesions are healed* Acyclovir: 400 mg po 5×/d or 5 mg/kg (if age ≥12 y) to 10 mg/kg (if age <12 y) iv q8 h Famciclovir: 500 mg po bid Valacyclovir: 1 g po bid
Eczema herpeticum/Kaposi's varicelliform eruption	*Recommend use for 10–14 days or (especially if immunocompromised) until all mucocutaneous lesions are healed* Acyclovir: 15 mg/kg (400 mg max) po 3–5×/d or, if severe, 5 mg/kg (if age ≥12 y) to 10 mg/kg (if age <12 y) iv q8 h Famciclovir: 500 mg po bid Valacyclovir: 1 g po bid
Genital herpes, recurrent in the setting of HIV infection	*Recommend use until all mucocutaneous lesions are healed* Acyclovir: 400 mg po tid Famciclovir: 500 mg po bid Valacyclovir: 1 g po bid
Chronic suppression in the setting of HIV infection	Acyclovir: 400–800 mg po bid–tid Famciclovir: 500 mg po bid Valacyclovir: 500 mg po bid
Acyclovir-resistant HSV in immunocompromised patients	Foscarnet: 40 mg/kg iv q8–12 h × 2–3 weeks (or until all lesions are healed) Cidofovir: 1% cream or gel qd × 2–3 weeks or (for severe disease) 5 mg/kg iv weekly × 2 weeks then every other week (together with probenecid)
VARICELLA–ZOSTER VIRUS INFECTIONS	
Varicella	Acyclovir: 20 mg/kg (800 mg max) po qid × 5 days Valacyclovir†: 20 mg/kg (1 g max) po tid × 5 days
Zoster	Acyclovir: 800 mg po 5×/d × 7–10 days Famciclovir: 500 mg po tid × 7 days Valacyclovir: 1 g po tid × 7 days
Immunocompromised	Acyclovir: 10 mg/kg (500 mg/m^2) iv q8 h × 7–10 days *or until cropping has ceased* (depending on the setting, consider continuing until lesions are healed)

*Indications for and efficacy of antiviral treatment for initial episodes of orolabial herpes in immunocompetent adults have not been defined, but the regimens used for initial genital episodes can be considered in individuals with severe disease; acyclovir 15 mg/kg (200 mg max) po 5×/d × 7 days (initiated within 3 days of disease onset) has been shown to be beneficial in young children with primary herpes gingivostomatitis.

†FDA-approved for ages 2–17 years; pharmacies can compound valacyclovir tablets into an oral suspension (25 or 50 mg/ml).

Table 80.4 Antiviral therapy for herpes simplex virus and varicella–zoster virus. bid, twice daily; iv, intravenously; po, orally; q2 h, every 2 hours; qd, once a day; qid, four times a day; tid, three times a day.

involvement of the oral mucosa (see Fig. 80.13D). Sparing of the distal and lower extremities is common. Older lesions evolve to form pustules and crusts and heal within 7 to 10 days. The presence of lesions in all stages of development is a hallmark of varicella.

The disease course is usually self-limited and benign in healthy children. However, prior to introduction of the varicella vaccine, complications resulted in 11 000 hospitalizations annually in the US. Secondary bacterial infection of the skin with subsequent scarring is the most common complication. CNS sequelae are uncommon (<1 : 1000 cases) and may include encephalitis and acute cerebellar ataxia[28]; Reye's syndrome (encephalitis plus fatty liver) is now rare due to avoidance of acetylsalicylic acid in children with varicella. Varicella in adolescents and adults is often more severe than that in children, with an increased number of skin lesions (see Fig. 80.13A) and more frequent development of pneumonia, which has a 10–30% mortality rate if untreated[29]. Occasional complications include thrombocytopenia, hepatitis, glomerulonephritis, optic neuritis, keratitis, arthritis, myocarditis, pancreatitis, orchitis and vasculitis.

Maternal varicella during the first 20 weeks of pregnancy is associated with a ~2% risk of congenital varicella syndrome (varicella embryopathy). Possible congenital defects include a low birthweight, cutaneous scarring, ocular abnormalities, cortical atrophy, psychomotor retardation and hypoplastic limbs. Children whose mothers had varicella during pregnancy may also develop zoster early in life without ever having extrauterine varicella. Lastly, severe neonatal varicella (without amelioration by maternal antibodies) can occur when maternal varicella develops between 5 days before and 2 days after delivery.

In immunocompromised individuals, varicella can lead to significant morbidity and mortality. These patients frequently have a more extensive and atypical cutaneous eruption, often with hemorrhagic or purpuric lesions[11]. Involvement of the lungs, liver and CNS is common.

Herpes zoster

Reactivation of VZV may occur at any time after the development of varicella. Herpes zoster begins with a prodrome of pruritus, tingling,

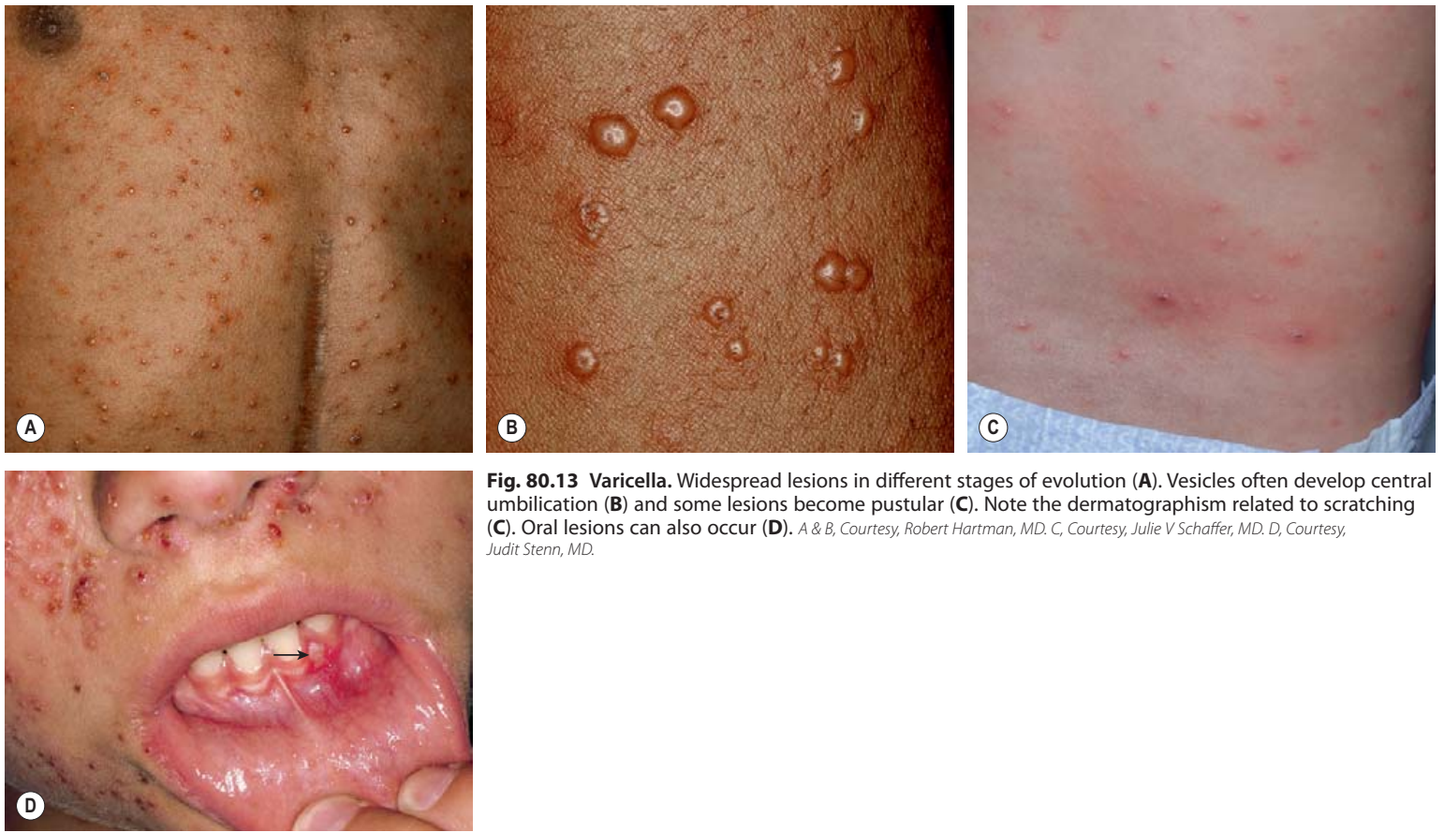

Fig. 80.13 Varicella. Widespread lesions in different stages of evolution (**A**). Vesicles often develop central umbilication (**B**) and some lesions become pustular (**C**). Note the dermatographism related to scratching (**C**). Oral lesions can also occur (**D**). *A & B, Courtesy, Robert Hartman, MD. C, Courtesy, Julie V Schaffer, MD. D, Courtesy, Judit Stenn, MD.*

tenderness, hyperesthesia and/or intense pain (which can mimic a myocardial infarction, surgical abdomen or toothache) in >90% of patients. These symptoms occasionally occur without subsequent skin lesions, a phenomenon referred to as "zoster sine herpete". However, most patients develop a painful eruption of grouped vesicles on an erythematous base in a dermatomal distribution (Figs 80.14 & 80.15); the lesions can involve more that one contiguous dermatome and occasionally cross the midline. Edematous papules and plaques may precede the appearance of vesicles, and progression to pustules or bullae can occur (see Fig. 80.15). Any cutaneous site may be affected, with the trunk representing the most common location, followed by the face. VZV DNA can often be detected in the peripheral blood and saliva of patients with herpes zoster, even after initiation of antiviral treatment[30,31].

Herpes zoster usually resolves without sequelae in children and young adults with intact immune systems. However, the pain, cutaneous lesions and complications of herpes zoster become more severe with increasing age and immune compromise. The most common complication is postherpetic neuralgia, which is characterized by dysesthetic pain (e.g. a burning or stabbing sensation, allodynia) that persists after the skin lesions have healed. This affects 10–20% of all herpes zoster patients and increases in both incidence and severity with age[32,33]. Complications of herpes zoster related to the dermatome that is affected are presented in Table 80.5. Other complications can include secondary bacterial infection, scarring, meningoencephalitis, pneumonitis and hepatitis. Cutaneous disorders that can develop within sites of previous herpes zoster, including granulomatous (Fig. 80.16) and pseudolymphomatous lesions, are listed in Table 80.6.

In immunocompromised hosts, herpes zoster may be more severe and can have unusual clinical presentations, e.g. persistent crusted, verrucous lesions in HIV-infected patients (Fig. 80.17) or postherpetic hyperhidrosis[11,34]. Disseminated cutaneous disease (defined as more than 20 vesicles outside the area of primary or adjacent dermatomes) and/or visceral involvement occurs in approximately 10% of immunocompromised persons with zoster (Fig. 80.18)[35].

Diagnosis and Pathology

A clinical diagnosis can usually be made based upon the history (including previous varicella or vaccine administration) and physical examination. A Tzanck smear and/or DFA (see above and Figs 80.10 & 80.11) can help to rapidly confirm the diagnosis. The latter (but not the former) can differentiate between HSV and VZV. Varicella and herpes zoster have the same histologic findings as HSV infections (see above and Fig. 80.12), but immunohistochemical staining can distinguish between the two viruses.

Additional laboratory tests include viral culture, serology and PCR. Viral culture is a very specific test; however, it is not very sensitive and results may not be available for >1 week. Serologic assays are diagnostic of VZV if the convalescent serum has at least a fourfold increase in the VZV titer relative to the acute serum. As a result, serology is only useful in retrospect. PCR is a highly sensitive and rapid technique, and its use for the detection of VZV is increasing.

Differential Diagnosis

The differential diagnosis of varicella may include vesicular viral exanthems (e.g. due to coxsackieviruses), disseminated HSV infection, pityriasis lichenoides et varioliformis acuta (PLEVA), rickettsialpox, drug eruptions, bullous insect bite reactions and even scabies. Although no longer naturally occurring, smallpox also manifests with a widespread vesicular eruption; its distinct clinical features are reviewed in Chapter 81. For herpes zoster, diagnostic considerations may include zosteriform HSV infections (which often recur in the same site), bacterial skin infections (e.g. cellulitis, bullous impetigo), localized contact dermatitis and phytophotodermatitis. The entities listed above can usually be differentiated from VZV infections based on the history and clinical presentation, but laboratory studies and histologic evaluation are sometimes needed.

Treatment and Prevention

Varicella

Varicella in immunocompetent children can be treated symptomatically with antipyretics (e.g. acetaminophen), antihistamines, calamine lotion and tepid baths. If started within 24 to 72 hours after the onset of the cutaneous eruption, acyclovir has been shown to decrease the duration and severity of varicella[36]. Oral acyclovir and valacyclovir are FDA-approved for the treatment of varicella in children (2–17 years of age) while acyclovir is approved for adults (see Table 80.4).

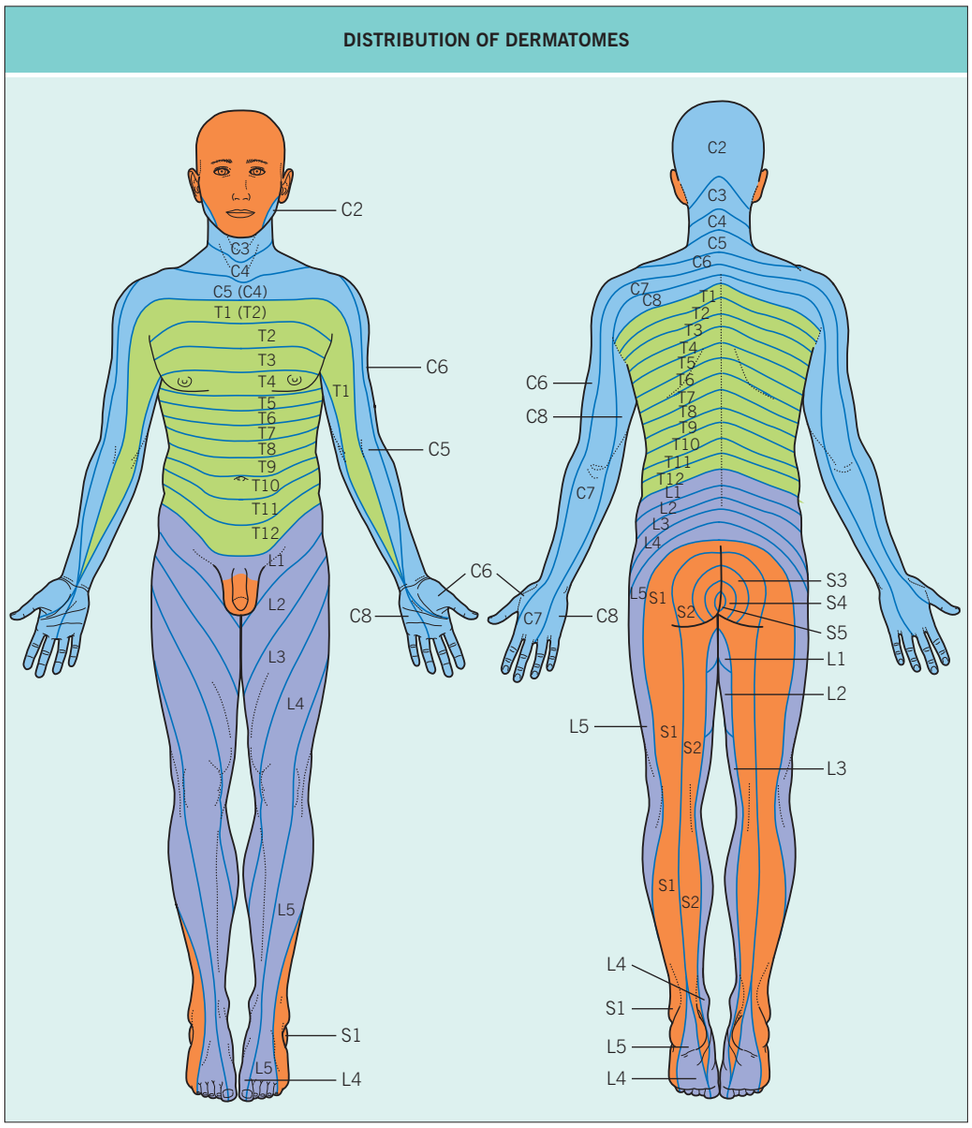

Fig. 80.14 Distribution of dermatomes.

CLINICAL FINDINGS RELATED TO THE DERMATOME INVOLVED IN HERPES ZOSTER		
Dermatome/nerve involved	**Cutaneous findings**	**Extracutaneous findings**
Ophthalmic division of the trigeminal nerve (V1; ~10–15% of zoster patients)	• *Hutchinson's sign* refers to increased risk of ocular involvement if skin lesions are in the distribution of the nasociliary branch, which supplies the nasal tip, dorsum and root of the nose and the medial canthus as well as the cornea	• ~50% of patients have ocular involvement, which can include conjunctivitis, (epi)scleritis, keratitis, uveitis, acute retinal necrosis and optic neuritis • May lead to ocular scarring and visual loss
Geniculate ganglion of the facial nerve – *Ramsay Hunt syndrome*	• Lesions affecting the external auditory canal, tympanic membrane, anterior two-thirds of the tongue and/or hard palate	• Ear pain • Facial nerve paralysis (peripheral) • Loss of taste in anterior two-thirds of the tongue • Dry mouth and eyes • If the vestibulocochlear nerve is also affected: tinnitus, hearing loss and/or vertigo
Cervical dermatome	• Lesions in a cervical dermatome	• Peripheral motor neuropathy of the arm, which may result in muscle atrophy with gradual recovery of strength • Diaphragmatic weakness (C3–5)
Thoracic dermatome	• Lesions in thoracic dermatome	• Abdominal muscle weakness • Abdominal wall pseudohernia
Lumbar dermatome	• Lesions in lumbar dermatome	• Peripheral motor neuropathy of the leg, which may result in muscle atrophy with gradual recovery of strength

Fig. 80.16 Granulomatous dermatitis in the site of previous herpes zoster. Pink papules and plaques developed several weeks after an episode of herpes zoster in the same dermatomes. A sharp midline demarcation was observed on the back. Histologically, a granulomatous dermatitis was present within the dermis and focally a perineural distribution pattern was seen. *Courtesy, Rebecca Vaughn, MD.*

Fig. 80.17 Chronic verrucous zoster in an HIV-infected patient.

Fig. 80.18 Disseminated cutaneous zoster with multiple violet–black papules on the feet. Patients with disseminated cutaneous skin lesions should be evaluated for possible visceral involvement, e.g. hepatic, pulmonary, CNS, especially if they are immunocompromised.

CUTANEOUS DISORDERS THAT CAN DEVELOP WITHIN SITES OF HERPES ZOSTER

Acneiform – comedones, furunculosis, "acneiform eruption", rosacea (trigeminal distribution)
Dermatitis and urticaria – contact dermatitis (allergic and irritant), chronic localized urticaria
Granulomatous – granuloma annulare (including perforating variant), granulomatous dermatitis (sarcoidal, tuberculoid, unclassified, periadnexal, perineural; see Fig. 80.16), granulomatous vasculitis, lichenoid and granulomatous dermatitis*
Infiltrative – pseudolymphoma†, xanthomatous, Rosai-Dorfman disease
Malignancies, hematologic – leukemia (especially CLL), lymphoma cutis
Malignancies, other – Kaposi sarcoma (HIV-associated form), angiosarcoma, solid-organ metastases
Papulosquamous – psoriasis, lichen planus, lichenoid GVHD*
Sclerosing – lichen sclerosus, morphea, hypertrophic scars/keloids
Ulcerative – trophic syndrome (trigeminal, cervical)
Miscellaneous – acquired perforating disorder (acquired perforating collagenosis), nodular solar degeneration, tinea

*"Giant cell lichenoid dermatitis" has also been described within herpes zoster scars in an allogeneic bone marrow transplant recipient.
†In patients with chronic lymphocytic leukemia, may actually represent leukemia cutis.

Table 80.6 Cutaneous disorders that can develop within sites of herpes zoster. List does not include routine scarring and acute complications such as bacterial infections. Additional possible associations include basal cell carcinoma and squamous cell carcinoma. CLL, chronic lymphocytic leukemia.

These antiviral agents are recommended for varicella in healthy adolescents and adults as well as in children with chronic or pulmonary disorders. Intravenous acyclovir is indicated for varicella in immunocompromised patients, including those receiving chronic systemic corticosteroid therapy, due to their increased risk of more severe disease and complications[36].

Administration of varicella zoster immune globulin (125 U/10 kg, 625 U maximum) within 96 hours of varicella exposure is recommended to provide passive prophylaxis to non-immune immunocompromised individuals and pregnant women as well as high-risk neonates (see above)[37]. Protection lasts for ~3 weeks. In the US, this product is currently only available under an FDA-approved investigational new drug expanded access protocol (24-hour telephone number: 800-843-7477). Another option for postexposure varicella prophylaxis in these patient groups is administration of intravenous immunoglobulin (IVIg; ≥400 mg/kg), which contains high levels of varicella-specific IgG[38]. Prophylactic oral acyclovir administration with usual varicella dosing (see Table 80.4) for 1 week, starting 7–10 days after exposure, can also be considered. Lastly, postexposure varicella vaccination (within 72–120 hours) may prevent or modify disease in non-immune individuals who are ≥12 months of age, immunocompetent and eligible to receive this live attenuated vaccine (see below).

Approved by the FDA in 1995, the live attenuated VZV vaccine (Oka strain; Varivax®) is highly efficacious, with seroprotection rates of ~85% after one dose and ≥99% after two doses in healthy children. Two doses of the vaccine, routinely given at ages 12–15 months and 4–6 years, are now recommended in order to improve protection and counteract waning vaccine-induced immunity (see below). Studies indicate that one dose of the vaccine is 70–90% effective in preventing infection and 95–100% effective in preventing severe disease, and recipients of two doses are more than threefold less likely to develop breakthrough varicella than those who received one dose. The incidence and severity of both varicella (usually due to wild-type VZV) and zoster (most often due to the attenuated Oka strain) (Fig. 80.19) are decreased in vaccine recipients compared to unimmunized children. However, in a report based on surveillance of 350 000 subjects who received one vaccine dose, loss of vaccine-induced immunity over time was observed, e.g. within 1 year of vaccination, there were 1.6 cases of varicella per 1000 person-years versus 58.2 per 1000 person-years at 9 years post-vaccination[39]. Of note, because this is a live viral vaccine, administration is contraindicated during pregnancy and in individuals with immunosuppression due to hematologic malignancies, HIV infection (if $CD4^+$ T-cell percentage is <15% or count <200 cells/μl), other T-cell immunodeficiencies, or systemic immunosuppressive therapy (e.g. prednisone ≥2 mg/kg daily or, if weight >10 kg, ≥20 mg daily for ≥2 weeks).

Fig. 80.19 Herpes zoster following varicella vaccination. This healthy 3-year-old boy developed an eruption of erythematous papulovesicles in the C5 and C6 dermatomes of the right arm. He had received the varicella vaccine in the right shoulder at age 12 months, and several erythematous, edematous papulonodules had appeared in the region of the injection 2 weeks later.

Herpes zoster

For herpes zoster, beginning antiviral treatment within 72 hours of the development of skin lesions is optimal, but initiation up to 7 days after onset also appears to be beneficial. Acyclovir, famciclovir and valacyclovir are all FDA-approved for the treatment of herpes zoster in immunocompetent individuals and result in decreased severity and duration of both skin lesions and pain (see Table 80.4). In controlled studies of immunocompetent individuals >50 years of age with acute herpes zoster, famciclovir and valacyclovir were equally effective (and similar or superior to acyclovir) at reducing the frequency and duration of postherpetic neuralgia[40]. Intravenous acyclovir is indicated for the treatment of zoster in immunocompromised patients as well as those with serious complications[23].

Multiple treatments are available for patients who develop postherpetic neuralgia. Low-dose tricyclic antidepressants have demonstrated considerable efficacy and appear to act by a mechanism independent from their antidepressant effects. In a randomized, controlled, multicenter trial, gabapentin (in doses up to 3600 mg/day) was found to be effective in the treatment of pain and sleep interference associated with postherpetic neuralgia[41]. Combined treatment with nortriptyline and gabapentin reduced pain more than either agent alone in another randomized controlled trial[42]. In one open study, the use of gabapentin together with valacyclovir during acute herpes zoster was more effective in preventing postherpetic neuralgia than treatment with valacyclovir alone in historical controls[43]. Although treatment with prednisone in addition to acyclovir can reduce acute pain in patients with herpes zoster, several controlled trials have failed to demonstrate a difference in the incidence or severity of postherpetic neuralgia with this combination compared to acyclovir monotherapy[44]. An 8% capsaicin patch, recently approved by the FDA for treatment of postherpetic neuralgia, was found to reduce pain for up to 12 weeks after a 1-hour application[45]. Other treatments used for postherpetic neuralgia include analgesics, EMLA cream, lidocaine patches, narcotic analgesics, pregabalin, nerve blocks and biofeedback.

Because reactivation of VZV is linked with states of decreased cell-mediated immunity, the varicella vaccine was studied as a method of prophylaxis for herpes zoster. Two initial investigations showed that vaccination increased immunity against VZV in elderly patients, while a third study demonstrated enhanced immunity for only 1 year after vaccine administration, with 10–15% of vaccine recipients failing to develop any enhanced immunity[8]. However, a subsequent large trial utilizing a 14-fold more concentrated version of the varicella vaccine in almost 40 000 adults (age ≥60 years) showed a 51% reduction in the development of herpes zoster and 67% decrease in the incidence of postherpetic neuralgia in vaccine recipients[46]. These results led to FDA approval of this live attenuated vaccine (Zostavax®) in 2006. The Advisory Committee on Immunization Practices (ACIP) recommends a single dose for all immunocompetent individuals ≥60 years of age, whether or not they have a history of varicella or herpes zoster[47]. It is not indicated as a treatment for active herpes zoster or postherpetic neuralgia.

EPSTEIN–BARR VIRUS (HHV-4)

Synonym: ■ Infectious mononucleosis – glandular fever

Key features

- EBV is responsible for a variety of clinical diseases, most notably infectious mononucleosis; it is also associated with lymphoproliferative disorders and lymphomas
- Knowledge of EBV-specific serologies and other laboratory tests for EBV is essential for the clinician

Introduction and History

EBV is a ubiquitous human herpesvirus (HHV-4) that is responsible for a broad spectrum of clinical diseases, including infectious mononucleosis, oral hairy leukoplakia (see Ch. 78), hydroa vacciniforme (see Ch. 87), and a variety of lymphoproliferative disorders, lymphomas (B- and T-cell) and other malignancies (Table 80.7). It replicates well in B lymphocytes and can lead to their immortalization. EBV was named after its two discoverers, who found this herpesvirus in an African Burkitt lymphoma in 1964. In 1968, a link between infectious mononucleosis and EBV was established[48]. Since then, various clinical disorders have been associated with EBV and are classified based on the type of cell infected and state of viral infection.

Epidemiology

In high-income countries, the prevalence of EBV infection in the general population approaches 95% by early adulthood. Peaks of incidence occur in individuals 1 to 6 and 14 to 20 years of age. Approximately 60–80% of young children in low-income countries are seropositive for EBV, compared to ≤50% in the US. Most children with primary EBV infection have either no symptoms or a mild, nonspecific febrile illness. In contrast, approximately 50% of adolescents and young adults with primary EBV infection develop infectious mononucleosis. In the US, EBV is commonly associated with B-cell lymphomas (~20%) and lymphoproliferative disorders (both polyclonal and monoclonal) in immunocompromised patients. Worldwide, EBV is also implicated in Burkitt lymphoma (particularly the African-endemic form) and nasopharyngeal carcinoma (primarily in Asia) (see Table 80.7).

Pathogenesis

EBV is transmitted primarily through infectious saliva and occasionally via blood transfusion, although its presence in genital secretions and breast milk has been reported[49,50]. The virus preferentially infects human mucosal epithelial cells and B lymphocytes, with primary infection originating within the oropharyngeal epithelium. Infectious mononucleosis results from active viral replication, which is subsequently terminated by the host immune response.

After infectious mononucleosis resolves, circulating B lymphocytes can become latently infected with EBV as the virus enters cells by specifically binding to cell surface complement receptors CR2 or CD21. As the B lymphocyte divides, expression of the EBV nuclear antigen-1

EBV-ASSOCIATED DISORDERS
Infectious mononucleosis
Gianotti–Crosti syndrome
Genital ulcers
Oral hairy leukoplakia
Hydroa vacciniforme and related conditions
• Typical hydroa vacciniforme
• Severe hydroa vacciniforme-like eruptions*
Severe hypersensitivity to mosquito bites*
Lymphadenitis, including Kikuchi's disease
Lymphoproliferative disorders and lymphomas
• Post-transplant lymphoproliferative disorder/lymphoma
• Childhood T- or NK-cell lymphoproliferative disorder/lymphoma
• X-linked lymphoproliferative syndrome
• Hemophagocytic lymphohistiocytosis
• Endemic Burkitt lymphoma
• Extranodal NK/T-cell lymphoma (nasal type)
• EBV-positive diffuse large B-cell lymphoma of the elderly
• Other non-Hodgkin lymphomas (including T-cell)
• Hodgkin disease
Other malignancies
• Nasopharyngeal carcinoma
• Gastric carcinoma
Smooth muscle tumors
*Present with bullous, necrotic and ulcerative skin lesions together with fever, lymphadenopathy, hepatosplenomegaly and natural killer (NK)-cell lymphocytosis; can progress to a T- or NK-cell lymphoma or hemophagocytic lymphohistiocytosis.

Table 80.7 EBV-associated disorders. Other skin conditions that are only occasionally associated with EBV include erythema nodosum, urticaria, erythema multiforme and pityriasis lichenoides (see text).

Fig. 80.20 Genital ulcers associated with primary EBV infection. Extreme pain with urination required placement of a Foley catheter in this 13-year-old girl. EBV-related genital ulcers are often misdiagnosed as a genital herpes simplex virus infection.

Fig. 80.21 Ampicillin-induced eruption in a patient with infectious mononucleosis due to EBV infection. Erythematous macules and papules have become confluent on the upper trunk.

gene (*EBNA-1*) is essential for replication of EBV DNA. Furthermore, the EBNA-1 protein and the virally encoded latent membrane protein-2 (LMP-2) are important in establishment of EBV latency within B lymphocytes and evasion from the cellular immune system[51]. In the presence of a normally functioning immune system, cell-mediated immune responses toward EBV antigens generally prevent the transformation and immortalization of B lymphocytes. However, in patients with deficient cell-mediated immunity, B lymphocytes can become immortalized and give rise to EBV-induced lymphoproliferative disorders.

Cell-mediated immunity to EBV infection is persistent and protects against developing infectious mononucleosis upon re-exposure to an EBV (including different types and strains) later in life. The humoral immune response, although it generates antibodies to a variety of EBV antigens, does not appear to be protective. Latent virus in EBV-infected B lymphocytes can subsequently reinfect the oropharyngeal epithelium, resulting in periodic EBV reactivation and viral shedding for the lifetime of the host.

Clinical Features

EBV-induced infectious mononucleosis most commonly occurs in adolescents and young adults between the ages of 15 and 25 years. After an incubation period of 30 to 50 days, a clinical triad of pharyngitis, fever and lymphadenopathy (especially cervical) occurs in >80% of patients. An initial prodrome of headache, malaise and fatigue may precede onset of the triad. Fever can last up to 10 days. Splenomegaly is found in >50% of patients and can be accompanied by hepatomegaly. Other clinical findings may include exudative pharyngitis (often gray–white), anorexia, nausea, vomiting, cough and arthralgias.

EBV infection can have a variety of dermatologic manifestations. A faint, nonspecific erythematous exanthem has been reported in up to 70% of hospitalized patients and ~10% of all patients with infectious mononucleosis[52]. The exanthem typically develops on day 4 to 6 of the illness and may last up to 1 week. It can be morbilliform, urticarial, scarlatiniform, vesicular, erythema multiforme-like, purpuric or petechial in nature, usually beginning on the trunk and proximal upper extremities with later extension to the face and forearms. Eyelid petechiae, periorbital edema, and petechiae at the junction of the hard and soft palate may also be observed. Resolution of the illness usually occurs after 2 to 3 weeks, although symptoms of fatigue and malaise may last longer. Painful genital ulcers, typically measuring >1 cm with ragged purple–red margins, occasionally develop in patients (especially adolescent girls) with primary EBV infection (Fig. 80.20); PCR or *in situ* hybridization has confirmed the presence of lesional EBV in some cases[53]. Cutaneous conditions that are occasionally associated with primary EBV infection include Gianotti–Crosti syndrome (see Ch. 81), erythema nodosum, urticaria, acrocyanosis, erythema multiforme, erythema annulare centrifugum, pityriasis lichenoides, and linear IgA bullous dermatosis.

Administration of ampicillin or amoxicillin, and less commonly penicillin or cephalosporins, to patients with infectious mononucleosis frequently (up to 90% with the former agents) leads to the development of a "hypersensitivity" skin reaction. This usually develops 7 to 10 days following institution of the antibiotic. Typically, a pruritic, pink to copper-colored, scarlatiniform or morbilliform eruption develops on extensor surfaces and pressure points and then becomes confluent as it spreads onto the trunk and extremities (Fig. 80.21). Desquamation occurs 1 week later. The mechanism of this enhanced immune response to aminopenicillins in the setting of EBV infection is not well understood. In general, such reactions (in the absence of a pre-existing allergy) do not preclude the use of this class of antibiotics after the infectious mononucleosis resolves.

EBV-induced infectious mononucleosis can have serious complications. Splenic rupture (usually after trauma) occurs in 0.2% of affected

adults. Significant enlargement of oropharyngeal lymphoid tissue can lead to airway compromise. Other potential complications include hepatitis, thrombocytopenia, hemolytic anemia, glomerulonephritis and CNS disturbances.

Diagnosis and Pathology

Laboratory findings in patients with infectious mononucleosis include mild to moderately elevated hepatic transaminase levels, mild thrombocytopenia, and an absolute and relative lymphocytosis (up to 50 000 cells/dl) with 20% to 40% atypical lymphocytes. Atypical lymphocytosis is not pathognomonic for EBV infection, as a variety of infectious agents and drugs can also cause this phenomenon. Diagnosis is usually made by a positive monospot test (a simple slide test that detects IgM heterophile antibodies) or increased titers of heterophile antibodies; the latter reach a titer of >1 : 40 in approximately 90% of young adults infected with EBV. Heterophile antibodies are capable of agglutinating sheep, horse or bovine erythrocytes, and they typically become detectable 1 week to 1 month after the onset of symptoms and persist for 3 to 18 months.

Because heterophile antibody titers are positive (≥1 : 40 titer) in only a minority of young children with a primary EBV infection, EBV-specific serologies are often necessary to establish the diagnosis in this age group. Titers of at least three different antibodies should be assessed to determine the stage of EBV infection, allowing differentiation between an acute primary, past/latent and reactivated infection (Table 80.8)[52].

PCR-based assays to detect EBV DNA in peripheral blood or tissue samples are also available. Markedly elevated peripheral blood levels are found in patients with infectious mononucleosis and in immunodeficient individuals with EBV-associated lymphoproliferative disorders (who do not mount an effective immune response). Of note, lower levels of EBV DNA can also be detected in the peripheral blood of healthy individuals with a latent EBV infection. *In situ* hybridization for EBV-encoded small RNA (EBER) represents a widely available, sensitive method to detect EBV-infected cells in the skin and other tissues. This assay can be performed on paraffin-embedded specimens, and EBER-positive cells are prominent in EBV-related dermatoses (e.g. T cells in hydroa vacciniforme) and malignancies, but absent in inflammatory dermatoses and lymphomas that are not related to EBV infection.

Primary EBV infection is not associated with any pathognomonic histologic findings. Features are similar to those observed with other viral exanthems, i.e. slight spongiosis, parakeratosis and a perivascular lymphocytic infiltrate. Additional findings may include focal keratinocyte necrosis, mild ballooning degeneration, and, rarely, multinucleated keratinocytes, but less prominent than with HSV and VZV. Aminopenicillin-induced eruptions in the setting of infectious mononucleosis often demonstrate vacuolar interface changes and spongiosis in association with a denser dermal inflammatory infiltrate. Biopsies of involved lymph nodes typically show reactive lymphoid hyperplasia.

Differential Diagnosis

The differential diagnosis of EBV-induced infectious mononucleosis includes drug reaction with eosinophilia and systemic symptoms (DRESS, see Ch. 21 and HHV-6 section below), which can be distinguished by exposure to an implicated drug and features such as eosinophilia and marked facial edema, as well as group A streptococcal infection, acute viral hepatitis, toxoplasmosis, lymphoma, and primary CMV, HHV-6 and HIV infections. A combination of history, physical examination, and laboratory studies can differentiate among these diseases.

Treatment

In most cases of infectious mononucleosis, the disease is self-limited and treatment is supportive. Although acyclovir does inhibit EBV replication, in controlled studies where primary EBV infection was treated with acyclovir or acyclovir combined with systemic corticosteroids, there was no effect on clinical outcome[54]. In one study of healthy individuals with a past/latent EBV infection, the administration of valacyclovir for 1 year reduced the number of EBV-infected B cells in the peripheral blood compared to an untreated control group[55]. Due to their multiple side effects, corticosteroids are reserved for only complicated cases of infectious mononucleosis associated with hemolytic anemia, severe thrombocytopenia or lymphadenopathy resulting in airway compromise[56]. In patients with EBV-associated lymphoproliferative disorders, reduction of immunosuppression can lead to spontaneous resolution, especially when the disorder is polyclonal.

CYTOMEGALOVIRUS (HHV-5)

Key features

- CMV is the leading infectious cause of congenital deafness and mental retardation (TORCH syndrome) as well as the leading cause of blindness (due to retinitis) in AIDS patients
- Neonates and immunocompromised hosts are at risk for severe clinical infections

Introduction

CMV is endemic in all parts of the world, and it is the most common cause of intrauterine infection in humans. In immunocompetent hosts, 95% of infections are asymptomatic or subclinical. Neonates and immunocompromised individuals, especially those with AIDS, allogeneic hematopoietic stem cell transplant recipients and patients receiving alemtuzumab, are at risk for severe clinical manifestations of CMV infection.

EBV SEROLOGIES					
Antibody	**Timing of appearance**	**Timing of disappearance**	**Acute primary infection**	**Past/latent infection**	**Reactivated (RA)/chronic active (CA)* infection**
VCA IgM	Prior to onset of symptoms	Usually within 3 months	Positive	Negative	Negative in RA/variable in CA
VCA IgG	With onset of symptoms	Persists for life	Positive	Positive	Positive
EA IgG†	With onset of symptoms	Usually within 3–6 months; positive if active infection‡	Positive	Negative	Positive
EBNA IgG	1–6 months after onset of symptoms, upon establishment of latency	Persists for life	Negative	Positive	Positive in RA/variable in CA

*Associated with hemophagocytic lymphohistiocytosis, lymphoproliferative disorders and lymphomas.
†Not usually included in routine serologic testing.
‡Also persists in ~20% of healthy individuals.

Table 80.8 EBV serologies. EA, early antigen; EBNA, EBV nuclear antigen; VCA, viral capsid antigen.

History

In 1881, Ribbert first observed "protozoan-like cells" in the organs of a stillborn baby with presumed congenital syphilis. Before the discovery of a viral etiology, the disease was initially called "cytomegalic inclusion disease" based on the characteristic enlarged cells (cytomegalia) and intranuclear inclusions. In 1956, human CMV was independently isolated *in vitro* by three groups of investigators led by Weller, Rowe and Smith. Originally known as the "salivary gland virus" or "salivary inclusion disease virus", cytomegalovirus was given its current name by Weller and his colleagues in 1960[57].

Epidemiology

The prevalence of CMV infection is inversely proportional to socioeconomic status. For example, 80–100% of the African population is CMV-seropositive compared with 60–70% of the US and Western European populations. The increased seroprevalence in low-income countries is thought to be due to crowded living conditions, poor hygiene and greater numbers of individuals caring for an infant. Age-related prevalence studies in the US have shown highest risks of CMV acquisition during early childhood, adolescence and the reproductive years.

Among toddlers in day-care centers, CMV seropositivity is especially high. In adults, CMV infections are often contracted through sexual contact. Blood transfusions carry a 3–4% risk of CMV infection per transfusion unit[58]. To decrease this risk, leukocyte-depleted blood can be used in immunosuppressed patients.

Due to an increasing number of HIV-seropositive individuals worldwide, higher rates of solid organ and hematopoietic stem cell transplantation, and more frequent use of immunosuppressive agents, the incidence of disseminated CMV infection has increased. CMV is considered to be one of the most important viral infections in patients with AIDS due to its significant morbidity (e.g. blindness, gastroenteritis) and mortality in this population. Of note, in the US, congenital CMV infection occurs in approximately 0.5–1.5% of all newborn infants[59].

Pathogenesis

Transmission of CMV is via body fluids, including saliva, blood, urine, semen, breast milk and cervical and vaginal secretions, as well as in transplanted organs and hematopoietic stem cells. CMV can also be spread indirectly by contaminated fomites, such as toys. Transplacental transmission of CMV to the fetus is more likely in the setting of a primary infection in the mother, with 40% of fetuses becoming infected, compared to <1% in recurrent cases.

CMV has an estimated incubation period of 4 to 8 weeks. It is a cytotoxic virus that causes cell enlargement (cytomegaly) and nuclear condensation (inclusion). Using blood leukocytes as a transport medium, the virus disseminates throughout the body, infecting various organs during the viremia. CMV infection may be either primary or recurrent, and the latter can result from either viral reactivation or reinfection with a different antigenic type.

Following primary infection, CMV persists in a latent state for the life of the host and rarely causes disease. In immunocompromised individuals, however, reactivation of latent virus can lead to recurrent infection characterized by persistent viral replication, viremia and dissemination to distant organs. Cell injury and tissue destruction contribute to organ damage by directly altering cellular function and producing an inflammatory response.

The organ infected depends on the age of the host. Infection in healthy children and adults often involves the lymphoid tissues, while fetal and neonatal infection commonly affects the salivary glands and neurons. Infection in immunocompromised individuals frequently involves the retina and lungs as well as the liver and gastrointestinal tract[60].

Clinical Features

Although most cases of CMV infection are subclinical (>90%), a "mononucleosis-like syndrome" similar to that seen with EBV is the most common clinical presentation in immunocompetent persons (Table 80.9). This syndrome has been described in both immunocompetent and immunocompromised individuals after a blood transfusion. Infected patients develop a sore throat without an exudate in addition to fever, malaise, myalgias, lymphadenopathy and hepatosplenomegaly.

CUTANEOUS MANIFESTATIONS OF CMV INFECTIONS
IMMUNOCOMPETENT HOST
Mononucleosis-like syndrome
• Maculopapular/morbilliform eruption
• Petechiae and purpura
• Ampicillin-induced eruption
• Urticaria
• Erythema nodosum
Congenital infections
• "Blueberry muffin" lesions (extramedullary erythropoiesis; see Ch. 121)
• Petechiae and purpura
• Vesicles
IMMUNOCOMPROMISED HOST
Cutaneous vasculitis
Maculopapular/morbilliform eruption
Petechiae and purpura
Ulcers
Vesicles
Verrucous plaques
Nodules and hyperpigmented plaques

Table 80.9 Cutaneous manifestations of CMV infections.

Fig. 80.22 TORCH syndrome due to cytomegalovirus. Multiple purpuric papules of dermal erythropoiesis. *Courtesy, Mary S Stone, MD.*

Atypical lymphocytosis and elevated liver enzymes may also occur. An exanthem, which can be morbilliform, urticarial, petechial or purpuric, develops in a small percentage of patients. As with infectious mononucleosis, the administration of ampicillin or related drugs during this symptomatic period leads to a cutaneous eruption in 80–100% of individuals. Although the clinical course of CMV-induced mononucleosis is self-limited, rare complications include hemolytic anemia, thrombocytopenia, granulomatous hepatitis, Guillain–Barré syndrome, meningoencephalitis, myocarditis, interstitial pneumonia, arthritis, and gastrointestinal and genitourinary manifestations.

Congenital CMV infection is the leading infectious cause of deafness and mental retardation in the US. Approximately 5–10% of infected neonates have symptoms at birth, presenting with jaundice, hepatosplenomegaly, intrauterine growth retardation, thrombocytopenia, chorioretinitis, seizures and/or intracranial calcifications. Cutaneous manifestations include purpuric papules and nodules of dermal hematopoiesis (Fig. 80.22) which are sometimes referred to as "blueberry muffin" lesions (see Ch. 121), as well as petechiae, purpura and vesicles. Another 10–15% of children are born with asymptomatic CMV infection and later develop sequelae, most often sensorineural hearing loss. Perinatal CMV infection is often asymptomatic; however, a limited number of infected infants develop pneumonitis, lymphadenopathy or hepatosplenomegaly[59].

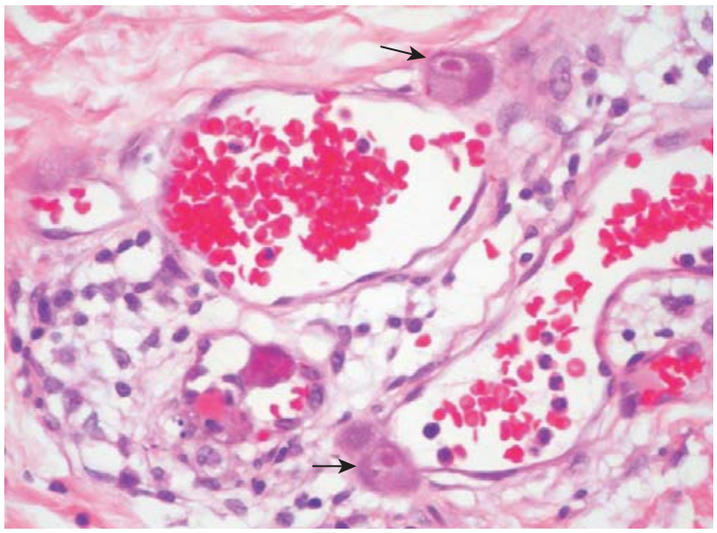

Fig. 80.23 Histology of cytomegalovirus (CMV) infection. Enlarged endothelial cells with a prominent intranuclear inclusion (arrows) are typical of CMV infection.

In AIDS patients, CMV may cause chronic ulcers of the perineum or leg, chorioretinitis, esophagitis, colitis and pneumonitis, as well as endocrine, bone marrow, CNS and renal abnormalities. Cutaneous manifestations are often atypical and range from vesicles to nodules to verrucous plaques. In recipients of solid organ and hematopoietic stem cell transplants, gastrointestinal involvement and interstitial pneumonia are the most serious manifestations of CMV infection, respectively[60].

Diagnosis and Pathology

The diagnosis of CMV infection is established by a variety of methods. Culture of CMV in human fibroblasts is the traditional diagnostic "gold standard", but this takes several days to weeks. Detection of CMV in tissue cultures within 24–48 hours is possible with the shell vial assay, in which monoclonal antibodies specific for early CMV antigens are employed. In addition to CMV-specific serologies, assays that detect CMV antigenemia (via recognition of the pp65 antigen within leukocytes) or CMV DNA (via PCR; necessary in neutropenic patients) are commonly employed to identify and monitor viremia and systemic infection[61]. CMV retinitis in patients with AIDS is diagnosed by ophthalmologic examination.

Like other viral exanthems, the histologic features of the acute exanthem of CMV infection include mild spongiosis and a sparse perivascular lymphocytic infiltrate in the upper dermis. Epidermal changes are minimal since CMV does not infect keratinocytes. However, it does infect endothelial cells, which can have an "owl's eye" appearance that is pathognomonic for CMV infection. The cells are enlarged two- to threefold and contain purplish, crystalline intranuclear inclusion bodies surrounded by a clear halo (Fig. 80.23). These cytomegalic cells are most likely to be evident in ulcers, and vascular dilatation is another common finding. CMV vasculitis, a manifestation of disseminated disease, is characterized by marked endothelial swelling and inflammation.

Differential Diagnosis

The clinical differential diagnosis of the mononucleosis-like syndrome of CMV infection includes EBV-induced infectious mononucleosis (which is generally more severe and often associated with exudative pharyngitis), toxoplasmosis, viral hepatitis, DRESS and lymphoma. A high index of suspicion is necessary to diagnose CMV-induced ulcers and atypical cutaneous manifestations in immunocompromised patients.

Treatment and Prevention

Management is targeted at prevention plus prophylactic antiviral treatment in susceptible immunocompromised individuals as well as antiviral treatment in those who are symptomatic. Treatment of CMV-induced mononucleosis in immunocompetent individuals, however, is only supportive. As a preventive measure, tissues (particularly hematopoietic stem cells) from CMV-seronegative donors are used preferentially for seronegative recipients and vice versa (i.e. seropositive recipients are matched with seropositive donors). While some clinicians utilize pre- and post-transplant CMV prophylaxis (especially when the donor and/or recipient are seropositive), others employ pre-emptive management by following blood CMV antigen or DNA levels and initiating therapy if they increase.

The first-line agents for treatment (as well as prophylaxis) of CMV infections in immunocompromised patients are ganciclovir (intravenous; intravitreal injections/implants for localized retinitis) and valganciclovir (oral). When patients fail to respond to these medications or develop significant side effects, foscarnet and then cidofovir are additional options[62] (Table 80.10). High-titer anti-CMV immunoglobulins are also occasionally used[62]. Relapse is common after discontinuation of any of these antiviral agents.

A live attenuated CMV vaccine has been found to induce a humoral immune response in healthy individuals and transplant recipients, with neutralizing antibodies that persist for over 4 years. It also decreases symptoms in transplant patients who received CMV-infected organs. Further studies are currently being conducted on alternative vaccines, including subunit and recombinant formulations.

TREATMENT FOR CMV INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

Medication	Route	Major side effects
Ganciclovir	iv, intravitreal implant or injection	Bone marrow suppression, GI symptoms > renal insufficiency, neuropathy
Valganciclovir	po	
Cidofovir	iv*, intravitreal injection	Renal toxicity
Foscarnet	iv, intravitreal injection	Renal toxicity
Fomivirsen	Intravitreal injection	

*Initially given weekly for 2 weeks for AIDS-related CMV retinitis.

Table 80.10 Treatment options for CMV infections in immunocompromised patients. iv, intravenous; po, orally.

HUMAN HERPESVIRUS TYPE 6 (HHV-6)

Synonyms: ■ Roseola infantum – exanthem subitum, sixth disease

Key features

- HHV-6 is the cause of exanthem subitum, a common febrile disease of early childhood
- Although it is usually a benign condition without long-term consequences, HHV-6 can be life-threatening if reactivated in the setting of immunosuppression

Introduction

HHV-6 is the etiologic agent of exanthem subitum (roseola infantum), one of the most common viral exanthems in infants and young children. Although HHV-6 infection usually is a benign disease without long-term sequelae, the virus remains latent and can be life-threatening if reactivated in the setting of immunosuppression.

History

Zahorsky distinguished exanthem subitum from other exanthems in 1910 and is credited for its first description. In 1988, Yamanishi and colleagues used serologic methods to confirm that HHV-6 caused exanthem subitum[63]. A subsequent study discovered two distinct variants of the virus: HHV-6A and HHV-6B, each with different biologic, immunologic and genetic characteristics. Variant B is primarily the cause of

exanthem subitum, while the pathogenic role of variant A is unclear, except that it is identified more frequently in patients with AIDS.

Epidemiology

HHV-6 is found worldwide. Infection is most common in young children, occurring between the ages of 6 months and 3 years in 95% of cases, with a peak incidence between 6 and 12 months of age. Boys and girls are equally affected. Seroprevalence studies have shown that maternal IgG against HHV-6 is transferred to 70–97% of fetuses. The level of these maternal antibodies in infants wanes by 6 months of age, but subsequent primary infections result in a peak HHV-6 seroprevalence of 90–100% at 3 to 4 years of age. Antibody levels then decline again, with a prevalence of 66% to 94% in adults[64]. Despite the high seroprevalence, only 30% of children develop clinical manifestations of exanthem subitum. Infections occur throughout the year but are most common in the spring.

Pathogenesis

HHV-6 has a tropism for $CD4^+$ T lymphocytes, but it can infect a variety of other cells, including neurons. Transmission is through infected saliva, although HHV-6 DNA has been isolated from the cervix and may cause perinatal infection. After primary HHV-6 infection, the virus establishes lifelong latency in $CD4^+$ T lymphocytes, with the potential for reactivation. Immunosuppressed patients are at particular risk for HHV-6 reactivation, sometimes with severe consequences[65]. Serologic studies suggest that HHV-6 can also be transmitted via transplanted tissues.

The effects of HHV-6 in HIV-infected patients are unclear. Some studies have shown an increase in the seroprevalence of HHV-6 in these patients, while others found a decrease or little difference from the overall population. *In vitro* studies have described both increased and decreased replication of HIV-1 in cells co-infected with HHV-6 and HIV-1. In AIDS patients, co-infection may cause further immunosuppression, but more research is needed to confirm or disprove this hypothesis[63].

Patients with lymphoproliferative malignancies such as Hodgkin disease, follicular large cell lymphoma, acute myelogenous leukemia, Burkitt's lymphoma and angioimmunoblastic T-cell lymphoma have higher HHV-6 antibody titers than healthy individuals, as do patients with systemic lupus erythematosus, multiple sclerosis and chronic fatigue syndrome. Of note, HHV-6 DNA has been demonstrated in lesions of Rosai–Dorfman disease[66], and HHV-6 has been postulated to have a role in the pathogenesis of pityriasis rosea (together with HHV-7; see below). The causal relationship of HHV-6 to these diseases is unproven. HHV-6 and other herpesviruses (e.g. EBV, CMV and HHV-7) have been implicated in the pathogenesis of DRESS syndrome (see Ch. 21). It has been postulated that drug-related immunosuppression or induction of viral replication by the drug leads to viral reactivation, which stimulates a cellular immune response directed against herpesviruses and likely cross-reacting with the drug.

Clinical Features

The classic clinical manifestations of exanthem subitum occur in about 30% of those with primary HHV-6 infections. Typically, an otherwise well-appearing infant presents with a high fever (102–105°F; 38.9–40.6°C) that lasts for 3–5 days, followed by a cutaneous eruption as the fever begins to subside. The incubation period ranges from 5 to 15 days, but it is most often 9 to 10 days. The fever may be intermittent and tends to peak in the early evening. The cutaneous eruption usually lasts for 24–48 hours and may develop before the temperature returns to normal or up to 2 days afterwards. The lesions are discrete, circular or elliptical, "rose-red" macules and papules that are 2–5 mm in diameter and occasionally surrounded by a white halo. The cutaneous eruption commonly affects the trunk (Fig. 80.24), proximal extremities, neck and less often the face; its appearance can be very similar to rubella or rubeola. An enanthem of red papules on the soft palate (Nagayama's spots) may also be seen, and ulcers on the uvula and at the palatoglossal junction represent a characteristic finding. Eyelid edema, mild upper respiratory symptoms, injection of the tympanic membranes, cervical or occipital lymphadenopathy and a bulging anterior fontanelle may also be evident.

Fig. 80.24 Exanthem subitum (roseola infantum). Small pink–red macules and papules developed on the trunk and neck of this 9-month-old boy during defervescence of a high fever that had lasted for 5 days. *Courtesy, Julie V Schaffer, MD.*

The most common complication of exanthem subitum is febrile seizures, which occur in 10–15% of affected infants and children[67]. Infection with or reactivation of HHV-6 in immunocompromised patients can lead to fever and a cutaneous eruption as well as more serious consequences such as hepatitis, pneumonitis, bone marrow suppression, encephalitis and transplanted tissue rejection[63].

Diagnosis and Pathology

In healthy individuals, HHV-6 infection is typically diagnosed clinically. Serology may be helpful in ambiguous situations. The presence of IgM antibodies indicates primary infection, but this assay is not reliable for the detection of reactivation. A fourfold increase in IgG in paired samples from the acute and convalescent phases of the disease can give retrospective confirmation of HHV-6 reactivation.

Other diagnostic tools include PCR-based assays and viral culture. PCR detection of cell-free HHV-6 DNA in serum or plasma has diagnostic utility. However, qualitative PCR using cellular specimens (e.g. peripheral blood mononuclear cells) cannot reliably distinguish between latent and active infection.

The histopathologic features of exanthem subitum are similar to those of other viral exanthems. A sparse perivascular lymphocytic infiltrate within the dermis is observed without other specific changes.

Differential Diagnosis

The differential diagnosis of exanthem subitum is primarily other viral exanthems (e.g. rubeola, rubella, and enterovirus, adenovirus, EBV and parvovirus infections); other considerations may include scarlet fever, Rocky Mountain spotted fever and Kawasaki disease (see Ch. 81).

Treatment

Although HHV-6 infection is usually self-limited, serious complications can occur in immunocompromised patients. Evidence-based recommendations regarding specific antiviral agents and dosages are not yet available to guide treatment in immunocompromised hosts. Some studies have shown that phosphonoacetic acid, foscarnet and ganciclovir may inhibit HHV-6, and a few case studies have reported successful treatment of serious infections with foscarnet and ganciclovir.

HUMAN HERPESVIRUS TYPE 7 (HHV-7)

Key feature

- HHV-7 is a lymphotropic virus that has been linked to reactivation of HHV-6 in some patients with exanthem subitum

HHV-7 is a ubiquitous lymphotropic herpesvirus that was first isolated by Frenkel et al.[68] in 1990. Its epidemiology appears to be similar to that of HHV-6, with a seroprevalence of over 85% in the US. Infections with HHV-7 mainly occur during the first 5 years of life (with a peak at 1–2 years of age) and then typically remain latent. Transmission via saliva is most likely, since HHV-7 is only known to replicate in human salivary glands; however, HHV-7 has also been found in cervical secretions.

Little is understood about the pathogenesis of HHV-7, except that it utilizes the CD4 molecule as its receptor. HHV-7 down-regulates the expression of CD4 molecules on lymphocytes and may down-regulate the infectivity of HIV, since both viruses compete for the same receptor. A T-lymphocytic viral vector utilizing HHV-7 has been developed for potential use in gene therapy for diseases affecting $CD4^+$ T lymphocytes, such as AIDS, autoimmune diseases and T-cell lymphomas[65].

The virus grows best in cord blood lymphocytes and has a limited range of host tissues compared to that of HHV-6, although HHV-7 antigen has been found in human lungs, mammary glands and skin[69]. Compared to HHV-6, HHV-7 is less cytopathic, associates more with cells and grows more slowly in culture. Significant homology exists between the two viruses and limited antigenic cross-reactivity has been demonstrated between HHV-7 and HHV-6A (but not HHV-6B)[65]. However, HHV-7 is serologically distinct from HHV-6, and immunity to HHV-7 is not conferred with HHV-6 antibodies (or vice versa).

HHV-7 has not been clearly established as a causative factor for clinical disease, although it has been linked to several conditions. A subset of cases of exanthem subitum have been associated with reactivation of HHV-6 (particularly variant B) in conjunction with primary infection with HHV-7. The cutaneous eruption associated with HHV-7-induced exanthem subitum is lighter in color and presents later in the disease course than that of primary HHV-6 infection[70]. Neurologic complications, such as febrile seizures and acute hemiplegia, have also been reported with HHV-7-induced exanthem subitum.

HHV-7 and pityriasis rosea (PR) were first associated when HHV-7 DNA was detected via PCR in blood monocytes, plasma and lesional skin from 12 patients with PR, but not in the plasma or skin of controls[71]. Although some subsequent studies were unable to isolate HHV-7 DNA from PR lesions, others supported a role for HHV-7, and possibly HHV-6, in PR[72].

Methods to detect HHV-7 infection include serologic tests, PCR, viral culture and immunohistochemical staining. The differential diagnosis is similar to that of exanthem subitum. There is no available treatment for HHV-7 infection, although several antiviral agents are under investigation.

HUMAN HERPESVIRUS TYPE 8 (HHV-8)

Synonym: ■ Kaposi sarcoma-associated herpesvirus (KSHV)

Key features

- HHV-8 is a latent virus found in virtually all lesions of all types of Kaposi sarcoma (KS) worldwide
- The seroprevalence of HHV-8 corresponds to the incidence rates of KS and varies by geographic location
- The features of primary infection with HHV-8 have not yet been identified, and its associated diseases are postulated to be a result of viral reactivation

Introduction

HHV-8, previously called Kaposi sarcoma-associated herpesvirus (KSHV), is a latent virus found in all types of Kaposi sarcoma (KS) worldwide.

History

In 1872, Moriz Kaposi described a rare cutaneous neoplasm, predominantly affecting elderly men of Ashkenazi Jewish and/or Mediterranean descent, that subsequently came to be known as Kaposi sarcoma (KS). There was little medical interest in this disease until its incidence suddenly increased in young homosexual men at the onset of the AIDS epidemic. In 1994, the association of KS and HHV-8 was recognized when herpes-like DNA sequences were identified in KS lesions from an AIDS patient. Associations of HHV-8 with other cancers in AIDS patients, such as Castleman's disease and body cavity-based lymphomas, were noted in 1995 and 1996.

Epidemiology

HHV-8 is found in KS lesions worldwide. The incidence of the classic form of KS peaks after the sixth decade of life, and it typically occurs in men of Mediterranean and Ashkenazi Jewish descent. In the era prior to antiretroviral therapy (ART; formerly referred to as highly active antiretroviral therapy [HAART]), HIV-positive men having sex with men developed KS at a rate 20 000 times greater than that of the general population[73]. In southern equatorial Africa, the African-endemic form of KS accounts for approximately 10% of all malignancies. This type of KS affects two distinct age groups: young adults (mean age, 35 years; men > women) and young children (mean age, 3 years).

Seroprevalence of HHV-8 varies geographically, ranging from less than 5% in North America, Britain and Northern Europe to about 10% in Southern Europe and 30% to 80% in African countries. In North America and Europe, HHV-8 antibodies are present in approximately 30% of HIV-1-infected men who have sex with men[74].

Pathogenesis

The mechanisms of HHV-8 transmission are not fully understood. Receptive anal intercourse appears to be a factor for transmission, as the seroprevalence of HHV-8 is higher in men who have sex with men than in HIV-infected women. The number of same-sex male partners and the presence of HIV infection may be other risk factors[65]. There is increasing evidence that exposure to saliva (e.g. via close non-sexual contact among family members or sexual practices involving saliva) represents an important route of HHV-8 transmission. In areas in Africa where HHV-8 is endemic, seroprevalence is high in young children, and some but not all studies have found that this is associated with mother-to-child horizontal transmission; vertical transmission is uncommon[75,76]. HIV-infected infants have a significantly increased risk of HHV-8 infection[76]. HHV-8 transmission by blood transfusion has also been demonstrated[77].

KS is an endothelial malignancy and the neoplastic cells are closely related to lymphatic endothelial cells. Although HHV-8 is found in the vast majority of cases in all types of KS, there is no agreement on the exact mechanism by which HHV-8 results in the development of KS. However, studies have shown that HHV-8 can infect both lymphatic and blood vascular endothelial cells and induce transcriptional reprogramming, leading to expression of lymphangiogenic molecules. Unlike co-infections with HHV-8 and HIV-1, co-infections with HHV-8 and HIV-2 do not often result in KS. While immunosuppression of the host is commonly thought to promote replication of the HHV-8 virus, it is noteworthy that KS is much more strongly associated with HIV-1 infection than with immunosuppression in transplant recipients, suggesting a more complex process.

Primary effusion lymphoma and multicentric Castleman's disease have also been associated with HHV-8. Exactly how these distinct diseases are related to this virus is still unknown.

Clinical Features

The four KS types (classic, HIV/AIDS-related, immunosuppression-associated, and African-endemic; see Ch. 114) have somewhat different presentations and clinical courses, although all typically feature red, brown or violaceous papules, plaques and nodules. Edema is often present in all types.

The lesions of *classic KS* tend to have a spongy feel during the early stage of the disease and become more firm with time. They initially develop as purplish-red plaques (Fig. 80.25), primarily on the lower legs of elderly men of Mediterranean descent, and can later become brown, hyperkeratotic and/or eczematous. The oral mucosa and gastrointestinal tract are rarely involved, and the disease typically has a slow progression.

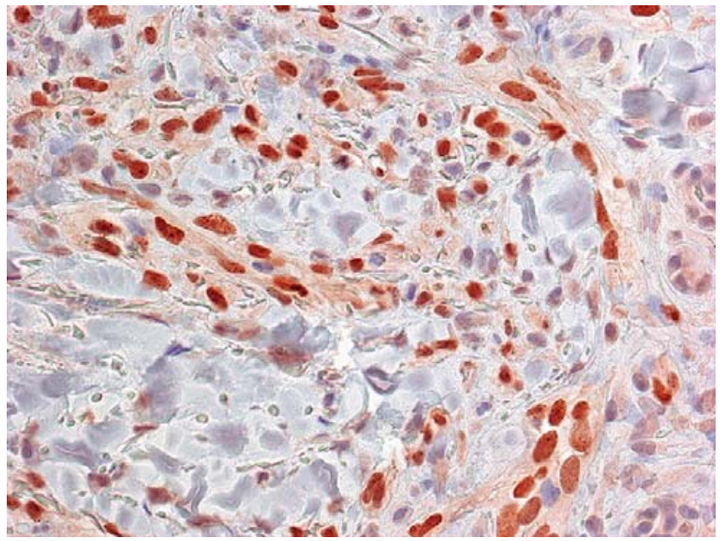

Fig. 80.26 Kaposi sarcoma. Immunohistochemical staining utilizing antibodies against a latent nuclear antigen (LNA-1) demonstrates the presence of HHV-8. *Courtesy, Shawn Cowper, MD.*

AIDS-related KS (see Ch. 78) typically presents as more widely distributed macules, patches or plaques, which occasionally become exophytic or ulcerative. Involvement of the oral cavity and face occurs more often than in classic KS and may be one of the first indications of HIV infection. Involvement of the genital mucosa, lungs and gastrointestinal tract (particularly the stomach and duodenum) is common. Approximately 80% of AIDS patients with KS develop gastrointestinal involvement. Oral lesions can cause significant discomfort as well as difficulties with speech and eating; gastrointestinal involvement may lead to nausea, vomiting, bleeding, perforation and/or ileus; and pulmonary involvement can result in persistent cough, bronchospasm or dyspnea. AIDS-related KS has a variable clinical course, and, in general, prognosis is related to the degree of immune impairment and overall health of the patient. However, flares of KS can occur as a manifestation of immune reconstitution following initiation of ART.

Immunosuppression-associated KS can have a clinical course similar to that of AIDS-related KS, with rapid progression and dissemination unless immunosuppressive medications are discontinued or their doses markedly decreased. Changing from a calcineurin inhibitor to sirolimus (rapamycin), which inhibits the HHV-8 lytic replication cycle and has antineoplastic and antiangiogenic as well as immunosuppressive effects, can result in improvement or disappearance of KS lesions (and avoid organ rejection in transplant recipients).

There are four subtypes of *African-endemic KS*: nodular, lymphadenopathic, florid and infiltrative. The nodular subtype is characterized by a small number of well-circumscribed cutaneous nodules and typically has an indolent course in young adults. The fulminant lymphadenopathic subtype predominantly affects the lymph nodes of children and is often fatal. The florid and infiltrative forms frequently have a large number of cutaneous lesions on one or more extremities. These latter two types are aggressive and may spread deeply into the subcutaneous tissue, muscle and bone.

Diagnosis and Pathology

The diagnosis of KS is confirmed by a skin biopsy of a suspected lesion. Serology for HHV-8 is not required. Immunohistochemical staining utilizing antibodies against latent nuclear antigen 1 can demonstrate the presence of HHV-8 within biopsy specimens of KS (Fig. 80.26)

The histologic features of each variant of KS are typically the same (see Ch. 114): vascular channels lined by atypical endothelial cells and surrounded by a proliferation of spindle-shaped cells. Characteristic histologic changes are associated with each stage of KS. During the patch stage, there is a proliferation of small, jagged, endothelial-lined spaces in the superficial dermis. These vessels may lead to separation of collagen bundles. A perivascular lymphocytic infiltrate (± plasma cells) is variably observed.

During the plaque stage, spindle cells that express endothelial markers infiltrate the dermal collagen bundles of the deeper dermis. Irregular, cleft-like vascular channels are seen along with hemosiderin deposits and hyaline globules. A perivascular lymphocytic infiltrate is prominent in this stage and remains throughout the disease course.

During the nodular stage, well-circumscribed sheets and fascicles of spindle cells within a network of slit-like vascular spaces infiltrate the dermis and subcutaneous tissue. Cytologic atypia, mitotic figures and single erythrocytes trapped within the network are seen.

Differential Diagnosis

The differential diagnosis of KS lesions may include the following: acroangiodermatitis (pseudo-KS), bacillary angiomatosis, ecchymosis, hemangiomas (e.g. microvenular, hobnail or spindle cell), angiosarcoma, pseudolymphoma/lymphoma and cutaneous metastases.

Treatment

The goals for treatment of KS are to reduce symptoms and slow progression. Options include cryotherapy, radiotherapy, topical alitretinoin, intralesional interferon-α, systemic chemotherapy, and, for AIDS-related KS, ART. The latter has markedly reduced the incidence of AIDS-related KS although, as noted above, flares of KS can occur with immune reconstitution. Surgery is usually not effective.

Unless they bleed, are cosmetically bothersome, or cause functional impairment, monitoring may be preferred for small, slowly growing, early-stage cutaneous lesions. When treatment is indicated, classic KS and AIDS-associated KS lesions often respond well to radiotherapy[78] (see Ch. 139). However, recurrences at the peripheral margin of the radiation ports are not uncommon. Topical alitretinoin gel is considered moderately effective[79].

Intralesional interferon-α has been reported to produce complete responses. Side effects include pain, local inflammation and flu-like systemic symptoms. For early lesions, intralesional vinblastine may result in improvement (at least for a period of several months) in a significant percentage of cases. Systemic chemotherapeutic agents, such as vinblastine and anthracyclines (e.g. doxorubicin, daunorubicin), have traditionally been used for extensive classic and endemic KS[80]. More recently, however, these have been replaced by liposomal-encapsulated anthracyclines (first-line therapy) and paclitaxel (partial or complete response in >50% of HIV-infected patients). Treatments that are being investigated include antiangiogenic agents (e.g. bevacizumab, lenalidomide), sirolimus, tyrosine kinase inhibitors (e.g. imatinib), matrix metalloproteinase inhibitors, and valganciclovir (which can inhibit HHV-8 replication)[81].

CONCLUSION

The eight human herpesviruses are associated with a wide spectrum of clinical features. During the past two decades, a marked expansion in the number of immunocompromised patients has led to significant increases in the diversity and severity of clinical presentations of human herpesvirus infections. Thus, it is imperative to be aware of the various manifestations of these viral infections and to initiate appropriate diagnostic tests. There are a number of antiviral drugs available for HSV, VZV and CMV infections, and the clinician must be aware of the indications, contraindications, dosages and limitations of these agents. Unfortunately, only two licensed vaccines exist for human herpesvirus, the varicella and varicella zoster vaccines. Therefore, public health measures remain critical for controlling the spread of these viruses. It is anticipated that better diagnostic tests, antiviral drugs and vaccines for human herpesviruses will become available in the near future.

RECOMMENDATIONS OF THE ADVISORY COMMITTEE ON IMMUNIZATION PRACTICES FOR ADMINISTRATION OF THE VARICELLA VACCINE

Category	Varicella vaccine administration
Routine childhood vaccination	• 2 doses – First at age 12–15 months – Second at age 4–6 years*
Individuals ≥13 years of age without evidence of varicella immunity, especially: – Students, teachers, residents/staff in institutional settings – Healthcare providers – If household contacts are immunocompromised or children – Postpartum/non-pregnant women of childbearing age – International travelers	• 2 doses, 4–8 weeks apart
Second dose catch-up vaccination for individuals >6 years of age who received 1 dose previously	• 1 additional dose – ≥3 months after previous dose if <13 years old – ≥4 weeks after previous dose if ≥13 years old
HIV-infected individuals: – 1–8 years of age with $CD4^+$ T-cell percentage ≥15% – >8 years of age with $CD4^+$ T-cell count ≥200 cells/mcl	• 2 doses, 3 months apart
Postexposure vaccination in individuals who received 1 dose previously	• 1 additional dose, ideally within 3–5 days, if: – ≥3 months after previous dose for those <13 years old – ≥4 weeks after previous dose for those ≥13 years old
Postexposure vaccination in individuals ≥1 year of age without evidence of varicella immunity	• Administer first dose within 3–5 days
Contraindications • Allergy to vaccine components • Immunocompromised states including: hematologic malignancies, HIV infection with $CD4^+$ T-cell percentage <15% or count <200 cells/mcl, other T-cell immunodeficiencies, systemic immunosuppressive therapy (e.g. prednisone ≥2 mg/kg/day or, if weight >10 kg, ≥20 mg/day for ≥2 weeks) • Pregnancy	
*May be given earlier provided that the interval between the two doses is ≥3 months.	

Recommendations of the Advisory Committee on Immunization Practices for administration of the varicella vaccine. Varicella vaccination is generally required for entry to child care centers, schools, colleges and other educational institutions. Skin lesions directly related to the attenuated virus (usually ≤5 papules or papulovesicles; localized to the area of injection in half of cases) develop in 5–10% of vaccinated individuals, usually 5–25 days after immunization.

INTRODUCTION

Viral infections are frequently associated with cutaneous manifestations, especially in children, in whom they are the most common cause of exanthems. An exanthem is defined as a skin eruption occurring as a sign of a general disease. Viral exanthems may present with distinctive cutaneous features or in an entirely nonspecific fashion, and at times they may pose a significant diagnostic challenge, even to the most astute clinician. While dermatologists are most likely to be consulted for atypical or less widely recognized exanthems, a solid working knowledge of the classic disorders, whether common (e.g. fifth disease) or rare in high-income countries (e.g. measles), is essential.

This chapter describes classic childhood exanthems, less common exanthems, eruptions associated with poxvirus infections, and the cutaneous manifestations of hepatitis A, B and C virus infections. Kawasaki disease, which features a polymorphic exanthem together with other mucocutaneous findings and systemic manifestations that can mimic a viral syndrome, is also discussed. In contrast to the symptomatic management of most viral exanthems, prompt recognition and initiation of therapy for Kawasaki disease is necessary to prevent potentially life-threatening complications. Herpesvirus infections, including infectious mononucleosis, are covered in Chapter 80. Structural features and sizes of major types of viruses that infect humans are shown in Figure 81.1.

Nonspecific viral exanthems are the most common type of exanthem seen in children. These eruptions lack distinctive features such as specific lesional morphologies, distribution patterns, natural histories, or enanthems (eruption on the mucous membranes). They most often present with blanchable erythematous papules and macules in a widespread distribution on the trunk and extremities, and less often the face. Associated symptoms such as a low-grade fever, myalgias, headache, rhinorrhea or gastrointestinal complaints may be present. Although multiple infectious agents can cause such exanthems, the most common etiologies in children are the non-polio enteroviruses (see below) in the summer/fall and respiratory viruses (including adenovirus, parainfluenza virus, respiratory syncytial virus and influenza virus) in the winter. Nonspecific exanthems tend to be self-limited, with spontaneous resolution within 1 week, and supportive therapy is usually sufficient. While identification of the exact etiologic agent

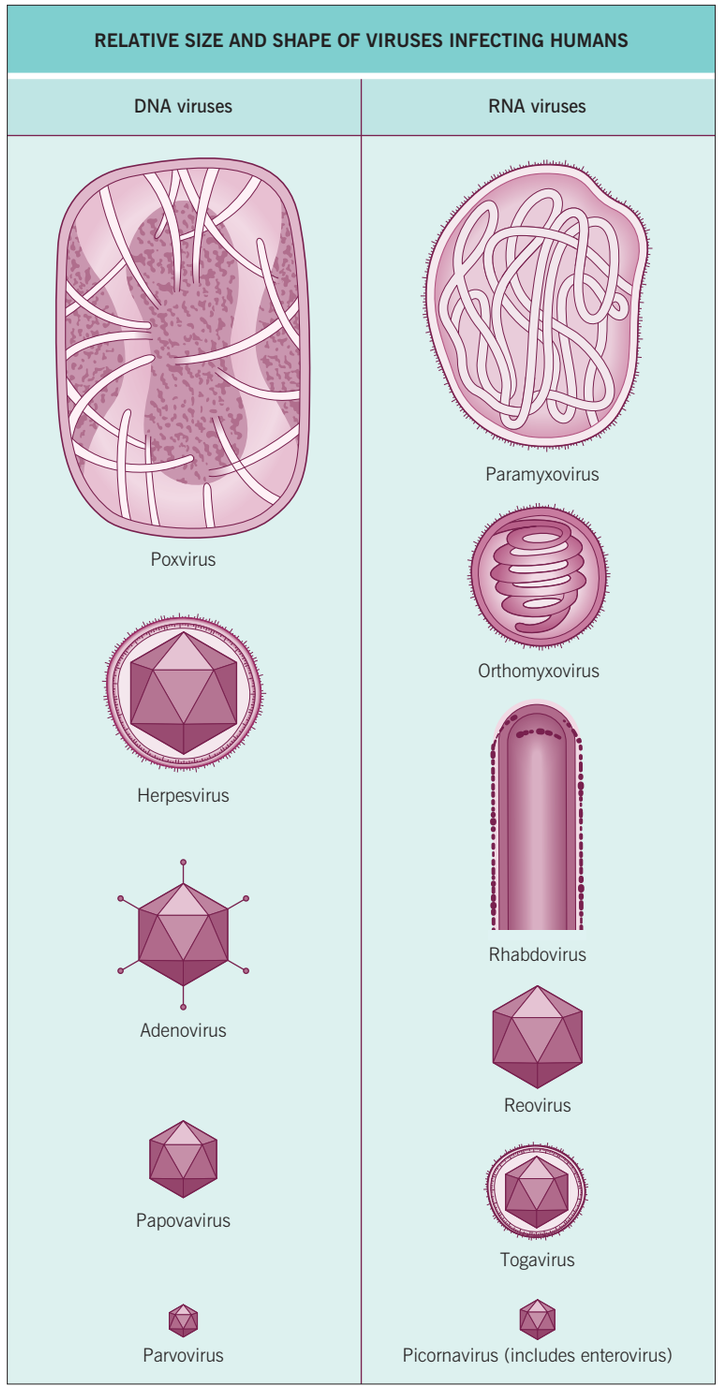

Fig. 81.1 Relative size and shape of viruses infecting humans. *Adapted from Hsiung's Diagnostic Virology Yale University Press, 1994.*

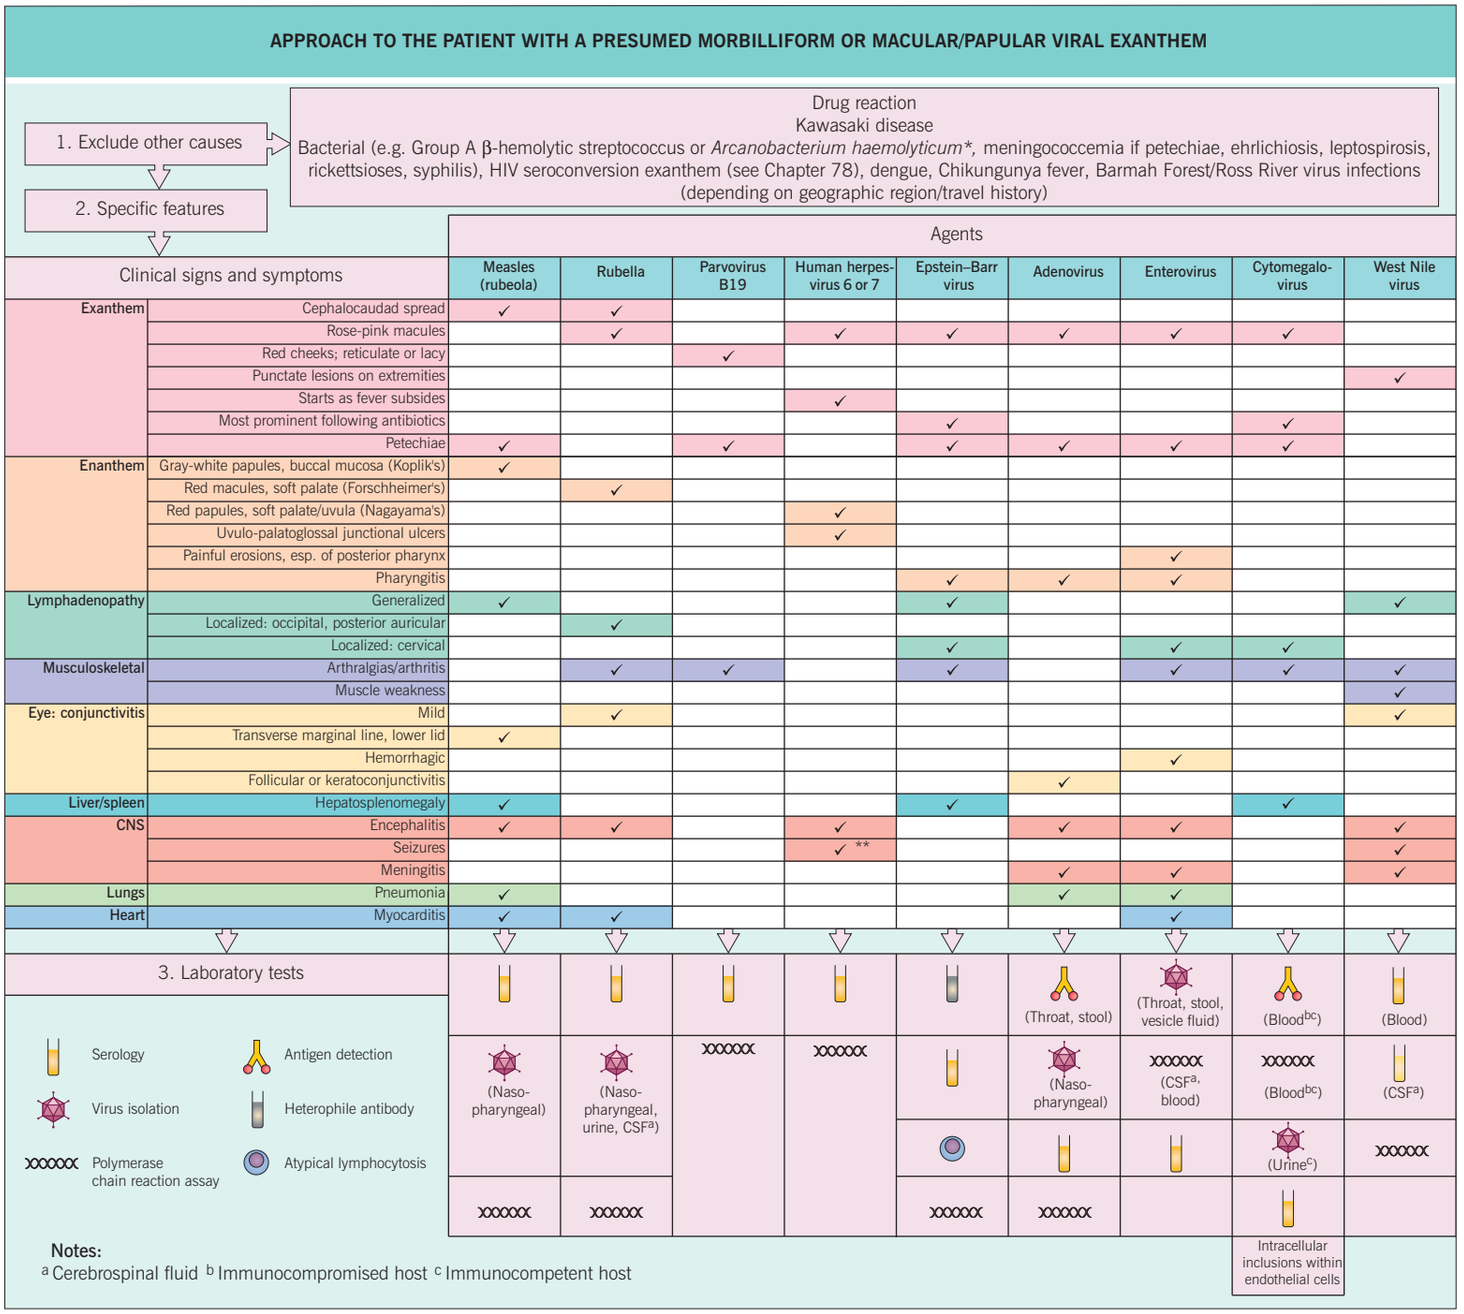

Fig. 81.2 Approach to the patient with a presumed morbilliform or macular/papular viral exanthem. *Gram-positive rod; may result in severe pharyngitis and scarlatiniform exanthem in adolescents and young adults. **Usually febrile seizures.

would be desirable, in many instances it is not necessary or clinically feasible. Figure 81.2 outlines the clinical features to be considered when evaluating the patient with a morbilliform ("maculopapular") viral exanthem, highlighting similar and different aspects of various etiologies. Diagnostic considerations in patients presenting with fever and a "rash" are listed in Figure 0.10.

ENTEROVIRUS INFECTIONS

Key features

- Most common in summer and fall
- Exanthems include erythematous, vesicular and petechial types
- Meningitis and encephalitis possible

Introduction

The enteroviruses, a subgroup of the picornavirus family, cause a wide array of illnesses associated with exanthems. The non-polio enteroviruses include echoviruses and coxsackievirus types A and B, with a total of 64 serotypes. These viruses consist of a single-stranded RNA genome with an unenveloped capsid.

Epidemiology

Enteroviral infections, a worldwide phenomenon, are usually transmitted human-to-human via fecal–oral or respiratory routes, and they can also be spread from mother to infant in the peripartum period. Exposure to virus in fecally contaminated water in swimming pools or via ingestion of oysters may be responsible for some infections. Clinical attack rates are highest in young children, and infections occur more frequently in lower socioeconomic groups. In temperate climates, infections are most common in the summer and fall. The usual incubation period is 3–6 days.

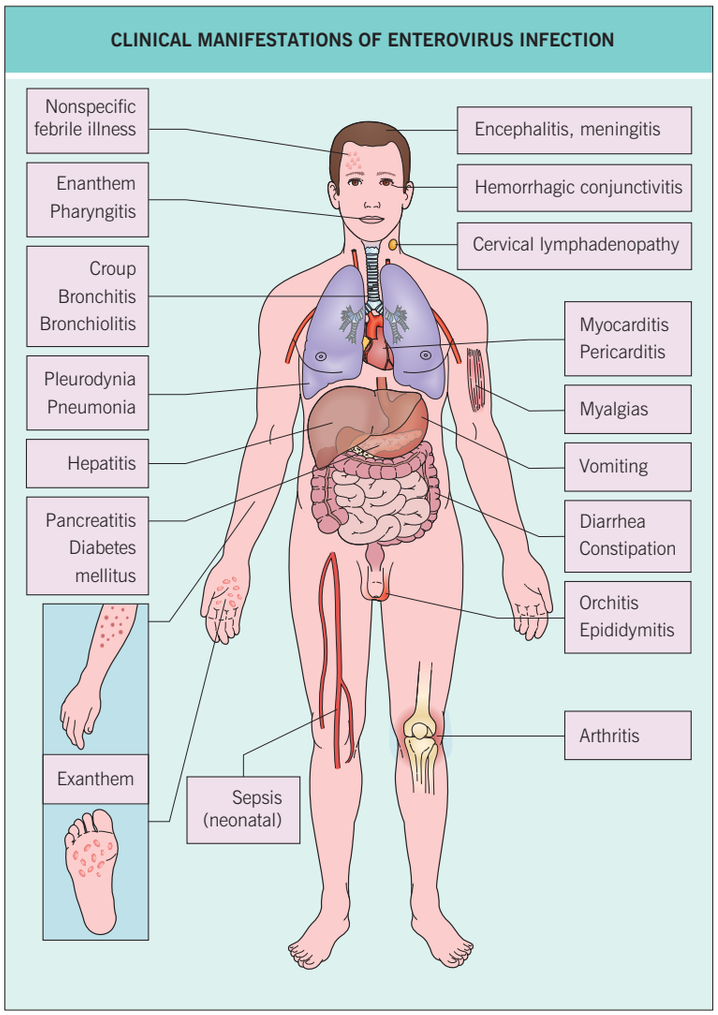

Fig. 81.3 Clinical manifestations of enterovirus infection.

Fig. 81.4 Hand-foot-and-mouth disease. Note the oval vesicle and erythematous macules on the plantar surface. *Courtesy, Julie V Schaffer, MD.*

Pathogenesis

Enteroviruses infect epithelial surfaces of the pharynx and lower alimentary tract. They then replicate in lymphoid tissues and disseminate via an initial minor viremia. Subsequently, replication may occur at multiple anatomic sites, including the CNS, heart, liver, adrenals, respiratory tract, skin and mucous membranes[1]. This replication correlates with the appearance of clinical symptoms. A major viremia occurs during the period of viral multiplication in the secondary infection sites.

Clinical Features and Differential Diagnosis

Figure 81.3 depicts the potential clinical manifestations of an enteroviral infection.

The most common and well-recognized exanthematous illness due to enteroviruses is *hand-foot-and-mouth disease* (HFMD). This disorder is characterized by a vesicular eruption on the palms and soles (Fig. 81.4) in conjunction with an erosive stomatitis. The dorsal aspect of the hands and feet may be involved as well as the buttocks and perineum; oral lesions are most common on the tongue, buccal mucosa, palate, uvula and anterior tonsillar pillars. Onychomadesis occasionally occurs following HFMD as a consequence of temporary nail matrix arrest related to the viral infection[2].

Patients with HFMD often present with fever and malaise, and they may have a mild prodrome prior to the onset of the exanthem. Numerous coxsackievirus serotypes have been implicated, most commonly type A16. Although HFMD generally runs a benign and self-limited course, since 1998 there have been multiple outbreaks of severe enterovirus 71 infection in the Asia-Pacific region, which have resulted in cardiopulmonary and neurologic complications and even deaths in affected individuals (primarily young children)[3].

Herpangina is a febrile illness, primarily of children 3–10 years of age, characterized by painful vesicles and erosions on the soft palate, uvula, tonsils, pharynx and buccal mucosa. An exanthem is usually absent. Coxsackievirus groups A and B, as well as echoviruses, are the usual pathogens.

In addition to the highly characteristic presentations of HFMD and herpangina, enteroviruses cause a diverse spectrum of exanthems that may be morbilliform, rubelliform, roseola-like, urticarial, scarlatiniform, vesicular, pustular and petechial. The majority of enteroviral exanthems feature erythematous macules and papules in a widespread distribution. Petechiae are fairly common, especially with echovirus 9 infection, and may lead to consideration of a more serious infection such as meningococcemia. Non-polio enteroviruses often infect newborns, producing a nonspecific erythematous exanthem and additional features such as fever, gastroenteritis, hepatitis, pneumonia and meningoencephalitis[4,5].

In 1969, Cherry et al.[6] reported four children with fever and transient, spontaneously resolving vascular papules (with dilated blood vessels but no proliferative component histologically) in association with echovirus 25 or 32 infection. Subsequently, three more children with similar lesions were described; although etiologic confirmation was not pursued, the nomenclature *eruptive pseudoangiomatosis* was proposed[7]. Since that time, more than 50 additional cases have been reported (including adults as well as children), with documentation of the viral agent (enteroviruses > cytomegalovirus [CMV] or EBV) in a small subset.

While HFMD and herpangina are fairly straightforward clinical diagnoses, other less specific exanthematous illnesses due to enteroviruses may have a broad differential diagnosis. Important factors that may point to the etiology include the season, exposure history, geographic location, and clinical signs and symptoms.

Specific confirmation of enteroviral infection may be accomplished via the use of viral culture or polymerase chain reaction (PCR)-based assays. The viruses can be recovered from throat and stool swabs or from fluid from cutaneous vesicles. Enterovirus polymerase chain reaction (PCR) is most widely employed for cerebrospinal fluid samples. Serologic diagnosis is difficult due to the large number of different serotypes and the time delay, which make it clinically less useful. Table 81.1 lists types of serologic assays of antibody responses.

Pathology

Skin biopsy is generally not a useful diagnostic procedure in enteroviral infections. Histopathologic features of the vesicular lesions of HFMD include epidermal necrosis with intraepidermal vesicles, a lack of inclusion bodies or multinucleation, and a nonspecific dermal inflammatory infiltrate.

Treatment

For the majority of enteroviral exanthems, the course is self-limited, the prognosis is excellent, and supportive care suffices. However, in

SEROLOGIC ASSAYS OF ANTIBODY RESPONSES	
Assay	**Principle**
Neutralization	Visual read of infected cell monolayers incubated with test sera, looking for CPE inhibition
Radioimmunoassay (RIA)	Ab and Ag bind, then radiolabeled antiglobulin added, *or* radiolabeled Ag added and it binds Ab; radioactivity measured
Enzyme-linked immunosorbent assay (ELISA)	Microplates coated with Ag, serum and enzyme-labeled antiglobulin added, then enzyme substrate added and color change measured
Western blot	Ag mixture separated by electrophoresis, transferred to membrane, serum added and then labeled antiglobulin; seen as colored bands
Latex agglutination	Ag-coated latex particles incubated with serum, Ab agglutinates particles
Hemagglutination inhibition (HI)	Serially diluted test sera mixed with viral Ag, then animal erythrocytes added; inhibition of agglutination measured
Complement fixation	Ag added to serially diluted test sera; Ag–Ab complex binds complement, so the latter is unavailable for lysis of sheep erythrocytes in the presence of Ab to erythrocytes
Immunodiffusion	Ab and soluble Ags combine to produce visible lines of precipitate in a gel
Immunofluorescence	Test sera added to infected cell monolayer, then fluorescein-labeled anti-IgG Ab added; examined with fluorescence microscope

certain patient populations (e.g. immunosuppressed individuals or neonates), an enteroviral infection may be associated with potentially life-threatening complications. Pleconaril, a drug that interferes with enterovirus attachment and uncoating by binding to the protein capsid, has been demonstrated to be effective both *in vitro* and in clinical studies, and it holds promise as a specific antiviral therapy for serious enteroviral infections[8].

MEASLES

Synonym: ■ Rubeola

Key features

- Incidence greatly decreased with vaccination
- Prodrome of cough, coryza, conjunctivitis and Koplik spots
- Cephalocaudad spread of exanthem

Introduction and History

The incidence of measles has markedly decreased since the introduction of the live vaccine in 1963. Despite high vaccination coverage, measles outbreaks continue to occur in both high-income and low-income countries, and the disease is still regarded as a major health burden. Use of the vaccine is estimated to have reduced global measles morbidity and mortality by 74% and 85%, respectively, compared with the prevaccine era[9].

Epidemiology

The incubation period of measles, which is highly contagious and spread via respiratory droplets, is 10–14 days. In the prevaccine era, measles was endemic throughout the year in heavily populated areas, without regard to age or gender. During the 1989–1990 epidemic, reported measles cases in the US increased six- to ninefold (over the mean of 3000 cases diagnosed annually between 1985 and 1988). Target populations during that epidemic were unvaccinated children younger than 5 years of age from low-income families and vaccinated school-aged children who failed to develop immunity against the virus. Sixty percent of the reported deaths during this epidemic were among children younger than 5 years of age. These statistics highlighted the need for more than one dose of vaccine; as a result, a two-dose measles vaccine schedule was recommended in 1989, which greatly influenced the incidence of measles in the US[10]. Although the median number of cases of measles diagnosed annually in the US is now ~50, outbreaks still occur; for example, there were 118 cases reported to the Centers for Disease Control and Prevention (CDC) from January to May of 2011, most in unvaccinated children and adults exposed to infection "imported" from Europe (which had a concurrent outbreak) and Southeast Asia[11]. Such observations underscore the importance of sustained efforts at universal vaccination against measles.

Fig. 81.5 Measles. Pink macules and minimally elevated papules. *Courtesy, Louis A Fragola, Jr, MD.*

Pathogenesis

Measles is caused by an RNA virus in the Paramyxoviridae family, and humans are the natural host and reservoir of infection. The disease starts with replication of the virus within the epithelial cells of the respiratory tract, with subsequent spread to the lymphoid tissue and blood, resulting in viremia. The virus can then disseminate to internal organs, including the lungs, liver and gastrointestinal tract.

Clinical Features and Differential Diagnosis

Measles classically presents with a prodrome of fever, cough, nasal congestion and rhinoconjunctivitis. A pathognomonic enanthem, Koplik spots, appears during the prodrome and is composed of gray–white papules on the buccal mucosa. The exanthem develops over 2–4 days and consists of erythematous macules and papules that begin on the forehead, hairline and behind the ears and then spread in a cephalocaudad direction (Fig. 81.5). On the fifth day, the exanthem starts to fade in the same order as it appeared.

The differential diagnosis of measles includes other viral infections (e.g. with enteroviruses or EBV), a drug eruption and Kawasaki disease (see Fig. 81.2). In a series of measles–mumps–rubella (MMR)-vaccinated children with measles- and rubella-like illnesses, the etiologies included enteroviruses, parvovirus B19 and human herpesvirus-6 (HHV-6)[12].

Atypical measles (due to exposure to wild-type virus in the setting of partial immunity) has been reported in several groups, including recipients of killed measles vaccine (used from 1963 to 1968), those who failed vaccination, and immunocompromised individuals. It is characterized by high fevers, cough and pulmonary infiltrates that reflect immune complex deposition (related to non-protective, complement-fixing antibodies). Coryza and conjunctivitis are generally absent, and the exanthem is variable, potentially including vesicles, petechiae, purpura and acral edema.

Complications of measles include otitis, pneumonia, encephalitis and myocarditis. Subacute sclerosing panencephalitis is a delayed neurodegenerative disorder that can occur as a complication of measles many years after the acute disease. It is characterized by seizures, personality changes, coma and death. Laboratory diagnosis of measles can be accomplished by virus isolation or detection via reverse PCR (RT-PCR) in nasopharyngeal secretions (or urine) as well as serologic assays for measles-specific antibodies (IgM or IgG).

Pathology

The histopathologic findings include a superficial perivascular lymphocytic infiltrate together with variable spongiosis and dyskeratosis.

Treatment

There is no specific antiviral therapy for measles. Because low serum vitamin A levels are associated with increased measles-related morbidity and mortality, the World Health Organization (WHO) recommends vitamin A administration for all children with acute measles (daily for 2 days; 200 000 IU if ≥12 months, 100 000 IU if 6–11 months, 50 000 IU if <6 months).

Prevention of measles by vaccination is the most effective way to reduce measles morbidity and mortality. The current recommended measles immunization strategy is for an initial dose of vaccine at 12–15 months of age and a second dose at 4–6 years of age[13]. For unvaccinated individuals exposed to measles, administration of the vaccine within 3 days or intramuscular or intravenous immunoglobulin (IM/IVIg) within 6 days of the exposure may provide some protection.

RUBELLA

Synonym: ■ German measles

Key features

- Exanthem of rose-pink macules with cephalocaudad spread
- Tender lymphadenopathy (especially occipital, posterior auricular)
- Joint involvement common
- Fetal infection associated with multiple congenital anomalies

Introduction and History

Rubella is caused by an RNA virus in the Togaviridae family. Although usually a mild, self-limited disease in children and adults, it can cause major complications when transmitted to a fetus *in utero*, including miscarriage, stillbirth and severe congenital malformations.

Epidemiology

The disease is spread via respiratory droplets, with an incubation period of 16–18 days. The incidence of rubella has markedly declined since the licensure of the MMR vaccine in 1969. For example, in the US, the incidence of rubella has declined more than 98% (<15 cases reported to the CDC annually in the past decade). Rubella has a worldwide distribution and occurs most often in the spring.

Pathogenesis

The primary site of infection is the nasopharynx, followed by spread to regional lymph nodes and a subsequent viremia.

Clinical Features and Differential Diagnosis

Rubella typically presents with a mild prodrome that includes fever, headache and upper respiratory symptoms. In children, many cases are subclinical. One to 5 days following the prodrome, an eruption of erythematous macules and papules appears on the face, spreading in a cephalocaudad direction. Erythematous petechial macules may also be present on the soft palate (Forchheimer's spots). The eruption is often accompanied by tender lymphadenopathy, especially of the occipital, posterior auricular and cervical regions. The cutaneous eruption tends to fade in 2–3 days in the same order as it appeared.

Complications of rubella include arthralgias and arthritis (especially in postpubertal girls and women) and, less frequently, hepatitis, myocarditis, pericarditis, hemolytic anemia and thrombocytopenia. Encephalitis occurs in approximately 1 in 6000 cases[14].

Rubella can be diagnosed by detection of anti-rubella IgM antibodies or a fourfold increase in specific IgG antibodies; virus isolation or detection via RT-PCR (e.g. from a nasal wash, throat swab or urine) is also possible. The exanthem of rubella is fairly nonspecific and the differential diagnosis includes other viral exanthems (e.g. adenovirus, enterovirus, measles, EBV) and toxin-mediated eruptions such as scarlet fever. The occipital lymphadenopathy and the typical progression of the eruption can be helpful in diagnosing the disease.

Congenital rubella occurs when a nonimmune pregnant woman transfers the virus to the fetus. Birth defects occur most commonly following infection during the first 16 weeks of pregnancy. Congenital rubella syndrome is characterized by cataracts, deafness, congenital heart defects (patent ductus arteriosus, ventricular septal defects) and CNS abnormalities (microcephaly, developmental delay). A "blueberry muffin baby" presentation due to dermal hematopoiesis is occasionally observed (see Ch. 121).

Pathology

Reported histopathologic findings include a superficial perivascular infiltrate with mild spongiosis. Atypical lymphocytes may be evident in the cutaneous infiltrate as well as in peripheral blood.

Treatment

Treatment of rubella is supportive. The current recommended immunization schedule for rubella vaccine (given in conjunction with the measles and mumps vaccines) is for an initial dose at 12–15 months and a second dose at 4–6 years[13]. In a pregnant woman who has been exposed to rubella, serologic testing (IgG and IgM) should be performed. Prophylaxis via administration of IM/IVIg to rubella-susceptible women exposed to confirmed rubella early in pregnancy may be considered, but it does not reliably prevent fetal infection. If rubella-specific IgM antibodies or a diagnostic rise in IgG anti-rubella antibodies (the latter not useful following IM/IVIg administration) are detected, the patient should be offered prenatal counseling.

ERYTHEMA INFECTIOSUM

Synonyms: ■ Fifth disease ■ "Slapped cheek" disease ■ Parvovirus B19 infection

Key features

- "Slapped cheeks" followed by lacy extremity-predominant eruption
- Marked affinity of parvovirus B19 for erythrocyte precursors
- Fetal infection may result in anemia, fetal hydrops or death

Introduction and History

Human parvovirus B19 (B19), the only parvovirus known to infect humans, was accidentally discovered in 1975 by Yvonne Cossart and colleagues, who were screening blood samples for hepatitis B virus. The small, single-stranded DNA virus, which was named after the panel of sera in which it was found (number 19, row B), was identified as the etiology of erythema infectiosum in 1983. Subsequent elucidation of the pathogenesis of human B19 infections has led to its association (both definitive and proposed) with a wide variety of clinical findings (Table 81.2).

PARVOVIRUS B19 CLINICAL ASSOCIATIONS
ESTABLISHED ASSOCIATIONS
Asymptomatic infection
Erythema infectiosum
Arthropathy
Hydrops fetalis
Papular-purpuric gloves and socks syndrome
Petechial eruptions in generalized, bathing trunk and acral + perioral distributions
Degos-like lesions
Transient aplastic crises in at-risk individuals*
Chronic anemia
Thrombocytopenic purpura
Hepatitis
POSSIBLE ASSOCIATIONS
Vasculitides: • Small vessel vasculitis • Henoch–Schönlein purpura • Polyarteritis nodosa • Wegener's granulomatosis
Neurologic disease
Chronic fatigue syndrome
Systemic lupus erythematosus-like illness
Unilateral laterothoracic exanthem
Hemophagocytic lymphohistiocytosis
*Patients suffering from decreased red cell production (e.g. iron deficiency, thalassemias) or increased red cell destruction (e.g. sickle cell anemia, hereditary spherocytosis, pyruvate kinase deficiency, glucose-6-phosphate dehydrogenase deficiency), as well as patients with HIV infection and recipients of allogeneic hematopoietic stem cell or solid organ transplants.

Table 81.2 Parvovirus B19 clinical associations.

Epidemiology

Infection with B19 occurs in a seasonal pattern, with a peak incidence of erythema infectiosum during the winter and spring. Transmission is via respiratory secretions, blood products, and vertically from a mother to her fetus, and the incubation period is between 4 and 14 days. B19 infection occurs worldwide and is most common in school-aged children. A cyclical pattern of epidemics of B19 infection seems to exist, with peaks about every 6 years[15] and individual community epidemics lasting 3–6 months. The seroprevalence of B19 antibodies increases in direct proportion with age, such that 2–15% of children 1–5 years of age are immune, 15–60% of those between 5 and 19 years, and 30–80% of adults.

Pathogenesis

B19 has a strong tropism for erythroid progenitor cells, and the erythrocyte "P antigen" (globoside) is the cellular receptor to which the virus binds. In fact, individuals who lack the P antigen (blood group P_1^k or p phenotypes) seem to be naturally resistant to B19 infection[16].

After initial infection of the respiratory tract, a B19 viremia occurs, ending at the time of the appearance of anti-B19 IgM antibody (around 8–10 days post inoculation; Fig. 81.6). During the period of viremia, a reticulocytopenia occurs, lasting 7–10 days[15]. One week after the appearance of IgM antibody, anti-B19 IgG appears and coincides with the appearance of the rash and arthralgia. An immune-mediated process is suggested by the temporal disconnect between the viremia and the clinical symptoms.

The anemia and reticulocytopenia tend to be inconsequential in the normal host but may result in transient aplastic crises or pancytopenia in at-risk individuals, such as those with disorders resulting in enhanced red blood cell destruction or decreased production (see Table 81.2). Fetal infection from intrauterine virus transmission causes fetal anemia of varying severity (see below).

Clinical Features and Differential Diagnosis

The most common illness caused by B19 infection is erythema infectiosum, which is most common in children between 4 and 10 years of age. Mild prodromal symptoms (e.g. low-grade fever, myalgias, headache) may occur 7–10 days before the characteristic exanthem appears. The initial stage of the exanthem consists of bright red macular erythema of the cheeks, with sparing of the nasal bridge and circumoral regions (Fig. 81.7A). One to 4 days later, the second stage appears in the form of erythematous macules and papules on the extremities and (to a lesser extent) the trunk, progressing to a lacy, reticulated pattern (Fig. 81.7B,C). This exanthem typically lasts from 1 to 3 weeks (occasionally longer) but fluctuates in intensity during this time, often with exacerbations upon exposure to sunlight or overheating. The differential diagnosis of erythema infectiosum may include scarlet fever, enteroviral infection and rubella, but the diagnosis is usually straightforward when the characteristic eruption is present. Although the evanescent exanthem of systemic-onset juvenile idiopathic arthritis (Still's disease) is also accentuated by heat, it is accompanied by episodic high fevers, has a more chronic course and often exhibits the Koebner phenomenon.

Arthralgia or arthritis occurs in up to 10% of patients with erythema infectiosum and is usually self-limited (typically resolving in 1–3 weeks but sometimes lasting for months). It tends to affect the small joints of the hands as well as the wrists, knees and ankles. Joint involvement related to B19 infection is more common in adults, especially women, occurring in up to 30–60% of those with acute infection[17]. Arthropathy may be seen without an accompanying exanthem.

The manifestations of fetal B19 infection range from self-limited anemia to hydrops, spontaneous miscarriage or stillbirth. The greatest susceptibility is associated with infections acquired before 20 weeks' gestation, and most fetal losses occur between 20 and 28 weeks' gestation. Third-trimester fetal demise may also occur, but it is less often associated with fetal hydrops[18]. The overall risk of fetal loss in the setting of acute B19 infection during pregnancy is 2–6%[19–21]. However, the majority of infants born to B19-infected mothers are delivered asymptomatic at term. There is no evidence for long-term neurodevelopmental sequelae for surviving infected infants, and congenital malformations have not been conclusively demonstrated.

A distinctive syndrome of painful erythema, petechiae and purpura involving the palms and soles was first described in 1990 by Harms et al[22]. Papular-purpuric gloves and socks syndrome (PPGSS) was subsequently demonstrated to be associated with acute B19 infection, although other infectious etiologies have also been reported (e.g. coxsackievirus B6, HHV-6). This syndrome is most often observed in the spring and may occur at any age (including children), but it has a predilection for young adults. The hallmark findings are edema and erythema of the palms and soles in association with petechiae and purpura (Fig. 81.8), with occasional extension onto the dorsal surfaces. Patients may complain of burning and pruritus. Additional manifestations can include an enanthem of erosions and petechiae involving the palate, pharynx and tongue, as well as fever and mild prodromal symptoms. Therapy is symptomatic, and spontaneous resolution occurs over 1–2 weeks. Although few studies have addressed the immune response in PPGSS, based on limited data it appears that patients develop the mucocutaneous lesions while still viremic, which implies contagiousness and therefore has different epidemiologic implications than the classic eruption of erythema infectiosum.

When diagnostic confirmation of B19 infection is indicated, detection of serum anti-B19 IgM antibody is the preferred method, and its presence indicates infection within the previous 2–4 months. PCR-based assays are especially useful for diagnosing infection in the immunocompromised host.

Pathology

Skin biopsy is generally not useful in the diagnosis of B19 infections. In patients with PPGSS, histologic evaluation has revealed a lymphocytic dermal infiltrate and positive staining of dermal blood vessel endothelial cells and epidermal keratinocytes with anti-B19 antibodies.

Treatment

No specific antiviral therapy is available for B19 infections. Children with erythema infectiosum usually feel quite well and often require no treatment. Nonsteroidal anti-inflammatory drugs are useful if symptomatic arthropathy is present. Predisposed patients with aplastic crisis

may require red blood cell transfusions. Pregnant women with confirmed primary B19 infection during the first two trimesters should undergo serial fetal ultrasonography, and management of severely affected fetuses is possible with *in utero* transfusions and other interventions such as digoxin therapy.

ROSEOLA INFANTUM

Synonyms: ■ Exanthem subitum ■ Sixth disease

Key features

- High fever followed by an exanthem at defervescence
- Affects primarily infants and toddlers
- Febrile seizures possible

Roseola infantum is a common febrile illness of infancy that is primarily caused by human herpesvirus-6 (HHV-6) infection (and occasionally associated with human herpesvirus-7 infection [HHV-7]) (see Ch. 80). The majority of cases occur between 6 months (when levels of protective maternal antibodies wane) and 3 years of age, with a peak incidence at age 6–12 months. Between 40% and 80% of children are seropositive for HHV-6 by 13 months of life[23,24], and the vast majority of the remainder by 3 years; however, less than a third of infections result in the classic clinical manifestations of roseola infantum. Roseola infantum may occur at any time during the year but is most common in the spring. The incubation period of HHV-6 is usually 9–10 days.

This common disorder is characterized by a high fever (to 40–40.5°C; 104–105°F) for 3–5 days in an infant who otherwise appears well. Seizures occur during the febrile period in up to 10% of patients. Defervescence is then accompanied by the appearance of rose-pink macules and papules on the trunk, neck, proximal extremities and occasionally the face. Mild upper respiratory symptoms, injection of the tympanic membranes, cervical or occipital lymphadenopathy, edematous eyelids and a bulging anterior fontanelle may also be present. An enanthem of red papules on the soft palate and uvula (Nagayama spots) can develop, and uvular and palatoglossal junctional ulcers represent a characteristic finding[25]. The skin eruption fades over a few days, and, in the majority of cases, patients do well with no sequelae. A substantial proportion of nonspecific fevers or fever with otitis media in infants may also be due to HHV-6 infection.

Additional pathogenic features and clinical manifestations of HHV-6 infection, including reactivation in the settings of immunosuppression and drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome, are discussed in Chapter 80.

UNILATERAL LATEROTHORACIC EXANTHEM

Synonym: ■ Asymmetric periflexural exanthem of childhood

Key features

- Initial unilateral distribution, most often affecting the axilla and lateral trunk
- Subsequent generalization, but maintains unilateral predominance
- Spontaneous resolution over 3–6 weeks
- Presumed to be viral in etiology, although exact cause unknown

Introduction and History

Unilateral laterothoracic exanthem (ULTE) was first described in 1962[26]. This papular exanthem of childhood is initially characterized by a unilateral periflexural (often axillary) location, with lesions spreading in a centrifugal pattern to the contralateral side as the disease progresses. The term "unilateral laterothoracic exanthem" was first introduced in 1992 based upon observations in a series of 18 children[27].

Epidemiology

ULTE occurs most commonly in toddlers and preschool-aged children, with an age range of 6 months to 10 years. The male to female ratio is 1:2, and most of the reported patients have been Caucasian. The disease is widespread in Europe and North America, and the majority of cases occur in the spring.

Pathogenesis

The etiology of ULTE remains unknown despite multiple attempts to identify a causative infectious agent. The seasonal pattern, associated prodrome, reports of familial cases and lack of response to systemic antibiotics suggest a viral etiology. In some published studies in which screening for multiple viruses (e.g. EBV, CMV, HHV-6, HHV-7 and others) was performed, no etiologic agent has been consistently demonstrated. A relationship to infection with *Spiroplasma*, parvovirus B19 and EBV has been suggested in individual cases[28,29].

Clinical Features and Differential Diagnosis

The eruption typically begins with a unilateral distribution (Fig. 81.9), most commonly in the axillary region, followed in frequency by the

Fig. 81.9 Unilateral laterothoracic exanthem. Erythematous macules and papules involving the left axilla and upper flank (**A**) and a slightly more extensive distribution on the left lateral trunk (**B**).

trunk, arm and thigh. It is usually morbilliform or eczematous in nature and tends to spread to contralateral areas but maintains a unilateral predominance.

The exanthem may be preceded by an upper respiratory or gastrointestinal prodrome. Mild fever, diarrhea, and/or rhinitis are noted in up to 60% of patients, and pruritus is reported in up to two-thirds of cases. Lymphadenopathy may also be present. The disease lasts 3–6 weeks and then resolves spontaneously, usually without recurrence.

The differential diagnosis includes contact dermatitis (the most common initial misdiagnosis), a nonspecific viral exanthem, a drug eruption, atypical pityriasis rosea, scabies, miliaria, tinea corporis and (if there is prominent involvement of the extremities) Gianotti–Crosti syndrome. An eczematous eruption with a distribution pattern similar to ULTE can occur in association with molluscum contagiosum in the same sites. Laboratory evaluation is generally unnecessary.

Pathology

Histologic features are nonspecific and include a superficial perivascular infiltrate that is predominantly lymphocytic, mild spongiosis, and exocytosis of lymphocytes into the epidermis. The dermal infiltrate may be accentuated around eccrine ducts.

Treatment

Supportive treatment is indicated in symptomatic patients, although topical corticosteroids tend to be of minimal help. Parents should be reassured that the exanthem will resolve spontaneously in about 3–6 weeks.

GIANOTTI–CROSTI SYNDROME

Synonyms: ■ Papular acrodermatitis of childhood ■ Papulovesicular acrolocated syndrome

Key features

- Symmetric papular eruption on the extremities, face and buttocks
- EBV represents the most common etiology
- Association with hepatitis B virus in some patients

Introduction and History

Gianotti–Crosti syndrome was first described by Gianotti in 1955 and by Gianotti and Crosti in 1956. This condition is characterized by the acute onset of a symmetric papular eruption localized to the face, extremities and buttocks, and it occurs primarily in children. In 1964, Gianotti and Crosti reported the coexistence of anicteric hepatitis and Gianotti–Crosti syndrome, and in the 1970s an association with hepatitis B virus was described by several groups. However, subsequent reports demonstrated that Gianotti–Crosti syndrome can be associated with a variety of viral triggers (Table 81.3).

"Papulovesicular acrolocated syndrome" was the term used by Gianotti in 1985 to distinguish a more vesicular variant that is characterized by a lack of hepatitis, greater degree of pruritus and more prolonged course[30]. Subsequent reports have suggested that differences in clinical manifestations are more likely related to host characteristics than to the etiologic agent[31], and "Gianotti–Crosti syndrome" is currently the most widely accepted nomenclature.

Epidemiology

Gianotti–Crosti syndrome has a worldwide distribution and occurs most often in young children. In one large series of patients, the age range was between 6 months and 14 years, with a mean age of 2 years[31]. It most commonly occurs in spring and early summer.

Pathogenesis

Gianotti–Crosti syndrome is regarded as a self-limited cutaneous response to various infections. Hepatitis B virus and EBV are the most frequently reported etiologic agents, with EBV being by far the most common cause in the US. Other potential etiologic associations are summarized in Table 81.3. Although the pathogenic mechanisms at play in Gianotti–Crosti syndrome are not clear, there is some suggestion that immunizations or immune imbalance may enhance the risk of developing the exanthem following certain infections.

Clinical Features and Differential Diagnosis

Gianotti–Crosti syndrome is often preceded by an upper respiratory syndrome with mild constitutional symptoms. The exanthem begins abruptly, with monomorphic, skin-colored to pink–red, edematous papules that are symmetrically distributed on the face, buttocks and extensor surfaces of the extremities (Fig. 81.10). In some patients, lesions may be limited to the face[32]. The trunk is usually spared, although some extension onto the trunk does not exclude the diagnosis[33]. Lesions tend to be asymptomatic and may occasionally be

*Reported most commonly in Europe. †Most common cause in US.

Table 81.3 Potential etiologies reported in association with Gianotti–Crosti syndrome. A pruritic Gianotti–Crosti syndrome-like eruption can also occur in patients with molluscum contagiosum.

Fig. 81.10 Gianotti–Crosti syndrome. **A** Monomorphic erythematous papules on the thigh. **B** A more exuberant eruption of coalescing edematous, erythematous papules on the thighs and knees.

vesicular or purpuric. Systemic manifestations include a low-grade fever and lymphadenopathy (mainly inguinal and axillary) that can persist for a few months; hepatomegaly and splenomegaly occur less often.

The differential diagnosis of Gianotti–Crosti syndrome may include a drug eruption, papular urticaria, other viral exanthems, erythema multiforme and molluscum contagiosum. An inflammatory response to molluscum contagiosum (often heralding clearance of the lesions) can present with an eruption of monomorphic erythematous papules that favor the elbows and knees; this "id" reaction-like phenomenon can resemble Gianotti–Crosti syndrome but tends to be extremely pruritic and to respond to treatment with topical corticosteroids.

Pathology

The histopathologic findings are nonspecific and include acanthosis, hyperkeratosis and a lymphohistiocytic perivascular infiltrate in the dermis with dilation of dermal capillaries. A lichenoid pattern has also been reported[34], as have marked papillary edema and increased numbers of cytotoxic T lymphocytes in the dermal infiltrate[35]. It has been suggested that the variety of histologic findings reflects the diversity of agents that may cause the condition.

Treatment

The treatment for Gianotti–Crosti syndrome is supportive, although topical corticosteroids are often of little benefit. A thorough history and physical examination should be performed, and laboratory tests for hepatitis or specific viral agents (e.g. hepatitis B virus, EBV) should only be obtained if clinically indicated. Spontaneous resolution usually occurs within 3–4 weeks, although the eruption may occasionally persist for up to 8 weeks.

POXVIRUS INFECTIONS

Key features

- The world was declared free from smallpox in 1980
- Molluscum contagiosum represents the most common poxvirus infection in humans

The family Poxviridae are large, brick- or ovoid-shaped, double-stranded DNA viruses that are characterized by cytoplasmic replication. Diseases caused by poxviruses include smallpox, vaccinia, cowpox, monkeypox, tanapox, orf, milker's nodules and molluscum contagiosum (Table 81.4). The most historically significant of these was smallpox, which at one time was endemic throughout the world and responsible for millions of human deaths. The last epidemic of smallpox in the US was in 1949, and in 1980, the World Health Assembly declared the world free from smallpox. However, two reference collections remain (one in the US, one in Russia), and fears have been expressed that smallpox could be exploited for bioterrorism. The infection that has clinical features most similar to smallpox is varicella; a comparison of these two conditions is provided in Table 81.5.

Because of concerns about smallpox being used as a bioterrorism agent[42,43], extensive recommendations have been adopted for handling of a suspected outbreak (*www.bt.cdc.gov/agent/smallpox/*). The current strategy is known as ring vaccination, and it involves isolation of patients with suspected infection and immunization of all identified contacts (as well as their contacts). If given within 3 to 4 days following exposure, smallpox vaccination may prevent or minimize the severity of disease. All first responders and healthcare workers who come into contact with a suspected patient should be prior vaccinees[44].

SELECTED POXVIRUS INFECTIONS

Disease	Virus/genus	Host	Clinical findings	Treatment	Comment
Smallpox	Variola/ Orthopoxvirus	Humans	*Major criteria** • Febrile prodrome (>101°F[†], 1–4 days prior to rash onset with headache, backache or abdominal pain) • Firm, deep-seated, well-circumscribed vesicles/pustules • Lesions in the same stage of development in any one area of the body *Minor criteria* • Centrifugal distribution[‡] • First lesions in the pharynx, oral mucosa • Patient appears "toxic" • Slow evolution of rash (i.e. 1–2 days for each stage: macule, papule, vesicle) • Lesions on the palms and soles See Table 81.5 for additional findings	Supportive; prophylaxis with vaccination	• Enters via respiratory tract • Incubation period – 7 to 17 days • Variola major = severe form with high mortality rate; variola minor (alastrim) = mild form • Complications: panophthalmitis, blindness, arthritis, encephalitis • Usual causes of death: toxemia, immune complex deposition, hypotension • High risk of smallpox – 3 major criteria; moderate risk – febrile prodrome + *either* 1 other major criterion *or* ≥4 minor criteria; low risk – no febrile prodrome or febrile prodrome + <4 minor criteria • Laboratory diagnosis: variola real-time PCR (+), orthopox real-time PCR (+), non-variola orthopoxvirus real-time PCR (–), EM (if available), viral culture (acceptable specimens: vesicular "touch prep", vesicle roof, vesicular swab, biopsy tissue) • Theoretically eradicated; potential use as bioterrorism agent
Vaccinia	Vaccinia/ Orthopoxvirus	Humans	• Papule at the vaccination site (usually deltoid or thigh) develops into vesiculopustules, then crust (Fig. 81.11A) • Occasionally, satellite lesions • Lymphadenopathy, fever, malaise common	Supportive; heals with pitted scar	• Used for smallpox vaccination (historically, general population; nowadays, military and first responders, including healthcare workers) • New live vaccine (ACAM2000™) from a single purified isolate of the previous vaccine (Dryvax®; last manufactured in 1978) that is aseptically propagated in cell culture began to be utilized in 2008 (with >200 million doses in the US Strategic National Stockpile) • Possible adverse events[§]: – superinfection of the vaccination site or regional lymph nodes – inadvertent autoinoculation (non-ocular) – contact transmission (non-ocular) – ocular vaccinia – generalized vaccinia (more severe in immunocompromised hosts) – eczema vaccinatum (atopic dermatitis, Darier disease) (Fig. 81.11B) – postvaccination non-viral pustulosis – progressive vaccinia (immunocompromised hosts) – erythema multiforme (Fig. 81.11C), Stevens–Johnson syndrome – fetal vaccinia – postvaccinial CNS disease – myo/pericarditis – dilated cardiomyopathy (controversial) • Additional cutaneous findings that can develop 1–3 weeks post vaccination include urticarial and exanthematous eruptions lasting 4–15 and 7–20 days, respectively • Laboratory diagnosis: variola real-time PCR (–), orthopox real-time PCR (+), non-variola orthopoxvirus real-time PCR (+), viral culture (acceptable specimens: same as for smallpox)
Monkeypox	Monkeypox/ Orthopoxvirus	Monkeys (especially captive), rodents, humans	• Malaise, fever and flu-like symptoms precede eruption • Number of lesions varies from a few to >100 • Papules progress to vesiculopustules then crust • Various stages may be present simultaneously • Usually has a centrifugal distribution[‡]; often involving the palms and soles • Lymphadenopathy and respiratory symptoms common	Supportive; post-exposure smallpox vaccination; cidofovir for severe cases; usually | self-limited course; lesions heal with scarring	• Primarily in Africa • Acquired via cutaneous inoculation or inhalation (human-to-human may be possible)[36,37] • Incubation period – approx. 10–12 days • Outbreak in US in 2003 due to human contact with infected prairie dogs exposed to an infected Gambian giant rat from Ghana[38] • Laboratory diagnosis: variola real-time PCR (–), orthopox real-time PCR (+), viral culture (acceptable specimens: same as for smallpox) • Smallpox vaccination protective

SELECTED POXVIRUS INFECTIONS					
Disease	**Virus/genus**	**Host**	**Clinical findings**	**Treatment**	**Comment**
Cowpox	Cowpox/ Orthopoxvirus	Cattle (now a rare host), cats, rodents, humans	• Painful papule at site of contact with lesions on infected animals (usually cats) • Hands and face most common sites of involvement • Erythematous, edematous papule rapidly becomes vesicular, pustular, then hemorrhagic • Progresses to ulcer with crust and eschar • Lymphadenopathy, fever and flu-like symptoms	Supportive; heals over 4 weeks with scarring; scars often large and depressed	• Primarily in Europe and Central Asia • Less common than orf or milker's nodule • May be transmitted by cats with subclinical infections • Incubation period – 7 days • Occasionally severe disease, including generalized eruptions in patients with atopic dermatitis
Orf (ecthyma contagiosum, sore mouth disease, scabby mouth disease, contagious pustular dermatosis, infectious pustular dermatitis)	Orf/ Parapoxvirus	Sheep, goats, reindeer, humans	• Papules (1 to few) on hands (Fig. 81.12A) at sites of contact with infected animals (lesions favor perioral area and udders of ewes), carcasses or fomites (e.g. fences, barn doors) • Progression through several stages: – maculopapular – targetoid – weeping nodule – regenerative dry stage with black dots – papillomatosis – regression with a dry crust • May be accompanied by lymphangitis, lymphadenopathy, malaise, fever	Supportive; topical imiquimod may stimulate early regression; usually heals without scarring	• Endemic in sheep and goats • At-risk occupations: shepherds, butchers, veterinary surgeons, sheepshearers • Histologic findings depend on stage of the lesion and include epidermal necrosis, vacuolated keratinocytes, a dense mixed dermal infiltrate, and delicate finger-like projections of the epidermis into the dermis; eosinophilic inclusion bodies (intracytoplasmic > intranuclear) (Fig. 81.12B) • Laboratory diagnosis: histologic examination of skin lesion ± EM; parapox real-time PCR (+), orf real-time PCR (+) • Erythema multiforme occasionally occurs 10 to 14 days later
Milker's nodules (bovine papular stomatitis, pseudocowpox)	Paravaccinia/ Parapoxvirus	Cattle, humans	• Papule develops at site of contact with lesions on infected animals (e.g. muzzles of calves, teats of cows) • Often single lesions; favor hands and forearms • Cutaneous lesions virtually identical to orf	Supportive	• Endemic in cattle • At-risk occupations: dairy farmers, ranchers, butchers, veterinary surgeons • Laboratory diagnosis: histologic findings ± EM (see orf); parapox real-time PCR (+), paravaccinia real-time PCR (+)
Deer-associated parapoxvirus infection	Parapoxvirus	Deer, humans	• Friable violaceous nodule at site of non-healing cut obtained while field dressing a deer carcass • Single lesion on a finger • Fever following biopsy in one patient	Supportive	• Reported in deer hunters in the Eastern US[39] • Histologic findings include epidermal hyperplasia ± necrosis, intracytoplasmic eosinophilic inclusion bodies in keratinocytes, dilated vascular spaces with swollen endothelial cells, and variable lymphohistiocytic and neutrophilic infiltrates • Parapox real-time PCR (+)
Tanapox	Tanapox/ Yatapoxvirus	Non-human primates, humans	• Isolated skin lesion, usually on the leg • Macular, papular, pustular, ulcerative and crusted stages • Local swelling and lymphadenopathy common • Associated fever and flu-like symptoms	Supportive; heals over 6–8 weeks with scarring	• Endemic in equatorial Africa • Transmission to humans probably occurs via an arthropod vector, although direct transmission also possible[40]

Table 81.4 Selected poxvirus infections (cont'd). EM, electron microscopy.

With the eradication of smallpox, molluscum contagiosum (MC) became the only remaining poxvirus infection to specifically afflict humans. This disorder is caused by the MC virus (MCV), a member of the *Molluscipox* genus of Poxviridae. Two molecular subtypes of the virus, MCV I and MCV II, result in indistinguishable skin lesions[45]. MC is a common, self-limited condition in children. It also occurs in adults, usually as a sexually transmitted disease, and has been observed with increasing frequency in immunocompromised hosts, most notably HIV-infected individuals. Transmission is via skin-to-skin contact and, less commonly, fomites.

MC lesions are firm, umbilicated, pearly papules with a waxy surface. They can occur anywhere on the skin surface but are most common in skin folds (e.g. axillae, neck); on the lateral trunk, thighs and buttocks; and in the genital region (Fig. 81.13A); facial lesions can also occur and are often especially distressing to the patient (Fig. 81.13B). Widespread, large and occasionally deforming lesions may be seen in the setting of immunosuppression, particularly AIDS (see Ch. 78). An associated molluscum dermatitis is common (Fig. 81.13C), especially in children with atopic dermatitis. Inflammation of MC lesions can occur and signals the development of a host immune response (Fig. 81.13B–D). As noted above, an id reaction-like eruption of pruritic erythematous papules that favor the elbows and knees occasionally develops in conjunction with an inflammatory response to MC.

The differential diagnosis of MC may include appendageal tumors, verrucae, condylomata acuminata, basal cell carcinoma, juvenile xanthogranuloma, melanocytic nevi (especially Spitz nevi), papular granuloma

Fig. 81.11 Smallpox vaccine. A Crusted papule at the site of vaccination, 14 days following administration. **B** Eczema vaccinatum in a patient with atopic dermatitis. Spread from the vaccination site (arrow) to areas of eczema occurred due to the impaired skin barrier. **C** Erythema multiforme-like reaction associated with marked erythema and edema at the vaccination site. *B, C, Courtesy, Louis A Fragola, Jr, MD.*

annulare and pyogenic granuloma. In immunocompromised hosts, infectious processes such as cryptococcosis or histoplasmosis can mimic MC. Inflammatory reactions to molluscum may resemble nummular dermatitis, staphylococcal furunculosis, Gianotti–Crosti syndrome or ULTE. Histologic evaluation of an MC lesion reveals large, intracytoplasmic inclusion bodies (molluscum bodies or Henderson–Patterson bodies, Fig. 81.13E) within epidermal keratinocytes, which increase in size as they move toward the skin surface.

MC resolves spontaneously in immunocompetent children, with the time interval between onset and clearance of the lesions ranging from several months to several years. However, treatment may be requested when there are numerous or cosmetically significant lesions. Therapeutic options include curettage, manual expression, cryotherapy, chemovesicants, and topical agents such as keratolytics, imiquimod and cidofovir (Table 81.6). In children, application of cantharidin (see Ch. 129) is a safe and reasonably effective treatment that has the benefit of non-traumatic in-office application. However, it may require more visits than curettage[46]. Treatment of molluscum dermatitis with a topical corticosteroid may help to reduce associated pruritus and prevent autoinoculation from scratching.

VIRAL HEMORRHAGIC FEVERS, INCLUDING DENGUE

The hemorrhagic fevers are a group of zoonotic viral infections that range in severity from a mild, self-limited febrile illness to a severe, life-threatening disease. Cutaneous manifestations of the hemorrhagic fevers are nonspecific and include petechiae, purpura and mucosal hemorrhage. Patients with serious infections suffer from shock, bleeding and multiorgan failure, with a high mortality rate. Viral hemorrhagic fevers are most common in South America and Africa, although a worldwide distribution is seen with some of the agents. In the US, hantavirus can cause an illness marked by respiratory failure and

COMPARISON OF VARICELLA/DISSEMINATED ZOSTER TO SMALLPOX		
	Varicella/disseminated zoster	**Smallpox**
Prodrome	None or mild fever and malaise	Fever ≥101°F* for 1 to 4 days prior to onset of eruption, plus prostration, headache, chills, backache and/or gastroinestinal symptoms
Distribution of lesions	Face/scalp initially; trunk affected more than distal extremities May have an enanthem	Lesions concentrated on face and limbs; can progress to involve entire body surface Enanthem often precedes cutaneous eruption
Stage of lesions	Different stages (papules, vesicles, pustules) are seen simultaneously in any one area of the skin	Adjacent lesions are all at same stage of development (synchronous)
Type of lesions	Relatively superficial, with evolution from macules/papules to vesicles to pustules	Begin as papulovesicles and then become firm, deep-seated pustules with a tendency to confluence
Course	Lesions tend to appear in crops over a 3-day period	Lesions spread over 1–2 weeks, and crusting develops over 1 week
Scarring	Rare in uncomplicated cases	Common and marked

*38.3°C.

Continued

cardiovascular collapse, but thrombocytopenia is not as prominent a feature as in Old World hantavirus infections. Table 81.7 lists the epidemiologic characteristics of several of these disorders, while dengue is discussed separately below.

Dengue, including dengue hemorrhagic fever (DHF), is a febrile illness caused by the dengue virus, of which there are four distinct serotypes: DENV-1, -2, -3 and -4. These viruses are members of the Flaviviridae family, and infection is transmitted to humans by mosquitoes. In endemic areas (Fig. 81.14), the virus can be transmitted vertically (i.e. from mother to fetus)[47]. Epidemics may occur when the virus is introduced into a new geographic area by travelers.

Each of the four dengue viruses has a spectrum of manifestations ranging from asymptomatic infection to potentially lethal disease[48]. After an incubation period of 3–8 days, affected individuals develop a biphasic fever, headaches, myalgias, nausea, vomiting and retro-orbital pain. A cutaneous eruption is present in up to 50% of patients; it may be morbilliform or scarlatiniform, with some areas of sparing ("white islands in a sea of red"). Minor hemorrhagic manifestations can occur, including petechiae, epistaxis and gingival bleeding; severe hemorrhage is rare[49]. DHF, the more serious variant of this viral infection, may be more common following reinfection with a second serotype of the virus. Dengue shock syndrome (DSS) with cardiovascular collapse rarely occurs. The diagnosis of DHF or DSS can be confirmed by recovery of the virus in culture, serologic assays or PCR analysis. No specific therapy exists for dengue, but with intensive supportive care the mortality rate can be decreased to 1%[49].

WEST NILE VIRUS INFECTION

West Nile virus (WNV), a single-stranded RNA virus in the Flaviviridae family, is an enzoonotic agent most commonly found in Africa, Europe and Asia. It is transmitted among wild birds (especially crows, ravens and jays) by *Culex* mosquitos. In the past decade, outbreaks of human disease have occurred, and since 1999 there has been geographic expansion of the virus within the US; human cases have been reported in all of the contiguous states, with >1000 deaths to date[50–52]. Although transmitted primarily by mosquito bites, transmission can also occur via blood transfusions, solid organ transplantation, and possibly breastfeeding[53,54].

West Nile virus infection most commonly occurs between late spring and early fall, during periods of active mosquito feeding. Approximately 80% of infections are clinically asymptomatic. In symptomatic patients, manifestations include fever, headache, malaise, anorexia, nausea, vomiting, eye pain, lymphadenopathy, encephalitis, myalgias and muscle weakness; the latter can sometimes be quite severe. Older patients have a higher risk of developing more severe neurologic disease.

An exanthem occurs in up to 25% of patients with West Nile virus infection. It has been described as a nonspecific macular, papular and erythematous eruption[53]. Both predominance on the extremities and small punctate lesions have been described. The diagnosis is confirmed by serum or cerebrospinal fluid IgM ELISA. Treatment is supportive; preventive measures include reducing the number of vector mosquitoes and avoidance of mosquito bites.

TREATMENT OF MOLLUSCUM CONTAGIOSUM
NO THERAPY
Eventual spontaneous involution in immunocompetent patients Risks of spread (especially in atopic patients), associated dermatitis and pruritus
PHYSICAL MODALITIES
Cryotherapy (liquid nitrogen) (2) Curettage (1) Electrodesiccation (3) Manual extraction (3)
TOPICAL AND INTRALESIONAL THERAPY
Cantharidin (2) Cidofovir (2) Imiquimod (1) Podophyllotoxin (1) Potassium hydroxide 10% solution (2) Salicylic and lactic acids (2) Retinoids (3) Silver nitrate paste (2) Trichloroacetic acid (1) Candida antigen, intralesional (2) Interferon-α, intralesional (3)
LASER THERAPY
CO_2 (3) Pulsed dye (2)
SYSTEMIC THERAPY
Cidofovir (in HIV-infected patients) (3) Cimetidine (2) Griseofulvin (3) Antiretroviral therapy (in HIV-infected patients) (3) Interferon-α, subcutaneous (3)

Table 81.6 Treatment of molluscum contagiosum. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

CHIKUNGUNYA FEVER

Chikungunya fever is due to the chikungunya virus, a member of the Togaviridae family that has three genotypes (Asian, East African and West African). It is transmitted primarily by infected *Aedes aegypti* and *A. albopictus* mosquitoes. Of concern is the rising incidence and spread of this infection, especially in India, the islands of the Indian Ocean and Southeast Asia; outbreaks have also occurred in Italy and Africa. Like dengue fever, patients develop fever, headache, myalgias, nausea, vomiting and a rash, but there is no associated hemorrhagic component or shock syndrome. Cutaneous manifestations include morbilliform eruptions; acral or facial (sometimes localized to the nose) erythema and edema; genital, intertriginous and oral ulcers; and prominent postinflammatory hyperpigmentation on the face and extremities (including freckle-like macules, flagellate streaks and diffuse areas of involvement)[55]. Widespread vesiculobullous eruptions are common in infants and occasionally occur in older children and adults[56]. Severe low back pain and debilitating arthralgia are characteristic, and the latter may last for weeks to months. No specific treatment is available.

BARMAH FOREST AND ROSS RIVER VIRUS INFECTIONS

Like the chikungunya virus, Barmah Forest and Ross River viruses are members of the Togaviridae family that are transmitted to humans by *Aedes* mosquitoes[57,58]. Both Barmah Forest and Ross River virus infections are endemic in Australia. Patients present with fever, lethargy, myalgias and arthralgias. Arthritis represents a common feature of Ross River virus infection, whereas an exanthem is a more frequent manifestation of Barmah Forest virus infection (occurring in up to 90% of patients). The rash often begins with facial erythema and edema (especially of the nose and ears), which is followed by a macular,

EPIDEMIOLOGIC CHARACTERISTICS OF THE MOST IMPORTANT VIRAL HEMORRHAGIC FEVERS

maculopapular, vesicular or purpuric eruption in a widespread distribution on the trunk and extremities. The diagnosis of either condition can be made by detection of specific antibodies via ELISA.

RABIES

Rabies is an acute viral disease that involves the CNS, can affect all mammals, and is transmitted by infected secretions. Most human exposures to rabies are via the bite of an infected animal, usually dogs in low-income countries and insect-eating bats in the US[59]. The etiologic agent is a neurotropic RNA virus belonging to the genus *Lyssavirus*. Following a bite, virus is inoculated into muscle and subcutaneous tissues, where it replicates locally. It then invades peripheral nerves, where it travels to the CNS (Fig. 81.15); the mean incubation period is 30–90 days, but it varies considerably and is shorter for a large inoculum via bites/lacerations in the head/neck region. Clinical features include prodromal flu-like symptoms followed by acute neurologic findings, either encephalitic (including hypersalivation and hydrophobia) or paralytic[60]. Rabies is nearly uniformly fatal, with death occurring within a few days of symptom onset. The diagnosis is confirmed by detection of rabies virus antigen in corneal smears or nuchal skin or brain biopsy specimens; PCR studies of saliva, skin and cerebrospinal fluid can also be performed to detect rabies virus RNA[59]. Post-exposure prophylaxis (consisting of wound cleansing, vaccination and administration of rabies immune globulin) is recommended for individuals exposed to the virus, and pre-exposure vaccination is recommended for those at high risk of rabies exposure[61].

CUTANEOUS MANIFESTATIONS OF HEPATITIS A, B AND C INFECTION

Infections with hepatitis A, B and C viruses (especially the latter two) are associated with a variety of cutaneous manifestations. Infections with hepatitis A, an RNA enterovirus, occasionally lead to cutaneous findings such as panniculitis, urticaria and a scarlet fever-like exanthem[62], whereas infections with hepatitis B and C viruses have been linked to the entities listed in Table 81.8.

CUTANEOUS MANIFESTATIONS OF HEPATITIS B AND/OR C INFECTION	
Small vessel vasculitis (B, C)	Necrolytic acral erythema (C)
Cryoglobulinemic vasculitis (C>B)	Porphyria cutanea tarda (B, C)
Urticarial vasculitis (B, C)	Pruritus (B, C)
Polyarteritis nodosa (B [classic]>C)	Lichen planus – particularly erosive oral disease (C)
Livedo reticularis (C)	Sarcoidosis (with interferon and/or ribavirin therapy; C>B)
Serum sickness-like reaction (B, C)	Erythema multiforme (B, C)
Urticaria (B, C)	Erythema nodosum (B>C)
Gianotti–Crosti syndrome (B>C)	

Table 81.8 Cutaneous manifestations of hepatitis B and/or C infection.

VIRAL-ASSOCIATED TRICHODYSPLASIA OF IMMUNOSUPPRESSION

Synonyms: ■ "Cyclosporine-induced" folliculodystrophy ■ Follicular dystrophy of immunosuppression ■ Pilomatrix dysplasia ■ Trichodysplasia of immunosuppression ■ (Viral-associated) trichodysplasia spinulosa ■ Viral-associated trichodysplasia

Viral-associated trichodysplasia is an increasingly recognized entity that was first described in 1999[63] and subsequently found to be associated with a novel polyomavirus[64]. More than 20 cases have been reported to date, all occurring in solid organ transplant recipients receiving immunosuppressive medications or in patients undergoing chemotherapy for a leukemia or lymphoma. Affected individuals present with numerous erythematous to skin-colored papules with a central spiny

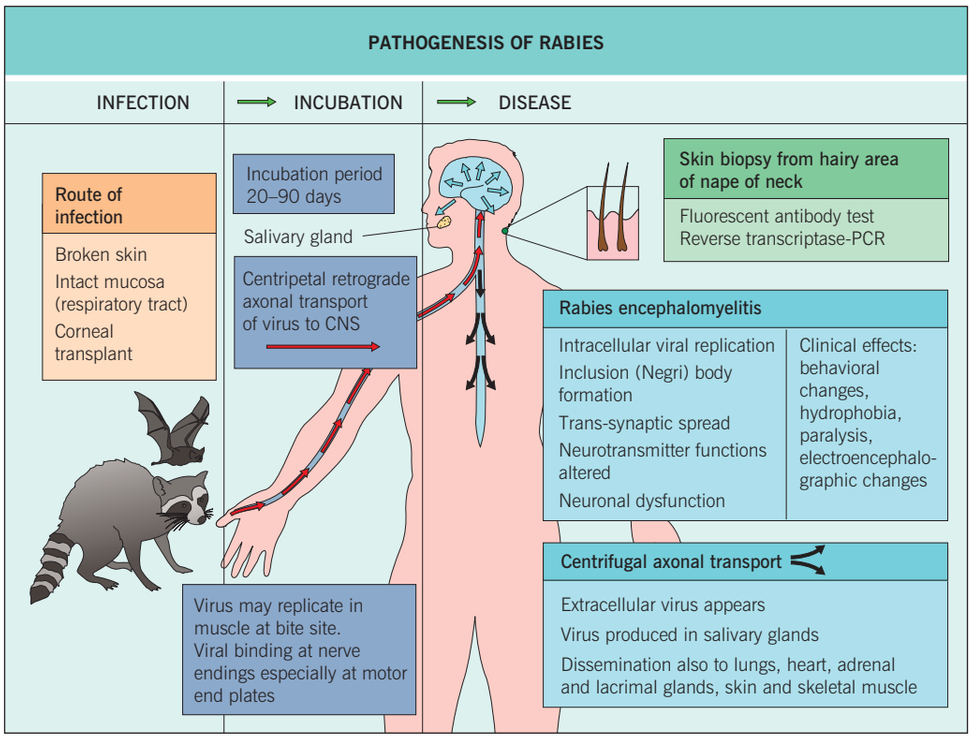

Fig. 81.15 Pathogenesis of rabies. *Reprinted from Cohen J, Powderly WG.Infectious Diseases, 2nd edn, 2004, Mosby, St Louis, with permission from Elsevier.*

projection on the face (especially the mid portion), ears, and (less often) extremities and trunk. Associated alopecia (of the eyebrows and eyelashes > other facial and body hair) and thickening of the skin resulting in a leonine appearance may also develop. Histologic evaluation shows distended follicles with abnormal maturation and a proliferation of nucleated eosinophilic cells with numerous large trichohyalin granules and abrupt inner root sheath-type cornification[65]. Electron microscopy demonstrates intranuclear icosahedral viral particles. The condition may improve following reduction or discontinuation of immunosuppressive medications, and successful treatment with topical cidofovir and oral valganciclovir has been described.

KAWASAKI DISEASE

Synonym: ■ Mucocutaneous lymph node syndrome

Key features

- Fever, conjunctival injection, oral mucosal changes, acral swelling and cervical lymphadenopathy
- Polymorphous exanthem, often with early perineal involvement
- Represents the most common cause of acquired heart disease in children in the US

Introduction and History

Kawasaki disease (KD) is an acute febrile multisystem disease that primarily affects children under 5 years of age. Initially described by Kawasaki in Japanese children[66], KD has subsequently been reported worldwide, and in the US it represents the leading cause of acquired heart disease in the pediatric population. Coronary artery aneurysms or ectasias develop in 15–25% of untreated KD patients, resulting in substantial morbidity and mortality. The clinical manifestations of KD can mimic a variety of other diseases, in particular viral exanthems, and the need to promptly treat KD in order to prevent potentially life-threatening complications makes differentiation among these entities essential.

Epidemiology

The peak incidence of KD is in children 2 years of age and younger, and 85% of patients with KD are <5 years of age; however, adults with KD have also been reported. The condition is 1.5 times more common in boys than in girls[67]. A peak incidence in late winter to early spring has been observed in North America. Epidemics have occurred in both Japan and the US and are characterized by a wave-like spread over a 2- to 4-year period[68]. KD is more common in children of Asian descent. Male gender and an age of <1 year or >6 years appear to be risk factors for the development of cardiovascular sequelae, which may be related to delayed diagnosis in the latter group[69].

Pathogenesis

The etiology of KD remains unknown, but several observations suggest an infectious cause, including the clinical features, seasonal variation in incidence, community outbreaks, rarity in infants under 6 months of age (who have potentially protective maternal antibodies), and infrequent recurrences[67]. However, conventional microbial cultures and serologic studies have failed to identify a causative agent. A pathogenic role for a bacterial toxin that acts as a superantigen has been hypothesized; although this remains unproven, it is supported by the increased prevalence of superantigen-encoded genes in the stool of KD patients compared to other febrile or healthy children[70].

In fatal cases of KD, IgA-producing plasma cells have been found in the coronary arteries, pancreas, kidney and upper respiratory tract; the latter finding is similar to that seen in children with fatal respiratory viral infections[71]. Oligoclonal KD antibodies synthesized *in vitro* have been shown to bind to cytoplasmic antigen in the proximal bronchial epithelium, coronary arteries and (in some tissues) macrophages of KD patients. Furthermore, electron microscopic studies have provided evidence of virus-like particles within intracellular inclusion bodies in the ciliated bronchial epithelium of patients with KD[72]. These findings are suggestive of a respiratory infectious agent with tropism for vascular tissue.

KD is characterized by marked activation of the immune system, with increased numbers of activated lymphocytes (both T and B) and mononuclear cells as well as increased levels of proinflammatory cytokines. A functional polymorphism in the inositol 1,4,5-trisphosphate 3-kinase C gene (*ITPKC*) has been shown to be significantly associated

with KD susceptibility and an increased risk of coronary artery lesions in children from the US and Japan. ITPKC acts as a negative regulator of T-cell activation through the nuclear factor of activated T cells (NFAT) signaling pathway, and the polymorphism (which reduces the efficiency of ITPKC splicing) may contribute to immune hyperreactivity in Kawasaki disease[73].

Clinical Features and Differential Diagnosis

The diagnostic criteria for KD include fever lasting at least 5 days plus the presence of four of the five following criteria:

- bilateral non-purulent conjunctival injection
- oropharyngeal changes including diffuse hyperemia, strawberry tongue and lip fissures
- cervical lymphadenopathy (usually unilateral)
- peripheral extremity changes including erythema, edema and (eventually) desquamation of the hands and feet
- a polymorphous exanthem.

The diagnosis of KD should be strongly considered in any child presenting with prolonged, unexplained fever in association with skin findings. The fever in KD is usually high-spiking (>39°C; 102°F), and it may not respond to antipyretics[67].

A cutaneous eruption is seen in >80% of patients with KD. It is usually composed of macular and papular erythematous lesions, often in a morbilliform pattern, but may also be erythema multiforme-like (Fig. 81.16A), urticarial, scarlatiniform or pustular. Vesiculobullous lesions, crusting and petechiae are all unusual in the exanthem of KD. In some patients, ulceration at the site of a bacillus Calmette-Guérin (BCG) vaccination has been observed during the course of the disease. A characteristic early cutaneous finding is erythema of the perineum, which often desquamates within 48 hours (Fig. 81.16A–C). Edema and brawny induration of the hands and feet are common early in the course of the disease (Fig. 81.6D), with eventual desquamation that is prominent in the periungual regions. Gangrene of the peripheral extremities occasionally occurs.

The conjunctival injection of KD is typically bulbar with sparing of the limbus (an avascular zone around the iris); it is not associated with increased tearing or an exudate. Keratitis and photophobia are uncommon and should suggest an alternative diagnosis. Oropharyngeal changes consist of dry, fissured lips, a "strawberry tongue" (Fig. 81.17) and (in some patients) diffuse hyperemia of the oral mucous membranes.

Cardiac involvement can include myocarditis, pericardial effusions, congestive heart failure and coronary aneurysms; the latter represent the source of greatest morbidity in KD. Valvular disease (usually mitral or aortic) may also occur. Tachycardia, murmurs, gallops or distant heart sounds may be noted on cardiac examination. Other possible sites of involvement include the CNS (extreme irritability, aseptic meningitis, cranial nerve palsies, sensorineural hearing loss), gastrointestinal tract (abdominal pain, diarrhea, hepatic dysfunction, obstructive jaundice, gallbladder hydrops), musculoskeletal system (arthralgias, arthritis) and the genitourinary tract (urethritis, meatitis, sterile pyuria).

"Incomplete" (sometimes called "atypical") KD may be diagnosed in patients with prolonged fever plus coronary artery disease (detected by echocardiography or coronary angiography) but fewer than four additional criteria (see above)[68,74]. This presentation tends to be more

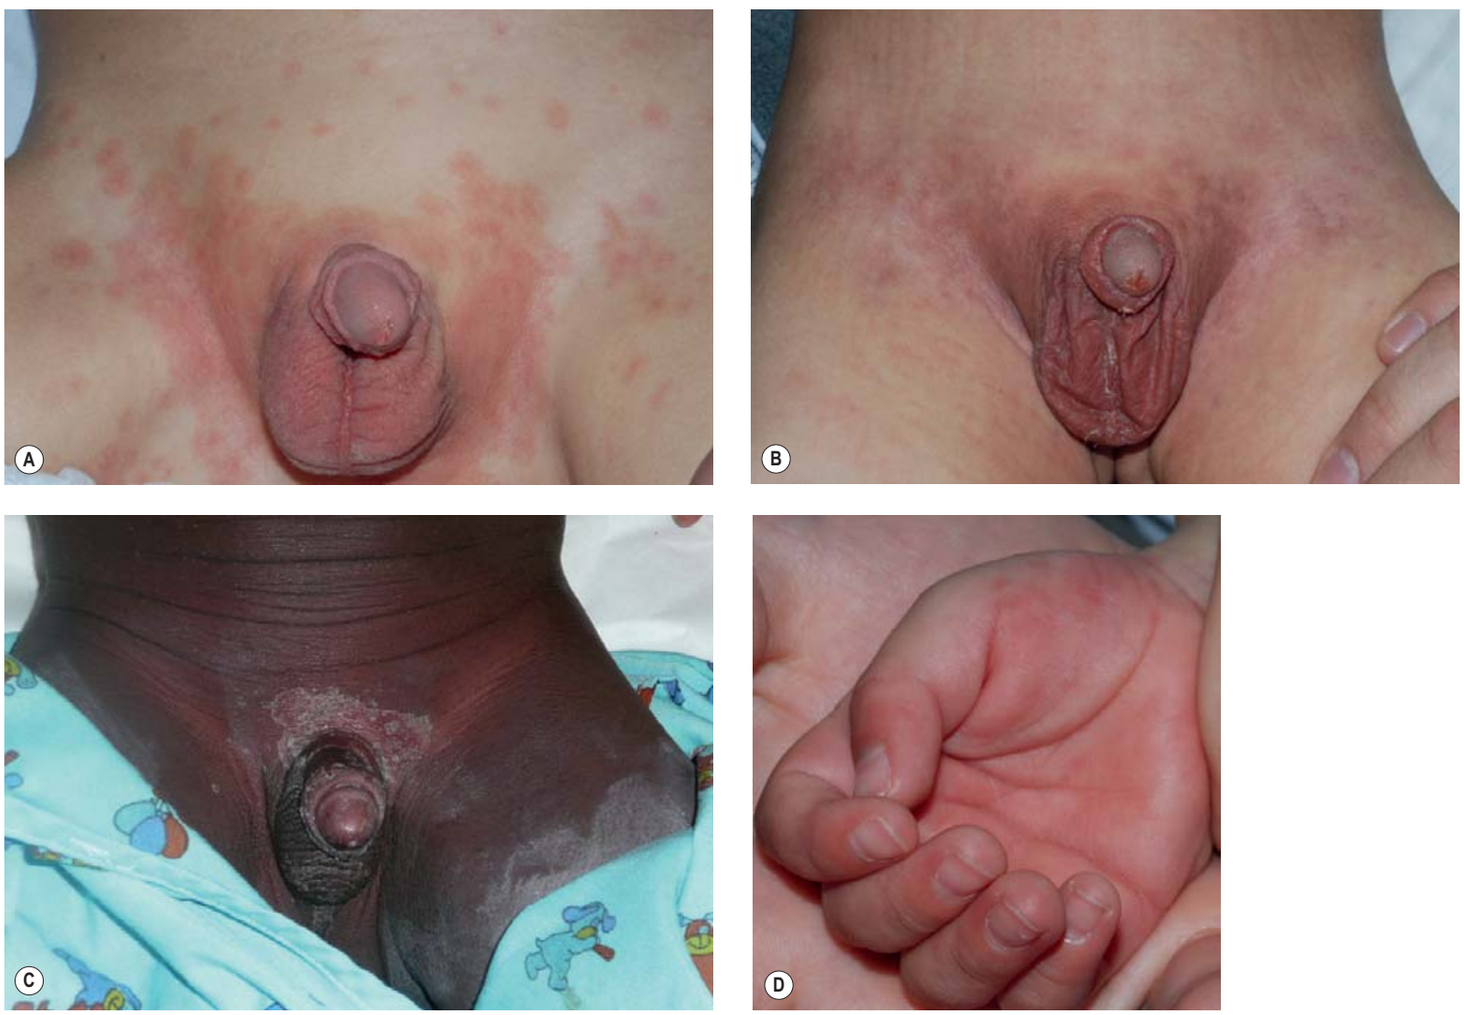

Fig. 81.16 Kawasaki disease. Erythema multiforme-like lesions becoming confluent in the perineal region on the second day of fever (**A**), followed by desquamation 2 days later (**B**). **C** Erythema (less evident due to the patient's darkly pigmented skin) and desquamation in the genital area. Involvement of the skin in this location is a characteristic early finding in Kawasaki disease. **D** Erythema and edema of the palm early in the disease course. *Courtesy, Julie V Schaffer, MD.*

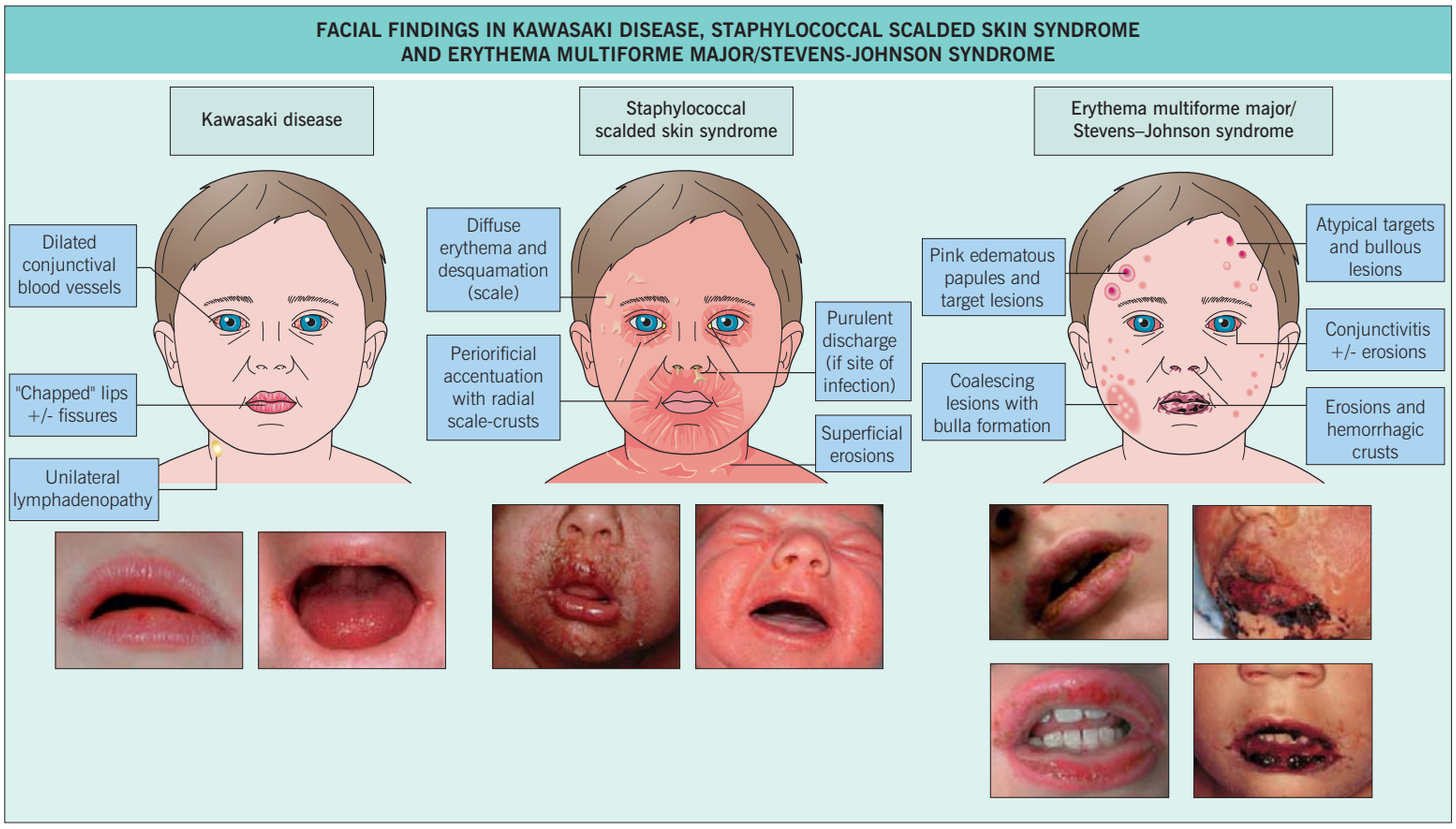

Fig. 81.17 Facial findings in Kawasaki disease, staphylococcal scalded skin syndrome and erythema multiforme major/Stevens–Johnson syndrome. Hemorrhagic crusting and erosions of the vermilion portion of the lips can also be seen in primary gingivostomatitis due to herpes simplex virus, pemphigus vulgaris and paraneoplastic pemphigus.

common in infants, and the diagnosis may be quite difficult to establish. In the child with prolonged fever, some diagnostic features of KD and laboratory evidence of an inflammatory process, KD should be strongly considered. An algorithm for evaluation of suspected incomplete KD has been proposed[74].

Laboratory findings in patients with KD include elevation of the white blood cell count (with neutrophil predominance), acute inflammatory markers (CRP, ESR) and hepatic transaminases, as well as hypoalbuminemia, sterile pyuria, anemia and (less often) thrombocytopenia. By the second to third week of illness, thrombocytosis is often present. Electrocardiographic findings include decreased R-wave voltage, ST-segment depression, and T-wave flattening or inversion.

The differential diagnosis of KD includes viral exanthems (e.g. measles, adenovirus), scarlet fever, toxic shock syndrome, staphylococcal scalded skin syndrome, erythema multiforme, a drug eruption, serum sickness-like reaction, systemic-onset juvenile inflammatory arthritis, infantile polyarthritis nodosa and periodic fever syndromes. Figure 81.17 shows the facial findings that differentiate KD from staphylococcal scalded skin syndrome and erythema multiforme major.

Pathology

Histologic findings are nonspecific and include dermal edema and a perivascular mononuclear infiltrate[68].

Treatment

During its acute phase, the treatment for KD is aimed at decreasing inflammation, and the current first-line therapy is IVIg administered in a single infusion of 2 g/kg over 10–12 hours. This regimen was demonstrated to be more efficacious in preventing coronary aneurysms than the prior recommendation of multiple daily infusions[75]. However, the mechanism of action of IVIg in the treatment of KD is unknown. With the utilization of IVIg, the incidence of coronary aneurysms decreases from 25% to ≤5–10%, and mortality from 2% to 0.3%. Aspirin is also recommended for the treatment of KD during its acute phase, with initial administration of 80–100 mg/kg daily divided into four doses (for 14 days or until afebrile for 48–72 hours), followed by a maintenance dosage of 3–5 mg/kg daily (usually for 6 to 8 weeks)[74].

Approximately 10–20% of children with KD have persistent or recrudescent fevers after receiving a single dose of IVIg. A second dose of IVIg may be given to patients who fail to become afebrile within 24–48 hours after completion of the first dose. Management options for refractory KD also include corticosteroids and infliximab[76–78]. One large randomized, double-blind trial found that initial treatment with pulsed corticosteroids plus conventional therapy (IVIg and aspirin) showed no benefit over conventional therapy alone in terms of hospital days, days of fever, rates of retreatment with IVIg or adverse events[79]. However, a recent randomized controlled study found that the addition of pulsed corticosteroids to initial IVIg therapy in patients at high risk of having refractory KD was associated with fewer days of fever and a lower likelihood of coronary artery dilation[79a]. Recent studies have shown that infliximab is well tolerated and effective (equally or more so than a second dose of IVIg) in the treatment of pediatric patients with IVIg-resistant Kawasaki disease[78,80].

Long-term cardiac follow-up of KD patients is recommended, as adults with a history of KD may have vascular endothelial dysfunction and an increased risk for early-onset atherosclerosis.

Chapter Contents

Syphilis 1367
Gonorrhea 1379
Chancroid 1383
Lymphogranuloma venereum 1386
Donovanosis (granuloma inguinale) 1387

INTRODUCTION

The term "venereal diseases" was historically used to refer to infections that are sexually transmitted, i.e. syphilis, gonorrhea, chancroid, lymphogranuloma venereum, and granuloma inguinale. These disorders are now referred to as "sexually transmitted diseases" (STDs) or "sexually transmitted infections" (STIs), names that directly reflect recognition that they are caused predominantly by sexual contact with an infected person. For infections caused by pathogens for which non-sexual routes of transmission predominate, e.g. yeasts or cytomegalovirus, the term "sexually transmissible infections" is used. Table 82.1 lists the names of commonly encountered sexually transmitted or transmissible pathogens.

SEXUALLY TRANSMITTED AND TRANSMISSIBLE PATHOGENS	
Bacteria	*Neisseria gonorrhoeae* *Treponema pallidum* *Haemophilus ducreyi* *Chlamydia trachomatis* *Mycoplasma hominis, M. genitalium* *Ureaplasma urealyticum* *Gardnerella vaginalis* *Atopobium vaginae* *Mobiluncus curtisii, M. mulieris* *Klebsiella (Calymmatobacterium) granulomatis* *Shigella* spp. *Campylobacter* spp. *Helicobacter cinaedi, H. fennelliae*
Viruses	Human immunodeficiency virus, types 1 and 2 Herpes simplex virus, types 2 > 1 Human papillomavirus Hepatitis viruses, B > C and (via fecal-oral contact) A Cytomegalovirus Molluscum contagiosum virus Human T-cell leukemia/lymphotrophic virus, types I and II Human herpesvirus, type 8
Protozoa	*Trichomonas vaginalis* *Entamoeba histolytica* *Giardia lamblia*
Fungi	*Candida albicans*
Ectoparasites	*Phthirus pubis* *Sarcoptes scabiei*

Table 82.1 Sexually trans.mitted and transmissible pathogens.

SYPHILIS

Synonym: ■ Lues

Key features

- Syphilis is a sexually acquired, chronic infection caused by *Treponema pallidum* and is characterized by a variety of clinical manifestations
- Syphilis can also be transmitted before birth (congenital)
- It is an intermittently active disease with primary, secondary and tertiary stages as well as a latent period of variable length that occurs before the onset of tertiary syphilis
- Mucocutaneous manifestations vary from genital ulcers to widespread papulosquamous eruptions to granulomatous nodules
- Syphilis facilitates the transmission of HIV, especially in countries with a high rate of both infections

History

Syphilis has been of great historical importance and has played a major role in medicine for over a century. The disease was named after an afflicted shepherd named Syphilus in 1530. Theories on the origin of the disease in the late fifteenth century are controversial. One theory proposes that Christopher Columbus and his crew acquired the disease from Native Americans living in the Caribbean islands and brought it back to a nonimmune population in Europe in 1493, as signs of syphilis have been found in skeletons of pre-Columbian Native Americans[1]. Another theory is that venereal syphilis may have already been endemic but became more widespread and severe as a consequence of the wars at that time in Europe. Lastly, the environmental theory claims that venereal syphilis is a variant of other diseases caused by *Treponema* spp. and became modified by environmental factors, especially temperature[2,3].

Information on the natural course of untreated syphilis (Fig. 82.1) has come primarily from two large studies. The Oslo Study[4] was a prospective investigation of infected, but untreated, individuals conducted between 1890 and 1910, with a follow-up period of 50 years. Approximately one-quarter of infected persons had at least one additional relapse of secondary syphilis, often occurring during the first year (90%). Approximately 15% of infected persons developed benign late syphilis with gummas of the skin (70%), bones (10%) and mucous membranes (10%). Cardiovascular syphilis was reported in approximately 14% of men and 8% of women, while neurosyphilis was observed in 10% of men and 5% of women. Altogether, the study concluded that 17% of men and 8% of women died as a result of untreated syphilis.

The Tuskegee Study was undertaken in 1932 in infected black men, with regular examinations for short- and long-term consequences of untreated infection. This represented a highly unethical investigation, as penicillin treatment was withheld without written consent. The principal finding was an increased mortality rate in the syphilitic group compared to the controls, with an approximately 20% loss-of-life expectancy at an interval of 12 years. Specific lesions of late syphilis were found in about 14% of infected men at the 20-year evaluation, and 12% after 30 years, with cardiovascular syphilis and neurosyphilis representing the primary causes of death[5–7].

Epidemiology

Syphilis is distributed worldwide and is particularly problematic in low-income countries, where it is a leading cause of genital ulcer disease. Worldwide, the rates of primary and secondary syphilis decreased dramatically with the introduction of penicillin treatment after the Second World War. In contrast to Western European countries, an increase in the infection rate was observed during the late 1980s in rural southern and urban regions of the US. Although the number of syphilis cases per year in the US subsequently declined and in 2000 fell to its lowest point since reporting began in 1941, in the past decade the number of primary and secondary syphilis cases diagnosed per year in men has more than doubled (Fig. 82.2). In 2010, the incidence rate of primary and secondary syphilis in the US was 7.9 cases per 100 000 population in men and 1.1 cases per 100 000 population in women. In the US, the incidence in black and Hispanic individuals, as well as in men who have sex with men (MSM), is 5- to 25-fold higher than in other population groups. In a Centers for Disease Control and Prevention (CDC) study of MSM receiving care at STD clinics in eight US cities, rates of syphilis seroreactivity increased from 4% in 1999 to 11% in 2008.

With the resurgence of syphilis in Eastern Europe in the 1990s and migration of sex workers from this region to Western Europe, syphilis has been observed more frequently in Western European countries over the past decade.

Biology of *T. pallidum*

T. pallidum is a member of the genus *Treponema* of the order Spirochaetales, and it was identified in 1905 by Schaudinn and Hoffmann (Table 82.2)[8]. The characteristics of this microorganism are outlined in Table 82.3. Figure 82.3 represents a darkfield photomicrograph of *T. pallidum*.

Pathogenesis of Untreated Syphilis

Syphilis is a chronic systemic infection that progresses through active and latent stages (Fig. 82.4). Inoculation and penetration occurs via mucosal surfaces and abraded skin, followed by attachment to host cells and multiplication of the microorganism. Within a few hours, treponemes disseminate to the regional lymph nodes and internal organs[9].

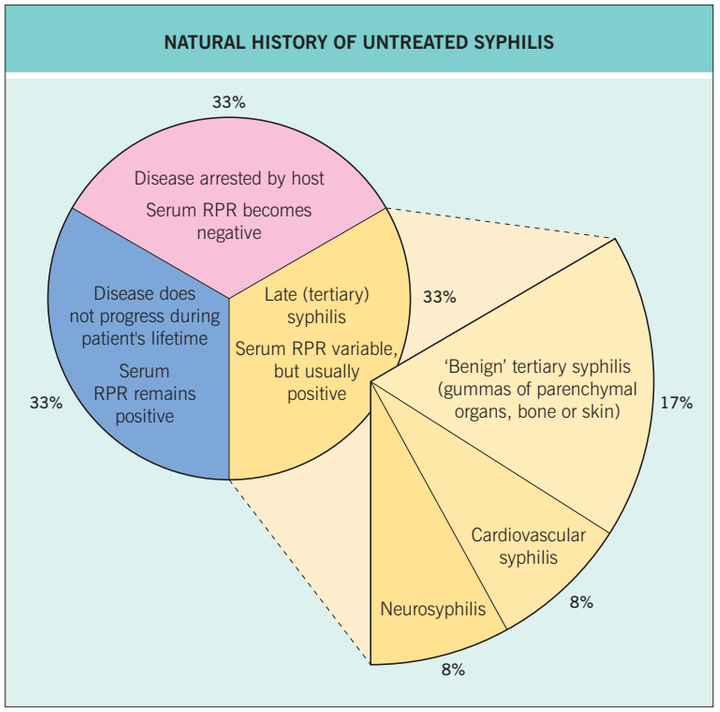

Fig. 82.1 Natural history of untreated syphilis. The data represent a composite of several studies. The specific antibody assays (e.g. MHA-TP) usually remain positive. RPR, rapid plasma reagin.

CLASSIFICATION OF THE SPECIES OF *TREPONEMA*

Order Spirochaetales
Genus *Leptospira*
Genus *Borrelia*
Genus *Treponema*

	Disease	Distribution	Transmission
T. pallidum subsp. *pallidum*	Venereal syphilis	Worldwide	Sexual, congenital (adults, newborns)
T. pallidum subsp. *pertenue*	Yaws	Tropics	Non-venereal (all ages)
T. pallidum subsp. *endemicum*	Endemic syphilis (Bejel)	Desert	Non-venereal (all ages)
T. carateum	Pinta	Tropics	Non-venereal (all ages)
T. denticola, *T. socranskii*	Periodontal disease	Worldwide	Non-venereal

Identical characteristics of organisms within the genus *Treponema*: morphology, antigenic properties, many DNA sequences, serologic detection, biochemical properties.

Different characteristics of organisms within the genus *Treponema*: transmission mode, geography, age of patients, appearance of clinical lesions.

Table 82.2 Classification of the species of *Treponema*.

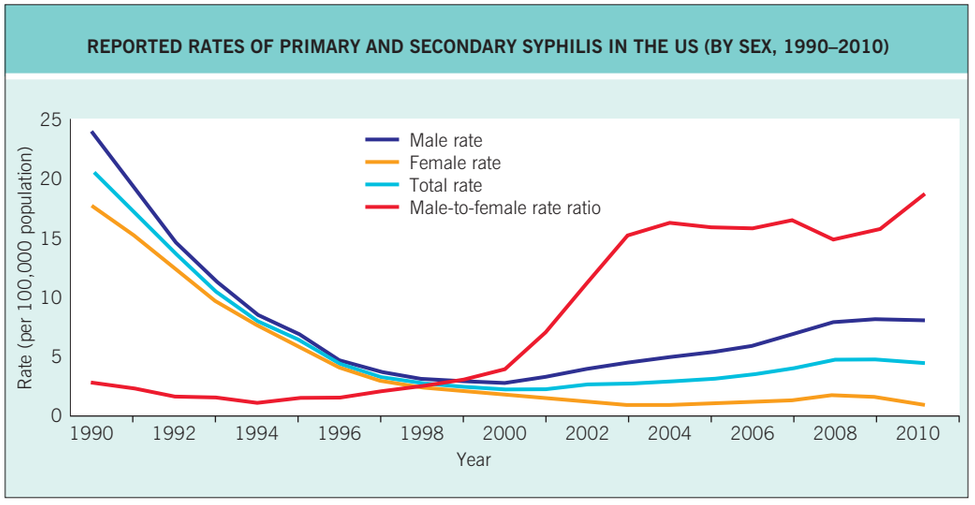

Fig. 82.2 Reported rates of primary and secondary syphilis in the US (by sex, 1990–2010). Note the elevated male : female ratio since 2000.

CHARACTERISTICS OF *TREPONEMA PALLIDUM*
• 6–20 microns in length, 0.1–0.18 microns in diameter
• Regular tight spirals
• Inability to survive outside an animal host
• Cannot be cultured *in vitro* for extended time period
• Limited capacity for DNA repair
• Outer membrane:
– lipid-rich
– contains uniform-sized *t*ransmembrane *r*are *o*uter *m*embrane *p*roteins (TROMP)
– lacks lipopolysaccharide
• Periplasmic flagella

Table 82.3 Characteristics of *Treponema pallidum*.

Fig. 82.3 Positive darkfield examination. Treponemes are recognized by their characteristic corkscrew shape, and deliberate forward and backward movement with rotation about the longitudinal axis. *From Morse et al. Atlas of Sexually Transmitted Diseases and AIDS, 3rd edn. London: Mosby; 2003.*

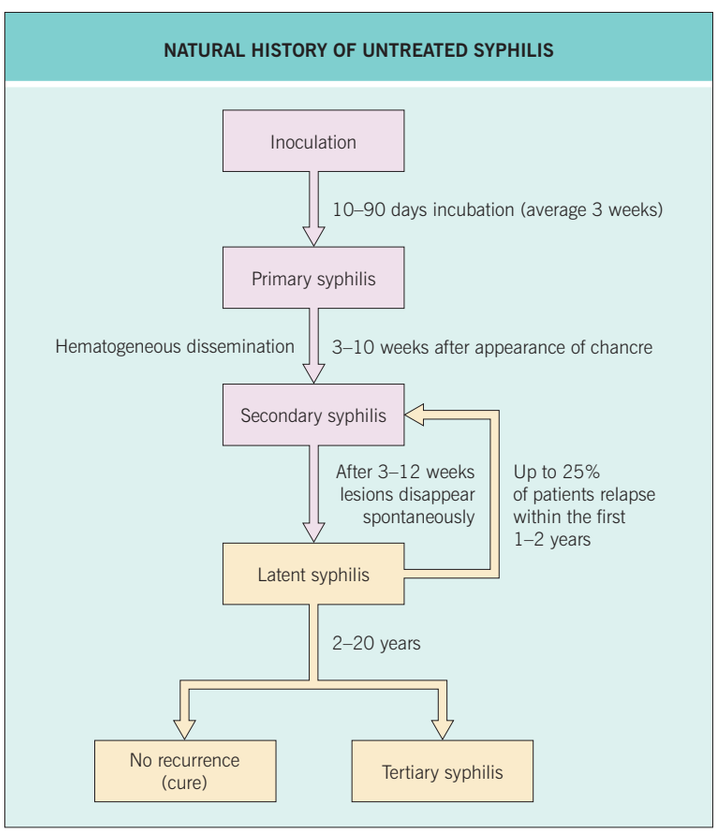

Fig. 82.4 Natural history of untreated syphilis. *Adapted from Rein MF, Musher DM. Late syphilis. In: Rein MF (ed.). Atlas of Infectious Diseases, Vol V: Sexually Transmitted Diseases. New York: Current Medicine, 1995:10.1–10.13.*

Primary stage

The primary lesion develops 10–90 days after infection (median of 3 weeks) as an indolent papule, followed by surface necrosis and the typical well-circumscribed ulceration that is firm to palpation (chancre), as well as enlarged regional lymph nodes. Histopathologically, the microorganism is observed among cells typical of a Th1-predominant cellular response; the latter leads to macrophage activation and destruction of a large number of treponemes. Several pathogenic mechanisms have been proposed, including an antigenically inert treponemal cell surface, resistance to phagocytosis, and premature down-regulation of the local host immune response.

Secondary stage

The secondary stage is characterized by dissemination and multiplication of the microorganism in different tissues, either simultaneously with or up to 6 months after healing of the primary local lesion. This stage follows primary syphilis in almost every patient in the absence of appropriate treatment. Circulating immune complexes (which contain treponemal outer membrane proteins), human fibronectin, antibodies and complement are present during this stage of the disease and play a role in the pathogenesis of the different types of lesions[10].

Secondary syphilis is characterized by a broad spectrum of clinical manifestations involving the skin as well as systemic signs such as malaise, fever and generalized enlargement of the lymph nodes. It lasts several weeks or months, with relapses in approximately 25% of patients. Pregnant women can infect a fetus via transplacental passage of the microorganism.

Latency

Latency is the period between healing of the clinical lesions and appearance of late manifestations, and it can last for many years. About 70% of untreated individuals will remain in this stage for the rest of their lives and are immune to new primary infection. Latent syphilis is divided into early (1 year or less) and late (more than 1 year) subsets, and it is characterized by positive serologic tests for specific antibodies (see below) without clinical signs or symptoms. Infectivity may occur intermittently due to the presence of treponemes in the bloodstream, and pregnant women with latent syphilis may infect the fetus *in utero*.

Tertiary stage

The tertiary stage is also called late syphilis and is characterized by the presence of a small number of organisms and a high cellular immune reactivity against the organism. Signs of late syphilis can be recognized in approximately one-third of untreated individuals several months to years after being infected with treponemes. The microorganisms may invade the central nervous and cardiovascular systems as well as the skin (and other organs), leading to damage related to host delayed-type hypersensitivity responses, which produce local inflammation and gummas in affected tissues.

Syphilis and HIV

Syphilis and other STIs that produce genital ulcers further increase the risk of acquiring HIV. Reasons for the increased risk of HIV transmission include:

- lack of an epithelial barrier due to ulceration of the skin or mucous membranes
- large numbers of macrophages and T cells with receptors for HIV
- production of cytokines by macrophages stimulated by treponemal lipoproteins.

In addition, syphilitic manifestations are altered in HIV-positive patients[11], with a higher likelihood of neurologic findings and (in those with secondary syphilis) ulcerative lesions.

Clinical Features

Syphilis is usually sexually acquired, but maternal–fetal transmission also occurs and can result in congenital syphilis. Syphilis is an intermittent disease with primary, secondary and tertiary stages as well as a latent period of variable length (divided into early and late subsets) that

precedes the onset of tertiary syphilis (see Fig. 82.4)[12]. The definitions of early and late syphilis by the CDC and World Health Organization (WHO) differ slightly. *Early syphilis* includes the primary and secondary stages as well as early latency (CDC: acquired <1 year previously; WHO: acquired <2 years previously). *Late syphilis* extends from late latency (CDC: acquired >1 year previously; WHO: acquired >2 years previously) through the tertiary stage.

Primary syphilis

The chancre usually presents as a single, indolent, round or oval, indurated ulcer (Fig. 82.5) that is associated with regional adenopathy. Some patients report a preceding painless papule that enlarged and ulcerated a few days later. The time of onset ranges from 10 to 90 days (average 3 weeks) after *T. pallidum* exposure. Untreated, chancres heal within a few weeks (Fig. 82.6).

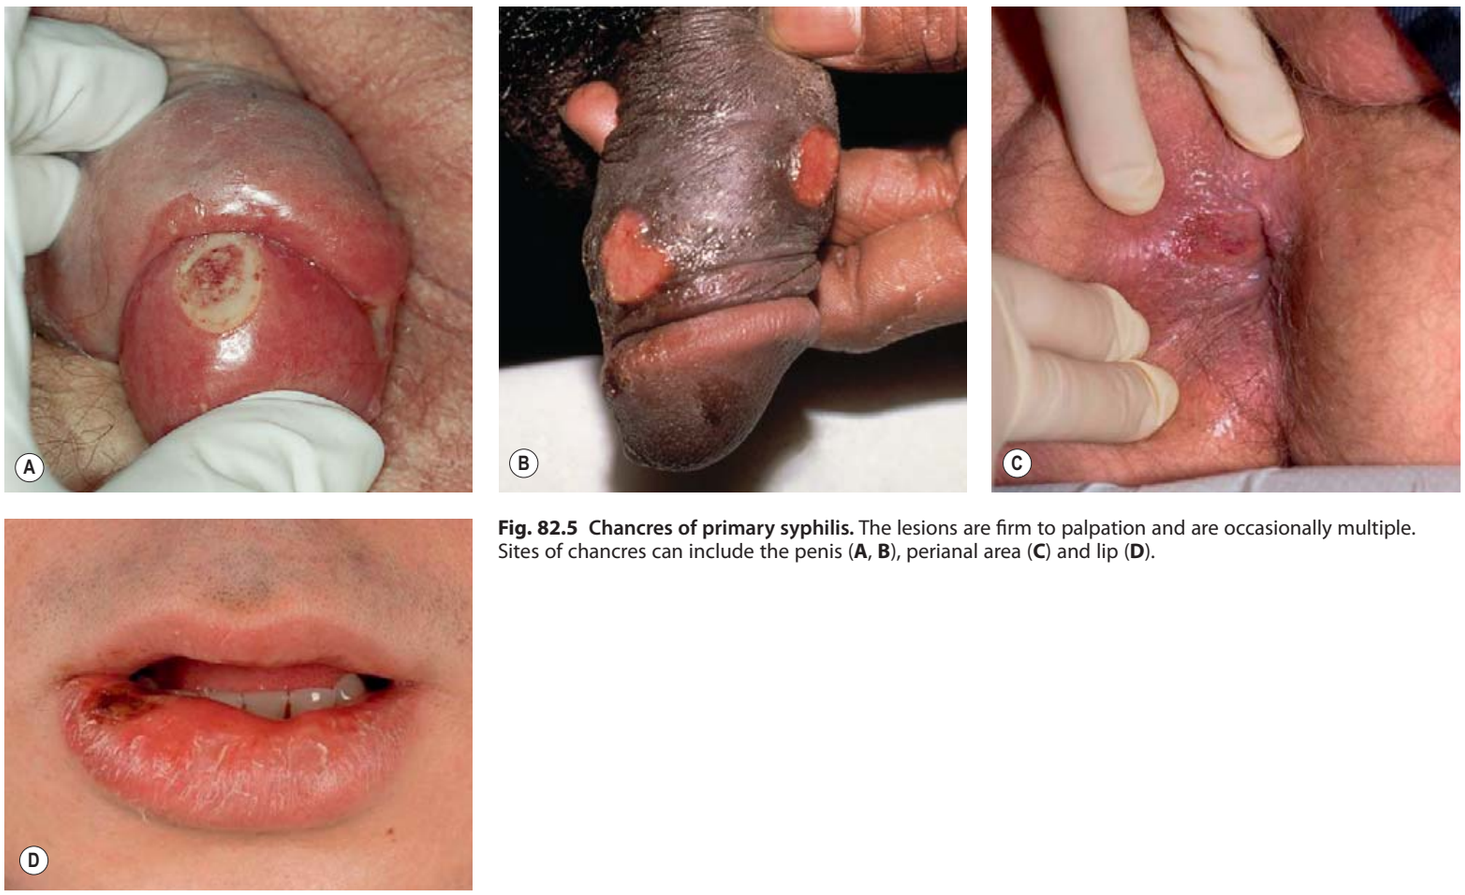

Fig. 82.5 Chancres of primary syphilis. The lesions are firm to palpation and are occasionally multiple. Sites of chancres can include the penis (**A**, **B**), perianal area (**C**) and lip (**D**).

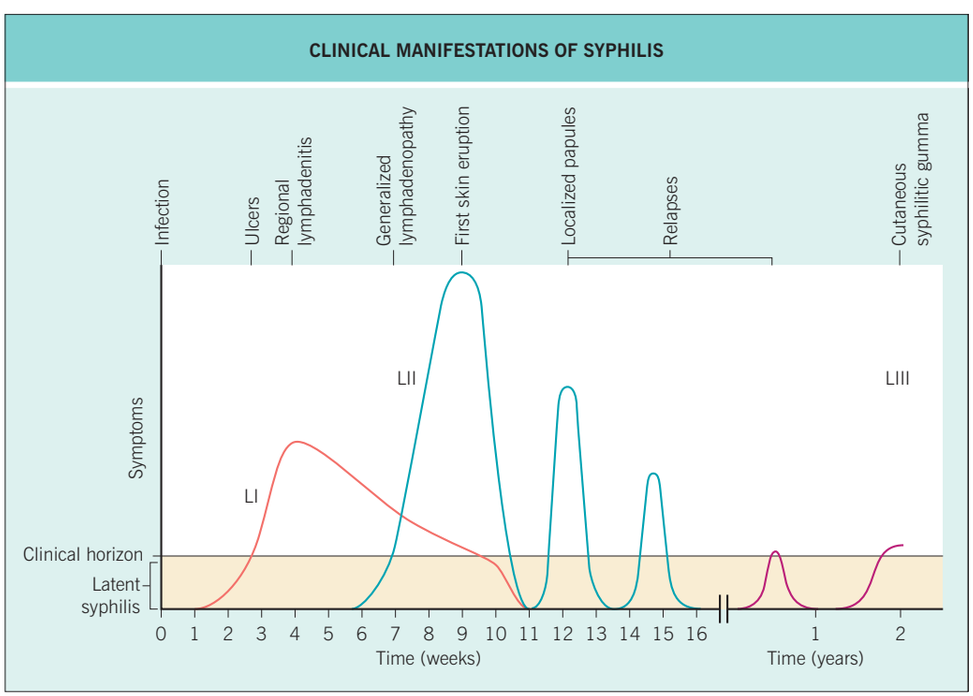

Fig. 82.6 Clinical manifestations of syphilis. LI, primary syphilis; LII, secondary syphilis; LIII, tertiary syphilis. *Adapted from Fritsch P, Zangerle R, Stary A. Venerologie. In: Fritsch P (ed.). Dermatologie und Venerologie. Berlin: Springer, 2004:865–886.*

Asymptomatic infections are common due to unrecognized chancres, especially when located in the cervical region in women; in these cases, syphilis is more frequently diagnosed during the secondary stage. The same applies to chancres located in the anal, perianal or rectal areas (see Fig. 82.5C), seen more commonly in men who have sex with men. The mechanism of spontaneous healing without treatment is not well understood and seems to depend on local immunity.

Laboratory diagnosis of primary syphilis includes the following:

- The presence of treponemes by darkfield microscopic examination of fluid from the surface of the chancre is the most sensitive and specific method for the diagnosis of primary syphilis (see Fig. 82.3).
- Antibodies to cardiolipin are present in about 80% of individuals at the onset of clinical symptoms. Cardiolipin, a component of mammalian cells, seems to be modified by treponemes such that antibodies are produced by the infected person and can be measured by the rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) assay.
- Antibodies to surface proteins of *T. pallidum* as detected by hemagglutination assays (*T. pallidum* *h*em*a*gglutination test [TPHA], *m*icro*h*em*a*gglutination assay for antibodies to *T. pallidum* [MHA-TP]) or *f*luorescent *t*reponemal *a*ntibody *abs*orption (FTA-ABS) assay are present in 90% of patients with clinical symptoms of primary syphilis. Since antibodies usually remain positive for life, a differentiation between primary syphilis and an earlier infection may not be possible and darkfield examination should be undertaken.

Secondary syphilis

The secondary stage of the disease results from the hematogenous and lymphatic dissemination of treponemes after a few weeks or months (3–10 weeks). It is characterized by recurrent activity of the disease, with mucocutaneous as well as systemic manifestations. Prodromal symptoms include low-grade fever, malaise, sore throat, adenopathy, weight loss, muscle aches and sometimes a headache from meningeal irritation (Table 82.4).

During the second stage of syphilis, the most commonly observed clinical presentation (80%) is a generalized, non-pruritic papulosquamous eruption (Fig. 82.7). Lesions can range from 1–2 mm to 15–20 mm in diameter, and they vary in color from pink to violaceous to red–brown. Mucosal lesions range from small, superficial ulcers that resemble painless aphthae to large gray plaques (Fig. 82.8A,B). Condylomata lata are often observed in the moist regions of the anogenital area (Fig. 82.8C,D) due to local spreading of the microorganisms. Lymph node enlargement is present in the majority of patients. Focal neurologic findings occasionally occur.

Additional clinical presentations of secondary syphilis include annular or figurate plaques with central hyperpigmentation on the face (Fig. 82.9A), non-scarring "moth-eaten" alopecia, split papules at the oral commissures (Fig. 82.9B), granulomatous nodules and plaques (Fig. 82.9C) and crusted necrotic lesions (Fig. 82.9D). Malignant syphilis (lues maligna) is extremely rare; the disseminated lesions resemble primary chancres (Fig. 82.9E).

Without treatment, the lesions resolve over several weeks to months. Relapse occurs in approximately 20% of patients within 1 year, often with mucosal or mucocutaneous manifestations in the anogenital area.

Laboratory diagnosis of secondary syphilis includes the following:

- Presence of treponemes by darkfield examination of serous exudates from localized lesions of the skin and mucous membranes (the exception being the oral cavity; see below).
- Serologic tests are more useful in secondary (as compared to primary) syphilis. Cardiolipin antibodies (e.g. RPR or VDRL tests) as well as specific antibodies are always positive in patients with secondary (as well as tertiary or latent) syphilis; a mistakenly or temporarily negative non-treponemal test rarely occurs due to the prozone phenomenon or HIV infection, respectively (see Table 82.8).
- Occasionally, spirochetes are detected in biopsy specimens (see below)

Management considerations for patients diagnosed with secondary syphilis include the following:

CLINICAL FEATURES OF SECONDARY SYPHILIS

- **Prodromal symptoms and signs:**
  Weight loss
  Low-grade fever
  Malaise
  Headache (meningeal irritation)
  Sore throat
  Conjunctivitis (iridocyclitis)
  Arthralgia (periostitis)
  Myalgias
  Hepatosplenomegaly (mild hepatitis)
- **Generalized lymphadenopathy with indolent enlargement of lymph nodes (50–85%)**
- **Skin manifestations:**
  Early (10%): generalized eruption; non-pruritic, roseola-like, discrete macules, initially distributed on the flanks and shoulders
  Late (70%): generalized maculopapular and papulosquamous eruptions; more infiltrated lesions, often copper-colored; annular plaques on the face; corymbose arrangement (satellite papules around a larger central lesion); occurs in successive waves and is polymorphic
  Localized syphilids (specific infiltrations of treponemes; positive darkfield examination):
  – palms and soles: symmetric papules and plaques with a collarette of scale (collarette of Biett)
  – anogenital area: condylomata lata
  – seborrheic area: "corona veneris" along the hairline
  Hypopigmented macules, mainly on the neck (postinflammatory; "necklace of Venus")
- **Manifestations involving mucous membranes (30%):**
  Syphilitic perlèche, split papules
  Mucous patches: "plaques muqueuses" in the oropharynx (equivalent to condylomata lata in the genital area)
  Syphilitic sore throat: inflammation of the whole pharynx
- **Patchy alopecia (7%):** "moth-eaten" localized areas of hair loss; toxic telogen effluvium

Table 82.4 Clinical features of secondary syphilis.

- All patients should be tested for HIV infection, and testing should be repeated in those who fail to respond to treatment.
- Patients with ocular symptoms (e.g. photophobia, visual changes) should undergo ophthalmologic evaluation to assess for uveitis and neuroretinitis, including slit-lamp examination.
- A lumbar puncture and cerebrospinal fluid (CSF) analysis should be performed in patients with ocular or neurologic (e.g. headache, hearing loss, cranial neuropathies) signs/symptoms and when treatment failure is suspected (e.g. persistent/recurrent signs/symptoms or failure of non-treponemal test titers to decline fourfold within 6–12 months). Patients with HIV are at increased risk for neurosyphilis, especially if they have a CD4 count <350 cells/ml and/or a RPR titer of ≥1 : 32; however, unless neurologic symptoms are present, CSF examination in HIV patients has not been associated with improved clinical outcomes.

Latent syphilis

After a period of 3–12 weeks, untreated secondary syphilis typically resolves spontaneously, leaving the patient in an asymptomatic state. Diagnosis is based on a positive syphilis serology test result in the setting of no clinical evidence of treponemal infection. The two stages are:

- Early latent stage: within 1 year of the onset of latency (CDC definition), with the possibility of recurrence of the disease. About 90% of secondary relapses occur within the first year.
- Late latent stage: after 1 year from the onset of the disease (CDC definition); relapses after 1 year are very infrequent. This disease state may last for many months or years.

Experience regarding the outcome of late latent syphilis in the absence of treatment is based upon several studies. About one-third of infected individuals have a non-reactive RPR test, no sign of reactivation during the remainder of their lives, and only the specific antibody assays (e.g. MHA-TP, FTA-ABS) remain positive (see Fig. 82.1). Another

Fig. 82.7 Secondary syphilis. Widespread exanthem of pink papules (**A**), pityriasis rosea-like lesions localized to the arms in an HIV-positive man (**B**) and generalized papulosquamous lesions (**C**). Lesions on the palms (**D**) and soles (**E, F**) can have a collarette of scale. *B, Courtesy, Kalman Watsky, MD.*

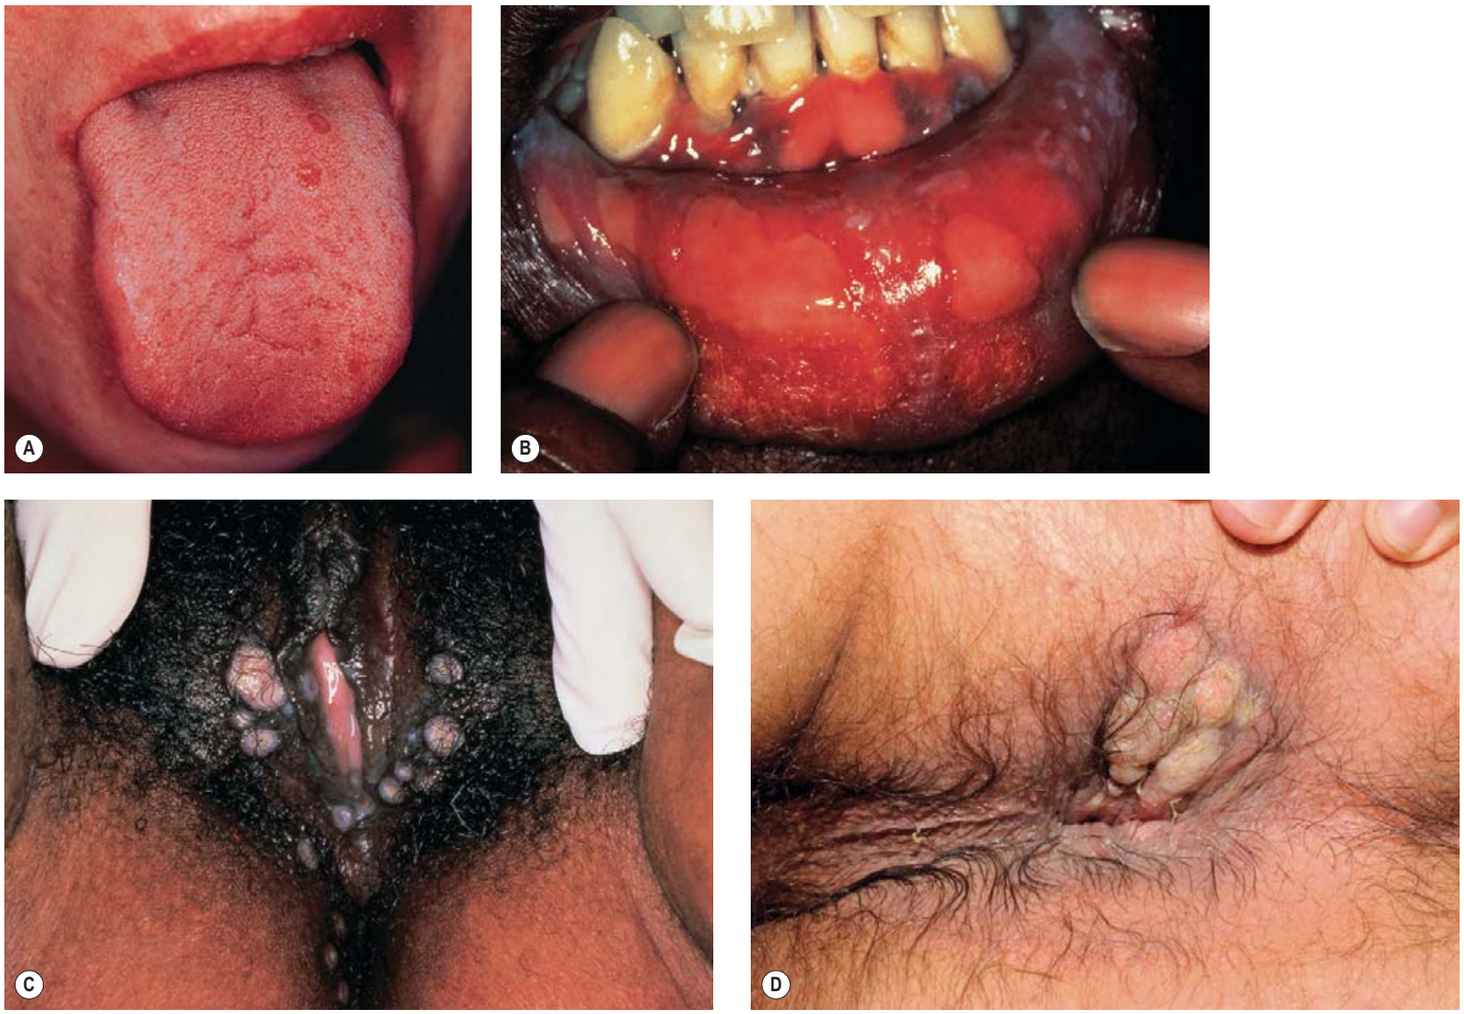

Fig. 82.8 Orogenital lesions of secondary syphilis. Oral lesions can vary from small superficial ulcers (**A**) to mucous patches (**B**). Condylomata lata in the vulvar (**C**) and anal (**D**) areas may be misdiagnosed as HPV infection (i.e. condylomata acuminata).

one-third of patients remain clinically asymptomatic for the rest of their lives, but antibodies against cardiolipin (e.g. RPR, VDRL) persist together with a positive MHA-TP or FTA-ABS assay. In the remaining one-third, clinical symptoms of tertiary syphilis occur.

Diagnosis of latent syphilis is established by reactivity in an RPR or VDRL assay, a positive MHA-TP or FTA-ABS test, and the absence of any clinical signs of the disease. The diagnosis is easy to establish if there is a history of a chancre or skin manifestations that fit the clinical picture of syphilis. In many cases, the medical history provides no useful information regarding the presence of clinical symptoms in the previous weeks to months or whether the patient was previously treated. In such instances, differentiation between early and late latency is not possible and patients are regarded as having late latent syphilis from a management standpoint (see below). Response of latent syphilis to treatment is indicated by a decline in the RPR or VDRL titer. Persistently high (e.g. lack of a fourfold decline within 12–24 months) or rising titers are a sign of treatment failure, and examination of the CSF should be performed.

Tertiary (late) syphilis

Classic tertiary syphilis, as a consequence of untreated syphilis, is nowadays rare. It has a variable range of manifestations that appear months to years after initial infection (Fig. 82.10). In particular, these include involvement of the skin, bones, CNS, heart and great vessels. Approximately one-half of patients with tertiary syphilis have "benign" late syphilis with the development of gummas (see Fig. 82.1), about one-quarter develop cardiovascular manifestations, and one-quarter develop neurologic symptoms (with additional overlap of different manifestations).

In tertiary syphilis, non-treponemal serologic tests are usually positive with high titers. Patients with tertiary syphilis (or any symptoms related to late syphilis) should undergo lumbar puncture and CSF examination to determine if neurosyphilis is present before therapy is initiated.

"Benign" late syphilis

The most common feature of late syphilis is gummas, which are locally destructive lesions in the skin, bones, liver and other organs. The gummas in the skin are nodular or noduloulcerative lesions, often with an arciform pattern (Fig. 82.11). They remain for weeks to months and then involute with scarring, but eventually new nodules reappear. With treatment, resolution of the lesions is prompt and complete. A solitary gumma that is located subcutaneously may become necrotic, similar to a "cold" abscess, resulting in ulceration of the skin or mucous membranes as well as destruction of underlying bones.

Bones are affected as frequently as the skin. The gumma is a destructive bony lesion that is typically accompanied by periostitis and osteitis. Clinical manifestations include pain, swelling and limited range of motion. Other sites that can be affected by gummas include the tongue and oral cavity, upper respiratory tract, myocardium, and digestive as well as nervous systems.

Cardiovascular syphilis

Cardiovascular syphilis has a late onset, with a latent period of 15–30 years, and it occurs in about 8–10% of individuals with untreated infection. During the early stage of the disease, *T. pallidum* demonstrates a predilection for the vasa vasorum of the proximal aorta and produces transmural inflammatory lesions, which lead to endarteritis of the

vessels. The organisms then remain there in a latent state for many years.

Neurosyphilis

Although classically a manifestation of tertiary syphilis, neurosyphilis can occur at any stage of the disease. Neurosyphilis is the reflection of a chronic (or sometimes acute) form of meningitis, with vascular and parenchymatous sequelae in the cerebrum and spinal cord (Table 82.5). Asymptomatic neurosyphilis is defined by the presence of abnormalities in the CSF (see below) but the absence of any neurologic symptoms or clinical findings. While in some individuals the CSF abnormalities may resolve spontaneously or persist into advanced age, asymptomatic neurosyphilis can progress to late symptomatic neurosyphilis.

The basic pathomechanism for cerebrovascular syphilis is an infarction secondary to syphilitic endarteritis; this can result in hemiparesis or hemiplegia. Parenchymatous neurosyphilis (general paresis, dementia paralytica, paretic neurosyphilis) is due to direct invasion of the cerebrum by treponemes. It is a rare and late form of neurosyphilis, with dementia and neurologic symptoms (e.g. paralysis) that (untreated) progress until death occurs.

Tabes dorsalis, which affects up to a third of patients with neurosyphilis after a long latent period, has a number of typical clinical signs and symptoms, including diplopia, lightning pains (painful paresthesias, especially of the extremities), loss of vibratory and position sense, reduced reflexes in the legs, ataxia, sphincter dysfunction, visceral crisis (abdominal, rectal and laryngeal pain), and Argyll Robertson pupils (abnormal pupillary light reflexes: loss of direct and consensual; retention of accommodation). Tabes dorsalis may burn out even without treatment.

Neurosyphilis in HIV-infected individuals

In the mid 1970s, the first cases of a so-called "atypical neurosyphilis" were described. With the subsequent recognition of co-infections with syphilis and HIV, it became apparent that neurosyphilis is common in HIV-infected individuals, and patients present with manifestations of early-onset neurosyphilis.

Laboratory diagnosis of neurosyphilis

In addition to the clinical findings, the diagnosis of neurosyphilis (including acute syphilitic meningitis, meningovascular syphilis and parenchymatous neurosyphilis) is based upon reactive blood and CSF serologies, which are almost always positive. CSF abnormalities include

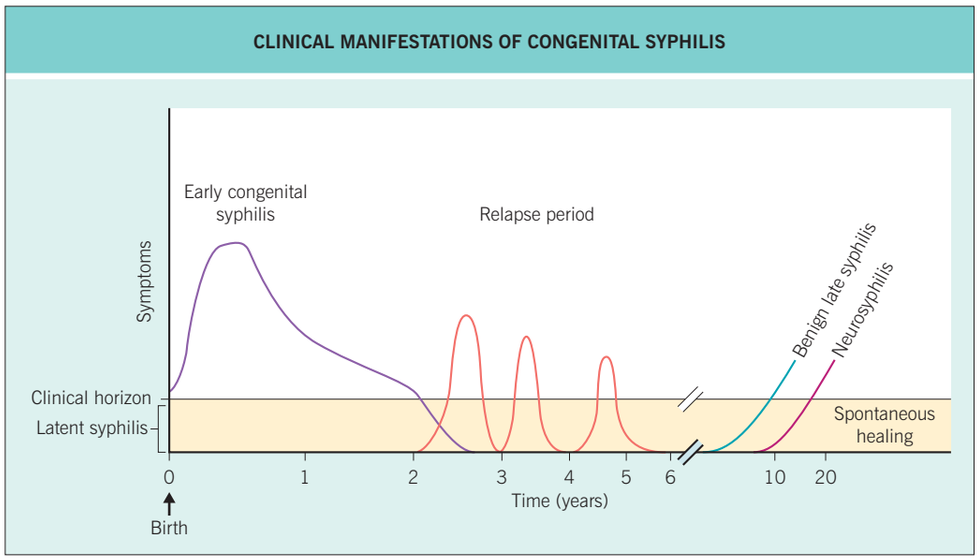

Fig. 82.12 Clinical manifestations of congenital syphilis. *Adapted from Fritsch P, Zangerle R, Stary A. Venerologie. In: Fritsch P (ed.). Dermatologie und Venerologie. Berlin: Springer, 2004:865–886.*

MOTHER-TO-CHILD TRANSMISSION OF UNTREATED SYPHILIS AND ITS CONSEQUENCES
RISK
• Infection of the mother from conception to 7th month of pregnancy: transmission in nearly 100% (often fetal demise or severe congenital syphilis)
• Infection at least 2 years before pregnancy: reduced risk of transmission to 50%
• Infection during 7th, 8th, or early 9th month: reduced risk of transmission
• Infection 3–6 weeks before labor: no placental transmission; risk of perinatal transmission
CONSEQUENCES OF INFECTION
• Spontaneous abortion (second or third trimester) (10%)
• Stillbirth (10%)
• Infant death (20%)
• Congenital syphilis (20%)
• Healthy child (40%)

Table 82.6 Mother-to-child transmission of untreated syphilis and its consequences.

Fig. 82.13 Congenital syphilis. Red–brown plaques on the plantar surface.

elevation of pressure, protein concentration and immunoglobulin level as well as a mononuclear pleocytosis. The presence of specific antitreponemal antibodies in the CSF is mandatory, but it is not proof of the diagnosis of neurosyphilis, since IgG antibodies can diffuse into the CSF or result from contamination of the CSF by blood. Establishment of local antibody synthesis is possible by using the CSF-IgG index, obtained by dividing the CSF to serum IgG ratio by the CSF to serum albumin ratio. A result >0.7 is indicative of IgG synthesis in the brain due to local inflammation. The intrathecal *T. pallidum* antibody index is calculated by dividing the TPHA titer in the CSF by the CSF to serum albumin ratio multiplied by a factor of 10^3, and an index >100 is indicative of the synthesis of treponemal-specific antibodies within the CNS. The presence of nonspecific antibodies, e.g. a positive VDRL test or RPR assay in CSF, is observed in most, but not all, cases, and a negative test does not exclude the presence of neurosyphilis.

Congenital syphilis

Congenital syphilis was initially described in 1497 and is therefore the oldest recognized congenital infection. In 1906, it was demonstrated via the Wassermann test that transmission of syphilis to the fetus required an infection in the pregnant woman.

There was an upsurge in congenital syphilis in Eastern Europe in the late 1990s, which paralleled the increased incidence of syphilis in adults and adolescents in this region. In the early 1990s, an increased frequency of congenital syphilis was also observed in some inner-city minority populations in the US[14]. In the US, there are currently approximately 10 cases of congenital syphilis per 100 000 live births. The risk of mother-to-child transmission of untreated syphilis and its potential consequences are listed in Table 82.6.

Early congenital syphilis

Infants generally present with symptoms during the neonatal period or within the first 3 months of life (Fig. 82.12). At the latest, they develop symptoms within the first 2 years of life. Typical manifestations are marasmic syphilis (i.e. cachexia) and skin lesions similar to those of acquired secondary syphilis (Fig. 82.13), except that they may be bullous (pemphigus syphiliticus) and tend to be more erosive. Additional clinical findings are "snuffles" (bloody or purulent mucinous nasal discharge), perioral and perianal fissures, lymphadenopathy and hepatosplenomegaly. Skeletal involvement (i.e. osteochondritis) may result in pseudoparalysis of Parrot because of reduced movement of the extremities due to pain; other manifestations include anemia, thrombocytopenia, syphilitic pneumonitis (pneumonia alba), hepatitis, nephropathy and congenital neurosyphilis.

Late congenital syphilis and stigmata

Late congenital syphilis in a child or adolescent corresponds to tertiary syphilis in an adult and is not infectious. The stigmata represent the

STIGMATA OF CONGENITAL SYPHILIS
CUTANEOUS
• Rhagades (radial periorificial [mouth, nose, eyes, anus] scars at sites of previous fissures)
DENTAL
• Hutchinson's teeth (peg-shaped, notched permanent incisors)* • Mulberry molars (multiple rounded rudimentary cusps on the permanent first molars) • Caries due to defective enamel
SKELETAL
• Saddle nose (depression of the nasal root due to destruction of cartilage/bone) • Frontal bossing of Parrot ("Olympian brow") • Hypoplastic maxilla, relatively prominent mandible • High palatal arch ± perforation • Higouménakis' sign (thickening of the medial clavicle) • Scaphoid scapulae • Saber shins (anterior tibial bowing) • Clutton's joints (painless synovitis and effusions of the knees)
OTHER
• Eighth nerve deafness* • Interstitial keratitis (leading to corneal ulcers and opacities)*
*Components of Hutchinson's triad.

Table 82.7 Stigmata of congenital syphilis.

LIMITATIONS OF NON-TREPONEMAL AND TREPONEMAL TESTS
NON-TREPONEMAL TESTS

• Lack of reactivity in early darkfield-positive primary syphilis
• Usually become negative with effective therapy (~15% of patients with early syphilis do not achieve a fourfold decline in titers 1 year after appropriate treatment, which is considered to represent a therapeutic failure)
• False-negative results
  • Prozone phenomenon: inhibition of flocculation in the setting of high titers of antibodies; requires serum dilution
  • Temporary negative result: secondary syphilis in the setting of HIV infection; reactive on subsequent testing
• Biologic false-positive results due to tissue damage
  • Pregnancy
  • Autoimmune diseases (e.g. lupus erythematosus)
  • Drug abuse
  • Lymphomas
  • Infectious diseases (e.g. malaria)
  • Vaccinations
  • Hepatic cirrhosis
  • Antiphospholipid syndrome
  • Idiopathic, familial
• False-positive: endemic treponematoses and borreliosis

TREPONEMAL TESTS
• Lack of reactivity in early darkfield-positive primary syphilis • Remain positive indefinitely, so not useful for monitoring response to treatment • Biologic false-positive: autoimmune diseases, HIV infection, hypergammaglobulinemia • False-positive: endemic treponematoses and borreliosis

Table 82.8 Limitations of non-treponemal and treponemal tests.

delayed consequences of localized inflammation at the sites of treponemal infection (Table 82.7). In about one-third of children, an interstitial keratitis is seen; this finding together with typical dental abnormalities (Hutchinson's teeth) and neural deafness forms the Hutchinson triad.

Laboratory diagnosis of congenital syphilis

A confirmed diagnosis of congenital syphilis requires laboratory demonstration of treponemes or child-specific antibodies. Serodiagnosis of congenital syphilis poses a difficult problem because IgG antibodies that are present may have been acquired transplacentally from the mother. A serum titer for a non-treponemal test that is fourfold higher than the mother's titer is suggestive of infection, but infected neonates may have lower titers. The detection of chromatographically separated 19S-antibodies in the FTA-ABS-19S-IgM test has a sensitivity of about 90%, similar to the IgM-capture ELISA. More recently, it has been shown that the detection of spirochetemia by PCR can improve the sensitivity of the diagnosis of congenital syphilis in neonates.

In late congenital syphilis, diagnosis is based on clinical findings in association with reactive serologic tests.

Laboratory Diagnosis of Syphilis

The diagnosis of syphilis is based on the direct detection of treponemes or treponemal DNA by microscopy or molecular biologic techniques as well as various serologic tests that assess antibody responses to either cardiolipin (non-treponemal tests) or treponemal antigens (treponemal tests). Diagnosis of the different stages of syphilis depends on the interpretation of laboratory test results, the presence of clinical signs and symptoms, and their history. All patients who have syphilis should also be tested for HIV infection.

Identification of T. pallidum

The detection of the microorganism depends on microscopic examination and molecular assays, since *T. pallidum* cannot be routinely cultured *in vitro*. For propagation and experimental studies, growth in rabbit testicles is possible.

Microscopic examination

Darkfield microscopy permits the definite diagnosis of syphilis by visual detection of motile spirochetes from lesions of the skin (see Fig. 82.3). It requires careful specimen collection, ideally consisting of serous fluid free of red blood cells. Identification is easy for an experienced microbiologist because of the typical episodic movements of the microorganism. Due to the presence of saprophytic spirochetes in the oral cavity, there is limited utility for darkfield examination of serous exudate from lesions in this site. Immunologic detection of the microorganism by the indirect fluorescent antibody test, which utilizes fluorescein-labeled anti-*T. pallidum* antibodies, is especially useful for oral lesions.

In the case of a negative result from microscopic examination, repeat testing is recommended. Serologic tests are also indicated.

Polymerase chain reaction-based assays

PCR-based assays for detection of *T. pallidum* DNA are commercially available and may be useful in special circumstances, e.g. neurosyphilis and congenital syphilis.

Serologic tests for syphilis

Non-treponemal tests

The VDRL and RPR tests and related assays such as the unheated serum reagin (USR), reagin screen test (RST) and toluidine red unheated serum test (TRUST) detect antibodies to cardiolipin. The latter is a component of mammalian cells that is incorporated and modified by treponemes, which results in the development of host antibodies against it (comparable with autoantibodies directed against phospholipids; see Ch. 23). All these tests measure IgG and IgM antibodies against this lipoprotein-like material released from damaged host cells and from treponemes.

Titers of these antibodies correlate with disease activity and are useful in screening and monitoring treatment (Fig. 82.14). *Qualitative* non-treponemal tests are suitable for screening purposes, and reactive results have to be confirmed by antibody titer. The performance of a *quantitative* non-treponemal test is generally requested even with a positive darkfield examination, in order to provide a baseline for longitudinal evaluation after antibiotic therapy. A fourfold decrease in the antibody titer indicates successful treatment, while a fourfold increase indicates relapse or reinfection. In the case of early and efficacious treatment, non-treponemal assays usually become negative. Limitations of the tests are listed in Table 82.8.

Treponemal tests

The major indication for treponemal tests for syphilis is confirmation of reactive non-treponemal tests. IgM and IgG antibodies are usually

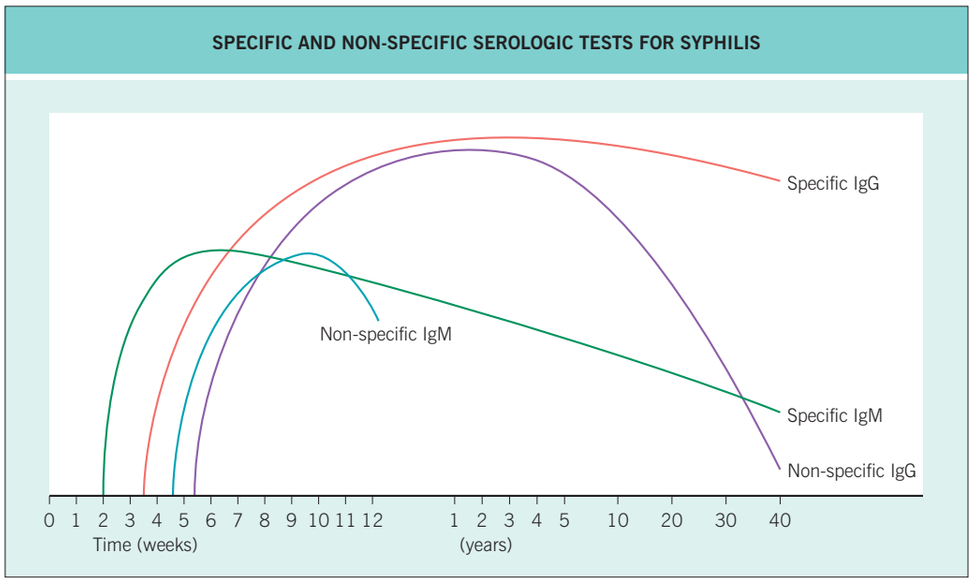

Fig. 82.14 Specific and nonspecific serologic tests for syphilis. These curves represent untreated patients. *Adapted from Fritsch P, Zangerle R, Stary A. Venerologie. In: Fritsch P (ed.). Dermatologie und Venerologie. Berlin: Springer, 2004:865–886.*

detected in these assays by the end of the fourth week after infection. Accurate quantitative evaluation is not useful. The specific treponemal tests generally remain positive indefinitely, and only in the case of treatment of very early syphilis do they revert to negative. The specificity is very high and false-positive reactions seldom occur. The sensitivity varies with the stage of syphilis: between 70% and 100% in primary syphilis, 100% in secondary and latent syphilis, and about 95% in late syphilis[15]. There is no differentiation between antibodies to *T. pallidum* and other treponemes and spirochetes.

Specific assays include the following:

- TPHA, MHA-TP, *T. pallidum p*article *a*gglutination test (TPPA): these assays measure antibodies directed against surface proteins of *T. pallidum* (sonicated fragments of treponemes) attached to rabbit erythrocytes as antigen carriers. Automatization is useful for large-scale testing and screening purposes. A positive result means that the patient had or still has active syphilis, but no assessment about the activity of the disease can be concluded from the qualitative result. Ninety percent of patients are positive at the time they seek medical care for a chancre.
- FTA-ABS assay: the serum reacts with the whole treponeme and forms antigen–antibody complexes visualized by fluorescein-isothiocyanate. To avoid nonspecific reactions with antibodies directed against saprophytic treponemes, a further step with Reiter treponemes is included to absorb nonspecific antibodies. The differentiation into IgM and IgG is possible by including selective anti-Ig antibodies.
- FTA-ABS-19S-IgM test: the isolated IgM antibody fraction is separately tested and provides a higher specificity than other tests. It is restricted to special situations, e.g. congenital syphilis or the differentiation of relapsing syphilis from reinfection.
- *S*olid *p*hase *hem*a*d*sorption test (SPHA) or IgM ELISA: the SPHA test is used for the detection of specific IgM antibodies that attach to the solid phase of microtiter plates by reacting with the treponemal antigen on rabbit erythrocytes as antigen carriers. IgM antibodies can also be measured by the ELISA technology. These tests are useful for the diagnosis of congenital syphilis, neurosyphilis (positive, but low-titer) and reinfection.

Pathology

In *primary syphilis*, there is ulceration and a diffuse dermal infiltrate of plasma cells, lymphocytes and histiocytes. Endothelial swelling is also present. Spirochetes may be detected with Warthin–Starry or immunohistochemical staining (see Fig. 0.32).

In *secondary syphilis*, the epidermis may be normal, psoriasiform, necrotic or ulcerated. Pustules may be found in the epidermis. Dermal infiltrates of plasma cells, lymphocytes and histiocytes can be perivascular, lichenoid, nodular or diffuse (Fig. 82.15). Older lesions of

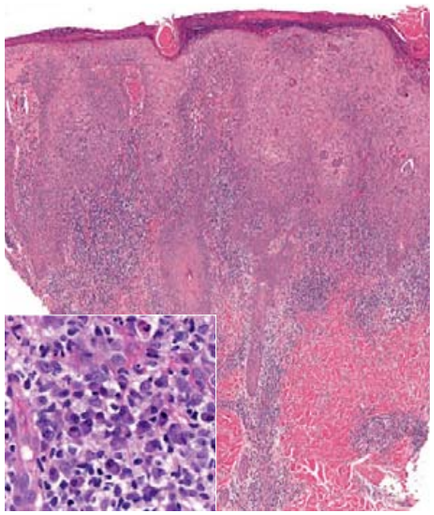

Fig. 82.15 Histology of secondary syphilis. Psoriasiform epidermal hyperplasia and a dense dermal infiltrate of plasma cells (see insert), lymphocytes and histiocytes are observed. *Courtesy, Lorenzo Cerroni, MD.*

secondary syphilis may be granulomatous and can resemble sarcoidosis except for the presence of plasma cells. Endothelial swelling and vascular proliferation can also be found in secondary syphilis. Spirochetes are identified in up to one-third of cases. Lues maligna is characterized by vasculitis.

In *tertiary syphilis*, tuberculoid granulomas (with or without caseation) are present together with plasma cells. Endothelial swelling is evident, but organisms are usually no longer seen.

Differential Diagnosis

The differential diagnoses for the different stages of syphilis are listed in Table 82.9.

Treatment

Penicillin G is still the treatment of choice for all stages of syphilis, and recommended regimens are listed in Table 82.10. A treponemicidal level of the antimicrobial should be achieved in the serum and (for patients with neurosyphilis) in the CSF. A penicillin level of >0.018 mg/l is considered treponemicidal, but the maximally effective *in vitro* concentration is considerably higher (0.36 mg/l)[16,17]. No tendency toward penicillin resistance has been detected in *T. pallidum*. Tetracyclines are used as second-line therapy if penicillin cannot be given; although a single 2 g dose of azithromycin can be effective[18], treatment failures due to macrolide-resistant *T. pallidum* have been reported.

DIFFERENTIAL DIAGNOSES FOR SYPHILIS
PRIMARY SYPHILIS
Other causes of genital ulcers should be considered: • Genital herpes • Genital trauma • Fixed drug eruption • Ulcerative genital carcinoma (e.g. squamous cell carcinoma) • Chancroid: jagged border, yellow exudate, painful • Lymphogranuloma venereum: transient, indurated, painless • Primary EBV infection • Behçet's disease
SECONDARY SYPHILIS
• Cutaneous: pityriasis rosea, guttate psoriasis, viral exanthems, lichen planus, pityriasis lichenoides chronica, primary HIV infection, drug eruption, nummular eczema, folliculitis • Mucous membranes: lichen planus; chronic aphthae; hand, foot and mouth disease; herpangina; perlèche • Condylomata lata: warts due to HPV, bowenoid papulosis, squamous cell carcinoma
TERTIARY SYPHILIS
• Cutaneous: lupus vulgaris, chromoblastomycosis, dimorphic fungal infections, leishmaniasis, lupus erythematosus, mycosis fungoides, sarcoidosis, tumors, venous ulcer

Table 82.9 Differential diagnoses for syphilis.

TREATMENT RECOMMENDATIONS FOR SYPHILIS IN SPECIAL SITUATIONS
PREGNANCY
Recommended: • Benzathine penicillin, 2.4 million units im weekly for two (early syphilis) or three (late syphilis) doses *or* • Procaine penicillin, regimen appropriate for the stage of syphilis (see Table 82.10)

In the case of penicillin allergy:
• Desensitization to penicillin *or*
• Alternative regimens*:
  • Azithromycin, 500 mg qd for 10 days *or*
  • Ceftriaxone, 1 g im or iv qd for 10–14 days

CONGENITAL
Neonate with proven or highly probable disease or born to mother with untreated early syphilis†: • Aqueous penicillin G, 50 000 U/kg iv q12h for the first 7 days of life, then q8h for 3 days (100 000–150 000 U/kg/day for a total of 10 days) *or* • Procaine penicillin, 50 000 U/kg im qd for 10–14 days
Neonate with no signs of disease born to mother with treated syphilis‡: • Benzathine penicillin, 50 000 U/kg im in a single dose
*Limited data; not recommended by the Centers for Disease Control (CDC) but included in the World Health Organization (WHO) and European Branch of the International Union against Sexually Transmitted Infections (IUSTI) guidelines. †CSF analysis should be performed prior to therapy. ‡Neonate with a normal physical examination and serum non-treponemal antibody titer less than fourfold the maternal titer; treatment is optional if the mother was fully treated before pregnancy.

Table 82.11 Treatment recommendations for syphilis in special situations. h, hours; im, intramuscularly; iv, intravenously; q, every; qd, daily.

TREATMENT RECOMMENDATIONS FOR SYPHILIS
EARLY SYPHILIS (PRIMARY, SECONDARY, AND EARLY LATENT [ACQUIRED <1 YEAR PREVIOUSLY])
Recommended: • Benzathine penicillin, 2.4 million units* im as a single dose *or* • Procaine penicillin, 1.2 million units im qd for 10 days†
Alternative regimens for penicillin-allergic patients‡: • Doxycycline, 200 mg qd (100 mg po bid preferred over a single 200 mg dose) for 14 days *or* • Tetracycline, 500 mg po qid for 14 days *or* • Ceftriaxone, 1 g im or iv qd for 8–10 days *or* • Azithromycin, 2 g po as a single dose§
LATE LATENT (ACQUIRED >1 YEAR PREVIOUSLY OR OF UNKNOWN DURATION), CARDIOVASCULAR AND GUMMATOUS SYPHILIS; RETREATMENT OF PRIMARY, SECONDARY OR LATENT SYPHILIS AFTER FAILED INITIAL TREATMENT¶
Recommended: • Benzathine penicillin, 2.4 million units* im weekly for three doses *or* • Procaine penicillin, 1.2 million units im qd for 20 days†
Alternative regimens for penicillin-allergic patients‡: • Doxycycline, 200 mg qd (100 mg po bid preferred over a single 200 mg dose) for 28 days *or* • Tetracycline, 500 mg po qid for 28 days
NEUROSYPHILIS AND OCULAR SYPHILIS
Recommended: • Aqueous penicillin G, 3–4 million units iv q4h (18–24 million units daily) for 10–14 days *or* • Procaine penicillin, 2.4 million units im qd plus probenecid, 500 mg po qid, both for 10–14 days
Alternative regimens for penicillin-allergic patients: • Ceftriaxone, 2 g im or iv qd for 10–14 days *or* • Consider desensitization
*In children, 50 000 U/kg up to the adult dose. †Alternative treatment regimen in the World Health Organization (WHO) guidelines (http://whqlibdoc.who.int/publications/2003/9241546263.pdf). ‡Limited data. §Resistance reported. ¶E.g. if RPR/VDRL titers fail to decrease fourfold or symptoms persist/progress; must first examine the CSF to exclude neurosyphilis.

Table 82.10 Treatment recommendations for syphilis. bid, twice daily; h, hours; im, intramuscularly; iv, intravenously; po, orally; q, every; qd, daily; qid, four times daily. Also see the Centers for Disease Control and Prevention (CDC) guidelines (www.cdc.gov/std/treatment/2010/STD-Treatment-2010-RR5912.pdf).

Recommended treatment regimens in the settings of pregnancy and congenital syphilis are summarized in Table 82.11. Although HIV-infected patients are at increased risk for neurologic complications and may have higher rates of treatment failure, prevention of these outcomes by altered therapeutic regimens has not been demonstrated. The CDC and International Union Against Sexually Transmitted Infections (IUSTI) currently recommend that HIV-infected individuals receive the same syphilis regimens as HIV-negative patients. Treatment guidelines and additional information are provided by the CDC (www.cdc.gov/mmwr) and IUSTI (www.iusti.org)[19]. Of note, a Jarisch–Herxheimer reaction characterized by the acute onset of fever, headache and myalgias can occur upon treatment of early syphilis.

The IUSTI recommends that non-treponemal tests (e.g. VDRL or RPR) be performed 1, 2, 3 and 6 months following antibiotic treatment of early syphilis, then every 6 months for up to 2 years post treatment[19]; the CDC suggests clinical and serologic evaluation at 6 and 12 months for uncomplicated cases, with more frequent and extended evaluation (e.g. at 3, 6, 9, 12 and 24 months) for HIV-infected patients. Evaluation of late syphilis at 6-month intervals for up to 3 years is recommended. In the setting of abnormal CSF findings, a CSF examination is recommended at 6-month intervals until cell counts are normal and the CSF-VDRL is negative. Evaluation of sexual partners and reporting are mandatory in many countries.

GONORRHEA

Synonyms: ■ Gonorrhea: "clap" ■ Disseminated gonococcal infection: arthritis-dermatosis syndrome

Key features

- Gonorrhea is the most common reportable STI in high-income countries
- It is caused by *Neisseria gonorrhoeae*, which infects the mucosal surfaces of the human genital tract (as well as the anus, rectum and mouth) after direct – usually sexual – contact with an infected person
- Cutaneous pustules as well as systemic symptoms such as arthritis and fever can result from hematogenous dissemination, which occurs in only a small percentage of infected individuals
- Overall, the incidence of gonorrhea has declined during the past several decades, although there has been a recent increase in Eastern Europe
- Over the past few decades, resistance of *N. gonorrhoeae* to various antimicrobials has increased in frequency

History

Gonorrhea was mentioned in ancient literature from China, Egypt, the Roman Empire and Greece, as well as in the Old Testament[20]. Over the centuries, several names have been used to denote infection with *N. gonorrhoeae*, including: "strangury", as used by Hippocrates; "clap", derived from the district of prostitution called "Les Clapier" in Paris; "gonorrhea", chosen by Galen (130 AD) to describe the urethral exudate as a "flow of seed"; and "M. Neisser", recognizing Albert Neisser, who discovered the microorganism in 1879 in stained smears from vaginal, urethral and conjunctival exudates.

Culture of *N. gonorrhoeae* was first described by Leistikow and Lüffler in 1882, and it was improved in 1964 by Thayer and Martin, who devised selective growth conditions on special agar plates[21]. Understanding the differences in the virulence of gonococci and studies of its molecular biology have led to greater insight into the pathology of the organism[22]. Treatment of gonococcal infections was problematic until sulfonamides were introduced in 1936 and penicillin in 1943. During the past 25 years, an increase in antimicrobial resistance to penicillin and other antibiotics, such as tetracyclines and quinolones, has been observed and has become problematic.

Epidemiology

During the past century, the incidence of gonorrhea was influenced by politics, with peaks at the ends of the First and Second World Wars. A sudden decrease in reported cases occurred after the introduction of penicillin and other effective antimicrobials. Subsequently, the sexual freedom of the 1970s led again to an increase in the incidence of gonorrhea. However, with the advent of the AIDS epidemic, sexual practices again changed due to concerns regarding transmission of HIV, and this had a remarkable impact on the incidence of gonorrhea. Gonorrhea rates in the US peaked in the mid 1970s and have remained relatively low and stable over the past 15 years.

Political changes in Eastern Europe led to an increased rate of gonorrhea (as well as syphilis) in the 1990s, especially in prostitutes and those with sexual exposure to prostitutes. Migration of sex workers with a high infection rate also increased the number of reported cases of gonorrhea in other regions of Europe, especially in urban areas and high-risk groups (e.g. men who have sex with men). This probably reflects an increase in unsafe sexual behavior, particularly among young people and in high-risk populations.

Similar to other venereal diseases, the incidence of gonorrhea varies with age and is highest in the 15- to 24-year-old age group, in which there is a higher rate in women than in men. In the US, African Americans have a 20-fold higher rate of gonococcal infections than Caucasian Americans. This may reflect different sexual behavior patterns and exposures as well as a better reporting system in public health institutions, which are more often utilized by African Americans.

Transmission

N. gonorrhoeae is a pathogen restricted to humans as its only host and transmitted primarily by sexual contact. The most efficient transmission occurs by vaginal or anal intercourse where there is physical contact with the mucosal surface of a sexual partner with an asymptomatic or mildly symptomatic infection. An exception is indirect contact among prepubescent girls sharing contaminated objects. There is no evidence that gonococci can be spread by air droplet transmission as occurs with meningococci. Vertical transmission can occur from an infected mother to the newborn during parturition, and this may lead to gonococcal conjunctivitis, pneumonia or even vulvovaginal infection.

Biology of *N. gonorrhoeae*

Gonococci are Gram-negative diplococci that typically grow in pairs. They exhibit multiple colony types when grown on hemoglobin-containing media in a 3% CO_2 atmosphere. The outer membrane structure of *N. gonorrhoeae* is typical for Gram-negative bacteria but, in contrast to *N. meningitidis*, it lacks the polysaccharide capsule that is responsible for the virulence of meningococci. Surface molecules on the outer membrane are involved in attachment, invasion and host injury, and they also represent important antigenic structures, especially the fibrillar pili (composed of 18 kDa pilin subunits)[23].

Gonococci require iron to grow, with sources including transferrin, lactoferrin and hemoglobin; acquisition of iron is mediated by binding to host proteins with a specific receptor. The microorganism cannot tolerate drying or low temperatures, and its growth is optimal at 35–37°C in a 5% CO_2 atmosphere on a complex growth medium containing inorganic iron, glucose, vitamins and cofactors as well as antibiotics.

Pathogenesis

Although there is increasing knowledge about the pathogenicity of this microorganism, the exact molecular mechanisms of invasion of gonococci into the host cell are still unknown. Several virulence factors are involved in the processes of adherence, inflammation and mucosal invasion[24]. Because pili increase adhesion to the host cell, they also play an important role in pathogenesis; this may explain why non-piliated gonococci have a reduced ability to cause infections in humans. The adherence of gonococci to the human epithelial host cell and to neutrophils is dependent not just on the pili but also on Opa ligands. Anti-pilus antibodies have been shown to block epithelial adherence and increase phagocytic killing. Expression of the transferrin receptor and full-length lipo-oligosaccharide (LOS) appear to increase infectivity. Gonococci are able to multiply and divide intracellularly, where they are immune to host defense mechanisms. Intracellular invasion is favored by expression of certain Opa proteins and non-sialylated LOS.

Gonococci have the ability to cause tissue destruction by production of a variety of peptides and lipids such as phospholipase, peptidases, lipid A and peptidoglycans. This plays a role in their damage of fallopian tubes and the development of postinflammatory arthritis.

Clinical Features

Gonorrhea has a broad spectrum of clinical manifestations in both men and women, including asymptomatic infections, local symptomatic mucosal infections (with or without local complications), and systemic dissemination (Table 82.12). Symptoms vary according to the site of infection and strain of organism.

The incubation period for gonorrhea is relatively short; it only takes 2–5 days until signs and symptoms of an infection with *N. gonorrhoeae* appear. Up to 10% of infected men and 50% of infected women lack clinical symptoms, which is especially common in rectal and pharyngeal infections[25].

Gonococcal infection in men

The most common clinical presentation of gonococcal infection in men is an acute anterior urethritis with dysuria and a urethral discharge that is typically purulent and profuse. In about one-quarter of infected men, the urethral symptoms are less pronounced, similar to those of non-gonococcal urethritis, and appear only after urethral manipulation ("stripping"). Without treatment, clinical symptoms disappear in most patients after about 6 months. Local complications can include inflammation of the Cowper's and Tyson's glands and gonococcal pyoderma; ascension of the infection may lead to epididymitis, prostatitis and vesiculitis. Patients with gonococcal epididymitis present with unilateral testicular pain and swelling accompanied by urethritis.

CLINICAL MANIFESTATIONS OF GONORRHEA
DISSEMINATED INFECTION
• Arthritis • Fever • Tenosynovitis • Acral cutaneous pustules • Scalp abscesses (in neonates at sites of fetal scalp monitor electrodes) • Endocarditis • Meningitis
DIRECT MUCOSAL INFECTION
• Urethritis • Cervicitis • Proctitis • Pharyngitis • Vulvovaginitis (children) • Ophthalmia neonatorum
LOCAL EXTENSION
• Prostatitis • Vesiculitis • Epididymitis • Salpingitis • Oophoritis • Pelvic inflammatory disease

Table 82.12 Clinical manifestations of gonorrhea.

Gonococcal infection in women

In about 50% of infected women, gonococcal infection is asymptomatic and therefore remains unnoticed. The primary site of gonococcal infection in women is the endocervical canal, with associated clinical symptoms consisting of increased vaginal discharge, dysuria, intermenstrual bleeding, and menorrhagia. Clinical inspection shows purulent cervical discharge with erythema and edema; swabbing of the endocervical canal results in a highly characteristic yellow color. Urethral colonization is present in 70–90% of infected women and is the usual site of infection in women who have had a hysterectomy. Occasionally, inflammation of Bartholin's glands is observed, with acute swelling of the labial folds and appearance of purulent discharge when pressure is applied to the gland.

The most common local complication in women is acute salpingitis or pelvic inflammatory disease (PID) due to ascension of the microorganisms. It occurs in approximately 10–20% of infected women (often developing immediately after a menstrual period) and may result in the long-term consequences of infertility, chronic pelvic pain and ectopic pregnancy. The clinical manifestations of PID vary and include lower abdominal pain, adnexal tenderness, elevation of the ESR, leukocytosis and fever. Gonorrheic perihepatitis (Fitz–Hugh–Curtis syndrome), with inflammation of the adjacent peritoneal area, is an infrequent complication in which symptoms of PID are accompanied by pain in the right upper quadrant that mimics acute cholecystitis.

Extragenital gonorrhea

Pharyngeal gonorrhea

This can occur in both men and women after oral sexual exposure. Because it is usually asymptomatic, the infection typically goes undetected and spontaneously resolves within a few weeks[26]. Pharyngeal gonorrhea may be an important source of urethral gonorrhea in men who have sex with men.

Rectal gonorrhea

Rectal gonorrhea is mainly seen in men who have sex with men and in heterosexual women who practice receptive anal intercourse. Rectal gonorrhea is asymptomatic in at least 50% of patients, but it may result in gonococcal proctitis that is accompanied by inflammation, rectal discharge, anal pruritus, bleeding, tenesmus and constipation.

Gonococcal infection in newborns is caused by inoculation with *N. gonorrhoeae* during delivery through an infected birth canal, and most often it presents with purulent conjunctivitis (ophthalmia neonatorum). Due to preventive application of antimicrobial ointment (usually erythromycin) immediately after birth, the rate of this gonococcal infection is currently low.

Fig. 82.16 Gonococcemia (arthritis–dermatosis syndrome). Pustule with surrounding erythema on the toe.

Gonococcal ophthalmia (including ophthalmia neonatorum)

Gonococcal ophthalmia is uncommon in adults but still represents a major cause of blindness in some low-income countries. Primarily due to self-inoculation and unusual sexual practices, it initially presents as purulent conjunctivitis and (if left untreated) can rapidly progress to severe keratitis followed by corneal opacification.

Gonococcal infection in newborns is caused by inoculation with *N. gonorrhoeae* during delivery through an infected birth canal, and most often it presents with purulent conjunctivitis (ophthalmia neonatorum). Due to preventive application of antimicrobial ointment (usually erythromycin) immediately after birth, the rate of this gonococcal infection is currently low.

Disseminated gonococcal infection

Arthritis–dermatosis syndrome (gonococcemia)

The most common clinical manifestation of gonococcal bacteremia is an acute arthritis–dermatosis syndrome, which occurs in approximately 0.5–1% of patients with mucosal gonorrhea[27]. Risk factors for disseminated gonococcal infection include menstruation (with the majority of cases in women developing during or immediately following menses) and deficiencies in the late complement components (C5–C9; see Ch. 60). The classic syndrome consists of fever, joint pain and a paucilesional eruption of hemorrhagic pustules. Gonococcal tenosynovitis affects primarily larger joints (e.g. knees, elbows, wrists, ankles) and is sometimes visible as erythema overlying the tendons.

The cutaneous lesions consist of scattered necrotic pustules due to an embolic septic vasculitis. They occur primarily on the distal portions of the extremities (Fig. 82.16) and contain gonococci. With a longer duration of symptoms, positive blood cultures become less common.

Laboratory Diagnosis

Laboratory diagnosis is based on the identification of *N. gonorrhoeae* in secretions from infected mucous membranes by using stained smears, cultures and/or molecular biologic techniques (Fig. 82.17). Samples are typically obtained from the endocervical canal in women (after wiping off exudate), the urethra in men (and occasionally in women who have had a hysterectomy), and (when indicated) the posterior pharynx. For diagnosis by nucleic acid amplification methods (see below), a vaginal swab or urine sample can also be used. Anorectal specimens should be obtained via direct visualization using anoscopy if possible.

Staining methods

Direct detection of Gram-negative diplococci within neutrophils in Gram-stained smears (Fig. 82.18) (or using a methylene blue stain) provides an immediate diagnosis, which is especially helpful in symptomatic individuals. Gram-stained urethral exudate detects between 95% and 98% of symptomatic infections in men, whereas Gram-stained cervical smears have a sensitivity of about 50%. The specificity of Gram-stained exudates depends primarily on the experience of the microscopist and on proper collection, and it may approach 100% in an optimal setting. However, when screening asymptomatic

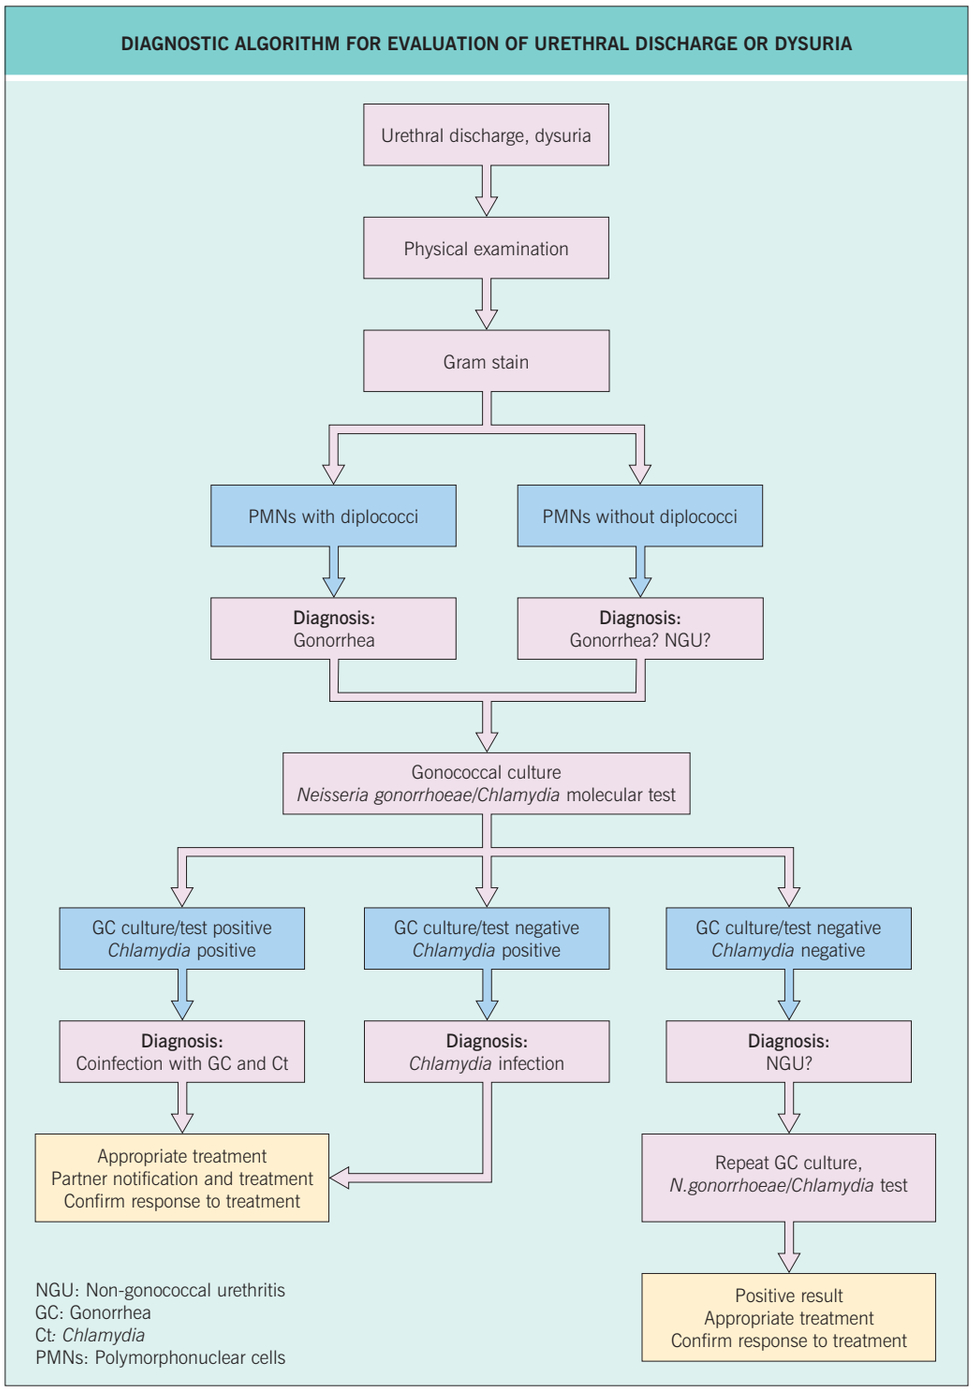

Fig. 82.17 Diagnostic algorithm for evaluation of urethral discharge or dysuria.

individuals, smears have lower sensitivity and are not cost-effective. Smears are not helpful for detection of rectal and pharyngeal gonorrhea due to the presence of a large number of other bacteria. Of note, Gram-negative diplococci may occasionally be seen in smears of the contents of pustules in disseminated gonococcal infections.

Culture techniques

Isolation of *N. gonorrhoeae* by culture is still considered to be the gold standard for the diagnosis of gonococcal infections, and positive results obtained by stained smears should be confirmed by culture. Culture is currently the only acceptable method for cases of rape or other medico-legal situations, and it allows sensitivity testing. Pustular lesions due to gonococcemia should be punctured for culture.

Currently available antibiotic-containing selective media (Thayer–Martin) or selective New York media have a sensitivity of 80–95% (depending on the symptomatic status of the infected person) for genital samples directly plated at the time of collection. Sensitivity is much lower for extragenital specimens such as those from the rectal area (<50%). The specificity of the culture is reported to be approximately 95% in the case of isolation from the genital region. Confirmation of a positive culture by *N. gonorrhoeae*-specific tests is recommended and is mandatory in cases of extragenital infection.

Non-culture techniques for gonococcal diagnosis

Diagnosis of gonococcal infections by molecular techniques is widely utilized and has advantages over culture when specimen transport and storage are potential problems. These tests also enable the diagnosis of chlamydial infection to be made from the same specimen collection tube and are more sensitive than culture for extragenital specimens. The disadvantage of non-culture techniques is the lack of antibiotic sensitivity testing. Therefore, if non-culture techniques are routinely used for gonococcal diagnosis, culture-based regional monitoring of gonococcal antimicrobial susceptibility is needed to determine the appropriate therapy.

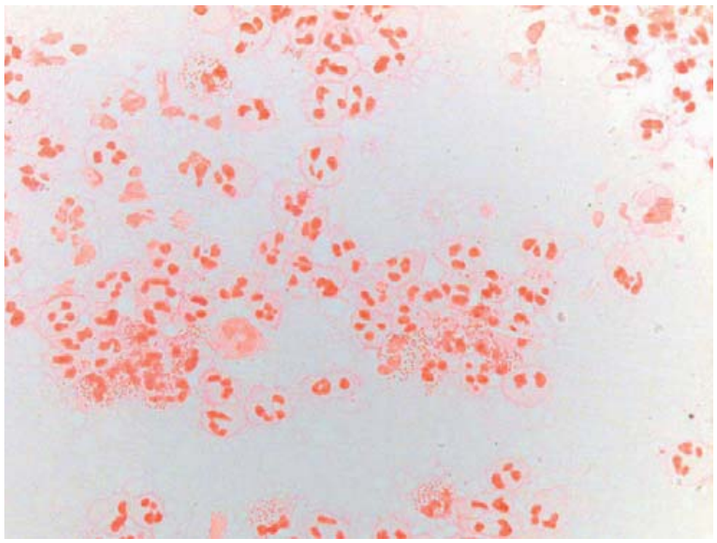

Fig. 82.18 Gonococci in a Gram-stained smear of urethral discharge. Neutrophils containing numerous Gram-negative diplococci, consistent with *Neisseria gonorrhoeae,* are evident.

Non-amplified DNA hybridization

The non-amplified DNA probe test (Gen-Probe PACE 2®) is still used in some parts of the world and is based on the hybridization of gonococcal RNA. It has a sensitivity and specificity comparable with that of culture.

Nucleic acid amplification techniques

Nucleic acid amplification tests (NAATs) that use PCR (e.g. COBAS Amplicor™, VERSANT® CT/GC DNA 1.0 Assay), transcription mediated amplification (APTIMA Combo 2®, APTIMA GC®) and the strand displacement amplification assay (ProbeTec™) detect gonococcal DNA or RNA (alone or in addition to chlamydial DNA). Advantages of these tests include use of "non-invasive" sample types (e.g. urine and vaginal or introital swabs)[28] and avoidance of problems with storage and transport (e.g. in field settings where culture facilities are not available). In asymptomatic patients and in samples from extragenital sites, amplification methods surpass the sensitivity of culture[29].

Pathology

Biopsies of skin lesions due to gonococcemia show epidermal necrosis with epidermal or dermal pustules. There is a septic neutrophilic vasculitis with extravasated erythrocytes and thrombi. Organisms are seldom demonstrated.

Differential Diagnosis

Other causes of urethral and cervical discharge in men and women must be considered, including infections with *Chlamydia trachomatis*, *Trichomonas vaginalis*, yeasts and anaerobic bacteria. The skin lesions of disseminated gonococcemia may need to be distinguished from folliculitis (e.g. bacterial), another disseminated infection, a neutrophilic dermatosis, cutaneous vasculitis or a pustular drug eruption.

Treatment

Although many antibiotics can be used for the treatment of gonorrhea, selection of therapy depends on the susceptibility of the organism that is isolated (or regional patterns), the anatomic site(s) of the infection, clinical symptoms, and the cost (especially in resource-poor settings) as well as potential side effects of the drug. Over the past few decades, strains of gonorrhea resistant to a number of antibiotics (including sulfonamides, penicillin, tetracyclines, erythromycin, spectinomycin and, more recently, quinolones) have emerged. The development of different types of resistance has led to regular revisions of gonococcal treatment recommendations. For example, in 2007, the CDC recommended that fluoroquinolones no longer be prescribed for the treatment of gonococcal infections in the US. Currently, third-generation cephalosporins are the antibiotics of choice for gonococcal infections (Table 82.13)[30]; however, treatment failures (especially with oral cephalosporins in Asian countries) and decreased *in vitro* sensitivity have been described. Single-dose therapy, preferably with intramuscular ceftriaxone, is recommended in order to maximize effectiveness and avoid patient non-compliance.

In the US, the empiric treatment of chlamydial infections concurrently with gonococcal treatment is recommended, because these two infections often occur together. However, if diagnostic testing for *Chlamydia* is negative, treatment of *C. trachomatis* is not necessary. Lastly, confirmation of cure, compliance with therapy, and partner notification are legal recommendations for gonococcal treatment and prevention in some countries.

TREATMENT RECOMMENDATIONS FOR GONOCOCCAL INFECTIONS
UNCOMPLICATED GONOCOCCAL INFECTIONS OF THE URETHRA, CERVIX OR RECTUM
Recommended regimens: • Ceftriaxone, 250 mg im as single dose (preferred) *or* • Cefixime, 400 mg po as single dose *or* • Other single-dose injectable cephalosporin regimens (e.g. ceftizoxime 500 mg im; cefoxitin 2 g im plus probenecid 1 g po; cefotaxime 500 mg im)
Alternative regimen: • Spectinomycin, 2 g im as single dose
UNCOMPLICATED GONOCOCCAL INFECTIONS OF THE PHARYNX
• Ceftriaxone, 250 mg im as single dose
GONOCOCCAL CONJUNCTIVITIS
• Ceftriaxone, 1 g im as single dose
DISSEMINATED GONOCOCCAL INFECTION
Recommended regimen: • Ceftriaxone, 1 g im or iv q24h until 24–48 hours after improvement begins, *then* cefixime, 400 mg po bid to complete at least 1 week of therapy
Alternative regimens: • Cefotaxime or ceftizoxime, 1 g iv q24h until 24-48 hours after improvement begins, then cefixime as above
Additional treatment for *C. trachomatis* (azithromycin 1 g as single dose or doxycycline 100 mg bid for 7 days) is recommended for all patients being treated for gonococcal infections, unless *Chlamydia* testing excludes co-infection
NEONATAL INFECTIONS
Disseminated gonococcal infection and gonococcal scalp abscesses in newborns • Ceftriaxone, 25–50 mg/kg iv or im qd for 7 days (10–14 if meningitis) *or* • Cefotaxime, 25 mg/kg iv or im q12h for 7 days (10–14 if meningitis)
Ophthalmia neonatorum or asymptomatic neonate born to mother with untreated gonorrhea • Ceftriaxone, 25–50 mg/kg iv or im as single dose, not to exceed 125 mg

Table 82.13 Treatment recommendations for gonococcal infections. bid, twice daily; h, hours; im, intramuscularly; iv, intravenously; po, orally; q, every; qd, daily.

CHANCROID

Synonyms: ■ Soft chancre ■ Ulcus molle

Key features

- Chancroid is characterized by acute genital ulcers and inguinal adenitis
- It is caused by the sexually transmitted Gram-negative and facultatively anaerobic bacterium *Haemophilus ducreyi*
- It is a rare disease in high-income countries, and its occurrence is closely linked with prostitution

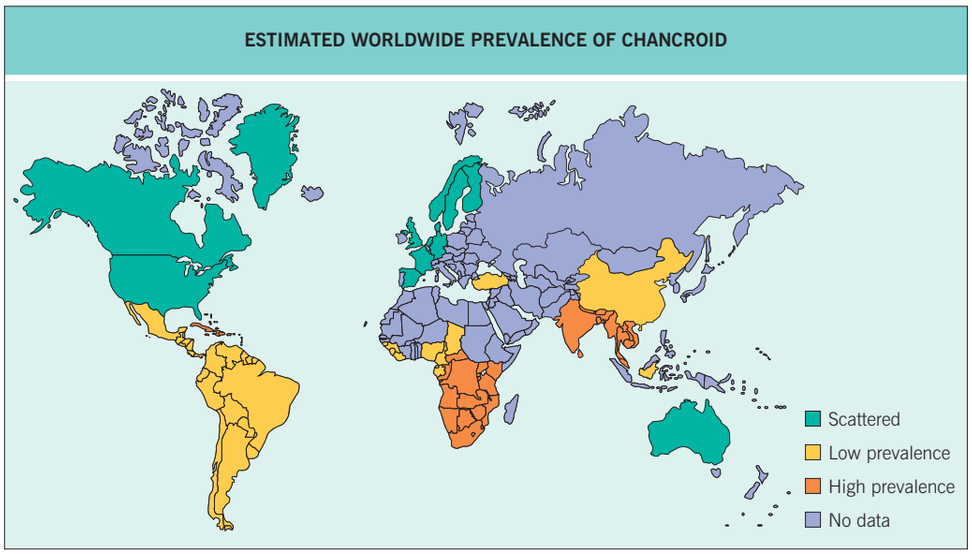

Fig. 82.19 Estimated worldwide prevalence of chancroid[32].

INFECTIOUS CAUSES OF GENITAL ULCER DISEASE				
Disease	**Incubation time**	**Clinical lesion**	**Diagnosis**	**Organism**
Genital herpes	3–7 days	Vesicles, erosions, ulcers; history of herpes infection; painful	DFA, Tzanck (if vesicles), culture, PCR	HSV 2 > 1
Primary syphilis	10–90 days, average 3 weeks	Non-purulent; usually single ulcer; indurated; relatively painless	Darkfield microscopy, serology	*Treponema pallidum*
Chancroid	3–10 days	Purulent; often multiple ulcers; soft, undermined edges; painful	Culture	*Haemophilus ducreyi*
LGV	3–12 days	Transient ulcer; indurated; painless	Serology, culture, PCR	*Chlamydia trachomatis* serovars L1–3
Donovanosis	2–12 weeks	Chronic ulcer; indurated, beefy red, friable	Smears, histology	*Klebsiella (Calymmatobacterium) granulomatis*

Table 82.14 Infectious causes of genital ulcer disease. DFA, direct fluorescent antibody assay; LGV, lymphogranuloma venereum.

History

In 1850, chancroid was first differentiated from syphilis. In 1889, Ducrey described the responsible organism as a streptobacillary rod, which he was able to subcultivate by serial autoinoculations into the forearm of a patient[31].

Epidemiology

The disease is common in parts of Africa, the Caribbean and Southeast Asia and endemic in many low-income countries (Fig. 82.19), with a worldwide annual incidence of about 7 million[33]. Outbreaks are occasionally reported in cities in high-income countries, predominantly within the US. In the US, the number of chancroid cases peaked in the early 1990s and has been very low for the past decade. In most of the disease settings, prostitutes are the reservoir for the microorganism, and men are much more frequently affected than women (ratio 10:1). In many low-income countries, chancroid is the most common cause of infectious genital ulcer disease (Table 82.14), with frequencies even higher than those of genital herpes.

Transmission

The source of infection is almost always sexual contact with infected women who have genital ulcers. The probability of transmitting chancroid after a single sexual contact is 0.35, and untreated infected women are estimated to be infectious for up to 45 days (while the clinical lesions are present)[34]. Asymptomatic carriers seem to be rare and there is no evidence that women harbor the organism for a significantly long period of time without clinical findings.

Chancroid and HIV

Chancroid and other diseases that produce genital ulcers are important risk factors for transmission of HIV. Men infected with HIV more often have had a history of genital ulcers compared with HIV-negative men[35]. The risk of acquiring HIV after having sexual contact with HIV-positive women was highest for uncircumcised men with genital ulcer disease compared with circumcised men with and without genital ulcer disease (29% versus 6% versus 2%). In women, the risk of becoming infected with HIV also increases with the number of episodes of genital ulcer disease.

The presence of increased numbers of $CD4^+$ lymphocytes and macrophages in ulcers due to infection with *H. ducreyi* provides an ideal opportunity for a latent HIV infection to become productive, with excretion of the virus into ulcer secretions. Genital lesions therefore become both a portal of viral entry for non-infected individuals and exit for HIV-infected persons[36].

Biology of the Organism

H. ducreyi is a Gram-negative, facultatively anaerobic bacillus of small size that shows a typical chaining pattern on Gram stain (Fig. 82.20). It does not share many similarities with other members of the genus *Haemophilus*.

Pathogenesis

The penetration of the microorganism occurs via microscopic barrier defects in the epidermis. Signs of inflammation develop due to infiltration of lymphocytes, macrophages and granulocytes in a primarily Th1

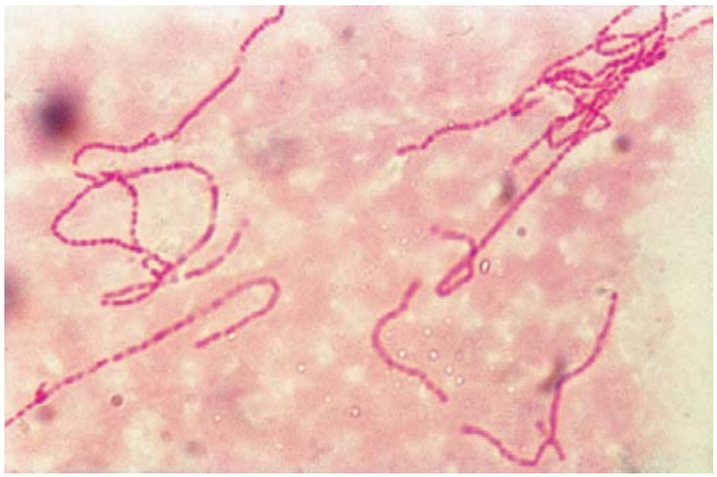

Fig. 82.20 Gram-stained smear in chancroid. This smear of exudate from a genital ulcer shows the characteristic chaining pattern of *H. ducreyi*.

cell-mediated immune response combined with pyogenic inflammation. Chancroid is associated with regional lymphadenitis due to the spread of the infection and resultant pyogenic inflammation.

Clinical Features

The incubation period is 3–10 days; usually, the onset of clinical symptoms occurs between days 4 and 7. In men, the lesion starts with a papule surrounded by erythema and soon progresses to a pustule and then a painful ulcer. The latter typically has a purulent base and soft, undermined edges and is sharply demarcated (Fig. 82.21A,B). In about one-half of infected men, several ulcers develop due to apposition with the initial lesion, and they can coalesce to form giant ulcers. Most lesions are located on the internal or external surface of the prepuce, in the coronal sulcus (particularly in uncircumcised men) or around the frenulum. They are often accompanied by edema of the prepuce.

Occasionally, a so-called "septic sore" can be observed on the shaft of the penis or prepuce, with pus trapped within the skin in the absence of an obvious ulcer. In this case, the pus that can be expressed is full of microorganisms[32]. In contrast to chlamydial infections, chancroid is symptomatic in almost all infected individuals.

Co-infections with syphilis or herpes simplex virus (HSV) are possible. In Kenya, approximately 4% of men with genital ulcer disease have a co-infection with both *T. pallidum* and *H. ducreyi* (ulcus mixtum) and about the same percentage have HSV plus *H. ducreyi*, which makes etiologic diagnosis based on clinical findings impossible.

In women, the majority of lesions are within the introital area; they may also occur on the cervix or vaginal wall, or in the perianal area, but rarely occur in an extragenital location. Lesions in women are sometimes only mildly symptomatic and are more often multiple.

In both men and women, painful inguinal lymphadenitis may accompany the genital lesions. It is more often observed in men (about 40% of patients) and is usually unilateral (see Fig. 82.21B). Inguinal buboes may rupture and lead to inguinal ulceration.

Pathology

Biopsies of chancroid classically have three zones of inflammation beneath the ulcers. The first zone has necrotic debris, fibrin and neutrophils. The middle zone is an area of granulation tissue, and the deepest zone contains lymphocytes and plasma cells. Gram-negative coccobacilli are only rarely found with tissue Gram or Giemsa stains and are best seen with smears.

Diagnosis

Material is usually obtained with a cotton swab, on which the organism can only survive for a few hours without being refrigerated at 4°C. Gram stain of *H. ducreyi* in a smear of the exudate shows a "school-of-fish" or "railroad track" pattern of small Gram-negative bacilli (see Fig. 82.20). The finding is not specific because other bacteria may have a similar arrangement, and it is insensitive because the responsible bacteria are only seen in about a third to a half of infected persons.

The accurate diagnosis of chancroid requires isolation of *H. ducreyi* on special culture media; small, non-mucoid semiopaque or translucent colonies appear after 24–72 hours if grown at 33–35°C in a 5–10% CO_2

Fig. 82.21 Chancroid. A Well-demarcated painful ulcers on the penis. **B** Multiple purulent ulcers with undermined borders. **C** Unilateral lymphadenitis with overlying erythema. *B, Courtesy, Joyce Rico, MD.*

atmosphere. Further identification methods are needed, such as the porphyrin test, to prove the requirement of hemin (factor X) for growth. There are variations in media (which are not widely available from commercial sources) and the sensitivity of culture is between 60% and 80%, depending on the quality and handling of the specimen, culture conditions and laboratory experience.

If culture is not possible or is inconclusive, diagnosis is based on the clinical picture and the exclusion of other microorganisms that cause genital ulcer disease, such as syphilis or genital herpes, as well as on the epidemiologic data and response to therapy.

Other diagnostic procedures, such as antigen detection methods, molecular biologic techniques or serologic tests, are under development and cannot yet be recommended for routine diagnosis. A PCR test may soon be on the market, allowing the diagnosis of a whole range of microorganisms causing genital ulcer disease, such as *T. pallidum*, *H. ducreyi* and HSV[37].

Differential Diagnosis

Other infections that cause genital ulcers have to be considered (see Table 82.14), as well as trauma, a fixed drug eruption, and, occasionally, carcinoma.

Treatment

Successful treatment can be achieved using several antimicrobial drugs (Table 82.15); ulcers improve within 3 days and typically heal in 14 days or less, depending on the initial lesions. The different treatment regimens cure about 95% of infected individuals, with azithromycin and ceftriaxone requiring only a single dose. Ciprofloxacin is contraindicated in pregnant and lactating women. In patients with HIV infection, the treatment recommendations are the same, but with a longer treatment course; close monitoring may be necessary because of delayed healing and possible treatment failures.

Sexual partners from the 10 days preceding the onset of symptoms should be examined and treatment offered regardless of whether the microorganism can be cultured or clinical symptoms are present.

LYMPHOGRANULOMA VENEREUM

Synonyms: ■ Durand–Nicolas–Favre disease ■ Climatic bubo ■ Strumous bubo ■ Poradenitis inguinale ■ Lymphogranuloma inguinale

Key features

- Lymphogranuloma venereum (LGV) is a rare STI caused by *Chlamydia trachomatis* serovars L1–3
- LGV is endemic in some areas of Africa, Asia and South America and is observed sporadically in other parts of the world
- The disease progresses through three stages: (1) initial infection of the genital mucosa; (2) inguinal lymphadenopathy that is usually unilateral; and (3) a firm mass and bubo with spontaneous drainage and involution, often accompanied by proctocolitis and involvement of perirectal or perianal lymphatic tissue

TREATMENT REGIMENS FOR CHANCROID
• Azithromycin, 1 g po, single dose
• Ceftriaxone, 250 mg im, single dose
• Ciprofloxacin, 500 mg po bid for 3 days*,†
• Erythromycin base, 500 mg po qid for 7 days†
*Contraindicated for pregnant or lactating women.
†Worldwide, isolates with intermediate resistance.

Table 82.15 Treatment regimens for chancroid. bid, twice daily; im, intramuscularly; po, orally; qid, four times daily.

History

Lymphogranuloma venereum (LGV) has been confused with other diseases that cause lymphadenopathy, especially syphilis, genital herpes and chancroid. A major diagnostic advantage arose with the introduction of the Frei test, a specific skin test established in 1925[38]. The first isolation of *Chlamydia* was reported in 1930, enabled by intracerebral inoculation of monkeys, followed in 1935 by cultivation in fertilized eggs[39].

Epidemiology

LGV is endemic in East and West Africa, Southeast Asia, India, South America and the Caribbean basin; it occurs sporadically throughout the rest of the world. In some countries, it is a reportable disease. LGV classically affects sailors, soldiers and travelers who acquire the disease in endemic regions. Data on the prevalence of LGV have often been based on the results of serologic tests and the Frei skin test, both of which are nonspecific and have cross-reactivity with other genito-ocular chlamydial infections.

LGV is reported more often in men than in women and the peak age correlates with the period of maximum sexual activity. However, the frequency of infection following sexual intercourse has not been well investigated. Since 2003, a series of outbreaks of LGV have been reported in Western Europe and the US[40]. The affected individuals were primarily men who lived in large cities and had sex with other men[41], many of whom had concurrent HIV infection and ulcerative proctitis.

Pathogenesis

Caused by specific *Chlamydia trachomatis* serovars (L1–3), LGV affects mainly the lymphatic tissue in the genitorectal area. The organisms enter the body via microscopic defects in the mucosa or the skin. The microorganisms then enter the lymphatics, leading to lymphangitis, perilymphangitis and infection of lymph nodes. Over a period of many weeks to months, the inflammatory process expands and results in periadenitis, involvement of a few neighboring lymph nodes, the development of abscesses (which can rupture), and the formation of fistulas and strictures. In the rectum, destruction and ulceration of the mucosa may occur. Local progression and systemic dissemination are both influenced by host immunity. Latent persistence of the microorganism within involved tissues may last for many years.

Clinical Features

The clinical manifestations of LGV can be separated into primary lesions, inguinal and ano-genito-rectal syndromes, and other manifestations (Table 82.16).

The initial clinical presentations vary, appearing after an incubation period of 3–12 days (see Table 82.16). In up to half of infected individuals, a herpetiform lesion develops at the site of exposure and heals rapidly without a scar. This transient lesion is most often located on the coronal sulcus in men and on the posterior vaginal wall in women, and it is usually accompanied by local lymphangitis. Cervicitis and urethritis are mild and often remain unrecognized. Rectal exposure might result in proctocolitis associated with rectal discharge, anal pain and tenesmus. Co-infection with other pathogens can sometimes be observed.

The secondary stage is characterized by the inguinal syndrome, in which unilateral lymphadenopathy (depending on the site of the primary infection) is accompanied by overlying erythema. The bubo is initially firm and then undergoes rapid enlargement, becoming more painful. Eventually the overlying skin develops a bluish discoloration and the bubo finally ruptures through the skin; pus may drain through numerous sinus tracts (Fig. 82.22), followed by healing. If untreated, relapses occur in about 20% of patients. Constitutional symptoms such as meningeal irritation, hepatitis and arthritis are rare and may occur due to systemic spread of the organism. Inguinal adenopathy is only observed in about one-third of infected women; proctitis and pain in the lower abdomen may be the only symptoms.

The manifestations of the ano-genito-rectal syndrome include proctocolitis and hyperplasia of the intestinal and perirectal lymphatic tissue, which lead to late manifestations dominated by local abscesses with anal fistulas as well as rectal strictures and stenoses[42].

CLINICAL MANIFESTATIONS OF LYMPHOGRANULOMA VENEREUM
INITIAL MANIFESTATIONS: 3–12 DAYS
• Papule • Erosion or ulcer • Herpetiform vesicle • Nonspecific urethritis or cervicitis
INGUINAL SYNDROME: 10–30 DAYS UP TO 6 MONTHS
• Regional lymphadenopathy (mostly inguinal and femoral; also perirectal, deep iliac) • Overlying erythema • Constitutional symptoms • Eruption of buboes • Pelvic inflammatory disease (PID), back pain
ANO-GENITO-RECTAL SYNDROME: MONTHS TO YEARS
• Proctocolitis • Hyperplasia of intestinal and perirectal lymphatic tissue • Perirectal abscesses • Ischiorectal and rectovaginal fistulas • Anal fistulas • Rectal strictures and stenoses
OTHER MANIFESTATIONS
• Urethro-genito-perineal syndrome • Peno-scrotal elephantiasis • Erythema nodosum • Submaxillary or cervical lymphadenopathy associated with oropharyngeal lesions

Table 82.16 Clinical manifestations of lymphogranuloma venereum.

Fig. 82.22 Lymphogranuloma venereum. Inguinal bubo that has ruptured and drained.

Additional manifestations include urinary incontinence because of papillary growth of the mucosa of the urethral meatus in women. Extragenital lesions in the oropharynx, due to infection from oral sexual contact, are difficult to diagnose.

Pathology

Histologically, the skin may be ulcerated. A diffuse mixed infiltrate of neutrophils, histiocytes, plasma cells and, sometimes, multinucleated giant cells is seen in the dermis. Although abscesses may occur in the skin, characteristic stellate abscesses are usually only observed in the lymph nodes. Organisms are rarely demonstrated within histiocytes (Gamma-Favre bodies) by Giemsa stain.

TREATMENT REGIMENS FOR LYMPHOGRANULOMA VENEREUM
• Recommended: doxycycline, 100 mg po bid • Alternative and in case of pregnancy: erythromycin base, 500 mg po qid
Duration for both regimens: at least 3 weeks

Table 82.17 Treatment regimens for lymphogranuloma venereum. bid, twice daily; po, orally; qid, four times daily.

Diagnosis

The diagnosis of LGV is based primarily on the detection of *Chlamydia*-specific DNA in lesional tissue by PCR or other nucleic acid amplification assays. This method is diagnostically more sensitive than is isolation of the organism via tissue culture. Typically, rectal specimens are tested for the presence of *C. trachomatis* and, if positive, are then genotyped in order to diagnose LGV. Serology testing is only recommended if it is performed in conjunction with DNA detection. In serologic assays, such as the complement fixation test or other assays that detect specific antibodies to the serovars L1–3 of *C. trachomatis*, the titer of antibodies is high. A differentiation of antibodies to L1–3 from those to other serovars is difficult but possible in the micro-immunofluorescence test. A disadvantage of this diagnostic procedure is the lack of commercial availability.

Differential Diagnosis

Other causes of lymphadenopathy in the genital region (e.g. chancroid, lymphoma, cat scratch disease) or of genital ulcers or erosions should be excluded by additional diagnostic procedures (see Table 82.14). Pyogenic and mycobacterial infections also need to be considered, as well as Crohn's disease, especially in the case of the ano-genital-rectal syndrome. Routine syphilis and HIV serologies are recommended and should be repeated after 3–6 months.

Treatment

Doxycycline is the treatment of choice, followed by macrolides (Table 82.17). Antibiotic treatment can cure the infection, but surgical intervention may be required in the case of large buboes.

Examination and treatment of sexual partners is required if contact occurred during the 30 days preceding the onset of symptoms. HIV-positive individuals may need prolonged treatment due to delayed resolution of symptoms.

DONOVANOSIS (GRANULOMA INGUINALE)

Synonyms: ■ Granuloma venereum ■ Granuloma inguinale tropicum ■ Granuloma venereum genitoinguinale ■ Granuloma genitoinguinale ■ Ulcerating sclerosing granuloma ■ Ulcerating granuloma of the pudendum ■ Serpiginous ulceration of the groin ■ Lupoid form of groin ulceration

Key features

- Donovanosis is a rare, chronic, progressive ulcerative bacterial infection with *Klebsiella granulomatis* (previously known as *Calymmatobacterium granulomatis*), a Gram-negative bacillus
- Ulcers occur primarily in the genital region
- The responsible microorganisms are found within macrophages in smears or biopsy specimens (Donovan bodies)

History

The disease was initially described in India as ulcerations followed by elephantiasis of the genitalia. The microorganism was first identified in 1905 by Donovan, who noted the characteristic Donovan bodies in macrophages and epithelial cells of the stratum malpighii[43]. In 1950,

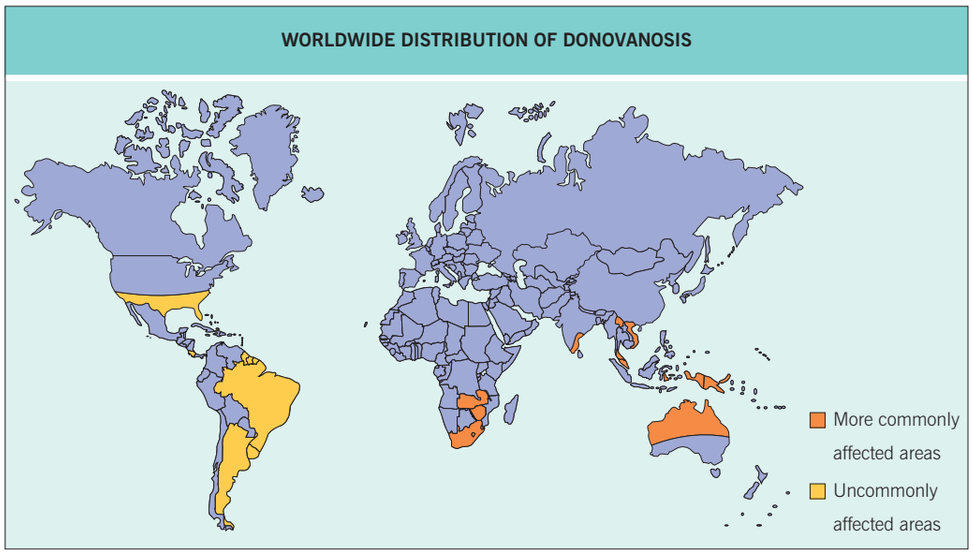

Fig. 82.23 Worldwide distribution of donovanosis.

Marmell and Santora proposed the name "donovanosis"[44]. Limited success in culturing the organism until the 1990s explains the slow progress in donovanosis research[45].

Epidemiology

In the pre-antibiotic era, donovanosis was distributed in both hemispheres, but now it is restricted to only a few low-income countries. A large number of cases, the majority in the 20- to 40-year-old age group, are reported from South Africa, India, Papua New Guinea and some parts of Australia (Fig. 82.23).

Although donovanosis is listed among the group of STIs, the disease can also occur in individuals who are not sexually active, and a wide variation in the prevalence of the infection (from 0.4% to 52%) is reported in sexual partners[46]. This is probably due to different diagnostic procedures and a long incubation period of up to 1 year. It is also not clear whether fecal contamination represents a route of non-sexual transmission.

Pathogenesis

Donovanosis is causes by *Klebsiella granulomatis* (previously known as *Calymmatobacterium granulomatis*), an intracellular Gram-negative bacillus. The primary lesion is a small cutaneous papule or nodule that contains mononuclear cells with cytoplasmic vacuoles that are filled with microorganisms. The cytoplasmic vacuoles can rupture and release bipolar Donovan bodies[47] of coccoid, coccobacillary and bacillary morphology.

Clinical Features

The average incubation period is thought to be approximately 17 days, but a range from 1 day to 1 year has been reported. A small papule or nodule initially appears and eventually ulcerates. The lesions of donovanosis are usually painless or mildly painful and slowly expand over a period of weeks to months. They are often highly vascular, with a beefy red appearance and a tendency to bleed (Fig. 82.24). Extensive tissue destruction may result, and a foul-smelling exudate is characteristic of necrotic donovanosis. Inguinal lesions occur in up to 20% of patients and are often combined with genital involvement. The most frequent sites of lesions in men are the prepuce, glans penis, frenulum and coronal sulcus. In women, the most common location is the vulvar area, where large ulcers as well as granulomatous or verrucous papules may be observed.

Extragenital lesions due to autoinoculation or secondary to dissemination have been observed in the skin, bones, abdominal cavity and oral cavity; they can involve any organ, with the bones most commonly affected. In some patients, primary extragenital lesions are seen.

Fig. 82.24 Donovanosis (granuloma inguinale). Large ulcers with a characteristic "beefy" appearance. *Courtesy, Joyce Rico, MD.*

Pathology

Histologically, ulceration with exuberant granulation tissue is evident. Pseudoepitheliomatous hyperplasia may be present at the ulcer edge. A diffuse infiltrate of histiocytes, plasma cells and a few lymphocytes is present in the dermis, sometimes with small neutrophilic abscesses. The organisms are easier to find in smears than in histologic sections. They are 1–2 microns in diameter and are within histiocytes, as is also characteristic of leishmaniasis, rhinoscleroma and histoplasmosis (see Table 77.16). Bipolar staining is found at two ends of the organisms (Donovan bodies), giving them a "safety pin" appearance.

Diagnosis

The diagnosis of donovanosis is usually based on the demonstration of Donovan bodies in smears from active lesions by Giemsa, Wright or Leishman stains. The smears are prepared from tissue scrapings or touch preparations of biopsies taken from the dermis or subcutis of lesions.

There are no serologic tests available for the diagnosis of donovanosis. Nucleic acid amplification assays such as PCR are under investigation, but they are not yet commercially available. Although successful culture of *K. granulomatis* has been reported in human peripheral blood

mononuclear cells and Hep2 cells, attempts to grow this organism in fertilized eggs or on routinely available artificial media have been unsuccessful.

Differential Diagnosis

Donovanosis is frequently confused with other diseases of the anogenital region. Other infectious causes of genital ulcer disease have to be considered (see Table 82.14); early lesions of secondary syphilis, especially condylomata lata, often have a clinical appearance similar to donovanosis. Carcinoma, amebiasis, tuberculosis, dimorphic fungal infections, pyoderma vegetans, Crohn's disease and pyoderma gangrenosum may represent additional diagnostic possibilities.

Treatment

The recommended treatment is doxycycline, but treatment regimens in different geographic areas reflect the availability of antibiotics; for example, in Papua New Guinea, chloramphenicol is used. Trimethoprim–sulfamethoxazole, quinolones and erythromycin (recommended during pregnancy) have also been shown to be effective in the treatment of donovanosis (Table 82.18). The recommended length of treatment is at least 3 weeks and until all lesions are healed. For azithromycin, successful treatment with a daily dose of 500 mg for 1 week has been reported[48]. However, the CDC 2010 guidelines recommend 1 g weekly for at least 3 weeks.

Examination of sexual partners is recommended if there has been sexual contact during the previous 60 days or if the partner is symptomatic. Relapses can occur 6–18 months later, despite effective initial treatment.

TREATMENT REGIMENS FOR DONOVANOSIS
RECOMMENDED:
• Doxycycline, 100 mg po bid
ALTERNATIVE:
• Trimethoprim–sulfamethoxazole, 1 double-strength (160 mg/800 mg) tablet po bid *or* • Ciprofloxacin, 750 mg po bid *or* • Erythromycin base, 500 mg po qid *or* • Azithromycin 1 g po once weekly
Duration for all regimens: until all lesions completely healed (at least 3 weeks)

Table 82.18 Treatment regimens for donovanosis. For any of the regimens, the addition of an aminoglycoside (e.g. gentamicin 1 mg/kg iv q8h) should be considered if lesions do not respond within the first few days of therapy.

Chapter Contents

Protozoa 1391
Leishmaniasis 1391
Cutaneous diseases caused by ameboid protozoa 1397
Trypanosomiasis 1399
Toxoplasmosis 1404
Worms (helminths) 1406
Cutaneous larva migrans 1406
Onchocerciasis 1409
Filariasis 1416
Schistosomiasis and swimmer's itch 1417
Cysticercosis and echinococcosis 1419

Key features

- Protozoa are responsible for many tropical diseases that not only affect large regions of the world but also can have different clinical presentations in the Old versus the New World (e.g. leishmaniasis)
- Protozoal infections (e.g. toxoplasmosis) can lead to significant morbidity in immunocompromised hosts
- Worms (helminths) are common parasites with a worldwide distribution; cutaneous manifestations vary considerably, from pruritus ani to elephantiasis
- Even helminthic diseases with a restricted geographic distribution, such as onchocerciasis and echinococcosis, may be observed in individuals from non-endemic areas as a result of tourism, disaster relief efforts or military service

PROTOZOA

LEISHMANIASIS

Synonyms: ■ Old World cutaneous leishmaniasis: oriental sore, Delhi boil, Baghdad boil ■ New World cutaneous and mucocutaneous leishmaniasis: chiclero ulcer (Mexico), uta and espundia (Peru), ulcera de Bauru (Brazil), bush or forest yaws, pian boi (Guyanas) ■ Diffuse cutaneous leishmaniasis: anergic, disseminated, lepromatous or pseudolepromatous leishmaniasis ■ Visceral leishmaniasis: kala-azar, Dumdum fever

Key features

- Chronic parasitic (protozoan) disease in which organisms are found within phagolysosomes of mononuclear phagocytes
- The clinical manifestations of leishmaniasis depend on the host's cell-mediated immune response and the species of *Leishmania* involved; clinical subtypes include cutaneous, mucocutaneous, diffuse cutaneous, and visceral leishmaniasis
- The most common cutaneous finding is a papule that develops at the site of inoculation and then enlarges and ulcerates
- The vector is a sandfly infected with promastigotes
- Has a worldwide distribution but is endemic in Latin America, the Mediterranean basin, and parts of Asia and Africa

Introduction

Leishmaniasis encompasses a spectrum of chronic infections in humans and several animal species. It is caused by over 20 species of *Leishmania* (Table 83.1), flagellated protozoans belonging to the order Kinetoplastidae. Transmission is via the bite of infected female sandflies from the genera *Phlebotomus* and *Lutzomyia*.

The disease has a worldwide distribution, affecting millions of people in South America, the Mediterranean basin, and parts of Asia and Africa[1] (Figs 83.1 & 83.2). There are four major clinical patterns: (1) cutaneous, which is restricted to the skin and is seen more often in the Old World; (2) mucocutaneous, which affects both the skin and mucosal surfaces and occurs almost exclusively in the New World; (3) diffuse cutaneous, which occurs mainly in the New World; and (4) visceral, which affects the organs of the mononuclear phagocyte system, e.g. liver, spleen[2,3].

Epidemiology

Worldwide, there are approximately 2 million new cases of leishmaniasis annually, with cutaneous or mucocutaneous disease in >75% of affected individuals, and it is estimated that 12 million people are currently infected[3a]. Over 90% of cutaneous infections with *Leishmania* occur in the Middle East (Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, Syria), Brazil and Peru, but the disease is also seen in the Mediterranean basin, sub-Saharan Africa, Central Asia, and India (see Fig. 83.1). South-central Texas is the only endemic area for cutaneous leishmaniasis in the US; most infections diagnosed in the US are acquired outside of the country[4]. Mucocutaneous leishmaniasis is endemic in Central America and the northern regions of South America. Although the visceral form of leishmaniasis has a worldwide distribution, it is seen most frequently in Africa and Asia[1,2,5].

Old World cutaneous leishmaniasis is usually due to *L. major* or *L. tropica*, and less often to *L. infantum* (Europe) or *L. aethiopica* (Ethiopia and Kenya) (see Table 83.1). In the New World, cutaneous leishmaniasis is caused primarily by subspecies of *L. mexicana* and mucocutaneous disease is associated with *L. braziliensis*. Diffuse cutaneous leishmaniasis is most commonly associated with *L. amazonensis*[3]. Infections with *L. donovani* (e.g. India, Bangladesh and the Sudan), *L. infantum* (e.g. Europe, especially in the setting of HIV infection) and *L. chagasi* (e.g. Central and South America) are the major causes of visceral leishmaniasis (Table 83.2). The species of *Leishmania* can also vary within a particular geographic region. For example, in the Middle East, *L. major* is found in rural areas where the primary animal reservoirs are desert rodents, whereas *L. tropica* is endemic in urban areas[5].

Canine and rodent species act as reservoirs for *Leishmania* (see Table 83.1). Transmission between these species (as well as to humans) is via sandflies, primarily of the genera *Phlebotomus* (Old World) and *Lutzomyia* (New World). Human-to-human spread of *L. tropica* can also occur. In general, humans contract leishmaniasis as accidental hosts when they intrude into the sandfly's habitat. Overall, the disease is seen most commonly in men between 20 and 40 years of age, but Old World cutaneous leishmaniasis occurs more often in children[2].

Pathogenesis

Leishmania spp. are obligate intracellular parasites that exist in two forms: the promastigote and the amastigote. In the gut of the sandfly,

EPIDEMIOLOGIC AND CLINICAL PATTERNS OF INFECTIONS WITH *LEISHMANIA* SPECIES

Complex	Major species	Major reservoirs	Major geographic distribution	Clinical patterns (in addition to cutaneous)	Clinical forms of the cutaneous pattern
Leishmania donovani	*L. donovani*	Humans	Sudan, Kenya, Tanzania, India, Bangladesh	**Visceral, PKD**, mucosal (rare)	(Uncommon)
	L. infantum	Dogs, foxes	Mediterranean region	**Visceral (favors children)**, PKD*, mucosal† (rare)	Favors children (uncommon)
	*L. chagasi***	Dogs, foxes, opossums	Central and South America		
Leishmania tropica	*L. major*	Rodents	Arid areas of Africa (north and south of the Sahara), Middle East and Central Asia	Mucosal (rare)	**Old World zoonotic/rural** (moist, early ulcerative with rapid course), recidivans (rare), lupoid (rare)
	L. tropica	Humans, dogs	Eastern Mediterranean region, Middle East, Central Asia	Visceral (rare), mucosal (rare)	**Old World anthroponotic/urban** (dry, late ulcerative with chronic course), recidivans, lupoid
	L. aethiopica	Hyraxes	Ethiopia, Kenya, Yemen	Diffuse cutaneous	
Leishmania mexicana	*L. mexicana*	Forest rodents	Mexico, Central America	Diffuse cutaneous (rare)	**New World** Variants include ulcerative, pustular, impetigo-like, erysipeloid, sarcoidosis-like, papulotuberous, verrucous, sporotrichoid, eczematous
	L. amazonensis	Forest rodents	South America	**Diffuse cutaneous**, mucocutaneous, visceral (rare), PKD (rare)	
	L. venezuelensis, pifanoi, garnhami	Unknown	Venezuela	Diffuse cutaneous (rare)	
Leishmania (Viannia) braziliensis	*L. braziliensis*	Forest rodents	Central and South America	**Mucocutaneous**, visceral†	
	L. guyanensis	Sloths, anteaters	Guyana, Brazil	Mucocutaneous	
	L. panamensis	Sloths	Panama, Costa Rica, Colombia	Mucocutaneous	
	L. peruviana	Dogs	Peru, Argentina		

*Rare/controversial; reported in children and in HIV-infected adults following antiretroviral therapy.
**Term used for *L. infantum* when found in the New World.
†Especially in immunocompromised hosts.

Table 83.1 Epidemiologic and clinical patterns of infections with *Leishmania* species. Common clinical patterns for particular species are in bold. Additional minor species include *L. garnhami*, *naiffi*, *lainsoni*, *colombiensis*, *shawi* and *archibaldi*. *Viannia* is a subgenus of *Leishmania*. Mucosal leishmaniasis refers to oronasal lesions not preceded or accompanied by cutaneous involvement. PKD, post-kala-azar dermal leishmaniasis. *Modified from Lupi O, Barlett BL, Haugen RN, et al. Tropical dermatology: tropical diseases caused by protozoa, J Am Acad Dermatol 2009;60:897–925 and Davidson RN, Leishmaniasis. In Cohen J, Powderly WG, eds, Infectious Diseases. Fig. 83.2 Distribution of visceral leishmaniasis. These organisms, in particular *L. infantum* and *L. donovani*, can also cause cutaneous disease. *Adapted with permission from Davidson RN, Leishmaniasis. In Cohen J, Powderly WG, eds, Infectious Diseases. Edinburgh: Mosby, 2004.*

EPIDEMIOLOGY AND CLINICAL PATTERNS OF VISCERAL LEISHMANIASIS		
Type of disease	**Major species**	**Major geographic distribution**
Kala-azar (60% 10–20 years of age)	*Leishmania donovani*	India, China (north of Yangtze River), Kenya, Sudan
Infantile kala-azar (90% <10 years of age)	*L. infantum*	Central Asia, China, Iraq, France, Italy, Egypt, elsewhere in the Mediterranean basin, Saudi Arabia
	L. chagasi	Brazil, Colombia, Venezuela, Central America, Mexico
Oronasal kala-azar	*L. infantum**	France
Post-kala-azar dermal leishmaniasis	*L. donovani* *L. infantum*† *L. amazonensis*	India, China, Kenya Mediterranean basin South America
Atypical kala-azar complex (typically in adults)	*L. tropica* *L. amazonensis* *L. brazilensis**	Northeast Saudi Arabia South America South and Central America

*Especially in immunocompromised hosts.
†Controversial (see Table 83.1).

Table 83.2 Epidemiology and clinical patterns of visceral leishmaniasis.

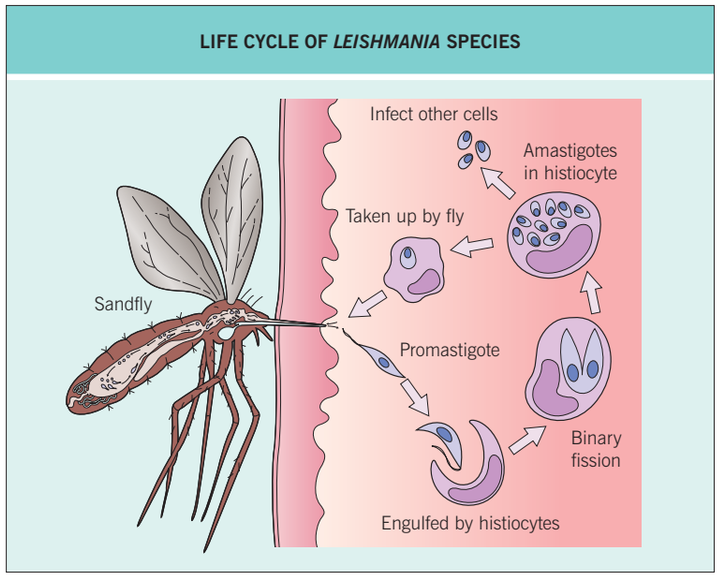

Fig. 83.3 Life cycle of *Leishmania* species. Promastigotes develop within the gut of the sandfly and then migrate to the proboscis.

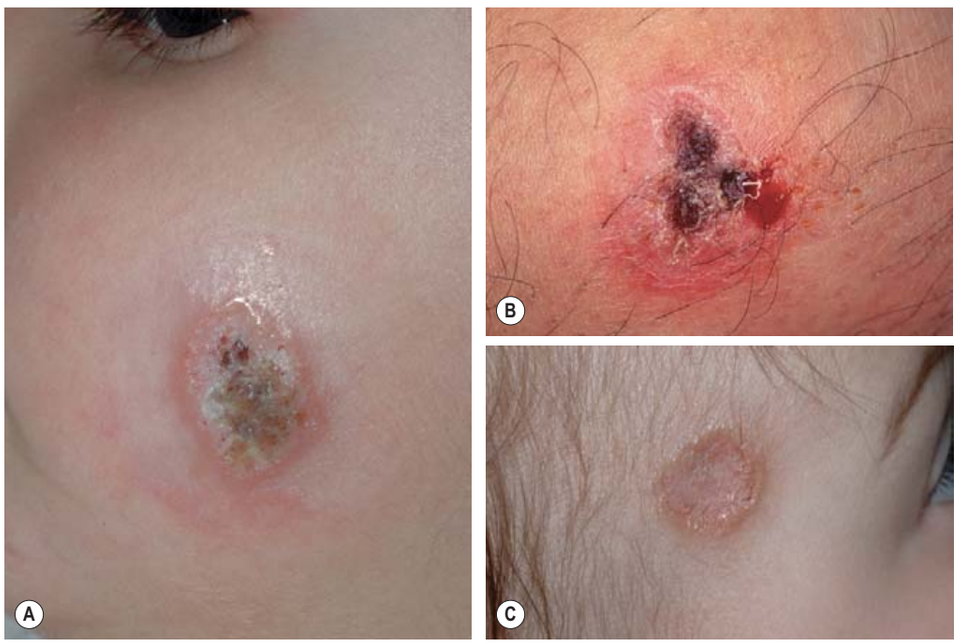

Fig. 83.4 Variable presentations of cutaneous leishmaniasis. Ulcerated plaques with rolled border (**A**) and central crusting (**A, B**). Plaque with translucent borders containing telangiectasias and central scarring (**C**). Cutaneous leishmaniasis is sometimes mistaken for a basal cell carcinoma. *A, C, Courtesy, Julie V Schaffer, MD.*

the organisms multiply as extracellular flagellated promastigotes. Following migration to the proboscis, the parasites are inoculated (in the promastigote form) via the sandfly bite. Once inoculated into the skin, the parasites are rapidly engulfed by the host's mononuclear phagocytes, where they transform into amastigotes and multiply via binary fission (Fig. 83.3). The incubation time from infection until the first clinical manifestation can vary from ≤2 weeks (cutaneous lesions; typically several weeks to 2 months) to more than 2 years (mucocutaneous lesions or visceral involvement; typically 3 to 9 months)[6].

The clinical manifestations of leishmaniasis primarily depend on the host's cell-mediated response and on the species of *Leishmania* involved (see Table 83.1). A robust Th1 response (i.e. production of interleukin-2 [IL-2] and interferon-γ [IFN-γ]) is associated with quicker resolution, whereas a lack of a Th1 response or the development of a Th2-type response (i.e. production of IL-4 and IL-10) is associated with progression of the disease[7–9]. Other factors that play a role in the parasite–human interaction include the amount of exposure to and the virulence of the parasite (e.g. macrophage-resistant strains of *Leishmania*). Mucocutaneous disease is associated with infection of the *Leishmania* organisms with *Leishmania* RNA virus-1 (LRV1); this virus is recognized by human Toll-like receptor 3, leading to a proinflammatory cascade that subverts the immune response to *Leishmania*, leading to persistence of the parasite and disease progression[9a].

IFN-γ is the most potent cytokine involved in the induction of cidal activity against the organisms residing within macrophage phagolysosomes. It leads to the production of oxygen species and activates naive $CD4^+$ cells to become Th1 cells (see Ch. 4). The latter differentiation process is aided by IL-12, which stimulates natural killer (NK) cells to produce IFN-γ[7,9,10]. Tumor necrosis factor-α (TNF-α) is also important for the control of *Leishmania* infections[8]. Produced by macrophages and NK cells, it amplifies the macrophage activation triggered by IFN-γ. Use of TNF-α inhibitors increases the risk of developing leishmaniasis, especially the visceral form[11].

Animals that have recovered from *L. tropica* or *L. donovani* infections acquire immunity against reinfection from the same species of *Leishmania*, but not against other species. Similarly, humans with the New World form of cutaneous leishmaniasis have been inoculated successfully with *L. tropica*. However, it has been reported that surviving an episode of visceral leishmaniasis confers lifelong immunity against all types of leishmaniasis.

Clinical Features

Cutaneous leishmaniasis

Cutaneous leishmaniasis is divided into two subsets based on the geographic region where the infection is acquired: Old World and New World. These two groups differ with regard to the causative organisms, vectors, reservoirs, clinical presentation, and prognosis[3]. Both Old World and New World cutaneous leishmaniasis usually begin as a small, well-circumscribed papule at the inoculation site. This lesion may slowly enlarge over several weeks into a nodule or plaque (Fig. 83.4) and then become ulcerated or verrucous. Exposed sites such as the face, neck, arms, and legs are most commonly involved (Fig. 83.5) For example, the chiclero ulcer results from infection on the ear in forest workers who collect gum from the chicle tree in Mexico and Central America. The lesions of leishmaniasis are often solitary but may be multiple, with the formation of satellites or lymphatic spread (sporotrichoid pattern; Fig. 83.6). The majority of acute cutaneous infections resolve spontaneously within several months with scarring[12] (cicatricial stage; Fig. 83.7), but a minority become chronic or disseminated.

Several clinical forms of Old World cutaneous leishmaniasis have been described, including zoonotic, anthroponotic, recidivans, and lupoid leishmaniasis. Zoonotic cutaneous leishmaniasis (rural, moist, or early ulcerative form) usually has a mild, rapid course and is caused by *L. major*. Anthroponotic cutaneous leishmaniasis (urban, dry, or late ulcerative), has a more chronic course and is caused by *L. tropica*[3]. Leishmaniasis recidivans is a chronic, destructive form that is characterized by recurrence at the site of an original ulcer, generally within 2 years and often at the edge of the scar[12]. Anthroponotic or, less frequently, zoonotic cutaneous leishmaniasis occasionally develops into chronic lupoid leishmaniasis, which clinically and histologically (epithelioid granulomas surrounded by lymphocytes) resembles the lupus vulgaris form of cutaneous tuberculosis. The amastigotes are few in number and difficult to find in lupoid leishmaniasis, making establishment of the diagnosis more challenging.

New World cutaneous leishmaniasis has a wide clinical spectrum, including patterns such as sporotrichoid, pustular, impetigo-like, eczematoid, sarcoidosis-like, erysipeloid, papulotuberous, and verrucous[12].

Diffuse (disseminated) cutaneous leishmaniasis

Diffuse cutaneous leishmaniasis usually develops in the setting of reduced cell-mediated immunity. *L. aethiopica* (in Africa) and *L. amazonensis* (in the Americas) are the most common causes (see Table 83.1). Multiple keloid-like lesions on the face and limbs are usually observed[3]. Nasal infiltration and ulceration may be present, but without destruction of the nasal septum. There may also be laryngeal and pharyngeal involvement[12].

Mucocutaneous leishmaniasis

After a time period ranging from a few months to more than 20 years, some patients infected with *Leishmania* spp. in the *Viannia* subgenus

Fig. 83.5 Ulcerative form of cutaneous leishmaniasis. A Multiple lower extremity ulcers in a rural worker. **B** Expanding ulcer on the leg as well as a positive Montenegro test. This type of lesion could be misdiagnosed as pyoderma gangrenosum. *A, Courtesy, Omar P Sangüeza, MD.*

SYSTEMIC FEATURES OF VISCERAL LEISHMANIASIS (*L. DONOVANI*)	
Clinical features	**Proportion affected (%)**
Age <9 years	20 (*L. infantum* and *L. chagasi* more commonly affect children and infants)
Age <15 years	45
Fever	85–100
Wasting	70–100
Loss of appetite	60–75
Cough	70–85
Epistaxis	45–55
Diarrhea	25–55
Vomiting	2–35
Splenomegaly	90 (adults); >95 (children)
Hepatomegaly	55–65
Lymphadenopathy	55–85 (uncommon outside of Africa)
Jaundice	2–7
Edema	2–7
Laboratory findings	
Globulin >30 g/l	95
Albumin <30 g/l	90
Anemia	60–90
Leukopenia	85
Thrombocytopenia	75
Elevated bilirubin	15
Elevated liver transaminases	20
Elevated alkaline phosphatase	40
Positive *Leishmania* serology	95
Parasitologically proven	95

Table 83.3 Systemic features of visceral leishmaniasis *(L. donovani)*. The duration of symptoms is usually 2 to 4 months, but it is typically shorter in children. *With permission from Davidson RN, Leishmaniasis. In Cohen J, Powderly WG, eds, Infectious Diseases. Edinburgh: Mosby, 2004.*

(most commonly *L. braziliensis*; rarely *L. panamensis*, *L. guyanensis* or hybrid genotypes) develop mucocutaneous disease[13]. Mucosal lesions range from edema of the lips and nose to perforation of the nasal and laryngeal cartilage as well as the palate. Infiltration and/or ulceration of the nose, lips and oropharynx is characteristic (Fig. 83.8). Only rarely are the ocular or genital mucosae involved. In some patients, there is extensive loss of tissue in both the mouth and nose, causing a characteristic "tapir face" known as espundia (Fig. 83.9). Alterations in phonation because of destruction of the vocal cords may also occur[12–14].

Visceral leishmaniasis (kala-azar)

Visceral leishmaniasis, or kala-azar, occurs when the parasite spreads to the bone marrow, spleen, and liver[3]. It is most commonly caused by infection with *L. donovani* in adults and *L. infantum* or *L. chagasi* in children. The incubation period ranges from 1 to 36 months. Fever, wasting, cough, lymphadenopathy and hepatosplenomegaly are the most common systemic findings (Table 83.3). There may be an abrupt onset or slow progression, and the fever may be continuous or intermittent. Additional complications include enteritis, oronasal or gastrointestinal hemorrhage, pneumonia and nephritis, which may lead to death[12]. Cutaneous findings may be disease-specific (e.g. papules, nodules or ulcers at infected sites) or nonspecific (e.g. purpura, hyperpigmentation, xerosis and kwashiorkor-like hair discoloration).

Post-kala-azar dermal leishmaniasis develops as a sequela of untreated or treated visceral leishmaniasis[3] (Fig. 83.10). This form of cutaneous leishmaniasis is most commonly seen in Sudan and India, where it occurs in 50% and 10% of patients cured of visceral leishmaniasis, respectively[15]. The onset can be during or up to 20 years after treatment[15]. Skin findings can include hypopigmented macules, malar erythema, skin-colored nodules and verrucous papules[16].

Leishmaniasis and HIV

Co-infection of HIV and leishmaniasis can alter the progression and presentation of leishmaniasis, especially the visceral form[17] (see Ch.

Fig. 83.10 Post-kala-azar dermal leishmaniasis. Nodules of various sizes, some pedunculated, are seen in this patient who had been treated for kala-azar over a period of 6 months, 20 years previously. *With permission from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

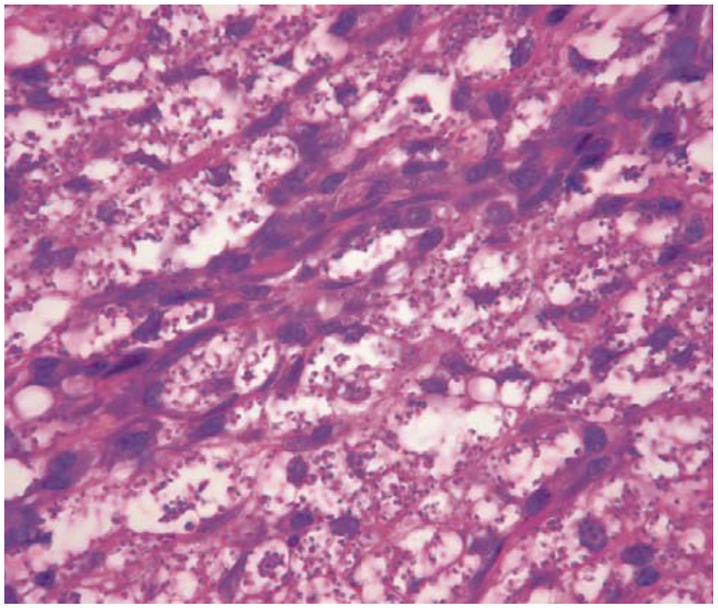

Fig. 83.11 Histopathology of leishmaniasis. Parasitized macrophages that contain amastigotes are seen in the dermis. *Courtesy, Jennifer McNiff, MD.*

78). HIV infection increases the risk of developing visceral leishmaniasis 100- to over 2000-fold. Co-infection often results in an atypical clinical presentation, reduced therapeutic response, and increased mortality. Chronic immune activation from the *Leishmania* infection may lead to increased HIV load and accelerated progression of AIDS, while the immunosuppressed state from HIV creates an ideal environment for parasitic growth[16]. Co-infection with HIV is thought to be present in 2% to >10% of patients with visceral leishmaniasis who live in *Leishmania*-endemic areas[17].

Pathology

Histologically, cutaneous lesions show areas of ulceration, pseudoepitheliomatous hyperplasia and a mixed inflammatory infiltrate composed of histiocytes, lymphocytes, plasma cells and neutrophils. Amastigotes are present within dermal macrophages (Fig. 83.11). Over time, lesions develop an increasing number of giant cells and a declining number of parasites; in chronic cutaneous leishmaniasis, caseation necrosis may be observed[14]. In the cicatricial stage, the epidermis becomes flattened and hyperpigmented in areas with dermal fibrosis. Identical changes are seen in mucosal lesions. The parasite can also be detected in the lymph nodes, bone marrow and spleen in patients with visceral leishmaniasis.

Diagnosis

The diagnosis of cutaneous leishmaniasis can be confirmed by demonstrating the presence of amastigotes in dermal macrophages within skin biopsy specimens, tissue impression smears (touch preparations), and smears of dermal scrapings[2,12,17a]. Giemsa, Wright or Feulgen stains are used to identify the organisms in smears and tissue: the cytoplasm appears blue, the nucleus pink and the kinetoplast a deep red[12]. The edge of a relatively new ulcer is the location of choice for obtaining dermal scrapings, a biopsy specimen or a needle aspirate; the latter two types of samples may be used for culture and polymerase chain reaction (PCR)-based assays (see below)[3,17a].

In longer-standing lesions of leishmaniasis, parasites may be scarce. In this context, the delayed skin reaction test (Montenegro skin test or Leishman reaction), which uses leishmanial antigens to induce a cell-mediated response, has traditionally been an important diagnostic tool. A phenolated suspension of killed promastigotes is injected intradermally, usually on the volar aspect of the forearm. The test is considered positive if a papule >5 mm in diameter forms at the site of inoculation after 48–72 hours (see Fig. 83.5B)[12]. It is positive in up to 90% of patients with cutaneous and mucocutaneous leishmaniasis of over 3 months' duration[3] and is invariably negative in patients with diffuse cutaneous (anergic) leishmaniasis[12]. However, the test (which is not approved by the US Food and Drug Administration [FDA]) cannot distinguish between past and present infections; positivity appears while the skin lesions are still active, and the test remains positive long after spontaneous cure. The test is usually negative during the febrile phase of visceral leishmaniasis, but it often becomes positive after cure.

For culturing *Leishmania*, specialized media are required, e.g. Nicolle–Novy–MacNeal (NNM) media or chick embryo media. Cultures are positive in approximately 40% of cases. Serologic and immunologic tests are also available, e.g. indirect immunofluorescence, ELISA, immunoprecipitation and isoenzyme electrophoresis. Serologic testing is most useful for visceral (and occasionally mucocutaneous) disease, although it is not specific due to cross-reactivity (e.g. with Chagas disease antibodies)[18]. PCR-based methods represent the most sensitive and specific diagnostic tests, and their availability is increasing[2,12]. The US FDA recently approved a real-time PCR assay for the diagnosis of leishmaniasis, and it is available through the Centers for Disease Control and Prevention (CDC)[17a].

Differential Diagnosis

The differential diagnosis of *cutaneous* leishmaniasis includes persistent arthropod bite reactions, basal cell carcinomas, non-tuberculous mycobacterioses and subcutaneous mycoses; other infectious causes of lesions in a lymphocutaneous pattern are listed in Table 77.15. *Mucocutaneous* leishmaniasis can resemble other infections such as paracoccidioidomycosis and tertiary syphilis. In addition, Wegener's granulomatosis and angiocentric NK/T-cell lymphoma should be considered when ulcerative mucocutaneous lesions affect the central part of the face (see Table 45.3). Histologic examination allows distinction between these diseases[13]. The histologic differential diagnosis includes other infections characterized by parasitized macrophages (see Table 77.16) and even neoplasms such as squamous cell carcinoma when pseudoepitheliomatous hyperplasia is present. The morphology and distribution of diffuse cutaneous leishmaniasis can mimic lepromatous leprosy; however, in the former the eyebrows are spared and the lesions are usually less infiltrative[12].

TREATMENT RECOMMENDATIONS FOR LEISHMANIASIS		
CUTANEOUS LEISHMANIASIS		
Drugs of choice	Sodium stibogluconate*	20 mg/kg/day IV or IM × 20 days
	Meglumine antimonate*	20 mg/kg/day IV or IM × 20 days
	Miltefosine	2.5 mg/kg/day PO (max 150 mg) × 28 days
Alternatives	Paromomycin	Topically BID × 10–20 days
	Pentamidine	2–3 mg/kg IV or IM daily or every other day × 4–7 doses
	Fluconazole†	200 mg/day or 6–8 mg/kg/day PO × 6 weeks
	Liposomal amphotericin B†	3 mg/kg on days 1-5, 14 and 21
MUCOCUTANEOUS LEISHMANIASIS		
Drugs of choice	Sodium stibogluconate*	20 mg/kg/day IV or IM × 28 days
	Meglumine antimonate*	20 mg/kg/day IV or IM × 28 days
	Liposomal amphotericin B	0.5–1.0 mg/kg IV daily or every other day × 4–8 weeks
	Miltefosine	2.5 mg/kg/day PO (max 150 mg) × 28 days

*Doses refer to mg of pentavalent antimony – 100 mg/ml for sodium stibogluconate (Pentostam®), 85 mg/ml for meglumine antimonate (Glucantime®).
†Limited evidence of efficacy; other azole antifungals that have been utilized (with variable results) include ketoconzaole (600 mg/day or 10 mg/kg/day PO × 4 weeks) and itraconzaole (7 mg/kg/day PO × 3 weeks).

Table 83.4 Treatment recommendations for leishmaniasis. The treatment regimen (drug, dose, duration) that is chosen depends upon the geographic region, species of *Leishmania*, location and severity (e.g. number and size of lesions) of disease, and host factors. The Centers for Disease Control (CDC) and World Health Organization (WHO) represent resources for up-to-date information. Sodium stibogluconate is not approved by the US Food and Drug Administration (FDA), but it is available from the CDC; meglumine antimonate, miltefosine and paromomycin are not readily available in the US. BID, twice daily; IM, intramuscular; IV, intravenous; PO, orally.

ADVERSE SIDE EFFECTS OF THE MOST COMMONLY USED DRUGS FOR LEISHMANIASIS		
Drug	**Side effect**	**Incidence**
Intralesional pentavalent antimony	Localized pain, erythema, edema	25–50%
Parenteral pentavalent antimony	Raised amylase/lipase and/or LFTs	>50%
	Myalgia, arthralgia	25–50%
	Abdominal pain/nausea	25–50%
	Thrombocytopenia/ leukopenia	<25%
	ECG changes or cardiotoxicity	<25%
Miltefosine	Motion sickness	>50%
	Nausea, vomiting and diarrhea	25–50%
	Elevated serum creatinine	25–50%
	Mildly elevated LFTs	<25%
	Teratogenicity*	>50%
Pentamidine	Nausea, vomiting and diarrhea	>50%
	Hyperglycemia	<25%
	Cardiotoxicity	<25%

*Contraindicated during pregnancy. Contraception is required during administration and for 2 months after the drug is discontinued.

Table 83.5 Adverse side effects of the most commonly used drugs for leishmaniasis. ECG, electrocardiogram; LFTs, liver function tests.

Treatment

Factors to consider when planning the treatment of leishmaniasis include the region of the world in which the infection was acquired, the species of *Leishmania*, the site(s) and severity of the infection, and host factors such as immune status and age. The risks and benefits of therapy need to be balanced, with goals of maximizing effectiveness while minimizing drug toxicity. Without treatment, Old World cutaneous leishmaniasis typically resolves within 2–4 months (*L. major*) or 6–15 months (*L. tropica*). New World cutaneous leishmaniasis caused by *L. mexicana* resolves within 3 months in >75% of cases. In contrast, cutaneous disease caused by *L. braziliensis* and *L. panamensis* spontaneously heals in less than 10% and 35% of cases, respectively. Cutaneous disease is treated to accelerate healing, to decrease scarring (especially important for lesions in cosmetically sensitive sites), and to prevent dissemination or relapse. Indications for treatment of cutaneous leishmaniasis include persistence for >6 months, location over a joint, and presence of multiple (≥5–10) or large (≥4–5 cm) lesions[19,20].

Parenteral pentavalent antimonials are the treatment of choice for cutaneous and mucocutaneous leishmaniasis, whereas liposomal amphotericin B is preferred for visceral leishmaniasis[19]. Table 83.4 summarizes first-line and alternative treatments for cutaneous and mucocutaneous leishmaniasis[20–25]. Table 83.5 lists frequent adverse reactions to the drugs most commonly used for the treatment of leishmaniasis. Additional interventions that have shown some efficacy for cutaneous and (in combination with other agents) mucocutaneous leishmaniasis include heat therapy[27], cryotherapy, photodynamic therapy and oral allopurinol.

Drugs or vaccines that completely prevent leishmaniasis have not yet been developed. The best form of protection is to avoid the bite of the sandfly and eliminate animal reservoirs. Personal protection includes applying DEET-based repellants, bed netting, barriers in the form of permethrin-treated clothing, and sleeping in minimal-risk areas. People are at increased risk of bites in the early morning and late evenings[21].

CUTANEOUS DISEASES CAUSED BY AMEBOID PROTOZOA

Ameboid protozoa (often referred to as amebas) are single-celled eukaryotes characterized by movement via pseudopodia (temporary cytoplasmic extensions). Organisms in this group that can produce cutaneous disease include *Entamoeba histolytica*, *Acanthamoeba* and *Balamuthia mandrillaris*. *E. histolytica* is a parasitic ameba with a worldwide distribution and may infect the skin via extension or inoculation from the gastrointestinal tract. *B. mandrillaris* and *Acanthamoeba* spp. are free-living amebas that can cause skin infections and granulomatous encephalitis in immunocompromised and (for *B. mandrillaris*) immunocompetent patients. Acanthamebiasis may present with papulonodules and ulcers on the trunk and extremities in patients with advanced HIV infection (see Ch. 78).

Amebiasis

Key features

- Amebiasis usually affects the gastrointestinal tract and rarely spreads to the skin
- The skin can become involved by extension of rectal amebiasis to the anus, perianal skin or vulva, as well as by a fistula from a liver abscess to the skin of the abdominal wall
- The cutaneous lesions are usually ulcers or verrucous plaques

Introduction

Amebiasis in humans is primarily a gastrointestinal infection caused by *Entamoeba histolytica*. However, there can be extraintestinal manifestations, including cutaneous involvement[28].

Epidemiology

E. histolytica infection results in approximately 50 million cases of invasive disease worldwide each year, causing 100 000 deaths annually[3]. A high prevalence of this infection is associated with poor sanitation, crowded living facilities and lower socio-economic status. In high-income countries, risk factors include a history of travel to or residence in high-prevalence areas, institutionalization immunosuppression, and promiscuous sexual behavior (especially involving men having sex with men). Humans are the reservoir for the disease, and an asymptomatic carrier may excrete up to 45 million cysts a day in the stool. Transmission of amebiasis is fecal–oral via contaminated hands, water or food and oral–anal sex.

Pathogenesis

Once the cyst is ingested, it makes its way to the colon, where it becomes a trophozoite. Although trophozoites can be excreted, cysts represent the primary excreted form[28,29]. The main mechanism by which *E. histolytica* produces disease is through tissue lysis[29]. The trophozoites kill target cells upon direct contact, due in part to the release of proteolytic enzymes, e.g. cathepsin B and collagenase. The trophozoites also have the capacity to destroy neutrophils, resulting in release of their intracellular contents, which further contribute to the destruction of host tissues. The mechanisms of defense against *E. histolytica* include mucosal immune responses (e.g. antiamebic IgA antibodies), cell-mediated immune defense (e.g. activated cytotoxic T lymphocytes and the production of lymphokines such as IFN-γ, which activate macrophages to kill the trophozoites), and non-immune host defenses (e.g. the production of mucus by colonic mucosa, inhibiting amebic adherence to and lysis of the mucosa).

Clinical features

Patients with symptomatic amebiasis due to *E. histolytica* typically present with colitis, i.e. abdominal pain, tenesmus, bloody diarrhea and mucosal ulcerations[28]. Extraintestinal complications, which can occur from hematogenous spread via invasion through the gastrointestinal epithelium, include hepatic abscesses, empyema and pericardial effusions[28,30]. The skin is affected in less than 1% of patients with amebiasis. Skin involvement occurs as a result of extension of rectal amebiasis to the anus, perianal skin or vulva; extension of a liver abscess to the skin of the abdominal wall; or inoculation of the penis during anal intercourse. Primary cutaneous amebiasis via external inoculation is exceedingly rare but has been reported on the face[31,32].

Fig. 83.12 Cutaneous amebiasis. Multiple large ulcers on the leg of a patient with amebiasis. Note the extensive tissue destruction and resemblance to pyoderma gangrenosum. *Courtesy, Omar P Sangüeza, MD.*

Cutaneous lesions can present either as ulcers (Fig. 83.12) or verrucous plaques. Ulcerative lesions are usually tender and somewhat oval in shape, with irregular borders and a gray–white necrotic base. One characteristic of these ulcers is extensive tissue destruction.

Pathology and diagnosis

Histologically, ulcerated lesions of cutaneous amebiasis have central necrosis with adjacent pseudoepitheliomatous hyperplasia. Mixed inflammatory infiltrates are present in the dermis and can extend into the subcutaneous tissue. Within the ulcerated and necrotic areas, it is possible to identify the trophozoites of *E. histolyticum*. They have ample, finely granular eosinophilic cytoplasm, eccentric nuclei and prominent nucleoli, and some may contain phagocytized red cells. Chronic lesions show prominent irregular epidermal hyperplasia and inflammatory infiltrates, with few organisms present. Touch and wet drop preparations from the pus may also be utilized to identify the trophozoites[3]. Examination of fresh stool has a low yield of demonstrating the trophozoite, and multiple stool samples must be obtained[28]. Where available, PCR may be used for detection of responsible organisms. If the diagnosis is made, consider evaluation of other body sites for involvement.

Differential diagnosis

In high-income countries, a patient with colitis and necrotic cutaneous ulcers would more likely have inflammatory bowel disease-associated pyoderma gangrenosum. Other infectious causes of skin ulcers, e.g. streptococci, dimorphic or opportunistic fungi, and mixed bacterial flora (phagedenic or tropical ulcer), should be excluded. Verrucous lesions in the anogenital region may be confused with condyloma acuminata and squamous cell carcinoma.

Treatment

For both adults and children, oral metronidazole is the drug of choice for amebiasis due to *E. histolytica*: for adults, 500–750 mg three times daily for 7–10 days, and for children, 35–50 mg/kg/day divided into three doses for 10 days. Other medications that have been used include diloxanide, tinidazole, pentamidine and iodoquinol[20].

Balamuthia mandrillaris Infection

Key features

- *B. mandrillaris* is a free-living ameba that causes a rare, usually fatal encephalitis in immunocompetent individuals
- Skin infection presents weeks to months prior to hematogenous spread to the central nervous system (CNS)
- Cutaneous lesions are slowly growing, indurated plaques on the central face

Introduction

B. mandrillaris is a free-living ameba that can infect the skin and subsequently lead to fatal encephalitis.

Epidemiology

At least three genera of free-living amebas cause disease in humans, including *Naegleria*, *Acanthamoeba* and *Balamuthia*[33]. These amebae are found worldwide in the soil and (especially for the former two organisms) fresh water. Cutaneous infection with *B. mandrillaris* or *Acanthamoeba* spp. may precede development of granulomatous encephalitis. Such infections may be acquired from exposure of microabrasions or open wounds in the skin to soil and water sources; encephalitis can also result from infection of the nasal/respiratory mucosa (e.g. via inhalation). *Naegleria fowleri* can cause an acute, fatal encephalitis but is not known to infect the skin.

B. mandrillaris is an uncommon but increasingly recognized cause of encephalitis, with approximately 200 cases reported worldwide to date, including more than 70 in the US[34]. Most of the affected individuals resided in warmer regions, including Latin America and the southern US[35]. Unlike *Acanthamoeba* infections, which only affect

Fig. 83.13 ***Balamuthia mandrillaris*** **infection. A** Indurated plaque on the nose. **B** Infiltration that has progressed to involve a large portion of the face. *With permission from Tyring S, Lupi O, Hengge U (eds), Tropical Dermatology. Churchill Livingstone, 2005.*

immunocompromised patients, most *B. mandrillaris* infections occur in immunocompetent individuals, favoring children as well as the elderly[3,5]. Boys and men are two to three times more likely to acquire the infection than girls and women[36]. In addition, nearly 50% of the *B. mandrillaris* infections identified in the US have been in individuals of Hispanic ethnicity[37,38]. Transmission of *B. mandrillaris* via solid organ transplantation has also been described.

Pathogenesis

B. mandrillaris is a free-living ameba that can exist both as a dormant cyst and as an infectious trophozoite. Because *B. mandrillaris* can cause disease in immunocompetent hosts, it is thought to be more virulent than *Acanthamoeba*. However, clinically unaffected individuals have been shown to have antibodies against *B. mandrillaris*[39]. The presence of predisposing factors (e.g. local disruption of the skin or mucosal barrier) are likely needed to acquire the infection. The trophozoites feed on human cells and spread to the CNS hematogenously[40].

Clinical features

B. mandrillaris causes a subacute to chronic granulomatous encephalitis that has a mortality rate of >80%[36,41]. In a subset of patients, CNS involvement is preceded by the development of a slowly expanding, indurated, asymptomatic plaque on the central face (Fig. 83.13) or (less often) other sites such as an extremity, the gluteal area or the oral mucosa[33]. A skin lesion may be present for weeks to months (average of 5–8 months) before the organism disseminates to the CNS[3]. As the plaque enlarges, it may become infiltrative (see Fig. 83.13B) and occasionally ulcerates. Although there is usually a single skin lesion, local "satellite" lesions or involvement of multiple sites can occur. Neurologic symptoms are similar to those in other forms of meningoencephalitis (e.g. headache, altered mental status, cranial nerve dysfunction), but may be more insidious and chronic.

Pathology and diagnosis

The diagnosis of *B. mandrillaris* infection is often made at autopsy or by skin biopsy[3]. In the dermis of affected skin, there is a mixed granulomatous infiltrate, which may obscure the cysts or trophozoites[3]. Immunohistochemical staining or PCR based analysis of skin specimens can provide definitive diagnosis[42]. Culture and isolation of *B. mandrillaris* requires a complex medium containing fetal bovine serum or a specialized cell type (e.g. monkey kidney cells, human lung fibroblasts)[42]. Examination of the cerebrospinal fluid (CSF) may show motile amebic trophozoites with pseudopod formation[33]. If the encephalitis is advanced, imaging studies will reveal calcified, mass-like brain lesions[43].

Treatment

Although various combinations of drugs (including pentamidine, sulfadiazine, azole antifungals, clarithromycin, flucytosine and miltefosine) have been tried for *B. mandrillaris* infection, none has been shown to be consistently effective.

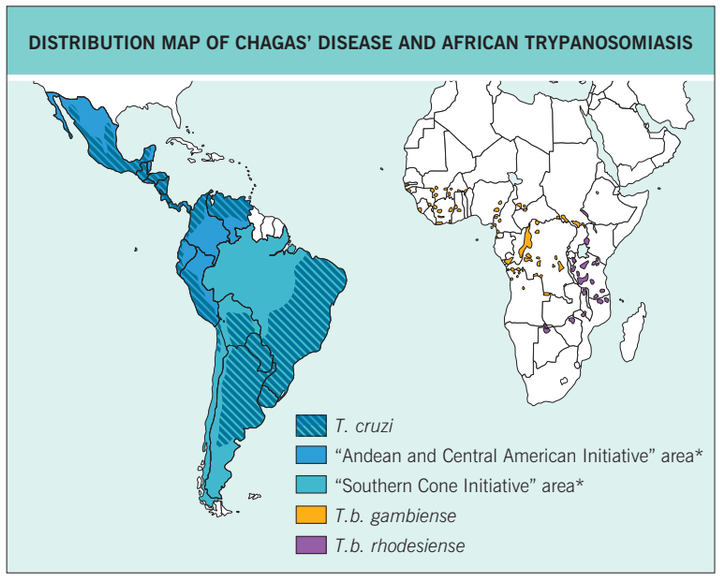

Fig. 83.14 Distribution map of Chagas disease and African trypanosomiasis. *Major programs begun in the 1990s to eliminate domestic vectors. *Adapted with permission from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

Synonyms: ■ American trypanosomiasis: Chagas disease, Chagas–Mazza disease ■ African trypanosomiasis: African sleeping sickness

TRYPANOSOMIASIS

Although the genus *Trypanosoma* consists of at least 20 species of protozoa, only two are known to cause human disease. American trypanosomiasis is caused by *T. cruzi* infection and is transmitted by reduviid bugs. African trypanosomiasis is caused by *T. brucei* infection and is transmitted by tsetse flies.

Key features

- An endemic disease in many areas of Central and South America
- Transmission of *T. cruzi* is via infected reduviid bugs and occasionally by contaminated blood
- A serious systemic disease with three phases (acute, indeterminate, and chronic). The chronic phase primarily affects the heart and gastrointestinal tract
- Following inoculation of the parasite into the skin, localized erythema and edema can develop in conjunction with regional lymphadenopathy (chagomas)
- When the conjunctiva is the portal of entry, edema of the palpebral and periocular tissue is seen (Romaña sign)

American Trypanosomiasis

Epidemiology

T. cruzi and its arthropod vectors (reduviid or kissing bugs) are found in the Americas, from the southern US to southern Argentina[44] (Fig. 83.14). Reduviid bugs feed mainly on human, animal or avian blood, but sometimes they engage in cannibalism or coprophagia, which may result in vector-to-vector transmission of *T. cruzi*. A favorite habitat for these bugs is cracks in the walls of mud huts in poor rural areas, and they are known as kissing bugs because of their habit of biting the face of humans. Direct transmission of *T. cruzi* via transfusion of contaminated blood can occur; since 2007, blood donated in the US has been screened for this organism[45]. In addition, transplacental transmission can result in congenital infection.

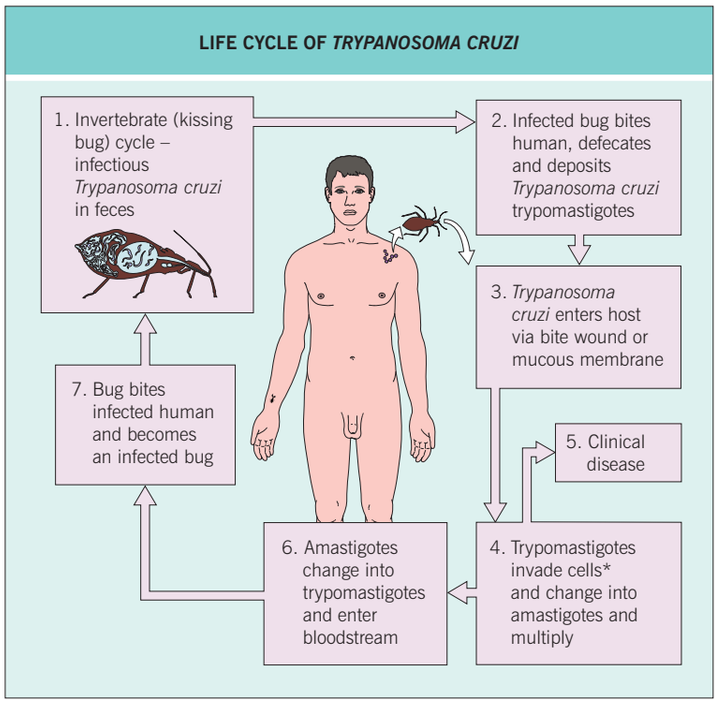

Fig. 83.15 Life cycle of *Trypanosoma cruzi*. *Smooth muscle of heart and skeletal muscle. *Adapted with permission from Keusch GT, Host response to infection. In: Cohen J, Powderly W, eds, Infectious Diseases, 2nd edition. London: Mosby, 2004.*

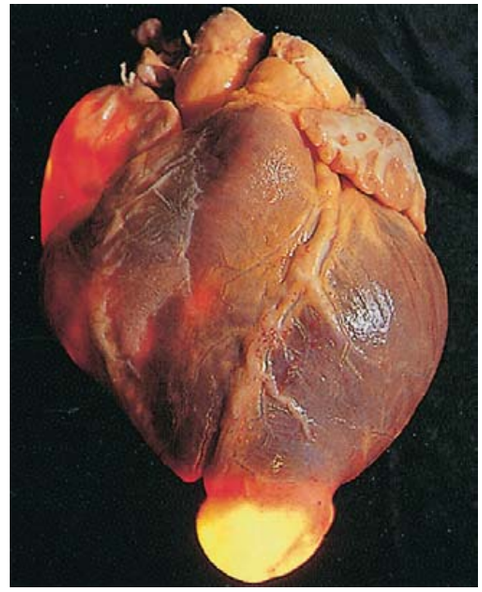

Fig. 83.17 Chagas disease: apical aneurysm of the heart. Mural thrombi may be present at the apex of the left ventricle, with marked thinning of the ventricular wall (illuminated). *With permission from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

It is estimated that 10 million people are infected with *T. cruzi*, and Chagas disease kills approximately 10 000 people per year[46], mostly in rural areas of Latin America. Chagas disease is the leading cause of parasitic death in Latin America and the third leading cause in the world. The acute form of the disease (see below) is seen more commonly in children, and, in some areas, 85% of children under the age of 10 years are infected. The incidence is much lower in the US, with most reported cases occurring in immigrants from Central America.

Pathogenesis

Blood-sucking reduviid bugs ingest trypomastigotes from the peripheral blood of vertebrate hosts (Fig. 83.15). Once the bug has become infected, it remains so for the rest of its life. The parasites transform into epimastigotes and multiply in the bug's midgut, later becoming metacyclic trypomastigotes in its hindgut. When the infected bug takes a subsequent blood meal, it usually defecates during or after feeding, depositing infective metacyclic trypomastigotes on the skin. The parasites penetrate the skin (generally via the bite wound) or mucosa (usually the conjunctiva). Following invasion of the host's cells, amastigotes multiply within the cytoplasm and then develop into trypomastigotes. The latter are released when the cells rupture and can either infect other cells or enter the bloodstream, where they may be ingested by new vectors.

The underlying pathogenesis of this disease is poorly understood, but the autonomic nervous system that innervates the heart and gastrointestinal tract appears to be a primary target. The visceral involvement seen in the chronic stage (see below) is thought to be a reflection of neuronal damage that occurs during the acute phase. An alternative hypothesis suggests that an autoimmune process is responsible for the systemic abnormalities seen during the chronic phase of the disease. In addition, trypomastigotes have the ability to penetrate the smooth muscle of the heart and the wall of the gastrointestinal tract[47].

Clinical features

Chagas disease has acute and chronic phases, and each has different clinical manifestations. Although the acute phase can affect individuals of any age, it is usually observed in children. At the cutaneous site of parasitic entry (see Fig. 83.15), some patients develop a chagoma, which is a localized area of erythema and swelling that is often accompanied by regional lymphadenopathy. When the conjunctiva is the portal of entry, the painless edema of the palpebral and periocular tissues that appears is referred to as the Romaña sign or ophthalmoganglionar complex[3] (Fig. 83.16). The Romaña sign occurs in approximately 80% of individuals infected by this route. In some patients, the swelling is accompanied by preauricular lymphadenopathy (Parinaud sign)[44].

These initial clinical findings can be accompanied by fever, malaise, anorexia and edema of the face and lower extremities. Some patients develop an eruption of erythematous macules, hepatosplenomegaly, thrombocytosis, leukocytosis and/or eosinophilia. The acute phase may last for up to 2 months, but it usually resolves spontaneously. In addition, inflammation at the sites of parasite entry can persist for several weeks[44]. Occasionally, patients develop myocarditis or meningoencephalitis that can be life-threatening[47].

After resolution of the acute phase, patients enter the indeterminate phase of Chagas disease. This stage is characterized by asymptomatic parasitemia and positive serology. Then, many years or even decades after the initial infection, an estimated 30% of patients will develop

Fig. 83.18 Chagas disease: radiograph of megaesophagus. Muscular degeneration and denervation of segments of the alimentary tract through destruction of the cells of Auerbach's plexus cause megaesophagus, megastomach and megacolon, which can be detected radiologically. *With permission from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

symptoms of the chronic phase of Chagas disease[48]. The heart is the organ most commonly affected (Fig. 83.17) and the clinical manifestations include congestive heart failure, arrhythmias and heart block[47]. The gastrointestinal tract is also frequently involved, leading to megacolon and megaesophagus (Fig. 83.18).

If patients who chronically harbor *T. cruzi* become immunosuppressed, reactivation of the disease can occur. When this happens, the disease is often more severe than in typical cases of Chagas disease and patients may develop ulcerative lesions[44].

Pathology

Histologically, at the site of parasite entry (chagoma), there is interstitial edema and a mononuclear cell infiltrate. Within cells in the subcutaneous tissue and muscle, aggregates of amastigotes may be seen. Enlarged lymph nodes are hyperplastic and intracellular amastigotes can be observed. In the chronic stage, trypanosomes are hard to find in affected organs.

Diagnosis and differential diagnosis

The diagnosis of acute Chagas disease is based upon the microscopic identification of either trypomastigotes in the blood (or CSF) or amastigotes within tissue. Because the concentration of parasites is low (even in the acute stage), hemoconcentration techniques are used to enhance the yield. If the parasites cannot be demonstrated microscopically, cultures of blood, CSF or tissue should be performed, as the latter is a more sensitive detection method. Xenodiagnosis represents a specific and relatively sensitive method for the diagnosis of Chagas disease; however, this technique is expensive and is only available in large laboratories in endemic areas. Specifically, trypanosome-free reduviid bugs are fed on patients and the feces or hindgut contents of the bugs are examined for epimastigotes 10 to 30 days later. This method can be used to confirm a serologic diagnosis in patients with chronic disease[44].

Serologic tests and PCR are useful for establishing the diagnosis of chronic Chagas disease. The most commonly employed serologic assays are indirect immunofluorescence, complement fixation, indirect hemagglutination and ELISA.

The nonspecific symptoms that may occur during the acute phase of Chagas disease (macular eruption and influenza-like symptoms) make the differential diagnosis broad. When the site of inoculation is the eye, other entities to consider include a reaction to a bite from another type of insect, angioedema and bacterial cellulitis.

Treatment

Treatment options for Chagas disease are limited and most effective during early disease[48]. The drug most commonly used is nifurtimox. It reduces the severity and duration of symptoms associated with the acute phase. However, parasitologic cure occurs in only 50% of treated patients and the efficacy of nifurtimox during the intermediate and chronic stages has not been proven. Another drug that is effective in the acute phase of the disease but less effective during the chronic stage is benznidazole (not available in the US)[49]. The side effects of these two medications are reviewed in Table 83.6.

Allopurinol and itraconazole have also been evaluated for the treatment of chronic Chagas disease[50]. However, to date, there is no evidence that pathologic changes of the chronic phase of this disease can be reversed by any therapy. Thus, chronic disease is managed primarily by supportive care (e.g. antiarrhythmics)[47].

Prevention of the infection involves education about sanitation and the use of residual insecticides in domestic areas. Vaccines are still being investigated but are not yet available.

Key features

- In West Africa, the disorder is due to *Trypanosoma brucei gambiense* infection, and in East Africa it is caused by *Trypanosoma brucei rhodesiense* infection
- The vectors are several species of tsetse flies
- Cutaneous manifestations include a localized bite reaction ("trypanosomal chancre") and an annular erythematous eruption that coincides with fever spikes

African Trypanosomiasis

Epidemiology

African trypanosomiasis affects approximately 30 000 individuals annually and results in over 3000 deaths per year[51]. The disease is almost invariably fatal if left untreated. There are two forms of African trypanosomiasis, which are named based on their non-overlapping geographic distributions in Africa (Table 83.7; see Fig. 83.14). The West African form, due to *Trypanosoma brucei gambiense*, is a chronic, anthroponotic disease with primarily neurologic features. The East African form, caused by *Trypanosoma brucei rhodesiense*, is an acute, zoonotic disease (with antelopes as a reservoir) that is often fatal. Fortunately, *T. b. rhodesiense* only occasionally infects humans, mainly farmers, hunters and tourists[52,53]. Both types of *T. brucei* are transmitted to humans by blood-sucking tsetse flies (genus *Glossina*), which are found in Africa. The flies become infected by ingesting blood from infected mammalian hosts (Fig. 83.19). Transmission transplacentally or via blood products may also potentially occur.

Pathogenesis

After inoculation, trypanosomes may produce a local chancre before spreading via the lymphatics to regional (and then distant) lymph nodes. The organisms disseminate to the bloodstream and eventually to the CNS, and they multiply by binary fission[54]. They escape significant immunologic response by continuously changing their surface glycoproteins[52,53].

Clinical features

Patients can develop an indurated, painful reaction at the portal of entry of the organisms, referred to as a "trypanosomal chancre" (Fig. 83.20). This is seen more commonly (70–80% of cases) in the East African form due to *T. b. rhodesiense*[44]. The lesion appears 1–2 weeks after the tsetse fly bite and heals spontaneously over several weeks.

The hemolymphatic stage occurs when the trypanosomes enter the lymphatic system and bloodstream 1–3 weeks after infection. Patients develop spiking fevers, malaise, and symmetrical lymphadenopathy. Enlargement of the lymph nodes of the posterior cervical triangle, referred to as Winterbottom's sign, is a classic finding in the West African form due to *T. b. gambiense*. Patients may have peripheral or facial edema, hepatosplenomegaly, and ascites[3]. A transient eruption (referred to as "trypanids") of annular and targetoid erythematous patches or urticarial plaques may occur in concert with fever spikes 6–8 weeks after onset of the illness. The eruption favors the trunk and is evident in 50% of fair-skinned patients[3,55].

ANTIHELMINTHIC DRUGS: THERAPEUTIC USES, SIDE EFFECTS AND CONTRAINDICATIONS				
Drug	**Therapeutic use**	**Toxicity and side effects**		**Precautions and contraindications**
		Systemic and cutaneous	**"Allergic"reactions**	
Thiabendazole	Strongyloidiasis, cutaneous larva migrans (second-line therapy), dracunculiasis	– GI: nausea, vomiting, anorexia > diarrhea, abdominal pain > elevated transaminases, cholestasis – Neurologic: dizziness, drowsiness > headache, paresthesias, weakness > tinnitus, seizures, hallucinations – Ocular: irritation, blurred vision, xerophthalmia – Other: crystalluria without hematuria, transient leukopenia, xerostomia	– Cutaneous: urticaria (3%), exanthem (<5%) > fixed drug eruption, pruritus, perianal "rash", flushing > angioedema, contact dermatitis, Jarisch–Herxheimer reaction, Stevens–Johnson syndrome – Fever, anaphylaxis	– FDA pregnancy category C – Discontinue during lactation – Use with caution if hepatic disease
Mebendazole	GI nematode infections (e.g. enterobiasis, ascariasis, ancylostomiasis), toxocariasis, trichinosis, sparganosis	– GI: nausea, vomiting, diarrhea, abdominal pain > elevated transaminases – Neurologic: dizziness, drowsiness > tinnitus, seizures – Hematologic: anemia, thrombocytopenia, leukopenia > agranulocytosis – Other: alopecia, oligospermia	– Cutaneous: exanthem, urticaria, angioedema, pruritus, flushing	– FDA pregnancy category C – Use with caution in children < 2 years of age
Albendazole	Cutaneous larva migrans, GI nematode infections (as above), echinococcosis, neurocysticercosis, toxocariasis	– GI: nausea, vomiting, diarrhea, abdominal pain, elevated transaminases > cholestasis – Neurologic: headache, dizziness > increased intracranial pressure (with treatment of neurocysticercosis), seizures – Hematologic: leukopenia > thrombocytopenia, agranulocytosis, pancytopenia – Other: alopecia	– Cutaneous: exanthem, urticaria > angioedema, Stevens–Johnson syndrome – Fever, anaphylaxis	– FDA pregnancy category C – Avoid during lactation – Use with caution if hepatic disease
Diethylcarbamazine	Filariasis, dirofilariasis, loiasis, toxocariasis (second-line therapy)	– GI: nausea, vomiting, anorexia – Neurologic: headache	– Mazzotti reaction: pruritus, lymphadenopathy > papular exanthem, fever, tachycardia, arthralgias, headache – Nodular swellings along the lymphatics – Leukocytosis, eosinophilia – Ocular: limbitis, punctate keratitis > uveitis, atrophy of the retinal pigment epithelium > retinal hemorrhage (*L. loa*) – Encephalitis (*L. loa*) – Proteinuria	– Appears to be safe for use during pregnancy (controlled studies show no fetal risk) – Avoid population-based administration in regions where onchocerciasis or loiasis is endemic
Ivermectin	Onchocerciasis, filariasis (second-line therapy), cutaneous larva migrans, ascariasis, strongyloidiasis	– GI: nausea, vomiting, diarrhea, elevated transaminases > cholestasis – Neurologic: dizziness > drowsiness, headache, tremor – Other: leukopenia	– Mazzotti-like reaction and ocular side effects (*O. volvulus*; see above) – Pruritus, urticaria, peripheral edema – Orthostatic hypotension	– FDA pregnancy category C – Considered safe during lactation
Praziquantel	Schistosomiasis; liver fluke and tapeworm infections (e.g. cysticercosis, sparganosis)	– GI: nausea, vomiting, abdominal discomfort > bloody diarrhea, elevated transaminases – Neurologic: headache, dizziness > drowsiness – Other: arrhythmias	– Cutaneous: pruritus > urticaria, exanthem – Arthralgias, myalgias – Fever – Meningismus, CSF pleocytosis, seizures (in neuro-cysticercosis)	– FDA pregnancy category B – Avoid during lactation – Contraindicated for ocular cysticercosis

Table 83.6 Antihelminthic drugs: therapeutic uses, side effects and contraindications. CSF, cerebrospinal fluid; GI, gastrointestinal.

Continued

The final stage (meningoencephalitic stage) of the disease is characterized by neurologic manifestations, including irritability, changes in personality, inability to concentrate, and daytime somnolence alternating with nighttime restlessness and insomnia, hence the term sleeping sickness[56]. Deep delayed hyperesthesia after a brisk tap or pinch (Kerandel's sign) reflects CNS involvement[55]. CSF examination demonstrates lymphocytic pleocytosis and increased protein content; in some patients, trypanosomes are evident when the fluid is centrifuged.

East African trypanosomiasis tends to follow a more acute course with earlier onset of CNS symptoms (which are often delayed months to years in the West African variant), and the stages are not as well

ANTIHELMINTHIC DRUGS: THERAPEUTIC USES, SIDE EFFECTS AND CONTRAINDICATIONS				
Drug	**Therapeutic use**	**Toxicity and side effects**		**Precautions and contraindications**
		Systemic and cutaneous	**"Allergic"reactions**	
Levamisole	GI nematode infections (e.g. ascariasis, ancylostomiasis; second-line therapy)	– GI: nausea, vomiting, diarrhea, abdominal discomfort – Neurologic: headache > dizziness, insomnia, paresthesias > multifocal leukoencephalopathy – Hematologic: leukopenia, anemia, thrombocytopenia > agranulocytosis – Other: dysgeusia, xerosis, alopecia, arthralgias	– Cutaneous: exanthem (5–10%) > pruritus, urticaria, angioedema, fixed drug eruption, lichenoid eruption, vasculitis/ vasculopathy (favors the ears), Stevens–Johnson syndrome – Stomatitis (5%) – Fever, anaphylaxis	– FDA pregnancy category C – Considered safe during lactation
Nifurtimox	Chagas disease	– GI: nausea, vomiting, anorexia > abdominal pain, diarrhea – Neurologic: paresthesias, weakness, headache, insomnia > psychiatric disturbances, seizures – Other: myalgias > leukopenia, oligospermia	– Cutaneous: exanthem, urticaria, angioedema – Fever, anaphylaxis	– FDA pregnancy category C
Benznidazole	Chagas disease	– GI: nausea, vomiting, anorexia – Neurologic: paresthesias, weakness – Hematologic: leukopenia > thrombocytopenia, agranulocytosis – Other: myalgias	– Cutaneous (more common than with nifurtimox): exanthem, urticaria, angioedema, generalized peripheral edema – Fever, lymphadenopathy, anaphylaxis	– FDA pregnancy category C
Suramin	African trypanosomiasis	– GI: nausea, vomiting > diarrhea, abdominal pain, elevated transaminases, cholestasis – Neurologic: palmoplantar hyperesthesia/paresthesias, weakness, headache > seizures – Ocular: blepharitis, conjunctivitis, photophobia, excessive lacrimation – Hematologic: leukopenia > agranulocytosis, hemolytic anemia, thrombocytopenia – Other: malaise, dysgeusia, proteinuria > renal or adrenal insufficiency	– Cutaneous: exanthem, urticaria > exfoliative dermatitis, generalized peripheral edema – Stomatitis – Fever, anaphylaxis (1 : 2000)	– FDA pregnancy category C – Use with caution if renal disease
Eflornithine	African trypanosomiasis (*T. brucei gambiense*)	– GI: diarrhea (40%) > nausea, vomiting, abdominal pain – Neurologic: dizziness, headache, seizures (~5%) – Hematologic: anemia (50%) > leukopenia (25%) > thrombocytopenia – Other: alopecia > hearing loss	– Cutaneous: exanthem – Fever	– FDA pregnancy category C

COMPARISON BETWEEN WEST AFRICAN AND EAST AFRICAN TRYPANOSOMIASIS		
	West African trypanosomiasis	**East African trypanosomiasis**
Causative agent	*T. brucei gambiense*	*T. brucei rhodesiense*
Vector	Tsetse fly	Tsetse fly
Main host	Humans	Wild game > humans
Reservoir	Humans	Antelope, cattle
Location	West/central regions of sub-Saharan Africa	Ethiopia, Uganda, Zambia, Botswana, Tanzania, Mozambique
Clinical presentation	• Chancre uncommon • Chronic neurologic symptoms • Posterior cervical (Winterbottom sign) and supraclavicular lymphadenopathy • Trypanids (10–50% of patients, especially if lightly pigmented skin)	• Chancre common (75% of patients) • Acute neurologic symptoms • Axillary and epitrochlear lymphadenopathy • Trypanids common (especially if lightly pigmented skin) • Myocarditis/heart failure
Treatment		
Hemolymphatic stage	• Pentamidine	• Suramin
CNS involvement	• Melarsoprol or eflornithine	• Melarsoprol

Table 83.7 Comparison between West African and East African trypanosomiasis.

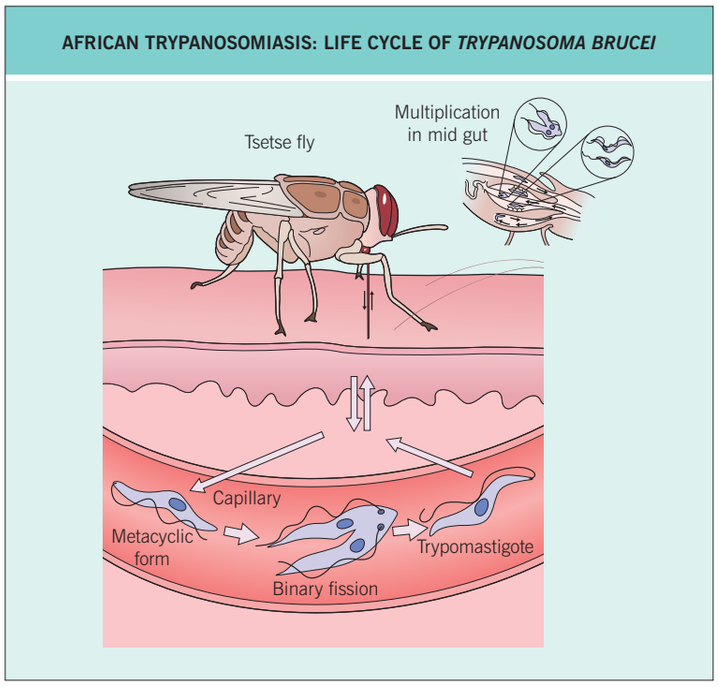

Fig. 83.19 African trypanosomiasis: life cycle of *Trypanosoma brucei*.

Fig. 83.20 Trypanosomal chancre. The bite reaction, the earliest clinical lesion, is known as a "trypanosomal chancre". It resembles a boil but is usually painless. Fluid aspirated from the nodule contains actively dividing trypanosomes. This reaction is seen more commonly in *T. b. rhodesiense* than in *T. b. gambiense* infection. *With permission from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

defined (see Table 83.7). In addition, East African trypanosomiasis may result in heart failure due to damage to myocardium, even before the onset of symptoms from CNS involvement[55,57].

Pathology and diagnosis

Definitive diagnosis requires identification of the parasites in the skin, blood (especially the buffy coat), lymph node or CSF. Routine histologic sections from skin lesions demonstrate a superficial perivascular lymphocytic infiltrate and mild spongiosis; trypanosomes are usually not seen. Serologic tests become positive about 2 weeks after the onset of infection[3]. PCR is the most sensitive test[58].

Differential diagnosis

The differential diagnosis of the chancre includes infectious disorders such as extragenital primary syphilis and primary inoculation tuberculosis, and entities that lead to an annular erythema are discussed in Chapter 19.

Treatment

The first-line treatments for the early/hemolymphatic stage of East and West African trypanosomiasis are suramin and pentamidine, respectively. For the meningoencephalitic stage, melarsoprol is the first-line treatment and eflornithine is an alternative for the West African form[3] (see Table 83.7).

Key features

- A common, worldwide disease caused by the protozoan *Toxoplasma gondii*
- Cutaneous involvement is unusual but occasionally occurs in immunocompromised individuals, pregnant women and neonates
- In congenital infections, the skin lesions are usually necrotic or hemorrhagic papules

TOXOPLASMOSIS

Introduction

Toxoplasma gondii is an intestinal coccidian parasite of domestic cats and other mammals. *Toxoplasma* infections in humans can be acquired or congenital. In immunocompetent hosts, the majority of infections are asymptomatic or produce only flu-like symptoms, with occasional development of lymphadenopathy or retinitis. In immunosuppressed patients, more severe disease can occur[59]. Cutaneous manifestations are rare and may be seen in both congenital and acquired forms of the disease[60].

Epidemiology

Worldwide, toxoplasmosis is a common infection in humans. The prevalence varies, depending upon geographic location and age. In the US, 50% of the population has antibodies against *T. gondii*, with higher rates in older individuals[61]. The main end host of *T. gondii* is the cat.

Pathogenesis

The life cycle of *T. gondii* is such that there are two major routes of infection (Fig. 83.21). The more direct route is ingestion of oocysts, which are excreted in the feces of host animals (usually the cat) and are highly resistant to environmental damage. Human infections are more commonly acquired by consumption of bradyzoite-containing cysts within meat. These cysts are found in all tissues of infected hosts but are most common in muscle and neural tissue (including the brain and eye) and therefore can be ingested in raw or undercooked contaminated meat. Milk is another source of bradyzoite-containing cysts. A particular concern for *T. gondii* infections acquired during early pregnancy is that tachyzoites can pass through the placental barrier to the fetus, leading to a serious infection and associated congenital abnormalities or miscarriage[62]. Infection can also be acquired through contaminated blood or through organ transplants from seropositive donors[62].

Clinical Features

Toxoplasmosis can be acquired or congenital, and the acquired form can be acute or chronic. In most instances (~90%), acute infection is asymptomatic. The most common clinical manifestations are lymphadenopathy (especially posterior cervical) and flu-like symptoms (e.g. fever, malaise, myalgia). In immunocompromised patients, symptoms are more severe and findings may include encephalitis, meningoencephalitis, pneumonitis, myocarditis, pericarditis, myositis and hepatitis[62].

Chronic acquired toxoplasmosis is usually asymptomatic, but some patients develop chorioretinitis. In this form, it is possible to identify

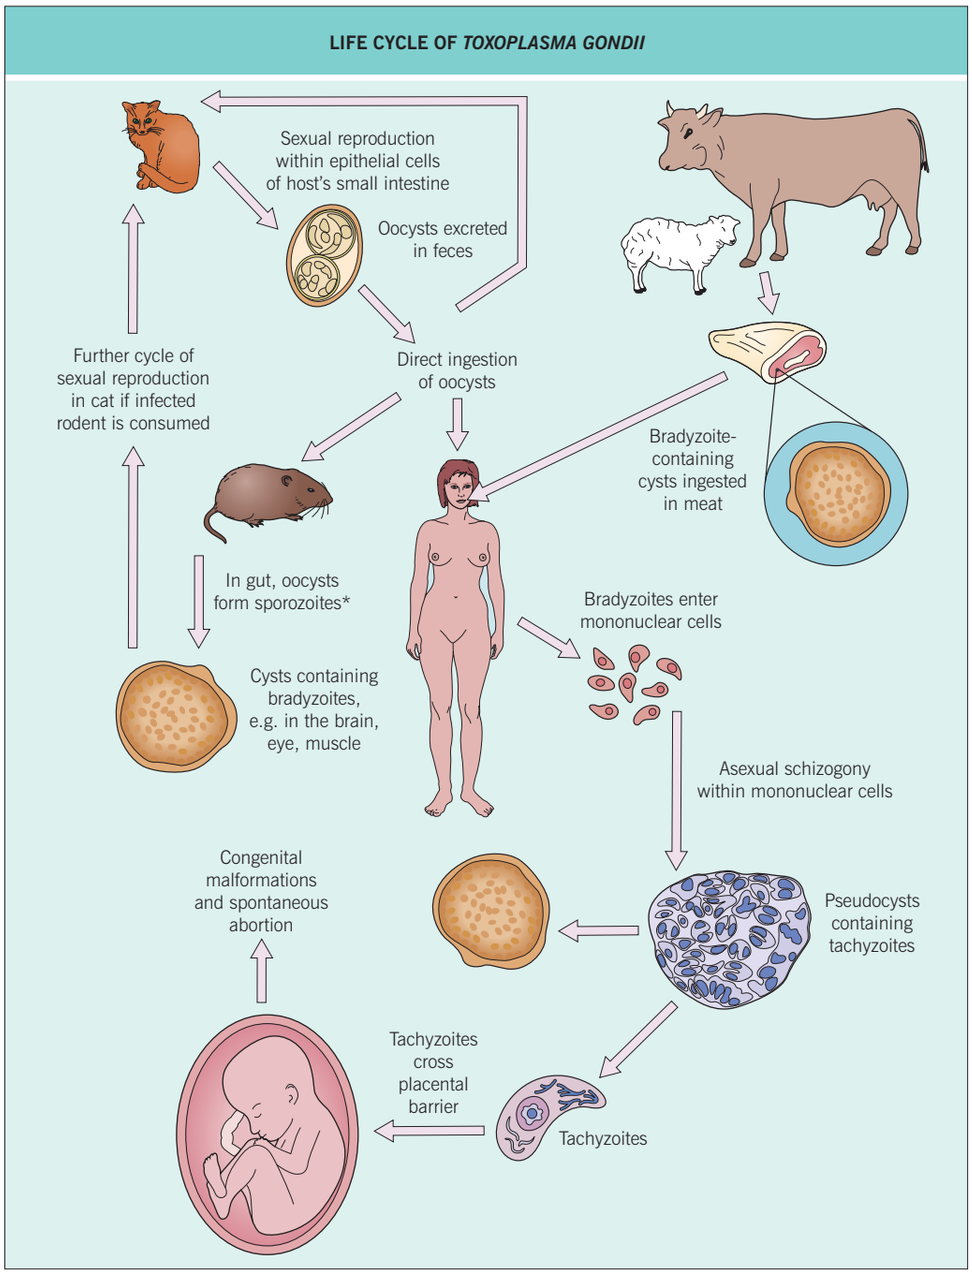

Fig. 83.21 Life cycle of *Toxoplasma gondii*. There is a wide range of mammalian hosts, the most important being the domestic cat. *Similar cycle of development in humans and other mammals. *Adapted from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

cysts within multiple organs, in particular the brain, heart and skeletal muscles.

The incidence of congenital toxoplasmosis is estimated to be 1 per 1000 to 1 per 10 000 live births in the US. Transmission of the disease is more likely if it is acquired by the mother during late pregnancy (10–25% in the first trimester versus 60–90% in the third trimester); however, the infection is more severe if transmission occurs early in gestation[63]. Most infected neonates are asymptomatic at birth (70–90%); however, in 10–30% chorioretinitis leads to visual loss, and >20% develop significant neurologic manifestations. The latter include deafness, microcephaly, hydrocephalus, developmental delay and seizures. Other potential findings in patients with congenital toxoplasmosis include hepatosplenomegaly, myositis, fever and thrombocytopenia.

Congenital toxoplasmosis can present with hemorrhagic or necrotic papules that favor the trunk. In acute acquired toxoplasmosis, cutaneous findings vary and may resemble roseola, erythema multiforme or papular urticaria; telangiectatic macules and vesicles are occasionaly observed[60]. Rarely, patients present with erythroderma, sclerodermatous manifestations or a dermatomyositis-like syndrome[64–66].

Pathology

Skin biopsy specimens can be helpful in establishing a specific diagnosis. In both congenital and acquired forms of toxoplasmosis, there is a superficial and deep perivascular infiltrate within the dermis, composed of lymphocytes, macrophages, plasma cells and eosinophils. In addition, dilated capillaries, foci of dermal hemorrhage and, occasionally, small vessel (leukocytoclastic) vasculitis can be seen. Although the cutaneous lesions are believed to reflect the immune response to the organism, tissue forms of *T. gondii* are found in approximately 50% of biopsy specimens of lesional skin. Trophozoites are seen within the cytoplasm of macrophages, both singly and inside small pseudocysts. Immunoperoxidase stains are very specific, and they are especially useful when there is only a small tissue sample[62]. Specific IgM and IgG antibodies against *Toxoplasma* can be detected in acute and convalescent serum samples from patients.

Differential Diagnosis

For neonates with congenital toxoplasmosis, other entities in the TORCH differential need to be considered (see Chs 80 & 121). For acquired toxoplasmosis, the differential diagnosis is extensive and

includes infectious diseases such as viral exanthems, meningococcemia and syphilis, as well as inflammatory diseases such as urticarial vasculitis, herpes simplex virus-associated erythema multiforme and autoimmune connective tissue diseases.

Treatment

Indications for treatment are severe acute infection, active chronic disease (e.g. in the skin or eye), congenital infection and an immunocompromised patient[59]. The most effective treatment is sulfadiazine (0.5–1.5 g four times daily in adults and 25–50 mg/kg four times daily in children) in combination with pyrimethamine (50–75 mg daily in adults and 1 mg/kg/day in children) and folinic acid. For patients allergic to sulfonamides, clindamycin can be used with pyrimethamine.

WORMS (HELMINTHS)

Medically important worms, or helminths, belong to two different phyla: Nematoda (roundworms) and Platyhelminthes (flatworms). The roundworms include free-living species as well as parasitic ones; they are unsegmented, and each species has two different sexes, a body cavity and a digestive tract. The flatworms are primarily parasitic worms that do not have a body cavity; they can be segmented or unsegmented, and most species are hermaphroditic. Flatworms can be further subdivided into two different classes: trematodes or flukes (the cause of schistosomiasis) and cestodes or tapeworms (the cause of cysticercosis and echinococcosis). Several helminthic infections have been chosen for more detailed discussion in the remainder of the chapter, and additional disorders are outlined in Table 83.8.

Of note, an alternative way of classifying worms is by their life cycle[67]. This schema divides associated infections into four classes: (1) soil-transmitted infections, including those due to hookworms (e.g. ancylostomiasis, cutaneous larva migrans; Fig. 83.22) and other nematodes (e.g. strongyloidiasis; Fig. 83.23) (Fig. 83.24); (2) infections transmitted mainly by insects, including onchocerciasis, filariasis and loiasis (Fig. 83.25); (3) infections due to trematodes (flukes) whose life cycle involves snails, such as fascioliasis and schistosomiasis (Fig. 83.26); and (4) infections acquired via ingestion, such as cysticercosis and echinococcosis (Fig. 83.27), enterobiasis (see Fig. 83.24), trichinosis (Fig. 83.28) and toxocariasis (Fig. 83.29).

Synonym: ■ Creeping eruption

Key features

- Due to larvae of animal hookworms (intestinal nematodes)
- Skin lesions are serpiginous and pruritic, representing the paths of migration of organisms within the epidermis
- The rate of migration is 1–2 cm per day
- Self-limited disease

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans is a serpiginous cutaneous eruption caused by the accidental penetration and migration of animal hookworm larvae through the epidermis. The infection has a worldwide distribution and occurs most frequently in warmer climates. The skin lesions are usually self-limited[67].

Epidemiology and Pathogenesis

Cutaneous larva migrans is caused by the larvae of hookworms that infect domestic dogs and cats (*Ancylostoma caninum*, *A. braziliense* and *Uncinaria stenocephala*). Although cutaneous larva migrans has a worldwide distribution[68], it is most commonly seen in warm climates, such as the southeastern US, Central and South America, Africa, and other tropical areas[67]. The infection is usually acquired by walking barefoot on ground contaminated with animal feces, but other body sites can become infected via contact with contaminated soil or sand. The larvae enter the skin and begin a prolonged process of migration within the epidermis. With rare exceptions, the parasite remains confined to the epidermis, producing visible tracts and intense pruritus. The parasite lacks collagenase, which is necessary to disrupt the basement membrane.

Clinical Features

Patients have intense localized pruritus that begins shortly after the hookworm penetrates the skin. Several days later, the pruritus is associated with small vesicles and/or one or more edematous, serpiginous "tracts" (see Fig. 83.22). Each larva produces one tract and migrates at a rate of 1 to 2 cm per day. The most frequent location is the distal lower extremities or buttocks. Additional sites of involvement may include the hands, thighs and, rarely, perianal area[68,69]. In severe infections, hundreds of such lesions may be found on a single patient. If untreated, a single larval tract may progress, then disappear for a few days, reappear, advance some more, and so on, for weeks or months, after which time it will spontaneously resolve. Unlike human hookworm disease and strongyloidiasis, the larvae rarely progress beyond the skin, and systemic manifestations such as migratory pulmonary infiltrates and peripheral eosinophilia (Loeffler's syndrome) are rarely seen. The only common systemic finding is a moderate peripheral blood eosinophilia. Due to intense pruritus and scratching, superimposed bacterial infections may complicate the clinical picture. Vesicles and bullae may develop in previously sensitized patients[67,70].

Pathology

Although the diagnosis is usually made clinically, based on the characteristic lesions and history of recent exposure (e.g. walking barefoot), biopsies are sometimes performed. It is unusual to see the parasite in biopsy specimens, but occasionally the larva can be identified within the epidermis. More commonly, cavities left by the parasite are located within the stratum corneum and are associated with spongiosis. In the dermis, there is a mixed inflammatory infiltrate composed of lymphocytes, histiocytes and numerous eosinophils. Occasionally, collections of eosinophils may be present in the epidermis and within hair follicles[67].

Differential Diagnosis

The clinical features of the cutaneous eruption are characteristic and the diagnosis is usually straightforward. The human species of intestinal hookworms (*A. duodenale* and *Necator americanus*) penetrate the skin prior to possible migration into venules (see Fig. 83.24), causing a pruritic nonspecific localized rash lasting 1–2 weeks that is referred to as "ground itch"[67,71]. Unlike cutaneous larva migrans, *A. duodenale* and *N. americanus* infections can progress to systemic hookworm disease, which manifests with anemia, malnutrition, and pulmonary and gastrointestinal symptoms (see Table 83.8). With these human species, autoinfection from larvae in the feces can occur, sometimes years after the initial infection.

The differential diagnosis may include allergic contact dermatitis, impetigo, inflammatory tinea, scabies, myiasis, and other nematode infections (e.g. strongyloidiasis). Larva currens is a localized (or occasionally more widespread) urticarial eruption that is caused by autoinfection with *Strongyloides stercoralis* in immunocompetent individuals (see Table 83.8); it typically begins perianally and then rapidly extends, as quickly as 5–10 cm per day, onto the buttocks, thighs and abdomen[72]. The lesions are relatively short-lived, lasting hours to days, but they often recur[73].

Treatment

Although cutaneous larva migrans is self-limited, its potential complications (e.g. impetigo and allergic reactions), together with the intense pruritus and the significant duration of the disease (sometimes several months), usually necessitate treatment. Freezing the leading edge of the skin track (cryotherapy) has been suggested, but this modality is rarely sufficient. Administration of a single 400 mg oral dose of

MAJOR PARASITIC WORMS THAT CAUSE DISEASES AND CUTANEOUS MANIFESTATIONS IN HUMANS								
Disease	**Organism**	**Distribution**	**Mode of spread**	**Skin findings**	**Systemic findings**	**Diagnosis**	**Therapy***	**Figure**
Ascariasis (roundworms), intestinal nematode	*Ascaris lumbricoides*	Widespread and high prevalence, esp. in tropical countries	Ingestion of eggs	None	Abdominal pain, diarrhea, intestinal obstruction, nutritional deficiencies, Loeffler's syndrome	Detection of eggs in the stools	Mebendazole Albendazole Pyrantel pamoate Ivermectin	83.24
Enterobiasis (pinworms), intestinal nematode	*Enterobius vermicularis*	Widespread and high prevalence, esp. in countries within temperate zones	Ingestion of eggs	Perianal and perineal pruritus	Restlessness Asymptomatic in most patients	Detection of eggs via adhesive cellophane tape pressed against perianal skin	Mebendazole Albendazole Pyrantel pamoate	83.24
Ancylostomiasis (hookworms), intestinal nematode	*Ancylostoma duodenale, Necator americanus*	Tropical and subtropical distribution	Percutaneous via contact with infective larvae in soil	Dermatitis ("ground itch") at the site of larval entry	Iron deficiency anemia, GI symptoms, Loeffler's syndrome, eosinophilia	Direct fecal smear examination for eggs	Mebendazole Albendazole Pyrantel pamoate	83.24
Strongyloidiasis, intestinal nematode	*Strongyloides stercoralis*	Occurs worldwide, esp. in tropical areas; in cooler climates found in warm humid mines	Percutaneous via contact with infective larvae; occasionally ingestion of larvae Autoinfection via penetration of perianal skin Hyperinfection in immunocompromised patients, due to penetration of intestinal mucosa	Generalized or localized urticarial eruption beginning perianally and extending to the buttocks, thighs, and abdomen (larva currens) "Thumbprint" purpura in hyperinfection (see Fig. 83.23)	Diarrhea, duodenitis, eosinophilia, pulmonary symptoms Symptoms more severe in immunocompromised patients	Examination of stool for larvae; rarely, diagnosis is made by lung biopsy or pulmonary cytology	Thiabendazole Ivermectin	83.24
Loiasis, tissue nematode	*Loa loa*	West and Central Africa	Transmitted by bite of tabanid flies of the genus *Chrysops* (mango flies) carrying infective larvae Mature in connective tissue	Transient localized subcutaneous edema (Calabar swellings), often of the hands, wrists and forearms; represent tracts of migrating adult worms; associated with pruritus and pain	Conjunctivitis (due to movement of adult worms under conjunctiva), eosinophilia, renal disease	Detection of microfilariae in blood during the daytime Occasionally, adult worms can be extracted from the eye	Diethylcarbamazine	83.25
Dirofilariasis, tissue nematodes of animals	*Dirofilaria immitis* (dog heartworms); *D. tunuis* (filaria of raccoons); *D. repens* (filaria of dogs and cats); *D. ursi* (filaria of bears)	*D. immitis* occurs worldwide; *D. tunuis* in Southeast US; *D. repens* in Europe and Asia; *D. ursi* in North America and Japan	Transmitted by mosquitoes carrying infective larvae Do not mature in humans	*D. tunuis, D. repens* and *D. ursi* cause small painful subcutaneous nodules with or without inflammation	*D. immitis* causes nodules in the lung	Detection of larvae by biopsy	Surgical excision Diethylcarbamazine Ivermectin	

*Details regarding the majority of these medications are provided in Table 83.6.

Table 83.8 Major parasitic worms that cause diseases and cutaneous manifestations in humans. Cutaneous larva migrans, onchocerciasis, filariasis, schistosomiasis, cysticercosis and echinococcosis are covered in the text.

Continued

MAJOR PARASITIC WORMS THAT CAUSE DISEASES AND CUTANEOUS MANIFESTATIONS IN HUMANS								
Disease	**Organism**	**Distribution**	**Mode of spread**	**Skin findings**	**Systemic findings**	**Diagnosis**	**Therapy***	**Figure**
Dracunculiasis (guinea worm), tissue nematode	*Dracunculus medinensis*	Africa, particularly Ghana and Sudan	Ingestion of infected water fleas of the genus *Cyclops* in drinking water migrate from intestine to subcutaneous tissue, usually of the legs	Papulonodule then blister and/or ulceration, usually of the lower extremity; calcified nodules	Anaphylactic shock, rheumatic symptoms	Confirmation of worms in the subcutaneous tissue Immunodiagnosis, e.g. ELISA Sequence analysis of 18S RNA	Gradual extraction of the worm (e.g. on a stick) ± metronidazole or thiabendazole	83.25
Trichinosis, tissue nematode	*Trichinella spiralis*	Widespread in temperate zones	Ingestion of encysted larvae from raw/undercooked animal meat, usually pork	Periorbital edema in severe infection, splinter hemorrhages	Most infections are subclinical Heavy infection also leads to fever, enteritis, myositis and eosinophilia; occasionally myocarditis and encephalitis	Confirmation of encysted larvae in the skeletal muscle; fluorescent antibody testing; ELISA	No satisfactory treatment Corticosteroids for severe symptoms plus mebendazole	83.28
Toxocariasis (visceral larva migrans), larval stage of dog roundworm, larval nematode	*Toxocara canis*	Worldwide distribution	Ingestion of eggs excreted by dogs Larvae migrate through the viscera as they are unable to mature into adults	Urticaria, cutaneous nodules	Cough, fever, hepatomegaly, eosinophilia; ocular and hepatic granulomas	Diagnosis is usually suggested clinically Confirmation by histologic examination is uncommon Serologic assay (Western blot)	Mebendazole Albendazole Diethylcarbamazine (second-line)	83.29
Sparganosis, larval stage of tapeworms of dogs and cats, cestode	*Spirometra*	Sporadic in most countries, seen most frequently in the Far East	Ingestion of larvae in intermediate hosts (e.g. snakes, frogs, fish) Occasionally application of frogs to eyes as poultice	Painless small subcutaneous nodules at sites of larval proliferation Edema if periorbital involvement	Rarely pulmonary or CNS involvement	Biopsy to identify larvae	Surgical excision Mebendazole Praziquantel	83.27
Fascioliasis (liver fluke), trematode	*Fasciola hepatica*	South America, Europe, Africa, China, Australia	Ingestion of metacercariae on aquatic plants, e.g. wild watercress	Ectopic fascioliasis is occasionally reported; cutaneous cysts	Fever, hepatomegaly, obstruction of bile duct (rare), eosinophilia	Detection of ova in feces or bile Abdominal CT	Bithionol Triclabendazole	83.26
Paragonimiasis (lung flukes), trematode	*Paragonimus westermani*	*Paragonimus westermani* in Far East; other species in West Africa, Central and South America	Consumption of flesh of freshwater crustaceans containing living metacercariae	Cutaneous paragonimiasis rare, but has been reported	Productive cough, hemoptysis, bronchitis, lung abscess, pleural effusion Symptoms related to ectopic worms in abdomen, brain, etc.	Examination of sputum or feces for eggs ELISA	Praziquantel Bithionol	83.26

*Details regarding the majority of these medications are provided in Table 83.6.

albendazole to adults and children >2 years of age produces cure rates of 45–100%, but a dose of 400–800 mg/day (in children, 10–15 mg/kg/

Synonyms: ■ River blindness ■ Enfermedad de Robles ■ Erysipelas (erisipela) de la costa ■ Craw-craw

Key features

- *Onchocerca volvulus* is a tissue-dwelling nematode that is mainly found in Africa and transmitted by black flies
- Most clinical manifestations are caused by microfilariae in the skin and eyes
- Cutaneous manifestations include subcutaneous nodules that contain adult worms, a pruritic papular dermatitis, lichenification and leukoderma
- The diagnosis can be established by identification of microfilariae via microscopic examination of a skin sample (skin snip) or slit-lamp examination of the eyes

day with a maximum of 800 mg/day) for 3–5 days results in more consistent efficacy (cure rates of 80–100%)[70]. A single ivermectin dose of 12 mg in adults or 150 mcg/kg in children leads to cure rates of 80–100%. Topical application of 10–15% thiabendazole solution or ointment to affected areas can be performed for localized disease, but this has limited value for multiple lesions and requires application three times daily for at least 15 days. Oral thiabendazole is also effective but is less well tolerated than either albendazole or ivermectin[70].

ONCHOCERCIASIS

Introduction

Onchocerciasis, or river blindness, predominantly affects cutaneous and ocular tissue and is caused by *Onchocerca volvulus*, a filarial nematode[74]. Onchocerciasis most commonly occurs in inhabitants of tropical Africa and occasionally develops in residents of tropical areas in Central and South America and the Middle East. In the earlier stages of the disease, cutaneous manifestations include subcutaneous nodules

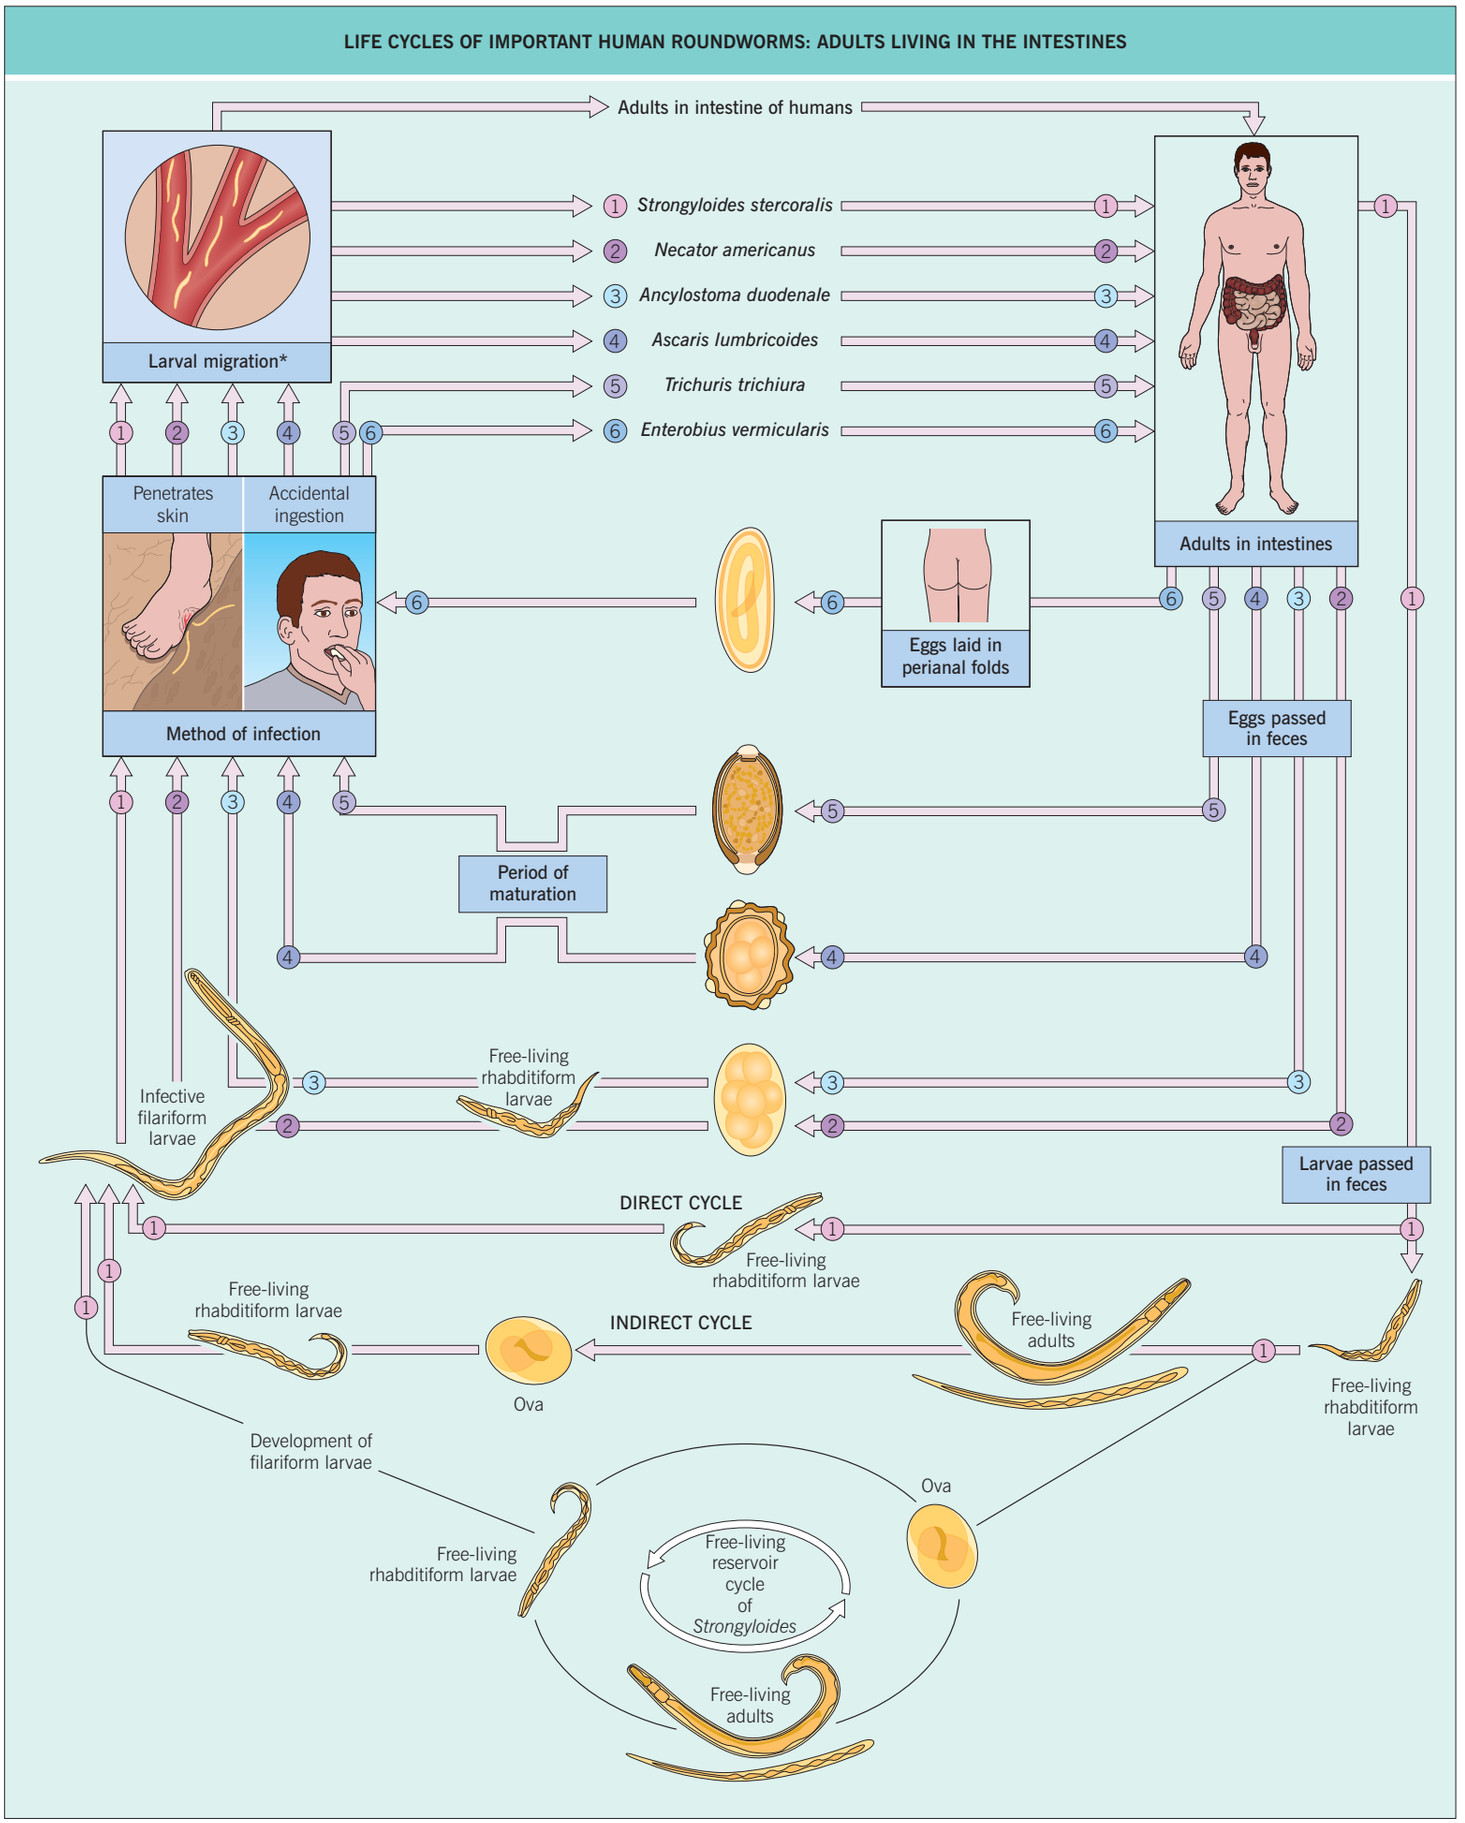

Fig. 83.24 Life cycles of important human roundworms: adults living in the intestines. *Larvae can migrate from venules into the right heart and lungs, then via alveoli into the trachea; eventually they are swallowed. *With permission from Cross JH, Helminths. and pruritic papular dermatitis, while skin thickening and leukoderma are later findings. Progressive sclerosing keratitis can lead to blindness.

Epidemiology

Although onchocerciasis is not a fatal disease, it is severely debilitating and is estimated to affect 37 million people worldwide, in particular those living for prolonged periods of time near fast-flowing rivers in endemic areas[75]. Well-oxygenated water plays a significant role in this disease, because the larvae of *O. volvulus* have an obligatory aquatic stage during which they require high oxygen tension[74,76]. Severe disease requires repeated exposures over many years. Approximately 99% of all cases are acquired in equatorial Africa, but there are some endemic foci in the Middle East and in Central and South America (Fig. 83.30), where infected slaves introduced the disease.

Pathogenesis

Onchocerciasis is transmitted by the bite of an infected black fly (*Simulium* spp.). Because these flies often assume a "hump-backed" stance, they are sometimes referred to as "buffalo gnats". Black flies feed by "rasping" (abrading) the surface of the skin until a pool of blood forms, which they lap up. Microfilariae previously residing in the

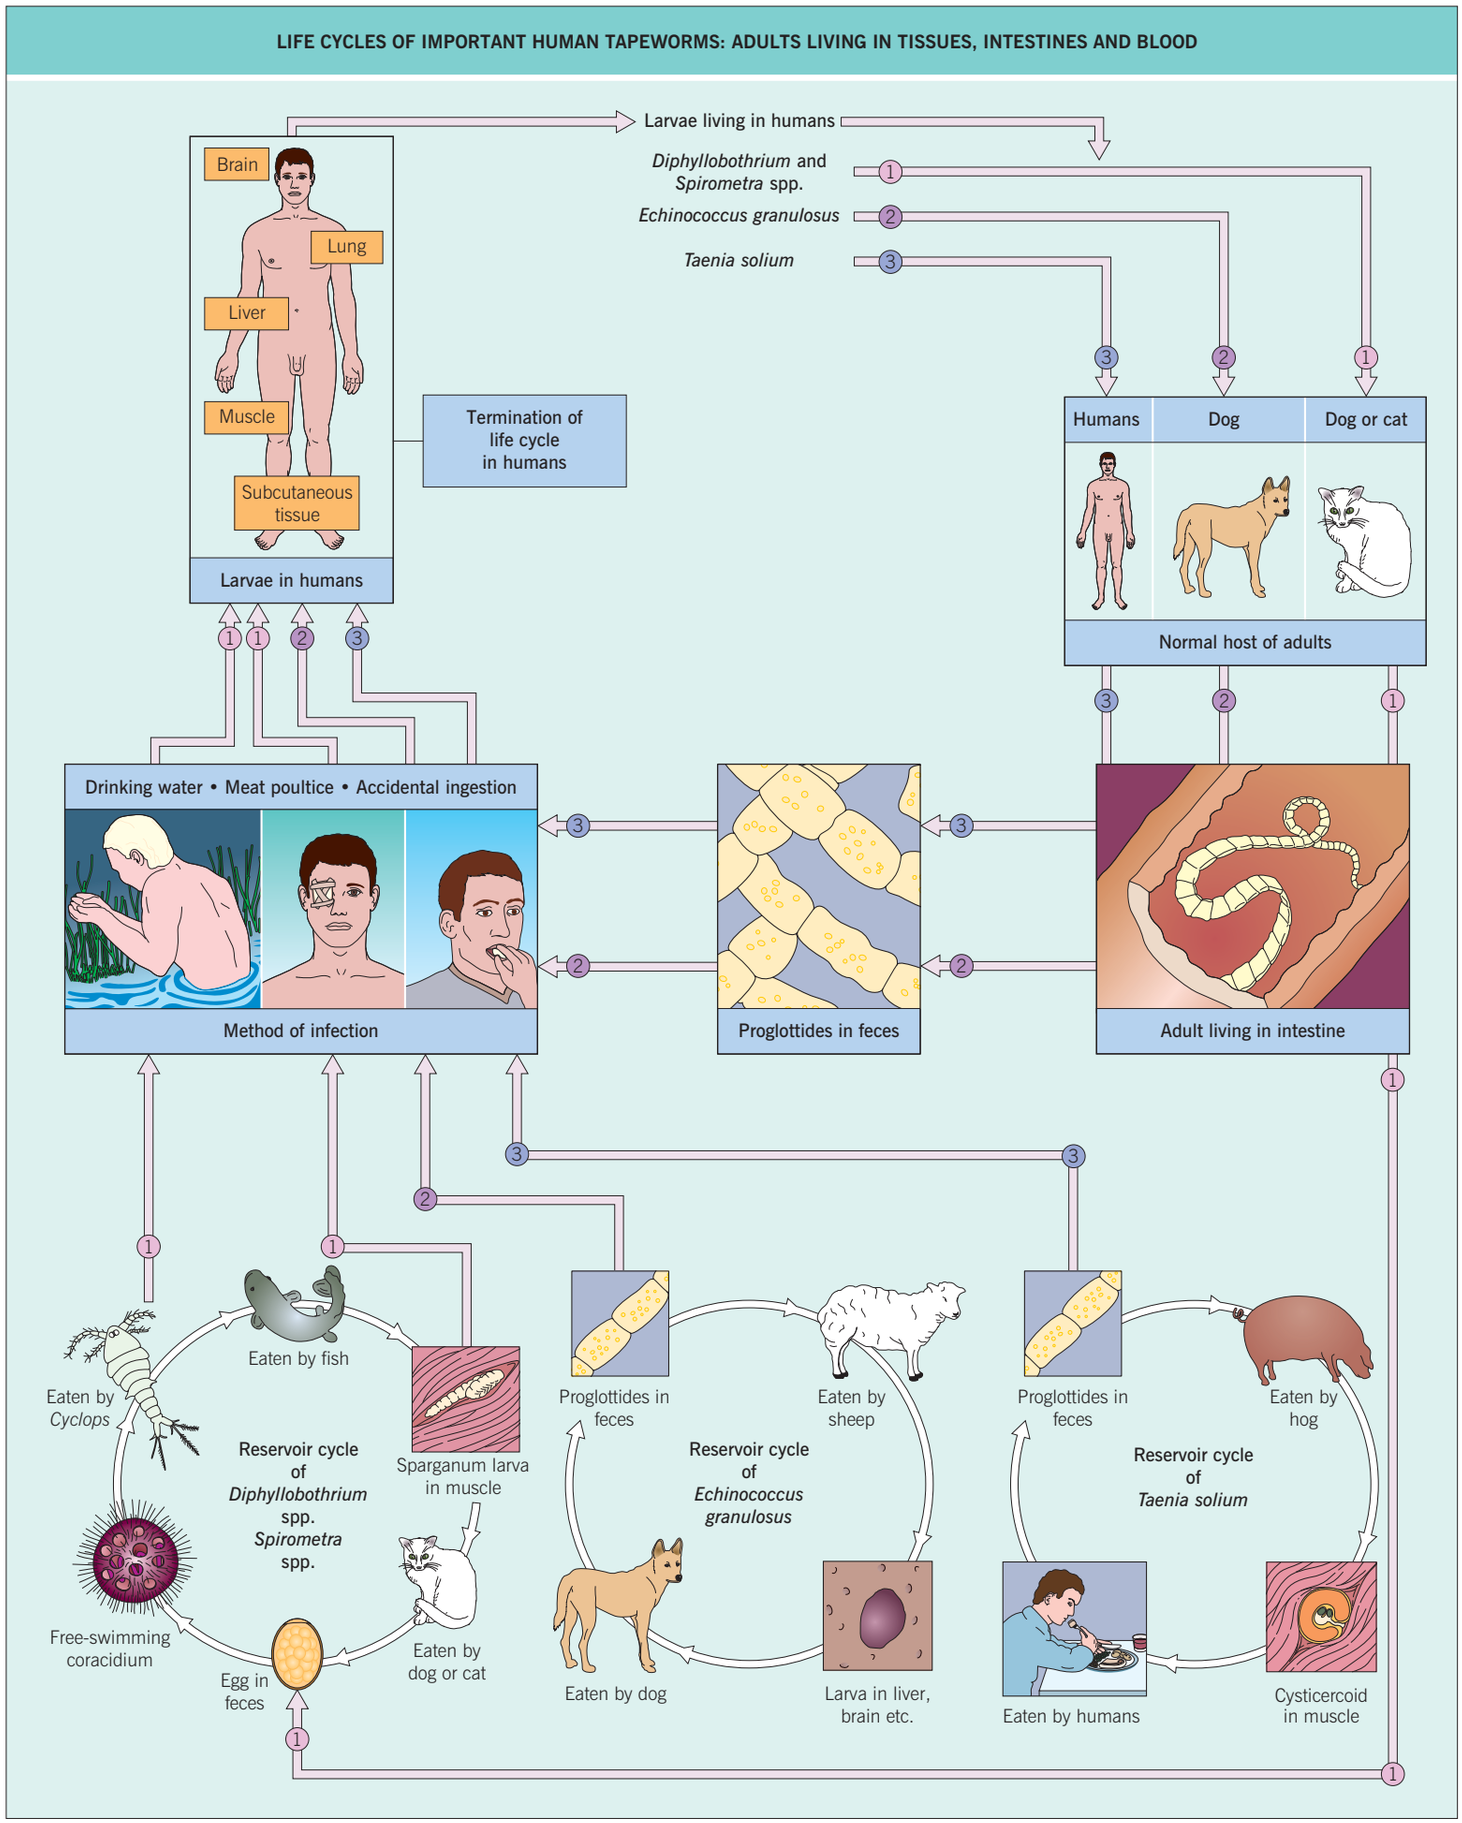

Fig. 83.27 Life cycles of important human tapeworms: adults living in tissues, intestines and blood. *Adapted with permission from Cross JH, Helminths. In Cohen J, Powderly W, eds, Infectious Diseases, 2nd edition. London: Mosby, 2004.*

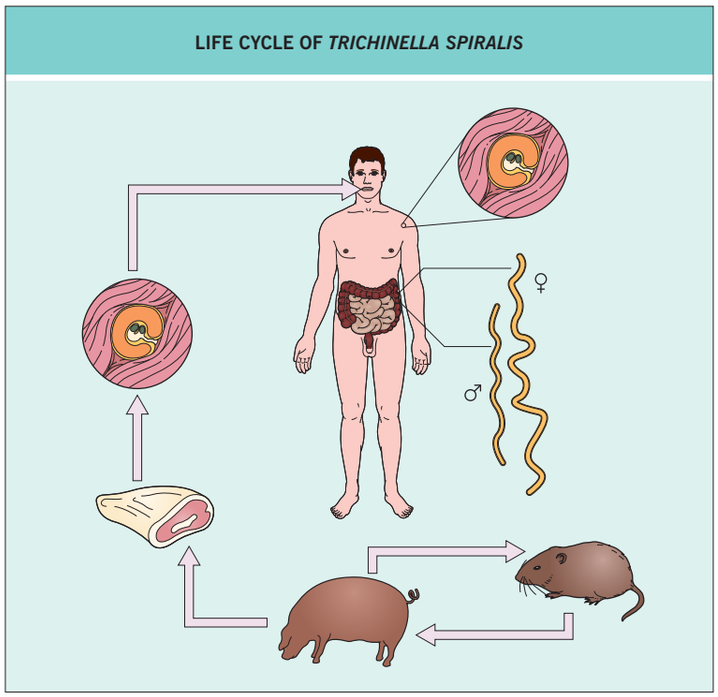

Fig. 83.28 Life cycle of *Trichinella spiralis*. This nematode is a zoonotic infection that circulates between rats and various carnivores. Trichinosis in humans commonly results from eating raw or inadequately cooked pork products such as sausages. Infection is acquired by eating muscle containing encysted larvae which excyst in the small intestine and develop into adults. Mature females deposit larvae which migrate from the gastrointestinal tract through tissues to reach skeletal muscles in which they then encyst. *With permission from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

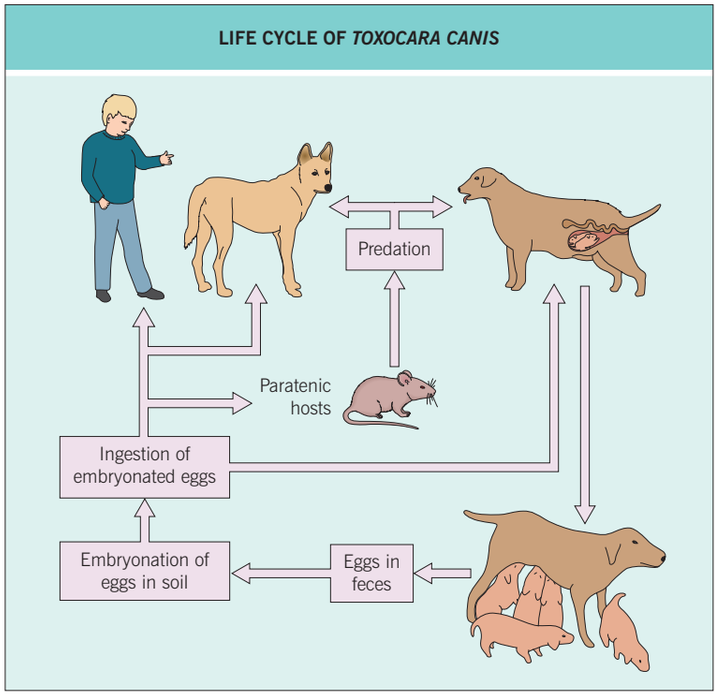

Fig. 83.29 Life cycle of *Toxocara canis*. This demonstrates the importance of transplacental transmission in maintaining canine infection, and the role of young dogs in transmitting infection to humans. *With permission from Gillespie S, Migrating worms. dermis are present in this blood, and they penetrate the gut wall of the insect and migrate to its thoracic muscles, where they develop into larvae. The larvae then migrate to the proboscis, from which they will be transmitted to another human host during a blood meal[76] (see Fig. 83.25). *Wolbachia* bacterial endosymbionts are required for normal development of *O. volvulus* larvae and embryos, are thought to support

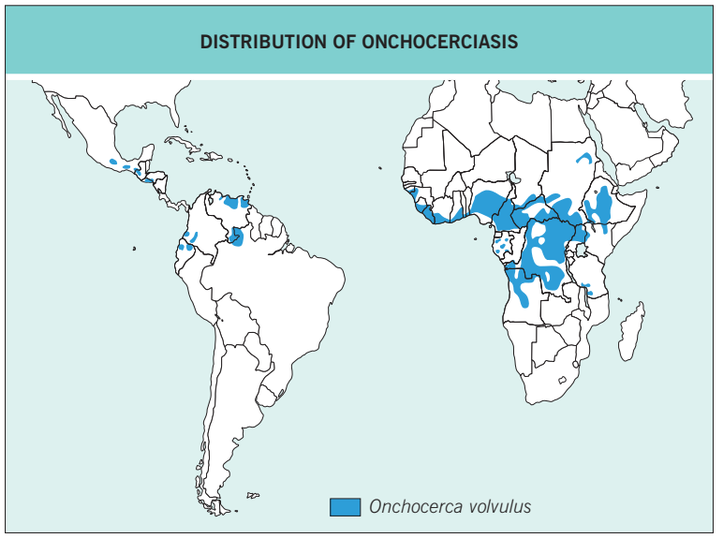

Fig. 83.30 Distribution of onchocerciasis. The disease is found primarily in Africa and Central and South America.

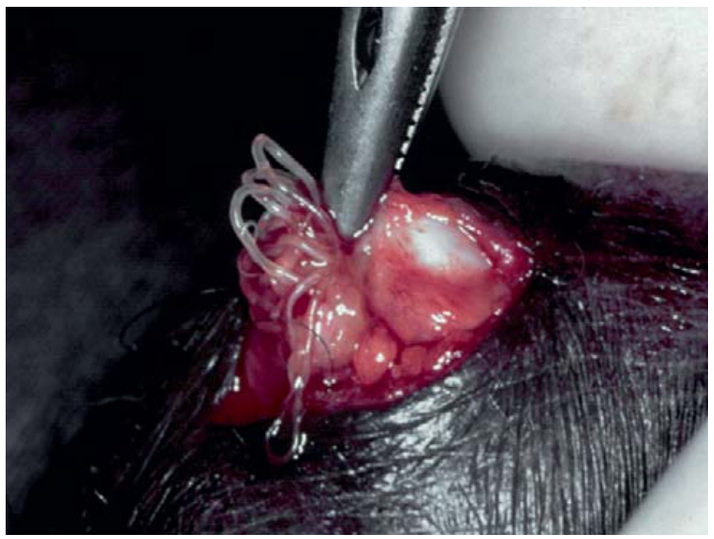

Fig. 83.31 Onchocerciasis. Extraction of adult worms from an onchocercal nodule on the buttocks.

the survival of adult worms, and drive immune responses that contribute to disease pathogenesis[76a].

Once in their human host, larvae take almost a year to reach maturity. The adult worms are large, measuring up to 50 cm in length. They are encapsulated within fibrous tissue and reside in nodules close to the surface of the skin or near joints. These nodules are known as "onchocercomas" (Fig. 83.31). Each female worm produces hundreds of microfilariae, which live for 1–2 years and migrate into the skin, connective tissue, eyes and lymph nodes. It is the microfilariae that cause most of the serious clinical features of onchocerciasis[77]. There is little inflammation until the microfilariae degenerate, which triggers a hypersensitivity reaction. In the skin, this results in intense pruritus and dermatitis.

Clinical Features

The primary manifestations of onchocerciasis involve the eye and the skin. Cutaneous findings are classified into the following groups: acute papular onchodermatitis, chronic papular onchodermatitis, lichenified onchodermatitis, onchocercal atrophy and depigmentation[78] (Fig. 83.32). Patients first present with subcutaneous nodules that are usually located over bony prominences; they favor the upper part of the body in patients living in Central and South America and the lower part of the body in those from Africa. The subcutaneous nodules represent fibrous tissue surrounding adult worms. An intermittent,

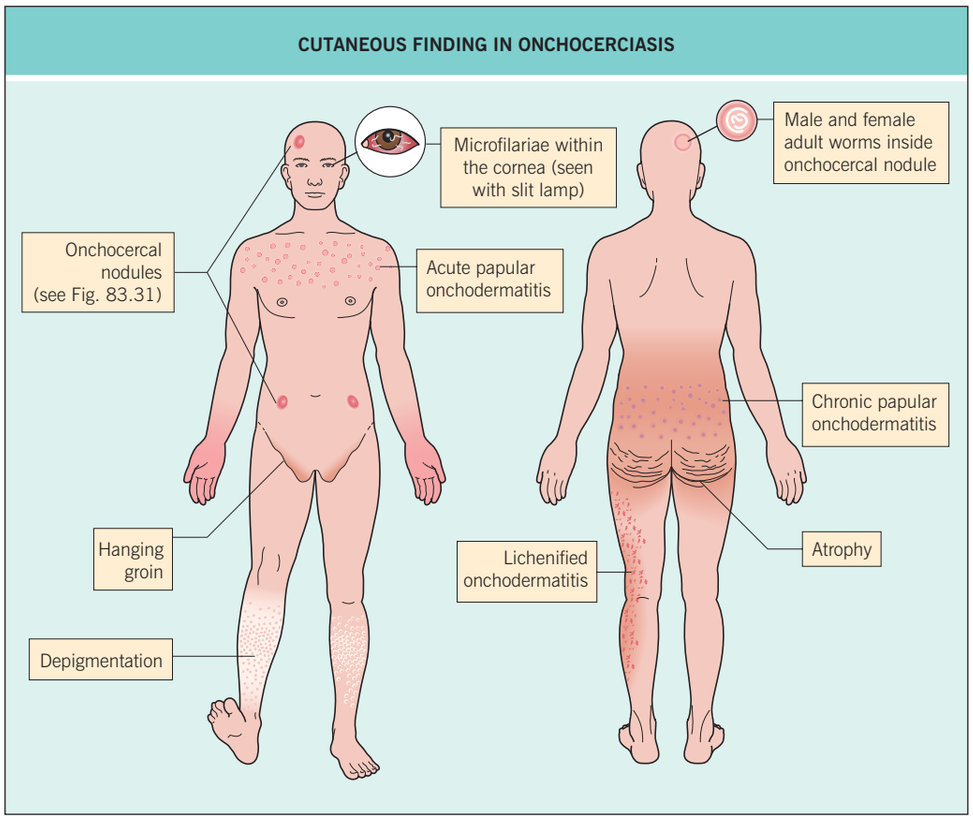

Fig. 83.32 Cutaneous findings in onchocerciasis.

Courtesy, Omar P Sangüeza, MD.

intensely pruritic acute papular onchodermatitis follows, in which small papules form around the microfilariae (called "craw-craw" in Africa).

In chronic onchocerciasis, the skin becomes thickened and wrinkled; this is accompanied by lichenification and hyperpigmentation (Fig. 83.33) and is sometimes referred to as "lizard" or "elephant" skin. The back, thighs and lower trunk are frequently affected, and sometimes hyperpigmentation is seen on one lower extremity in association with inguinal lymphadenopathy. Atrophy and a loss of pigment with sparing of perifollicular skin are also seen in late stage onchocerciasis. The latter changes, sometimes referred to as "leopard" skin, are most often evident on the shins[79] (see Ch. 66). Chronic lymphatic obstruction and involvement of the inguinal lymph nodes can lead to hanging groin or elephantiasis of the genitalia.

In Central America, young patients who are heavily infested may develop erythema on the face or upper trunk (erisipela de la costa). Older patients may have violaceous papules or plaques (mal morado), which can lead to leonine facies.

In addition to skin lesions, microfilariae can also be found in the conjunctivae; from there they can move through the cornea into the anterior and posterior chambers of the eye, leading to conjunctivitis, sclerosing keratitis, uveitis, chorioretinal lesions, optic atrophy and glaucoma[74]. Blindness occurs in the most severe cases. Dead microfilariae in the cornea can induce a tissue reaction that produces characteristic "snowflake" opacities.

Pathology

In onchodermatitis, microfilariae are present in all levels of the skin but are most concentrated in the dermal papillae, where they can infect black flies during feeding. Microfilariae are ~250 microns long with two or three pairs of anterior nuclei. Initially, they are surrounded by an infiltrate with numerous eosinophils. Lymphocytes, macrophages, plasma cells and mast cells may become more prominent at later stages, and epidermal hyperplasia (secondary to rubbing) may develop. The final outcome is fibrosis surrounding the microfilariae with minimal inflammation[80].

The adult female worms are found in a subcutaneous nodule. They are initially surrounded by an infiltrate containing many eosinophils, with progressive development of fibrosis.

Diagnosis

The clinical diagnosis of onchocerciasis is usually not difficult in endemic areas. It is confirmed by microscopic visualization of microfilariae as they emerge from multiple skin snips placed in saline (Fig. 83.34); these small, thin discs (including superficial dermis) are taken from skin near a nodule and over the shins, iliac crests or scapulae[81]. Onchocerciasis can also be diagnosed by the identification of the adult worm in an excised nodule. In heavily infected individuals, microfilariae can be found in the blood, sputum and urine. By slit-lamp examination, microfilariae (when present) are easily visualized within the anterior chamber of the eye. When skin snips are negative, the "Mazzotti test" may be helpful in diagnosing onchocerciasis: 50 mg of diethylcarbamazine (DEC) is administered orally, and a pruritic eruption develops within 15 minutes (as the microfilariae die) if the patient

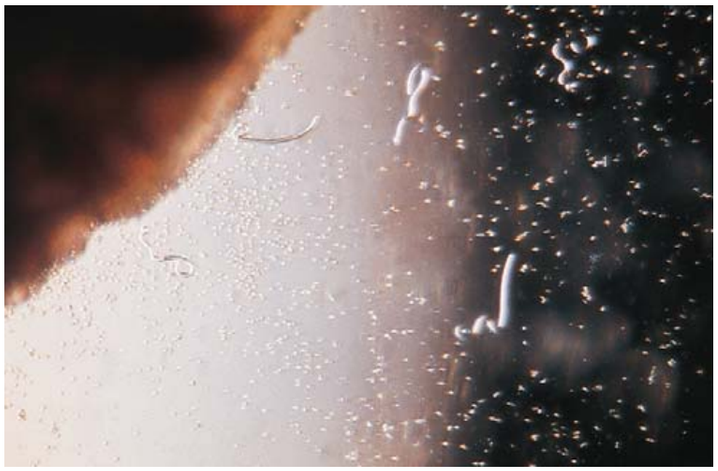

Fig. 83.34 Living microfilariae of *Onchocerca volvulus*. After some time, actively moving microfilariae emerge from the skin snip into the surrounding saline, where they can be counted. *With permission from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

is infected. In the "Mazzotti patch test", DEC is applied topically (e.g. in a 10% lotion under occlusion) to a small area of skin, which is examined 24 hours later for the development of papules and edema; this diagnostic method is not as sensitive as oral administration of DEC but less likely to produce a systemic reaction. A recently developed dipstick test to detect *Onchocerca volvulus* antigen in the urine or tears has a sensitivity of >90% and a specificity of 100%[82]. Tests based on antibody detection cannot distinguish between active and past infections.

Differential Diagnosis

Early lesions of onchocercal dermatitis must be distinguished from insect bites, scabies and atopic or allergic contact dermatitis. The chronic skin lesions may be mistaken for chronic eczema with postinflammatory pigmentary changes, leprosy or the leukoderma of scleroderma. The differential diagnosis of elephantiasis includes other types of filarial infestation (see Fig. 83.25), and a false-positive skin snip can occur if the tissue is contaminated with blood filariae, especially *Mansonella perstans* or *Loa loa*.

Treatment

Therapy for onchocerciasis has drastically improved as a result of the widespread use of oral ivermectin since 1987[83]. As the drug of choice, it is effective in rapidly killing microfilariae and in preventing their escape from gravid females. Ivermectin causes few or no adverse reactions and no Mazzotti reaction, whereas older drugs, e.g. diethylcarbamazine and suramin, are associated with severe hypersensitivity or dangerous toxic reactions. Ivermectin is administered as a single dose of 150 mcg/kg every 3 to 12 months. After treatment, microfilariae usually disappear from the skin within 1 week and from the eye within 3 months. Although multiple doses of oral ivermectin can kill adult worms, treatment is typically continued for the worm's lifetime (10–15 years). Administration of doxycycline (100–200 mg/day for 6 weeks) to target *Wolbachia* endosymbionts represents a promising therapeutic approach that can markedly reduce or eliminate microfilariae for >18 months[83a,83b]. Nodulectomy (see Fig. 83.31) is a popular method of treatment in countries where nodules on the head are common; their removal reduces the chance of ocular disease.

Preventive measures consist of spraying black fly breeding sites with larvicides and mass treatment of the population in endemic areas. In Africa, the use of a bacterium called *Bacillus thuringiensis israelensis* HI4 (BTI) to destroy the aquatic stages of *Simulium* black flies has reduced transmission.

Synonym: ■ Lymphatic filariasis, elephantiasis ■ Elephantiasis

Key features

- Filariasis is an infection of the lymphatic system by tissue nematodes (roundworms) acquired via mosquito vectors
- There are acute, chronic and asymptomatic forms of filariasis
- Manifestations of the acute phase include lymphangitis and orchitis
- Chronic disease is characterized by the sequelae of lymphatic obstruction, e.g. lymphedema, elephantiasis, hydroceles and chyluria; associated skin findings include hyperkeratosis, verrucous changes, soft tissue hypertrophy and fibrosis

FILARIASIS

Introduction

Lymphatic filariasis is an infection of the lymphatic system by two genera of filarial nematodes (roundworms). Several species of mosquitoes act as vectors (see Fig. 83.25). Cutaneous findings during the acute and chronic stages include lymphangitis and lymphedema accompanied by changes of elephantiasis.

Epidemiology

There are two major forms of filariasis, Bancroftian (due to *Wuchereria bancrofti*), causing 90% of infections, and Malayan (due to *Brugia malayi* and *B. timori*). The disease affects over 120 million people living in more than 80 countries located primarily within the tropical and subtropical regions of South America, Africa, Asia and the Pacific Islands. *W. bancrofti* is found worldwide, whereas *B. malayi* is restricted to South and East Asia. The distribution of *B. timori* is limited to islands in the Indonesian archipelago[84].

A number of mosquito species act as vectors for these filarial nematodes. The most important ones for *W. bancrofti* are *Culex quinquefasciatus*, *Anopheles gambiae*, *Anopheles funestus*, *Aedes polynesiensis*, *Aedes scapularis* and *Aedes pseudoscutellaris*. Both *B. malayi* and *B. timori* are transmitted by *Anopheles barbriostris*. *B. malayi* can also be transmitted by several species of *Aedes* and *Mansonia* mosquitoes[84,85].

Pathogenesis

Multiple bites from infected mosquitoes seem to be required to produce symptomatic infections, and the incubation period varies from 2 to 18 months. Larvae enter lymphatic vessels and then, once mature, the adult worms mate within the lymphatics or lymph nodes and release sheathed microfilariae into the bloodstream[84]. The mosquito then acquires microfilariae during a blood meal. Over several days, the microfilariae develop into larvae within the mosquito, which can then transmit infection to other humans during subsequent blood meals (see Fig. 83.25).

The clinical manifestations of lymphatic filariasis reflect a complex interplay of the pathogenic potential of the parasite, the immune response of the host, and secondary bacterial and fungal infections. Maturing adult worms provoke an eosinophilic and chronic inflammatory cell infiltrate around lymphatic vessels, leading to dilation and valvular damage with eventual scarring and obstruction of lymphatic flow. The death of worms within lymphatic vessels and lymph nodes results in an intense inflammatory reaction with granulomatous changes and necrosis[84]. *Wolbachia* bacterial endosymbionts are required for the worms' development, embryogenesis and survival; *Wolbachia* also stimulates an innate and adaptive immune response that leads to expression of vascular endothelial growth factors (VEGFs) that promote lymphangiogenesis, lymphatic endothelial proliferation and dilation of lymphatic vessels[83a].

Clinical Features

There are acute, chronic and asymptomatic forms of filariasis. Acute episodes of lymphangitis and fever typically last approximately one week and are usually recurrent, with 6 to 10 episodes per year. Early on, the affected body part appears clinically normal in between these episodes. Other common findings include orchitis and epididymitis.

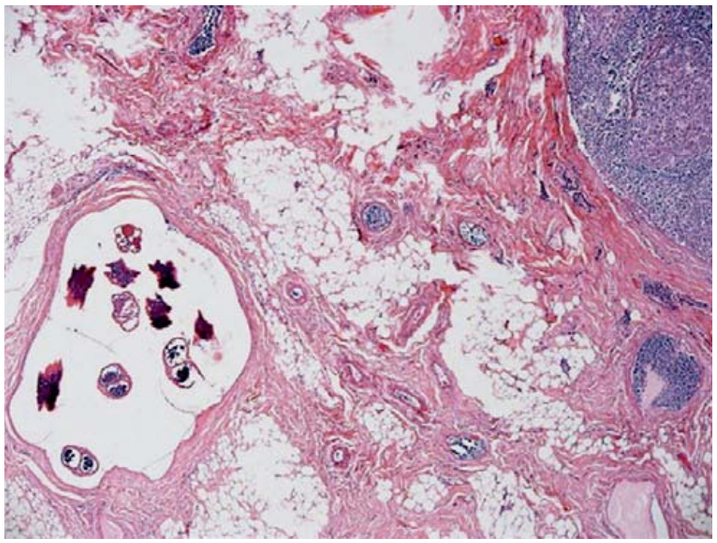

Fig. 83.35 Histopathology of filariasis. Dilated lymphatic with a mature adult worm and surrounding enlarged inguinal lymph nodes.

After 10 to 15 years of infection, the clinical features of chronic disease, i.e. the sequelae of lymphatic obstruction, are noted. These include lymphedema, elephantiasis, hydroceles and chyluria. Of note, in some communities in endemic regions, 40–60% of all the adult men have hydroceles. In sites of lymphedema and elephantiasis, the skin can be hyperkeratotic, verrucous and fibrotic with soft tissue hypertrophy and redundant folds. Fissures, ulceration and gangrene may also occur. Secondary bacterial and fungal infections are very common.

The two most commonly affected sites are the lower extremities and the genitalia. There are two major reasons for this particular distribution: (1) the female mosquito flies near the ground, thus it is more likely to bite the lower limbs, which is followed by retrograde involvement of the inguinal region; and (2) due to gravitational forces, the legs are at greater risk for venous hypertension and valvular incompetency and therefore more susceptible to the development of chronic lymphedema[84].

Tropical pulmonary eosinophilia occurs in some patients with filarial infections. Clinical findings include cough, wheezing, dyspnea, chest pain and fever accompanied by marked eosinophilia and pulmonary infiltrates. This may progress to restrictive pulmonary disease[86].

Travelers to endemic areas who became infected do not manifest the classic findings of filariasis. Instead, they have a hyperresponsive clinical presentation, known as "expatriate syndrome", with more intense inflammatory reactions to the filarial parasites. Clinical findings include lymphangitis, lymphadenitis and genital pain from the associated lymphatic inflammation, as well as urticaria, nonspecific cutaneous eruptions and peripheral eosinophilia[84].

Diagnosis

Detection of circulating filarial antigen is now the preferred method for diagnosis of Bancroftian filariasis, but similar tests are not currently available for Malayan filariasis. Alternatively, the diagnosis can be established by the demonstration of microfilariae in the blood, urine or other body fluids and tissues or by the identification of adult worms[87,88] (Fig. 83.35). Visualization of motile adult worms may be possible using ultrasound to evaluate infected lymphatics. As the parasite exhibits a nocturnal periodicity in humans, 10 p.m. to 2 a.m. is the optimal time period for collection and then direct smear of blood or other fluids. More recently, the use of filters with a pore size of 3 microns has improved the rate of detection of microfilariae in the blood and urine. However, parasite detection is not a particularly reliable method because many symptomatic patients are amicrofilaremic. Peripheral eosinophilia and elevated serum IgE are very common laboratory findings. In addition, more than 50% of microfilaremic patients with *W. bancrofti* infections have hematuria and/or proteinuria[88].

Differential Diagnosis

The differential diagnosis depends upon the stage of the infection. Acute infection may be misdiagnosed as a bacterial lymphangitis. Lymphedema and elephantiasis have multiple possible etiologies, including recurrent bacterial lymphangitis, severe venous hypertension, lymph node dissections, Milroy disease and Klippel–Trenaunay syndrome[89].

Treatment

The drug of choice is diethylcarbamazine, which is active against microfilariae but has a limited effect on adult worms. The usual course is 6 mg/kg/day for 12 days. Mass drug administration programs give at-risk individuals single yearly doses of two medications for at least 5 years: albendazole plus either diethylcarbamazine or (in regions where onchocerciasis is co-endemic) ivermectin[90]. Doxycycline (200 mg/day for 4–8 weeks) targeting the *Wolbachia* endosymbiont can also eliminate microfilariae, kill adult worms and improve lymphatic drainage. During the treatment period, antihistamines and glucocorticoids may be useful in decreasing the allergic reaction that may result from massive disintegration of microfilariae. Because severe reactions may follow the administration of diethylcarbamazine in patients who have loiasis or onchocerciasis, it is important to exclude other helminthic diseases before instituting therapy[89]. Other management strategies include elevation of the affected body part, compression stockings, anti-inflammatory drugs, treatment of secondary infections, and protection of the affected area from trauma[89].

Synonyms: ■ Schistosomiasis: bilharziasis ■ Swimmer's itch: clam digger's itch

Key features

- Schistosomiasis is a trematode (fluke) infection caused by five species of anthropophilic schistosomes, each with a specific geographic distribution and distinct intermediate host (snails)
- The disease is most commonly seen in Africa, the Far and Middle East, and South America
- Clinical stages include of cercarial dermatitis, Katayama fever, and chronic fibro-occlusive disease involving the liver, intestine and urinary tract
- The cercariae of more than 20 species of animal schistosomes may penetrate human skin and cause a transient dermatitis called swimmer's itch

SCHISTOSOMIASIS AND SWIMMER'S ITCH

Introduction

Schistosomiasis is a trematode (fluke) infection endemic to the tropics and subtropics caused by members of the superfamily Schistosomatoidea[91]. The disease has a worldwide distribution, affecting more than 200 million people in over 75 countries. Human disease can be caused by five schistosome species, most often *Schistosoma haematobium*, which infects the urinary system, and *S. japonicum* and *S. mansoni*, which infect the gastrointestinal tract[91]. In addition, when the cercariae of a number of other species that usually infect birds and mammals penetrate human skin, they can evoke "swimmer's itch", a local inflammatory response associated with marked pruritus.

Epidemiology

Schistosomes have a two-host life cycle (see Fig. 83.26). Snails serve as the intermediate host, while the definitive host is species-dependent. Humans are the major definitive host for five schistosome species[91], each of which has a specific geographic distribution (Fig. 83.36): *S. mansoni* occurs in Africa, South America and the Caribbean; *S. japonicum* in Japan, China and the Philippines; *S. haematobium* in Africa

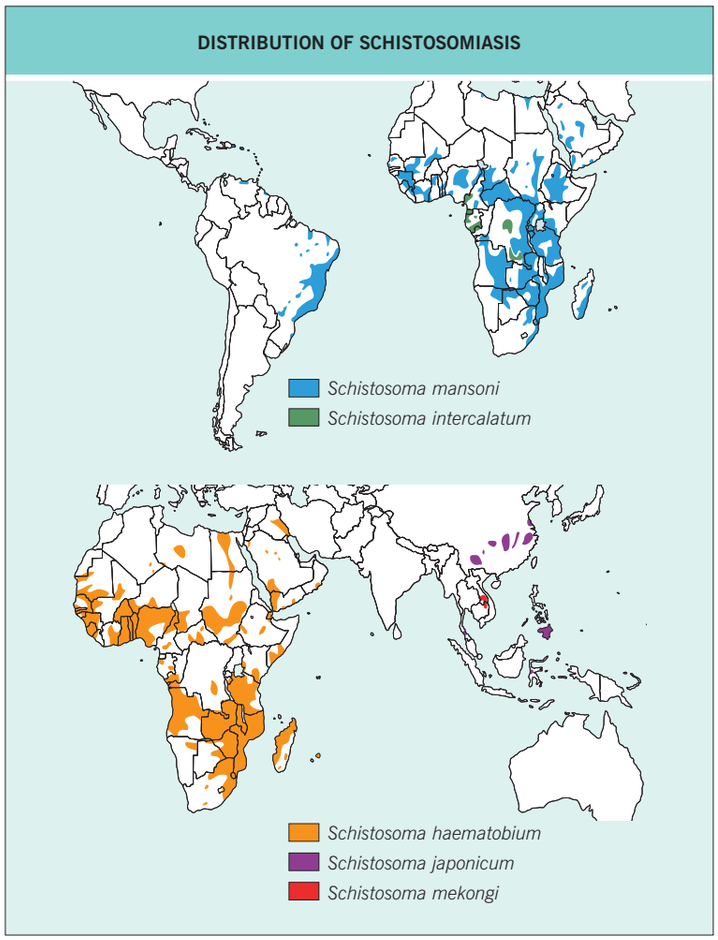

Fig. 83.36 Distribution of schistosomiasis. *Adapted from Peters W, Pasvol G, Tropical Medicine and Parasitology, 6th edition. London: Mosby, 2007.*

and the Middle East; *S. mekongi* in Southeast Asia; and *S. intercalatum* in West and Central Africa.

The geographic distribution of schistosomiasis has changed significantly in recent decades. It has almost been eradicated from Japan and the Caribbean islands, and the transmission cycle has been interrupted in North Africa, the Philippines, Saudi Arabia and Venezuela. However, environmental changes related to water resource development and population movements have led to spread of the disease to previously non-endemic areas such as sub-Saharan Africa. Schistosomiasis is now present in and around several major cities in northeastern Brazil and is a major public health problem in certain regions of China.

Swimmer's itch (cercarial dermatitis) is due to over 20 species of schistosomes that usually infect birds and mammals (e.g. *Trichobilharzia*, *Gigantobilharzia*, *Ornithobilharzia* spp.). It is a cutaneous disease with a worldwide distribution, having been documented in every continent except Antarctica. In the US, it has been observed most often in the north central states. Outbreaks of swimmer's itch are episodic.

Pathogenesis

Adult worms live in the venous system of the liver, rectum or urinary bladder of their definitive host. The eggs penetrate the rectum or bladder, to be passed into the feces or urine (see Fig. 83.26). In fresh water environments, the eggs hatch and release miracidia that penetrate the body of a snail, which acts as an intermediate host. For each schistosome species, a specific snail species acts as an intermediate host. In the snail, the miracidia develop into cercariae, the infective forms that can penetrate human skin on contact[92].

The species that are responsible for swimmer's itch complete their life cycle in birds and animals, including ducks, cows, sheep and rodents. In contrast to human schistosomes, which cause systemic disease, the cercariae of animal schistosomes die after penetration into human skin, inducing only a local inflammatory reaction. Because humans cannot support the development of these schistosomes, we represent incidental, "dead-end" hosts[91,93].

Fig. 83.37 Swimmer's itch. Numerous edematous dark red papules on the feet and ankles. *Courtesy, Kalman Watsky, MD.*

Clinical Features

The cutaneous manifestations produced by the anthropophilic species of schistosomes can be classified into five categories: cercarial dermatitis, Katayama fever, late nonspecific allergic dermatitis, perigenital infiltrative granulomas and extragenital infiltrative lesions[94–96]. Cercarial dermatitis is associated with cutaneous penetration by the cercariae. Though fairly common, patients rarely present with this transient, erythematous, pruritic papular or urticarial eruption at the site of inoculation. The reaction is relatively nonspecific and is more severe with *S. japonicum* and *S. mansoni* infections. Within hours of contact, macules develop and then either disappear or, more commonly, are replaced by small pruritic papules that may persist for a few days[92].

In some patients, a systemic allergic reaction (Katayama fever) occurs during the acute phase of a moderate or heavy infection. Affected individuals have an acute onset of fever, chills, sweats and headaches, in association with peripheral blood eosinophilia and urticaria. Katayama fever is seen most commonly with *S. japonicum* infections and is due to circulating immune complexes. Approximately 4 to 6 weeks later, some patients may experience another transient cutaneous reaction with nonspecific findings ranging from urticarial or purpuric lesions to periorbital edema[93,94,96].

Bilharziasis cutanea tarda is characterized by papular, granulomatous or verrucous lesions of the genital and perineal skin secondary to the deposition of ova within dermal vessels in this area[93,96]. Occasionally, "ectopic" cutaneous lesions have been observed due to inflammatory reactions to deposited ova. They have been described as hyperpigmented lichenoid papules in several patients[94] and may have a zosteriform distribution on the trunk.

Systemically, chronic infections with *S. mansoni* and *S. japonicum* are associated with hepatic fibrosis and cirrhosis (as a reaction to the ova), portal hypertension (including ascites and esophageal varices) and splenomegaly. Additional findings may include colonic polyps (which contain ova) and granulomas around ova in the liver, lung and colon (Hoeppli reaction). Urogenital infections with *S. haematobium* can lead to polypoid lesions composed of numerous ova, fibrosis and calcification. Calcified ova may be seen through the atrophic epithelium, leading to "sandy patches" that are pathognomic

of schistosomiasis on cystoscopy[97]. Additionally, the presence of numerous ova can lead to obstruction of the urinary tract and the development of hydronephrosis. Carcinoma of the bladder is a life-threatening complication.

Lesions of swimmer's itch have an appearance similar to that of cercarial dermatitis, i.e. pruritic papules at sites of inoculation (Fig. 83.37). As a result, areas of skin covered by clothing are spared[98]. The eruption may last for days but is self-limited.

Pathology

Histologically, cercarial dermatitis is characterized by spongiosis and a mixed inflammatory infiltrate composed of histiocytes, lymphocytes, neutrophils and eosinophils. Edema is present in the dermis. Genital and perineal lesions of bilharziasis cutanea tarda show hyperkeratosis and acanthosis and occasionally prominent pseudoepitheliomatous hyperplasia. The dermis may contain numerous ova, which can be associated with a granulomatous reaction. "Ectopic" extragenital lesions contain ova in the superficial dermis associated with granuloma formation.

Diagnosis

The diagnosis is usually established by microscopic detection of eggs in the urine or feces. In the case of *S. japonicum* and *S. mansoni* infections, microscopic evaluation of mucosal biopsy specimens may point to the diagnosis. An ELISA to detect antischistosomal IgG, IgM and IgE is available and is used to distinguish acute from chronic infection[5].

In addition, monoclonal antibodies that detect circulating antigens are quite sensitive and specific for establishing the diagnosis as well as assessing response to therapy (including cure)[99].

Differential Diagnosis

The diagnosis of cercarial dermatitis or swimmer's itch requires a history of exposure to contaminated water. The lesions may be confused with arthropod bites, but the distribution is clearly distinct from that of seabather's eruption, which affects areas under the swimsuit. The differential diagnosis of anogenital and ectopic cutaneous ova deposition includes secondary syphilis (in particular the granulomatous form), condyloma acuminatum, cutaneous Crohn's disease, granuloma inguinale and lichen planus.

Synonyms: ■ Echinococcosis: hydatidosis, hydatid disease

Key features

- Cestodes (tapeworms) that commonly affect animals (e.g. *Taenia solium*, *Echinococcus granulosus*) can also infect humans
- Cutaneous cysticercosis is characterized by small papulonodules that are usually multiple and asymptomatic; the brain (neurocysticercosis), eye, heart, other muscles and peritoneal cavity may also be affected
- In echinococcosis, the liver and lungs are the major sites of involvement, with development of one or more hydatid cysts. Allergic symptoms, such as urticaria, asthma and anaphylaxis, are uncommon

Treatment

Praziquantel is an antihelminthic agent that is safe and effective against all five human schistosomal species[100]. It is administered as two to three oral doses of 20 mg/kg over a single day. Side effects are mild and include abdominal discomfort, fever and headache.

Although topical remedies (e.g. phenolized calamine) and antihistamines have been recommended for swimmer's itch, no controlled studies have defined the most effective therapy[98,101]. If left untreated, the acute episode resolves spontaneously within 7–10 days.

The most effective way to prevent swimmer's itch is to avoid lakes and bodies of fresh water known to be infested, at least during those periods of the year when cercariae are most plentiful, i.e. during the early and mid summer in temperate regions. One method of environmental control is to treat feed corn so that ducks are cured of their worms. This minimizes the environmental impact because it obviates the need to add poisonous substances to lakes and ponds to kill the snails.

CYSTICERCOSIS AND ECHINOCOCCOSIS

Introduction

In the two stages of their life cycle (adult and larval), cestodes (tapeworms) can cause disease in humans. The adult worms reside in the *definitive* host's intestines (including humans) and are associated with mild or no clinical manifestations (see Fig. 83.27). In *intermediate* hosts, the larval stage can lead to clinical disease, e.g. cysticercosis or echinococcosis in humans[102].

Epidemiology

The four most common human cestodes (tapeworms) are *Taenia solium* (pork tapeworm), *Taenia saginata* (beef tapeworm), *Diphyllobothrium latum* and *Hymenolepis nana*. In humans, they cause primarily gastrointestinal symptoms, but the larval stage of *T. solium* also causes cysticercosis. Cysticercosis in pigs and cattle can be caused by larvae of *T. solium* and *T. saginata*, respectively. Cysticercosis has a worldwide distribution, affecting more than 50 million people, and it is more common in rural areas. Endemic regions include Central and South America, sub-Saharan Africa, India and East Asia[103].

Echinococcosis is a zoonosis caused by *Echinococcus* species, the definitive hosts of which are dogs and other members of the family Canidae. Humans are only infected by the larval stage, i.e. they are intermediate hosts and develop cysts within viscera. Most human disease is due to larval stages of *E. granulosus* and *E. multilocularis*. Echinococcosis occurs in tropical and subtropical countries worldwide, primarily in sheep- and cattle-raising areas. Endemic regions include the southern province of Brazil, the Middle East, parts of Asia, and Northern and East Africa. It is particularly common in Lebanon and Greece[102,103].

Pathogenesis

The adult tapeworm can reach a length of up to 30 feet in the intestinal tract of its definitive host. Its body has two main parts: a single head (scolex) for attachment to the host and many proglottids, each of which has male and female reproductive organs. Fertilized eggs accumulate in large numbers inside the uterine horns of the proglottids; the eggs can be released directly into the host's intestine or the entire gravid terminal proglottid can be excreted by the host[102]. Both eggs and proglottids are found in the host's stool (see Fig. 83.27).

When eggs or proglottids are ingested by a susceptible *intermediate* host, they develop into larvae called oncospheres. In humans, oncospheres can develop into encysted forms (cysticerci in cysticercosis) or generate germinal tissue with a cyst (hydatid in echinococcosis). Subsequent ingestion of cyst-containing tissues by a susceptible definitive host allows the development of the larvae into adults and completion of the life cycle[104].

Humans are the only definitive host for *T. saginata* (beef tapeworm) and *T. solium* (pork tapeworm), becoming infected with the adult form after eating poorly cooked muscle of a diseased animal (see Fig. 83.27). Humans are also intermediate hosts of *T. solium*, developing cysticercosis as a result of ingestion of food or water contaminated with infected human feces or via autoinfection from anus to mouth. In contrast, humans are only intermediate hosts of *E. granulosus* (as are sheep and cattle) as a result of ingesting contaminated dog feces. Dogs are the definitive host of *E. granulosus*, becoming infected with adult tapeworms after eating infected beef or lamb.

When humans are infected by the adult stage of *T. solium* (i.e. are the definitive host), the tapeworms within the intestine usually cause no morphologically identifiable change in the mucosa or submucosa. Some patients may develop moderate peripheral eosinophilia. Immunity plays only a limited role during infections with the adult stage and has little effect on the duration of infection or on the susceptibility to reinfection. However, immunity plays an important role when humans

are the intermediate host, i.e. develop cysticercosis. After penetrating the host's intestinal wall and disseminating, the oncosphere matures rapidly and by 10 weeks is fully developed. The cyst that forms is usually 0.5–1.0 cm in diameter and remains viable for 3 to 5 years before degenerating. At this time, the inflammatory response is markedly intensified, and calcification also often takes place[103,105,106]. The signs and symptoms triggered by these reactions depend on the location of the cysts. For example, if there are cysts at the base of the brain, a cysticercic meningitis may ensue. In brain tissue itself, cysts that calcify may cause seizures.

When humans ingest the eggs of *E. granulosus*, oncospheres penetrate the mesenteric vessels. While the majority are trapped by the liver sinusoids, some bypass the liver and are carried in the bloodstream to other organs and tissues. Within hours, an inflammatory response may be seen. If the larvae survive, they develop into hydatid cysts within 5 days. Cell-mediated immunity controls dissemination during the early phase of infection.

Clinical Features

In cysticercosis, cysts can develop in almost any organ or tissue in the body. Within the skin, small papulonodules are more often palpable than visible[105]. They are usually multiple and asymptomatic. The brain, eye, heart, other muscles and peritoneal cavity may also be affected. In a Brazilian study of 30 patients with cysticercosis, 90% had cysts in the subcutaneous tissue, skeletal muscle or mucous membranes, while the CNS was affected in <10%[103].

In echinococcosis, the cysts may be single or multiple and they affect primarily the liver (50–75%) and lungs (20%). The skin is involved in fewer than 2% of the patients. Cysts increase in size at the rate of approximately 1 cm/year. The clinical features are highly variable and reflect the location and size of the cysts. Most symptoms are due to mechanical pressure by the cyst mass or an allergic reaction (urticaria, wheezing, anaphylaxis) to foreign antigens in leaking cyst fluid[103].

Soft tissue cysts may present as firm subcutaneous nodules or as masses that are fluctuant and non-tender. *E. multilocularis* has been noted to cause multiple supraumbilical dermal and subcutaneous nodules with associated ulceration, local inflammation and painless cutaneous fistulas[103].

Diagnosis

The diagnosis of cysticercosis is often made by X-ray examination of the head or extremities, which reveals the calcified cysts. CT or MRI can also demonstrate lesions. ELISA and hemagglutination tests utilizing cyst vesicular fluid as antigen are 80–95% sensitive and specific. An enzyme-linked immunoblot assay is the serologic test of choice, as its specificity and sensitivity approach 100% and 94%, respectively[103].

The diagnosis of echinococcosis is based on detection of cysts via ultrasound, CT or MRI. Examination of the contents of the cyst and identification of the parasite provides confirmation. Peripheral

SCABIES

Synonyms: ■ Itch mite infestation ■ "Seven-year itch"

Key features

- Human scabies is a pruritic condition caused by infestation with the host-specific mite *Sarcoptes scabiei* var. *hominis*, which lives its entire life within the epidermis
- Although the scabies mite is not a known vector for any systemic disease, secondary bacterial infections with *Streptococcus pyogenes* or *Staphylococcus aureus* may develop
- Transmission typically occurs via direct close contact with an infested person; fomite transmission is also possible and is much more common in severe and/or crusted cases
- Tolerance to standard topical scabicides is beginning to develop

Introduction

The scabies mite continues to plague all countries of the world. An estimated 300 million individuals are affected. Pruritus associated with this infestation is usually severe, especially at night, and treatment requires prescription scabicidal therapy.

History

Scabies has been a common companion of the human species for over 2500 years[1].

Epidemiology

Scabies is a worldwide problem and all ages, races and socioeconomic groups are susceptible. Environmental factors hastening spread include overcrowding, delayed treatment of primary cases, and lack of public awareness of the condition. There is considerable variation in prevalence, with rates in low income countries ranging from 4% to 100%[1,2]. Higher incidences occur with overcrowding related to natural disasters, wars, economic depression and refugee camps[1,2]. Scabies can be transmitted directly by close personal contact, sexual or otherwise, or indirectly via fomites. Prevalence is higher in children and people who are sexually active. Spread of the infestation among family members and other close contacts is common[2], but scabies is not a known vector for systemic disease.

Crusted scabies (formerly called Norwegian scabies) is found in individuals with compromised immune systems (e.g. the elderly, people infected with HIV, and solid organ transplant recipients) as well as those with decreased sensory functions and/or ability to scratch (e.g. patients with leprosy, HTLV-1 infection or paraplegia). Such individuals may experience minimal pruritus despite their infestation with a large number of mites and are highly contagious[3].

Pathogenesis

The highly host-specific, eight-legged mite *Sarcoptes scabiei* var. *hominis* causes human scabies (Fig. 84.1). Mites from animals are not a source of human infestation, but they can produce bite reactions (see Ch. 85). The scabies mite is 0.35 × 0.3 mm in size and too small to be seen by the naked eye. The entire 30-day life cycle of mites is completed within the epidermis (Fig. 84.2). Each day a female mite lays 3 eggs, which require approximately 10 days to mature. The number of mites living on an infested host can vary greatly, although there are usually fewer than a hundred and often no more than 10–15. However, patients with crusted scabies may have thousands of mites on their skin surface. In the environment of individuals suffering from this severe condition, live mites can be recovered in debris from sheets, the floor, screening curtains and chairs[4]. Scabies mites usually live 3 days or fewer off a human host, but those from patients with crusted scabies may live up to 7 days by feeding on sloughed skin.

The incubation period before symptoms develop can range from days to months. In first-time infestations, it usually takes 2–6 weeks before the host's immune system becomes sensitized to the mite or its by-products, resulting in pruritus and cutaneous lesions. A subsequent infestation is usually recognized within 24–48 hours. Asymptomatic scabies-infested individuals are not uncommon, and they can be considered "carriers"[4].

Clinical features

The epidemiologic history (e.g. pruritus in household members or close personal contacts), the distribution and types of lesions, and pruritus form the basis of the clinical diagnosis. The intense pruritus is classically accentuated at night and by a hot bath or shower. Pruritus may be present before any overt physical signs appear. Cutaneous lesions are symmetrical, typically involving the interdigital webbing of the hands, flexural aspect of the wrists, axillae, posterior auricular area, waist (including the umbilicus), ankles, feet and buttocks. In men, penile and scrotal lesions are common, while in women, the areolae, nipples and vulvar area are often affected. In infants, the elderly and immunocompromised hosts, all skin surfaces are susceptible, including the scalp and face[1,4].

Typically, small erythematous papules are present in association with a variable degree of excoriation (Fig. 84.3). Vesicles, indurated nodules, eczematous dermatitis and secondary bacterial infection are also common. The pathognomonic sign is the burrow, representing the tunnel that a female mite excavates while laying eggs. Clinically, the burrow is wavy, thread-like, grayish-white and 1–10 mm in length. Many patients, however, do not have any obvious burrows on inspection, especially in warm climates.

Acral vesiculopustules can represent a clue to the diagnosis of scabies in infants. Crusted scabies often manifests with marked hyperkeratosis that favors acral sites (including subungual areas; Fig. 84.4) but may be widespread. Areas of affected skin have sometimes been referred to as pachyderma. Secondary bacterial infections with *Staphylococcus aureus* or *Streptococcus pyogenes* sometimes develop. Peripheral eosinophilia can be the primary sign of scabies in patients with disorders of keratinization.

Confirmation of the diagnosis can be achieved by light microscopic examination of mineral oil preparations of skin scrapings (from infested

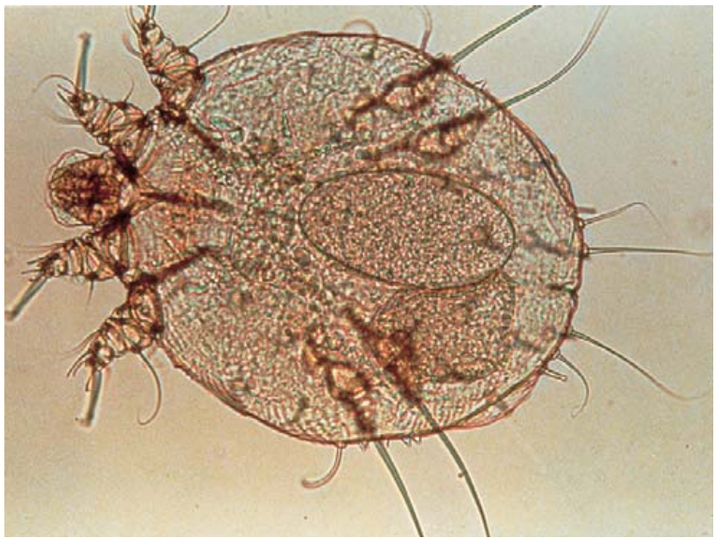

Fig. 84.1 Female scabies mite with egg. The female scabies mite in a potassium hydroxide wet mount obtained from skin scrapings, revealing a flattened, oval body with wrinkle-like corrugations, eight short legs, and an egg ready for deposition (40×). *With permission from Taplin D, Meinking TL. Infestations. In: Schachner LA, Hansen RC (eds). Pediatric Dermatology. 4th edn. Edinburgh: Mosby, 2011:1141–80.*

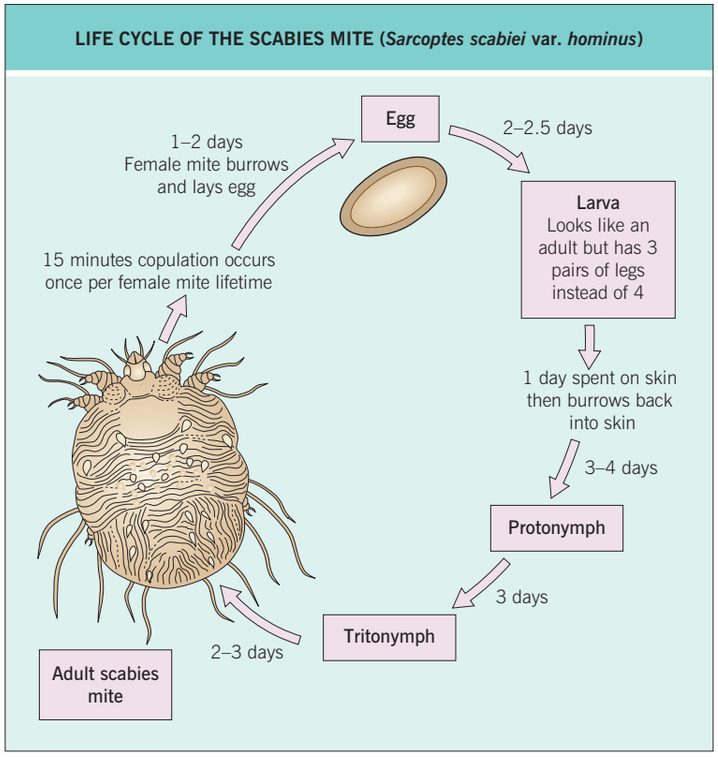

Fig. 84.2 Life cycle of the scabies mite (*Sarcoptes scabiei* var. *hominus*).

areas) for adult mites, eggs and/or fecal pellets (scybala; Fig. 84.5). A scalpel or curette may be used to obtain the skin sample. Microscopic examination of transparent adhesive tape following its application to infested areas of skin represents another diagnostic technique[4a]. Dermoscopy and confocal microscopy can prove useful for direct *in vivo* visualization of mites and eggs. A skin biopsy may confirm the clinical diagnosis, but only if the specimen obtained happens to contain the mite or its eggs. Often, however, the diagnosis simply rests on the clinical impression and response to treatment.

Pathology

A patchy to diffuse infiltrate with prominent eosinophils as well as lymphocytes and histiocytes is noted in the reticular dermis. On transection, a scabies mite may occasionally be seen within the epidermis (Fig. 84.6). Pink "pigtail"-like structures attached to the stratum corneum (which represent fragments of the adult mite exoskeleton) can serve as a clue to the diagnosis of scabies when mites, scybala and eggs are not identified[5].

Differential diagnosis

Unless burrows or (via dermoscopy) mites and eggs are noted clinically, a wide variety of pruritic skin diseases have to be considered in the differential diagnosis. These include atopic, allergic contact, autosensitization ("id" reaction) and nummular dermatitis as well as arthropod bites, pyoderma, dermatitis herpetiformis and bullous pemphigoid. Occasionally, scabies can mimic Langerhans cell histiocytosis clinically and histologically, as a dense infiltrate of Langerhans cells may be present. The clinical and histologic features of infantile scabies may also resemble those of the inflammatory stage of incontinentia pigmenti.

Treatment

Two topical treatments (1 week apart) with a prescription antiscabietic medication should be recommended (Table 84.1). The topical preparation is applied overnight to the entire body surface, from head to toe, in infants and the elderly. In other age groups, the face and scalp can be excluded from treatment. Special attention should be paid to the interdigital spaces, intergluteal cleft, umbilicus and subungual areas. To reduce the potential of reinfestation by fomite transmission, at the time of each treatment, clothing, linens and towels used within the previous week can be either washed in hot water and dried on high heat or stored in a bag for 10 days. The relatively common occurrence of asymptomatic mite carriers in households necessitates that all family members and close contacts be treated simultaneously, even if they have not developed any pruritus or clinical signs. Pets cannot harbor human mites and do not have to be treated.

Pruritus and lesions can persist for 2–4 weeks (or occasionally longer, especially for acral vesiculopustules in infants or nodular lesions) after successful treatment. This is referred to as "postscabietic" pruritus or dermatitis. Patients should be informed that such reactions do not imply treatment failure, but rather represent the body's response to dead mites that are eventually sloughed off (within 2 weeks) along with natural epidermal exfoliation. Many patients, however, experience relief from pruritus within 3 days. The second application of topical medication is performed in order to reduce the potential for reinfestation from fomites as well as to ensure killing of any nymphs that may have survived within the semi-protective environment of the egg and subsequently hatched (see Fig. 84.2).

Permethrin

Permethrin is a synthetic pyrethroid formulated in a 5% cream that is currently the standard topical scabicide. Like other pyrethroids, it inhibits sodium transport in arthropod neurons, thereby causing paralysis. Adverse reactions are rare and are usually related to brief stinging on application. Signs of tolerance to permethrin have been noted, but resistance has not been documented.

Lindane

Lindane (gamma-hexachlorocyclohexane), an organochlorine agent, is marketed worldwide in a 1% lotion or cream. CNS side effects may occur from increased percutaneous absorption through damaged skin, misuse, overuse or accidental ingestion. Because of the potential for CNS toxicity, lindane is contraindicated in premature infants, individuals with crusted scabies and other skin conditions (e.g. extensive atopic dermatitis) that may increase its systemic absorption, and patients with an uncontrolled seizure disorder. Worldwide, the development of lindane-resistant scabies is increasing[1]. Potential toxicity, relatively poor efficacy, widespread resistance, and issues related to environmental contamination make lindane an inferior treatment choice compared to permethrin or ivermectin. In 2003, the US Food and Drug Administration (FDA) issued a "black box" warning for lindane products, stating that they should be used with caution in infants, children, other individuals who weigh <110 pounds (50 kg) and the elderly due to an increased risk of neurotoxicity[6].

Crotamiton

An alternative scabicide is crotamiton, which is formulated in a 10% lotion and cream. Although it has an antipruritic effect, crotamiton can

TOPICAL AND ORAL TREATMENTS FOR SCABIES					
Therapy	**Administration**	**Concerns**	**Efficacy & resistance**	**Use in infants**	**FDA pregnancy category**
Permethrin cream (5%)	Topically overnight on days 1 and 8	Allergic contact dermatitis in individuals with sensitivity to formaldehyde	Good, but some signs of tolerance developing	FDA approved for infants ≥2 months of age	B
Lindane lotion or cream (1%)	Topically overnight on days 1 and 8	Potential CNS toxicity, especially in individuals weighing <110 pounds (50 kg), the elderly and those with crusted scabies, other skin conditions or a history of seizures	Poor, resistance very common	Not recommended for infants, children or breastfeeding mothers; contraindicated in premature infants	C (but not recommended)
Sulfur ointment (5–10%)	Topically overnight for 3 successive days	Toxicity studies not performed	Not evaluated	Not established, but considered safe	Not rated, but considered safe
Crotamiton lotion or cream (10%)	Topically overnight for 3–5 days	Irritant contact dermatitis, especially in areas of denuded skin	Very poor; has antipruritic properties and may be used for postscabetic pruritus	Not established, but considered safe	C
Ivermectin (available as 3 mg tablets)	Oral dose of 200–400 mcg/kg on day 1 and repeat on day 8 or 14*	Potential CNS toxicity in infants and young children	Excellent	Safety not established for children weighing <33 pounds (15 kg) or breastfeeding mothers	C (but generally not recommended for scabies in pregnant women)

*Administration of second dose at 2 weeks recommended by CDC (www.cdc.gov).

Table 84.1 Topical and oral treatments for scabies.

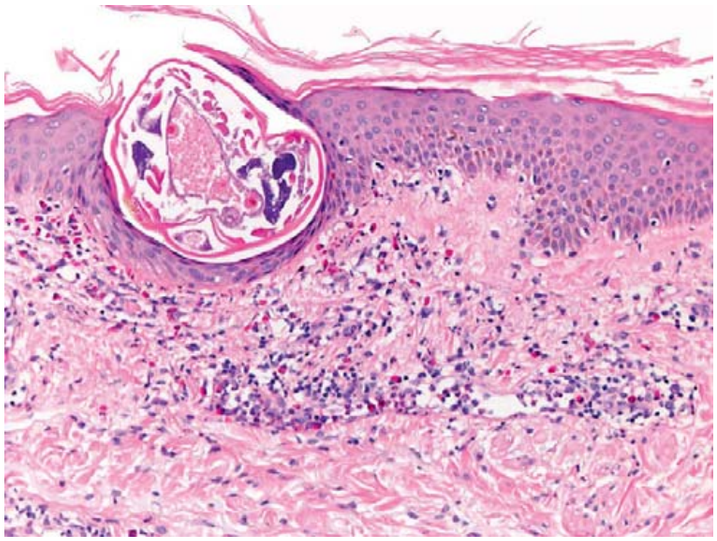

Fig. 84.6 Scabies – histologic features. A mite is evident in the stratum corneum and an eosinophil-rich dermal infiltrate is present. *Courtesy, Lorenzo Cerroni, MD.*

cause irritation of denuded skin. Of note, this topical medication is less effective than all of the other prescription options[7].

Sulfur ointment

Another alternative therapy for scabies is three consecutive overnight applications of 5–10% sulfur in a petrolatum base. A pharmacist must compound the medication, and toxicity studies have not been performed. Sulfur is messy, malodorous and irritating to the skin and can stain clothing. However, its efficacy has been reported to be as high as 92%[8].

Ivermectin

Ivermectin, although not FDA-approved for this indication, has been found to be effective for treating ectoparasites[1,9]. By blocking transmission across nerve synapses that utilize glutamate or γ-aminobutyric acid (GABA), it causes paralysis of peripheral motor function in insects[1,9]. In humans, GABA and glutamate are neurotransmitters within the cerebral cortex, and from early infancy on, the blood–brain barrier protects against potential ivermectin toxicity. In general, alternative therapies are recommended for children who weigh <33 pounds (15 kg), pregnant women and breastfeeding mothers because of the lack of safety data in these groups[1].

In clinical studies, ivermectin has proven to be extremely safe. Over 18 million people over 5 years of age are treated annually with ivermectin in the World Health Organization (WHO) Onchocerciasis Eradication Program. A single, questionable report of an increased death rate in patients receiving ivermectin[10] has been discounted as unrelated by the WHO, medical examiners and the scientific community.

Oral ivermectin can cure scabies. A dose of 200–400 mcg/kg is usually administered twice, 1–2 weeks apart[1,9]. Although there is only one report of mite resistance to this agent to date[11], increasing tolerance has been described in communities with a high prevalence of scabies[12]. Topical ivermectin in a 1% concentration appears to be effective, but further testing is warranted before recommending its widespread use[13]. In patients with subungual disease, addition of a topical scabicide is recommended because the oral medication will not penetrate into thickened keratotic debris.

HEAD LICE

Synonyms: ■ Pediculosis capitis ■ "Cooties"

Key features

- This worldwide infestation is caused by bloodsucking, wingless, six-legged insects that live only on the hairs of the scalp
- Diagnosis is usually confirmed by the presence of 0.8 mm eggs ("nits") firmly attached to scalp hairs
- Head lice are spread by head-to-head contact as well as by fomite transmission
- Resistance to traditional over-the-counter preparations (pyrethrins, permethrin) is growing; topical malathion and oral ivermectin can be used in resistant cases

Introduction

Lice are bloodsucking, wingless insects belonging to the suborder Anoplura. With 12 million cases per year in the US alone, a head lice

Fig. 84.7 Head louse family. From left to right: female, male and nymph.

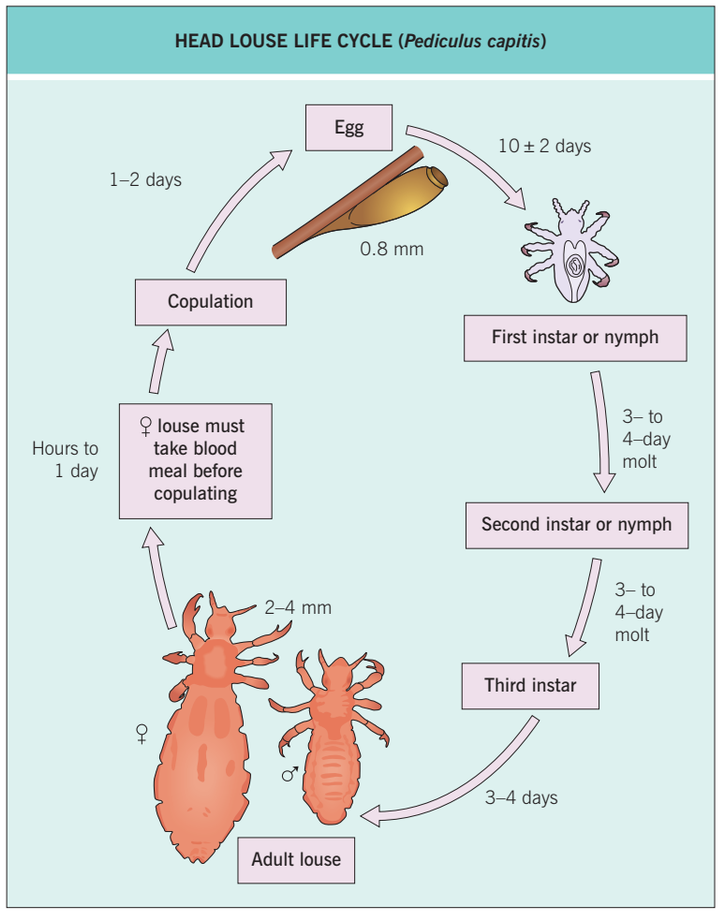

Fig. 84.8 Head louse life cycle (*Pediculus capitis*).

epidemic persists and resistance to standard treatments is rising. Treatment of resistent cases with prescription products (e.g. topical malathion or oral ivermectin) is becoming essential, requiring more physician involvement.

History

Head lice have infested mankind for thousands of years. Nits have been found on the hair of Egyptian and Peruvian mummies[1].

Epidemiology

Head lice are found worldwide with no strict limitations based upon age, sex, race or socioeconomic class. Children 3–11 years of age have the highest incidence, varying from 10% in Malaysia to 40% in Taiwan[1]. Infestation with head lice is more frequently observed in girls, probably due to their tendency to have longer hair as well as the common exchange of brushes, barrettes and other hair accessories. Head lice are distinctly uncommon in African-Americans, as lice in the US are unable to properly position themselves to lay eggs on coarse curly hair[14].

Pathogenesis

The head louse, *Pediculus capitis*, is a highly host-specific insect approximately the size of a sesame seed (2–3 mm; Fig. 84.7). These obligate human parasites feed exclusively on the blood of the host approximately every 4–6 hours. The female louse lives for 30 days, during which time she lays between 5 and 10 eggs a day on hair shafts (Fig. 84.8). The oval egg capsules (nits) measure 0.8 mm in length and are usually laid close to the scalp for warmth; in general, eggs located within 1 cm of the scalp are unhatched. In warm climates, however, viable nits may be found 15 cm or more from the scalp, especially in the area above the nape of the neck. The nits are cemented to individual hairs by means of a proteinaceous matrix that closely resembles the amino acid constituents of the human hair shaft itself[14,15]. Head lice rarely live for more than 36 hours away from the host without a blood meal; however, given an appropriate temperature (82–90°F/28–32°C) and humidity (70–90%), nits can survive and hatch after 10 days away from the host. Transmission occurs via direct head-to-head contact or by fomites such as combs, brushes, blow-dryers, hair accessories, bedding, helmets and other headgear[16].

Clinical features

Skin findings of head lice infestations are limited to the scalp, behind the ears and the nape of the neck. The classic symptom of intense pruritus can vary among patients. In the first infestation, it may take 2–6 weeks before pruritus is evident, reflecting the development of an immunologic response to the irritant components of the lice saliva or excreta. In repeat infestations, pruritus develops within the first 24–48 hours. However, a number of individuals are asymptomatic and can be considered "carriers". Although excoriations, erythema, pyoderma, and scaliness of the scalp and posterior neck are common findings, the diagnosis is made by the identification of nits and/or adult lice on the scalp hair. Viable eggs are usually tan to brown in color, whereas hatched eggs are clear to white (Fig. 84.9).

An occasional patient will present with a low-grade fever, irritability, lymphadenopathy and a secondary bacterial infection. Head lice can carry *S. aureus* and *Str. pyogenes* on their surfaces and are a common cause of pyoderma of the scalp[1].

Pathology

The epidermis and dermis may reveal signs of inflammation, but these alterations are neither specific nor diagnostic.

Differential diagnosis

Although several dermatoses, such as seborrheic dermatitis and psoriasis, can cause pruritus of the scalp, the finding of nits or adult lice is diagnostic. Nits are more firmly adherent to the hair shaft than dandruff, dried hair products (e.g. sprays, gels) or hair casts, and they must be differentiated from other causes of hair shaft nodules such as piedra (white or black) and trichorrhexis nodosa (see Fig. 77.1).

Treatment

The choice of treatment is based on the efficacy and potential toxicity of different agents, louse resistance patterns to insecticides in a particular geographic area, and ease of access to prescription remedies. Pediculicides remain the mainstay of therapy (Table 84.2). With all topical preparations (regardless of package instructions), two applications, 1 week apart, are advisable in order to: (1) kill any nits that survived treatment; (2) better defend against the seemingly growing resistance

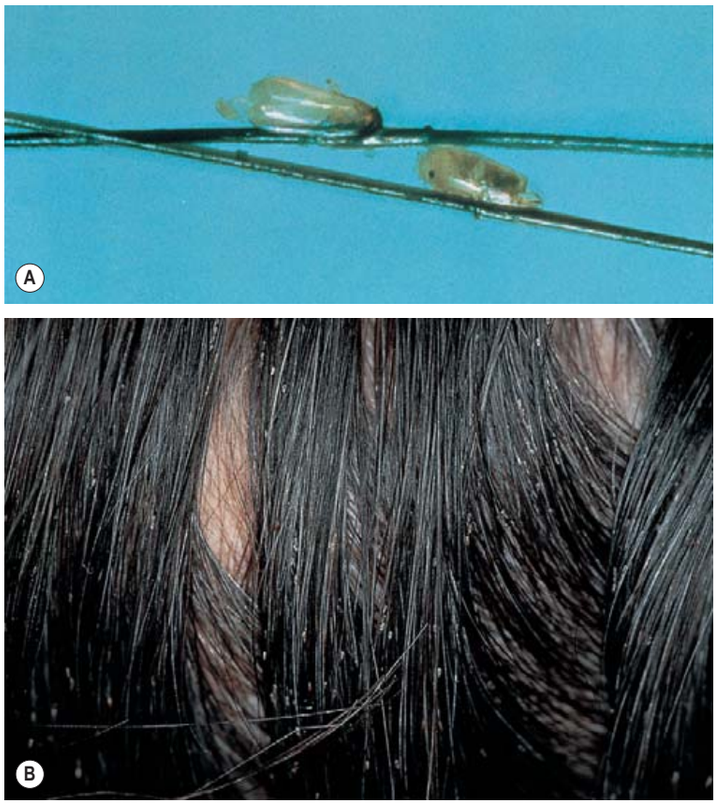

Fig. 84.9 Head lice. A The head louse egg or nit is 0.8 mm in length. **B** Head lice nits on hair. *With permission from Taplin D, Meinking TL. Infestations. In: Schachner LA, Hansen RC (eds). Pediatric Dermatology. 4th edn. Edinburgh: Mosby, 2011:1141–80.*

to most pediculicides; and (3) reduce the risk of reinfestation by means of fomites.

Unsubstantiated claims of successful treatment with alternative, non-pesticidal products, including petroleum jelly, hair pomade, olive oil, mayonnaise, vegetable oil and mineral oil, persist. Such products may slow the movements of adult lice and allow them to be more easily combed out of the scalp, but these substances are not lethal to lice. Some essential oils have been reported to be effective as lice therapy, and they are incorporated into various products that are usually found in health food stores. However, appropriate clinical studies are still necessary to confirm their safety and efficacy. Oral trimethoprim–sulfamethoxazole improves efficacy of topical agents but is not curative by itself[17].

Many school authorities enforce a "no-nit" policy and do not allow children to return to school if they have nits, regardless of whether they are viable or not. As a result, the tedious task of physically removing all nits via combs with closely spaced metal teeth is required. Currently there are no products that easily aid in nit removal[18]. Flexibility and understanding by school boards are more important than a straight adherence to a "no-nit" policy.

Pyrethrins

Pyrethrin insecticides are derived from a natural extract of flower heads of *Chrysanthemum cinerariaefolium*. Patients allergic to chrysanthemums, ragweed or related plants have experienced wheezing and dyspnea with use of the crude extract. In the US, pyrethrins and permethrin (see below) are the two FDA-approved, over-the-counter (OTC) pediculicides. Pyrethrins are presently formulated into lotions, shampoos, foam mousse, and cream rinses. The addition of piperonyl butoxide slows the biotransformation of pyrethrins by partially inhibiting the insects' cytochrome P450 enzymes, thereby initially improving effectiveness. Pyrethrin products are applied to the head for 10 minutes

TREATMENTS FOR HEAD LICE

Treatment	Group	Administration on days 1 and 8	Concerns	Efficacy & resistance
Permethrin cream rinse or lotion (1%)*	Synthetic pyrethroid	Topical application for 10 minutes to clean, dry hair	None	Poor–fair; resistance common
Permethrin cream (5%)†	Synthetic pyrethroid	Topical overnight application to clean, dry hair	Allergic contact dermatitis in individuals with sensitivity to formaldehyde	Poor–fair; resistance common
Pyrethrins (0.33%) synergized with piperonyl butoxide (4%), various formulations*	Natural botanicals	Topical application for 10 minutes to dry hair	Allergic reactions in individuals with sensitivity to chrysanthemums, ragweed and related plants	Poor–fair; resistance common
Malathion lotion or gel (0.5%)‡	Organophosphate cholinesterase inhibitor	Topical application for 8–12 hours to dry hair (Ovide® and gel products with isopropyl alcohol base are effective at 20 minutes)	Flammable isopropyl alcohol base; burning or stinging at sites of eroded skin	Excellent (in US); resistance noted in UK and France, but to date not in US
Carbaryl shampoo (0.5%)	Carbamate cholinesterase inhibitor	Topical application for 8–12 hours	Possible carcinogen	Poor–fair; resistance common (not approved in the US)
Lindane shampoo (1%)	Organochlorine	Topical application for 4 minutes to clean, dry hair, then add water to lather and rinse	Potential CNS toxicity; not recommended for infants, children, breastfeeding mothers or pregnant women (category C)	Poor; resistance common
Benzyl alcohol lotion (5%)§	Alcohol	Topical application for 10 minutes to dry hair	Potential skin irritation	Fair–good; no resistance noted to date
Spinosad cream rinse (0.9%)¶	Bacterial fermentation product	Topical application for 10 minutes to dry hair	None	Good; no resistance noted to date
Ivermectin (available as 3 mg tablets)	Avermectin	Oral dose of 200–400 mcg/kg	Potential CNS toxicity; not recommended for children weighing <33 pounds (15 kg), breastfeeding mothers or pregnant women (category C)	Excellent; no resistance noted to date

*Over-the-counter products.
†Approved for individuals ≥2 months of age; pregnancy category B.
‡Approved for individuals ≥6 years of age; pregnancy category B.

¶Approved for individuals ≥4 years of age; pregnancy category B.

Table 84.2 Treatments for head lice. All treatments should be given on two separate occasions, 1 week apart.

and then rinsed off. Treatment failures are now commonplace due to resistance[1,19].

Permethrin
Permethrin is the only synthetic pyrethroid that is used worldwide for head lice. The OTC 1% permethrin cream rinses and lotions are applied for 10 minutes; however, an 8–12-hour application of the 5% cream for scabies is an alternative therapy. Unfortunately, resistance to even the higher-concentration products has developed in head lice and other insects. Point mutations in the gene encoding the α-subunit of the insects' voltage-sensitive sodium channels commonly lead to a reduction in the binding affinity of permethrin and other pyrethroids. However, a recent German study found a >90% success rate for treatment with permethrin in children whose lice had these mutations (representing >90% of the entire head lice patient population), suggesting that other factors have a role in pyrethroid resistance[19a].

Lindane
Lindane, a chlorinated hydrocarbon, is available as a 1% prescription shampoo that is applied for 4 minutes. Because of possible CNS side effects, especially after prolonged applications beyond recommended time intervals, lindane is reserved for patients who fail to respond to other approved lice therapies. However, resistance is commonly observed. The FDA has issued a "black box" warning for lindane products (see above)[6].

Malathion
The prescription organophosphate malathion is a cholinesterase inhibitor. The current recommendation is to apply topical malathion for 8 to 12 hours, but a 20-minute application time appears to be sufficient[19]. The existing US product (Ovide® lotion) contains 78% isopropyl alcohol, which enhances its effectiveness but raises the issue of flammability. Although resistance to malathion products has appeared in the UK, in the US, resistance has not been observed to date with the currently available product (see Table 84.2)[20].

Carbaryl
Like malathion, carbaryl is a cholinesterase inhibitor. It is available in a 0.5% lotion and shampoo in the UK and other countries. This product is not presently available in the US. In comparison to malathion, carbaryl is potentially more toxic to patients, while being less lethal to lice.

Ivermectin
Oral administration of the antiparasitic agent ivermectin has had encouraging results for head lice[1]. In a recent European double-blind clinical trial, 95% of patients with resistant head lice (previously failed topical therapy with a pyrethrin or malathion) who received 400 mcg/kg of ivermectin on days 1 and 8 were lice-free on day 15, compared to 85% of those treated with topical malathion[21]. Ivermectin is an option for patients whose disease is resistant to topical therapies. As discussed above for scabies, children who weigh less than 33 pounds (15 kg) and pregnant or breastfeeding women should probably not receive oral ivermectin since safety data on these populations are not available.

Benzyl alcohol
In 2009, the FDA approved 5% benzyl alcohol lotion as a prescription treatment for head lice in children ≥6 months of age. Benzyl alcohol is thought to act via asphyxiation by preventing lice from closing their respiratory spiracles, which become blocked by the lotion; it is not ovicidal. In two randomized, double-blind, controlled clinical studies (total n = 250), 75% of patients were lice-free 14 days after the last of two 10-minute applications of benzyl alcohol (administered 1 week apart), compared to 5–25% of those treated with a vehicle control.

Spinosad
In 2011, spinosad was approved by the FDA as a new therapy for head lice in children ≥4 years of age. It is a fermentation product of the bacterium *Saccharopolyspora spinosa* that induces muscle spasms and paralysis in lice when applied topically. A clinical trial showed that 0.9% spinosad cream rinse left on for 10 minutes without nit combing had superior efficacy to 1% permethrin cream with nit combing, and spinosad had no significant clinical or laboratory side effects[22].

CRAB LICE

Synonyms: ■ *Pthirus pubis* or *Phthirus pubis* ■ Pubic lice ■ Pediculosis pubis ■ "Crabs"

Key features
- More properly designated "crab lice" (rather than "pubic lice") because infestations may involve other hair-bearing sites such as the beard, eyelashes, axillae and perianal region
- Transmitted by sexual or close contact and to a lesser extent via contaminated clothing, towels and bedding

Introduction
Infestation with *Pthirus pubis*, the crab louse, causes discomfort, pruritus and embarrassment and may coexist with other sexually transmitted infections.

History
The parasitic relationship between humans and crab lice dates back to prehistoric times.

Epidemiology
The incidence rate seems to be slightly higher in men, probably due to their increased amount of coarse body hair. Infestations with crab lice can be found in all socioeconomic and ethnic groups, although those of Asian descent or with minimal pubic hair are rarely infested. The highest prevalence is in men who have sex with men. Infestation is most frequently observed in those 15 to 40 years of age, correlating with increased levels of promiscuous sexual activity. Although infestation is often considered a sexually transmitted disease, individuals who have had no sexual exposures are occasionally infested via fomite transmission from contaminated clothing, towels or bedding[1].

Pathogenesis
Crab lice, *Pthirus pubis*, are approximately 1 mm in length with a wider, shorter body than head lice, and they resemble tiny crabs (Fig. 84.10). Their eggs, which are found attached to human hairs, are viable for up to 10 days; the adult crab louse can live for at least 36 hours away from the host. Crab lice have serrated edges on their first claw that enable them to ambulate on the entire body surface. Thus, infestation occurs not only in pubic hair, but also in hair of the scalp, eyebrows, eyelashes, moustache, beard, axillae and perianal area. Indeed, 60% of patients with pubic lice are infested in at least two

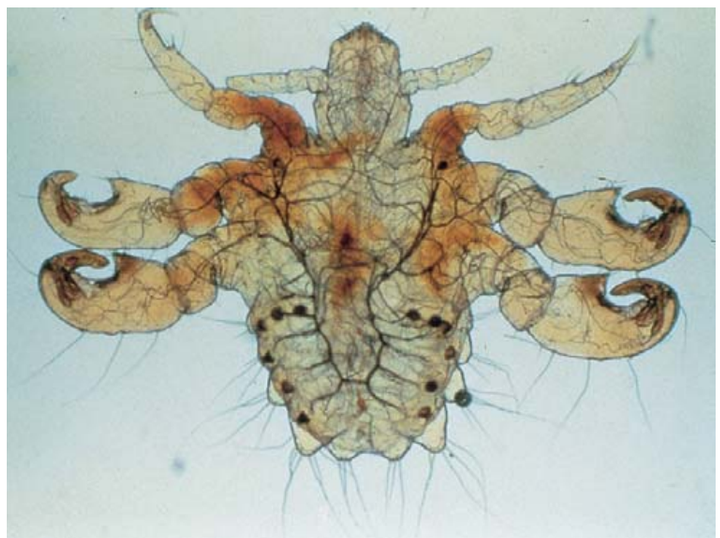

Fig. 84.10 Adult crab louse. Respiratory spiracles and circulatory system are easily seen (45×). *Courtesy, Tony Burns, MD.*

different hair-bearing sites. When the pubic area is shaved or treated, surviving crab lice can travel to other hairy areas of the body, including the scalp.

Clinical features

Crab lice infestations typically present with pruritus in the pubic region. Crab lice cling to the base of hairs (Fig. 84.11A), and they can be skin-colored or mimic hemorrhagic crusts. Other findings may include nits at the base of hair shafts, erythema around the hair follicles, excoriations, evidence of a secondary bacterial infection and lymphadenopathy. When the eyelashes are affected (Fig. 84.11B), feces that accumulate can resemble flecks of mascara. Macula caerulea are asymptomatic cutaneous lesions on the trunk and thighs that may be seen in individuals with chronic crab lice infestations. They are slate-gray to bluish, irregularly shaped macules measuring 0.5–1 cm in diameter. The breakdown of bilirubin to biliverdin by enzymes in louse saliva has been postulated to cause these lesions.

The possibility of additional sexually transmitted infections should be considered and the original source of the infestation sought in order to reduce the risk of recurrence.

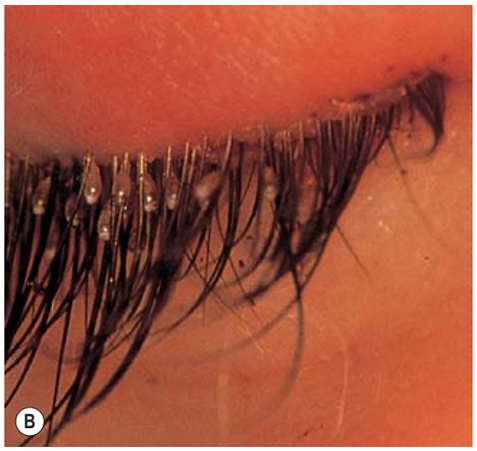

Fig. 84.11 Crab lice. **A** Both adult crab lice and nits are evident on pubic hairs. **B** Crab lice nits and feces on the eyelashes. *A, Courtesy, Louis A Fragola, Jr, MD. B, With permission from Taplin D, Meinking TL. Infestations. In: Schachner LA, Hansen RC (eds). Pediatric Dermatology. 4th edn. Edinburgh: Mosby, 2011:1141–80.*

Pathology

Crab lice cause nonspecific inflammatory changes in the epidermis and dermis. Because lice live on the surface of the skin, they would not be evident histologically.

Differential diagnosis

The identification of crab lice and/or their nits is diagnostic (see Fig. 84.10). Skin diseases associated with pruritus have to be considered in the differential diagnosis, including other infestations (e.g. scabies) and arthropod bites. Nits on pubic or axillary hairs must be distinguished from white piedra and trichomycosis pubis or axillaris.

Treatment

Topical insecticides are the standard therapy for crab lice. Sexual partners should be treated simultaneously. Most commonly, permethrin (1% or 5%) and synergized pyrethrin products are utilized (Table 84.3). As with head lice, all topical insecticides should be applied on two occasions, 1 week apart, to ensure a proper therapeutic approach to hatched eggs. Moreover, all hairy areas of the body must be inspected for the existence of lice and then treated if there is any possibility of their presence. A single application of these topical products to only pubic hair may limit success rates to as low as 55%[23].

Currently, the safest and most effective topical treatment is 5% permethrin cream applied generously overnight to all possibly infested hairy areas, and then repeated 1 week later[23]. Lindane has poor efficacy and higher toxicity, and the shampoo is not approved for extensive body application. Oral ivermectin on days 1 and 8 can be used for patients with perianal or eyelash involvement or when topical therapy is unsuccessful (see Table 84.3)[24].

BODY LICE

Synonyms: ■ Pediculosis corporis ■ Clothing lice

Key features

- An infestation of humans and their clothing, body lice infestation is most commonly found in the homeless, refugees, and victims of war and natural disasters
- Body lice do not live or lay eggs on people but in their clothing
- Infections transmitted by body lice include epidemic typhus, trench fever and relapsing fever

TREATMENTS FOR CRAB LICE

Treatment	Administration on days 1 and 8	Concerns	Efficacy
Permethrin (1%) cream rinse or synergized pyrethrin shampoo*	Topical application for 10 minutes to clean, dry hair	None	Fair
Permethrin cream (5%)	Topical application for 8–12 hours	Allergic contact dermatitis in individuals with sensitivity to formaldehyde	Good
Lindane shampoo (1%)	Topical application for 4 minutes to dry hair, then add water to lather and rinse	Potential CNS toxicity; not recommended for infants, children, breastfeeding mothers or pregnant women (category C)	Poor
Ivermectin (available as 3 mg tablets)	Oral dose of 250 mcg/kg	Potential CNS toxicity; not recommended for children <33 pounds (15 kg), breastfeeding mothers or pregnant women (category C)	Excellent

*Over-the-counter products.

Table 84.3 Treatments for crab lice. All crab lice treatments should be given on two separate occasions, 1 week apart, i.e. days 1 and 8.

Introduction

Body lice infestations are associated with overcrowding, poor hygiene, poverty, wars and natural disasters. These insects are the primary vectors for diseases caused by *Rickettsia*, *Borrelia* and *Bartonella* spp. (see Chs 74 & 76). Body lice look very similar to head lice but are larger in size.

Epidemiology

Body lice are found worldwide. Increased prevalence rates of body lice are tied to poor hygiene, poverty and homelessness. There are no racial, age or sex restrictions.

Pathogenesis

Pediculosis corporis is caused by an infestation of humans and their clothing by *Pediculus humanus* var. *corporis*. Besides exposure to conditions conducive to obtaining body lice, infestation requires an inability to wash and change clothes.

Several important human diseases are transmitted by the body louse. These include epidemic typhus (*Rickettsia prowazekii*) and relapsing fever (*Borrelia recurrentis*) as well as several diseases caused by *Bartonella quintana* – trench fever, bacillary angiomatosis and endocarditis[1]. Transmission of microorganisms from body lice to humans occurs not from the louse bites, but rather by contaminated fecal pellets being scratched into the bite site or excoriated skin or by inhalation of dry, powdery louse feces from infected bedding or clothing.

Clinical features

P. humanus var. *corporis* measures between 2.5 and 4.0 mm in length. Unlike head and crab lice, the nits and lice are rarely found on the patients' skin, save for feeding, as they reside primarily on the clothing of their hosts. This infestation leads to severe pruritus. The back, neck, shoulders and waist areas are commonly involved. Clinical findings include pinpoint red macules, small erythematous papules, crusts and excoriations, occasionally complicated by impetigo and lymphadenopathy. Blood and fecal pellets often stain clothing and bedding. On inspection, nits and adult lice are found along clothing seams that are in contact with the neck, axillae and waistline (Fig. 84.12).

Pathology

The epidermis has minimal spongiosis with nonspecific infiltrates of eosinophils and neutrophils in the dermis.

Differential diagnosis

Other causes of widespread pruritus and excoriations that may be considered in the differential diagnosis of body lice include systemic diseases (e.g. hepatic or renal impairment), drug reactions, atopic dermatitis, contact dermatitis (irritant or allergic), and other infestations (e.g. scabies).

Treatment

Preferably, the clothing and bedding of infested individuals are discarded in tightly sealed, plastic biohazard bags and incinerated. Only if the latter is not possible should disinfection be attempted. This involves fumigating the clothing or laundering it using hot water (temperature of ≥130°F/55°C) then machine drying it with high heat. Hot ironing of the seams of upholstered furniture can also be performed, and exposure to untreated infested items should be strictly avoided for 2 weeks. Topical insecticides are often applied to the body with regimens similar to those used for scabies, and this can eradicate concurrent infestations with scabies or crab lice as well as kill any body lice adherent to hairs.

Mass delousing in crowded, large populations due to natural disaster, war or famine is accomplished by dusting powders. These powders may contain DDT, malathion, dieldrin, lindane or permethrin.

Fig. 84.12 Body lice eggs in the seams of clothing.

TUNGIASIS

Synonyms: ■ *Tunga penetrans*: chigoe flea, jigger flea, burrowing flea, sand flea ■ Pique ■ Nigua ■ Pio and bicho de pie

Key features

- This infestation is caused by the burrowing flea, *Tunga penetrans*
- It is endemic in the Caribbean islands and parts of Central and South America, Africa, Pakistan and India
- The female flea burrows into the skin, then enlarges to create a 1 cm nodule with a central punctum through which eggs are ejected

Introduction

The burrowing flea, *Tunga penetrans*, is the causative agent of tungiasis. A female flea burrows into the upper dermis and enlarges to approximately 1 cm in diameter, creating a nodule with a central punctum through which eggs (fertilized or unfertilized) are eventually discharged.

History

Tungiasis was first reported in crew members on Christopher Columbus' original trip to the New World in 1492.

Epidemiology

Tungiasis can occur in anyone exposed to the flea, regardless of sex, race or age. It is indigenous to the Caribbean islands, with a prevalence ranging from 15% to 50%. Other areas of high incidence include parts of Central and South America, Africa, India and Pakistan.

Pathogenesis

Tunga penetrans is a wingless flea, 1 mm in size, that usually lives in warm, dry soil. Both sexes of this flea require an occasional blood meal from a warm-blooded animal for maturation[25]. Due to the fleas' limited jumping ability, the most common location for bites is the feet. Female fleas, rather than simply obtaining a blood meal, burrow headfirst into mammalian skin. They subsequently undergo marked abdominal hypertrophy, growing to 1 cm in diameter. The flea protrudes its rear cone through a central punctum that is always maintained; whether or not fertilization occurs via mating of the embedded female flea with a free-roaming male flea, over a hundred eggs are discharged within 3 weeks[26]. After expelling the eggs, the female dies and its remains are eventually sloughed from the skin.

Clinical features

Bites of immature fleas cause no symptoms; however, burrowing of the female flea into the skin can cause significant clinical morbidity. The burrowing is initially asymptomatic, but varying degrees of pain or pruritus usually develop. The first sign of disease is a small black dot, which evolves into a pearl-like whitish papule and then a larger nodule that is said to resemble a watch glass, with a clearly demarcated white halo surrounding the black central punctum. A peripheral zone of erythema is frequently evident. When the flea dies, a black crust covers the involuting lesion. The most common site of disease is the periungual area of the toes, followed by the soles and toe webs (Fig. 84.13). Ulceration, secondary infection and lymphangitis can accompany the infestation, and less common complications include tetanus, gangrene and amputation of a digit[25]. Over half of periungual infections lead to deformation or loss of the nail[27].

Fig. 84.13 Tungiasis in a child.

Pathology

A nonspecific inflammatory infiltrate surrounds the flea within the dermis.

Differential diagnosis

The differential diagnosis may include myiasis, tick bite reactions, cercarial dermatitis, pyoderma, plantar warts, verruga peruana and squamous cell carcinoma.

Treatment

Spontaneous recovery does occur; however, most clinicians and patients prefer to cure the infestation by removal of the female flea. In an early infestation, a sterile needle can be used to pry the insect from the skin. If treatment is delayed, curettage, electrodesiccation or surgical excision may be required. Careful cleaning of the cystic cavity speeds clinical resolution. Tetanus prophylaxis should be strongly considered. Substantial clinical benefit from topical and oral therapies for tungiasis has not been demonstrated. Topical application of ivermectin, metrifonate or thiabendazole may lead to more rapid demise of embedded fleas[28]. In a randomized controlled study, oral ivermectin was not found to have significant efficacy compared to placebo. Preventative measures include the use of insect repellents, wearing closed shoes or boots, and avoiding ground contact (e.g. sitting on sandy beaches) in endemic areas.

CUTANEOUS MYIASIS

Synonyms: ■ Names for the various flies associated with this entity include human botflies, screwworms, blowflies, fleshflies and tumbu flies

Key features

- Infestation of the skin by fly larvae (maggots)
- The larvae inhabit cutaneous wounds (wound myiasis) or burrow into the dermis causing boil-like lesions (furuncular myiasis)
- Although they usually cause minimal morbidity, larvae can cause problems when they involve the nasal cavity and sinuses

Introduction

Cutaneous myiasis is an infestation of the skin by developing larvae (maggots) of a variety of fly species within the arthropod order Diptera. The two main clinical types are wound and furuncular myiasis.

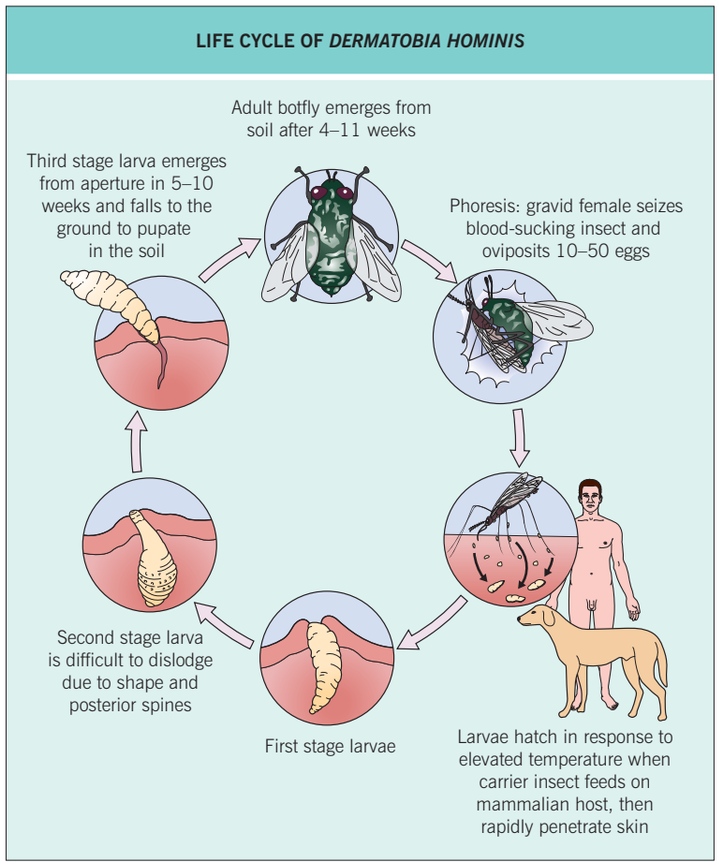

Fig. 84.14 Life cycle of *Dermatobia hominis* in cutaneous myiasis.

History

Maggots were central to Francisco Redi's experiment rejecting the theory of spontaneous generation. Wound debridement by maggots has been used for centuries, including during the American Civil War and by Napoleon's troops.

Epidemiology

Myiasis is a worldwide infestation with seasonal variation whose prevalence is related to latitude and the life cycle of the various species of flies. Its incidence is higher in the tropics and subtropics of Africa and the Americas. The flies responsible prefer a warm and humid environment, thus they are restricted to the summer months in temperate zones, while living year-round in the tropics.

Pathogenesis

Myiasis is the infestation of living humans (or other vertebrates) with dipterous larvae that feed on the host's tissues, liquid body substances or ingested food. Myiasis can be caused by several species of arthropods within the order Diptera, the two-winged true fly. The causative flies can be classified by: (1) taxonomic family; and (2) differences in pathogenic behavior of the fly species.

Worldwide, the most common flies that cause human infestation are *Dermatobia hominis* (human botfly) and *Cordylobia anthropophaga* (tumbu fly). The routes of transmission of fly larvae to human hosts differ among the fly species. For example, *D. hominis* lays its eggs on mosquitoes, which in turn deposit them on a warm-blooded mammal (Fig. 84.14). *C. anthropophaga* deposits its eggs on moist clothing and soiled blankets and in sand. The larva can live 15 days without feeding, but once it makes contact with a host, it penetrates the skin, which initiates further maturation. In endemic areas, people often iron their clothes after hanging them out to dry to kill the fly eggs. In wound myiasis, an open wound or orifice attracts flies to deposit their eggs. Any body area can be infested, and the most serious sequelae occur when the nasal cavity, sinuses or scalp are involved. The incubation

Fig. 84.15 Cutaneous myiasis. A Furuncular myiasis presenting as a papulonodule with a central punctum on the leg. **B** Wound myiasis in an amputation stump. **C** Botfly larva. *B, Courtesy, Louis A Fragola, Jr, MD.*

period for larvae to mature into adulthood depends on the fly and can range from 1 to 12 weeks.

Clinical features

Furuncular cutaneous myiasis, which is caused by the human botfly and tumbu fly, causes boil-like lesions. Whereas myiasis from the tumbu fly typically occurs on the trunk, thighs and buttocks, botfly lesions are usually on exposed areas of the body, including the scalp, face, forearms and legs. A pruritic papule develops within 24 hours of penetration, enlarging to 1–3 cm in diameter and up to 1 cm in height (Fig. 84.15A). These lesions can be painful or tender and may become crusted and purulent; there may be a sensation of movement.

In *wound* myiasis, the larvae are deposited in a suppurating wound or on decomposing flesh. *Cochliomyia hominivorax*, a screwworm, is the most common cause of this form of myiasis in the Americas, while *Chrysomya bezziana* is typically seen in Africa, Australia and Asia. The diagnosis is obvious when larvae are visible on the surface of the wound (Fig. 84.15B) and more difficult when they have burrowed beneath the surface.

Creeping (or migratory) cutaneous myiasis may be caused by *Hypoderma bovis* if there is exposure to infested cattle, or by *Gasterophilus intestinalis* in those who work with horses. This form of myiasis resembles cutaneous larva migrans, but the fly larvae migrate more slowly, persist for longer (often months), and are larger than helminth larvae[29].

Myiasis is a self-limiting infestation with minimal morbidity in the vast majority of cases. The major reasons for treatment are reduction of pain, cosmesis, and psychological relief. However, larvae such as *C. hominivorax* can infest around orifices of the head and may burrow into brain tissue. Ultrasound can assist in establishing the diagnosis, determining the size of the larvae, and evaluating the course of treatment[30].

Pathology

Histologically, an inflammatory response occurs in stages in which lymphocytes, giant cells, neutrophils, eosinophils, mast cells and plasma cells participate. The larvae can be seen in cross-section.

Differential diagnosis

Furuncular cutaneous myiasis should be differentiated from a ruptured epidermoid cyst, an abscess, furunculosis, a foreign body reaction, onchocerciasis, tungiasis, an exaggerated arthropod bite reaction, and lymphadenopathy.

Treatment

The larva in furuncular cutaneous myiasis should not be forcibly removed through the central punctum because its tapered shape with rows of spines and hooks prevents simple extrusion (Fig. 84.15C). Surgical debridement under local anesthesia is curative, although a foreign body reaction can occur if parts of the larva remain. Occlusion/suffocation approaches involve placement of petroleum jelly, liquid paraffin, beeswax, nail polish, heavy oil, lard or strips of bacon over the central punctum. Such blockage forces the aerobic larva to surface for air over the course of several hours – at which time, forceps aid in their capture. Alternatively, ethyl chloride sprays, liquid nitrogen, chloroform in vegetable oil or insecticides have been used alone or in combination. In addition, lidocaine can be injected into the base of the tissue cavity which the larva inhabits, thereby forcing the larva to the surface[29]. After removal of larvae, antiseptic dressings are indicated, as are antibiotics if secondary infection is present.

Wound myiasis requires debridement with irrigation to eliminate the larvae from the wound, or surgical removal. If burrowing has occurred, the method of extraction is identical to that for furuncular cutaneous myiasis.

An alternative treatment for all types of myiasis is oral ivermectin, which has proven especially helpful with oral and orbital involvement[29]. Surgical removal is not required unless requested by the patient, as the larvae are naturally sloughed within 2 weeks.

Myiasis can be a portal of entry for *Clostridium tetani*, and vaccination of affected individuals should be considered.

Preventative measures

In endemic areas, it is important to avoid activities that increase the risk of myiasis, such as wearing damp clothing or resting in sandy areas. The use of insect repellents (including on the scalp) can be useful in preventing mosquitoes that are harboring the larvae of the human botfly from depositing their living cargo.

INSECTS

Insect Bites And Stings (Class Insecta)

Key features

- Excoriated pruritic papules sometimes progress to persistent prurigo nodularis-like lesions
- Papular urticaria may be localized to sites of bites or generalized
- Vesicles and bullae can mimic bullous pemphigoid
- Pseudolymphomatous nodules occasionally develop
- Anaphylaxis is mainly related to hymenopterid stings
- Secondary infection is most often staphylococcal

Introduction

Insect bites and stings are prevalent throughout the world. In temperate climates they are primarily a seasonal phenomenon, although indoor infestations can persist year-round. Insects are important disease vectors worldwide, and personal protection against bites plays a major part in the prevention of disease[1]. Arthropods produce a wide spectrum of clinical lesions. Bullous arthropod reactions may suggest a diagnosis of immunobullous disease, and positive direct immunofluorescence has been reported, especially in the setting of scabies infestation. Pseudolymphomatous arthropod reactions can also create diagnostic confusion (see Ch. 121).

Pathogenesis

Insect venoms and saliva are complex. Immediate reactions are commonly related to histamine, serotonin, formic acid or kinins. Delayed reactions are typically manifestations of the host's immune response to proteinaceous allergens. Secondary infection is common. Although staphylococcal infections are seen most frequently, streptococcal infections also occur and inoculation of organisms via insect bites and stings is occasionally implicated in other infectious diseases such as nocardiosis and sporotrichosis. The list of vector-borne diseases is staggering, and many new and emerging infectious diseases are linked to arthropod vectors. For example, tick-borne encephalitis has rapidly become an important disease in Europe.

While some diseases have a single arthropod vector, others have multiple vectors and/or other means of transmission. For example, bites from ticks and handling of infected animals are the most common modes of tularemia transmission in the US, but the disease can also be acquired through bites by deerflies and other horseflies. The vector has an important influence on the patient population affected by a particular disease. For example, cat ownership is a risk factor for cat scratch disease, which is associated with *Bartonella henselae* transmission by fleas, while homelessness is a risk factor for trench fever, which is caused by *Bartonella quintana* transmission by lice; however, either organism–vector pair can cause *Bartonella* endocarditis and bacillary angiomatosis, explaining why these diseases affect both patient populations. Vector-borne diseases often become epidemic during war or following natural disasters, and poverty and homelessness contribute to the spread of vector-borne disease.

Roughly a quarter of reported cases of anaphylaxis are related to stings from insects in the order Hymenoptera (meaning membranous wings), which includes bees, wasps, hornets and ants. These insects can possess specialized stingers and produce complex venoms that contain substances such as formic acid, kinins and proteinaceous allergens. Insect sting hypersensitivity is more common in those with an atopic diathesis, and severe immediate reactions may also be an indication of underlying mastocytosis.

Clinical features

Characteristic insect bite reactions are grouped or disseminated, 2 to 8 mm, erythematous urticarial papules that are markedly pruritic and often excoriated (Fig. 85.1); they typically resolve over 5–10 days. Occasionally, bite reactions present as evanescent wheals or longer-lasting "papular urticaria" lesions that persist for weeks or even months, sometimes reactivating when new bites occur in different locations. In addition to lesions restricted to the sites of bites, papular urticaria may develop as a generalized phenomenon following insect bites. Edematous plaques, nodules and vesiculobullous reactions also occur frequently (Fig. 85.2). Chronic and resolving lesions are often hyperpigmented and can resemble prurigo nodularis. Insect bite reactions are most frequent in children 2–10 years of age and tend to involve exposed areas of the head, neck and extremities. Commonly, only one member of a family is affected, as most clinical manifestations relate to the individual's immune response rather than the bite itself.

Papulovesicular and nodular lesions resembling bites have been described in patients with chronic lymphocytic leukemia (see Ch. 33) and (less frequently) other hematologic malignancies. Although the lesions frequently appear months after the diagnosis of leukemia and are unrelated to its course or therapy, they can also herald development or recurrence of leukemia or lymphoma[2]. The clinical appearance, distribution and histologic features (including the presence of degranulating eosinophils) of the lesions suggest that they represent exaggerated bite reactions; although patients often do not recall having been bitten, reactivity to intradermal injection of mosquito antigen has been documented. Hypersensitivity to mosquito bites with development of bullous or necrotic skin lesions has also been described in individuals (typically Asian or Hispanic children and adolescents) with chronic EBV infection and proliferation of EBV-carrying natural killer (NK) cells (see Ch. 80)[3]. Screening for hematologic malignancies, latent EBV infection (including *in situ* hybridization to detect EBV RNA in biopsy specimens of lesional skin if positive serology) and NK-cell lymphocytosis should be considered in patients with unusual arthropod bite reactions.

Bee and wasp stings typically produce immediate burning pain, which is followed by the development of local erythema and swelling that usually subsides within a few hours to days but can be more severe and persistent in sensitized individuals. Atrial arrhythmias have been reported after bee stings, in the absence of anaphylaxis. Killer bee and wasp attacks may be associated with myoglobinuria or hemoglobinuria and acute tubular necrosis[4]. Although some patients with inflammatory arthritis have looked to bee stings as an alternative therapy, beekeepers may develop a chronic arthropathy related to stings.

Fig. 85.1 Insect bite reactions. In this patient, there are papulovesicles as well as excoriated papules with hemorrhagic crusting. In more darkly pigmented individuals, residual hyperpigmentation is common and can persist for months. *Courtesy, Julie V Schaffer, MD.*

Pathology

Histologic features suggestive of a bite or sting include the presence of a wedge-shaped perivascular lymphocytic infiltrate with eosinophils, endothelial prominence and overlying spongiosis or focal epidermal necrosis. Spongiosis may result in blister formation.

Differential diagnosis

Arthropod reactions account for many "cryptic" chronic skin eruptions. Features that should suggest an arthropod reaction include grouping of papules, patterns of eruption that correlate with exposure, and the histologic features noted above. When the physician suspects an arthropod reaction, a detailed history of outdoor exposure, pets, work and hobbies may be helpful.

Treatment

Camphor and menthol lotion and gel formulations may be useful in the control of pruritus. Topical anesthetic preparations can also be helpful, and those containing pramoxine are readily available and present a low risk of contact dermatitis. For more persistent bite reactions, topical corticosteroids are often required. In young children, mid-strength corticosteroid preparations may suffice, while in older children and adults, I generally recommend class 1 or 2 corticosteroids. These agents can be applied under occlusion to enhance efficacy, but this should be limited to a few applications to avoid potential side effects of cutaneous atrophy and striae.

When topical agents fail, intralesional injection of a corticosteroid (e.g. triamcinolone 10 mg/ml) or excision of the pruritic nodule may be necessary. Occasionally, pseudolymphomatous nodules may require triamcinolone concentrations as high as 40 mg/ml. Cutaneous atrophy can occur, especially if a higher concentration of corticosteroid is injected superficially. Atrophy may also be noted in a distribution corresponding to lymphatic drainage.

Prevention of bites is best accomplished through the use of protective clothing and repellents. Commonly used repellents are listed in Table 85.1. Factors that can influence the choice of a repellent include its efficacy, cost, convenience, odor and potential for irritation, as well as common arthropod pests in the area and the time of day, duration and environment of the exposure. DEET (N,N-diethyl-3-methylbenzamide, previously called N,N-diethyl-m-toluamide) remains the most widely used repellent for the prevention of bites from mosquitoes and most other insects. DEET is applied to exposed skin and can also be applied to clothing. While mosquitoes that carry dengue virus tend to bite during the day, the anopheline mosquitoes that carry malaria tend to bite at night, and pyrethroid-impregnated mosquito netting and chemoprophylaxis are additional preventative measures.

The duration of efficacy of DEET depends primarily upon the dose applied. It is also affected by the sex of the individual, with women receiving less protection than men (an observation that appears to be independent of serum estradiol levels). Efficacy may be reduced by the presence of skin abrasions. Rare toxic reactions include anaphylaxis and encephalopathy, and high concentrations of DEET can occasionally produce dramatic bullous eruptions.

Because of the potential for toxicity, the lowest effective DEET dose should be selected, especially in children. Many products with 10% or lower concentrations are available, although the American Academy of Pediatrics has stated that concentrations as high as 30% can be used safely in children 2 months of age or older (see Table 85.1). Although sunscreens have been shown to enhance DEET absorption in studies using artificial membranes and animal models, this is not thought to be clinically significant with normal use.

Fig. 85.2 Insect bite reactions. Sometimes patients develop large, erythematous, edematous plaques (**A**) or frank bullae (**B**). *Courtesy, Julie V Schaffer, MD.*

COMMONLY USED INSECT REPELLENTS	
CONVENTIONAL REPELLENTS IN EPA CLASSIFICATION	
DEET (N,N-diethyl-3-methylbenzamide)*	Effective against a wide range of arthropods
	Long history of use
Picaridin	Good evidence for mosquitoes
	Fewer studies support repellent effect against ticks
BIOPESTICIDE REPELLENTS IN EPA CLASSIFICATION	
IR3535 (3-[N-butyl-N-acetyl]-aminopropionic acid, ethyl ester)	Good evidence for mosquitoes in some, but not all, studies
	Fewer studies support repellent effect against ticks
p-Menthane-3,8-diol†	Good evidence for mosquitoes
	Fewer studies support repellent effect against ticks
Botanicals (e.g. soybean oil, citronella, neem oil, fennel oil, geraniol)	Have consumer appeal as "natural" repellents
	Best published evidence is for neem oil
	Lack of evidence does not necessarily equate to lack of efficacy, but available evidence to date suggests they are inferior to the synthetic repellents listed above

*There is a plateau of efficacy at 30% with long-acting products, and higher concentrations should generally be avoided. Because sunscreens require frequent reapplication and DEET does not, combination products with these ingredients are not recommended.
†The active ingredient of oil of lemon eucalyptus; use on children less than 3 years of age is not recommended.

Table 85.1 Commonly used insect repellents. Agents are listed in order of decreasing evidence of efficacy. EPA, Environmental Protection Agency.

Other effective repellents are available, and improved extended-release formulations are being developed[5–9]. Picaridin, IR3535 and p-menthane-3,8-diol perform reasonably well against a variety of mosquitoes and generally outperform soybean oil, citronella, neem oil, fennel oil and geraniol (see Table 85.1)[10]. For protection against the common mosquitoes *Aedes aegypti* and *Culex quinquefasciatus*, IR3535 may be comparable to DEET. The Mediterranean monk's pepper plant (*Vitex agnus-castus*) has demonstrated efficacy against *Ixodes ricinus* and *Rhipicephalus sanguineus* ticks as well as some mosquitoes, biting flies and fleas.

Because insect stings are often unexpected, allergic individuals should carry an epinephrine (adrenaline) autoinjector with them at all times. The EpiPen® autoinjector contains 0.3 ml of epinephrine 1:1000 (for individuals weighing >66 pounds [>30 kg]), while the EpiPen® Jr. contains 0.3 ml of epinephrine 1:2000 (for children weighing 33–66 pounds [15–30 kg]). Patients must receive instructions regarding the use of the autoinjector, which needs to be protected from heat and light as well as inspected periodically for brown discoloration of the contents. Bee stingers should be removed as rapidly as possible, with less concern for the exact method of removal.

Venom immunotherapy has been shown to improve quality of life for patients allergic to stings[11], reducing anxiety as well as the incidence and severity of local and systemic reactions. Desensitization protocols vary and should be discussed with an allergist. Rush (accelerated) immunotherapy can be performed for those with severe reactions, and it has a reasonable safety profile. In the setting of mastocytosis, immunotherapy may need to be continued indefinitely, frequently induces immediate hypersensitivity reactions, and is only partially effective. Omalizumab has been used in conjunction with immunotherapy for patients refractory to standard regimens, and this may help to prevent immunotherapy-related anaphylaxis[12].

Fire Ants

Key features

- Imported fire ants are red–brown in color and 1–2 mm in length
- When their mounds are disturbed, the ants swarm and sting in great numbers
- Immediate burning pain is followed by intensely pruritic grouped vesicles and pustules
- Fire ant allergy is an important cause of anaphylaxis in endemic areas

Introduction

The range of *Solenopsis invicta*, the red imported fire ant (originally from South America), has spread to encompass much of the southern and southwestern US, and its territory continues to expand. The size of fire ant mounds varies in proportion to the amount of rainfall. The mounds may be inconspicuous during periods of drought, but they can reach more than a foot (30 cm) in height after heavy rains. When the mound is disturbed, the ants swarm. Because of their small size, they are not felt until they all begin to sting simultaneously in response to a chemical signal. Fire ants are attracted to electrical boxes and therefore present a hazard to electricians. Indoor attacks by swarms of fire ants can be particularly dangerous to infants and elderly individuals with impaired mobility[13].

Pathogenesis

Fire ant venom is complex, and it acts by increasing membrane permeability and allowing release of histamine from mast cells. Allergic responses are directed at proteins within the venom. The venom is less concentrated in winter months, so winter sting reactions may be milder.

Clinical features

Fire ant stings begin as extremely painful wheals, then evolve into intensely pruritic vesicles and sterile pustules (Fig. 85.3). The fire ant

Fig. 85.3 Fire ant bites presenting as clusters of sterile pustules on the foot.

first grasps the skin with its mandibles; it then pivots and delivers a series of stings in a circular fashion, which may produce a rosette pattern. Scattered individual lesions are also common, especially when the victim is able to remove the ants before they have a chance to sting again. Secondary staphylococcal infections can occur after fire ant stings. The absence of persistent tenderness can help differentiate sterile pustular reactions from secondary infections. Life-threatening anaphylactic reactions to fire ant stings have become an important problem in the southern US[14].

Treatment

Patients with a life-threatening fire ant allergy should carry an epinephrine autoinjector with them at all times. Immunotherapy improves quality of life for those with severe fire ant allergies, and rush immunization protocols can be successful for those at high risk of stings[15,16]. Unfortunately, it is often impossible to avoid stings in endemic areas[17]. Local reactions may be treated with potent topical or intralesional corticosteroids. A variety of methods of fire ant control are available, including bait insecticides that have a low environmental impact and are reasonably effective as well as insecticide treatments for individual mounds.

Bedbugs

Key features

- Flattened oval body that is red–brown in color and 5–7 mm long in adults
- Segmented abdomen and vestigial wings
- Blood-sucking insects that feed at night and produce rows of pruritic, edematous papules

Introduction

In the past decade, there has been a worldwide resurgence of bedbugs, which are now frequently recognized in homes, hotels and dormitories[18–20]. Increases in international travel, expanded immigration, changes in pest control practices, and development of insecticide resistance have likely contributed to this trend.

Bedbugs belong to the family Cimicidae (order Hemiptera) and are blood-sucking mammalian and avian ectoparasites. They have a flattened oval body, a segmented abdomen, a retroverted labium (sucking mouthpiece), a semicircular to triangular scutellum (dorsal sclerotic plate), and antennae with four segments (Fig. 85.4). *Cimex lectularius* (the common bedbug) and *C. hemipterus* (found in warmer climates) affect humans most frequently; *C. lectularius* also parasitizes bats, chickens and other domestic animals. *C. lectularius* ranges in size from 5 to 7 mm, with females slightly longer than males. *C. hemipterus* is roughly 25% longer than *C. lectularius*. Interspecies mating occurs in nature.

Fig. 85.4 Bedbugs. Red–brown in color with a segmented abdomen and vestigial wings.

Bedbugs are nocturnal; they hide in cracks and crevices or behind peeling paint during the day and feed at night. There is a particularly high prevalence of bedbugs in homeless shelters and refugee camps.

Pathogenesis

Bedbug bite reactions result from an immune response to salivary proteins (e.g. nitrophorin) injected by the insect while feeding. Bedbugs digest their blood meal very slowly. The blood in the bug's gut remains relatively unclotted and is not membrane-bound. These factors may affect this arthropod's potential competence as a disease vector.

Clinical features

Bedbug bites typically present as pruritic, erythematous, edematous papules, sometimes with a visible central hemorrhagic punctum. As with other insect bites (see above), the clinical appearance and duration of lesions vary depending on the patient's degree of sensitization. Some individuals have little or no reaction to bedbug bites, and it is common for only one or a few family members (even among those sleeping in the same bed) to report lesions. Bites are often noted in linear groups of three (referred to as breakfast, lunch and dinner) but can also be otherwise clustered or scattered, favoring areas of the body that are exposed during sleep (e.g. the head, neck, shoulders, arms, legs and waist). Although affected individuals classically awake with new lesions, bite reactions can take several days to appear, and the latency tends to decrease with exposure to additional bites[18,20].

Bedbugs may be vectors for hepatitis B virus, although this is highly controversial. They have also been suspected to be vectors of American trypanosomiasis (Chagas disease). Fortunately, it appears unlikely that bedbugs present a significant risk for transmission of HIV. Bedbug dung may play a role in asthma.

Treatment

Bedbug bites can be treated as described above for other insect bites (e.g. with topical corticosteroids). Eradication of bedbugs from infested homes is difficult and often requires the assistance of professional exterminators. Elimination of cracks and crevices and removal of roosting bats or birds are essential. Various insecticides have activities against bedbugs, dichlorvos being among the best. Although insect repellents demonstrate some degree of efficacy against bedbugs, those bedbugs that still bite take progressively smaller meals in the face of increasing concentrations of repellent. Paradoxically, this may increase the chance of bedbugs spreading disease as they go from one individual to another. Insecticide-treated bed nets used to protect sleepers from mosquitoes in areas with endemic malaria have also been shown to reduce bedbug infestation, but this practice may contribute to pyrethroid resistance among bedbugs.

Triatome Reduviids

Synonyms: ■ Reduviid bugs ■ Kissing bugs ■ Assassin bugs

Key features

- Half-membranous wings (hard proximally and membranous distally) whose tips overlap
- Tan and dark "tiger stripes" on the abdomen
- Vector for American trypanosomiasis
- Bites can produce large, persistent edematous plaques

Introduction

Like bedbugs, triatome reduviids are true bugs of the order Hemiptera. They have half-membranous wings that overlap. Characteristically, the wings fail to cover the lateral portions of their "tiger-striped" abdomen (Fig. 85.5). The antennae are long, thin and composed of four segments; the position of the antennae is used to classify the bugs. The labium

Fig. 85.5 Triatome bug. Note that the wings fail to cover the lateral portions of the abdomen and the tan and dark "tiger stripes" on the abdomen.

(sucking mouthpiece) is straight and composed of three segments. Behind the head is a triangular pronotum (first segment of the thorax) with a broad posterior base.

Triatome reduviids are vectors for American trypanosomiasis (Chagas disease; see Ch. 83). The bugs have a pronounced gastrocolic reflex, defecating as they eat. Infectious feces are then inoculated into the bite site or conjunctiva by scratching or rubbing.

Triatome reduviids are often found in peri-domestic sites in Central and South America and the southern US, especially cracked stone walls and piles of tiles or bricks. They commonly feed on domestic animals, and trypanosome transmission may cross over between domestic and sylvatic life cycles. Control of this vector has been difficult, and insecticide spraying in affected communities is often followed by reinfestation originating from nearby livestock enclosures or wild populations of triatome reduviids.

Clinical features

Triatome reduviid bites are typically painless, and the first sign is delayed erythema, swelling and pruritus at the site. Exaggerated responses in the form of large urticarial plaques or vesiculobullous lesions are occasionally observed. Triatome reduviids are known as "kissing bugs" because of their tendency to bite the face, especially around the lips. Unilateral eyelid and periorbital swelling 1–2 weeks after conjunctival exposure to infected triatome feces is referred to as Romaña sign and represents a chagoma. Trypanosomes subsequently infect the autonomic nervous system, resulting in chronic complications that include cardiomegaly and megacolon (see Ch. 83). Triatome reduviids and cockroaches share antigens that are strongly immunogenic in atopic patients.

Blister Beetles

Synonyms: ■ Spanish fly ■ Rove beetle

Key features

- Oblong bodies and antennae composed of multiple short segments
- Wide variety of colors and patterns
- Contact with beetles results in vesicles and bullae due to their production of cantharidin

Introduction

Blister beetles (order Coleoptera) include members of the families Meloidae and Staphylinidae. The Meloidae are the best known, with species worldwide that result in blistering. Members of the family Oedemeridae are classified as "false" blister beetles but can also produce blistering. The blistering agent cantharidin is derived from blister beetles, where it appears to serve a protective function.

Much of what is known about blister beetles is extrapolated from studies of a few species. In *Epicauta funebris*, cantharidin has been identified in all ten life stages of the beetle, and it accumulates during the first five larval stages. When threatened, larvae protect themselves by exuding cantharidin in a milky oral fluid, rather than in the hemolymph that adult beetles discharge from leg joints. Adult male beetles contain up to 10% cantharidin by weight. If kept in isolation, females lose their larval reserves and must mate to preserve their stores of cantharidin. During mating, the female acquires cantharidin from her mate as a copulatory gift. She then transfers the cantharidin to her eggs, rendering them resistant to predation.

Clinical features

Contact with blister beetles typically results in vesicles and bullae. Epidemics of bullous skin lesions in hospital wards with open windows have been related to the light-seeking behavior of some species. "Nairobi eye", or rove beetle blistering, is caused by *Paederus eximius*, a blister beetle found in Northern Kenya. Eruption of pustules on an erythematous base due to contact with rove beetles in Pakistan has also been described.

Pathology

Histologic sections of the blisters demonstrate acantholysis in suprabasal keratinocytes. Disruption of cell outlines and cellular necrosis may be noted. The profile of adhesion molecule loss in cantharidin blisters is similar to that seen in Darier disease.

Treatment

Avoidance is the best measure, but immediate washing with soap and water may be of some benefit.

Fleas

Key features

- Laterally compressed bodies and large hind legs
- The most common flea on dogs is *Ctenocephalides felis*, the cat flea
- Produce intensely pruritic papules, vesicles and bullae, often grouped on the lower extremities
- Serve as vectors for endemic (murine) typhus, flea-borne spotted fever and plague

Introduction

Fleas (order Siphonaptera) are ubiquitous pests and show little host specificity. The most common flea on dogs is *Ctenocephalides felis*, the cat flea. *Pulex irritans*, the human flea (Fig. 85.6), is a common dog flea in some locations. It is also found on wild animals with no human contact. *Ctenocephalides* fleas have two ctenidia (combs) that resemble a mane of hair (pronotal comb) and mustache (genal comb) (Table 85.2).

Clinical features

Flea bites present as intensely pruritic papulovesicles, usually located on the lower legs. Other parts of the body may also be affected, especially when an infested pet has been groomed or held. Flea allergy is common, and allergic patients tend to react to a wide range of fleas. Flea pupae can lie dormant for many months then hatch rapidly in response to vibration. Individuals who enter a vacant house can find that fleas rapidly besiege them.

Fleas serve as vectors for endemic (murine) typhus, flea-borne spotted fever, plague and (primarily among cats) *Bartonella henselae* infections (see Chs 74 & 76). Endemic typhus is common in southern Texas and California, where the cat flea and *Xenopsylla cheopsis* (the oriental rat flea) are the primary vectors, respectively. The disease has also emerged with a worldwide distribution. Feeding alone can transmit endemic typhus, although fleas also defecate infectious bloody feces when feeding.

Tungiasis (caused by the jigger or sand flea, *Tunga penetrans*) usually presents with papular necrotic lesions on the feet, often located adjacent to the great toenail (see Ch. 84). The incidence peaks during dry weather. A gravid female flea is typically found within the upper dermis

Fig. 85.6 ***Pulex irritans*****, the human flea.** The body is laterally compressed and no combs are present.

Fig. 85.7 Characteristic train-track hemorrhage associated with exposure to ***Megalopyge opercularis*** **(puss caterpillar).**

CHARACTERISTIC ANATOMIC FEATURES OF SEVERAL COMMON TYPES OF FLEAS	
Flea	**Characteristics**
Pulex	Round frons (forehead); single pair of hairs behind antennae
Xenopsylla	Round frons; several pairs of hairs behind the antennae; pleural rod (vertical thickening in mesothorax)
Ctenocephalides felis	Two ctenidia (combs) on the head*; sloped frons; six hair-bearing notches on dorsal hind tibia
Ctenocephalides canis	Two ctenidia (combs) on the head*; round frons; eight hair-bearing notches on dorsal hind tibia
Sticktight flea	Flat frons; broad lacinia (serrated piercing lance-like mouthpart)
*Resemble a mane of hair and a mustache.	

Table 85.2 Characteristic anatomic features of several common types of fleas.

of the lesions. Infestation most often occurs in beach areas and urban slums, and the flea is common on dogs, cats and rats.

Treatment

Lufenuron, an agent that prevents fleas from reproducing, is effective for animals in oral and injectable formulations. Fipronil is effective as a topical agent for the prevention of flea infestation. Boric acid, growth regulators such as pyriproxyfen, and insecticides may be helpful adjunctive treatments for the infested environment. The best source of information is a knowledgeable veterinarian.

Tungiasis is usually treated surgically. A double-blinded randomized controlled trial of oral ivermectin (300 mcg/kg on two consecutive days) showed it to be ineffective in treating patients with multiple lesions.

Lepidopterism

Key features

- Caterpillar dermatitis is caused by the larval form of a butterfly or moth
- Dermatitis may also result from the hairs or scales of adult lepidopterids
- Severe systemic reactions may occur with some species
- Important cause of ophthalmia nodosa

Introduction

Lepidopterism refers to the broad spectrum of adverse reactions to caterpillars, cocoons, butterflies and moths. Some authors use the term erucism for solely cutaneous reactions to these organisms or specifically for reactions to caterpillars[21,22]. A wide variety of species has been implicated[21].

Pathogenesis

Much of the irritation due to contact with the hairs of lepidopterids is purely mechanical in nature. Toxin-mediated reactions may be related to histamine, kinins, plasminogen activators and other proteinaceous toxins associated with hairs (setae), spines or hemolymph. Allergy usually does not play a significant role in the reactions.

Clinical features

Cutaneous manifestations include pain, pruritus, erythema, swelling, hemorrhage (Fig. 85.7), papules and urticaria. Cutaneous reactions may be accompanied by systemic reactions (e.g. respiratory distress or a bleeding diathesis with intracranial hemorrhage) (Table 85.3). Contact with Australia's white-stemmed gum moth (*Chelepteryx collesi*) produces yellow discoloration of the skin.

Dermatitis due to gypsy moth caterpillars may result from direct contact with the caterpillar or from hairs on clothesline-dried clothing. Erythematous urticarial papules and macular erythema with pruritus are commonly localized to the flanks, feet, inner aspects of the arms and legs, and collar region.

Ocular lesions caused by caterpillar hairs (ophthalmia nodosa) are similar to those caused by tarantula hairs. Ocular reactions to hairs include acute "toxic" conjunctivitis, chronic mechanical keratoconjunctivitis, subconjunctival granulomatous nodules, iritis and vitreoretinal involvement. The hairs tend to migrate inward in the direction of the sharp tip.

Children who ingest caterpillars tend to develop focal or diffuse erythema and edema of the lips, tongue and buccal mucosa. Esophageal and tracheobronchial involvement can also occur. Removal of hairs and spines may require endoscopy.

ARACHNIDS

Tick Bites (Class Arachnida: Subclass Acarina)

Key features

- Hard ticks are important disease vectors (e.g. Lyme borreliosis, RMSF)

CUTANEOUS AND SYSTEMIC REACTIONS ASSOCIATED WITH LEPIDOPTERISM			
Moth/caterpillar common name	**Scientific name**	**Locale**	**Clinical findings**
Gypsy moth caterpillar	*Lymantria dispar*	Northeastern US	"Dermatitis" from direct contact or from hairs on clothesline-dried clothing
Io moth caterpillar	*Automeris io*	US	Immediate stinging sensation, "dermatitis" (often transient urticarial papules)
Saddleback caterpillar	*Acharia stimulea* (formerly *Sibine stimulea*)	US	Immediate stinging sensation, "dermatitis" (often transient urticarial papules)
Buck moth caterpillar	*Hemileuca maia*	Eastern US	Immediate stinging sensation, "dermatitis"
Puss caterpillar	*Lagoa crispata* (also known as *Megalopyge crispata*)	Oklahoma and eastern US	Immediate burning sensation, "dermatitis"; in Oklahoma, spines contain high concentrations of tannins (ingested from oak trees)
Southern flannel caterpillar, puss caterpillar, wooly asp	*Megalopyge opercularis*	Southern US, Mexico and Central America	Immediate intense radiating pain; characteristic "railroad track" pattern of hemorrhage (Fig. 85.7); edema, hives and systemic symptoms may occur
Saturniid moth caterpillar, giant silkworm moth	*Lonomia achelous, L. oblique*	Latin America	Local and severe systemic reactions, especially a bleeding diathesis (with complications such as renal failure)
Processionary caterpillars: pine, Cyprus and oak (characteristically travel single-file)	*Thaumetopoea pityocampa*, *T. wilkinsoni*, *T. processionea*	Mediterranean region, central Europe, Britain	Urticaria (often immunologic), angioedema, anaphylaxis, conjunctivitis, respiratory distress, abdominal pain, hypertension, lytic bone lesions in the digits; airborne urticating hairs are spread by the wind
Pine moth caterpillar and cocoon	*Dendrolimus punctatus*	China, imported elsewhere	"Dermatitis", arthritis (usually monoarticular), chondritis, ophthalmia nodosa
Tussock moth caterpillar	*Orgyia pseudotsugata*	Western US, especially Pacific Northwest	"Dermatitis", pruritus of the skin and eyes as well as respiratory symptoms (irritant and allergic mechanisms); forestry workers
Yellowtail moth (adult female)	*Hylesia metabus*, *H. alinda*	Mexico and South America (including *H. metabus* in the Venezuelan port of Caripito)	Papular urticaria ("Caripito itch"); ship crew members are classically affected

Table 85.3 Cutaneous and systemic reactions associated with lepidopterism. "Dermatitis" can include pruritic urticarial papules as well as eczematous reactions. Tape stripping of skin has been used to identify caterpillar hairs (setae). Caterpillars can have short spines projecting from a long slender shaft or short tapered shafts with ball-in-socket structures resembling trichorrhexis invaginata.

- *Ornithodoros* soft ticks transmit borrelial relapsing fever
- *Dermacentor* ticks hidden in the scalp represent an unusual cause of paralysis
- Correctly identifying the tick allows patients to be counseled appropriately
- Tick control measures are important in preventing disease

Introduction

Patients with tick bites often present with the tick still attached[23]. They are usually aware of the diagnosis, although some individuals may misinterpret the tick as a "new mole". Scalp attachments are particularly common for *Dermacentor* ticks, and the patient may be completely unaware of a tick that is hidden by hair. This is of concern considering that *Dermacentor* ticks produce a neurotoxin that can cause paralysis when these ticks are attached for ≥4 days[24,25]. Symptoms resolve rapidly when the tick is removed, but rare fatalities from tick paralysis have been reported. Any child presenting with rapidly progressive ascending flaccid paralysis should be examined for ticks. In Australia, *Ixodes* ticks can cause paralysis, but this occurs primarily in dogs.

Correct identification of an attached tick provides the physician with an opportunity to discuss tick control measures and symptoms of tick-borne disease[26,27]. Most hard ticks have a three-host life cycle. Larval (seed) ticks have six legs and feed on small animals in nature (see Fig. 76.1). The nymphs and adults feed on larger animals. Nymphs resemble small adult ticks, with eight legs, but are sexually immature. Because they attach for one long blood meal during each phase of the life cycle and search for a new host for each blood meal, ticks are efficient disease vectors. Hard ticks have a hard dorsal plate (scutum) and account for most medically important ticks, transmitting human diseases including Lyme borreliosis, ehrlichiosis, granulocytotropic anaplasmosis and a variety of rickettsial infections (including Rocky Mountain spotted fever; RMSF) (see Table 76.1). Soft ticks such as *Ornithodoros* (the vector of borrelial relapsing fever) lack a scutum and have retroverted mouthparts. These ticks tend to live in close association with a single host.

Clinical features

Once the tick has been removed, hypersensitivity reactions at the site are common. Papular, nodular and vesiculobullous lesions can occur and are typically pruritic. Hypersensitivity reactions presenting as erythematous plaques are commonly misinterpreted as erythema migrans. Nodules with pseudolymphomatous histology can also develop.

Treatment

Milder tick bite reactions may respond to application of a potent (class 1 or 2) topical corticosteroid; lesions may fail to improve unless the agent is occluded. More intense reactions often require intralesional corticosteroid injection, and some only respond to surgical excision. Often, the pruritus is so severe that patients express little concern about the discomfort and scar associated with the surgical procedure.

Most tick-borne diseases respond readily to tetracyclines. Empiric treatment of suspected RMSF is always appropriate, and therapy should never be delayed until confirmatory tests are available. The consequences of delayed diagnosis and treatment of RMSF are evidenced by reports of deaths in children[28]. Doxycycline is the drug of choice for children as well as adults with RMSF. Staining of teeth is unlikely with a short course of doxycycline, and chloramphenicol is less effective for RMSF.

Environmental measures

Exclusion of animal hosts from communities and recreational areas can be helpful in control of tick-borne illness (Table 85.4), although this may be difficult to achieve for small animal hosts (e.g. mice, rabbits). There is evidence that communities located close to wildlife reserves have higher rates of tick-borne illnesses. Oral agents, such as the

TICK CONTROL MEASURES	
Personal	**Environmental**
Protective clothing tightly laced, snapped or tied	Removal of leaf debris
Clothing treated with permethrin	Area acaricide application
Clothing treated with repellents such as DEET	Exclusion of animal hosts
Regular tick inspections	Acaricide-treated feed corn

Table 85.4 Tick control measures.

avermectins, can be placed in corn eaten by deer to kill ticks that feed on the deer. Injectable ivermectin is helpful in reducing tick infestation of livestock. Removal of leaf debris is a critical part of tick control efforts because it: (1) enables acaricides to reach the ticks; and (2) leads to a reduction in tick numbers via dehydration of adults (which require leaf debris to maintain hydration) and eggs (which require sufficient humidity to hatch).

Repellents

Permethrin, a pyrethroid insecticide with little mammalian toxicity, has been marketed as a tick repellent. The spray formulation is the most widely available form. Once applied to clothing, it is stable through several wash cycles. It is also suitable for treating sleeping bags, tents, and fabric used for insect screening. A liquid concentrate has been used to impregnate fabric for as long as the life of the garment. Permethrin is particularly helpful in the prevention of tick and chigger bites. These crawling arthropods must travel across the treated fabric, whereas flying insects tend to be attracted directly to exposed skin. The combination of a DEET-containing repellent and permethrin-treated clothing is generally highly effective against a wide range of biting arthropods.

Some North African camel ticks have demonstrated high-level resistance to permethrin. Instead of killing the tick, permethrin may produce a pheromone-like attachment response. This attachment phenomenon has not yet been described in North American ticks, but permethrin resistance does occur. High-level permethrin resistance in cattle ticks has been linked to outbreaks of bovine babesiosis and anaplasmosis in Mexico[29].

Methods to eliminate and prevent tick infestations in dogs include monthly topical application of products containing fipronil or permethrin, as well as collars impregnated with amitraz and pyriproxyfen[30].

Tick removal

Several plastic tick removal devices are marketed. I have had particular success with the "Tick Nipper™", an inexpensive plastic device that grasps the tick just behind the mouthparts without severing them. Similar devices have been made out of plastic spoons and credit cards with the aid of a sharp pair of scissors or hot blade. Petroleum jelly, fingernail polish, isopropyl alcohol and hot matches are generally ineffective.

Ticks should be removed as completely as possible, and care should be taken not to squeeze the abdomen. Gentle traction is generally preferred, but a twisting motion can also be used. Although the latter technique may leave a small mouth part, this is of little clinical consequence. Hands should be washed if they were in contact with the tick.

Antibiotic prophylaxis after tick bites

Antibiotic prophylaxis after tick bites remains controversial, and most authorities do not recommend its routine use. Certainly, it would be difficult to justify the cost and risks of widespread use of prophylactic antibiotics for every tick bite. On the other hand, if the ticks are correctly identified as endemic disease vectors and are heavily engorged, the risk–benefit ratio may weigh in favor of prophylactic treatment.

If the dose is sufficient and the antibiotic is given at the appropriate time, prophylaxis is capable of preventing tick-borne disease. However, because incubation periods vary, timing of a *single* dose of an antibiotic can be difficult. In the case of RMSF, a single dose can prevent disease if given shortly before the expected onset of illness, but a single dose may only delay the onset of clinical symptoms if administered too early in the course of incubation.

Therefore, because of this difficulty with correct timing, if the decision is made to administer a prophylactic antibiotic, I recommend a full 10-day course of therapy rather than single-dose prophylaxis. This recommendation also applies to *Ixodes* tick bites and Lyme disease; however, some authors do recommend single-dose prophylaxis for Lyme disease on a case-by-case basis (see Ch. 19). A controlled trial compared 10 days of oral doxycycline (with or without a single intravenous dose of ceftriaxone) versus 20 days of oral doxycycline for the treatment of early Lyme disease. During a 30-month follow-up, the response rate was similar for all three treatment groups in both on-study and intention-to-treat analyses.

Special consideration must be given to the prophylactic treatment of pregnant women. In such cases, the risks of prophylactic therapy for both the mother and the unborn child must be weighed against the risks and responsiveness to treatment of disease in both individuals.

Amblyomma Ticks

Synonym: ■ Lone star tick

Key features

- Ornate scutum (hard dorsal plate)
- Single white dorsal spot on female *Amblyomma americanum*
- Papular, nodular and bullous lesions at attachment sites
- *Amblyomma* ticks are vectors of ehrlichiosis, several rickettsial infections, southern tick-associated rash illness (STARI), and tularemia

Introduction

Amblyomma ticks are particularly common in the southern US. This, plus the characteristic white dorsal spot of the female *A. americanum* (Fig. 85.8), has given rise to the common name "lone star tick". Males have ornate markings that often form pale "inverted horseshoes" on the posterior portion of their dark scutum. *Amblyomma* ticks have prominent eyes, festoons (grooves in the posterior edge of the scutum) and long anterior mouthparts.

A. americanum has a wide distribution, from Texas to Iowa and Connecticut (see Fig. 76.10). The range of this tick is expanding, partly because of the explosion in the white-tailed deer population[31]. Other species of *Amblyomma* ticks are common in Africa, the Caribbean, and Central and South America. Some *Amblyomma* ticks attach to birds, and migration of avian hosts has been implicated in dissemination of tick-borne diseases.

Clinical features

Amblyomma tick attachments favor the legs, buttocks and groin and often affect people who work outdoors or take part in outdoor recreation (e.g. construction workers, fishermen, hunters, hikers), especially when new development displaces the tick's usual hosts. Patients usually become aware of *Amblyomma* tick bites while the tick is still attached. This is partly because the ticks often attach in large numbers. Once the tick has been removed, delayed-type hypersensitivity to tick antigens can lead to a reaction at the attachment site. Papular, nodular and bullous lesions are common.

A. americanum is the major vector of *Ehrlichia chaffeensis*, the agent of human monocytotropic ehrlichiosis[32]. This disease has been documented in more than 30 states, with systemic symptoms similar to those of RMSF (e.g. fever and headache) and variable cutaneous manifestations (see Ch. 76). *A. americanum* is also the primary vector for *Ehrlichia ewingii* infection.

Southern tick-associated rash illness (STARI; "Missouri Lyme disease") was originally described in Missouri but can also occur in other southern states[33]. It presents with an expanding erythematous annular plaque 3–14 days after *A. americanum* attachment, often in association with fever, headache, myalgias and arthralgias. Although the symptoms resemble those of Lyme disease, *Borrelia burgdorferi* does not appear to be involved, other infectious agents (e.g. *Borrelia*

Fig. 85.8 ***Amblyomma americanum*** **(lone star tick).** Note the characteristic white dorsal spot on the female ticks. The female's scutum often covers only a portion of the body to allow room for engorgement.

lonestari) have not been consistently identified, and the cause remains unknown.

Amblyomma ticks have been implicated in the transmission of RMSF (*Rickettsia ricketsii*; primarily in Central and South America, where it may be referred to as Brazilian spotted fever), American tick bite fever (*Rickettsia parkeri*), African tick bite fever (*Rickettsia africae*) and tularemia (see Chs 74 & 76).

Dermacentor Ticks

Synonyms: ■ *D. andersoni:* Rocky Mountain wood tick ■ *D. variabilis*: American dog tick

Key features

- Large ticks
- Ornate scutum (hard dorsal plate) with deep punctuations
- The adult tick prefers to attach to the head, neck and shoulder
- *D. variabilis* is the major vector for RMSF in the United States, while *D. andersoni* can transmit Colorado tick fever as well as RMSF

Introduction

Dermacentor ticks are commonly found in open areas with low bushy vegetation, but they are scarce in heavily wooded areas. Peak abundance of the tick is in April and May, declining by July. *Dermacentor* ticks have an ornate scutum, prominent eyes and festoons (grooves in the posterior scutum), small anterior mouthparts, and a rectangular basis capituli. Both *D. variabilis* (Fig. 85.9) and *D. andersoni* have brown legs, and coxa 1 (the attachment base for the first pair of legs) is bifid. Coxa 4 is greatly enlarged in the male, and males have no ventral plates. As in most hard ticks, the scutum in the female is smaller, leaving a portion of the abdomen exposed.

D. variabilis is found throughout the US, except for the Rocky Mountain states. In parts of Canada, its range overlaps with that of *D. andersoni*, which is generally confined to the Rocky Mountains. In Georgia and South Carolina, *D. variabilis* is the second most common tick found on humans (*A. americanum* being the most common).

Pathogenesis

During the course of engorgement, *D. andersoni* saliva downregulates cell-mediated immunity. This phenomenon may explain the delayed onset of many nodular tick bite reactions. It might represent an adaptive mechanism, allowing the tick to feed unnoticed.

Clinical features

Dermacentor ticks preferentially attach to the head and neck region; in contrast, *Amblyomma americanum* prefers the lower legs, buttocks and groin, and *Ixodes scapularis* shows less site preference but most often attaches to the trunk. Prolonged attachment of a *Dermacentor* tick is the most frequent cause of tick paralysis in the US (see above).

Fig. 85.9 ***Dermacentor variabilis*** **tick (engorged female) with an ornate scutum.** This species is the major vector for Rocky Mountain spotted fever in the US.

D. variabilis is the major vector for RMSF in the US. The highest incidence of RMSF is in the eastern states where this tick resides, especially in North Carolina (see Fig. 76.2). RMSF typically presents with fever and headache. An acral eruption of erythematous macules and/or petechiae may be evident but is commonly absent, especially early in the disease process. As many as 40% of patients with RMSF are not aware of a recent tick bite. As the mortality rate in RMSF is heavily dependent on the time between onset of symptoms and initiation of antibiotic therapy, the disease should be considered in every patient with fever and a headache in endemic areas.

D. andersoni is the major vector for RMSF in the Rocky Mountain states, and it is also the vector for the viral illness Colorado tick fever. Because the symptoms of Colorado tick fever overlap with those of RMSF, specific diagnostic tests such as paired serologic studies (acute and convalescent) and immunohistochemical staining, direct immunofluorescence or PCR-based analysis of lesional skin biopsy specimens can help to confirm the diagnosis of RMSF (although empiric treatment should not be delayed until the results are available). Additional diseases that can be transmitted by *Dermacentor* ticks include tularemia, rickettsial infections in Europe and Asia, and (occasionally) monocytotropic ehrlichiosis and Q fever (*Coxiella burnetii*).

Rhipicephalus Ticks

Synonym: ■ Brown dog tick

Key features

- Common dog ticks
- Most are brown with brown legs, a teardrop shape and inornate scutum (hard dorsal plate)
- Vectors for Boutonneuse fever and (occasionally) RMSF in the southwestern US

Introduction

Rhipicephalus ticks (Fig. 85.10) are common dog ticks that are typically brown in color with an inornate scutum. They have prominent eyes and festoons (grooves in the posterior scutum), but small mouthparts attached at a hexagonal basis capituli.

Fig. 85.10 ***Rhipicephalus*** **ticks.** Common brown dog ticks; the lower tick is engorged with blood.

Fig. 85.11 ***Ixodes scapularis*** **tick.** The inornate brown scutum is overshadowed by the large, cream-colored, engorged abdomen.

Clinical features

Rhipicephalus ticks carry RMSF (primarily in the southwestern US and Mexico) and Boutonneuse fever (see Ch. 76). They may also be vectors for Congo-Crimean hemorrhagic fever virus, although *Hyalomma* ticks usually transmit this condition.

Ixodes Ticks

Synonyms: ■ Black-legged tick ■ Deer tick

Key features

- Teardrop shape, often with dark legs
- Inornate brown scutum (dorsal hard plate) that is small relative to the large abdomen in females
- Vectors for Lyme disease, human granulocytotropic anaplasmosis, and babesiosis

Introduction

Ixodes scapularis (formerly also known as *I. dammini*), the eastern black-legged tick, is the best known of the *Ixodes* ticks. Adult females are typically found attached to the host in late fall and spring. Their small, inornate brown scutum is often overshadowed by a large, soft, cream-colored engorged abdomen (Fig. 85.11). These ticks have short anterior mouthparts, prominent broad "antennae" and an upside-down U-shaped ventral groove with its apex anterior to the anus.

Clinical features

Ixodes ticks are vectors for Lyme disease, babesiosis and human granulocytotropic anaplasmosis[34,35]. Babesiosis is a malaria-like illness, whereas anaplasmosis is an acute febrile illness characterized by leukopenia, thrombocytopenia and increased serum hepatic transaminases. In the western US, *I. pacificus* (the western black-legged tick) is the major vector for Lyme disease (see Fig. 76.10). In the Great Lakes region and eastern US, *I. scapularis* is the major vector. *I. ricinus* and *I. persulcatus* are important vectors for Lyme disease in Europe and Eurasia, respectively. Because the larval and nymph stages of the tick often attach to birds in the spring and summer, avian migration (particularly of robins) may be responsible for the broad geographic distribution of the tick and of Lyme disease.

A single *Ixodes* tick may transmit more than one disease. In one study of a rural New Jersey county, 55% of adult *I. scapularis* ticks carried at least one disease (Lyme disease, 43%; babesiosis, 5%; anaplasmosis, 17%) and 10% carried more than one of the three diseases. Co-infection with more than one of these three diseases is also common in Wisconsin and Minnesota, and *I. scapularis* has been reported to carry both Lyme disease and anaplasmosis in New York City parks. *Ixodes* ticks carry viral encephalitis in Europe and transmit rickettsial infections in Europe and Australia (see Table 76.1).

Mites (Class Arachnida: Subclass Acarina)

Key features

- Mites are identified by their mouthparts and legs; the shape of their body, dorsal plates, and shields (sternal, anal and genitoventral); and the setae (bristles or hairs) on the latter structures
- Trombiculid mites are typically larval (chiggers; six-legged) when attached to a host; they are vectors for scrub typhus
- *Cheyletiella* mites are commonly found on pets and may produce papular or vesiculobullous lesions in the owner
- Species that parasitize birds, mammals and grains can produce dermatoses; the house mouse mite is a vector for rickettsialpox

Introduction

Mites are small arachnids that range from 0.1 to 2 mm in length. Tens of thousands of species exist worldwide (Table 85.5). The majority are free-living, but thousands of species parasitize animals or plants. Like fleas, most mites lack host specificity. Mites of medical importance may cause skin lesions, incite allergic reactions (especially in atopic individuals), or spread disease (Table 85.6). Like ticks, mites mature through larval, nymph and adult stages. Typically, there is a single larval stage (referred to as chiggers in trombiculid mites) and several nymphal stages. Most mites lay eggs, but some, such as the spiny rat mite (*Laelaps echidninus*), are viviparous, producing non-motile larvae. The

MITE FAMILIES	
Acaridae	Food mites
Demodicidae	Follicle mites
Dermanyssidae	Bird, rodent mites
Glycyphagidae	Food mites
Haemoganasidae	Straw mites
Psoroptidae	Mange, scab mites
Pyemotidae	Grain mites, straw mites
Sarcoptidae	Scabies mites
Trombiculidae	Chigger, harvest mites

Table 85.5 Mite families.

MITES OF MEDICAL IMPORTANCE	
Acarus siro	Grain mite: hay, grain, house dust
	Baker's itch
Cheyletiella spp.	**Walking dandruff on pets**
Cheyletus malaccensis	Wheat mite
	Wheat warehouse itch (Japan)
Demodex spp.	**Folliculitis; possibly rosacea, blepharitis; demodectic mange in dogs and cats**
Dermanyssus gallinae, *D. avium*	Fowl mite: chickens, wild birds, rodents, rabbits
Dermatophagoides farinae, *D. pteronyssinus*	Dust mite (**allergy**): dust, blankets, mattresses, pillows, pets, stored foods and grains
Euroglyphus maynei	Dust mite (**allergy, cross-reactions with other dust mites**)
Glycyphagus domesticus	Cheese mite, barn mite, grocer's mite: cheese, grains, hay, mattresses
	Grocer's itch
Laelaps spp., *Androlaelaps* spp., *Eulaelaps* spp.	Rodent mites
Lepidoglyphus destructor	Dust mite, hay mite
Liponyssoides (Allodermanyssus) sanguineus	House mouse mite
	Rickettsialpox
Neotrombicula autumnalis	Harvest mite (Northern Europe)
Ophionyssus natricus	Snake mite
Ornithonyssus sylviarum, *O. bacoti*, *O. bursa*	Tropical rat mite, fowl mite, tropical fowl mite, northern fowl mite: rodents, chickens, wild birds, carnivores
Pyemotes ventricosus, *P. tritici*	Straw itch mite, grain mite: parasites of insects in grains and straw
Trombicula (Eutrombicula) alfreddugesi	Chigger mite, red bug
Trombicula (Leptotrombidium) akamushi, *L. deliense*, *L fletcheri*, *L arenicola*, *L. pallidum*, *L. pavlovskyi*, *L scutellare*	Scrub mite
	Scrub typhus
Tyrophagus putrescentiae	Mold mite, grain storage mite
	Copra itch

Table 85.6 Mites of medical importance. Scientific names, common names and associated diseases (in bold) are listed.

straw itch mite (*Pyemotes tritici*) retains its young until they emerge as sexually mature mites. Sarcoptic mites are relatively species-specific and complete their entire life cycle on the host (see Ch. 84).

Clinical features

Cutaneous reactions to mites are common and include papular, papulovesicular, bullous, urticarial and morbilliform eruptions (Fig. 85.12).

Fig. 85.12 Avian mite bites. Multiple erythematous pruritic papules, several of which have hemorrhagic crusts. The exposure was birds nesting on the patient's house. *Courtesy, Jean L Bolognia, MD.*

PREPARATION OF COLLECTED MITES FOR MICROSCOPIC EXAMINATION
PREFERRED METHOD
• Clear with either lactic acid or lactophenol (may take hours to days) • Wash with water • Mount in Hoyer's medium*
RAPID METHOD
• Mount live or alcohol-fixed mites directly in Hoyer's medium* • Mount live mites in Permount™ (details of mites less obvious)
*Prepared by adding 30 g of gum Arabic to 50 ml distilled water, then adding 200 g chloral hydrate followed by 20 g glycerin; filter through cheesecloth.

Table 85.7 Preparation of collected mites for microscopic examination. If mites are collected onto filters inside a vacuum cleaner, the filter samples are treated with KOH, then floated in a concentrated sugar solution to collect the mites.

Chigger bites most often affect the lower legs, skin at the edges of underwear, and the genital region. Larvae of trombiculid mites in Asia are vectors for scrub typhus, while house mouse mites transmit rickettsialpox (see Ch. 76). Eschars at the site of the bite are a clue to rickettsial disease, and serologic testing can be helpful. As with tick-borne rickettsial diseases, biopsy of the eschar can be sent for immunohistochemical staining to distinguish typhus group organisms from the spotted fever group.

Differential diagnosis

Mite-induced dermatoses are often misdiagnosed. Bullous lesions are especially common, and false-positive direct immunofluorescence has been described. Histologic features resembling those of an insect bite may suggest the correct diagnosis, as may a clinical pattern of skin lesions corresponding to areas of contact. However, eosinophil-filled subepidermal bullae occur in both mite infestation and pemphigoid, so a careful history is essential.

Mite-induced dermatitis can be associated with pets, rodents, straw bedding, bird nests, grains and even onion bulbs (see Table 85.6). Avian mite dermatitis may also be associated with pet rodents, such as gerbils. Pets should be examined by a knowledgeable veterinarian, and skin scraping, adhesive tape stripping or biopsy may reveal the mite(s) on the animal. Vacuum cleaners can also be fitted with filters to collect mites (Table 85.7). Another helpful technique is to spray areas of dandruff or crust on a pet with an acaricidal agent recommended by a veterinarian. A fine-toothed comb or toothbrush is then used to remove the scale-crust, which is placed in a sealed bag. When alcohol is added to the bag, scale-crust and hair will sink, whereas mites will float.

Treatment

Some types of mites inflict a "bite and run" injury, while others remain attached for a prolonged meal. Scraping, tape stripping or vigorous washing with soap and water are all effective in removing or killing many of the attached mites. Scrapings, tape strippings and biopsy specimens may be helpful diagnostically as well as therapeutically.

Definitive treatment requires avoidance or treatment of the infested source. Mite identification can be helpful in establishing the likely source. Management of free-living, zoonotic and grocery mites will differ. An acarologist can be of immeasurable value in this setting. Gary Mullen and Lance Durden have written a superb text that I strongly recommend entitled "Medical and Veterinary Entomology". As noted above, animals should be examined and treated by a veterinarian. In public parks and training areas, animal exclusion and acaricides may be helpful measures. Personal protection with permethrin-treated clothing is also of value.

Skin lesions in humans may be treated with topical antipruritics such as camphor and menthol, or with topical anesthetics such as pramoxine. Potent topical corticosteroid preparations can be helpful, especially when occluded. Intralesional corticosteroid injections and excision of pruritic nodules may be necessary. Bullous and excoriated lesions can develop secondary infections, and wound care is important. Popular home remedies typically center around efforts to remove or kill attached mites, and counterirritants (e.g. propylene glycol in deodorant sticks) are often applied in an effort to reduce itching. Patients may present with irritant and allergic contact dermatitis to antiseptics, nail polish or even battery acid.

Chiggers

Introduction

Trombiculid mites are oviparous, depositing their eggs on the ground, leaves or blades of grass. After several days, the egg cracks, but the mite remains in a quiescent prelarval stage. After the prelarval stage, the six-legged larvae (chiggers) actively search for a suitable host. It is the larval mite that is found attached to the host. After a prolonged meal, the larvae drop off and mature through the eight-legged free-living nymph and adult stages.

Clinical features

Chigger bites are intensely pruritic, especially in highly sensitized individuals. Grouped papules, vesicles or bullae are typically found on the lower extremities, or where elastic meets the skin. Seasonal penile swelling associated with pruritus and dysuria in children is referred to as the "summer penile syndrome", and it appears to represent a hypersensitivity response to chigger bites.

Treatment

The topical antipruritics and anesthetics discussed above may be helpful. Most patients presenting to a dermatologist require potent topical or intralesional corticosteroid therapy. Vigorous washing with soap and water immediately after the exposure is helpful. Treatment of clothing with permethrin is a useful strategy for prevention.

Cheyletiella

Introduction

Cheyletiella are non-burrowing mites that are commonly found on cats (*C. blakei*), rabbits (*C. parasitovorax*) and dogs (*C. yasguri*). In humans, they are a frequent cause of cryptic mite-induced dermatitis. Infestations in animals are variably pruritic and produce a subtle dermatitis that presents with dry white scales, which is sometimes termed "walking dandruff". The animal should be evaluated by a veterinarian, and it is important to note that a single negative scraping does not exclude cheyletiellosis. In a study of dogs with *Cheyletiella*, samples collected by using a vacuum cleaner on the dog were shown to be significantly more sensitive than tape stripping, hair plucking, or skin scraping.

Clinical features

The typical patient with *Cheyletiella* dermatitis is a young or middle-aged woman who presents with grouped pruritic papules (Fig. 85.13).

Fig. 85.13 ***Cheyletiella*** **bites.** These mites are non-burrowing and are found on cats, rabbits and dogs.

It is uncommon to find the mite on the patient. Bullous eruptions caused by *Cheyletiella* mites may also mimic immunobullous disease (see above section).

Treatment

Skin reactions in humans should be treated as described above. Ectoparasitic dips or shampoos are often used by veterinarians to treat the infested animal. Fipronil (in a pump spray formulation applied to the animal) can be used in conjunction with permethrin spray (applied to the environment) to treat canine cheyletiellosis. Topical amitraz (used to treat canine scabies) may also be effective for *Cheyletiella*.

Spider Bites (Class Arachnida: Order Araneae)

Introduction

Spiders are arachnids, related to scorpions, ticks and mites. Many species of toxic spiders are found worldwide. The bite of *Phoneutria* wandering spiders in Brazil can be fatal in children, but most spider bites result only in a local cutaneous reaction. Toxic spiders are often regional in distribution, and many are poorly characterized. The most clinically significant spiders are discussed below. It is noteworthy that many important species in the US were not native to North America, but were imported in recent years as a result of worldwide travel and commerce. Examples are the hobo spider and *Loxosceles laeta* spider.

Widow Spiders (*Latrodectus*)

Key features

- Black widows are large, shiny black spiders with a round abdomen
- A variety of black, brown and red widow spiders exist worldwide
- In *Latrodectus mactans*, a red hourglass shape is seen on the ventral abdomen
- Acute pain and edema occurs at the bite site
- Systemic symptoms mimic acute abdomen and may include rhabdomyolysis

Introduction

Widow spiders (*Latrodectus* spp.) are found worldwide, with five species (including black, brown and red variants) in North America alone. *Latrodectus mactans* is the most common black widow spider in North America, with a range that extends to the Caribbean islands. *L.*

tredecimguttatus, *L. curacaviensis* and *L. indistinctus* are black widow spiders found in Europe, South America, and Africa (where referred to as a button spider), respectively. Female black widow spiders from North American species have a red hourglass-shaped mark on the ventral abdomen, while other species from various areas of the world have different red patterns. Brown (*L. geometricus*) widow spiders (characterized by an orange ventral hourglass shape) have a widespread distribution that includes the US, South America, and Africa. Australia has the red-back spider (*L. hasselti*) and New Zealand the red katipo spider (*L. katipo*).

Widow spiders are typically found in woodpiles, in shoes and under outhouse seats. Human envenomation usually occurs when the spider's environment is disturbed, and the spider is inadvertently trapped or pressed against the skin. Widow spiders are more aggressive when protecting an egg sack.

Pathogenesis

Black widow venom contains latrotoxins that act by depolarizing neurons, increasing intracellular calcium and stimulating uncontrolled exocytosis of neurotransmitters. Divalent cation-dependent tetramers related to α-latrotoxin can insert into lipid bilayers, forming membrane pores. Calcium-independent receptors for latrotoxin have also been identified.

Clinical features

The degree of morbidity caused by widow spider bites varies depending upon the species, age and sex of the spider (with only adult females capable of envenomation), amount of venom injected and site of the bite. Local skin reactions are usually limited to transient erythema, edema, sweating and piloerection. Extracutaneous manifestations are often prominent and can include painful muscle spasms (initially around the bite site, then more widespread), symptoms suggestive of an acute surgical abdomen, headache and nausea; generalized diaphoresis may also occur. The symptoms of brown widow bites tend to be milder and restricted to the tissues near the bite.

Treatment

Benzodiazepines and intravenous calcium gluconate can be helpful for associated tetany. In one study, calcium gluconate was shown to be superior to methocarbamol (Robaxin®). Antivenin can produce rapid relief of tetany and complications such as priapism that are unresponsive to other agents.

Loxosceles Spiders

Key features

- Brown recluse spider (*Loxosceles reclusa*) has a small body and long legs
- Dark brown fiddle pattern present on cephalothorax
- Dermonecrotic reactions
- Systemic reactions include shock, hemolysis, renal insufficiency and disseminated intravascular coagulation
- Other *Loxosceles* spiders can produce similar reactions

Introduction

Loxosceles spiders are found throughout the world and classically have a dark brown violin-shaped marking on the dorsal cephalothorax (Fig. 85.14). In the US, bites from *L. reclusa* (the brown recluse spider), *L. laeta*, *L. rufescens*, *L. deserta* and *L. arizonica* can cause skin necrosis, although reactions to the last three species are generally mild. Many other spiders are capable of producing dermonecrotic or systemic reactions, and bites of other spiders are often erroneously attributed to the brown recluse spider. Brown recluse spiders are most common in the south central US, from Tennessee and Missouri to Oklahoma and Texas (Fig. 85.15). They are often found in woodpiles, in attics and under radiators.

Most bites occur when the spider has been disturbed. *Loxosceles* spiders are non-aggressive, and there are reports of families living in houses infested by thousands of brown recluse spiders without a single bite. This suggests that brown recluse bites are over-diagnosed, especially in regions where the spider is rare. The diagnosis can be confirmed either by an enzyme immunoassay to detect *Loxosceles* venom in a skin biopsy or plucked hairs (obtained up to 4 days after the bite) or by a passive hemagglutination inhibition test (as long as 3 days after the bite).

Fig. 85.14 Brown recluse spider (*Loxosceles reclusa*). This spider has a small body, long legs, three pairs of eyes, and a dorsal violin pattern on the cephalothorax.

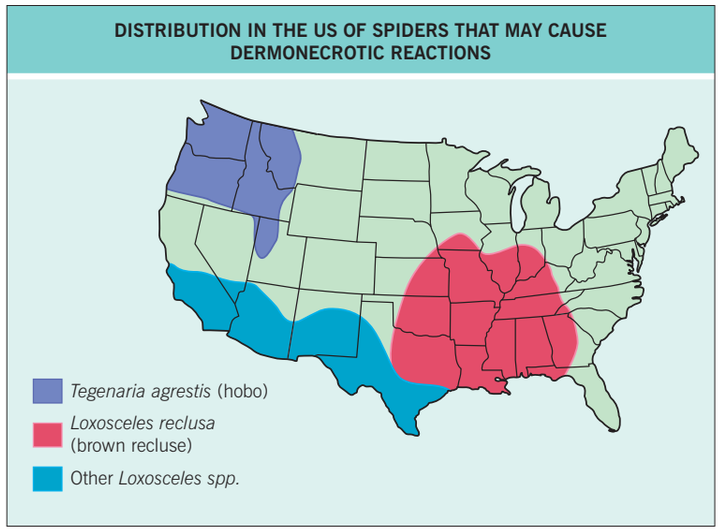

Fig. 85.15 Distribution in the US of spiders that may cause dermonecrotic reactions. *Adapted from: Sams HH, Dunnick CA, Smith ML, et al. Necrotic arachnidism. J Am Acad Dermatol. 2001;44:561–73.*

Pathogenesis

Sphingomyelinase D is the major toxin in brown recluse venom, and it interacts with serum amyloid protein. Hyaluronidase allows eschars to spread in a gravity-dependent fashion. Neutrophils are not directly activated by the venom, and neutrophil activation may be dependent upon the interaction between the venom and endothelial cells. The venoms of geographically diverse spiders such as *L. reclusa*, *L. laeta*, *L. deserta*, *L. gaucho* and *L. intermedia* have similar sphingomyelinase activity and electrophoretic profiles, with a major protein band at 32–35 kDa. All contain hyaluronidase as well as metalloproteinases with fibrinogenolytic activity. The similarity of these venom components and documented cross-reactivity suggests the potential for a single global *Loxosceles* antivenin[36].

Clinical features

Even in the case of brown recluse spiders, the majority of bites do not cause serious reactions. Local pain is frequently delayed until several hours after the bite, which most often occurs on an extremity. Cutaneous reactions typically begin with erythema and then develop central vesiculation or duskiness with a blanched halo, which may evolve into hemorrhagic bullae and necrosis (Fig. 85.16)[37]. Dermonecrotic reactions can eventuate in dry, necrotic eschars or ulceration. Upper airway obstruction caused by envenomation of the neck by brown recluse spiders has been reported. Systemic reactions include disseminated intravascular coagulation (DIC) and Coombs'-positive hemolytic anemia[38,39]. *L. arizonica*, a spider found in the southwestern US, causes less severe necrosis but has been implicated as a cause of shock.

Pathology

Histologic findings have been best described in laboratory models of brown recluse spider envenomation in rabbits[40]. The findings are time-dependent, with early biopsy specimens demonstrating a neutrophilic infiltrate. Later changes include "mummified" coagulative necrosis of the epidermis, adnexal epithelium and superficial dermis. A neutrophilic band-like infiltrate may still mark the border between viable skin and eschar. Small vessel vasculitis and thrombosis are often evident adjacent to the neutrophilic band, and larger vessel vasculitis resembling polyarteritis nodosa may account for the extent of tissue necrosis seen after some bites. Arterial thrombosis leading to gangrene of the foot has been reported[41].

Treatment

Optimal treatment to prevent dermonecrotic reactions remains elusive. Most bites can be treated with rest, ice and elevation. Intradermal injection of polyclonal anti-*Loxosceles* Fab antibody fragments can attenuate necrosis in an animal model up to 4 hours after envenomation, and antivenin may reduce the ultimate size of the necrotic area even when administered up to 48 hours after envenomation[42]. Hyperbaric oxygen therapy may decrease the final size of ulceration, although results have varied. Studies with more widely available agents such as dapsone, colchicine, triamcinolone and prednisone have been inconsistent and often disappointing. Dapsone therapy is complicated by the potential for hemolysis, especially in individuals who have an inherited glucose-6-phosphatase dehydrogenase (G6PD) deficiency. Given the potential for harm and the lack of consistent data showing any benefit, I do not recommend therapy with any systemic agent except antivenin (if available) and prednisone (in the case of systemic reactions). On the basis of anecdotal human data and limited animal data showing some suggestion of efficacy, intralesional triamcinolone can be tried[43].

Funnel Web Spiders

Key features

- Large, hairy, aggressive spiders found in dark, moist areas such as basements
- Funnel-shaped webs
- *Tegenaria agrestis* (hobo spider, aggressive house spider), found in the northwestern US, Canada and Europe, is 4–5 cm in diameter and may cause necrotic arachnidism
- Other funnel web spiders can produce local and systemic reactions

Introduction

When *Tegenaria agrestis* (hobo spider) was imported to North America from Europe, this funnel web spider found few major competitors and became common in human dwellings in the northwestern US (see Fig. 85.15), usually in basement webs at soil level in contact with concrete or stone. In Europe, the hobo spider has a largely rural habitat while the less aggressive *T. gigantea* (also known as *T. duellica*; giant house spider) and *T. domestica* (domestic house spider) are more likely to be found in human dwellings. The sternum of the hobo spider has a lightly colored center, with dark vertical bands on the sides. Medically important funnel web spiders are also found in Australia.

Fig 85.16 Brown recluse spider bite with central dusky necrosis.

Pathogenesis

Hobo spider toxins may cause local necrosis and directly affect the CNS. Australian funnel web spider robustoxin binds to autonomic and motor neurons. Agatoxins from *Agelenopsis apena*, the native American funnel web spider, target ion channels.

Clinical features

T. agrestis bites may produce necrosis, although there are few dermonecrotic reactions to bites from this spider documented in the literature. Bites are uncommon in Europe, because the spider is rarely found in European homes. Systemic symptoms can include headache, nausea and weakness; hemolysis and thrombocytopenia may also occur. Bites of Australian mygalomorph spiders, including the funnel web spiders of the genera *Hadronyche* and *Atrax* and mouse spiders of the genus *Missulena*, are often associated with severe pain, puncture marks, local redness and bleeding. Severe systemic symptoms (including myocardial injury) are more likely with funnel web spiders than with mouse or trapdoor mygalomorph spiders.

Tarantulas (Family Theraphosidae)

Key features

- Typically large hairy spiders, up to 15 cm in diameter
- Normally non-aggressive
- Urticating hairs are thrown at skin and eyes
- Important cause of ophthalmia nodosa

Introduction

Tarantulas are large hairy spiders common in the southwestern US. Many related species occur throughout the world. They are often sold in pet stores. Most tarantula bites do not produce severe systemic toxicity.

Many species of tarantulas possess urticating hairs in a characteristic patch on the dorsal abdomen. These hairs are used in a defensive fashion to drive predators from the spider's burrow. Vibrations of the hind legs are used to flick hairs at the perceived attacker. Urticating hairs are absent on most African and Asian species.

Clinical features

Itching at the site of urticating hair penetration may persist for several weeks after exposure. Hairs that penetrate the cornea can result in ophthalmia nodosa, a chronic granulomatous reaction that can lead to loss of vision.

Pathology

Urticating tarantula hairs penetrate the stratum corneum and epidermis and may extend as deep as the reticular dermis.

Scorpions (Class Arachnida: Order Scorpiones)

Key features

- Large anterior claws
- When threatened, the long tail is curved upward to sting
- Blunt thorn on the tail of *Centruroides* spp.

Introduction

Many toxic scorpions exist worldwide. Scorpions are typically found under tabletops, in woodpiles and in shoes. They sting when disturbed and accidentally trapped by a hand or foot. Several clinically relevant species are listed in Table 85.8.

Clinical features

Local and systemic symptoms (e.g. pain, paresthesia) are typically out of proportion to cutaneous signs such as erythema and edema, which are not usually prominent at the site of the sting.

Treatment

Antivenin is available in endemic areas and, along with supportive care, has been shown to reduce morbidity and mortality from severe scorpion envenomation[44,45]. However, application of ice is sufficient for most minor scorpion envenomations[46].

DIFFERENT SPECIES OF CLINICALLY IMPORTANT SCORPIONS

Locale	Species	Comments
Africa	*Parabuthus granulatus, P. capensis, P. transvaalicus, Uroplectes lineatus* and *Leiurus quinquestriatus*	Fat tails; highly toxic
Asia and North Africa	*Androctonus australis* and *Buthus occitanus tunetanus*	
Asia	*Androctonus crassicauda*	
Brazil	*Tityus serrulatus*	Yellow in color; implicated as a cause of death in children
Southwestern US, especially Arizona	*Centruroides exilicauda*	Rarely associated with deaths; public health risk has been overestimated
Central US, especially Texas	*Centruroides vittatus*	Painful sting
US, Mexico and Central America	*Centruroides noxious, C. limpidus* and C. *suffusus*	Toxic; some deaths attributed to *Centruroides exilicauda* may be due to these species

Table 85.8 Different species of clinically important scorpions.

CENTIPEDES (CLASS CHILOPODA) AND MILLIPEDES (CLASS DIPLOPODA)

Key features

Centipedes

- Long, worm-like bodies that are flattened dorsoventrally
- 17 or more segments; up to 20 cm in length
- Each segment, except the last one, has one pair of legs
- Pain, edema and erythema at bite sites

Millipedes

- Long, cylindrical, worm-like bodies with many segments
- Each segment has two pairs of legs and two pairs of respiratory spiracles
- Do not bite (biting jaws are absent), but can cause chemical irritant contact dermatitis

Introduction

Centipedes are fierce hunters. They inject a neurotoxic venom through venom ducts in their jaws. Millipedes do not bite but can cause burn-like reactions.

Clinical features

Centipede bites may produce pain, erythema and edema. They can bleed profusely and are frequently associated with paresthesia. Centipede ingestion by children can result in systemic toxicity. Rarely, bites lead to severe systemic symptoms such as coronary ischemia, rhabdomyolysis, proteinuria and renal failure. The Vietnamese centipede, *Scolopendra subspinipes*, is a large, aggressive tropical centipede that has recently become popular as a pet, and local bite reactions can be severe.

Millipedes do not bite, but they can secrete noxious substances that result in a chemical irritant contact dermatitis. Millipede burns frequently involve the eyes, and millipedes in line-dried clothing can produce widespread dermatitis. Of note, millipede burns and associated brownish skin discoloration (which can persist for months) may be misdiagnosed as child abuse.

Treatment

Centipede bites seldom require more than symptomatic treatment, although systemic symptoms may be very frightening to the patient. Children bitten by a centipede often report they have been bitten by a snake. The minor degree of edema compared to that associated with snake bites as well as the characteristic chevron shape of the centipede bite can be helpful distinguishing features. Ice packs, analgesics and hot water immersion provide similar improvements in pain after centipede envenomation[47], and ice is the most easily administered of these treatments.

SNAKE BITES

Key features

- Rapid onset of pain and swelling
- Symptoms depend on species and amount of venom injected
- Antivenin may be life-saving, but it does not prevent all complications and may cause anaphylaxis

Introduction

Snake bites occur primarily in individuals who engage in outdoor activities, especially camping and hiking. Occupational bite injuries may also affect those who raise snakes and are particularly common in those who extract venom. Death from a snake bite is rare in the US, but more common in Africa and Asia[48]. Although the overall incidence of severe rattlesnake bites in the US has decreased over time, the incidence of fatal rattlesnake bites has remained relatively stable[49].

Clinical features

Snake bites are typically associated with marked edema within an hour of the envenomation. Hemorrhage and necrosis are common. The presence of paired bite marks is often noted.

Treatment

Antivenin therapy is an important part of management and may be of benefit even after significant delays in administration. Adverse reactions to antivenin usually take the form of serum sickness or anaphylaxis. Preparations to treat anaphylaxis should be made before initiating antivenin therapy. Hypersensitivity to antivenin is a particular problem

for those who have been previously treated. The evaluation of antivenin reactions is complicated because serum sickness and snake bites share some signs and symptoms, and repeated snake bites can be independently associated with IgE-mediated anaphylaxis. Even in individuals who have never received previous treatment, snake antivenin can result in anaphylactoid reactions.

Thrombocytopenia induced by rattlesnake venom is only partially reversed by Antivenin (Crotalidae) Polyvalent administration, and DIC caused by North American crotalid snakebites can occur even after antivenin treatment. DIC also occurs with envenomation by some exotic vipers. In India, where the cost of antivenin therapy is a critical factor, low-dose regimens have been shown to be an effective alternative. However, data on Australian brown snake envenomation suggest that many patients are underdosed with antivenin.

Tourniquets have been associated with tissue ischemia if improperly applied. Studies have not been performed for all snakes, but for at least some, tourniquet application appears to be of little benefit.

DOG AND CAT BITES

Key features

- Bites may be unprovoked, especially with dogs
- Infection is common and pathogens include *Pasteurella* spp. and *Capnocytophaga canimorsus*
- Antibiotic treatment is generally considered mandatory

Introduction

Cat bites are commonly provoked, whereas the majority of dog bites are unprovoked[50]. Dog bites are particularly common in children, and the dog is usually a family pet or a neighbor's dog.

Rabies still occurs almost everywhere in the world, with exceptions including New Zealand, parts of Europe, parts of South America, and isolated Pacific islands. Rabies associated with dog bites remains a problem in low-income countries. Fortunately, because of vaccination programs, rabies related to dog bites is rare in high-income countries, where most human rabies is associated with bat exposure. In the US, rabies is carried primarily by bats, raccoons and skunks. Although unvaccinated dogs occasionally acquire rabies from wild animals, the canine rabies virus variant that is responsible for dog-to-dog transmission has not been identified in the US since 2004. Oral rabies vaccination programs using bait to target gray foxes and coyotes in Texas and raccoons in the eastern US have helped to decrease the spread of rabies.

Local health authorities should be contacted to report a dog or cat bite and (if necessary) to arrange for quarantine. Latex agglutination testing of dog saliva for rabies antigen is 95% sensitive compared to fluorescent antibody testing on brain smears.

Clinical features

Common pathogens associated with bite wounds include streptococci, staphylococci, *Pasteurella* spp., *Capnocytophaga canimorsus* and anaerobes. Breast implant infection and lung abscesses due to *Pasteurella multocida* have both been linked to cats, and staphylococcal endocarditis has been reported after a cat bite (without a preceding local infection); brain abscess formation has been observed following a dog bite. In immunocompromised patients, there is a significant risk of *Pasteurella* or *Capnocytophaga* sepsis. *Capnocytophaga canimorsus* sepsis has a high mortality rate and has been associated with purpura fulminans. Human bites have a higher likelihood of infections with *Staphylococcus aureus* and *Eikenella corrodens*. The most common pathogens associated with bite wound infections are listed in Table 85.9[51–54].

Treatment

A combination of a β-lactam antibiotic and a β-lactamase inhibitor (e.g. amoxicillin/clavulanic acid) provides good coverage for most organisms associated with dog and cat bites[51–54]. Alternatives include: (1) second-generation cephalosporins with anaerobic activity; (2) penicillin plus a first-generation cephalosporin; or (3) clindamycin plus a fluoroquinolone. Hospitalization of patients due to *Pasteurella*-infected animal bite wounds is strongly associated with initial use of suboptimal antibiotic therapy. With appropriate antibiotic therapy, primary repair is appropriate for dog bites to the face.

PATHOGENS ASSOCIATED WITH HUMAN AND ANIMAL BITE WOUND INFECTIONS

Bite	Pathogens
Human bites	*Staphylococcus aureus* *Streptococcus pyogenes* *Eikenella corrodens* Various anaerobes†
Cat bites	*Pasteurella multocida* (75%)* *Moraxella* spp. *Neisseria weaveri* *Bergeyella zoohelcum* Various anaerobes†
Dog bites	*Pasteurella* spp. (*canis* > *multocida*) (50%)* *S. aureus* (20%) *S. pyogenes* *N. weaveri* *Capnocytophaga canimorsus* *B. zoohelcum* Various anaerobes†
Horse and sheep bites	*Actinobacillus* spp. *Pasteurella* spp. Various anaerobes†
Marine animal bites	*Vibrio* spp. *Aeromonas hydrophila* *Pseudomonas* spp. *Plesiomonas shigelloides*

*Relatively short incubation period of 12–24 hours.
†May include *Fusobacterium, Bacteroides, Porphyromonas* and *Prevotella* spp.

Table 85.9 Pathogens associated with human and animal bite wound infections. Most infections are polymicrobial and include aerobic and anaerobic bacteria (median of 4–5 isolates), which can originate from the skin of the patient as well as the oral flora of the biting animal or human.

LEECHES

Key features

- Associated with fresh water
- Purpura and bleeding

Introduction

Leech attachments occur after contact with bodies of fresh water such as ponds or rivers.

Pathogenesis

Leeches prevent blood coagulation, partly through interference with platelet aggregation. Medical leeches have been associated with *Aeromonas hydrophila* wound infection.

Clinical features

Leech attachment sites often become purpuric and may bleed freely when the leech is removed. Leeches can attach to the tonsils (resulting in hemoptysis) or inside the nose (causing epistaxis). Disordered coagulation associated with massive bleeding and anemia has been reported after a leech bite[55].

Treatment

Leech removal is often complicated by bleeding or infection. Saturated salt solutions have been used to facilitate leech removal.

Leech therapy

Medical leeches and hyperbaric oxygen have been used together to enhance the survival of skin flaps subjected to venous occlusion. Sated leeches can be induced to continue feeding from the flap by posterior crop (stomach) incision and immersion in a serotonin solution.

MARINE INJURIES

Key features

- Marine organisms contain some of the most potent toxins known
- Drowning can occur after loss of consciousness following envenomation
- Penetrating injuries are prone to secondary infection
- Marine *Vibrio* infections are more common in patients with liver disease
- First aid for most marine venoms includes immersion in hot, but not scalding, water

Introduction

Penetrating marine injuries may be complicated by secondary bacterial infection. *S. aureus* is the most common organism, but *Vibrio* infections also occur. *Vibrio vulnificus* sepsis is strongly associated with liver disease, especially cirrhosis (see Ch. 74). Although most infections are related to ingestion of oysters or injuries in brackish water, the organism can survive on the skin for more than 24 hours, and infection has been reported after a penetrating injury on dry land. Seal finger, resulting from seal bites to the hand, is caused by *Mycoplasma* infection. Cutaneous infections with *Erysipelothrix rhusiopathiae* (see Ch. 74), *Aeromonas hydrophila* and *Mycobacterium marinum* (see Ch. 75) can also be acquired from trauma in an aquatic environment[56].

Pathogenesis

Cnidarians (including jellyfish, corals and sea anemones) are aquatic animals that produce specialized epidermal cells called cnidocytes with organelles referred to as nematocysts or stinging capsules. A physical (e.g. contact with a foreign body) or osmotic trigger causes a coiled, inverted, hollow filament within the nematocyst to be ejected externally and discharge its toxic contents.

Clinical features

Sea urchins are echinoderms with fragile spines that break easily in the skin. Pigment from the spine often diffuses into the wound, making it difficult to find and remove the spine. Only about 80 of the roughly 600 species of sea urchin have been described as being hazardous to humans. Long-spined urchins such as the black sea urchin (*Diadema setosum*) are often a problem and spines embedded near joints have been associated with synovitis and arthritis. Sea cucumbers, another type of echinoderm, can eject an irritating visceral liquid.

Seabather's eruption (sea lice) is characterized by pruritic papules located under the bathing suit (Fig. 85.17) and in intertriginous areas. It may be caused by a variety of stinging larvae, including the larvae of the thimble jellyfish (*Linuche unguiculata*), common in southern waters. Off the coast of Long Island, New York, it is caused by larvae of a sea anemone (*Edwardsiella lineata*). Swimmer's itch, in contrast, affects exposed areas, is more common in fresh water, and is related to cercariae (free-swimming larvae) of avian schistosomes (see Ch. 83).

Jellyfish stings result in immediate pain as well as delayed and (occasionally) recurrent cutaneous reactions. Erythematous, urticarial or hemorrhagic streaks may be observed (Fig. 85.18), and they tend to be longer and fewer in number following contact with larger jellyfish. A lichen planus-like eruption has been reported to follow jellyfish envenomation[57]. Inflammation distant from the site of envenomation has also been reported[58]. *Chironex fleckeri*, the Pacific box jellyfish or sea wasp, is generally considered the most dangerous of the jellies, and stings commonly result in shock. Confirmation of envenomation can be obtained by tape stripping of nematocysts from skin. *Physalia physalis*, the Portuguese man of war, is common in southern waters of the Atlantic. *Physalia utriculus*, the blue bottle jellyfish, is seen in the Pacific. *Cyanea* and *Chrysaora* sea nettles are common causes of jellyfish dermatitis. Storms often drive the jellies into shallow water in great numbers.

Haloclava producta, the "ghost anemone", is a burrowing sea anemone found off the east coast of the US and in the Gulf of Mexico. It is responsible for summer outbreaks of dermatitis off the coast of Long Island, New York. Corals are another group of stinging cnidarians in the same class (Anthozoa) as sea anemones. Coral cuts can be slow to heal and should be washed vigorously. Fire corals are false corals that produce intense stinging and a papular eruption that can last for several days. Cnidarian nematocysts found in seaweed and in the dorsal papillae of nudibranch sea slugs can also cause dermatitis. In addition, seaweed dermatitis may be caused by algae.

Red sponges and fire sponges (members of the phylum Porifera) both cause dermatitis. Sponge dermatitis is related to spicules embedded in the skin, but sponge diver's disease is caused by the stings of sea anemones attached to the base of sponges. Local itching and burning progress to erythema and vesiculation. Systemic symptoms such as nausea, vomiting and headache are common.

Two classes of the phylum Mollusca, cephalopods and gastropods, have been linked to human envenomation. The blue-ringed octopus contains a potent venom. This small cephalopod is often only 10 cm long and is found in waters off the coast of Australia. Envenomation from cone shells (marine gastropods) may be associated with a 20% mortality rate. The shells are about 10 cm in length and tend to be found in shallow water, mainly in tropical and subtropical climates.

Encounters with stingrays can result in soft tissue injury and embedded spines. Death has been reported after a penetrating chest injury from a stingray barb resulting in venom-induced myocardial necrosis. Injuries inflicted by stingrays occur in both fresh and salt water, and pain is the major manifestation. Venom injuries respond to hot water immersion.

Lionfish are common in subtropical and tropical waters. Since August 2000, lionfish have been reported along the eastern coast of the US, from Florida to New York. Lionfish belong to the family of scorpionfish (Scorpaenidae). The family includes the genera *Pterois* (lionfish), *Scorpaena* ("true scorpionfish", bullrout and sculpin) and *Synanceia* (stonefish). Stonefish are the most toxic members of the family, although all produce local pain as well as systemic symptoms. Catfish spine injuries occur in both salt and fresh water. They may be associated with local pain, bleeding and systemic symptoms.

Pathology

Marine *Vibrio* infections cause intense cellulitis affecting the subcutis and dermis. The superficial dermis is devitalized and lacks an inflammatory infiltrate. Bullae are subepidermal in location and non-inflammatory. Many organisms are present, especially around vessels.

Sea urchin spines examined by polarized light microscopy exhibit an ornate symmetric structure produced by calcite crystals. Cutaneous granulomatous reactions may occur.

Histologic sections from sites of jellyfish stings may demonstrate nematocysts penetrating the epidermis and papillary dermis.

Treatment

Avoidance is the best means of preventing injury, which can result from specimens in salt water fish tanks as well as in the ocean. When envenomation occurs in a swimmer, the individual should immediately be removed from the water to prevent drowning. Initial treatment for all marine envenomations includes soaking the site in hot, but not scalding, water to denature some of the venom proteins.

Antivenin is available for some of the more toxic species such as *C. fleckeri*, and it can neutralize cardiovascular effects of *C. fleckeri* envenomation in an animal model. In contrast, verapamil does not improve cardiovascular status and increases mortality in the same animal model. In an animal model of envenomation by *Chiropsalmus* species of box jellyfish, pretreatment with *C. fleckeri* antivenin or $MgSO_4$ did not have any effect on the venom-induced hypertensive response or the subsequent cardiovascular collapse. This highlights the importance of species identification following box jellyfish envenomation.

In a study of acute *Carybdea alata* box jellyfish stings, hot water immersion (40–41°C) was more effective than papain meat tenderizer or vinegar. Topical jellyfish sting inhibitors, including lotions in which they are combined with sunscreens, are available. Sea water can be used to remove jellyfish tentacles. Inactivation with acidic or alkaline solutions can be risky, as unexpected discharge of nematocysts may occur. Treatment with topical corticosteroids and calcineurin inhibitors may be helpful for delayed reactions[59].

Most fish envenomations should be treated with hot water immersion. In a study of fresh water ray envenomation, hot water immersion controlled acute pain, but it did not prevent skin necrosis.

Ultraviolet Light 86

Thomas M Rünger

Key features

- Exposure of the skin to UV light has acute, short-term effects and chronic, long-term effects, both of which are wavelength-dependent. Profound effects also occur with non-erythemogenic doses of UV light
- UV light affects the skin's immune system, exerting both pro- and anti-inflammatory responses
- UV light induces several different types of DNA damage in a wavelength-dependent manner, such as pyrimidine dimers and oxidative guanine base modifications
- Several DNA repair pathways are involved in the processing of UV light-induced DNA damage, including nucleotide excision repair, base excision repair, translesional DNA synthesis, and recombination repair
- UV light-induced mutations, which play a pivotal role in photocarcinogenesis, are different from those induced by other mutagens. Some base substitution mutations (e.g. C→T, CC→TT) are so typical for UV light that they have been termed "signature mutations", and they are commonly found in UV-induced skin cancers
- Disorders with an increased frequency of UV-induced skin cancers are characterized by an impaired cellular or host response to the effects of UV light

INTRODUCTION

Dermatologists are confronted daily with the effects of UV light on the skin, and often deal with them in a seemingly contradictory way. On the one hand, they have the responsibility of warning their patients against the deleterious effects of sunlight, such as sunburn, photoaging and sun-induced skin cancers, and on the other hand, they use UV radiation to treat skin disease. As with all medical interventions, dermatologists are weighing the risks versus the benefits when they use UV light for therapeutic purposes. In the phototherapy of inflammatory skin diseases, dermatologists also try to avoid the proinflammatory properties of UV radiation (e.g. the capability to induce sunburn) by choosing sub-erythemogenic doses. This clearly indicates that doses of UV light that do not induce sunburn still have profound effects on the skin. This applies not only to its short-term effects, but also to its long-term effects. A third and important aspect of photodermatology is the diagnosis and treatment of photosensitive or photoaggravated skin disorders (see Ch. 87).

Spectrum of UV Light

The sun emits UV radiation as part of an electromagnetic spectrum (see Fig. 134.1). It is usually subdivided, rather arbitrarily, into UVA (400–315 nm), UVB (315–290 nm), and UVC (290–200 nm). UVA has been further subdivided into UVA1 (400–340 nm) and UVA2 (340–315 nm). Of note, some authors use 320 nm as the demarcation between UVA and UVB. More than 95% of the sun's UV radiation that reaches the earth's surface is UVA. Practically all of the UVC, and much of the UVB, are absorbed by the oxygen and ozone in the earth's atmosphere, so that UV radiation below 290 nm is virtually undetectable at ground level. Nevertheless, the remaining UV radiation can still be absorbed by biologic molecules (DNA, protein, lipids), and it can damage and kill unprotected cells.

To survive in our environment, all living organisms had to develop protective mechanisms in order to prevent UV-induced killing and to maintain the stability of their genome. Such defenses include the development of UV-absorbing surface layers, enzymatic and non-enzymatic antioxidative defenses, repair processes, and removal of damaged cells. Through evolution, humans have lost most of the UV-protective fur, which remains an effective UV-protector only on the scalp (of most individuals). Nevertheless, the human skin is quite effective in protecting the rest of the organism from the harmful effects of solar UV irradiation, since UV radiation does not penetrate any deeper than the skin. Within the skin, the depth of penetration of UV light is wavelength-dependent[1,2] – i.e. the longer the wavelength, the deeper the penetration (Fig. 86.1). While UVA readily reaches the dermis, including its deeper portions, most of the UVB is absorbed in the epidermis, and only a small proportion reaches the upper dermis. UVC, if it reached the earth's surface, would be absorbed or reflected predominantly in the stratum corneum and in upper layers of the epidermis.

Some of the UV light reaching the skin is absorbed by biomolecules, thus eliciting photochemical and photobiological responses. A light-absorbing molecule is called a chromophore. Upon absorption of the radiation's energy, this chromophore is elevated to an excited state. Ensuing photochemical reactions may either change the chromophore directly, or, through energy transfer in a so-called photosensitized reaction, indirectly change a molecule other than the chromophore. Affected cells react, which in turn may lead to visible changes in exposed skin. When thinking about the biologic effects of different wavelengths in the different layers of the skin, it is necessary to consider that a particular wavelength can even have a biologic effect in a layer that it does not reach; for example, via secretion of a proinflammatory mediator in a higher layer[3].

Both short-term and long-term effects of exposure to UV light are wavelength-dependent. However, when comparing the photobiologic properties of UVB with those of UVA, it is important to remember that they are not two different entities, but rather a continuum of wavelengths, with gradually changing properties, and that the division between UVA and UVB is rather arbitrary. As noted previously, some authors use 320 nm, rather than 315 nm, as the demarcation between UVA and UVB.

Sunburn and Tanning

Visible, short-term, cutaneous effects of UV radiation include sunburn (solar erythema, possibly blister formation, desquamation) and tanning. Microscopically, short-term effects include epidermal edema with spongiosis, formation of sunburn cells (apoptotic keratinocytes), acanthosis, hyperkeratosis, depletion of Langerhans cells and an increase in basal layer and suprabasal melanin content, in addition to inflammatory infiltrates of lymphocytes and neutrophils and vasodilation. On a cellular and molecular level, UV exposure induces a multitude of damage responses, including the induction of stress proteins, repair processes and cytokine production. In a dose-dependent manner, exposed cells can either undergo apoptosis (visible histologically as sunburn cells) or cease proliferating (cell cycle arrest) in order to undergo repair (see Ch. 107). Hyperproliferation may follow the initial growth arrest, visible histologically as epidermal thickening.

The ability to induce sunburn (Fig. 86.2) rapidly declines with increasing wavelength. For example, UV light with a wavelength of 360 nm is approximately 1000-fold less erythemogenic than light with a wavelength of 300 nm. A UVB-induced sunburn reaches its peak between 6 and 24 hours after exposure. An immediate erythema reaction is rarely observed. In contrast, after exposure to a very high dose of UVA, an immediate erythema reaction can occur, followed by a distinct delayed erythema reaction after 6 to 24 hours. However, unless patients have increased UV sensitivity (e.g. decreased minimal

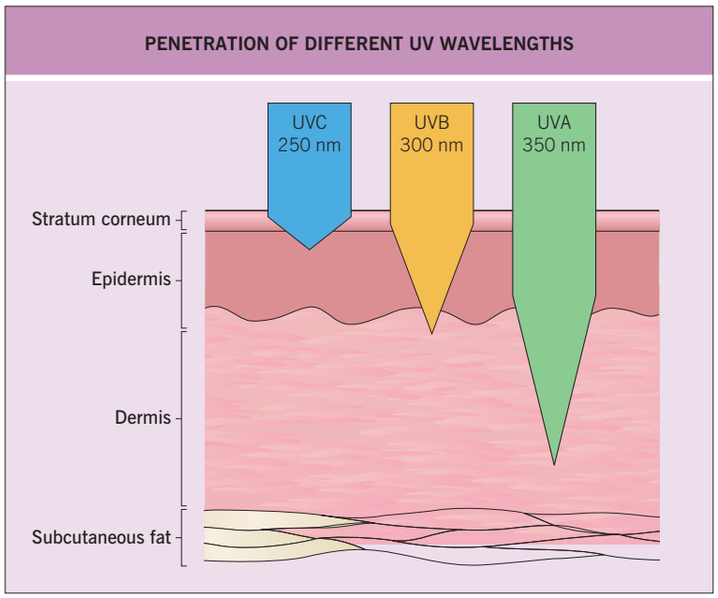

Fig. 86.1 Depth of penetration of different wavelengths of UV light into human skin. Depth of penetration varies greatly with the thickness of the different skin layers and their composition (e.g. melanin content). The beginning of the wedge-shaped portion of the penetration symbol represents a decrease to approximately one-third of the incident energy density, and the tip of the symbol represents a decrease to approximately 1%. Figure not drawn to scale.

Fig. 86.3 Sequelae of exposure to UV light. **A** UVA-induced tan with reduced pigmentation within an area of relative ischemia (due to pressure while lying on a tanning bed); this leads to reduced UVA-induced, oxygen-dependent melanin oxidation within this area. **B** Sharp demarcation of solar lentigines and the dyspigmentation of photodamaged skin in a "sun worshipper". *Courtesy, Jean L Bolognia, MD.*

erythema dose [MED] to UVA; see Ch. 134), the doses of UVA present in natural sunlight are not sufficient to induce a sunburn. DNA is thought to be the chromophore for the delayed erythema reaction associated with UVB[4].

The tanning response of human skin to sun exposure is biphasic and also wavelength-dependent. Immediate pigment darkening occurs during and immediately after exposure, and is due to alteration (e.g. oxidation) and redistribution of existing melanin. It is most prominent with UVA. Delayed tanning is usually the result of an exposure to UVB, and it peaks approximately 3 days after sun exposure. Fair skin (skin type II) usually tans only with UVB doses above the erythema threshold (i.e. only with prior sunburn). Darker skin (skin types III and higher) also has a significant tanning response to sub-erythemogenic doses (without prior sunburn). A UVB-induced tan is based on an increased number of melanocytes, increased melanin synthesis, increased arborization of melanocytes, and increased transfer of melanosomes to keratinocytes (see Ch. 65). Again, it is necessary to emphasize that differences between UVA and UVB are gradual; for example, the shorter wavelengths of UVA (UVA2) exhibit tanning properties similar to those of UVB. However, a UVA-induced tan, such as from the use of a tanning bed (Fig. 86.3A), provides 5–10 times *less* protection against a sunburn from subsequent UV exposure than does a UVB-induced tan, probably due to the less pronounced epidermal thickening and hyperkeratosis that accompanies an UVA-induced tan.

EFFECTS OF ULTRAVIOLET LIGHT ON THE IMMUNE SYSTEM
CLINICAL OBSERVATIONS
Suggestive of proinflammatory/immune-stimulating effects
• Sunburn • Dermatoheliosis • Photodermatoses (phototoxic and photoallergic) • Photoaggravation of inflammatory skin diseases (e.g. psoriasis, atopic dermatitis, pityriasis rubra pilaris) • Induction of autoimmune connective tissue diseases (e.g. cutaneous lupus erythematosus (LE), flares of systemic LE) • Efficacy of UV phototherapy for the treatment of skin infections (e.g. lupus vulgaris)
Suggestive of anti-inflammatory/immunosuppressive effects
• Activation of recurrent orolabial herpes simplex • Increased risk of photocarcinogenesis in the setting of immunosuppression (e.g. solid organ transplant recipients) • Efficacy of UV phototherapy for the treatment of inflammatory skin diseases
CELLULAR AND MOLECULAR EVENTS IN UV-IRRADIATED SKIN
Mediating proinflammatory/immune-stimulating effects
• Release of proinflammatory mediators by resident and non-resident skin cells (e.g. serotonin, prostaglandins, IL-1, IL-6, IL-8, TNF-α) • Induction of antimicrobial peptides (hypothesized to explain why UV-irradiated skin is not prone to bacterial infections)
Mediating anti-inflammatory/immunosuppressive effects
• Depletion of Langerhans cells or modulation of their antigen-presenting function • Release of anti-inflammatory mediators by resident and non-resident skin cells (e.g. IL-10, α-MSH) • Induction of regulatory T cells (antigen-specific)

Table 86.1 Effects of ultraviolet light on the immune system. IL, interleukin; MSH, melanocyte-stimulating hormone; TNF, tumor necrosis factor.

An individual's tendency to develop sunburn and tanning after sun exposure has been used to categorize skin phototypes (see Table 134.3). These categories of an individual's susceptibility to short-term effects also correlate with the individual's susceptibility to long-term effects following sunlight exposure. In general, those individuals with higher acute sun sensitivity are also at greater risk for developing skin cancer after chronic UV exposure.

Effects on the Cutaneous Immune System

A sunburn exemplifies the profound effect that UV light has on the skin's immune function, in this case a proinflammatory effect. This, plus the clinical observations outlined in Table 86.1, provide evidence for the pro-inflammatory/immune-stimulating effects of UV light on the skin. On the other hand, UV light clearly has anti-inflammatory/immunosuppressive properties as well, exemplified by the efficacy of UV phototherapy in the treatment of inflammatory skin disorders. However, it is unlikely that there is a simple threshold between the UV doses that have proinflammatory and those that have anti-inflammatory effects. Proinflammatory, anti-inflammatory and immunomodulatory changes occur side-by-side within different arms of cellular and humoral immune reaction cascades, with varying dose–responses as well as modulation by wavelengths and many individual factors far beyond just the degree of skin pigmentation (skin types). An example of individual factors would be the observation that the majority of patients with psoriasis improve with UV phototherapy, but a small minority flares.

UV light-induced effects on the immune system involve not only the areas of skin directly exposed to UV light, but also non-irradiated sites[5–7]. An example of systemic immunosuppression is the development in non-exposed skin of antigen-specific immune tolerance to antigens that were initially applied to UV-exposed skin. This effect is known to be mediated by the release of immunosuppressive cytokines such as interleukin (IL)-10 and then ultimately by UV-induced regulatory T cells. Whereas in mice this UV-induced tolerance is highly reproducible, in humans it is highly variable – yet another example of the influence of individual factors. An example of systemic immune-stimulating effects is the UV-induced exacerbation of systemic disease in patients with systemic lupus erythematosus. Recently, it has been suggested that the immunosuppressive effects of UV light affect primarily the adaptive, antigen-specific immune system, while immunostimulatory effects target the innate immune system[8].

Cellular photoreceptors that mediate the signaling that leads to UV-induced immune responses are: DNA (via formation of DNA damage [DNA photoproducts]), urocanic acid in the stratum corneum (via UV-induced isomerization from the *trans*- to the *cis*-isoform), and membrane lipids (via UV-induced alteration of the membrane redox potential). While the immunosuppressive effects of UVB are well established, the relative contribution of UVA to the immunomodulatory properties of solar UV radiation is still a matter of debate, but evidence is accumulating that UVA also has prominent effects. Even less is known about the relationship of wavelength to the immunostimulatory effects of UV light.

Photoaging and Photocarcinogenesis

Long-term effects of chronic sun exposure include photoaging and photocarcinogenesis. In the case of photocarcinogenesis, UV exposure provides a one-two punch – not only does it generate DNA damage that leads to mutation formation and malignant transformation, but its immunosuppressive properties, including the induction of specific tolerance to antigens from UV-induced skin tumors, reduce the ability of the host immune-defense system to recognize and remove malignant cells. UV irradiation also impairs immune surveillance against cells infected with oncogenic viruses (e.g. certain HPV types) and may thereby further promote skin cancer formation. This may explain why cutaneous squamous cell carcinomas (SCCs) develop more frequently than basal cell carcinomas (BCCs) in immunosuppressed patients (e.g. solid organ transplant recipients), in contrast to immunocompetent individuals, in whom BCCs occur more commonly than SCCs.

The advantage of reduced immune reactivity following exposure to UV light is the prevention of illicit (auto)-immune reactions to transiently UV-altered cells. Any shift in the balance between pro- and anti-inflammatory responses toward a more immunosuppressed state increases the risk of UV-induced tumor formation, as occurs in chronically immunosuppressed patients. However, tilting this balance toward proinflammatory responses and autoimmunity increases the risk of developing photodermatoses or photoaggravated skin diseases such as lupus erythematosus. The critical nature of this balance is also exemplified by the observation that effective photoprotection commonly leads to spontaneous resolution of actinic keratoses, even though these precursor lesions have identifiable genetic changes that provide growth advantage over non-mutated cells (see Ch. 107).

In contrast to photocarcinogenesis, where the anti-inflammatory effects of UV light play a pivotal role, photoaging is characterized by a chronic inflammatory response to UV light. One of the most prominent features of cutaneous photoaging is wrinkling, which is due primarily to a loss of collagen fibers and deposits of abnormal degenerative elastotic material within the dermis (actinic elastosis). These changes are thought to be mediated by inflammation, with subsequent upregulation of extracellular matrix-degrading proteases and down-regulation of collagen synthesis. However, if the latter were due solely to UV-induced inflammation, wrinkling should be reversible with complete photoprotection, but of course this does not occur. Explanations for this lack of reversibility include UV-induced mitochondrial mutations[5] which lead to loss of cellular functions. In addition to changes within the dermal connective tissue, photoaging affects other components of the skin, including the epidermis, pigmentary system and vasculature.

As photocarcinogenesis commonly occurs in photoaged skin, this further demonstrates the simultaneous occurrence of pro- and anti-inflammatory responses to UV light. Both processes, photoaging and photocarcinogenesis, usually require several years of sun exposure before clinical manifestations are apparent (Fig. 86.3B). However, initial pigmentary changes of photoaging can sometimes be seen just weeks or months after a sunburn (e.g. the large-sized lentigines of the upper back that follow a blistering sunburn, also referred to as "sunburn freckles").

Due to its ability to penetrate deeper into the dermis, UVA in particular is thought to play an important role in the dermal changes of photoaging. Figure 86.4 depicts unilateral facial photoaging in an office

Fig. 86.4 Unilateral photoaging following 15 years of unilateral sun exposure through window glass. This individual had been working in the same office for 15 years, close to a window, with the left cheek always facing the window. Biopsy confirmed the diagnosis of nodular cutaneous elastosis with cysts and comedones (Favre–Racouchot disease). Since UVB does not penetrate window glass, this observation identifies UVA as an effective agent in photoaging. *Reproduced with permission from Moulin G, Thomas L, Vigneau M, Fiere A. Un cas unilateral d'élastose avec kystes et comédons de Favre et Racouchot. Ann Dermatol Venereol. 1994;121:721–3.*

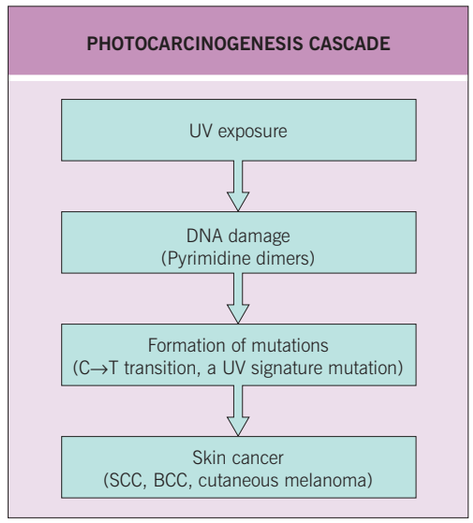

Fig. 86.5 Photocarcinogenesis cascade. UV-induced DNA damage generates mutations, which, after accumulation of a sufficient number of mutations in critical genes, may finally result in malignant transformation of single keratinocytes or melanocytes and with that formation of skin cancer.

worker whose face had been consistently side-on to the window during office hours for 15 years[6]. This case strikingly demonstrates the ability of UVA to induce photoaging, since only UVA, and not UVB, penetrates through window glass. The deeper penetration of UVA into the skin is significant for the process of photoaging, but it is not thought to be as important in photocarcinogenesis, since all UV-induced skin cancers (SCCs, BCCs and melanomas) arise from cells that reside within the epidermis, not from dermal cells. It is somewhat difficult to imagine that this difference (between epidermal and dermal cells) in their susceptibility to UV-induced carcinogenesis is due only to the more protected location of fibroblasts within the skin, given that fibroblasts are located just underneath the basal layer of epidermal cells. However, in mice, fibrosarcomas are readily induced by UVB, suggesting that the fibroblast is also susceptible to UV irradiation; therefore, it may just be that the thickness of the human epidermis prevents the malignant transformation of the fibroblast.

PHOTOCARCINOGENESIS

UV-Induced Tumor Formation

It is well established that exposure of the skin to UV light is a major risk factor for the development of cutaneous melanoma and non-melanoma skin cancer[7]. It is a process that, like cancer in general, involves a stepwise accumulation of specific genetic changes in a single cell, with subsequent clonal expansion. Usually, it takes decades until a tumor arises. It is commonly accepted that UV-induced skin cancers (BCC, SCC and melanoma) develop along the photocarcinogenesis chain of events outlined in Figure 86.5. The three major steps are:

- DNA damage formation after UV exposure
- mutation formation following DNA damage formation
- malignant transformation following mutation formation (see below).

There is limited information regarding which wavelengths of the UV spectrum are responsible for these effects. While the carcinogenic properties of short-wavelength UV light, in particular UVB, have been well established for some time, UVA has long been thought to be harmless due to its relative inability to induce sunburn. In recent years, however, it has been shown that UVA is capable of inducing cutaneous SCC in mice and is now recognized as an independent class I carcinogen[7]. Although a published photocarcinogenesis action spectrum for cutaneous SCC in mice showed a steep decline in tumor rate with increasing wavelength[9], it does not completely exclude a role for UVA. This is because natural sunlight contains much more UVA than UVB (depending on the time of day and weather: 20- to 100-fold more), which offsets at least some of the weaker effects of UVA. Additionally, UVA is less filtered by window glass or clothing, and it penetrates more effectively to the basal layer of the epidermis; these two factors may serve to increase its relative contribution to the long-term effects of sunlight exposure.

Even less is known about the action spectrum for the induction of melanoma, the deadliest form of skin cancer. However, there are some indications that UVA may play a particular role[10]. These suggestions come from the following:

- Experiments in melanoma-susceptible fish, in which UVA was much more effective in inducing melanoma.
- Another animal model, the opossum *Monodelphis domestica*, in which not only UVB but also UVA induced melanoma precursor lesions.
- Meta-analyses of multiple retrospective studies and one large prospective study indicate that the use of tanning beds (which contain mostly high-dose UVA emitters) increases the risk for melanoma[11,12]; a recent case control study found adjusted overall melanoma risks of 2.86 and 4.44 for users of UVB-enhanced and primarily UVA-emitting devices, respectively[12a].
- Reports that the use of sunscreens (which for decades contained no effective UVA filters and even today usually do not protect as efficiently against UVA as against UVB) increased melanoma risk[13], possibly due to an increased exposure to unfiltered UVA.

However, a role for UVA in the pathogenesis of melanoma has been questioned, as only UVB, not UVA, induced melanoma in a transgenic mouse model[14].

Cutaneous SCC and lentigo maligna melanoma are associated with a significantly high cumulative exposure to UV radiation, and they occur most commonly in chronically sun-exposed areas, such as the face, dorsal aspect of the hands, and extensor forearms. In contrast, the most common types of cutaneous melanoma (e.g. superficial spreading) usually arise in sites with intermittent sun exposure (e.g. the back in men and the lower legs in women), rather than in chronically sun-exposed areas, and they are associated with a history of sunburns. Several explanations for these phenomena have been proposed. One hypothesis suggests that melanocytes might be more prone to UV-induced mutagenesis following a single high dose of UV light, because of their relative inability to undergo apoptosis[15]. Possibly due to high levels of anti-apoptotic proteins such as Bcl-2, sunburn-induced apoptosis has not been described in melanocytes. Therefore, melanocytes with a high amount of DNA damage are more likely to survive than keratinocytes, which readily undergo apoptosis. Adaptive responses following repeated low-dose UV radiation, such as increased pigmentation or upregulation of DNA repair (see below for "intrinsic protective mechanisms"), protect both melanocytes and keratinocytes against the mutagenic assault from further low-dose UV exposures. However, in this situation, keratinocytes would be more prone to UV-induced mutagenesis, since they are proliferating more rapidly and are, therefore, more likely to replicate unrepaired DNA, thus leading to an increased

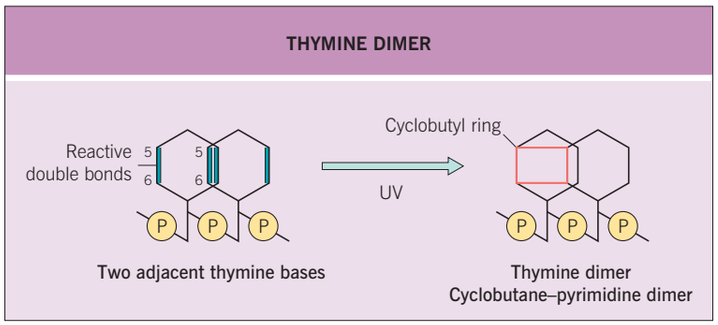

Fig. 86.6 Thymine dimer. Following excitation of the bases by UV light, a cyclobutane–pyrimidine dimer is formed by covalent linkage between two adjacent pyrimidines (here two thymine bases) and formation of a cyclobutyl ring.

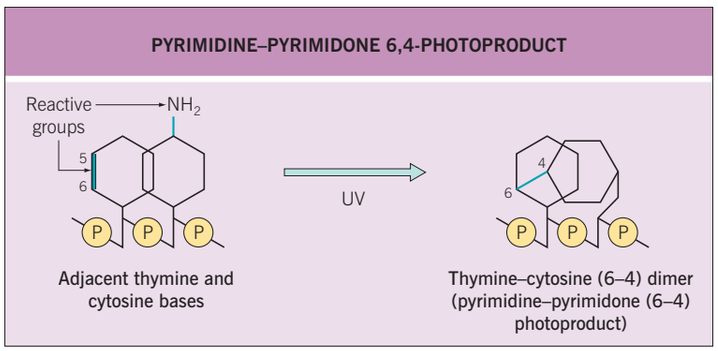

Fig. 86.7 Pyrimidine–pyrimidone 6,4-photoproduct. A pyrimidine–pyrimidone (6–4) photoproduct is formed by covalent linkage between C-6 and C-4 of two adjacent pyrimidines (here a thymine and a cytosine base), following excitation of the bases by UV light.

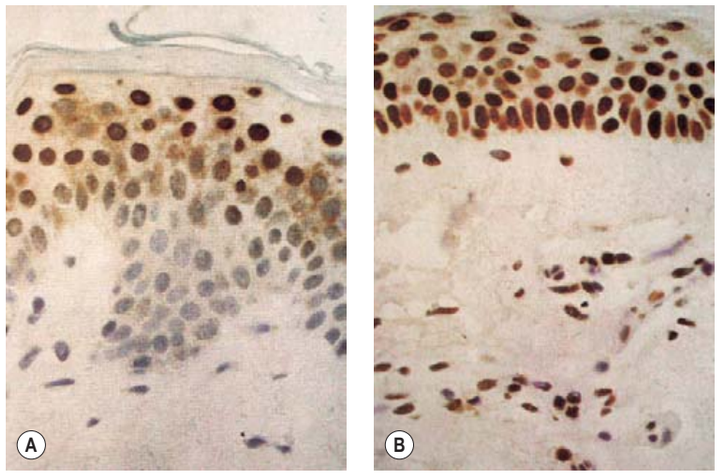

Fig. 86.8 A wavelength of 300 nm is more effective than one of 290 nm in inducing thymine dimers in the basal layer of the human epidermis. A After irradiation of human skin with monochromatic 290 nm UVB (2 MED) and staining with anti-thymine dimer antibodies, most cells in the basal layer show only blue counterstaining, while suprabasal layers demonstrate pronounced reactivity. **B** In contrast, with 2 MED of monochromatic 300 nm UVB, a pronounced immunostaining is also evident in the basal layer of the epidermis (as well as in cells within the dermis). *Reproduced with permission from Young AR, Chadwick CA, Harrison GI, et al. The similarity of action spectra for thymine dimers in human epidermis and erythema suggests that DNA is the chromophore for erythema. J Invest Dermatol. 1998;111:982–8.*

frequency of mutations. This could explain why keratinocytes are more vulnerable to the repeated low-dose UV irradiations of chronic sun exposure than are melanocytes.

UV Induction of DNA Damage

Different wavelengths of UV light induce different types of DNA damage. UVC and UVB, but much less so UVA, are capable of exciting the DNA molecule directly and subsequently generate DNA photoproducts[16]. Indeed, DNA is regarded as the chromophore for most of the biologic effects of UVB and UVC, including erythema, tanning, immunosuppression, mutagenesis and carcinogenesis[4]. DNA photoproducts are dimers, formed by covalently binding two adjacent pyrimidines in the same polynucleotide chain. The two major types of pyrimidine dimers are cyclobutane dimers (Fig. 86.6) and 6,4-photoproducts (Fig. 86.7).

Following acute cellular injury, including DNA damage, cells initiate damage response pathways, which may result in cell cycle arrest, apoptosis, induction of DNA excision repair pathways, changes in the expression of cell surface proteins, secretion of cytokines, etc. This explains how UV-induced DNA damage can result in acute effects, such as erythema or immune reactions (see Table 86.1). An upregulation of the transcription factor p53 plays a pivotal role in many of these cellular damage response pathways. However, the initial cellular sensor for the induction of damage response pathways has not been clearly identified. For DNA damage, the unwinding and bending of the DNA double helix by, for example, DNA photoproducts is important for at least DNA damage recognition and initiation of DNA repair.

Cyclobutane–pyrimidine dimers (CPDs) are the most common DNA photoproduct formed by UV irradiation of the skin. They are generated upon saturation of the 5,6 double bonds and formation of a four-membered cyclobutyl ring (see Fig. 86.6). CPDs are observed at all possible dipyrimidine sites, with the thymine–thymine dimer (T-T) being the most common, followed by C-T and T-C dimers. C-C dimers are the least common. The formation of CPDs is not a random phenomenon: it is influenced by the sequence and conformational context of the affected DNA sequence.

The 6,4-photoproduct is a non-cyclobutane dipyrimidine photoproduct, which is formed upon covalent linkage between the C-6 position of one pyrimidine and the C-4 position of the 3′ adjacent pyrimidine (see Fig. 86.7). The T-C (6–4) dimer is the most common dimer of this type, but C-C and T-T dimers are also observed after UV irradiation. Upon further irradiation with UV wavelengths between 280 and 360 nm, the normal isomers of 6,4-photoproducts can be converted to their Dewar valence isomers, which are less mutagenic than the normal isomers but may still contribute to solar mutagenesis[17]. A few other rare DNA photoproducts have been described, such as complex purine lesions and pyrimidine hydrates, but their physiologic significance in cutaneous photobiology is unknown.

The absorption maximum of DNA is at 260 nm. This makes UVC the most effective wavelength for the induction of DNA photoproducts in naked DNA. However, *in vivo*, due to the absorption of shorter wavelengths in upper layers of the epidermis, 300 nm (UVB) is the most effective wavelength for inducing DNA photoproducts in the basal layer of the epidermis (which harbors the most relevant cells for skin carcinogenesis). Figure 86.8 demonstrates how 300 nm is much more effective than 290 nm in inducing cyclobutane T-T dimers in the basal layer of human epidermis[4]. It has recently been shown that UVA can also generate pyrimidine dimers, albeit at a lower frequency than UVB (when solar-available doses are compared).

While formation of UVB-induced pyrimidine dimers results from the direct absorption of photons by bases of DNA, UV radiation can also damage DNA indirectly[18]. After absorption of photons by chromophores other than DNA, energy can be transferred either to DNA (type I photosensitized reaction) or to molecular oxygen, with reactive oxygen species in turn being able to damage DNA (type II photosensitized reaction). Of note, many of the biologic properties of UVA, including its toxicity to cells, are strictly dependent upon the presence of molecular oxygen[19], which points to a prominent role for reactive oxygen species. Although these reactive oxygen species are also formed by UVB, UVA has been shown to be responsible for almost all oxidative DNA damage after exposure of cells to natural sunlight[20]. Formation of pyrimidine dimers by UVA may involve a type I photosensitized reaction[21], unlike their direct formation by UVB.

UV-induced reactive oxygen species include singlet oxygen and probably other non-radical and radical reactive oxygen species, such as hydrogen peroxide and the superoxide radical[22]. Even the highly reactive hydroxyl radical may be formed by a reaction of hydrogen peroxide with

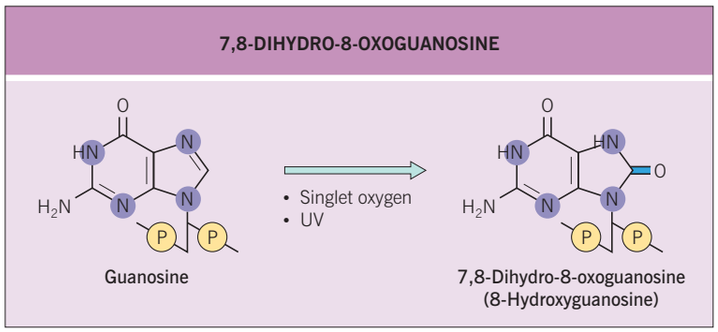

Fig. 86.9 7,8-Dihydro-8-oxoguanosine. 7,8-Dihydro-8-oxoguanosine (tautomer: 8-hydroxyguanosine) is an oxidation product of guanosine. It is formed by singlet oxygen, which is generated through a photosensitized reaction after excitation of a cellular chromophore by UV.

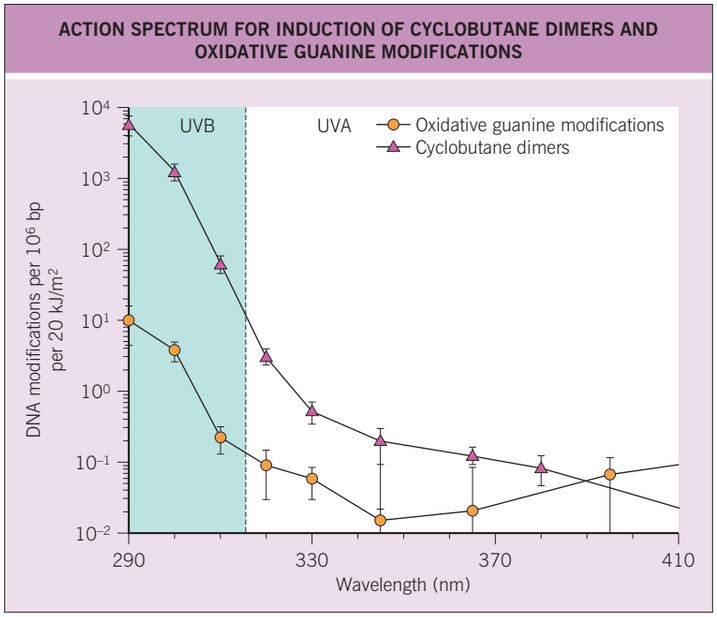

Fig. 86.10 Action spectrum for the induction of cyclobutane dimers and oxidative guanine modifications in Chinese hamster ovary cells. The number of DNA lesions was assessed by the ability of repair enzymes to incise DNA from cells irradiated with different wavelengths from a monochromator. The ability of UV light to induce cyclobutane dimers and oxidative DNA damage rapidly declines with increasing wavelengths, e.g. 320 nm UV light is approximately 1000-fold less capable of inducing cyclobutane dimers than is 290 nm UV light. This decline parallels well with the decline of skin cancer formation in mice from 300 to 340 nm (Utrecht–Philadelphia skin cancer action spectrum[9]). This decline does not mean that longer wavelengths do not contribute to photocarcinogenesis, because longer-wavelength UVA is much more abundant in natural sunlight than is UVB, which offsets at least some of the weaker effects of UVA. The second peak of oxidative base damage formation in the UVA range parallels with a second peak of skin cancer formation at 380 nm. Since there is no second peak of cyclobutane dimer formation with UVA, this has been interpreted as evidence that oxidative base damage contributes to mutagenesis and skin cancer formation. However, more recent data indicate that pyrimidine dimers are the most important pre-mutagenic DNA lesion not only for UVB, but also for UVA.

nuclear metals through a Fenton reaction. This oxidative stress affects not only DNA, but also membranes and proteins. The relative contribution of each (oxidative membrane damage, oxidative protein damage, oxidative DNA damage) to the different biologic effects of UV irradiation has not been well established. Singlet oxygen and the other reactive oxygen species react predominantly with guanine and generate several DNA changes, including the mutagenic and well-studied 7,8-dihydro-8-oxoguanosine (8-oxoG; Fig. 86.9).

Kielbassa et al.[23] published a UV action spectrum for the formation of dimers and oxidative guanine base modifications in mammalian cells (Fig. 86.10). Differences between the DNA-damaging properties of

Fig. 86.11 Xeroderma pigmentosum. Multiple skin cancers and lentigines on the face of a 12-year-old Hispanic boy. *Courtesy, Stanley Miller, MD.*

UVA, UVB and UVC are gradual, and, as noted previously, only a few pyrimidine dimers are generated by UVA. That said, there is mounting evidence that pyrimidine dimers are the most important pre-mutagenic DNA lesions not only in UVB-induced, but also in UVA-induced, mutation formation (see below), with oxidative DNA damage playing a minor role in mutagenesis[24,25]. Lastly, DNA double-strand breaks are probably not formed by either UVB[26] or UVA[26a].

Repair of UV-Induced DNA Damage

To counteract potentially mutagenic and cytotoxic effects, UV-induced DNA damage requires excision and replacement of damaged nucleotides by DNA repair pathways. No correction procedure is absolutely exact and error-free. If it were, UV-induced skin cancers would not occur in DNA repair-proficient individuals.

The bulky DNA photoproducts (pyrimidine dimers) are mutagenic, but they can be repaired by the nucleotide excision repair (NER) pathway. As exemplified by the hereditary disorder xeroderma pigmentosum (XP), a defect in this repair pathway increases UV sensitivity and UV mutagenesis in cells and results in non-melanoma and melanoma skin cancers in patients[27,28] (Fig. 86.11). The NER pathway is now well understood, in part through the identification and characterization of the different XP genes. XP includes seven genetic complementation groups (XPA through XPG), which represent different proteins in the NER pathway (Table 86.2), in addition to a separate form, XP variant. Although cells of some XP complementation groups usually exhibit a more impaired DNA repair than others (XPA, XPB, XPC and XPD), it is not possible to determine the affected DNA repair gene (XP complementation group) by the clinical phenotype alone. In addition, different mutations in the same gene can impair NER and/or the clinical phenotype to a varying degree.

NER involves recognition of DNA damage, incision of the DNA strand containing a lesion, and DNA synthesis and ligation to replace an excised oligonucleotide (24 to 32 residues). This is shown schematically in Figure 86.12. In active genes, the transcribed strand is corrected up to 10 times faster than the non-transcribed strand. Here, recognition of DNA damage is mediated via the RNA polymerase stalled at the site of a pyrimidine dimer plus recruitment of CSA and CSB (protein products of Cockayne syndrome complementation group A and group B genes); this initiates *transcription-coupled repair*. In non-transcribed genes and non-coding regions, the XPC and XPE proteins bind to UV-damaged DNA, marking it for further processing; this initiates *global genome repair*. After either form of DNA damage recognition, all subsequent steps of NER are identical. A key intermediate is an open, unwound structure formed around a DNA lesion in a reaction that uses the helicase activities of XPB and XPD. This creates sites for

DEFICIENT DNA REPAIR GENES		
Complementation group or inherited disorder	**Function of affected gene product in DNA repair**	**Also associated with:**
	NUCLEOTIDE EXCISION REPAIR	
XPA	High affinity for injured DNA (single strands) Has many interactions with other NER proteins Might have a role in assembling the DNA repair machinery around the DNA lesion	–
XPB	Subunit of the transcription factor TFIIH Unwinds the DNA helix around the DNA lesion with its 3′→5′ helicase function	XP/CS*, TTD
XPC	DNA damage recognition Only required for global genome repair, not for transcription-coupled repair	–
XPD	Subunit of the transcription factor TFIIH like XPB Unwinds the DNA helix around the DNA lesion with its 5′→3′ helicase function	XP/CS*, TTD
XPE	Affinity for UV-damaged DNA Might have an auxiliary role in DNA damage recognition	–
XPF	5′-repair endonuclease The ERCC1/XPF complex cuts at the single-strand to double-strand transition 5′ of the DNA lesion	–
XPG	3′-repair endonuclease Cuts at the single-strand to double-strand transition 3′ of the DNA lesion Stablilizes TFIIH	XP/CS*
TTDA	Subunit of TFIIH (TFB5) See XPB and XPD	
CSA	Only required for transcription-coupled repair Regulates recruitment of repair factors and chromatin remodelers upon stalling of RNA polymerase at the DNA lesion	–
CSB	Only required for transcription-coupled repair Regulates recruitment of repair factors and chromatin remodelers upon stalling of RNA polymerase at the DNA lesion	–

XP variant	DNA polymerase-η Bypasses T–T dimers with correct insertion of two A residues	–

*Xeroderma pigmentosum/Cockayne syndrome overlap syndrome.

Table 86.2 Deficient DNA repair genes. Deficient DNA repair genes underlie xeroderma pigmentosum (XP) complementation groups XPA to XPG, trichothiodystrophy (TTD), Cockayne syndrome (CS), and XP variant. In addition, mutations in TTDN1, a protein that may have a role in maintaining cell cycle integrity, can lead to a non-photosensitive form of TTD. ERCC1, excision repair cross complementing gene 1; NER, nucleotide excision repair; TFIIH, transcription factor IIH.

cutting by the endonucleases XPG on the 3′ side of the lesion and the XPF–ERCC1 complex on the 5′ side. A 24- to 32-residue oligonucleotide is released, and the gap is filled by DNA polymerase δ or ε and then sealed by DNA ligase 1.

Defects in NER are found not only in XP, but also in two other photosensitive disorders, Cockayne syndrome and the photosensitive form of the brittle hair syndrome trichothiodystrophy[28,29]. These disorders are not cancer-prone, but sometimes have features that overlap with those of XP. It is remarkable how different mutations in the XPB, XPD and XPG genes are associated with specific clinical phenotypes, i.e. only XP or XP/Cockayne syndrome overlap or trichothiodystrophy (see Table 86.2). There is no clear correlation between disease phenotype and specific mutations or between the severity of the DNA repair defect and the clinical phenotype. The transcription/repair syndrome hypothesis has been put forward in an attempt to explain these various discrepancies. According to this hypothesis, mutations in XPD or XPB could affect the repair function of transcription factor IIH (TFIIH; see Fig. 86.12), resulting in photosensitivity and cancer development, and/or affect the transcription function of TFIIH, accounting for the typical phenotypes of trichothiodystrophy and Cockayne syndrome.

Individual cancer and skin cancer risks are determined not just by a pronounced NER deficiency, as in XP, but also by more subtle variations in DNA repair efficiency, e.g. as a consequence of polymorphisms in DNA repair genes[30,31]. Likewise, a decline in DNA repair efficiency with age has been linked to the increasing risk of skin cancer with advancing age[32].

Cells from patients with XP variant have an intact NER (Table 86.3), yet a phenotype that is indistinguishable from the other XP complementation groups. Cells from these patients do not have a deficit in repairing DNA photoproducts, but a deficiency in what they do with unrepaired DNA photoproducts during replication (in the S phase of the cell cycle)[33]. Replicative DNA polymerases usually stall at unrepaired DNA lesions and detach from the DNA strand. For this situation, cells have a number of specialized DNA polymerases that are able to bypass different kinds of DNA damage and extend replication forks through damaged sites. Different polymerases perform this "translesional DNA synthesis" with variable fidelity.

Due to a mutation in the pol-η gene, cells from patients with XP variant lack the particular ability of DNA polymerase-η to bypass T-T dimers with correct insertion of two A residues[34]. This indicates that NER does not always repair all DNA lesions and that the function of a high-fidelity translesional DNA polymerase is crucial for maintaining genomic stability (if cells enter S phase with unrepaired DNA damage). In cells from patients with XP variant, NER can remove most of the T-T dimers, but because polymerase-η is deficient, any remaining dimers are more likely to be bypassed by polymerases that insert incorrect residues. This causes a UV-mutator phenotype. If DNA polymerase-η (or any other specialized translesional DNA polymerase) fails to bypass DNA damage during S phase, the cell is faced with a stalled replication fork. In these instances, DNA recombination repair, which utilizes strand invasion from the sister chromatid, can resolve the stalled replication fork. More recently, DNA recombination repair was also observed to occur after exposure to UV irradiation[26].

In contrast to the bulky pyrimidine dimers, which can only be repaired by NER, the non-bulky oxidative DNA base modifications can be processed by base excision repair[27,35]. As the name implies, the initial

step in base excision repair is the removal of a base rather than a nucleotide. This step is carried out by a DNA glycosylase, which removes the damaged DNA base by cleaving hydrolytically the base–deoxyribose glycosyl bond, leaving an apyrimidinic/apurinic (AP) site for further processing. This DNA glycosylase has substrate specificity for a particular kind of DNA base damage. The human DNA glycosylase, 8-oxoG DNA glycosylase 1, has specificity for oxidized guanine bases such as 8-oxoG (see above and Fig. 86.9), and it initiates processing of these lesions via base excision repair. Loss of this enzyme generates a cellular hypersensitivity to UVA, but does not increase UVA-associated mutation formation, further casting doubt regarding an important role for 8-oxoG in UVA-induced mutagenesis[36].

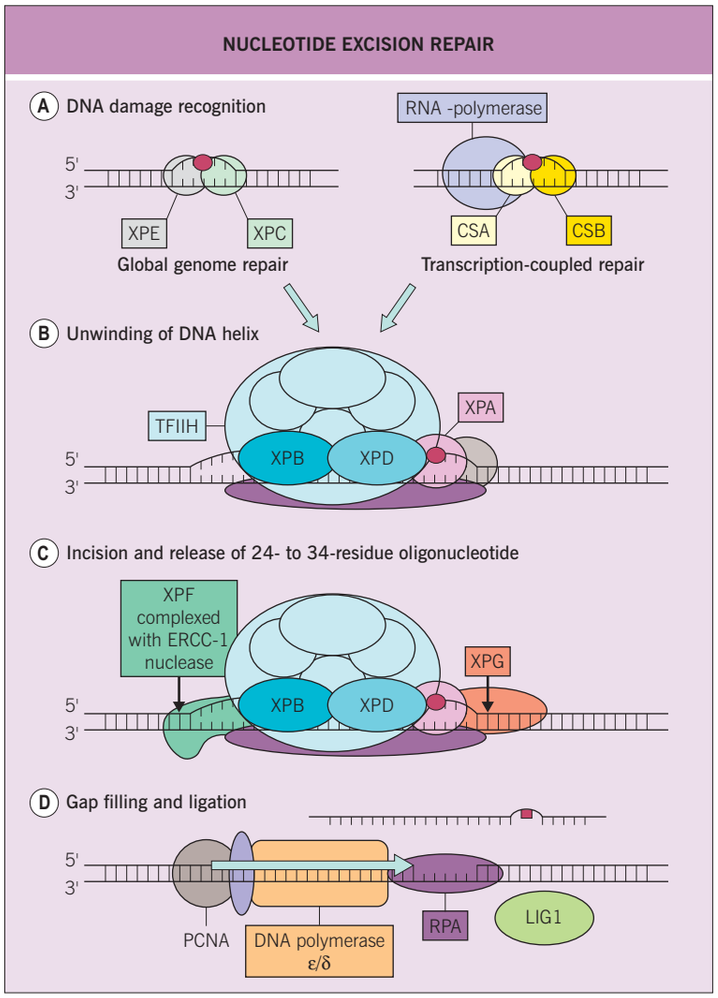

Fig. 86.12 Nucleotide excision repair. This pathway repairs "bulky" DNA lesions, including pyrimidine dimers (red dot). **A** DNA damage recognition in global genome repair is mediated by XPC and XPE. In transcription-coupled repair, DNA damage recognition is mediated by a stalled RNA polymerase plus recruitment of CSA and CSB. These two types of DNA damage recognition are then followed by identical steps in DNA repair. **B** Formation of an open bubble around the lesion by the helicase activity of XPB and XPD. **C** Incision 5′ and 3′ of the lesion by the endonucleases XPF and XPG. **D** Repair synthesis and gap closing after release of a 24- to 34-residue oligonucleotide. Quality control by DNA repair. Science. 1999;286:1897–905.*

Mutation Formation

Many of the previously discussed forms of UV-induced DNA damage can result in mutation formation. Because mutations in several specific genes are usually required for a normal cell to undergo malignant transformation and these mutations are quite unlikely to occur in a single cell, genetic instability (a mutator phenotype) is thought to be required for the development of cancer, including skin cancer[37]. XP serves as an example of inherited genetic instability. While the amount of DNA damage formed in the skin following UV exposure is the same as in normal individuals, deficient repair of this damage introduces many more mutations at sites of DNA damage (compared to repair-intact individuals).

A somatic mutation in the p53 tumor suppressor gene is an example of an acquired UV-mutator phenotype. This gene encodes a 53 kDa transcription factor that has a critical role in cell cycle regulation and induction of apoptosis after DNA damage. Loss of p53 function can result in impaired cell cycle arrest following UV exposure. This then increases the likelihood that DNA will be replicated before removal of UV-induced DNA damage. This increases the frequency of mutation formation because replication of damaged DNA with misincorporation of bases across DNA damage is the most important mechanism for the formation of base substitution mutations.

Mutations in *p53* can be found in most cutaneous SCCs and actinic keratoses (see Ch. 107). In addition, chronically sun-exposed skin harbors many clonal proliferations of keratinocytes with *p53* mutations, which are undetectable by light microscopy. This indicates that *p53* mutations are an early event in the pathogenesis of UV-induced cutaneous SCC. Most of these clones, and some of the actinic keratoses, regress after cessation of sun exposure. This indicates that loss of p53 function through a *p53* mutation is not sufficient for malignant transformation, but that other mutations (probably many) need to accumulate in one cell, before this cell can undergo complete malignant transformation and develop into a tumor.

Most of the *p53* mutations in cutaneous SCCs and their precursors are C→T single base transition mutations at dipyrimidine sites[38]. Tandem CC→TT transition mutations are found in 10% of cutaneous SCCs. This spectrum of *p53* mutations is very different from *p53* mutations found in malignancies of internal organs; the latter do not have the preponderance of C→T mutations and have no CC→TT mutations. This, together with the fact that pyrimidine dimers most commonly cause C→T and some CC→TT mutations, provides convincing evidence for a crucial role of pyrimidine dimers in cutaneous photocarcinogenesis. Therefore, C→T, and especially CC→TT (Fig. 86.13), mutations have been termed "signature mutations" for UV mutagenesis. The latter can arise from either UVB or UVA[25] and represent the most common types of mutation produced by these wavelengths[24,39].

A possible explanation for why UVA causes more mutations per pyrimidine dimer than does UVB is that UVB induces a more protective, antimutagenic cellular response which leads to a reduction in the frequency of mutation formation at pyrimidine dimer sites[24,40]. Thus, exposure to a pure UVA source, as in phototherapy (high-dose UVA1) or tanning parlors, might be more carcinogenic than exposure to a UVA source that also contains UVB light.

The identification of UV signature mutations in the *p53* gene of cutaneous SCCs and actinic keratoses provides clear molecular

INHERITED DISORDERS WITH ABNORMAL DNA REPAIR – TYPES OF IMPAIRED FUNCTION

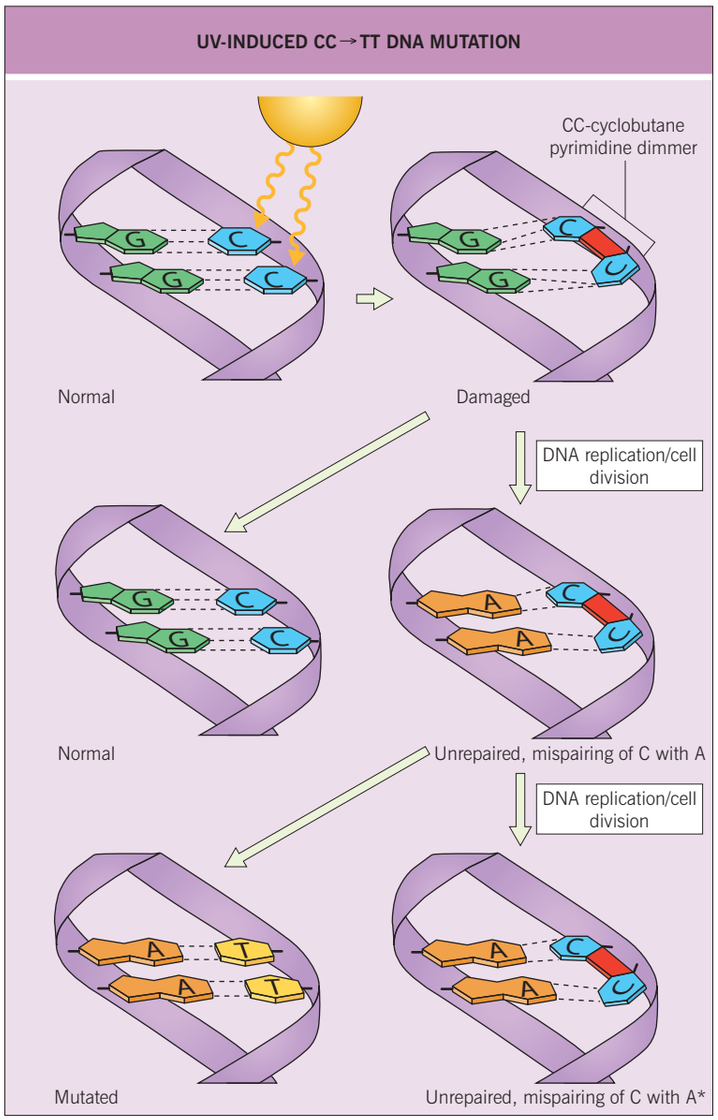

Fig. 86.13 UV-induced CC→TT DNA mutation. Following formation of a pyrimidine dimer between two adjacent cytosines and subsequent cell division, a CC→TT mutation results. This represents a UV signature mutation. *May give rise to more C→T mutations.

evidence that these lesions are induced by exposure to UV light. As noted previously, these *p53* mutations are found in very early precursor lesions and they result in a UV-mutator phenotype, clearly implicating UV exposure in the earliest stages of skin carcinogenesis (tumor initiation). The picture is different in BCCs and cutaneous melanomas, where *p53* mutations are later events in tumor progression. However, when they do occur in these two tumor types, the *p53* mutations are often C→T transitions as well. These findings point to UV exposure as not only an initiator of skin cancers, but also a contributor to its progression.

Most BCCs are characterized by an aberrant activation of the hedgehog signaling pathway, with mutations in *PTCH* and *SMO* (see Ch. 107). Many of the mutations in these genes are UV signature mutations, clearly implicating UV exposure in the pathogenesis of BCC. In cutaneous melanoma, several crucial genes have also been shown to carry C→T transitions, including *PTEN* and *CDKN2A* (see below)[41,42]. Recently, the entire genome of a melanoma metastasis cell line was sequenced and then compared to the sequence of a lymphoblastoid cell line from the same person[43]. A total of 33 345 somatic single and tandem base substitution mutations were detected in the melanoma cells, of which the majority (~70%) were UV signature mutations (C→T transitions). While the etiology of melanoma is clearly complex, these findings provide molecular evidence for UV exposure playing a significant role. Both melanomas and melanocytic nevi have a high frequency of T:A→A:T mutations in *BRAF* at one particular site (amino acid substitution V600E). Because these *BRAF* mutations have been found predominantly in melanomas from intermittently sun-exposed areas (and much less frequently in melanomas from unexposed areas or chronically UV-exposed areas), it has been suggested that this type of mutation is UV-induced[44]. However, such a mutation is not generated by any of the common types of UV-induced DNA lesions, and the pre-mutagenic lesion (i.e. the type of DNA damage that causes this type of mutation) remains elusive. Perhaps it is an unidentified, UV-induced thymine or adenine adduct.

Protection Against Photocarcinogenesis

To ensure that most of the damage inflicted by sun exposure will not lead to the formation of skin cancer, UV-exposed cells have several lines of defense against the photocarcinogenesis cascade (Fig. 86.14).

- In order to prevent DNA damage as a consequence of UV exposure, the epidermis has constitutive as well as inducible melanin. It can increase its thickness (which reduces UV exposure in the basal layer), and there are antioxidative enzymes within the epidermis which quench reactive oxygen species and reduce the formation of oxidative DNA damage[45]. Cellular melanin is a mixture of different polymerized pigments that absorb UV radiation (see Ch. 65). Illumination of the brown to black eumelanin generates the superoxide radical within the molecule, which is very rapidly scavenged. The red or yellow pheomelanin is a less effective radical scavenger; upon UV exposure, pheomelanin is degraded, with a net formation of superoxide. Therefore, pheomelanin is regarded as a photosensitizer, rather than a photoprotector like eumelanin.
- In order to prevent mutation formation after DNA damage has been introduced, cells have several different DNA repair systems (see above) as well as the ability to bypass DNA damage without inducing mutations. Cells also have the ability to halt proliferation (cell cycle arrest) in order to allow more time for repair, reducing the chance of replicating a damaged template, or they can die via apoptosis when they accrue overwhelming DNA damage.
- Even after mutations have fixed the inflicted damage for the lifetime of the affected cells, the organism still removes most of these cells, e.g. via immune surveillance.

Some of these protective mechanisms can be upregulated, facilitating an adaptive response to repeated UV "attacks". These include pigmentation, skin thickening, and antioxidant enzymes. DNA excision repair can also be upregulated in an SOS-like response[46]. In contrast, immune surveillance is down-regulated following UV exposures, likely contributing significantly to photocarcinogenesis (see above).

Exposure to UVA cannot be regarded as harmless, and dermatologists must warn not only against UVB but also UVA exposure. There are at least three areas where increased exposure to UVA might pose a public health risk.

- The use of high-dose UVA emitters for cosmetic purposes in tanning parlors is currently growing exponentially, and many researchers fear a second "melanoma epidemic" for that reason. It is estimated that approximately 35 million Americans use tanning beds or sunlamps every year[46a], especially teenagers and young adults.
- An increase in UVA exposure can also result from the use of sunscreens. According to Autier et al.[47], sunscreens are often used for their ability to prolong sun exposure. Since broad-spectrum sunscreens still do not filter UVA as efficiently as UVB, an increase in UVA exposure as a consequence of sunscreen use remains a problem.
- High-dose UVA1 phototherapy has been shown to be an effective treatment for atopic dermatitis, scleroderma, cutaneous T-cell lymphoma, and other dermatoses. However, the long-term risks of this treatment have not been established. Considering the possible role of UVA in the development of cutaneous melanoma, one must weigh the risks and benefits of the use of high-dose UVA1, especially in children.

In addition to the intrinsic protective mechanisms that counteract the chain of events leading to the formation of skin cancer, there are

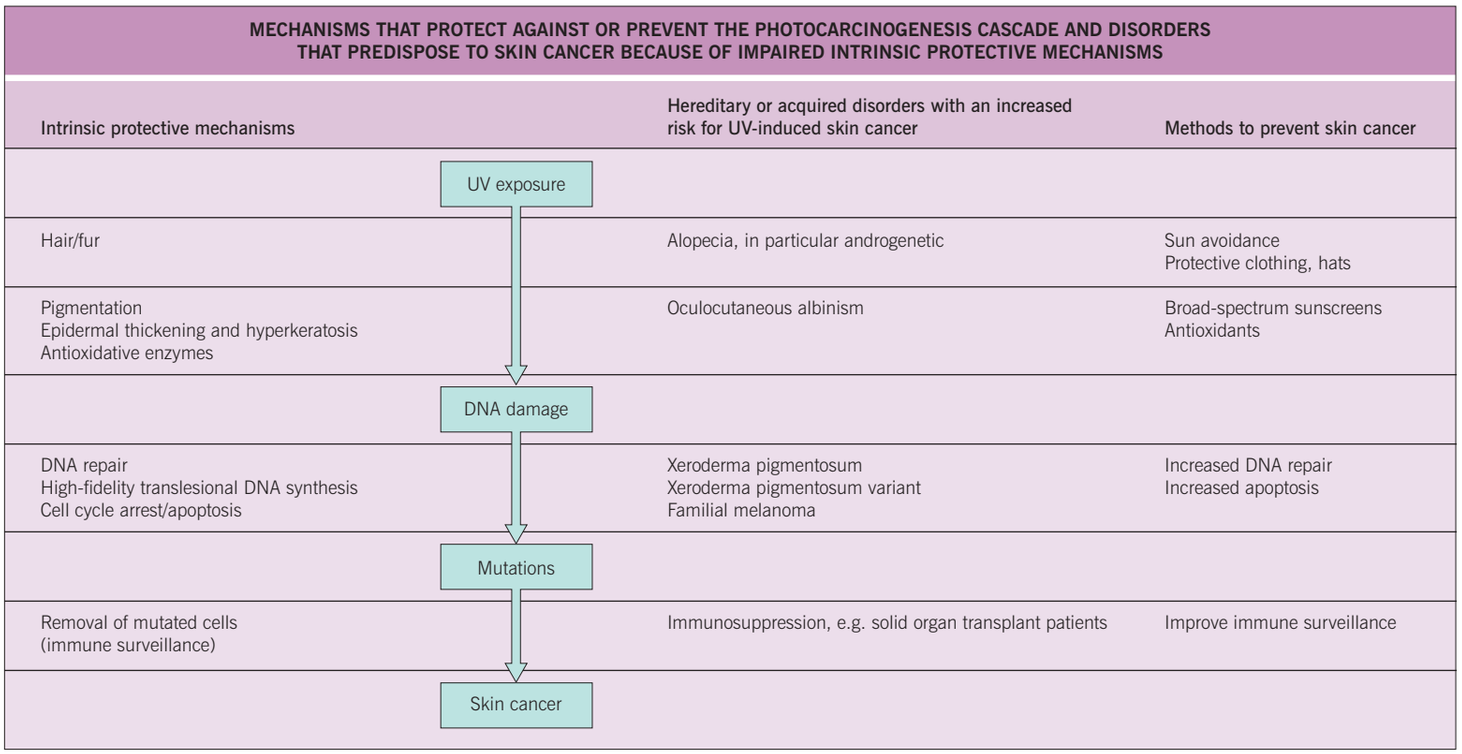

Fig. 86.14 Mechanisms that protect against or prevent the photocarcinogenesis cascade and disorders that predispose to skin cancer because of impaired intrinsic protective mechanisms. Several intrinsic mechanisms protect against the formation of skin cancer following UV exposure at different points of the photocarcinogenesis cascade of events. These mechanisms are impaired in disorders with increased risk for UV-induced skin cancer. Each step of the photocarcinogenesis cascade can be targeted for therapeutic modification and reduction of skin cancer risk.

extrinsic protective agents and protective behaviors that can help individuals reduce their skin cancer risk (see Fig. 86.14).

In order to prevent or reduce UV irradiation of the skin, one can avoid the sun, especially around midday, stay in the shade, wear protective clothing and/or wear sunscreens. Sunscreens are topical preparations that attenuate UV radiation before it enters the skin, by reflection, absorption or both (see Ch. 132). Reflectant products reflect UV from a film of inert metal particles, usually zinc oxide or titanium dioxide in a suitable vehicle. Absorbent sunscreens absorb UVB, UVA or both into specific chemicals (UV filters) and re-emit the energy as insignificant quantities of heat.

Sunscreens protect not only against the acute skin injury of sunburn, but also against UV-induced immune suppression, photoaging and skin cancer. The sun protection factor (SPF) of sunscreens, which indicates by what factor sunburn is prevented by sunscreen use (see Ch. 132), does not correlate well with protection factors for other non-erythema endpoints. Therefore, the SPF cannot be regarded as a reliable guide to non-erythema and chronic endpoints[48].

A good sunscreen should provide broad-spectrum protection against UVB and UVA, ideally in a balanced way with equal protection against both UVA and UVB. Additionally, it should have a comfortable vehicle to ensure its regular use and be photostable. Filters that degrade with UV exposure lose their effectiveness and need reapplication. In addition, degradation products may induce further reactions. This is why unstable sunscreen filters are more likely to cause photoallergic reactions.

In order to prevent oxidative damage – in particular, oxidative DNA damage – the addition of antioxidants to sunscreens has been advocated. However, their protective effects against any of the above-mentioned endpoints have not been well established, or are marginal at best. In addition, the finding that oxidative DNA damage might not contribute significantly to UVA-induced mutagenesis (as was previously thought) brings into question whether antioxidants provide any protection against skin cancer.

In order to be effective, sunscreens need to be applied in sufficient thickness and to all UV-exposed areas. Also, sunscreens should not be used to prolong sun exposure, because this would offset any protective effect and might even increase exposure to unfiltered or less-well-filtered wavelengths, such as UVA. As noted previously, this is one of the explanations for the seemingly contradictory finding (in some studies) that the use of sunscreens might increase, rather than decrease, the incidence of skin cancer, especially melanoma[49].

Topical application of DNA repair enzymes has been shown to increase DNA repair in skin cells and to accelerate removal of DNA photoproducts. In patients with XP, such applications have been reported to reduce the occurrence of actinic keratoses[50]. This indicates that it may be possible to prevent the formation of mutations after the introduction of DNA photoproducts with the use of such "enzymatic sunscreens". Similarly, it may be possible in the future to accelerate or improve the removal of damaged or mutated cells (e.g. by increasing apoptosis of damaged cells) or to improve immune surveillance (e.g. by vaccination).

RELATED DISEASES

Many disorders with an increased risk of UV-induced skin cancer are characterized by a deficiency in the intrinsic protective mechanisms discussed above (see Fig. 86.14). For example, men with androgenetic alopecia have a much higher risk of developing skin cancers on the scalp than do men who have retained their UV-protective hair cover. Diminution or lack of protective melanin, as in oculocutaneous albinism, increases the amount of DNA damage in the basal layer of the epidermis after UV irradiation and, subsequently, the risk of skin cancer, especially SCC. The different DNA repair defects of XP and the DNA damage-processing defect of XP variant (see Table 86.3) generate a UV-mutator phenotype, with an increased chance that DNA damage will result in the formation of a mutation.

Some cases of familial melanoma are caused by a germline mutation in the *CDKN2A (INK4A)* locus, which encodes two protein products, p16 and $p14^{ARF}$ (see Ch. 107). Intact p16 induces a G1 cell cycle arrest by inhibiting cyclin-dependent kinases 4 and 6, which in turn inhibits the phosphorylation of the retinoblastoma protein. Loss of p16 function, therefore, entails a loss of the G1 checkpoint, leading to abnormal

proliferation, unrestricted progression into S phase, and, importantly, no cell cycle arrest after UV irradiation. The second protein product, $p14^{ARF}$, is an upstream regulator of p53, which is also an important factor in mediating UV-induced growth arrest.

It is not easy to explain why disruption of cell cycle control due to silencing of or loss-of-function mutations in *CDKN2A* predisposes a person to primarily melanoma and much less so to internal neoplasms. Of note, loss of p16 or $p19^{ARF}$ (murine equivalent of $p14^{ARF}$) function not only impairs cell cycle control, but also impairs the ability of affected cells to repair DNA photoproducts (leading to a UV-mutator phenotype), perhaps providing an answer as to why silencing or mutations of *CDKN2A* predispose an individual to primarily UV-induced tumors[51]. The fact that germline *CDKN2A* mutations predispose to melanoma, but not to SCC or BCC, might be explained by the previously mentioned resistance of melanocytes to undergo apoptosis, while keratinocytes require another mutation (mostly in *p53*) to fail to undergo apoptosis despite increased UV-induced DNA damage[52].

In addition to inducing apoptosis in cells with overwhelming UV-induced DNA damage, p53 protects against UV mutagenesis by inducing cell cycle arrest after UV-induced damage and by stimulating DNA repair by directly binding to DNA repair enzymes. Consequently, loss of p53 function has been shown to result in a UV-mutator phenotype and reduced repair of UV-induced DNA damage. Li–Fraumeni syndrome is characterized by a germline mutation in the *p53* gene, and patients are predisposed to developing malignancies of various internal organs and possibly cutaneous melanoma[53].

Photodermatologic Disorders 87

Henry W Lim and John LM Hawk

All skin is photosensitive as a result of containing molecules of appropriate shape (chromophores) that absorb ultraviolet radiation (UVR) energy during exposure. The latter is then either re-emitted harmlessly as less active radiation or diverted to power thermochemical reactions, leading to molecular, cellular, tissue and clinical changes, some repaired, some permanent. DNA is the most ubiquitous absorber, initiating UVR-induced changes including sunburning, tanning, hyperplasia, aging and carcinogenesis. Only certain individuals develop abnormal reactions, otherwise known as the photodermatoses, as a result either of *abnormal* tissue responses following normal absorption by endogenous molecules, or of largely *expected* responses following absorption by porphyrins or exogenously ingested or applied photosensitizing drugs or chemicals (Table 87.1). An algorithmic guide to the diagnosis of cutaneous photosensitivity is provided in Figure 87.1.

CLASSIFICATION OF PHOTODERMATOSES
• Immunologically mediated disorders (see Table 87.2) • Defective DNA repair disorders • Photoaggravated dermatoses • Chemical- and drug-induced photosensitivity – Exogenous: ingested or externally applied drugs or chemicals – Endogenous: cutaneous porphyrias; perhaps the Smith–Lemli–Opitz syndrome

Table 87.1 Classification of photodermatoses.

CLASSIFICATION OF IMMUNOLOGICALLY MEDIATED PHOTODERMATOSES
• Polymorphic light eruption • Actinic prurigo • Hydroa vacciniforme • Chronic actinic dermatitis • Solar urticaria

Table 87.2 Classification of immunologically mediated photodermatoses.

ABNORMAL CUTANEOUS EFFECTS OF UVR EXPOSURE

Polymorphic light eruption is consistently the most common photodermatosis, based upon relative frequency analyses from photodermatology centers worldwide; it is followed (in decreasing order of frequency) by photoaggravated dermatoses, drug-induced photosensitivity, chronic actinic dermatitis and solar urticaria[1]. It has been well documented that photodermatoses have a significant negative effect on patients' quality of life[2,3].

Immunologically-Mediated Photodermatoses

This group of disorders is outlined in Table 87.2.

Polymorphic light eruption

Synonyms: ■ Polymorphous light eruption ■ Benign summer light eruption (one clinical variant) ■ Juvenile spring eruption (one clinical variant)

Key features

- The most common photodermatosis
- Presents with papules, vesicles or plaques within hours of sun exposure; lasts for a few days
- Action spectra: UVB, UVA, and, rarely, visible light
- Management: photoprotection, narrowband (NB)-UVB, PUVA; occasionally, brief courses of oral corticosteroids for acute attacks

Introduction

Polymorphic light eruption (PMLE) is a common, sunlight-induced eruption affecting individuals of all races and skin colors[4]. Attacks are intermittent and follow minutes to hours (rarely days) of exposure of the skin to sunlight or artificial UVR. Non-scarring, pruritic, erythematous papules, papulovesicles, vesicles or plaques then develop minutes to hours later. The eruption is generally most severe in the spring and early summer, usually disappearing completely in the winter.

History

PMLE was first described by Carl Rasch in 1900 and mentioned again by Haxthausen in 1918.

Epidemiology

PMLE affects men and women of every race and skin type. The prevalence in the general population is inversely related to latitude, being highest in Scandinavia (22%), high in the UK and northern US (10–15%), and low in Australia (5%) and equatorial Singapore (around 1%)[4]. This is probably due to the development of UVR-induced immunologic tolerance, sometimes referred to as "hardening", secondary to constant solar exposure in sunny climates. Women are affected slightly more often than men, with the second and third decades being the most common times of onset.

Pathogenesis

Attacks of PMLE are produced by exposure to UVR (and perhaps, on occasion, visible light) from sunlight or other sources such as tanning beds. Spring and summer sunlight in temperate regions is most likely to induce outbreaks, however, generally at lower than the *m*inimal *e*rythema *d*ose (MED). Action spectra range from broadband UVB (BB-UVB) to UVA and rarely to visible radiation. Photoprovocation studies have shown a positive response in 50% of patients to narrowband UVB (NB-UVB), 50% to BB-UVA, and 80% to both UVB and UVA[5].

PMLE appears to be a delayed-type hypersensitivity (DTH) response to as yet undefined, endogenous cutaneous photoinduced antigens[3], although a form of heat shock protein has been suggested as one possible antigen[6]. Timed biopsy specimens, following solar-simulated irradiation (~0.6 MED), have shown perivascular infiltrates of lymphocytes, primarily $CD4^+$ (within hours) and $CD8^+$ (within days), in association with an increased number of dermal and epidermal antigen-presenting cells. Overall, these findings are suggestive of a DTH response. In addition, E-selectin, vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) are expressed in the same pattern as in other DTH responses.

Susceptibility to PMLE appears to be genetic, with up to 70% of the population having a propensity for developing this condition, but not all expressing it, because of variations in disease penetrance[7]. The inherited abnormality appears to be a *resistance* to the normal

UVR-induced suppression of the induction[8], but not the elicitation[9], of cutaneous DTH responses. As a result, in PMLE, a lesser degree of cutaneous immunosuppression following UVR exposure (compared to normal individuals) likely results in a persistent ability to mount a DTH response against UVR-altered endogenous cutaneous molecules, leading to the development of clinical lesions. Possible underlying mechanisms include: (1) an under-expression of apoptotic-cell clearance genes in keratinocytes, thus prolonging antigen presence; and/or (2) inefficient free radical removal, thereby increasing photo-antigen production. In evolutionary terms, UVR-induced cutaneous immunosuppression may protect against developing disruptive PMLE, but it can increase the risk of skin cancer; of note, PMLE patients appear to have a reduced tendency to develop such cancers[10].

Clinical features

PMLE occurs most commonly during the spring and early summer, following minutes to hours (occasionally days) of sun exposure. Outbreaks may also occur after exposure to snow-reflected sunlight or tanning bed use. The eruption develops minutes to hours after UVR exposure, then fades over one to several days or occasionally weeks, particularly with continuing exposure. However, the likelihood of occurrence often diminishes or ceases as summer or a sunny vacation proceeds, probably from the development of immunologic tolerance[9], sometimes called 'hardening'.

Typically, some, but virtually never all, of the exposed skin is affected. Lesions are basically symmetrically distributed, but frequently in a patchy fashion. Areas that are normally exposed to sunlight (e.g. face,

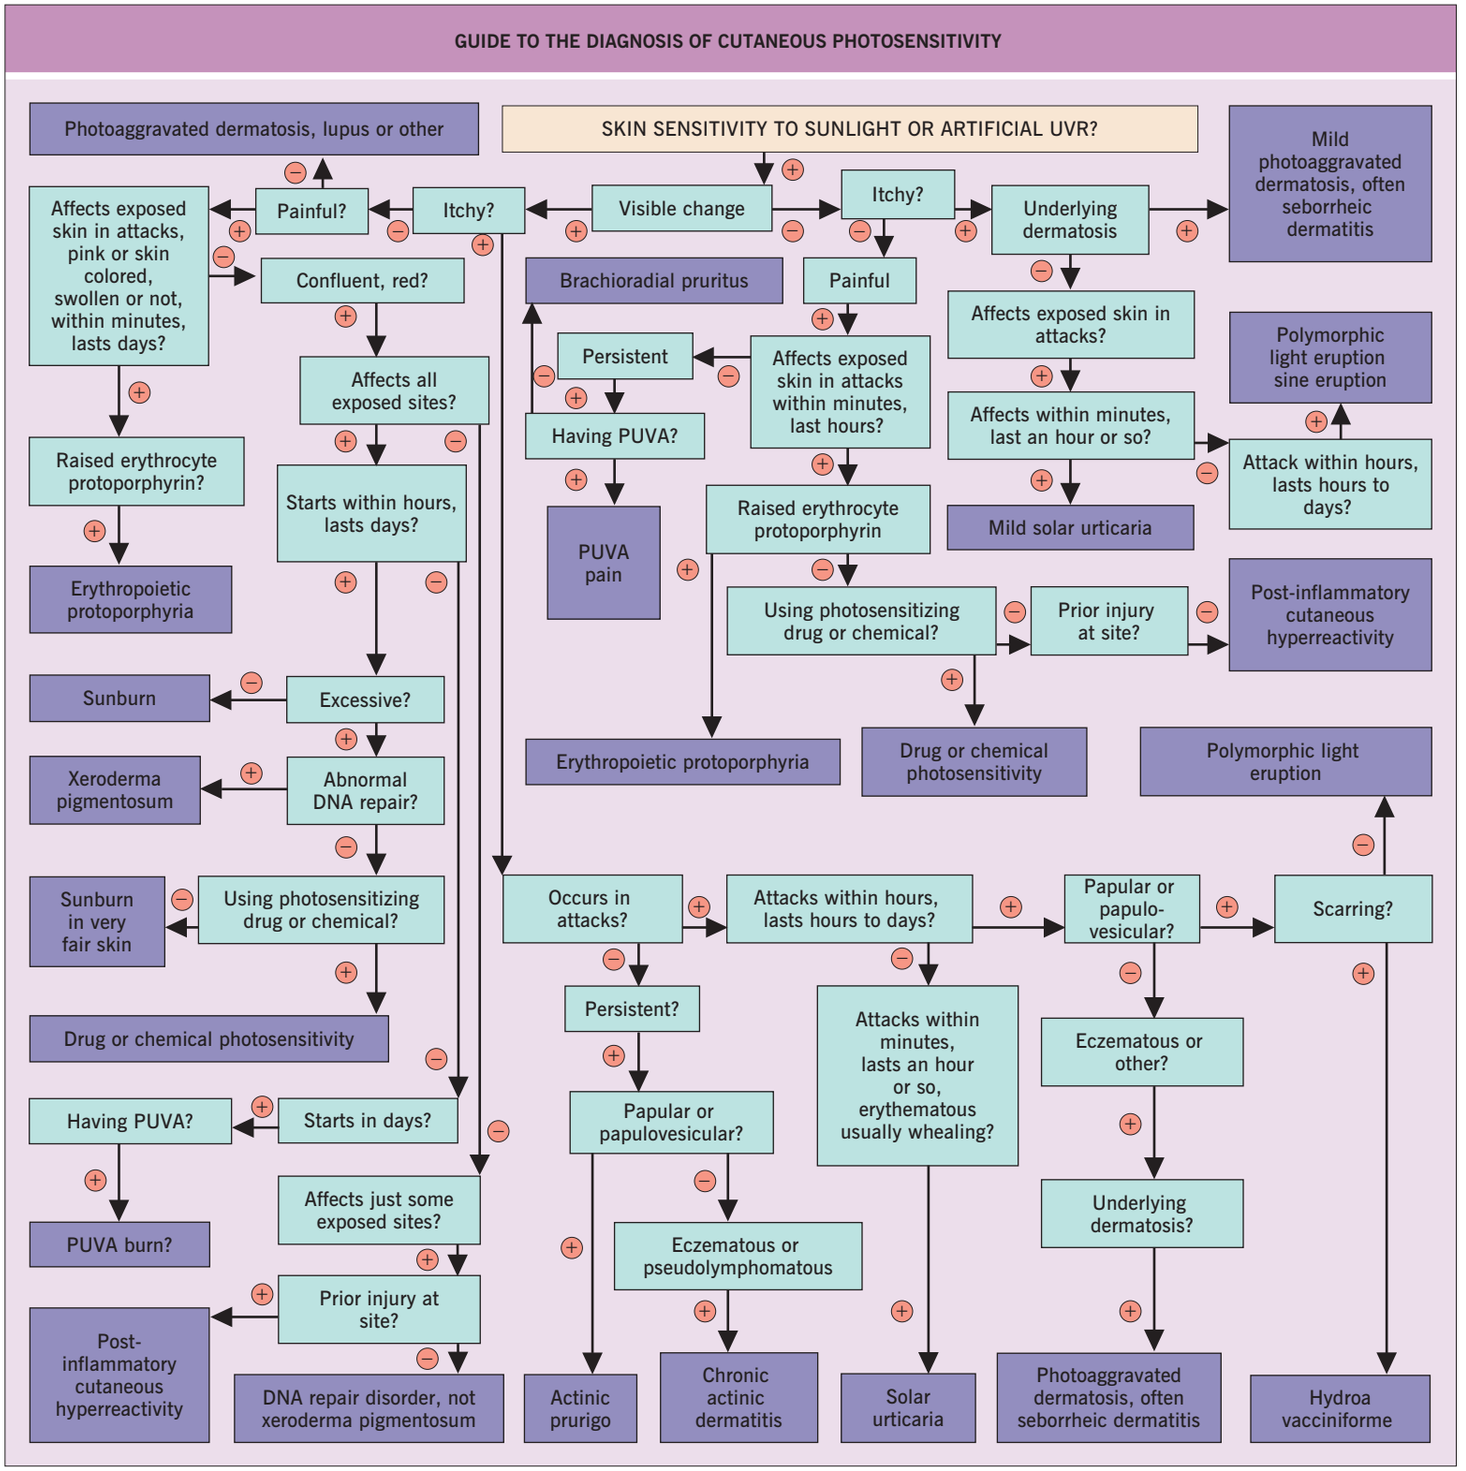

Fig. 87.1 Guide to the diagnosis of cutaneous photosensitivity. The diagnosis can generally be made from patient history and clinical findings, provided the titers of antinuclear antibodies and other LE-associated antibodies are normal.

Fig. 87.2 Polymorphic light eruption. Edematous erythematous plaques on the cheeks in a young child.

Fig. 87.3 Polymorphic light eruption of the upper extremity. Small papules (**A**), papulovesicles (**B**), and larger edematous papules and plaques (**C**).

dorsal hands) are often spared. The distribution pattern and type of lesions in a given patient are usually consistent. Areas commonly affected are the face, neck, outer aspects of the arms, and dorsal surfaces of the hands (Figs 87.2 & 87.3), but there may be more widespread involvement of sun-exposed sites (Fig. 87.4).

Lesions vary widely amongst patients, but are generally mildly to markedly pruritic, grouped, erythematous or skin-colored papules of varying sizes, not infrequently coalescing into large, smooth or unevenly surfaced plaques. In darkly pigmented individuals, the most common morphology is grouped, pinhead-sized papules in sun-exposed areas (see Fig. 87.3A). Vesicles, bullae, papulovesicles and confluent edematous swelling (particularly of the face) are also observed; rarely, only pruritus occurs. Occasionally, the helices of the ears (particularly in boys) may be principally affected, often with vesicles, in a form of PMLE referred to as juvenile spring eruption. General malaise, headache, fever, nausea and other symptoms rarely occur. PMLE may be lifelong; however, in a 32-year follow-up of 94 patients, the disease improved or resolved in 58% over a period of 16 years, and in 75% over a period of 32 years.

Pathology

There is variable epidermal spongiosis and a superficial and deep, perivascular and periappendageal, lymphohistiocytic dermal infiltrate, often with scattered eosinophils and neutrophils. Significant papillary dermal edema occurs commonly (Fig. 87.5). Rarely, difficulty in distinction from cutaneous lupus may occur if interface changes are significant, or from lymphoma if the dermal inflammatory cell infiltrate is marked.

Differential diagnosis

PMLE is distinguished from lupus erythematosus (LE), photoaggravated dermatoses (e.g. atopic dermatitis, seborrheic dermatitis), solar urticaria, and, rarely, erythropoietic protoporphyria (EPP) by history, clinicopathologic correlation and laboratory evaluation (Table 87.3; see Fig. 87.1). For photoaggravated dermatoses, the characteristic clinical features of the primary disorder and negative phototesting usually allow distinction.

Treatment

PMLE in its milder forms may respond to photoprotection. In patients with more severe disease, prophylactic, two-to-three times weekly sessions of NB-UVB phototherapy or psoralen photochemotherapy (PUVA), usually for 15 sessions in the spring, will be effective for several months[11]. For NB-UVB, an initial starting dose of 50–70% of the MED for NB-UVB is recommended, with the dose then increased by 10–15% per treatment. For PUVA, 0.5–0.6 mg/kg of 8-methoxypsoralen is given one hour before UVA exposure; the starting UVA dose ranges from 0.5 to 3 J/cm^2, depending upon skin phototype. Oral prednisone (0.5–1 mg/kg) may be used during the initial seven to ten days of phototherapy to minimize photoexacerbation. Once hardening is achieved, patients are asked to expose themselves weekly to noonday sunlight for 15–20 minutes (without sunscreen) for the remainder of the sunny season as maintenance.

Other treatment modalities include oral prednisone (<0.5 mg/kg, usually given for 5–7 days during vacations)[12] and, in very severe cases, azathioprine or cyclosporine. The efficacy of antimalarials, although popular, has been inconsistent in controlled trials[13,14].

LABORATORY EVALUATION OF PHOTOSENSITIVITY
Routine histology
Antinuclear antibodies
Anti-Ro/SSA, -La/SSB antibodies
Plasma porphyrins, followed by complete porphyrin profile if positive (see Ch. 49)
Phototesting to UVA, UVB and visible light
Photopatch testing (see Fig. 87.12)
In infants and children, urinary amino acids

Table 87.3 Laboratory evaluation of photosensitivity.

Actinic prurigo

Synonyms: ■ Hutchinson's summer prurigo ■ Familial (or hereditary) polymorphous light eruption of American Indians ■ Hydroa aestivale

Key features

- Severe form common in Native Americans (especially Mestizos), often with cheilitis and conjunctivitis
- Can occur in all races, including Caucasians
- Childhood onset; often resolution by adolescence, but can persist indefinitely
- Intensely pruritic, crusted papules or nodules in sun-exposed sites
- Strong association with HLA-DR4 (DRB1*0401) and subtype DRB1*0407
- Management: photoprotection, NB-UVB, PUVA, thalidomide, topical calcineurin inhibitors

Introduction

Actinic prurigo is a not uncommon, sunlight-induced, pruritic and crusted, papular or nodular eruption involving uncovered and, to a lesser extent, covered skin[4,15]. A similar condition, first described in the 1960s and 1970s, affects North, Central and South Americans of native or mixed race. Actinic prurigo may be a persistent variant of PMLE.

History

Hutchinson first described this disorder in 1879, followed in 1918 by Haxthausen, who described it as a PMLE variant. In 1968, Londoño coined the term "actinic prurigo".

Epidemiology

Actinic prurigo is particularly common in Native Americans, especially Mestizos (mixed American Indian and European ancestry) and those living at high altitudes. It also occurs, but much less commonly, in Europe and the Far East. A familial form is relatively common.

Pathogenesis

UVR exposure is the provocative factor in actinic prurigo, in that the condition flares during the spring and summer and phototesting results are abnormal in approximately two-thirds of patients. Lesions can be provoked by UVB or UVA, with the remainder of patients (~1/3) having normal results.

The immunologic nature of actinic prurigo is supported by a study of Mexican Mestizo patients, where the remarkable therapeutic efficacy of thalidomide has been shown to be associated with an inhibition of TNF-α synthesis and the modulation of interferon-γ-producing $CD3^+$ cells[16]. The presence of a dense lymphocytic infiltrate and lymphoid follicles in lesional biopsy specimens from the lips provides further support for this concept[15].

Actinic prurigo may represent a persistent variant of PMLE, as clinical conversion between actinic prurigo and PMLE has been observed and in family studies, the two disorders are closely linked[17]. A strong association with HLA-DR4 (DRB1*0401) and subtype DRB1*0407 has been observed in both UK[17] and Mestizo patients[4], and this could well be the genetic factor that transforms PMLE into actinic prurigo. Indeed, the presence of this subtype is strongly suggestive of the diagnosis.

Clinical features

In general, actinic prurigo appears during childhood and is more frequently seen in girls. It often resolves by adolescence, but may persist indefinitely[4,15]. The eruption is usually worse during the summer in temperate climates, but is often not clearly related to sun exposure. In tropical regions of Latin America, it can persist year-round.

Erythematous papules or nodules, sometimes with hemorrhagic crusts due to excoriation, are present in sun-exposed sites, especially the face (including the nose) and the distal limbs (Fig. 87.6). Lesions may be scattered or densely distributed, and there are sometimes eczematous features or lichenification. Fine linear or pitted scars may appear as facial papules heal. In patients from the UK, involvement of covered sites, particularly the buttocks, has been well described

Fig. 87.6 Actinic prurigo. A The clinical features, including a photodistribution and worsening in the summer, are somewhat suggestive of polymorphous light eruption, but the lesions were persistent and the HLA type was that seen in association with actinic prurigo. Note the involvement of the ears. **B** The crusted papules are more dense on the distal arms.

Fig. 87.7 Actinic prurigo. This patient with severe actinic prurigo has involvement of the buttocks.

Fig. 87.8 Actinic prurigo. Significant cheilitis that is more severe on the lower lip in a Peruvian man with Native American (as well as European) ancestry.
Courtesy, Jean L Bolognia, MD.

(Fig. 87.7). Cheilitis and conjunctivitis are common in Native Americans, with cheilitis being the only clinical manifestation in up to 30% of Mestizo patients (Fig. 87.8)[4].

Pathology

In early lesions, there is epidermal spongiosis, acanthosis and a dermal perivascular mononuclear cell infiltrate with occasional eosinophils, but, unlike in PMLE, papillary edema is usually absent[15]. Later, crusts, more pronounced acanthosis, variable lichenification, excoriations, focal dermal papillary fibrosis and a heavier mononuclear cell infiltrate can be seen. These latter features may resemble those of chronic dermatitis, prurigo nodularis, or, very rarely, cutaneous B-cell lymphoma. Dermal lymphoid follicles have been observed in biopsy specimens taken from the lips[15]. Direct immunofluorescence microscopy is negative.

Differential diagnosis

Clinicopathologic correlation and laboratory evaluation (see Table 87.3) aid in excluding LE and childhood porphyrias. Insect bites are generally less persistent over time, while scabies is much more generalized and diagnosed by skin scrapings. Prurigo nodularis is not accentuated in sun-exposed skin.

Treatment

Constant photoprotection is helpful. For milder disease, topical corticosteroids and topical tacrolimus may be used. NB-UVB or PUVA should be considered next, with protocols similar to those for PMLE (see above). Resistant disease is best treated with oral thalidomide (50–100 mg nightly)[8,15], administered for several weeks until remission is achieved and then tapered to as low a maintenance dose as possible (e.g. 50 mg every second or third night). However, the risks of teratogenicity and peripheral neuropathy require very careful patient selection and supervision (see Ch. 130). Other possible systemic therapies include corticosteroids, azathioprine and cyclosporine.

Hydroa vacciniforme

Synonym: ■ Bazin's hydroa vacciniforme

Key features

- Very rare, childhood-onset photodermatosis
- Papules and plaques develop umbilicated vesiculation, followed by hemorrhagic crusting (often severe) and varioliform scarring
- Epstein-Barr viral infection has been detected in a number of patients
- Management requires very careful photoprotection, including against UVA, and perhaps low-dose phototherapy to avoid provocation

Introduction
Hydroa vacciniforme (HV) is a rare, sunlight-induced, childhood-onset, intermittent but permanently scarring disorder.

History
The condition was first reported by Bazin in 1862.

Epidemiology
HV is well recognized globally, including in the US, UK, continental Europe, Korea and Japan; it has a predilection for lightly pigmented individuals. Its rarity and lack of specific diagnostic tests (apart from its characteristic early histology) have made precise assessment of its distribution difficult. The condition typically has its onset during childhood, affecting boys slightly more often than girls and with more severe disease in boys. The disorder usually resolves during adolescence or early adulthood; rare familial cases have been noted[4,18].

Pathogenesis
Summer sunlight is generally required to provoke the eruption, although abnormal erythematous, or rarely vesicular, phototest responses to repeated monochromatic or broad-spectrum UVR exposure can be seen. While the exact nature of the reaction is unknown, its distribution, early time course and early clinical features are similar to those of PMLE, suggesting it may be a scarring variant of that condition. There have also been multiple reports from Asia and Latin America as well as Europe and the US of the presence of Epstein-Barr virus (EBV) within cutaneous lesions of apparent HV[19,20]. In these patients with chronic EBV infection, the clinical presentations can range from 'typical' HV to so-called severe HV-like eruptions. While no hematologic abnormalities were detected in the former group, those in the latter group had NK-cell lymphocytosis, exaggerated reactions to mosquito bites, and hemophagocytic syndrome. Several of the patients with severe HV-like eruptions have died of EBV-associated NK- or T-cell lymphoma or the hemophagocytic syndrome[19].

In a recent Japanese series, T cells positive for EBV RNA were detected in lesional skin infiltrates from 94% of children with clinically typical HV (17/18) and 11/11 patients with severe HV-like eruptions associated with systemic symptoms, but 0/32 skin biopsy samples from patients with various other dermatoses, including photodermatoses[19]. While the relationship between EBV infection and true photosensitive HV has yet to be firmly established, it is likely that HV and severe HV-like eruptions represent a clinical spectrum[20].

Clinical features
Symmetrical, clustered, pruritic or stinging erythematous macules develop in a photodistribution, especially on the face and dorsal aspects of the hands, within hours of summer sun exposure. Over the next several hours, the macules become tender papules or plaques surmounted by vesicles (Fig. 87.9) or bullae (often hemorrhagic), before umbilicating and condensing into hemorrhagic crusts over several days (Fig. 87.10). Healing then occurs over a period of weeks, leaving individual or confluent, sometimes telangiectatic, varioliform scars (see Fig. 87.10). Generalized malaise with fever or headache rarely accompanies the attacks. Of note, the quality of life in affected children was shown to be negatively impacted by their inability to play outdoors[18].

Fig. 87.9 Hydroa vacciniforme – early phase. There is a polymorphic light eruption-like appearance, but with vesicles around the mouth and umbilicated lesions on the nose.

Fig. 87.10 Hydroa vacciniforme. Hemorrhagic crusts are admixed with varioliform scars; the latter are the sequelae of repeated acute attacks. **A** Note the telangiectasias on the nasal tip. **B** More severe crusting and scarring.
A, Courtesy, Jean L Bolognia, MD.

Pathology
Progressive epidermal spongiosis precedes almost pathognomonic findings: prominent, reticular keratinocyte degeneration; the formation of intraepidermal vesicles containing fibrin and acute inflammatory cells; and confluent epidermal and occasionally focal upper dermal necrosis (Fig. 87.11)[4]. Early on, a perivascular lymphohistiocytic infiltrate is also seen, followed by neutrophilic invasion. Direct immunofluorescence microscopy findings are nonspecific.

Differential diagnosis
While LE and childhood porphyrias can be excluded by clinicopathologic correlation and laboratory evaluation (see Table 87.3), herpes simplex is excluded by a negative DFA assay or viral culture. In patients with severe HV-like eruptions associated with systemic EBV-related disease, the skin lesions typically become more severe and more widespread to include sun-protected sites; additional features include facial swelling (Fig. 87.12), ulcerated nodular skin lesions, exaggerated reactions to mosquito bites, high-grade fevers and hepatosplenomegaly, as

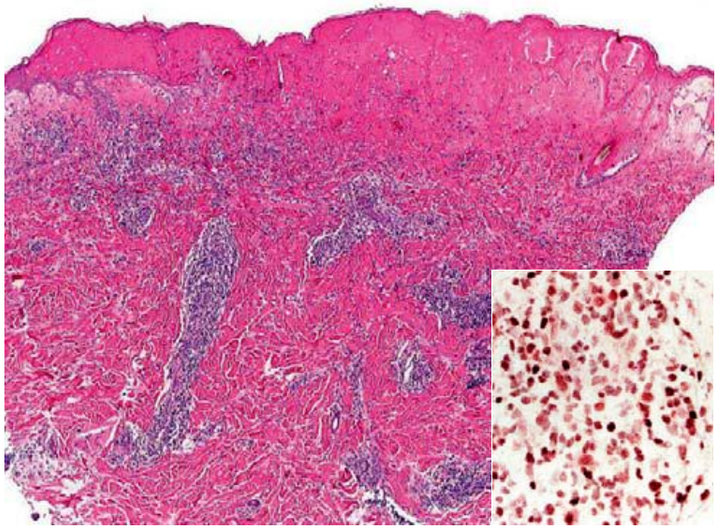

Fig. 87.11 Hydroa vacciniformis. Necrosis of the epidermis with dense, mainly perivascular, infiltrates of lymphocytes within the entire dermis. Note positivity of lymphocytes for Epstein-Barr virus as detected by *in situ* hybridization for EBER-1 (insert). *Courtesy, Lorenzo Cerroni, MD.*

Fig. 87.12 EBV-associated hydroa vacciniforme-like eruption. This Hispanic child had >50 000 copies of EBV DNA/100 000 WBCs as well as EBV DNA within skin lesions by *in situ* hybridization; he subsequently died of lymphoma. Note the facial edema, erythema, papulovesicles, hemorrhagic crusts and varioliform scars. *Courtesy, Richard Antaya, MD.*

well as leukopenia, thrombocytopenia, elevated hepatic transaminases and increased NK lymphocytes. A high circulating EBV DNA load is generally detected by PCR.

Treatment

HV is almost always refractory to treatment[4,18]. Photoprotection, including the use of tinted windows, can be useful in mild to moderate disease. Anecdotally, the following have been claimed as helpful: BB-UVB, NB-UVB, PUVA, β-carotene, antimalarials, azathioprine, thalidomide, cyclosporine and dietary fish oil.

Chronic actinic dermatitis

Synonyms: ■ Photosensitivity dermatitis and actinic reticuloid (PD/AR) syndrome ■ Persistent light reaction ■ Actinic reticuloid (severe clinical variant) ■ Photosensitivity dermatitis (milder UVB- and UVA-sensitive variant) ■ Photosensitive eczema (milder UVB only-sensitive variant)

Key features

- In sun-exposed areas, chronic eczematous eruption (acute, subacute or chronic lichenified) or pseudolymphomatous lesions
- Most common in men over 50 years of age
- Phototests positive to UVB; UVB and UVA; UVB, UVA and visible light; or just UVA
- Positive patch or photopatch tests common
- Management by photoprotection, avoidance of (photo)contact sensitizers, intermittent oral and topical corticosteroids, topical tacrolimus, low-dose PUVA, cyclosporine, azathioprine or mycophenolate mofetil
- Probability of spontaneous resolution is 10% over 5 years, 20% over 10 years

Introduction

Chronic actinic dermatitis (CAD)[21] is a rare, persistent, often disabling dermatosis of uncovered (and to a lesser extent, covered) skin, generally affecting older men, particularly in the summer. It is evoked by UVR and occasionally also visible light exposure, and probably represents a contact allergy-like DTH response against photoinduced endogenous antigen(s).

History

Reference to a condition suggestive of CAD was first made in 1933 by Haxthausen, then in the 1960s by Wilkinson in the UK and Jillson and Baughman in the US, with the latter authors terming it "persistent light reaction". In 1969, its severe form, actinic reticuloid, was described, followed shortly after by reports of two milder variants, photosensitive eczema and photosensitivity dermatitis. In 1979, the current global term, CAD, was introduced by Hawk and Magnus[22].

Epidemiology

CAD has been regularly observed in the US, continental Europe, UK, Far East, India and the African continent.

Pathogenesis

The action spectra for CAD include: UVB; UVB and UVA; UVB, UVA and visible light; and, rarely, just UVA, with UVB plus UVA representing the most common action spectrum. The eczematous clinical and histologic appearances of CAD, its dermal infiltrate of primarily $CD8^+$ T lymphocytes, and its pattern of adhesion molecule activation all closely mimic those of the DTH response of allergic contact dermatitis, strongly suggesting that CAD is a similar response, presumably against endogenous, photoinduced, cutaneous antigen(s).

CAD most commonly affects older outdoor workers and enthusiasts, often with a pre-existing allergic or photoallergic contact dermatitis to exogenous sensitizers such as *Compositae* or sunscreens, respectively[21,23]. It is therefore possible that chronic photodamage may partially ablate normal cutaneous immunosuppression in such individuals, with any exogenous contact dermatitis present simultaneously further enhancing cutaneous immune responsiveness against a presumptively weak endogenous photoantigen. It should be noted that positive patch testing to *Compositae*, commonly observed in the UK, has not been confirmed in the US and Japan[23].

It is likely that DNA, RNA or associated molecules may be involved in the pathogenesis of CAD, in that the shape of the CAD induction spectrum resembles that of sunburn inflammation, for which UVR absorption by DNA is now known to be responsible[21].

Clinical features

CAD occurs primarily in temperate zones, most commonly affecting older men of any race[21]; familial incidence has not been noted. The disorder may develop in previously normal skin, in patients with a prior history of dermatitis (in particular, photoallergic or allergic contact dermatitis), or perhaps rarely following longstanding oral drug photosensitivity or PMLE. Coexistent allergic contact sensitivity to plant antigens, fragrances or topical medications is also common. The CAD eruption is pruritic, patchy or confluent, and the eczematous lesions can be acute, subacute or chronic in nature; the latter is frequently associated with lichenification (Fig. 87.13). Scattered or widespread,

Fig. 87.13 Chronic actinic dermatitis. Chronic eczematous changes of the posterior neck with lichenification and a sharp cut-off at the collar in a patient with phototype V skin.

Fig. 87.14 Chronic actinic dermatitis. Lichenification and hyperpigmentation in sun-exposed sites with areas of depigmentation. Note the sparing of sun-protected areas (nasolabial fold and shoulder).

Fig. 87.15 Chronic actinic dermatitis. Chronic eczematous changes of the dorsal hand and wrist with associated hyperpigmentation and scaling. Note the sharp cut-off at the distal forearm.

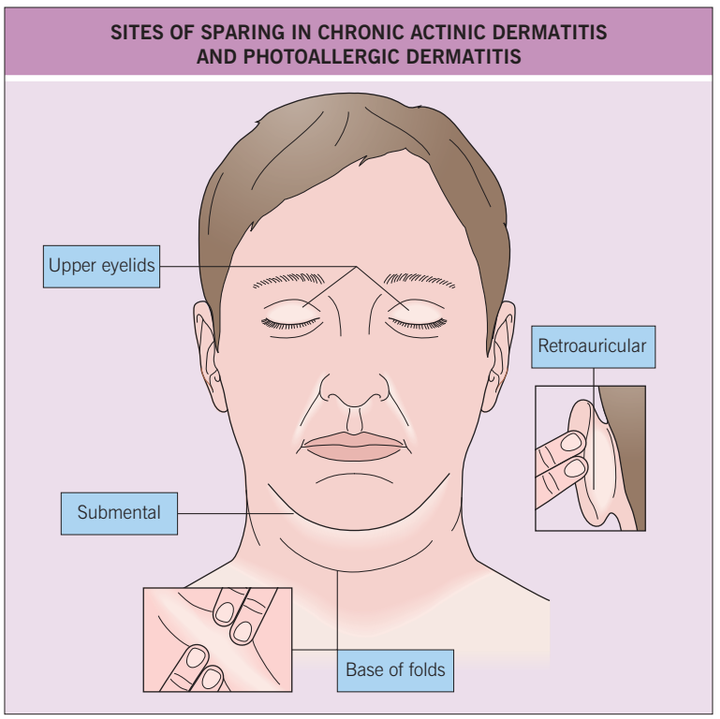

Fig. 87.16 Sites of sparing in chronic actinic dermatitis and photoallergic dermatitis. Relatively sun-protected sites include the upper eyelids, the nasolabial folds, the retroauricular areas, the submental region and the deepest portion of skin furrows. In airborne contact dermatitis these areas may be involved.

erythematous, shiny, infiltrated, pseudolymphomatous papules or plaques may be present in severely affected individuals.

Lesions develop primarily within sun-exposed sites (Figs 87.14 & 87.15), frequently with a sharp cut-off at the lines of clothing, and often with sparing in the depths of skin furrows, upper eyelids, finger webs, nasolabial folds or postauricular areas (Fig. 87.16). Occasionally, palmoplantar eczematous changes may also be present, while eyebrow or scalp hairs may be stubbly or lost from rubbing or scratching. Erythroderma rarely develops in severely affected patients. The probability of resolution has been estimated to be 10% over 5 years, 20% over 10 years, and 50% over 15 years[24].

Pathology

There is epidermal spongiosis and acanthosis, lymphocytic exocytosis, and a superficial and deep, often dense, perivascular lymphohistiocytic dermal cellular infiltrate, often containing eosinophils and plasma cells[21]. In more severely affected skin, erosions, focal epidermal necrosis, Pautrier microabscess-like epidermal cellular collections, dermal–epidermal junction fibrin deposition, dermal neutrophils with nuclear dust, vertically streaked papillary dermal collagen, and/or small, multinucleated dermal giant cells are often seen; in addition, the dense infiltrate, epidermal lymphocyte exocytosis and frequent nuclear polymorphism may on occasion suggest the erroneous diagnosis of cutaneous T-cell lymphoma (CTCL).

Differential diagnosis

Photoaggravated dermatoses are differentiated by the characteristic clinical features of the primary disorder and normal cutaneous irradiation responses. In drug- and chemical-induced photosensitivity, evidence is usually present of exposure to an inducing substance (see below).

In rare instances, patients with CTCL (see Ch. 120) may demonstrate a CAD-like photosensitivity, but phototesting abnormalities, if present, are usually mild and in the UVA range. In addition, CAD infiltrates are predominantly $CD8^+$ cells[21] and T-cell receptor gene rearrangement studies are negative. Very rarely, primary CTCL may present with severe CAD features; this should be considered if apparent CAD is totally refractory to treatment[25]. Erythrodermic CAD must be differentiated from other causes of erythroderma, if necessary by phototesting after the erythroderma has been controlled following days in the dark.

Treatment
Strict photoprotection and the avoidance of relevant contact allergens are of primary importance. Of note, computer and television screens are safe. Museum film or other filters can be placed on home and car windows. Topical or intermittent oral corticosteroid therapy along with emollient use is generally needed, while topical tacrolimus may also be helpful[21]. Therapy for refractory disease includes very-low-dose PUVA with initial high-dose oral and topical corticosteroid coverage over months, cyclosporine (3.5–5 mg/kg/day), azathioprine (1.0–2.5 mg/kg/day), and mycophenolate mofetil (1–2 g/day).

Solar urticaria

Key features
- A physical urticaria induced by sun exposure; lesions appear within 5 to 10 minutes and resolve over 1 to 2 hours
- The action spectrum generally includes both UVA and visible light, but rarely UVB
- There is a slight female predominance, with onset at any age
- Estimated probability of resolution is 15% at 5 years, 25% at 10 years
- Management: photoprotection; high-dose, non-sedating antihistamines; low-dose UVA; PUVA; plasmapheresis; and IVIg

Introduction
In solar urticaria, transient wheals appear within 5 to 10 minutes of exposure to UV or visible radiation. Lesions then resolve over 1 to 2 hours.

History
In 1905, solar urticaria was reported in a 47-year-old woman.

Epidemiology
Solar urticaria is a relatively uncommon disorder, with a prevalence in Tayside, Scotland, of ~3.1 per 100 000[26]. There is a slight female predominance, and the onset is most frequently during the fourth or fifth decade of life. Solar urticaria may occasionally coexist with PMLE, CAD and, very rarely, EPP[26].

Pathogenesis
As in other forms of urticaria (see Ch. 18), mast cells play a major role. Although factors triggering their degranulation have not been fully elucidated, an IgE-mediated response against photoinduced, endogenous cutaneous antigen(s) is a likely mechanism. This is supported by observations that whealing may be induced by previously *in vitro*-irradiated injections of autologous serum, and then blocked by anti-IgE antibody-containing serum. Also, in some patients, plasmapheresis is an effective treatment.

Clinical features
Patients present with whealing limited to sun-exposed areas, in particular the upper chest and outer aspects of the arms, within 5 to 10 minutes of sun exposure (Fig. 87.17). Occasionally, erythema without urtication may occur. The lesions then resolve over 1 to 2 hours. Patients almost invariably note an accompanying pruritus, burning sensation, or rarely pain, while severe attacks are rarely associated with malaise, light-headedness, nausea, bronchospasm and/or syncope.

Solar urticaria is best classified by its action spectrum, which may, however, gradually change over the ensuing years[27]. Most commonly, visible light is responsible, but usually with extension into the UVA waveband; UVB sensitivity is much less common. On occasion, continued regular skin exposure to UVR may decrease the likelihood of developing solar urticaria, a phenomenon referred to as hardening. The probability of spontaneous resolution has been estimated as being 15% at 5 years and 25% at 10 years after onset[26].

There are several uncommon manifestations of this disorder. *Fixed* solar urticaria is limited to specific areas, presumably due to mast cell alterations just at those sites[28]. In *delayed* solar urticaria, lesions last longer than 24 hours; however, this disorder probably represents a form of PMLE. *"Drug-induced"* solar urticaria has been reported following exposure to chlorpromazine, tetracycline, or tar.

Fig. 87.17 Solar urticaria. Wheal and flare responses within minutes of exposure to UVB irradiation in a patient undergoing phototesting.

Pathology
The histologic findings are similar to those of other urticarias, namely, mild dermal edema with a perivascular mixed neutrophilic and eosinophilic infiltrate; infiltration by mononuclear cells may also be seen. In addition, eosinophil major basic protein has been demonstrated within the dermis by immunofluorescence.

Differential diagnosis
The differential diagnosis includes other forms of urticaria, particularly heat urticaria, PMLE and, very rarely, EPP. A detailed history should differentiate solar urticaria from idiopathic urticaria and other physical urticarias. Phototesting of affected patients generally results in typical whealing within minutes (see Fig. 87.17), while the use of a water filter in front of the light source eliminates heat to exclude heat urticaria. The rare association of solar urticaria with EPP can be excluded by determination of RBC protoporphyrins (see Ch. 49). The time course of PMLE is distinct from that of solar urticaria, and LE can be excluded via laboratory evaluation (see Table 87.3).

Treatment
Oral non-sedating antihistamines, often in high doses and taken regularly or about an hour or so before expected sun exposure, are effective in ~50% of patients. Those with very mild disease may occasionally require only photoprotective measures; however, sunscreens do not generally protect well enough against UVA and visible light to be effective[29]. Graduated exposures to UVA or PUVA are occasionally helpful[30]. If these measures fail, more aggressive therapies such as plasmapheresis[31], omalizumab (anti-IgE antibody) or IVIg[32] can be tried. Graduated UV exposure has provided some patients a benefit for years.

Inherited Disorders Characterized by Defective DNA Repair

The major disorders characterized by both defective DNA repair and photosensitivity are discussed below and outlined in Table 87.4. The underlying pathogenesis is reviewed in greater detail in Chapter 86. Four of the disorders are associated with defects in one of the nucleotide excision repair (NER) proteins: xeroderma pigmentosum, Cockayne syndrome, UV-sensitive syndrome, and the photosensitive form of trichothiodystrophy[33–35]. A fifth disorder with an NER defect, cerebro-oculo-facio-skeletal (COFS) syndrome, has no associated photosensitivity, so it will not be discussed.

Xeroderma pigmentosum

Introduction
Xeroderma pigmentosum (XP) is an autosomal recessive condition associated with a marked increase in the development of malignancies, especially cutaneous. Seven genetically different complementation groups and an XP variant have been delineated.

History
XP was first described by Hebra and Kaposi in 1874.

INHERITED PHOTOSENSITIVITY DISORDERS ASSOCIATED WITH DEFECTIVE DNA NUCLEOTIDE EXCISION REPAIR OR CHROMOSOME INSTABILITY					
Disorder	**Clinical features**	**Inheritance**	**Photosensitivity**	**Action spectrum**	**Laboratory findings**
Xeroderma pigmentosum (XP)	• 1 per million in Western countries; 1 per 40 000 to 100 000 newborns in Japan • Photosensitivity, early-onset lentigines (typically by 2 years of age) • Basal cell carcinomas, squamous cell carcinomas and melanomas in sun-exposed areas • Median age for development of first non-melanoma skin cancers: 8 years • Photophobia, keratitis, corneal opacification and vascularization • Neurologic abnormalities: hyporeflexia, deafness, seizures (most common in groups A and D; do not usually occur in XP variant) • XP variant patients usually have no neurologic problems • Support group: www.xps.org	AR	Yes	290–340 nm	• Complementation groups A to G: defective global genomic nucleotide excision repair (GG-NER) of UVR-induced DNA damage (e.g. pyrimidine dimers) from any part of the genome • XP variant: defective DNA polymerase-η, resulting in insertion of incorrect residue during replication of DNA with UVR-induced damage • Defective genes for all the XP groups have been identified • Cells are hypersensitive to killing by UVR
Cockayne syndrome (CS)	• Over 180 patients reported to date • Photosensitivity without pigmentary changes. Loss of adipose tissue, prominent ears, dental caries, thinning of skin and hair • Hypogonadism, stooped posture, joint contractures, short stature with extremely thin body habitus ("cachectic dwarfism"), microcephaly, mental retardation, deafness • Calcification of basal ganglia, demyelination, pigmentary retinal degeneration, osteoporosis • No increase in malignancies in "pure" CS • CS type I: 80% of patients; onset at 2 years of age, progressive; life expectancy: second to third decades • CS type II: symptoms at birth, life span = 6–7 years • CS type III: late onset, normal growth and development • No correlation between genotype and phenotype • Combined XP/CS: solar lentigines, skin cancers, pigmentary retinal degeneration, basal ganglion calcification • Support group: www.cockayne-syndrome.org	AR	Yes	Unclear	• Defective transcription-coupled nucleotide excision repair (TC-NER), which targets transcriptionally active regions of the genome • CS cells are defective in the repair of pyrimidine dimer photoproducts and oxidative DNA base modifications typically induced by UVB and UVA, respectively • Two complementation groups: CS-A (mutations in *ERCC8*) and CS-B (mutations in *ERCC6*); identical phenotypes • Mutations in *XPB, XPD* and *XPG* genes have been associated with combined XP/CS phenotypes
UV-sensitive syndrome (UV^{S}S)	• Fewer than 10 patients reported to date • Considered to be a mild variant of CS • Photosensitivity, solar lentigines; otherwise normal	AR	Yes	Unclear	• Similar to CS: defective TC-NER, normal GG-NER; however, unlike CS, patients with UV^{S}S only defective in repair of UVB-induced photoproducts (not in repair of oxidative damage) • Mutations in *CSB, CSA*, and an undefined gene
Trichothiodystrophy (TTD)	• Over 100 patients reported to date • PIBI(D)S: *p*hotosensitivity, *i*chthyosis, *b*rittle hair, *i*ntellectual impairment, *d*ecreased fertility, short stature • Other features: microcephaly, receding chin, protruding ears • No increase in malignancies	AR	Yes (in 50% of patients)	Unclear	• Hair shaft: alternating light and dark bands ("tiger tail banding"), trichoschisis, trichorrhexis nodosa-like changes, "ribboning" • Reduction of cysteine-rich matrix proteins and low sulfur content in hair shafts • Mutations in *XPD, XPB*, general transcription factor IIH polypeptide 5 (*GTF2H5* or *TFB5*), and *C7orf11*
Bloom syndrome	• Over 250 patients reported to date; Ashkenazi Jews account for ~25% of families • Malar erythema and telangiectasias, café-au-lait macules and areas of hypopigmentation, elongated face with malar hypoplasia and prominent nose, short stature, diabetes mellitus, recurrent respiratory and GI infections • Increased frequency of leukemia, lymphoma, GI adenocarcinoma • Normal intelligence • Men: sterile due to defective sperm; women: reduced fertility • Patient registry: Bloom Syndrome Registry (www.med.cornell.edu/bsr)	AR	Yes	Unclear	• Decreased IgA, IgM, sometimes IgG • Mutations in *BLM (RECQL3)*, resulting in chromosomal instability (increased sister chromatid exchanges, chromosomal breakage and rearrangement) • Quadriradial configurations in lymphocytes and fibroblasts are diagnostic

Table 87.4 Inherited photosensitivity disorders associated with defective DNA nucleotide excision repair or chromosome instability.

Continued

INHERITED PHOTOSENSITIVITY DISORDERS ASSOCIATED WITH DEFECTIVE DNA NUCLEOTIDE EXCISION REPAIR OR CHROMOSOME INSTABILITY					
Disorder	**Clinical features**	**Inheritance**	**Photosensitivity**	**Action spectrum**	**Laboratory findings**
Rothmund–Thomson syndrome	• Over 300 patients reported to date • Erythema, edema and vesicles on the cheeks and face during the first few months of life, followed by poikiloderma that also typically affects the dorsal aspect of the hands/forearms and the buttocks • Sparse hair (scalp, eyebrows, eyelashes), hypoplastic nails, acral keratoses (in adolescents and adults), short stature, skeletal (e.g. radial ray defects, osteoporosis) and dental abnormalities, juvenile cataracts, chronic diarrhea/vomiting during infancy, pituitary hypogonadism (may be associated with midface hypoplasia/"saddle nose") • Osteosarcoma (10–30%), squamous cell carcinoma (<5%; often acral) • Normal immune function, intelligence and lifespan (in the absence of malignancy)	AR	Transient (early childhood)	UVA	• Mutations in *RECQL4*; protein product is a DNA helicase • Genomic instability may account for propensity for malignancies

Table 87.4 Inherited photosensitivity disorders associated with defective DNA nucleotide excision repair or chromosome instability (cont'd). AR, autosomal recessive.

Epidemiology

XP has an estimated incidence of one per million in newborns in Western countries, and 1 per 100 000 newborns in Japan[36].

Pathogenesis

In XP, there are seven genetically different complementation groups (A to G), each associated with a different site of impairment in global genomic nucleotide excision repair (GG-NER), i.e. impairment in the removal of DNA damage from any part of the genome[33]; the damaged DNA then accumulates, leading to mutations and cancer. XP-A through -G represent different proteins in the NER pathway (see Fig. 86.12). It should be noted that different mutations in the *XPB*, *XPD* and *XPG* genes can be associated with different phenotypes – either XP or XP/Cockayne syndrome – and mutations in the *XPB* and *XPD* genes can also be associated with trichothiodystrophy (see below). XP variant, which has normal NER, is due to mutations in the gene that encodes DNA polymerase-η (also known as Pol η, Pol H or hRad30A). This enzyme is responsible for bypassing the unrepaired DNA photoproduct during DNA replication; mutations thus result in the insertion of erroneous residues during replication.

Phototesting in XP patients has shown the action spectrum for inflammatory erythema of the skin to be in the 290 to 340 nm range. The MEDs corresponding to those wavelengths are generally quite reduced, with the peak responses often vesicular and delayed by a day or two.

Fig. 87.18 Xeroderma pigmentosum. A 17-year-old with skin phototype V who has hyper- and hypopigmentation admixed with scarring, lentigines and seborrheic keratoses. Note the squamous cell carcinoma *in situ* of the lower lip in association with severe actinic cheilitis. *Courtesy, Julie V Schaffer, MD.*

Clinical features

Patients usually have marked photosensitivity as well as the early onset of all major types of skin cancer (see Table 87.4). Starting from an early age, many also easily develop sunburns with erythema, edema and vesicles following minimal sun exposure. By the age of 2 years, practically all patients have developed solar lentigines. With continuing exposure, however, the skin gradually becomes xerotic, leading to the term 'xeroderma pigmentosum', or dry pigmented skin (Fig. 87.18).

Actinic keratoses, basal cell carcinomas (BCCs), squamous cell carcinomas (SCCs) and, less frequently, melanomas then develop in sun-exposed sites, also prematurely. In one study, the median age for initial non-melanoma skin cancer development was 8 years[37]. SCC of the tip of the tongue has also been reported, presumably secondary to UVR exposure.

Ocular abnormalities are observed in ~40% of patients. Severe photophobia, keratitis, corneal opacification and vascularization are common manifestations, while loss of eyelashes, ectropion, and SCC and melanoma of the UVR-exposed parts of the eyes are also frequently reported[37].

Approximately 20–30% of XP patients develop neurologic abnormalities, the most severe presentation being the DeSanctis–Cacchione syndrome, in which microcephaly, progressive mental retardation, retarded growth and sexual development, deafness, choreoathetosis, ataxia and quadriparesis may all occur. However, some XP patients develop a limited number of clinical manifestations, such as isolated hyporeflexia and progressive deafness. XP variant patients usually have no neurologic problems. Deep tendon reflex testing and routine audiometry are good screening tests for the presence of neurologic involvement. It has been postulated that these neurologic abnormalities are due to defective DNA repair in nerve cells, resulting in neuronal death. Patients with XP also have an approximately 10- to 20-fold increase in the incidence of internal malignancies, including tumors of the brain, lung, oral cavity, gastrointestinal tract, kidney and hematopoietic system.

Treatment

Management consists of extremely rigorous photoprotection. Oral calcium and vitamin D supplementation should also be recommended for these patients. Cryotherapy, electrodesiccation and curettage, and surgical excision are used to manage the premalignant and malignant skin tumors. Oral retinoids can be administered as chemopreventive agents, and, anecdotally, topical imiquimod has been reported to be useful. Topical application of the bacterial DNA repair enzyme T4 endonuclease V (T4N5) formulated in a liposomal delivery vehicle has been successful in decreasing the development of actinic keratoses and BCCs[38], although this product is currently not commercially available.

Cockayne syndrome

Introduction
Cockayne syndrome is a rare photosensitivity disorder transmitted in an autosomal recessive fashion (see Table 87.4); to date, over 180 patients have been reported[33].

History
This entity was first described by Cockayne in 1936.

Epidemiology
Cockayne syndrome has been reported from the US, Europe and Japan.

Pathogenesis
Cells from affected patients are hypersensitive to killing by UVR[33]. However, the fundamental defect in NER in Cockayne syndrome is different from that of XP. In the former, there is defective transcription-coupled NER (TC-NER), which requires a subset of NER proteins plus additional factors and targets the transcriptionally active regions of the genome. The dysfunction results in the inability to recover RNA synthesis after exposure to UVR. In contrast, XP cells have defective global genomic NER (GG-NER; see above).

In contrast to XP, to date there has never been a report of cancer in a patient with Cockayne syndrome, whose average lifespan is only 12 years (although there is considerable variation)[39,40]. One explanation is that cells with low-level damage due to defective TC-NER are eliminated in patients with Cockayne syndrome, protecting the body from carcinogenesis at the expense of accelerated aging.

There are two complementation groups with identical phenotypes: CS-A due to mutations in *ERCC8* (also known as *CSA*) and CS-B due to mutations in *ERCC6* (also known as *CSB*); 80% of patients have been assigned to the CS-B complementation group[36]. Several patients with an XP–Cockayne syndrome complex have also been reported (with mutations in *XPB, XPD* or *XPG*), typically demonstrating the solar lentigines and cutaneous neoplasms of XP, along with the pigmentary retinal degeneration and basal ganglia calcification of Cockayne syndrome[40].

Clinical features
Patients with Cockayne syndrome have been classified into three types based upon severity of symptoms and age of onset (see Table 87.4)[39]. Unlike individuals with XP, these patients have photosensitivity without significant pigmentary changes, but the action spectrum of the photosensitivity has not been determined. Progressive signs of premature aging occur, as does growth failure affecting the weight more than the length (i.e. cachectic dwarfism).

Treatment
This consists of symptomatic treatment only.

UV-sensitive syndrome

UV-sensitive syndrome (UV^sS) is a rare, photosensitive, autosomal recessive disease; to date, fewer than 10 patients have been reported, mostly from Japan[41,42]. It is considered to be a mild variant of Cockayne syndrome. Clinically, patients present with lentigines, but no neurologic abnormalities, nor an increased frequency of skin or internal cancers. All patients have photosensitivity, although the action spectrum has not been studied. The molecular defects are summarized in Table 87.4.

Trichothiodystrophy

Introduction
Trichothiodystrophy (TTD) is an autosomal recessive disorder with over 110 patients reported to date (see Table 87.4)[43].

History
The term 'trichothiodystrophy' was coined by Price in the late 1970s.

Epidemiology
The disorder appears to occur worldwide and affects men and women.

Pathogenesis
TTD with severe photosensitivity is associated with mutations in *ERCC2/XPD* (95% of patients), and rarely in *ERCC3/XPB*[35]. Mutations in chromosome 7 open reading frame 11 (*C7orf11*) underlie a non-photosensitive form of TTD, while mutations in a fourth gene that encodes the tenth subunit of transcription factor II H (TFIIH; see Ch. 86) also lead to TTD.

Clinical features
TTD has heterogeneous clinical manifestations, and several previously described syndromes (e.g. Amish brittle hair, Marinesco–Sjögren, Sabinas, Pollitt, Tay and IBIDS) are probably part of its spectrum. Unlike XP, TTD is not associated with skin cancers, and pigmentary alterations are uncommon.

The clinical features of TTD are frequently described by the acronym PIBI(D)S[43]:

Photosensitivity: Photosensitivity has been reported in up to 50% of affected patients, but the action spectrum is not known. Most patients with photosensitivity can be assigned to the XP-D complementation group. It should be noted that *XPD* mutations associated with XP result in impaired NER function, while *XPD* mutations that underlie TTD lead to an *in vitro* basal transcription defect[44]; this may explain the lack of an association of skin cancer with TTD.

Ichthyosis: A non-bullous congenital ichthyosiform erythroderma phenotype is commonly observed during infancy, and patients occasionally present with a collodion membrane. The erythema tends to fade over time, eventuating in ichthyosis of variable severity (see Ch. 57).

Brittle hair: This is the hallmark of TTD and is present in most, but not all, patients[43,45]. By polarizing microscopy, hair shafts demonstrate alternating bright and dark bands ('tiger tail banding') (see Fig. 69.20) Light microscopic findings include an irregular contour, trichoschisis (transverse fractures through the shafts) and, sometimes, trichorrhexis nodosa-like features. Hair shafts are flattened and may fold like a ribbon. There is also a reduction in cysteine-rich matrix proteins, resulting in defective cross-linking of the intermediate keratin filaments and a low sulfur content within the hair shaft. This defect may also account for the brittle nails and the ichthyosis seen in TTD.

Intellectual impairment: This ranges from mild to severe retardation.

Decreased fertility: This has been reported in patients of both sexes, but is not a prominent feature.

Short stature: Growth retardation is present to a varying degree.

Other manifestations include a characteristic facies with a receding chin and protruding ears, sideroblastic anemia, eosinophilia, and hepatic angioendotheliomas.

Treatment
No specific treatment is available.

Inherited Disorders Characterized by Chromosomal Instability

Bloom syndrome

Synonym: ▪ Congenital telangiectatic erythema

Introduction
Bloom syndrome is transmitted in an autosomal recessive fashion (see Table 87.4); as of the end of 2009, 265 patients were listed in the Bloom Syndrome Registry (www.med.cornell.edu/bsr)[46].

History
The condition was first reported by David Bloom, a New York City dermatologist, in 1954.

Epidemiology
Bloom syndrome was initially described as occurring most frequently amongst Ashkenazi Jews; however, of the 222 families in the Bloom Syndrome Registry, 75% were non-Jewish[39].

Pathogenesis
The gene (*BLM*), on chromosome 15q26.1, is a member of the RECQ helicase family. The functions of its protein product include unwinding

DNA and maintaining genomic stability. Mutations in *BLM* result in a tenfold increased rate of spontaneous sister chromatid exchanges, chromosomal breakage and rearrangements[47], while quadriradial configurations of chromosomes in lymphocytes and fibroblasts are a diagnostic feature.

Clinical features
Beginning within the first few weeks of life, patients typically develop erythema and telangiectasias of the malar areas and occasionally the dorsal aspects of the hands and forearms. Café-au-lait macules with adjacent areas of hypopigmentation are also common. While photoexacerbations of the erythema have been reported, the action spectrum remains unclear. Growth delay and short stature with a disproportionately small head are usually the most common reasons for parents to seek medical care[39].

Among the 265 patients in the Registry, the average age at death was 26 years[46]. In addition to recurrent infections due to an associated immunodeficiency, the chromosomal instability leads to a 150- to 300-fold increase in the frequency of malignancies, including lymphomas and leukemias (see Table 87.4).

Treatment
Symptomatic management and photoprotection are the only treatment strategies.

Rothmund–Thomson syndrome

Synonym: ■ Poikiloderma congenitale

Introduction
Rothmund–Thomson syndrome is a rare entity with autosomal recessive inheritance; to date, over 300 cases have been reported in the English literature[48] (see Table 87.4).

History
The disorder was first recognized by Auguste Rothmund, a German ophthalmologist, in 1868, before Sydney Thomson, a British dermatologist, described a similar entity in 1923. In 1957, William Taylor proposed the eponym Rothmund–Thomson syndrome.

Epidemiology
Patients have been reported from the US, Canada, Central and South America, Europe, Australia, Japan and Israel.

Pathogenesis
The majority of patients with Rothmund–Thomson syndrome have mutations in the *RECQL4* gene[49]. The protein product is a DNA helicase, which unwinds DNA and stabilizes the genome. *RECQL4* is in the same gene family as *BLM* (Bloom syndrome), and dysfunction of the helicase is thought to account for the increased susceptibility to cancers.

Clinical features
Patients typically present in the first few months of life with photodistributed erythema, edema and vesicles of the cheeks and face, which may extend to involve the buttocks and extremities. Over months to years, poikiloderma develops. In one patient, the action spectrum of the photosensitivity was in the UVA range. Up to one-third of patients develop osteosarcoma[48]. Other features are summarized in Table 87.4.

Differential diagnosis
In addition to the entities listed in Table 87.4, the differential diagnosis includes poikiloderma with neutropenia, an autosomal recessive disorder due to mutations in *C7orf57* that was first described in Navajo Native Americans[49a].

Treatment
Treatment is symptomatic and preventative only.

Kindler Syndrome
Kindler syndrome (see Ch. 63) is an autosomal recessive disorder with transient early-onset photosensitivity and blistering, followed by persistent poikiloderma; it is due to loss-of-function mutations in *KIND1* (*FERMT1*)[50–52]. This gene encodes the focal adhesion protein, fermitin family homolog-1, which is implicated in integrin activation. A decreased MED to UVB, and in some patients to UVA, has been reported.

PHOTOAGGRAVATED DERMATOSES
• Acne vulgaris
• Atopic dermatitis
• Bullous pemphigoid
• Carcinoid syndrome
• Cutaneous T-cell lymphoma (Sézary Syndrome)
• Dermatomyositis
• Disseminated superficial actinic porokeratosis
• Erythema multiforme
• Familial benign chronic pemphigus (Hailey–Hailey disease)
• Hartnup syndrome
• Keratosis follicularis (Darier disease)
• Lichen planus
• Lupus erythematosus
• Pellagra
• Pemphigus, including pemphigus foliaceus (erythematosus)
• Pityriasis rubra pilaris
• Psoriasis
• Reticular erythematous mucinosis (REM)
• Rosacea
• Seborrheic dermatitis
• Transient acantholytic dermatosis (Grover's disease)
• Viral infections, including herpes simplex, exanthems

Table 87.5 Photoaggravated dermatoses.

Photoaggravated Dermatoses

Key features
- The underlying disease is not caused, but rather exacerbated, by sun exposure, sometimes severely
- The most common of these conditions is photoaggravated seborrheic dermatitis, followed by rosacea, LE, Grover's disease, and psoriasis
- Monochromatic phototesting is usually normal (LE being the exception)
- Therapy focuses on treatment of the underlying disease

Introduction
A number of skin diseases that are not directly caused by UVR exposure may, in some patients, be worsened by it (Table 87.5). The reasons for such aggravation, however, have been poorly studied, with the exception of LE (see Ch. 41)[53].

History
By the 1930s, the photoaggravation of dermatoses was formally recognized, especially in psoriasis. Studies on UV exacerbation of viral exanthems were performed in the 1950s, followed by examination of the photosensitivity in LE during the 1960s.

Epidemiology
These dermatoses occur worldwide[53]. In photodermatology referral centers, as a group, the prevalence ranges from 15% to 25%[1].

Clinical features
The basic dermatosis may be mildly or severely exacerbated by UVR exposure (Fig. 87.19), usually within minutes to hours, but sometimes a day or more later. The UVR-exacerbated eruption is usually limited to sites characteristically involved by the underlying condition; less often the flare involves all sun-exposed sites. However, it is important to remember that the majority of patients with disorders such as psoriasis will improve following sun exposure or phototherapy.

Fig. 87.19 Photoaggravated atopic dermatitis induced by the solar simulator. This was the appearance 24 hours after irradiation.

Pathology
The histology is that of the underlying dermatosis.

Differential diagnosis
In general, photoaggravated dermatoses are recognized by the presence of the underlying skin disease (see Table 87.5). The differential diagnosis often includes PMLE, although PMLE is typically papular and pruritic, has negative lupus serology, and can be induced by photoprovocation tests (~80% of patients). It is important to note, however, that PMLE may sometimes coexist with photoaggravated dermatoses, in particular photosensitive psoriasis and LE. Photoaggravated atopic dermatitis, if widespread, may be confused with CAD; however, phototest results are positive in CAD. Lastly, UVR-induced exacerbations need to be distinguished from flares due to heat exposure.

Treatment
Treatment should focus on the underlying disorder and photoprotection. Topical corticosteroids, low-dose NB-UVB or PUVA may sometimes lead to improvement; rarely, short courses of oral corticosteroids are required.

Chemical- and Drug-Induced Photosensitivity

Key features
- Phototoxicity is characterized by an exaggerated sunburn-like reaction, usually caused by systemic agents
- Photoallergy presents with eczematous lesions, most commonly related to topical photoallergens
- The cutaneous porphyrias are an example of phototoxicity induced by endogenous agents
- Management: identification and avoidance of the offending agent; if avoidance is not possible, careful photoprotection; occasionally, evening dosing of medications such that their peak systemic levels occur during the night

Exogenous
Introduction
Photosensitivity induced by exogenous agents can be divided into phototoxicity and photoallergy (Table 87.6). Phototoxicity is the result of direct tissue and cellular injury following UVR-induced activation of a phototoxic agent; theoretically, phototoxicity can be induced in every individual. In contrast, photoallergy is a delayed-type hypersensitivity response consisting of a sensitization phase, an incubation period of 7 to 10 days (following the first exposure), and a clinical reaction after any subsequent challenge; only sensitized individuals can develop photoallergy.

COMMON PHOTOTOXIC AND PHOTOALLERGIC AGENTS

Common phototoxic agents	Common photoallergic agents
• Antiarrhythmics – Amiodarone – Quinidine • Triazole antifungals – Voriconazole • Diuretics – Furosemide – Thiazides • Nonsteroidal anti-inflammatory drugs – Nabumetone – Naproxen – Piroxicam • Phenothiazines – Chlorpromazine – Prochlorperazine • Psoralens – 5-Methoxypsoralen – 8-Methoxypsoralen – 4,5′,8-Trimethylpsoralen • Quinolones – Ciprofloxacin – Lomefloxacin – Nalidixic acid – Sparfloxacin • St. John's wort – Hypericin • Sulfonamides • Sulfonylureas • Tar (topical) • Tetracyclines – Doxycycline – Demeclocycline	Topical agents: • Sunscreens (e.g. oxybenzone [benzophenone-3]) • Fragrances – 6-Methylcoumarin – Musk ambrette – Sandalwood oil • Antimicrobial agents – Bithionol – Chlorhexidine – Fenticlor – Hexachlorophene • Nonsteroidal anti-inflammatory drugs – Diclofenac – Ketoprofen • Phenothiazines – Chlorpromazine – Promethazine Systemic agents: • Antiarrhythmics – Quinidine • Antimalarials – Quinine • Antifungals – Griseofulvin • Antimicrobials – Quinolones (e.g. enoxacin, lomefloxacin) – Sulfonamides • Nonsteroidal anti-inflammatory drugs – Ketoprofen – Piroxicam*

*Often have positive patch test to thimerosol.

Table 87.6 Common phototoxic and photoallergic agents.

History
Phototoxic agents have been used as medications from as early as 4000 BC, with the inhabitants of Mesopotamia (and later the Indians and Egyptians) employing plant-derived psoralens for the treatment of leukoderma. In 1913, Meyer-Betz demonstrated hematoporphyrin-induced phototoxicity on himself, while the current method of PUVA therapy was introduced in the 1970s. For almost a century, medications have been known to cause unwanted phototoxic reactions. Photoallergy was first recognized in 1939 based on a classic study by Epstein on sulfanilamide.

Epidemiology
While the exact prevalences of phototoxicity and photoallergy in the general population are unknown, their frequency in photodermatology referral centers has ranged from 5% to 15% for phototoxicity and from 4% to 8% for photoallergy[1,54,55].

Pathogenesis
The pathogenesis of phototoxicity involves the generation of oxygen free radicals, superoxide anions, hydroxyl radicals and singlet oxygen, which leads to a host of cytotoxic tissue effects. Other mechanisms of damage include the generation of stable photoproducts (reported with chlorpromazine and tetracyclines), the formation of photoadducts (reported with psoralens), and the generation of inflammatory mediators (reported with porphyrins and demeclocycline)[56].

The pathogenesis of photoallergy is identical to that of allergic contact dermatitis, with the exception of the requirement for the presence of UVR to induce photoallergen formation.

Fig. 87.20 Exogenous drug-induced photosensitivity and hyperpigmentation. Gray–brown patches involving the sun-exposed skin of a patient receiving diltiazem.

COMMONLY EMPLOYED PHOTOPATCH TEST AGENTS

Substance	Concentration (%)
Sunscreen agents	
Octyl methoxycinnamate (octinoxate)	10
Benzophenone-3 (oxybenzone)	10
Octyl dimethyl PABA (padimate 0)	10
Butyl methoxydibenzoylmethane (avobenzone)	10
4-Methylbenzylidene camphor (enzacamene)*	10
Benzophenone-4 (sulisobenzone)	10
Isoamyl methoxycinnamate*	10
Phenylbenzimidazole sulfonic acid (ensulizole)	10
Musk ambrette	1
Tribromosalicylanilide	1
Sesquiterpene lactone mix	0.1
Nonsteroidal anti-inflammatory agents†	
Naproxen	5
Ibuprofen	5
Diclofenac	1
Ketoprofen	2.5

*Not approved in the US.
†Observed as topical sensitizers primarily in Europe.

Table 87.7 Commonly employed photopatch test agents. Modified from ref. 62.

Clinical features

Phototoxicity

Following cutaneous or systemic exposure to a phototoxic agent *and* appropriate UVR, phototoxicity develops within hours; for the vast majority of such agents, the action spectrum is in the UVA range. Erythema and edema as well as burning and stinging sensations characterize the initial presentation, with vesicles and bullae seen in severely affected patients. Phototoxic reactions due to oral medications resemble an exaggerated sunburn. These reactions then resolve spontaneously with desquamation and hyperpigmentation once the photosensitizer or UVR is avoided.

Other less common manifestations of phototoxicity include pseudoporphyria (frequently caused by nonsteroidal anti-inflammatory drugs [NSAIDs], especially naproxen), photo-onycholysis (reported with tetracyclines and psoralens), slate-gray hyperpigmentation (reported with amiodarone, tricyclic antidepressants and diltiazem) (Fig. 87.20)[57], lichenoid eruptions (seen with quinine and quinidine), and a burning or painful sensation (amiodarone). Evolution of phototoxicity reactions into CAD (see above) has rarely been reported following exposure to thiazides, quinidine, quinine or simvastatin. The medications most commonly associated with phototoxicity are listed in Table 87.6.

5-Fluorouracil (5-FU), methotrexate and retinoids, three commonly used medications in dermatology, have also been associated with photosensitivity reactions; however, none is associated with UVR-induced activation of the drug. Exacerbation of 5-FU-induced inflammation by UVR usually occurs in sites with actinic keratoses. The administration of methotrexate occasionally causes a recurrence ('recall') of previous UVR-induced erythema. However, phototesting in patients taking methotrexate has been normal[58], and the mechanism for this 'recall' reaction remains unclear. Phototesting in patients taking isotretinoin or etretinate, or applying topical tretinoin, is also usually normal[59], and the propensity for these patients to develop UVR-induced erythema is most likely due to retinoid-induced thinning of the stratum corneum.

Phytophotodermatitis is another phototoxic reaction, with linear streaks of erythema occurring a day or so after skin contact with plants containing furocoumarins plus exposure to sunlight. Linear postinflammatory hyperpigmentation is a classic finding. Plants capable of inducing phytophotodermatitis include yarrow, parsley, celery, lime and fig (see Ch. 17). Therefore, this condition most commonly occurs in individuals whose outdoor activities expose them to such plants, such as vegetable harvesters and bartenders who mix drinks outdoors. Roofers and road workers occasionally develop phototoxicity secondary to exposure to tar and concomitant UVA from sunlight.

St John's wort (*Hypericum perforatum*), used to treat a variety of ailments including depression, contains hypericin, another known phototoxic agent. Increasingly, voriconazole is being prescribed for immunocompromised hosts, often for months or years in patients with allogeneic hematopoietic stem cell transplants and chronic GVHD. This can lead to phototoxic reactions as well as an increased risk for developing large hypertrophic actinic keratoses, aggressive cutaneous squamous cell carcinomas and perhaps cutaneous melanoma.

Photoallergy

In previously sensitized individuals, exposure to photoallergens and sunlight results in the development of a pruritic eczematous eruption. In more severely affected patients, vesicles and bullae may develop, though less commonly than in phototoxic reactions. In general, phototoxic and photoallergic reactions can be distinguished, as phototoxic reactions resemble a sunburn whereas the lesions of photoallergic reactions often resemble allergic contact dermatitis. That said, a detailed history and clinical examination of sites of involvement always provide insight.

In a study involving 2715 patients in the UK, sunscreen agents (especially benzophenone-3 [oxybenzone]) were the most common causes of photoallergy[60]; this finding has since been confirmed in a second study of 1155 patients[61]. However, the actual prevalence of photoallergy amongst sunscreen users is very low. Other common photoallergens include medications such as promethazine and NSAIDs, as well as fragrances and antibacterial products (see Table 87.6). Photoallergy can generally be confirmed by photopatch testing, where duplicate sets of photoallergens are placed on the patient's back and only one set is irradiated with UVA (Table 87.7). The interpretation of results from such testing is shown in Figure 87.21.

Pathology

Phototoxicity is characterized by scattered necrotic keratinocytes ('sunburn cells') and a dermal infiltrate of primarily lymphocytes and neutrophils. In contrast, photoallergy is characterized by epidermal spongiosis plus a dermal lymphohistiocytic infiltrate, indistinguishable from other causes of spongiotic dermatitis.

Differential diagnosis

Inflammatory phototoxic reactions should be distinguished from ordinary sunburn, which requires more UVR exposure, and LE (see Table

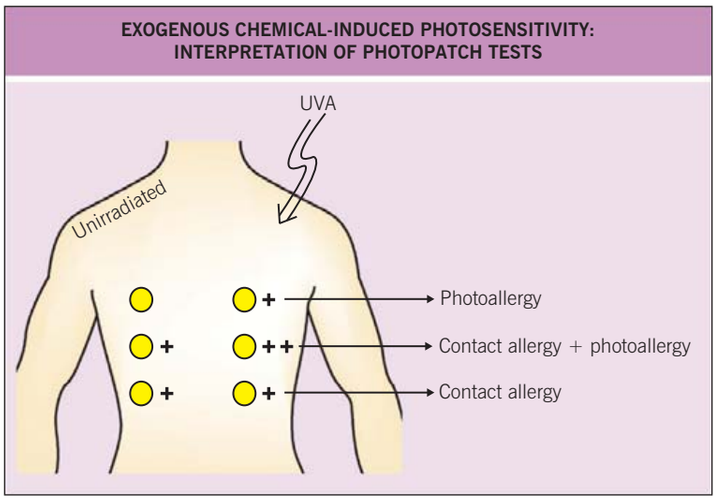

Fig. 87.21 Exogenous chemical-induced photosensitivity: interpretation of photopatch tests. This schematic demonstrates the interpretation of photopatch tests. The UVA dose is usually the lower of 5 J/cm^2, or 50% of the MED to UVA.

87.3). The differential diagnosis of photoallergic reactions includes all other forms of dermatitis that can involve sun-exposed areas, particularly airborne contact dermatitis and seborrheic and atopic dermatitis. In airborne contact dermatitis, all exposed sites can be involved, including the upper eyelids, submental region and postauricular areas; these sites are frequently spared in photoallergic contact dermatitis (see Fig. 87.16).

Treatment

The identification and avoidance of the offending agent are of prime importance. Sometimes this is not possible and strict photoprotection (UVB and UVA) is required. For phototoxic reactions, analgesia may be helpful. Topical corticosteroids, and, for severe flares, short courses of systemic corticosteroids, can be used for photoallergic dermatitis. Occasionally, evening dosing of a phototoxic drug can be done so that peak systemic levels occur during the night.

Endogenous

The cutaneous porphyrias, discussed in Chapter 49, represent the most obvious examples of photosensitivity induced by endogenous agents. The mechanism of porphyrin-induced phototoxicity involves reactive oxygen species, the complement system, mast cells and neutrophils (Fig. 87.22).

Smith–Lemli–Opitz syndrome, an autosomal recessive disorder with early onset of photosensitivity to UVA in 55% to 75% of patients, is probably another example[63,64]. Its frequency has been estimated to be 1 in 20 000 to 1 in 40 000 births in populations with northern and central European ancestry. Mutations in *DHCR7*, which encodes 7-dehydrocholesterol reductase, result in an accumulation of 7-dehydrocholesterol. The mechanism of the photosensitivity is unknown.

NORMAL CUTANEOUS EFFECTS OF UVR EXPOSURE

Key features

- Acute and subacute effects of UVR exposure include acute inflammatory erythema (sunburn), pigment darkening, delayed pigmentation, epidermal hyperplasia, immunologic changes and vitamin D_3 synthesis
- Chronic effects include photoaging and photocarcinogenesis
- UVR has been implicated in the development of actinic keratoses, squamous cell carcinoma, basal cell carcinoma and melanoma
- UVR effects are attenuated in individuals with pigmented skin

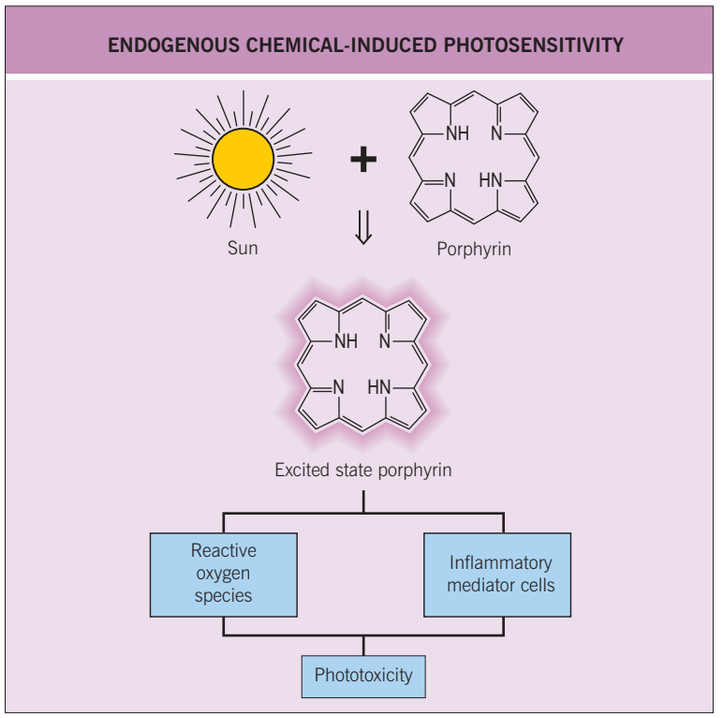

Fig. 87.22 Endogenous chemical-induced photosensitivity. The pathophysiology of phototoxicity as seen in the cutaneous porphyrias is shown.

This discussion is limited to the clinical aspects of UVR, as the underlying mechanisms are reviewed in Chapter 86.

Acute and Subacute Effects

These effects are primarily the result of UVR absorption by DNA, the exception being vitamin D synthesis.

Acute inflammatory erythema (sunburn)

Excessive UVR exposure leads to the acute inflammatory reaction of sunburn. Wavelengths around 300 nm are the most erythemogenic, with those between 260 and 280 nm a little less so. The lowest dose capable of inducing erythema, the so-called minimal erythema dose (MED), in individuals with Fitzpatrick skin type I is about 100 J/m^2 (10 mJ/cm^2) for UVC (100–280 nm), 300 J/m^2 (30 mJ/cm^2) for broadband UVB (280–315 nm), and 300 kJ/m^2 (30 J/cm^2) for broadband UVA (315–400 nm).

In a few individuals, brief immediate erythema occurs within seconds of UVR exposure and lasts for minutes[65]. Otherwise, the typical delayed bright red appearance of a sunburn develops confluently on all sufficiently exposed skin, beginning within 30 minutes to 8 hours, peaking at 12 to 24 hours and diminishing over hours to days in the case of UVB exposure. With UVC, the response is pinker in color and shorter in duration, starting within hours, peaking at 5 to 8 hours and fading over hours to a day or so; in the case of UVA, however, the reaction is deeper red in color, is usually more persistent, and often begins during irradiation, before fading over hours to days. After excessive exposure, edema and blistering may occur, which, if widespread, may lead to associated systemic symptoms such as chills and malaise. Such reactions are generally followed by pruritus and desquamation over a period of days to weeks.

Photoprotection is the best prevention[29]. However, once excessive UVR exposure has occurred, only symptomatic treatment can be offered (e.g. increased fluid intake, emollient creams or lotions); topical or oral nonsteroidal or steroidal anti-inflammatory agents must be administered as soon as possible after irradiation, or they will not help. If the sunburn is severe or life-threatening, hospitalization and treatment as for thermal burns are necessary.

Pigment darkening and delayed tanning

Immediate, often grayish, tanning of irradiated skin that lasts for 10–20 minutes may occur within seconds of ~20–120 kJ/m^2 of UVA

CUTANEOUS SIGNS OF SIGNIFICANT PHOTODAMAGE

Continued

irradiation, and perhaps also short-wavelength visible light, particularly in more darkly pigmented individuals[65]. This phenomenon, known as *immediate pigment darkening*, results from photo-oxidative darkening and the cellular redistribution of melanin within epidermal melanocytes. Pigmentation that persists for more than 2 hours after irradiation is referred to as *persistent pigment darkening*; it is brownish in color, lasts for up to 24 hours, and is also due to oxidation of pre-existing melanin. Persistent pigment darkening then blends with *delayed pigmentation,* or *tanning*, which develops in genetically competent individuals over hours to days and persists for weeks to months following approximately: 400 J/m^2 of broadband UVB (a little higher than the MED, particularly in fair-skinned persons); 150–200 kJ/m^2 of broadband UVA (a little less than the MED); or 100 J/m^2 of UVC (about equal to the MED). As a result of delayed tanning, later sunburning sensitivity is mildly decreased by a factor of two to four.

Epidermal hyperplasia

Hyperplasia lasting a month or so occurs over a period of hours to days following UVB or UVC, but generally not UVA, exposure. This results from a markedly increased cellular mitotic rate and DNA, RNA and protein synthesis, following several initial hours of inactivity[65]. Hyperplasia of the viable epidermis and thickening of the stratum corneum result in several-fold protection against later sunburning; this adds to, and may exceed, that simultaneously provided by delayed tanning, particularly in fair-skinned individuals.

Immunologic changes

Cutaneous UVB, UVC, and, to some extent, UVA irradiation alters epidermal Langerhans cell function, generates suppressor T lymphocytes, and changes the cutaneous cytokine profile[66]. This topic is discussed in greater detail in Chapter 86.

Vitamin D_3 synthesis

UVB (maximum: 300 ± 5 nm) irradiation quickly converts epidermal 7-dehydrocholesterol into previtamin D_3 (see Fig. 51.6)[67]; the latter then isomerizes to vitamin D_3 (cholecalciferol), which is then converted in the liver to 25-hydroxyvitamin D and subsequently in the kidneys to 1,25-dihydroxyvitamin D, its active form. UVR-induced vitamin D_3 synthesis is maximal at suberythemogenic doses.

Other changes

On occasion, otherwise healthy individuals develop *photo-onycholysis* and increased skin fragility with blistering (*pseudoporphyria*) following intense exposure to sunlight or tanning beds. This may be due to photosensitization by normal levels of endogenous substances such as porphyrins. *Mid-dermal elastolysis* is characterized by patches of finely wrinkled skin and the loss of elastic fibers in the mid-reticular dermis (see Ch. 99); its onset is frequently associated with intense UVR exposure. *Brachioradial pruritus*, characterized by primary pruritus of the outer arm, is associated with cervical radiculopathy; however, in many patients, UVR may act as a trigger of the symptoms (see Ch. 6).

Chronic Effects

Photoaging in fair-skinned patients

Photoaging refers to cutaneous changes secondary to long-term exposure to sunlight (Table 87.8). Characteristic clinical manifestations are outlined below.

Solar elastosis refers to thickening as well as yellow discoloration of the skin in chronically sun-exposed areas, often in association with marked wrinkling and most commonly seen on the face (Fig. 87.23A,B). Histologically, there is a marked increase in dermal

Fig. 87.23 Cutaneous signs of significant photoaging (cont'd) **D** Poikiloderma of Civatte with sparing of the anterior neck. **E** Multiple open comedones of the periorbital region in Favre–Racouchot syndrome. **F** Brown discoloration of the dorsal hand due to hemosiderin deposits from recurrent solar purpura. **G** Fragility of atrophic photodamaged skin of the shin. **H** Erosive pustular dermatosis of the bald scalp.
F, G, Courtesy, Jean L Bolognia, MD.

elastosis. Similar changes occur on the posterior neck and are sometimes referred to as *cutis rhomboidalis nuchae* (Fig. 87.23C), characterized by deep skin wrinkling and furrowing associated with a leathery texture.

A *solar lentigo* is a light brown to dark brown, even-colored or reticulated macule that occurs in sun-exposed areas, and although sometimes solitary, such lesions are more often multiple. The dorsal aspects of the hands, extensor forearms, upper trunk and face are the most commonly affected sites (see Ch. 112).

An *ephelide*, also known as a freckle, presents as a light brown to medium brown macule, usually less than 6 mm in diameter. Such lesions occur primarily on exposed areas of the face, but also on the shoulders and outer aspects of the arms. Numerous lesions are usually present.

Histologically, a solar lentigo is associated with elongation of the rete ridges and a mild increase in the number of melanocytes, while hyperpigmentation of the basal layer without elongation of the rete ridges is observed in an ephelide.

Poikiloderma of Civatte refers to reticulated red to red–brown patches with telangiectasias that spare perifollicular skin. It is most commonly observed on the lateral aspects of the neck in fair-skinned individuals with significant cumulative sun exposure (Fig. 87.23D). Characteristically, there is sparing of the central submental region. Mild atrophy and hyperpigmentation are sometimes present. Histologically, telangiectasias, dermal atrophy and irregular hyperpigmentation of the basal layer are observed.

In *Favre–Racouchot syndrome*, multiple large open comedones develop on the lateral and inferior aspects of the periorbital area (Fig. 87.23E), in association with marked solar elastosis of the surrounding skin. Histologically, there are dilated pilosebaceous openings and cyst-like spaces filled with horny material.

Colloid milium is characterized by translucent yellow papules that measure 1–3 mm in diameter. There are usually numerous, closely spaced lesions in chronically sun-exposed sites, especially the neck, face and dorsal hands. Histologically, homogeneous masses of colloid are present in the papillary dermis, which are PAS-positive and diastase-resistant.

Erosive pustular dermatosis classically presents as sterile pustules, crusts, erosions and mild inflammation arising within the photodamaged skin of a bald scalp (Fig. 87.23H). However, similar clinical findings can occur on the lower extremities of patients with venous hypertension and atrophic skin[68] and following perinatal scalp injuries. One theory is that the disorder is related to cutaneous atrophy. Erosive pustular dermatosis may be misdiagnosed as folliculitis, pyoderma or hypertrophic actinic keratoses, while the possibility of the Brunsting–Perry variant of mucous membrane (cicatricial) pemphigoid also needs to be considered. Although therapeutic responses vary, successful treatment with topical agents, in particular potent corticosteroids, tacrolimus and calcipotriene (calcipotriol), as well as oral isotretinoin, zinc sulfate and nimesulide (an NSAID that inhibits the respiratory burst of granulocytes) has been reported.

Photoaging in patients with skin of color

Photoaging is much less pronounced and has a delayed onset in individuals with more darkly pigmented skin[69] (Fig. 87.24). Small seborrheic keratoses, melasma and mottled hyperpigmentation are common signs of photoaging in East Asians, such as Chinese, Japanese and Koreans; in addition, any wrinkles are fine and do not appear before 50

Fig. 87.24 Photoaging in an African-American. Given her age, this 93-year-old woman has relatively fine wrinkling of her face, in addition to scattered seborrheic keratoses.

Fig. 87.25 Grover's disease. Crusted papules of the trunk **(A)** and obvious sparing of the sun-protected skin of the buttocks **(B)** in this patient with significant photodamage. *A, B, Courtesy, Jean L Bolognia, MD.*

years of age. South Asians, such as Indians, Pakistanis, Sri Lankans and Bangladeshis, often have darker skin; dyspigmentation and fine wrinkles are their main signs of photoaging. Lightly pigmented Latinos have changes similar to those seen in whites, while those with brown skin photoage in a manner similar to that seen in South Asians. Black-skinned individuals, including African-Americans, Afro-Caribbeans and people from Africa, have a wide range of Fitzpatrick skin types, from III to VI. Dyspigmentation is common in them, before fine wrinkles appear late in life.

Photocarcinogenesis

Chronic sun exposure has been associated with the development of actinic keratoses (AKs), SCC, BCC and melanoma, in particular lentigo maligna. Epidemiologic studies have shown that SCCs tend to develop within chronically sun-exposed areas in fair-skinned individuals; e.g. people who migrate to Australia early in life have a higher risk of developing SCC than immigrants who arrive when older. Furthermore, the incidence of BCC is higher in native-born Australians than immigrants, and a statistically significant association between *intermittent* sun exposure and the risk of BCC has also been reported. These findings are supported by the observation that the use of sunscreens led to a decrease in the development of AKs, SCCs, and, to a lesser extent, BCCs.[70] Exposure to tanning beds seems to be associated with an increased risk for developing these tumors as well as cutaneous melanoma[71]. Lastly, nevus density, considered a likely surrogate for melanoma development, has correlated with the degree of individual sun exposure[72,73].

Melanoma development in populations with more darkly pigmented skin has also been studied. An analysis of patients with cutaneous melanoma in the SEER database (1992–2001) concluded that a higher melanoma incidence was associated with an increased UV index and lower latitude only in non-Hispanic whites, but not in black or Hispanic populations[74]. This is also consistent with the observation that the proportion of acrolentiginous melanoma among all melanoma subtypes is greatest in people of color, especially in black-skinned individuals[75].

Grover's disease

Grover's disease, also known as transient (and later persistent) acantholytic dermatosis, most commonly occurs in Caucasian men over 40 years of age with significant photodamage. It peaks during the winter months, with a second peak at the end of summer. Pruritic, often crusted, skin-colored to pink papules and papulovesicles appear on the trunk, primarily in sun-exposed sites (Fig. 87.25). In addition to UV exposure, exacerbating factors include sweating, heat, friction, xerosis and, occasionally, ionizing radiation. While lesions may resolve over weeks to months, they commonly recur. Histologically, four patterns are seen (sometimes in combination): Darier disease-like; Hailey–Hailey disease-like; pemphigus vulgaris- or foliaceus-like; and spongiotic with acantholysis. The differential diagnosis of Grover's disease includes folliculitis, miliaria rubra, arthropod bites, multiple lichen planus-like keratoses, early pemphigus foliaceus and, when chronic, Darier disease. Except for the latter two entities, histologic examination allows distinction; the focal nature of the histologic findings, negative immunofluorescent microscopy and lack of additional clinical features (e.g. palmar keratoses, erythronychia with notching) points to the diagnosis of Grover's disease. Therapy can be frustrating, but includes primarily topical agents (e.g. corticosteroids, pramoxine, calcineurin inhibitors, vitamin D analogues) and oral antihistamines, in addition to avoidance of exacerbating factors. Occasionally, oral retinoids, PUVA and UVA1 have been tried.

The skin is the primary interface with the environment. Humans are unique among the Earth's creatures in their ability to manipulate the environment by manufacturing clothing, shelter, and heating and cooling devices to allow them to live in a variety of environmental extremes. Despite technologic advances that have allowed humans to live, work and play in most of the environments on the planet, deliberate or inadvertent exposure to those environments may subject individuals to injury. The following discussion will focus upon temperature-related skin diseases, water immersion injury, electrical burns, chemical injury, heavy metals in cutaneous disease, frictional and traumatic skin injury, sports-related dermatoses, and skin problems of instrumental musicians.

INJURY DUE TO HEAT EXPOSURE

Heat-Related Illnesses and Thermal Burns

Synonyms/variants: ■ Heat-related illnesses: heat cramps, heat syncope, heat edema, heat exhaustion, heat stroke ■ Thermal burns: burns

Key features

- Heat-related illnesses occur when the body's thermoregulatory mechanisms fail; correction of fluid and electrolyte balance is critical in their management
- For thermal burns, need to assess depth of burn (i.e. first, second or third degree) and surface area involved
- Burn treatment includes prevention of infection, serial excisions and skin substitutes

Introduction

Humans, like all other mammals and all birds, are homeothermic organisms, maintaining their core body temperature within a narrow range by varying cutaneous and visceral blood flow. Normal core body temperatures vary between 36°C and 37.5°C (96.8°F and 99.5°F). At normal core temperature, cutaneous blood flow is about 4% of cardiac output or 250 ml/min. Alteration of the cutaneous blood flow is performed by the hypothalamus in a delicate balancing act between heat retention and loss. Cutaneous, muscle and spinal cord temperature sensors send signals to the preoptic area of the anterior hypothalamus. Communication with the posterior hypothalamus sets up thermoregulatory mechanisms of vasomotor control, sweating and shivering.

When prolonged exposure to a hot environment leads to an increase in core temperature, the subsequent decrease in sympathetic output results in peripheral vasodilation, allowing an increase in cutaneous blood flow of up to 6–8 l/min. Cholinergic output stimulates sweating. These changes allow radiant, conductive, convective and evaporative heat loss. In contrast, cold temperature exposure leads to increased sympathetic output with peripheral vasoconstriction. Countercurrent heat exchange between parallel arteries and veins further reduces heat loss to the skin, helping to conserve core heat. The behavioral response of shivering generates heat through muscular activity[1].

When the normal hypothalamic regulatory setpoint is overcome by extremes of temperature, pathologic conditions result (Table 88.1). The following discussion will explore heat-related illnesses and thermal burns. Heat-induced urticaria is covered in Chapter 18.

History

It is speculated that King Edward and his armored crusaders lost the final battle of the Holy Land because the Arab horsemen were adapted and dressed appropriately for the severe heat.

Epidemiology

The frequency of heat-related illnesses is unknown, since milder forms resolve with simple measures. Heat-related illness accounted for more than 8000 deaths in the US between 1979 and 1999, and is responsible for 7% of wilderness deaths[1,2]. Risk factors are listed in Table 88.2.

Burn injuries are far more commonly reported, occurring in 2 million people per year in the US alone, and resulting in 60 000 hospitalizations and 6000 deaths, half of which occur in children[3,4]. The male:female ratio is 2:1. The main sources of burns in children are scald, flame and electrical. Abuse or neglect may account for up to 20% of pediatric burns. Mortality rates have declined in recent years due to improved resuscitative and surgical management. In the 1940s, burns in children involving 50% body surface area (BSA) had a 50% survival rate, whereas today, 50% of children with 90% BSA burns survive[3,4].

A unique form of burn injury is that due to fireworks, particularly sparklers[5]. In the US, fireworks account for over 12 000 emergency department visits annually. Blast injuries of the hand and eyes are seen in addition to burns.

Pathogenesis

Athletic activity can generate 800 to 1000 kcal/h of heat for prolonged periods. This results in a 1°C rise in core body temperature every 5 to 8 minutes. The normal thermoregulatory mechanisms dissipate this heat as it is generated. When the regulatory mechanisms fail, heat injury occurs. Heat illnesses are not defined by a specific temperature, but by the abnormal response to heat. Table 88.1 outlines the pathogenesis of heat-related disorders.

Thermal burns occur when skin is exposed to infrared radiation (800 to 170 000 nm) from an external heat source with a temperature exceeding 44°C (111°F). Time and temperature curves have been developed to determine maximum thermal exposure times. Necrosis of the epidermis occurs in about 45 minutes at 47°C (117°F) but in only 1 second at 70°C (158°F). Denaturation and coagulation of cellular proteins occur in thermal injury. Interstitial edema develops from altered osmotic pressure and capillary permeability. Several chemical mediators with vasoactive and tissue-destructive properties are released,

HEAT-RELATED ILLNESSES				
Condition	**Core temperature**	**Clinical features**	**Treatment**	**Pathogenesis**
Heat cramps	Normal	Painful spasm in large muscle groups, weakness, fatigue, N/V, **marked sweating**, tachycardia, ↑BP	Fluid and salt replacement	Dilutional hyponatremia due to free water, but not electrolytes, being replaced
Heat syncope	Normal	Nausea, sighing, yawning, restlessness, fainting (brief)	Avoid standing still in heat, flex legs, lie down if prodrome, cool off, replace fluid	Decreased cerebral blood flow due to volume depletion, peripheral vasodilation and decreased vasomotor tone in poorly acclimatized or elderly individuals
Heat edema	Normal	**Dependent edema** from vasodilatory pooling	None needed (self-limited)	Vasodilatory pooling
Heat exhaustion	Normal to 39°C (102.2°F)	Weakness, dizziness, headache, N/V, irritability, dyspnea/hyperventilation, malaise, myalgias/muscle cramps, tachycardia, orthostatic hypotension, **profuse sweating, piloerection**, impaired judgment, syncope Hypernatremic form: thirst, rare cramps Hyponatremic form: fatigue, cramps, history of excessive free water intake, altered mental status	Intravenous fluids and electrolytes, sprinkle water and fan or use ice packs, rest, cool environment	Volume and/or salt depletion
Heat stroke	>40°C (104°F)	**Anhidrosis to profuse sweating**, ↓BP, N/V, diarrhea, altered mental status (profound), seizures, coma, cardiac arrhythmias, ↑ transaminases, rhabdomyolysis, acute renal failure, DIC, respiratory alkalosis Poor prognostic indicators: T >42.2°C (108°F); coma >2 h; AST >1000 (day 1)	Rapid lowering of core temperature to 38°C (100.4°F), intravenous hydration, intensive care unit	End result of thermoregulatory failure; volume depletion leads to peripheral vasoconstriction and reduced transfer of heat peripherally; resultant core heating leads to organ failure

Table 88.1 Heat-related illnesses[1,2]. Cutaneous features are indicated in bold. AST, aspartate transaminase; BP, blood pressure; DIC, disseminated intravascular coagulation; N/V, nausea and vomiting; T, temperature.

RISK FACTORS FOR HEAT-RELATED ILLNESS	
• Occupational exposure	• Age (elderly, young child)
• Poverty	• Insufficient acclimatization
• Alcoholism, mental illness, dementia	• Obesity
• Medications (anticholinergics, phenothiazines, diuretics; see Table 39.9)	
Medical conditions • Excessive fluid loss (e.g. diarrhea, diabetes mellitus) • Suboptimal sweating (e.g. ectodermal dysplasias; see Tables 39.8 & 39.10) • Excessive sweating (see Tables 39.2 and 39.3) • Inadequate fluid intake (see above) • Decreased thirst (cystic fibrosis; see Table 39.12) • Abnormal thermoregulation (prior heat illness, malnutrition)	

Table 88.2 Risk factors for heat-related illness[1,2].

Fig. 88.1 Thermal burn. This superficial second-degree burn is characterized by bullae that contain serous fluid. *Courtesy, Kalman Watsky, MD.*

including prostaglandins, bradykinin, serotonin, histamine, lipid peroxides and oxygen radicals[4].

Clinical features

Although heat-related illnesses are not primary skin diseases, they can present with cutaneous findings. Their clinical features are summarized in Table 88.1.

Thermal burns of the skin differ in their clinical presentation, depending upon the depth of injury (Table 88.3)[4,6,7]. Conventional nomenclature categorizes cutaneous burn wounds as *first degree* (superficial; limited to epidermis), *second degree* (partial-thickness) and *third degree* (full-thickness). Second-degree burns are further subdivided into superficial (Fig. 88.1) and deep variants. Burns involving deeper structures such as muscle are sometimes referred to as fourth-degree burns. However, a definitive diagnosis of wound depth may not be possible for the first 24 to 72 hours because of vascular occlusive changes.

At sites where the dermis is thinner (ears, volar forearms, medial thighs, perineum), burns may be deeper than the initial presentation might suggest; this is also the case in the comparatively thinner skin of children and the elderly. Wounds that appear dull red from entrapment of clot (denatured hemoglobin) imply full-thickness injury[6].

The severity of burn injuries is based upon depth and BSA involvement. BSA is estimated in adults by the "rule of nines" (Fig. 88.2). This formula cannot be applied to children, since the head accounts for approximately 19% BSA in a 2-year-old, 15% in a 7-year-old, and 13% in a 12-year-old. Lund & Browder charts are useful for more accurate assessment of BSA involvement[4,6]. Initial evaluation should address airway and circulatory status; associated inhalation injury is seen in up to 25% of burn patients. Cardiovascular evaluation must address the issue of hypovolemic shock, regardless of burn severity. Urine output must be monitored because of the significant fluid loss and rhabdomyolysis that may compromise renal function[3,4,6].

Pathology

Pathologic features of thermal burns are summarized in Table 88.3.

Differential diagnosis

The differential diagnosis of heat injury is listed in Table 88.1. Although there is considerable overlap in clinical features, an important distinction is the degree of neurologic compromise. The most important

CLINICAL AND PATHOLOGIC FEATURES OF THERMAL BURNS			
Type	**Depth**	**Clinical features**	**Pathology**
First degree	Epidermis only	Pain, tenderness, erythema No blistering Heals without scar	Upper epidermal necrosis
Second degree – superficial	Epidermis and superficial dermis	Severe pain, tenderness, serous or hemorrhagic bullae, deep rubor, erosion and exudation Heals in 10–21 days with mild but variable scarring	More extensive epidermal necrosis with vertical elongation of keratinocytes Necrotic areas may have serous crust with neutrophils, fibrin and cellular debris Subepidermal bullae possible
Second degree – deep	Epidermis and most of dermis destroyed, including deep follicular structures	Intense pain but reduced sensation, deep red to pale and speckled in color Serosanguineous bullae and erosions May appear devitalized initially Prolonged healing time Hypertrophic scars and marked wound contracture	Destruction of entire epidermis, dermal collagen and most of adnexal structures Collagen bundles may be fused, with eosinophilic appearance Thrombosis of deep vessels common Granulation tissue present at junction of normal and injured tissue
Third degree	Full-thickness epidermal and dermal destruction	Dry, hard, charred, non-blanching, insensitive areas of coagulation necrosis Small lesions heal with significant scarring Most require surgical correction	Necrosis of entire epidermis and dermis, with extension into subcutis Inflammatory infiltrate at interface between burned and normal skin If scar forms, it exhibits hyalinized collagen, decreased elastic tissue, loss of arrector pili muscles

Table 88.3 Clinical and pathologic features of thermal burns[4,6,7].

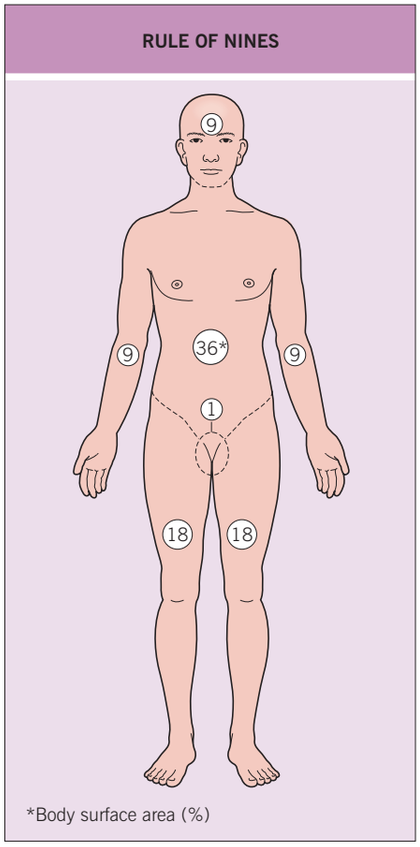

Fig. 88.2 Rule of nines. In adults, an estimate of burn extent is often based upon this surface area distribution chart. Infants and children have a relatively increased head : trunk surface area ratio. These estimates are also used for primary cutaneous disorders.

diagnostic issue with thermal burns is the depth of the injury (see Table 88.3).

Treatment

Management of heat-related injuries involves removal from the hot environment, rest, rehydration, restoration of electrolyte balance, and evaluation of involved systems (Table. 88.1; see Lugo-Amador et al.[1] for more details).

Initial management of burn victims includes assessment of cardiopulmonary status as well as the extent and depth of the burn. Information regarding resuscitation of burn victims is beyond the scope of this text, but can be found in references 3, 4 and 6. Management of the burn wound should start with cool compresses to ease pain and reduce heat. Then, the wound should be cleaned gently to remove any foreign material. The next step is prevention of infection, followed by creation of a proper healing environment (see Ch. 141). Topical antimicrobial agents shown to be effective in burn wound care include silver sulfadiazine, mafenide acetate and silver nitrate. Silver sulfadiazine has gained wide acceptance for both pediatric and adult burn treatment. However, percutaneous absorption can lead to leukopenia. Also, silver sulfadiazine produces a pseudoeschar that may interfere with burn depth assessment and prolonged application may lead to localized argyria. Superficial wounds may require little additional therapy[3,4,6].

Deeper burn wounds need more aggressive therapy, the most popular approach being serial excision. Third-degree burns are excised early, with indeterminate and deep second-degree wounds delayed until maximum depth and extent are known. Biologic dressings (e.g. pig skin, human allograft) were popular for several years, but have been largely displaced due to higher infection risk and poor healing. Newer skin substitutes such as acellular dermal matrix (AlloDerm®), bilaminar collagen-chondroitin sulfate and silicone (Integra®) and cultured epithelial autografts are gaining popularity[6] (see Ch. 145).

Erythema Ab Igne

Synonyms: ■ Toasted skin syndrome ■ Fire stains

Key features

- Localized areas of reticulated erythema and hyperpigmentation
- Chronic exposure to heat below the threshold for a thermal burn
- Commonly in lumbosacral region (heat applied to relieve pain) and shins (in regions without central heating in homes)
- Squamous atypia histologically
- Risk of cutaneous malignancy, particularly squamous cell carcinoma

Introduction

Chronic exposure to low levels of infrared heat can lead to the characteristic reticulated cutaneous pattern of erythema ab igne (EAI), with subsequent risk of malignant degeneration.

History

EAI, once a very common entity, was first described in the UK as a result of standing near stoves fired with peat. In the southern US, the custom of sitting around pot-bellied stoves to keep warm while

HEAT SOURCES REPORTED TO CAUSE ERYTHEMA AB IGNE	
• Heating pads	• Steam radiators
• Hot water bottles	• Heated car seats
• Electric stove/heater	• Heated reclining chairs
• Open fires	• Heating blanket
• Coal stoves	• Hot bricks
• Peat fires	• Infrared lamps
• Wood stoves	• Microwave popcorn
• Sauna belt	• Laptop computer*

*Anterior thighs » abdomen.

Table 88.4 Heat sources reported to cause erythema ab igne[8–10].

socializing also led to its development. Although the advent of central heating in much of the industrialized world has led to a dramatic decline in incidence, creative cultural and therapeutic applications of various heating devices continue to induce EAI[8–10].

Epidemiology

In the past, EAI was seen up to 10 times more frequently in women than in men. The vast majority of those affected were middle-aged or older. Risk factors include lack of central heating, occupations with close heat exposure, and medical conditions with symptoms relieved by heating or associated with decreased sensation. Recent reports of EAI due to laptop computers have appeared, including in teens engaged in prolonged gaming[11].

Pathogenesis

Long-term exposure to heat below the threshold for thermal burn is the primary etiologic factor in EAI. The precise pathophysiology is unknown, but the pattern corresponds with the dermal venous plexus. Repeated exposure to heat below 45°C (113°F) produces reticulated erythema followed by hyperpigmentation in the same pattern[9]. Heat sources reported to cause EAI are found in Table 88.4[8–10].

Clinical features

The initial presentation is a transient macular erythema in a broad reticulated pattern that easily blanches. The entire size and shape often approximates that of the heat source. As the heat exposure continues over time, the erythema evolves into a dusky hyperpigmentation, with lesions fixed and no longer blanchable (Fig. 88.3). Epidermal atrophy may overlie the reticulated pigmentation. Later-stage lesions may become somewhat keratotic and bullae may appear. Lesions are characteristically asymptomatic, although a slight burning sensation is sometimes noted[8].

Once the heat source is identified, it is important to determine if it is being used to relieve pain and, if so, the cause of the pain. A lumbosacral location usually points to musculoskeletal disease or, less often, bony metastases. EAI of the abdomen, flank or mid-back may reflect an attempt to relieve pain from inflammation (e.g. pancreatitis, peptic ulcer disease) or malignancy (e.g. pancreatic, gastric). Symptoms of pain should prompt a thorough review of systems and consideration of a search for occult disease. An inquiry into occupation and hobbies is also important, as EAI can develop in exposed areas, e.g. the forearms of bakers, the face or arms of glass blowers and foundry workers, and the anterior thighs in those with prolonged use of laptop computers[8,9,11].

The possible development of cutaneous squamous cell carcinoma (SCC) or Merkel cell carcinoma represents the major long-term risk. The latent period may be 30 years or more. Apparently, the risk of developing SCC is highest with hydrocarbon-fueled heat exposures, e.g. "peat fire cancers" on the shins of women, Japanese "Kairo cancers" and Tibetan "Kangri ulcers" due to coal-fired clothing warmers, and Chinese "Kang cancers" from sleeping on coal fire-heated bricks[8,9].

Pathology

The earliest histopathologic changes include epidermal atrophy, vasodilation and dermal pigmentation (both melanin and hemosiderin) (Fig. 88.4). As lesions progress, the epidermal atrophy becomes more pronounced, with flattening of the rete ridges. Focal hyperkeratosis and dyskeratosis are noted along with squamous atypia. Basal cell vacuolization has been reported and the dermal–epidermal junction may exhibit an interface dermatitis. The dermis appears thinned and sometimes

Fig. 88.3 Erythema ab igne – clinical features. **A** Earlier phase with pink reticulated patches predominating over reticulated hyperpigmentation. **B** Later phase with large area of reticulated hyperpigmentation and superimposed pink keratotic plaques centrally. *A, Courtesy, Jeffrey Callen, MD. Fig. 88.4 Erythema ab igne – histologic features. The blood vessels within the superficial dermis are markedly dilated. There is hyperkeratosis and a mild perivascular infiltrate. Note also thinning of the epidermis with some apoptotic keratinocytes and atypical cells. *Courtesy, Lorenzo Cerroni, MD.*

edematous, with accumulation of abnormal elastic tissue and pigment as well as ectatic capillaries. Dermal capillaries may exhibit enlarged endothelial cells with hyperchromatic nuclei. Later lesions may also show basophilic degeneration of connective tissue. Hemosiderin deposition and prominent telangiectasias are seen most often in leg lesions. Ultrastructural evaluation also shows increased melanocyte dendritic processes, suggesting melanocyte activation[8,9,12].

Differential diagnosis

EAI needs to be distinguished from livedo reticularis, which is a temperature-sensitive vasculopathy (see Ch. 106) that favors the extremities but only occasionally develops associated hyperpigmentation. Cutis marmorata (see Ch. 106) and cutis marmorata telangiectatica congenita are less commonly considered in the differential diagnosis of EAI. The presence of telangiectasias along with atrophy and hyperpigmentation raises the possibility of poikiloderma and its various causes, e.g. cutaneous T-cell lymphoma (see Ch. 120), dermatomyositis (see Ch. 42) and several genodermatoses (see Ch. 63).

Treatment

Management consists primarily of removal of the offending heat source. The epidermal atypia is comparable to that of actinic keratoses, and anecdotally it has been treated successfully with topical 5-fluorouracil. As mentioned above, the use of heat to treat symptoms of pain should prompt a determination of the cause of this pain[8,9].

Burns Associated with Fluoroscopy and Magnetic Resonance Imaging (MRI)

Key features

- MRI may produce first-, second- or third-degree burns due to metal or wire contact with skin, creating a closed-loop conduction system
- Fluoroscopy, particularly when repeatedly performed in patients with cardiovascular disease, may result in radiation-induced injury

Introduction

The radiologic literature is replete with reports of superficial to full-thickness thermal or electrical burns occurring during MRI. Risk factors for MRI burns are listed in Table 88.5[13–15]. In addition, there are reports in the radiologic and dermatologic literature of ulcerations on the back following repeated fluoroscopy[16,17].

Pathogenesis

Although the precise cause of MRI burns is unknown, the presence of both pulsed radiofrequency and pulsed magnetic gradient fields is thought to play a role. If an electrically conductive loop is formed between the patient and an electrode, patient and wiring, or even small areas of skin–skin contact, current can be produced by the changing magnetic flux, causing a thermal or electrical burn. Resistance at the skin surface may create a thermal injury, while contact with wiring in a capacitative coupling may create electrical injury. Alternatively, the burn may result from formation of a resonant conducting loop with an extended wire creating a resonant antenna, heating maximally at the antenna tip[13–15,18].

The mechanism behind fluoroscopy-induced radiodermatitis is related to the dose of radiation that is delivered. Repeated procedures are notorious for increasing the risk[17]. Patients with diabetes mellitus, obesity, autoimmune connective tissue diseases (e.g. systemic sclerosis) or genetic defects involving repair of radiation-induced injury, as well as individuals receiving chemotherapy, appear to be more prone to developing this complication at lower doses of radiation[16].

Clinical features

Thermal burns appear soon after MRI, and may be partial- to full-thickness (see Table 88.3). The shape and size of the burns are determined by the conductor causing the injury (e.g. circular burns under ECG electrodes; figurate burns conforming to the shape of metallic wires or tattoo pigment deposition)[13,18].

RISK FACTORS FOR BURNS DURING MAGNETIC RESONANCE IMAGING	
ECG leads	Metallic body piercing jewelry
Monitoring cables	Tattoos
Pulse oximeter	Extremity skin-to-skin contact
Pins in halo fixation device	Clothing with metal threads
Transdermal patches	

Table 88.5 Risk factors for burns during magnetic resonance imaging[13–15]. ECG, electrocardiogram.

Fig. 88.5 Fluoroscopy-induced radiation dermatitis. The left upper back is a characteristic location for patients who have undergone attempts at coronary artery revascularization (e.g. angioplasty, stent placement). *Courtesy, Jeffrey Callen, MD.*

Fluoroscopy-induced radiation dermatitis may be acute, but, as time passes and the acute injury resolves, the patient may continue to develop further changes, including epilation of hair, desquamation, permanent erythema and eventual ulceration (Fig. 88.5)[16]. The left upper back is a characteristic location for patients with cardiovascular disease who have had cardiac catheterizations with attempts at revascularization (e.g. angioplasty, stent placement)[17].

Differential diagnosis

Because of the proximity of the MRI event to the detection of a burn injury, the diagnosis is generally straightforward. However, in the case of a tattoo burn, allergic contact dermatitis or foreign body granuloma formation within the tattoo may be considered. Timing of the event plus the sensation of a burn rather than pruritus should allow a distinction.

The differential diagnosis of fluoroscopy-induced disease includes fixed drug eruptions, contact dermatitis, herpes virus infection, impetigo and spider bites.

Treatment

Prevention of this injury by avoiding risk factors is ideal. However, when burns occur, they should be managed as any other thermal burn, or, in the case of fluoroscopy-induced injury, by limiting the dose delivered.

Airbag Burns

Key features

- Deployment of airbags causes numerous cutaneous injuries, including frictional and blunt trauma, thermal burns and, possibly, chemical burns
- Friction due to contact with the bag, thermal burning from the bag and its released gases, and exposure to corrosive aerosol produce the injuries

Introduction

Automobile airbags provide additional crash protection, with a resulting reduction in driver and passenger fatalities by up to 30%. Although patented in 1953, US manufacturers only began installation of airbags in the mid-1970s. European airbag installation began in 1981. Since 1997, new cars in the US have been required to have airbags. By 1999, 45% of cars and 41% of trucks in the US were thought to be compliant. Despite the beneficial effect, numerous injuries have resulted from airbag deployment, including burns, abrasions and lacerations[19,20].

Pathogenesis

Airbag activation consists of detection, inflation and deflation phases. The sudden deceleration caused by impact triggers sensors in the front bumper to fire a sodium azide canister inside the nylon rubber bag. The sodium azide ignites with an explosive release of hot nitrogen gas which inflates the bag in about 10 milliseconds at speeds exceeding 160 km/h. The hot nitrogen gas and other by-products are then vented out the upper sides of the bag away from the occupant, thus deflating the bag. Vented aerosol contains nitrogen, carbon mono- and dioxides, sodium hydroxide, ammonia, nitric oxide, metallic oxides and other trace gases, creating a corrosive environment. Friction and pressure from the bag, heat from the bag and gases, and contact with the corrosive aerosol may produce injury[19–21].

Clinical features

The cutaneous injuries produced by airbag deployment are summarized in Table 88.6. Chemical burns occur rarely, but appear to be a result of skin exposure to small amounts of the corrosive alkaline aerosol. The aerosolized particles need to dissolve in a water layer such as tears or sweat before creating a corrosive injury. Of note, alkali burns of the skin may continue to deepen and extend over time, unless all the corrosive chemical is washed away[19–21].

Differential diagnosis

The pattern of injury and history of airbag deployment makes the diagnosis obvious. However, it is important to determine whether a burn injury is purely thermal or if it has a chemical component. Assessment of tissue pH and monitoring for continued extension of the burn help determine whether an alkali injury exists.

AIRBAG INJURIES TO SKIN		
Type	**Frequency**	**Clinical features**
Abrasions/friction burns	64%	Patches of erythema or ecchymosis, typically with superficial erosion
Contusion	38%	Ecchymosis
Lacerations	18%	Variable severity
Thermal burns	8%	First and second degree most common (see Table 88.3)
		Localized full-thickness burn may result from metallic accessories or melted clothing
		Face and forearms, followed by hands, chest
Chemical burns	?	Painful, superficial, violaceous erythema and edema
		Partial- to full-thickness, often in splash pattern
Irritant dermatitis	?	Erythema and edema of upper chest, arms, face
		Burning or stinging sensation
		Desquamation and postinflammatory hyperpigmentation common

Table 88.6 Airbag injuries to skin[19–21].

Treatment

Prevention is, of course, the most valuable therapy. Newer airbag design modifications include repositioning of the exhaust vents to direct the escape of hot gases away from possible areas of skin contact. Seats should be positioned as far back from the airbag module as possible. Children too small to benefit from the adult three-point restraint should not be in the front passenger area. Children in any type of car seat or booster should never be put in the front seat. When a thermal or frictional injury occurs, local wound care and protection from secondary infection usually suffice.

Alkali burns require copious irrigation to dilute the corrosive substance. Acidic neutralization is contraindicated because of possible extension of injury by the resulting exothermic reaction. When the tissue pH is normal, local wound care is adequate.

INJURY DUE TO COLD EXPOSURE

Frostbite

Synonym: ■ First-degree frostbite – frost-nip

Key features

- Frostbite can occur when the skin temperature drops below about –2°C (28°F)
- Erythema, edema and numbness are replaced by marked hyperemia and pain
- Tissue freezing, vasoconstriction and inflammatory mediator release are central to the pathophysiology of frostbite
- Rapid rewarming in a warm water bath is the cornerstone of therapy

Introduction

Exposure to cold environments, whether during occupational or recreational activities, poses a risk of cold-related injury. Prolonged exposure may lead to hypothermia, frost-nip or frostbite. Hypothermia (i.e. a decline in core temperature below 35°C [95°F]) is a systemic process with minor cutaneous features and therefore will not be discussed in detail.

History

Cold injury predates recorded history – the quest for clothing, shelter and fire as protection from the elements must have preoccupied prehistoric humans. Mass casualties from cold injury have historically been seen most often in military conflicts. However, as interest in outdoor activities and the number of homeless individuals have risen, there has been increased exposure to cold among the general population[22,23].

Epidemiology

A 10-year retrospective assessment (1986 to 1995) of cold injury in members of the British Antarctic Survey found an incidence of 65.6 per 1000 per year seeking medical attention. Ninety-five percent had frostbite, 3% hypothermia and 2% cold water immersion foot. Superficial frostbite was the most common injury (74% of cases), and the face (nose and ears) was the most frequent site of involvement. Seventy-eight percent of the victims were injured during recreational activities. Although temperature and wind chill had no influence on severity of injury, the prevalence of cold injury increased with falling temperature, with a maximum prevalence at –25°C to –30°C (–13°F to –22°F). A major risk factor was prior cold injury[24].

In addition to homelessness, risk factors for frostbite include altered mental status, vehicular trauma, circulatory impairment, smoking and high altitude.

Pathogenesis

The underlying pathophysiology of frostbite is a combination of freezing, vascular insufficiency (constriction and occlusion) and damage due to inflammatory mediators. As extremities cool, the "hunting response of Lewis" (alternating vasoconstriction and vasodilation) occurs, ending with vasoconstriction. This tends to conserve the core temperature at the expense of the extremity, which tends toward ambient temperature. The head does not exhibit a vasoconstrictor response, except for the nose and ears. The trunk surface may cool slightly, but the core temperature is maintained. Frostbite is therefore unusual on the trunk or head (except the nose and ears), unless there is direct contact with ice or a refrigerant. The pathophysiologic stages of frostbite are summarized in Table 88.7, along with key clinical features[22,23].

FOUR STAGES OF FROSTBITE

Phase	Physiologic events	Clinical findings
I (cooling)	Cyclic vasoconstriction and vasodilation Extracellular ice formation (–2°C, 28°F) Intracellular ice crystal formation (if rapid freeze of >10°C or 18°F/min) Intravascular ice formation leads to erythrocyte sludging, vessel occlusion	Cool extremity Blanched appearance Numbness Hard, woody texture
II (thawing and rewarming)	Ice melts Dehydrated cells start to swell Loss of integrity of vessel walls, creating edema Vascular tone is compromised, leading to vasodilation Inflammatory mediator release leads to aggregation of platelets and leukocytes, causing thrombosis	Erythematous to violaceous color Intense pain Blisters form
III (extension of injury)	Thromboxane A2 levels increase Platelet and leukocyte aggregation extends into bordering tissue, creating vascular compromise	Blisters rupture
IV (resolution)	Tissue either re-epithelializes or desiccates and mummifies Vasomotor instability may persist indefinitely	Healing or amputation

Table 88.7 Four stages of frostbite[23].

Fig. 88.6 Frostbite. **A** Erythema, edema and hemorrhage are seen on the fingertips in a first-degree frostbite. **B** Bullae filled with clear fluid on the distal plantar surfaces in a second-degree frostbite. *B, Courtesy, Timothy Givens, MD.*

Clinical features

Frostbite has been divided into four categories of severity, analogous to burn injuries. These are only recognizable upon rewarming. *Frost-nip* (first-degree frostbite) presents with erythema, edema, cutaneous anesthesia and transient pain (Fig. 88.6A). Full recovery is expected, with only mild desquamation. *Second-degree frostbite* is characterized by marked hyperemia, edema and blistering, with clear fluid in the bullae (Fig. 88.6B). Healing occurs, but many patients have long-term sensory neuropathy, often with significant cold sensitivity.

Third-degree frostbite consists of full-thickness dermal loss, with hemorrhagic bulla formation or development of waxy, dry, mummified skin. The latter features are poor prognostic indicators for tissue loss. *Fourth-degree frostbite* is a full-thickness loss of the entire part, with skin, muscle, tendon and bone damage. Injuries of this severity lead to amputation[22–24]. Some authors advocate simple designation as superficial or deep injury, citing better prognostic accuracy.

Pathology

Superficial dermal edema and subepidermal bulla formation are typical findings in frostbite. Vascular permeability leads to hemorrhage, most pronounced in deep injury. The epidermis and involved dermis become necrotic, with an inflammatory infiltrate and granulation tissue at the junction with normal tissue[7].

Differential diagnosis

Frostbite injuries should be readily recognizable, given exposure history and typical presentation. A greater diagnostic challenge is determination of the depth of the injury (see above). One possible diagnosis in the differential is cold water immersion foot (see Table 88.9).

Treatment

Fundamental therapeutic goals in frostbite are rapid rewarming, prevention of further cold exposure, and restoration of circulation. Once the patient is in a setting in which re-freezing cannot occur, rapid water bath rewarming is indicated. The water bath temperature should be about 37–39°C (99–102°F). Rubbing the frozen extremity with ice, using dry heat, and slow rewarming are all contraindicated. In the hypothermic patient with frostbite injury, it is important to complete fluid resuscitation and core rewarming before limb rewarming, to prevent sudden hypotension and shock. Routine wound care, protection of the frostbitten part, and tetanus prophylaxis should then follow. Radiologic evaluation (MRI, bone scan, plain films) may help determine extent of injury and prognosis. Nowadays, triple-phase bone scans are considered the standard of care for assessing tissue viability during the initial days following injury[22].

Additional therapeutic suggestions have been based on animal studies, case reports or small series. Because of increased blood viscosity and sludging, thrombolytic therapy (e.g. heparin, streptokinase, iloprost, limaprost) has been suggested. Superficial white (nonhemorrhagic) bullae may be debrided to avoid prolonged exposure to prostaglandins and thromboxanes in blister fluid. Aloe vera, a thromboxane inhibitor, has been shown to be useful as a topical agent in superficial frostbite. The problem of vasoconstriction has been addressed by sympathectomy, with the most impressive effect being prevention of re-injury with repeat exposure to cold conditions. Pentoxifylline has been found to be useful, as have anti-inflammatory agents such as methylprednisolone, methimazole and aspirin[22,23,25].

Pernio

Synonyms: ■ Chilblains ■ Perniosis ■ Kibes

Key features

- Cold-sensitive inflammatory disorder in which erythrocyanotic discoloration of acral skin is accompanied by a sensation of itching or burning
- Common trigger is exposure to cold, wet, non-freezing conditions
- Must be distinguished from chilblain lupus erythematosus and cold-sensitive blood dyscrasias
- Nifedipine can be used to treat moderate to severe pernio

Introduction

Pernio is an abnormal inflammatory response to cold, damp, non-freezing conditions[26]. It is most common in areas without central heating.

History

Over a hundred years ago, pernio/chilblains was apparently common enough in Europe and the UK that the condition was well recognized. In 1881, Piffard[27] described it quite well:

"This affection, so common in cold climates, affects, by preference, the face, hands, nose, and ears. It is characterized by redness, usually with a purplish tinge, together with more or less pain of a burning character giving little or no trouble during the summer, but causing inconvenience and suffering as cold weather sets in."

Epidemiology

Exposure to cold, wet conditions is the major risk factor for pernio. This condition is common in the UK and northwestern Europe, particularly in those whose homes lack central heating. Women, children and the elderly are most commonly affected. Elderly patients may have a prolonged course, while younger patients improve spontaneously[28–30].

Pathogenesis

The precise pathogenesis of pernio is unknown, but the condition is thought to have a vascular origin. In children, it may be associated with cryoglobulins or cold agglutinins[30].

Clinical features

Pernio presents with single or multiple erythematous to blue–violet macules, papules or nodules (Fig. 88.7A). In severe cases, blistering and ulceration may be seen. Lesions are often symmetrically distributed on the distal toes and fingers, and less often on the heels, nose and ears. Deep pernio may be seen on the thighs, calves and buttocks as blue-erythrocyanotic plaques. Patients describe itching, burning or pain. Lesions often resolve in 1 to 3 weeks, except among elderly patients with venous insufficiency, in whom lesions can become chronic[29–32].

Pathology

Pernio has a nonspecific histology consisting of dermal edema plus a superficial and deep lymphohistiocytic infiltrate with peri-eccrine accentuation (Fig. 88.7B). The infiltrate is composed predominantly of T lymphocytes. Necrotic keratinocytes and lymphocytic vasculitis have been noted[29].

Differential diagnosis

Idiopathic pernio needs to be distinguished from several other cold-induced syndromes (Table 88.8)[28–33]. The latter can be assessed by laboratory evaluation including: (1) complete blood count to exclude hemolytic anemia and myelomonocytic leukemia; (2) cryoglobulin, cold agglutinin and cryofibrinogen levels to eliminate cold-sensitive dysproteinemia; and (3) serum protein electrophoresis and immunofixation electrophoresis to exclude a monoclonal gammopathy. Chilblain lupus erythematosus (Hutchinson), whose clinical features are similar to pernio, typically exhibits histologic features compatible with discoid lesions of lupus erythematosus and occurs in a patient with serologic evidence of autoimmunity (e.g. positive antinuclear antibody screen). Diagnosis of the lupus pernio form of sarcoidosis, which favors the nose, is confirmed by the presence of the histologic features of sarcoidosis[28,33].

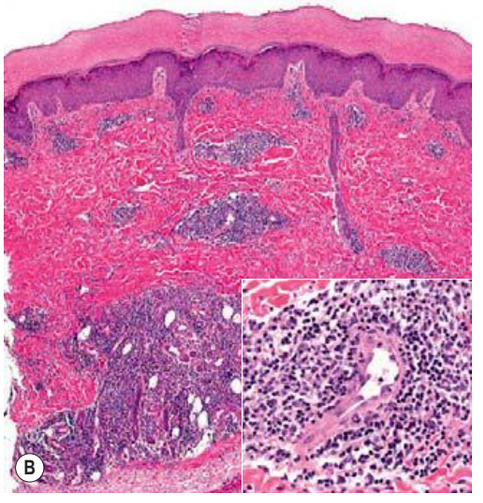

Fig. 88.7 Pernio – clinical and histologic features. A Violaceous macules and patches, primarily on the toes, but also on the plantar surface of the foot; note the associated scaling. **B** A dense perivascular and peri-eccrine lymphocytic infiltrate. Detail of predominantly lymphocytic perivascular infiltrate without atypical features (insert). Note the thickened stratum corneum characteristic of an acral site. *A, Courtesy, Jean L Bolognia, MD. B, Courtesy, Lorenzo Cerroni, MD.*

Treatment

Adequate clothing and avoidance of cold, damp conditions are important preventive measures, as are keeping feet dry and avoidance of smoking. In a double-blind, placebo-controlled trial, nifedipine (20 to 60 mg daily) was found to be efficacious for the treatment of pernio. None of the nifedipine-treated patients relapsed, while all of the placebo-treated patients developed new lesions[34]. It is effective in about 70% of patients with pernio. Other anecdotal remedies include topical corticosteroids, oral nicotinamide, phenoxybenzamine, sympathectomy and erythemogenic UVB phototherapy[28].

INJURY DUE TO WATER EXPOSURE

Immersion Foot

Synonyms: ■ Trench foot ■ Tropical jungle foot ■ Shelter foot ■ Paddy-field foot ■ Swamp foot ■ Jungle rot ■ Foxhole foot ■ Peripheral vasoneuropathy

Key features

- Injury occurs after continuous exposure of feet to moist, occluded conditions
- Cold water, warm water and tropical variants exist
- The underlying pathologic process is overhydration of the stratum corneum
- Neuropathy may persist indefinitely
- Feet exposed to immersion injury are more sensitive to re-injury

DIFFERENTIAL DIAGNOSIS OF SKIN LESIONS INDUCED BY NON-FREEZING COLD EXPOSURE			
Disorder	**Features**	**Possible associated conditions**	**Chapter reference**
Acrocyanosis	Red to purple discoloration Hands and feet Painless	Erythromelalgia Cryoproteins Anorexia nervosa	106 23 51
Pernio	Erythrocyanotic Symmetric distribution Painful		88
Raynaud's phenomenon	Clearly demarcated pallor, followed by blue then red discoloration Idiopathic form usually does not ulcerate	AI-CTD Blood dyscrasias Drugs Trauma	43
Livedo reticularis	Bluish, broad reticulated patches May be idiopathic	AI-CTD Hematologic disorders Vascular occlusive diseases Infections Medications	106
Cold panniculitis	Erythematous indurated plaques, most often on cheeks Children Clears in 2 weeks		100
Cold urticaria	Cold-induced wheals May be idiopathic	Cryoproteins Infections Malignancies Familial cold autoinflammatory syndrome	18
Chilblain lupus	Cold-induced acral lesions Histologic features of lupus erythematosus Coexistent lupus erythematosus		41
"Pulling boat hands"	Rowing in cold, wet conditions Papules to vesicles Itching, burning, tenderness		
Retiform purpura due to cryoproteins*	Favors acral sites		23
Cryoglobulins	Cold serum protein precipitate	Plasma cell dyscrasias Lymphoproliferative disorders	
Cryofibrinogen†	Cold plasma protein precipitate	Infections Malignancies	
Cold agglutinins†	RBCs agglutinate in cold Occasional RBC lysis in cold	Infections (e.g. with *Mycoplasma*, EBV, CMV) Lymphoproliferative disorders	
Cold hemolysins†	RBC lysis in cold Paroxysmal hemoglobinuria	Infections (e.g. viral, syphilis)	

*Acrocyanosis, Raynaud's phenomenon, livedo reticularis and cold urticaria can also be observed in association with cryoproteins.
†Rarely cause cold-related occlusion syndromes.

Table 88.8 Differential diagnosis of skin lesions induced by non-freezing cold exposure[28–33]. AI-CTD, autoimmune connective tissue disease; CMV, cytomegalovirus; EBV, Epstein–Barr virus; RBC, red blood cell.

Introduction

Immersion injury occurs in either cold or warm environments when the feet are exposed to continuous moisture with no opportunity for intermittent drying. Severe injury may produce permanent peripheral neuropathy and long-term morbidity.

History

Soldiers on the Western Front in World War I spent extended periods of time in the cold, wet, muddy conditions of trench warfare. The Second World War produced another variant, with shipwrecked troops spending days in partially submerged lifeboats. The Korean conflict and the Vietnam War led to more variations and tremendous numbers of casualties. The most recent military experience with immersion foot occurred during the Falklands War. Civilian immersion foot also occurs singly or in small groups, particularly among the homeless[35–38].

Epidemiology

Susceptibility to immersion foot is widely variable. Use of sandals or open shoes, constant activity, thinner plantar stratum corneum, and intermittent air drying seem somewhat protective. Risk factors for immersion foot include: prolonged occupational or recreational exposure to wet conditions, immobility, constrictive clothing, dehydration, poor nutritional status, smoking, altered mental status, peripheral vascular disease, uncontrolled diabetes, trauma, prolonged dependency of feet, and homelessness[35,37].

Pathogenesis

The underlying pathophysiology of all forms of immersion foot is overhydration of the stratum corneum. The permeability coefficient of plantar skin is approximately 10 times that of the dorsal foot skin, leading to increased water absorption. The plantar stratum corneum can absorb approximately 200% of its dry weight in water, with a proportionately higher absorption of fresh water than saline.

Warm water immersion foot (WWIF) results from severe hyperhydration of the stratum corneum, with subsequent maceration. Plantar skin temperature reaches body core temperature after about an hour in an impervious boot with 19°C (66°F) water. As the injury continues, inflammatory changes develop and may progress to a lymphocytic vasculitis with vascular compromise and erythrocyte extravasation (*tropical immersion foot* [TIF]). Eventual involvement of the dorsal foot skin develops with striking inflammation. Secondary infection may develop in the compromised tissue after 3–4 days, further complicating management and worsening morbidity[23,35,36,39].

Cold water immersion foot (CWIF) is more severe due to the addition of cold-induced vasospasm. Because water conducts heat 23 times

IMMERSION FOOT: WARM WATER, TROPICAL AND COLD WATER VARIANTS					
Variant	**Exposure temperature**	**Exposure time**	**Clinical features**	**Complications**	**Duration**
Warm water	15.5–32°C (60–90°F)	1–3 days	Thickening, softening and exaggerated wrinkling of soles (thicker soles worse) Ambulation painful ("walking on rope")		3 days
Tropical	21–32°C (70–90°F)	3–7 days	Prolonged warm water exposure In addition to plantar hyperhydration, dorsal foot becomes inflamed and edematous Pruritus, erythema and scattered vesicles Later purpura, brawny edema, maceration and scaling Fever, lymphadenopathy		>5 days
Cold water	15.5–21°C (60–70°F)	>7 days	Feet cold, heavy, stiff and numb May appear swollen Waxy white to mildly cyanotic	Infection Muscle atrophy Chronic venous stasis Joint contractures	
			Three phases after rewarming: 1. pre-hyperemic – feet cold, edematous and numb, with stocking anesthesia; purpura, blisters and necrosis possible; pulses not palpable	Trophic ulcers Myonecrosis Permanent axonal damage Bony changes such as hammer toe	Hours to days
			2. hyperemic – return of vascular and nerve function; tingling, pain and throbbing; increasing erythema and edema; skin anhidrotic, hot and painful to touch; ambulation difficult; vasomotor instability; dependent rubor, pallor upon elevation; bullae, intermittent cyanosis; infection risk high		Up to 10 weeks
			3. post-hyperemic – cold sensitivity with digital blanching, intermittent edema, hyperhidrosis, persistent peripheral neuropathy		Years

Table 88.9 Immersion foot: warm water, tropical and cold water variants[23,35,36].

faster than air, the cold water immersion invokes "thermo-protective" peripheral vasoconstriction. This creates hypoxic injury to nerves (initially large myelinated axons, but eventually all types) and muscle, with later injury to subcutaneous fat and blood vessels.

Clinical features

The clinical syndromes of immersion foot (Table 88.9)[23,35,36] are divided into the three variants previously discussed: WWIF, TIF, and CWIF. Although TIF is sometimes viewed simply as a prolonged and more severe variant of WWIF, it is discussed separately because prolonged warm water exposure does produce different clinical features.

Pathology

All forms of immersion foot demonstrate edema, thickening and fragmentation of the stratum corneum. Variable superficial dermal edema is noted. In more severe forms (TIF, CWIF), superficial dermal capillaries are narrowed due to edema or even frank lymphocytic vasculitis. CWIF produces much deeper damage in blood vessels (narrowing and fibrosis), muscle, nerves and bone.

Differential diagnosis

The differential diagnosis of immersion foot includes dermatophyte infection, cellulitis, pitted keratolysis, erythrasma, Gram-negative or complex toe web infections, and (occasionally in diabetics) candidiasis. The latter three conditions are usually confined to toe web spaces, and dermatophytosis is usually more patchy, with fine scale and no significant maceration outside the web spaces. Pitted keratolysis can be distinguished by history and by the presence of punched-out tiny pits in the plantar surface of the forefoot and heel. Cellulitis is not limited at the immersion water mark, and it can progress proximally.

Treatment

Prevention is the best treatment. Jungle boots have been shown to decrease the risk of WWIF when compared with thicker hiking boots. Once the condition develops, thorough and rapid drying is essential to restore function. CWIF patients must remain some distance from a heat source because the neuropathic insensitivity poses further risk of inadvertent thermal injury. WWIF can be prevented by frequent drying breaks and the use of silicone grease. The silicone has minimal value in TIF and is of no use in CWIF[36,38,39].

INJURY DUE TO ELECTRICITY

Electrical Burns

Key features

- The extent of an electrical burn injury may be much worse than the cutaneous contact burns suggest
- Contact point burns may be partial- to full-thickness
- Neurovascular, muscular and skeletal tissue may be damaged
- Lightning strikes can result in an erythematous, transient fern-like pattern on the skin

Introduction

Although electricity and lightning claim hundreds of lives each year, many more non-fatal injuries occur. The majority of electrical burns are work-related, particularly among electricians, linesmen and construction workers. Children are also a major risk group, with low-voltage (<1000 V) injury more common under 6 years of age and high-voltage injury in older children and adolescents. A survey of 700 electrical injury admissions to Parkland Memorial Hospital over a 20-year period showed electric arc (flash burn, no current) injury to be the most common (40%), followed by high voltage (38%), low voltage (20%), and lightning strikes (2%). Mortality was highest with lightning strikes[40].

Lightning is the second leading cause of weather-induced death in most of the world, with the incidence peaking during the summer months. Most lightning strike victims are men (usually between 15 and 45 years of age) involved in outdoor activities. In the US, lightning-associated injuries occur most commonly along the Gulf Coast and in the Rocky Mountains[40,41].

Pathogenesis

The severity of an electrical injury depends upon the strength and frequency of the electrical field, the duration of exposure, path of current, and relative resistance of the tissue. Acute tissue damage by strong (high-voltage) low-frequency fields is due to holes punched in cell membranes (electroporation), Joule heating of the extracellular fluid, and cell membrane protein denaturation through electroconformational coupling. The thermal effects (i.e. Joule and dielectric) depend upon tissue resistance to the flow of current. For example, bone has the most resistance of any body tissue, therefore generating the most heat. Resistance then decreases through fat, tendon, skin, muscle, blood vessels, and, finally, nerves (least resistance). An additional indirect effect is a field-generated formation of free radicals with subsequent lipid peroxidation and membrane disruption[42,43].

Lightning injury follows similar electrothermal principles, but with three important differences: (1) current and voltage are massive, e.g. 30 000 to 50 000 amperes (A), and a difference between clouds and object of 2 million V/m; (2) the superheating of air through which the current passes to 30 000°K, creating a high-pressure thermoacoustic shock wave (thunder) that may generate 100 atm of air pressure locally; and (3) the creation of internal conduction loops as the large magnetic field passes through the body. Injury can occur from a radial spread of current after lightning strikes the ground, from a direct hit, from flashover (current around body), or from blast effect[41].

Clinical features

Electrical burns usually range from partial- to full-thickness, and high-tension burns often involve deep tissue, with the current damaging muscle, nerves and vessels. Erythema, edema and blisters (partial-thickness damage) may result from a current of 20 to 35 mA/mm^2 with an exposure time of 20 seconds (heats skin to 50°C). At a higher current of 75 mA/mm^2 with the same exposure time, the temperature could rise to 90°C, causing skin perforation and charring.

Identification of so-called "entrance" and "exit" wounds is of no value, since 60 Hz alternating current (AC) has current changing directions 120 times per second. More important is determination of the extent of skin and internal injury. In some cases, current may arc between body parts, creating "kissing" wounds. High-voltage injuries may result in electroplating of skin with black metallic debris that leaves charred craters when removed. Additional thermal injury may occur when clothing or nearby items are ignited by an electrical arc[41,42].

Deep tissue injury can be considerably more severe than the cutaneous wounds might suggest. Muscle injury may be deceptively deep, since bone (with higher electrical resistance) retains heat more readily than other tissues. Edema in deep burns may result in compartment syndromes. High-tension AC and direct current (DC) can cause ventricular asystole, whereas low-tension AC, such as household current, is more likely to produce ventricular fibrillation, plus some patients develop chronic and recurrent arrhythmias. Considerable nerve, blood vessel and musculoskeletal injury may also be seen[41–43].

Lightning burns generally are more superficial due to the very brief contact. A unique pattern of skin lesions after a lightning strike is the "lightning print", "feathering" or Lichtenberg figures. These markings are erythematous, transient linear fern-like patterns that resolve in hours to days. While not a true burn, they are pathognomonic of lightning strike injury. Other cutaneous changes may include patchy mottling, erythema, blistering, full-thickness punctate skin loss, flash burns, thermal burns from ignited clothing, and contact burns from grounding. Although internal burn injuries are uncommon in lightning strikes because of the very brief duration, the internal electrical currents that are created are strong enough to cause cardiac arrest or seizures. Additional sequelae include profound neuromuscular shutdown (kerauno-paralysis), confusion, temporary amnesia, deafness and blindness, and prolonged or permanent neurologic disturbances, e.g. peripheral sensory neuropathy[41,42].

Pathology

Electrical burns are characterized by epidermal necrosis, with cytoplasmic strands extending into the cavity between damaged and normal skin. Keratinocytes may be elongated vertically, and collagen appears homogenized. Severe electrical burns destroy the entire skin, including the subcutis, often with accompanying necrosis of deeper blood vessel walls. The Lichtenberg figures after lightning injury display subcutaneous hemorrhage[7].

Treatment

Electrical injuries are very complex, often involving multiple organ systems, since any organ in the path of current can be damaged, and initial assessment may underestimate the extent of injury. Although full management of electrical burns should be carried out in level one trauma centers, initial management includes isolation of the patient from the power source, assessment of vital signs, cervical spine immobilization, determination of contact points on the skin, and, if possible, venous access. For more details, see the section above on thermal burns.

One special circumstance should be noted. Toddlers who sustain oral commissure burns from biting into electrical cords are at risk for delayed bleeding. About 10–14 days after the burn, the eschar comes off, often exposing a damaged labial artery. Direct pressure will control the bleeding, pending definitive care[41–43].

Chemical Burns and Exposures

These entities are discussed in several chapters, including those on irritant contact dermatitis (Ch. 15), occupational dermatoses (Ch. 16), plant dermatoses (Ch. 17) and child abuse (Ch. 90).

INJURY DUE TO CHEMICAL EXPOSURE

Chemical Hair Discoloration

Synonym: ■ Green hair – chlorotrichosis

Key features

- Hair discoloration may be a voluntary cosmetic change or the result of a chemical or metal exposure
- Green hair may result from exposure to copper or selenium
- Most hair discoloration normalizes over time

Introduction

Decorative hair coloring has risen to new heights with the flamboyant artistry of the past three decades. Brilliant pink, green, purple, blue and orange, and myriad styles, from a buzz cut to dramatic multicolored spikes, adorn many of today's youths. Much of this is deliberate decoration, but hair discoloration at any age may be an inadvertent, and sometimes unwanted, occurrence as well.

History

Green hair among copper workers was noted as early as 1654. More recently, such discoloration has been attributed to swimming pools[44].

Epidemiology

Most patients with unwanted hair discoloration have blond or white hair, although black hair may become discolored as well. Risk factors include exposure to the substances in Table 88.10[44–48], in addition to frequent contact with chlorinated water (especially swimmers), use of an alkaline shampoo, coloring or peroxide bleaching of hair, and mechanical or sun-induced hair damage[44,45].

Pathogenesis

Green hair discoloration due to copper occurs when metallic copper is released from pipes under acidic conditions into domestic or swimming pool water, or when copper algicides or chlorination are used to sanitize swimming pools. Damage to the hair cuticle by permanent wave treatments, frequent water exposure and sunlight allow the copper to penetrate the hair more readily. The copper content of discolored green hair (or golden hair in Asian patients) is considerably higher than in non-discolored hair in the same individual. Increased systemic copper may lead to elevated levels in hair, but does not cause a greenish

CAUSES OF UNINTENTIONAL HAIR DISCOLORATION		
Green	**Yellow to orange to golden**	**Purple**
• Copper	• Tar shampoo	• Alkalinized anthralin
• Selenium sulfide	• Anthralin	
• Tar shampoo	• Minoxidil	
• Cobalt	• Copper	
• Chromium		
• Nickel		
• Yellow mercuric oxide		
• Hypothyroidism*		
• Phenylketonuria*		
*Speculative.		

Table 88.10 Causes of unintentional hair discoloration[44–48]. See Table 66.11 and Fig. 66.11 for causes of diffuse hypomelanosis of scalp hair.

color change. The mechanism of selenium-induced green hair is unknown[44–46].

Yellowish hair discoloration appears to result from staining of lighter-colored hair, but the mechanisms are not known[47,48]. Nanko et al.[45] speculated that the golden color of Japanese swimmers' hair is due to water friction injury of the cuticle, allowing hypochlorous acid from the chlorination process to invade the cortex and degrade melanosomes. Copper seems to play a role as well, but the mechanism is uncertain.

Clinical features

The presenting concern is a progressive yellow to green discoloration of the hair. Scalp hair is the only hair involved, and the surface hair is more noticeably discolored than underlying hair.

Pathology

By electron microscopy, loss of the hair cuticle and wearing of the cortex layers were seen in discolored, golden hairs in Japanese swimmers[45]. In addition, there was a reduced number and density of melanosomes in the discolored hair relative to controls. X-ray spectrography demonstrated an increased chlorine content in both the discolored and normal hair of swimmers relative to controls, and a reduced sulfur content in only the discolored hairs.

Differential diagnosis

Hair discoloration is readily visible. The specific etiology and subsequent therapy needed may be determined by ascertaining the type of exposure (see Table 88.10) that led to the color change. For example, copper from cosmetic plant extracts and metallic eyeglass frames can produce green hair.

Treatment

Discontinuation of the offending exposure would seem the most prudent remedy. Numerous anecdotal remedies have been described, including hot oil, hydrogen peroxide, alkaline shampoos, penicillamine- or EDTA-based shampoos, commercial hair decolorizers, and hydroxyethyl diphosphonic acid[44].

Arsenical and Heavy Metal Dermatoses

Key features

- Chronic arsenic exposure may occur via drinking water contamination or occupational exposure
- Chronic arsenicism is characterized by mottled hyperpigmentation with areas of hypopigmentation, keratoses on the palms and soles (and other sites), and multiple non-melanoma skin cancers, particularly Bowen's disease
- Histologically, arsenical neoplasia is almost identical to actinic neoplasia

CLINICAL FEATURES OF ACUTE AND CHRONIC ARSENIC POISONING
ACUTE
Skin
• Flushing, erythema, facial edema, acrodynia, urticaria
• Loss of hair and nails
• Remaining nails show Mees' lines after 8 weeks
Gastrointestinal
• Nausea, vomiting, severe abdominal pain, profuse watery diarrhea, malabsorption
Neurologic
• Acute peripheral neuropathy
• May progress to Guillain–Barré-like ascending paralysis
Other
• Pancytopenia, metallic breath odor, cardiac arrhythmias, renal failure, respiratory failure
CHRONIC
Skin
• Hyperpigmentation of axillae, groin, nipples, palms, soles and pressure points, with superimposed guttate hypopigmentation ("raindrops on a dusty road")
• Alopecia
• Arsenical keratoses – precancerous papules on palms and soles (Fig. 88.8)
– Symmetric, yellow, punctuate, corn-like papules measuring 2–10 mm
– Favor thenar and hypothenar eminences, distal palms, lateral fingers, dorsal aspect of IP joints, weight-bearing plantar surfaces
– Rarely on trunk, proximal extremities, eyelids, genitalia
– May coalesce to plaques
• Blackfoot disease (vascular occlusive disease with blackening of skin)
Other
• Nasal septum perforation
• Peripheral neuropathy
• Bone marrow hypoplasia
• Diarrhea
• Hepatomegaly, hepatic fibrosis
• Obstructive or restrictive lung disease
• Diabetes mellitus
Malignancies
• Bowen's disease
– Any skin surface
– If no HPV, occurrence on sun-protected skin might suggest arsenic exposure
– Skin-colored to red papules and plaques that become keratotic
– Scale-crust removal leaves red, moist, papillomatous base
– Multiple lesions common
– Invasive squamous cell carcinoma develops in 5–20%
• Squamous cell carcinoma
– Arising in arsenical keratosis or Bowen's disease, has more aggressive behavior
– Metastasis in one-third
• Basal cell carcinoma
– Multiple, superficial, may resemble Bowen's disease
• Extracutaneous malignancies
– Genitourinary, especially bladder
– Lung
– Liver

Table 88.11 Clinical features of acute and chronic arsenic poisoning[49–53]. HPV, human papillomavirus; IP, interphalangeal.

Introduction

Arsenic is a ubiquitous metal, ranking 20th in abundance among all the elements. Exposure occurs via drinking water, agricultural uses, ore mining, and medicinal applications. Chronic exposure poses significant health risks, including development of benign and malignant tumors (Table 88.11)[49–53]. The other toxic and heavy metals and their cutaneous impact are outlined in Table 88.12[49–61]. Allergic contact dermatitis due to metals is covered in Chapter 14.

History

Medicinal effects of arsenic have been known since the days of Hippocrates and Galen. Early applications of arsenic included the treatment

TOXIC AND HEAVY METALS AND THEIR CUTANEOUS IMPACT					
Metal	**Form**	**Cutaneous health hazards**	**Treatment and protection**	**IDLH***	**Cancer risk**
Aluminum	Alum, sulfates	Irritant contact dermatitis	Wash off	–	–
Antimony	Metal	Irritant contact dermatitis	Soap wash immediately	50 mg/m^3	–
Arsenic	Inorganic	(see Table 88.11)	Avoidance, chelation	–	Lung, bladder and skin cancer
Barium	Chloride, nitrate	Irritant contact dermatitis, burns	Water flush immediately	50 mg/m^3	–
Beryllium	Metal	Dermatitis, granulomas	–	–	Lung cancer
Bismuth	Telluride	Irritant contact dermatitis	Soap wash immediately	–	–
Boron	Borates, oxide	Erythema, irritant contact dermatitis	Soap wash, water flush	–	–
Cesium	Hydrate, hydroxide	Irritant contact dermatitis, burns	Water flush immediately	–	–
Chromium	Hexavalent	Allergic and irritant contact dermatitis, skin ulceration, burns; systemic absorption can lead to renal failure, hepatic failure, anemia, coagulopathy	Water flush promptly	–	Lung cancer
Cobalt	Metal dust	Dermatitis, diffuse nodular fibrosis	Soap wash	20 mg/m^3	–
Copper	Metal dust	Dermatitis	Soap wash promptly	100 mg/m^3	–
Gold	Elemental salts	Most common: lichen planus, lichenoid drug eruption, allergic contact dermatitis, eczematous dermatitis, PR-like eruption, pruritus, flushing, erosive stomatitis Less common: chrysiasis, erythema nodosum, erythema multiforme, toxic epidermal necrolysis, exfoliative dermatitis	Avoid gold-laden liquor	–	–
Indium	Metal	Irritant contact dermatitis	Soap wash	–	–
Iron	Salts	Irritant contact dermatitis, mucosal irritation	Soap wash	–	–
Lead	Metal	Irritant contact dermatitis, gingival lead line	Soap wash promptly	100 mg/m^3	–
Lithium	Hydride	Irritant contact dermatitis, burns	Brush off gently, DO NOT WASH	0.5 mg/m^3	–
Magnesium	Carbonate	Irritant contact dermatitis	–	–	–
Manganese	Cyclopentadienyl tricarbonyl	Irritant contact dermatitis	Soap wash	–	–
Mercury	Elemental, inorganic, organic	Acrodynia, tattoo reaction (cinnabar), granulomas, exanthem, cutaneous hyperpigmentation, allergic and irritant contact dermatitis, baboon syndrome	Soap wash promptly	10 mg/m^3 (elemental) 2 mg/m^3 (organic)	–
Nickel	Elemental	Allergic contact dermatitis	Water wash immediately	10 mg/m^3	Lung and nasal cancer
Osmium	Tetroxide	Irritant contact dermatitis	Soap wash immediately	1 mg/m^3	–
Platinum	Metal	Irritant contact dermatitis	Soap wash	–	–
Polonium	^{210}Po radionuclide	Erythema, alopecia; ulceration in higher doses	Avoid ingestion; wash off	0.1–0.3 GBq (fatal in 3–4 weeks)	
Selenium	Elemental, alloy	Irritant contact dermatitis, skin burns	Soap wash immediately	1 mg/m^3	–
Silver	Metal	Argyria, irritant contact dermatitis, skin ulceration	Water flush	10 mg/m^3	–
Tellurium		Dermatitis, garlic smell of sweat	Soap wash promptly	25 mg/m^3	–
Thallium	Soluble	Alopecia, acneiform papules, keratotic plaques on hands and feet, Mees' lines	Water wash promptly	15 mg/m^3	–
Tin	Metal, organic	Irritant contact dermatitis, skin burns, pruritus	Water flush immediately	100 mg/m^3 (metal) 25 mg/m^3 (organic)	–
Tungsten		Irritant contact dermatitis	Soap/water wash immediately	–	–
Uranium		Irritant contact dermatitis, skin burns	Soap/water wash immediately	10 mg/m^3	Lung cancer
Vanadium	Dust, fume	Irritant contact dermatitis, green tongue	Soap wash promptly	–	–
Zinc	Chloride	Irritant contact dermatitis, skin burns (fixes tissue *in situ*), mucocutaneous hyperpigmentation	–	–	–

*Concentration posing immediate danger to life and health (IDLH). Since 1979, the National Institute for Occupational Safety and Health (NIOSH) has not allowed detectable levels of known carcinogens. Therefore there are no values in the IDLH column for carcinogens.

Table 88.12 Toxic and heavy metals and their cutaneous impact[49–61]. GBq, gigabecquerel; PR, pityriasis rosea.

of psoriasis, eczema, pemphigus, urticaria, furuncles, warts, lupus, epitheliomas, syphilis, leprosy, molluscum contagiosum, and lichen rubor[27]. Even in the late 1800s, cutaneous side effects of arsenic exposure were noted, including pruritus, papulosquamous eruptions, and palmoplantar keratoses.

Chemical forms of therapeutic arsenic include Fowler's solution (liquor potassii arsenitis), arsenici bromidum, arsenici iodidum, Pearson's solution (liquor sodii arseniatis), arsenicum hydrogenisatum, Donovan's solution (liquor arseni et hydrargyri iodidi), and Asiatic pills (arsenic with opium or pepper)[27,51]. Apparently, Fowler's solution and Asiatic pills are the most widely used, with the latter still available in India and the Far East. Traditional Chinese medicine may continue to use inorganic arsenic. Most of the Western World has abandoned arsenicals, although treatment of asthma with Fowler's solution continued until the 1960s in parts of the US. Arsenic trioxide is now used therapeutically for acute promyelocytic leukemia[49,50].

Metallic arsenic has been consumed in large quantities by the arsenic eaters of the Swiss and Austrian Alps, believing that such consumption improved physical strength. Inorganic arsenic (the toxic form) is believed to have caused Napoleon's death during his second exile at St Helena[49].

Epidemiology

Accidental exposure to arsenic still occurs via contaminated drinking water in more than 30 countries, including India, China, Taiwan, Chile, Argentina, Mexico, the Philippines, Bangladesh, Thailand and the US. Careless contamination of drinking water has resulted from mining of ores containing silver, gold, tin, copper, lead, tungsten, zinc and cobalt. The current World Health Organization provisional guideline value and the US Environmental Protection Agency limit of arsenic concentration in drinking water is 0.01 mg/l. This was recently decreased from the previous limit of 0.05 mg/l, since cutaneous and internal cancers may develop with the latter level of exposure. However, no chronic skin changes have been noted with arsenic concentrations <0.017 mg/l in drinking water. It is estimated that globally more than 100 million people are exposed to higher arsenic levels in drinking water than the 0.01 mg/l[49–53].

An estimated cumulative dose of arsenic capable of producing arsenical keratoses or skin cancer is about 0.5 to 1 g. Adverse effects have been noted when arsenic is in drinking water at a concentration as low as 0.05 mg/l, although many authors suggest that higher concentrations of 0.4 to 0.6 mg/l are required[51,52].

Chronic exposure to inorganic arsenic poses an increased risk for developing cancer (see Table 88.11). Trivalent inorganic arsenic is the most toxic form, with a latent period for chronic manifestations of 30 to 50 years[49]. Occupational exposure to arsenic may occur during the use of pesticides, herbicides or treated wood, and during electroplating, mining, smelting, wine making, carpentry, and manufacture of gallium arsenide computer microchips[49,53].

Pathogenesis

Many of the toxic effects of arsenic are through interference with cellular respiration and uncoupling of oxidative phosphorylation. Arsenic can cause chromosomal alterations and gene amplification, induce sister chromatid exchanges, inhibit DNA repair, and transform mammalian cells *in vitro*. The precise mechanism of tumor promotion is unknown, but arsenic has been shown to modulate expression of several key transcription factors, including tumor suppressor p53, nuclear factor-κB, and activating protein-1[49–53].

Clinical features

Arsenic exposure can be divided into acute and chronic forms. Acute exposure (medicinal, homicidal, suicidal) produces myriad cutaneous and systemic features. Chronic arsenic exposure (drinking water, occupational) produces altered pigmentation, keratoses and substantial malignancy risk (Fig. 88.8). See Table 88.11 for a summary of clinical features of acute and chronic arsenic poisoning.

Pathology

Arsenical keratoses exhibit marked hyperkeratosis with scattered parakeratosis and mild to moderate keratinocyte atypia. Vacuolation of keratinocytes may be noted and adnexal structures are spared. Basophilic degeneration of dermal connective tissue is highly variable. There are no features that clearly distinguish arsenical keratoses from actinic keratoses.

Arsenical Bowen's disease exhibits the same epidermal histologic features as common Bowen's disease (see Ch. 108). Although the superficial type is most commonly observed, the basal cell carcinomas associated with arsenic can be any of the clinicopathologic subtypes (see Ch. 108)[49,51].

Fig. 88.8 Cutaneous manifestations of exposure to arsenic. **A** Guttate hypopigmentation superimposed on hyperpigmentation resembles "raindrops on a dusty road". **B, C** Arsenical keratoses on the plantar and palmar surface. *A, Courtesy, John Steinbaugh, MD. C, Courtesy, Jeffrey Callen, MD.*

Differential diagnosis

Arsenical keratoses may resemble punctate palmoplantar keratoderma (including the porokeratotic variant) and verrucae vulgaris. Small pits are often noted when central keratotic plugs are removed from the papules in the inherited keratodermas, but not with arsenical keratoses. Family history and early onset are helpful in distinguishing palmoplantar keratodermas. In the nevoid basal cell carcinoma syndrome, there are persistent pits due to the localized absence of stratum corneum; additional clues are the characteristic facial features (see Ch. 108), odontogenic jaw cysts, and typical basaloid proliferative histology in the palmar pits.

Treatment

Chelation therapy is the mainstay of treatment for acute arsenicism. Dimercaprol (British anti-lewisite; BAL) is the most widely used agent. Other chelating agents reported as efficacious include dimercaptosuccinic acid and dimercaptopanesulfonic acid. For chronic arsenicism, chelation is controversial, but may reduce arsenic stores. Oral retinoids have been reported to reduce arsenical keratoses and decrease formation of arsenical basal cell carcinomas. Surgical extirpation, curettage, cryosurgery, topical chemotherapy, topical keratolytics and photodynamic therapy have been reported with some success. These treatments are all anecdotal or based upon small series[49,51].

FRICTIONAL AND TRAUMATIC INJURY TO THE SKIN

Corns and Calluses

Synonyms: ■ Corn – clavus, heloma ■ Hard corn – heloma durum ■ Soft corn – heloma molle ■ Callus – callosity, tyloma, intractable plantar keratosis

Key features

- Corns and calluses are keratotic lesions resulting from repeated trauma
- Ill-fitting footwear, bony protuberances and specific activities are contributing factors
- Hard corns are found on the dorsal aspects of the toes, while soft corns are in the interdigital web spaces
- Proper footwear and medical management usually suffice

Introduction

Repeated mechanical trauma to the feet, whether from poorly fitting footwear, anatomic differences, or work or leisure activities, produces hyperkeratosis. This otherwise natural protective response to injury may result in the formation of uncomfortable thickened areas of skin known as corns or calluses. Corns are more narrowly based and sharply defined, whereas calluses are broad based. Calluses also form on the hands from repeated trauma, but are usually asymptomatic[62].

Epidemiology

Risk factors for the development of corns and calluses on the feet include bony protuberances, abnormal biomechanical foot function, poorly fitted shoes, and repetitive trauma due to athletic activity[62].

Pathogenesis

Bony protuberances such as the condyles of metatarsal and phalangeal bones create outward pressure on the skin. Footwear and activities (walking, running) create counterpressure at these sites. The repeated friction and pressure leads to hyperkeratosis. The latter further compromises the site by increasing pressure. The cycle of friction, pressure and thickening continues until a corn or callus develops (Fig. 88.9)[62].

Fig. 88.9 Callus plus hard corns. Calluses are broad based and have increased skin markings while corns are round, more sharply defined papules with a central translucency and an interruption in dermatoglyphics. The skin overlying the second and third metatarsal heads is a common location for such lesions.
Courtesy, Jean L Bolognia, MD.

Clinical features

Hard corns (heloma durum) are firm, small, dome-shaped papules with translucent central cores, most commonly found on the dorsolateral fifth toes and dorsal aspects of other toes. Soft corns (heloma molle) are painful keratoses in the interdigital web spaces; they often become macerated. Opposing toes may exhibit "kissing lesions". Broad keratotic plaques, often under the metatarsal heads, are calluses.

A unique callus is seen on the tip of the second (and sometimes third) toe, with associated transverse ridging, thickening and splinter hemorrhages in the nail. This is known as tennis toe (see Fig. 88.14) or center's callus. Also seen in gymnasts, soccer players, runners, football players and dancers, it results from sudden stops with repeated collision between toe tip and shoe. In many cases, the second toe is found to project further forward than the hallux[62,63].

Differential diagnosis

These common lesions rarely elude diagnosis, but must be distinguished from verruca vulgaris. Warts and corns interrupt dermatoglyphics, while calluses often demonstrate accentuated lines. Paring of a corn reveals a central translucent whitish yellow core, as opposed to the thrombosed capillaries and multiple bleeding points seen in a wart. Paring of a callus reveals layers of yellowish keratin, without the multiple punctate thrombosed capillaries of a mosaic plantar wart.

Treatment

Treatment should be directed toward both symptomatic relief and correction of the biomechanical conflict. Paring of the callosity, with removal of the corn's central core, provides prompt relief. Filing after warm water soaking can be performed periodically. Topical agents such as salicylic acid or urea help soften the callosity. Soft cushions (silicone sheet, sheepskin) reduce friction and improve comfort. Properly fitted footwear and the use of appropriate orthotics lead to long-term solutions. If all of these maneuvers fail, a plain film to look for exostoses and referral to orthopedic surgery may be indicated[62,63].

Black Heel and Palm

Synonyms: ■ Talon noir ■ Tache noir ■ Calcaneal petechiae ■ Post-traumatic punctate intraepidermal hemorrhage ■ Post-traumatic cutaneous intracorneal blood

Key features

- Black macules on the palms or soles due to hemoglobin within the thickened stratum corneum
- Lesions are secondary to impact trauma and resolve with paring or time

Introduction

Black heel (or palm) is a post-traumatic intraepidermal hemorrhage seen most often in athletes. This harmless and self-healing process is a potential source of concern because of its dark black color.

History

Black heel was first described in 1961 by Crissey and Peachey[64] as calcaneal petechiae. A variety of subsequent reports under different monikers (see above) has led to confusion and debate over the proper nomenclature. The association with sports has been recognized since the beginning, with basketball the prototypical sport.

Epidemiology

Adolescents and young adults comprise the majority of patients with this entity. Sports participation is of paramount importance, particularly basketball, lacrosse, tennis, football, gymnastics and marching. Elderly patients with unusual palm and sole trauma may also be predisposed. Self-inflicted hammer injury can produce a similar clinical finding[64–66].

Pathogenesis

Black heel is a traumatic phenomenon thought to be due to shearing forces, often produced by sudden stopping or landing on the floor or ground. These shearing forces rupture papillary dermal blood vessels, with subsequent leakage of blood into the epidermis[66]. Hemoglobin resides in the stratum corneum for a longer transit time, and the position of the blood is out of reach of the phagocytic cells, maintaining the intact molecular structure of the hemoglobin[65,66].

Clinical features

The black or violet–black macules are asymptomatic and may be isolated or in clusters. They can form linear or horizontal arrays on the posterior or posterolateral aspect of the heel (Fig. 88.10A). Lesions are usually unilateral and favor the edge of the thick plantar keratin. Forefoot, toe and palmar lesions have also been observed (Fig. 88.10B,C); in patients with thickened stratum corneum due to disorders of cornification, extra-palmoplantar lesions can be seen. Paring of the stratum corneum reveals red–brown to red–violet specks of dried blood, and dermoscopy can also prove useful.

Pathology

Hyperkeratosis with "lakes of pigment"[66] within the stratum corneum form the characteristic histopathology. Iron stains may be negative (especially Prussian blue). Both the benzidine and Patent Blue V stains for hemoglobin are positive, perhaps because the intracorneal location has no phagocytic or proteolytic activity to allow formation of hemosiderin[65,66].

Differential diagnosis

The major entities in the differential diagnosis are cutaneous melanoma and verruca vulgaris. The ability to remove the lesion with gentle paring allows one to exclude a melanocytic lesion; positive staining for hemoglobin provides additional evidence. One author found the standard hemoccult test useful for confirming the presence of hemoglobin in parings[66].

Treatment

Once the diagnosis is ascertained, treatment is unnecessary.

Chondrodermatitis Nodularis Helicis

Synonyms:
- Chondrodermatitis nodularis chronica helicis
- Chondrodermatitis nodularis chronica helicis et antihelicis
- Ear corn

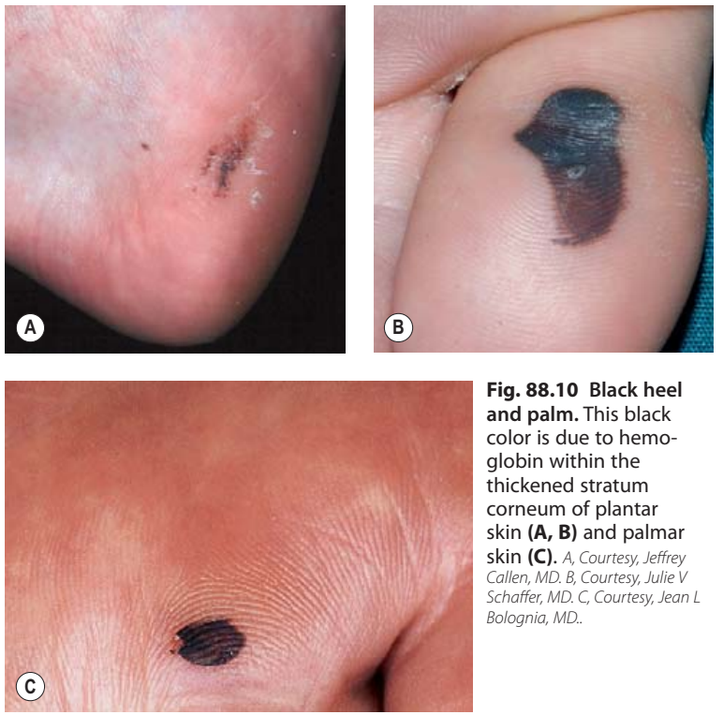

Fig. 88.10 Black heel and palm. This black color is due to hemoglobin within the thickened stratum corneum of plantar skin **(A, B)** and palmar skin **(C).** *A, Courtesy, Jeffrey Callen, MD. B, Courtesy, Julie V Schaffer, MD. C, Courtesy, Jean L Bolognia, MD..*

Key features

- Exquisitely tender nodules appear on the pinnae
- Most patients have unilateral lesions and are over 50 years of age

Introduction

Chondrodermatitis nodularis helicis (CNH) is a tender inflammatory process of the ear that was first described in 1915. Lesions are most common after age 40 years, with ~95% of cases occurring in those between 50 and 80 years of age. Both men and women are affected, with men having more lesions on the helix, and women, the antihelix. Bilateral lesions are seen in 6–10% of patients. Several cases of childhood CNH have been reported[67,68].

Pathogenesis

The precise etiology of CNH is unknown. Predisposing factors include actinic damage, cold exposure, trauma, local ischemia, and, occasionally, radiotherapy. A suggested pathogenesis is that helical lesions begin with perichondritis or folliculitis, extending secondarily to the skin. On the contrary, antihelical lesions may begin with pressure-induced ischemia, involving the cartilage secondarily. These concepts remain speculative[68].

Clinical features

CNH presents as skin-colored to erythematous, dome-shaped papulonodules with central crusts or keratin-filled craters (Fig. 88.11A). Surrounding inflammation may be noted. The majority of lesions occur on the upper helical rim or the middle to lower antihelical rim; these sites often correspond to the outermost portions of the pinna. The lesions of CNH are often exquisitely tender to palpation, and sleeping on the side of the affected ear may be impossible[68,69].

Pathology

The epidermis exhibits a well-circumscribed area of acanthosis, parakeratosis and hypergranulosis. A central crater with epidermal disruption may be filled with a keratotic plug or dermal debris. The underlying dermis shows degenerative changes with acellular collagen,

Fig. 88.11 Chondrodermatitis nodularis helicis. **A** Tender, erythematous papulonodule with central scale-crust on the mid antihelix of an older woman. This represented the site most susceptible to pressure-induced ischemia. **B** Central scale-crust, epithelial hyperplasia, fibrosis, granulation tissue and degenerated cartilage are seen on histologic examination. *A, Courtesy, Kalman Watsky, MD. B, Courtesy, Ronald P Rapini, MD.*

fibrosis (Fig. 88.11B), and variable lymphohistiocytic inflammation that is often granulomatous. Epithelioid cells may be present. The infiltrate extends into a thickened perichondrium[67–69].

Differential diagnosis

Lesions that are most commonly confused with CNH are squamous cell carcinomas, basal cell carcinomas, actinic keratoses, cutaneous horns, and weathering nodules. Additional entities to consider include verrucae, keratoacanthomas, calcinosis cutis, gouty tophi, and reactive perforating collagenosis. Although the marked tenderness and characteristic locations point to the diagnosis of CNH, histologic evaluation may be necessary to confirm the diagnosis[68].

Treatment

A variety of treatment modalities have been suggested for CNH, although few controlled studies have been performed. Small series of patients treated with topical corticosteroids or topical antibiotics showed variable success. The use of specially designed pillows to relieve pressure is operator-dependent. Intralesional corticosteroid injections have been successful in some small series.

Numerous surgical approaches have been suggested, including cryosurgery, electrodesiccation and curettage, full-thickness excision, carbon dioxide laser ablation, and excision of skin with partial cartilage excision. Surgical excision seems to be the favored modality, although a paucity of data exists. A retrospective cohort study of 41 patients treated surgically and 15 patients treated conservatively (circular foam pad with headband) showed that 66% of the surgical and 87% of the non-surgical patients were healed at follow-up. Selection bias, small sample size and variable follow-up times were problematic. Additional controlled studies will be necessary before conclusions can be drawn regarding optimal therapy[68,69].

Acanthoma Fissuratum

Synonyms: ■ Granuloma fissuratum (of the ears) ■ Spectacle frame acanthoma ■ Eyeglass frame acanthoma

Key features

- Retroauricular nodules with a central vertical groove or fissure occur at the site of eyeglass frame contact
- Refitting of the spectacle frame leads to resolution

Introduction

Ill-fitting eyeglass frames create a frictional injury in the postauricular sulcus or upper lateral nose leading to development of acanthoma fissuratum. The entity "granuloma fissuratum" was first described by Epstein[70] in 1965 and the term was derived from an earlier report of a buccal mucosal lesion of that name. The term "spectacle frame acanthoma" and the currently accepted designation "acanthoma fissuratum" were added to the literature in the 1970s[71,72].

Pathogenesis

Acanthoma fissuratum is thought to be due to pressure and friction created by eyeglass frames in the retroauricular sulcus or the upper lateral nose. Chronic irritation leads to collagen deposition. The collagen then appears to deteriorate, leading to local inflammation as a means of eliminating the abnormal collagen[73]. Additional factors that may contribute to the pathogenesis are composition and weight of the eyeglasses, roughness of the eyeglass frame, perspiration or local areas of dermatitis[72].

Clinical features

The classic lesion is a firm, skin-colored to erythematous nodule or plaque in the upper portion of the postauricular sulcus or upper lateral nose. The center of the lesion is characterized by the presence of a vertical groove or fissure (Fig. 88.12). There may be occasional tenderness, serous discharge or slight hyperkeratosis. A surrounding inflammatory halo may be noted[71–73].

Pathology

The epidermis exhibits irregular acanthosis, most marked at the lesion's periphery. In some instances, the appearance may be that of pseudoepitheliomatous hyperplasia. The central depression may show epidermal thinning or variable epidermal separation. Compact orthohyperkeratosis is noted over most of the lesion, with patchy areas of parakeratosis near the central groove. Dermal papillae exhibit dilated vessels and a moderately dense perivascular inflammatory infiltrate comprised of lymphocytes, histiocytes and plasma cells, with occasional neutrophils. Slight fibrosis may be noted in the superficial and mid dermis. Elastic tissue stains show no significant elastin within the nodule[71–73].

Differential diagnosis

These lesions are most commonly mistaken for cutaneous malignancies (e.g. basal cell carcinoma, Bowen's disease) or lichen simplex chronicus superimposed on seborrheic or allergic contact dermatitis and, less often, keloids. Although histologic examination can readily exclude the cutaneous carcinomas, the presence of pseudoepitheliomatous hyperplasia may create some confusion. However, the cellular atypia of squamous cell carcinoma should be absent in acanthoma fissuratum.

Fig. 88.12 Acanthoma fissuratum. Thin pink plaque with scale of the postauricular sulcus (arrow). Note the linear fissure.

Fig. 88.13 Weathering nodules. Multiple asymptomatic, small, whitish papules along the helix of an older man with photodamage. *Courtesy, Jean L Bolognia, MD.*

Treatment

Lesions should clear within a few months of discontinuation, replacement or proper adjustment of the offending spectacles. Excision should be considered for persistent lesions. Anecdotal success of intralesional corticosteroids has been reported[71,72].

Weathering Nodules of the Ear

Key features

- Asymptomatic whitish papules (2 to 3 mm) along the helices of middle-aged or elderly Caucasian men
- Histologically, a fibrous tissue spur with cartilage metaplasia
- No treatment needed

Introduction

Asymptomatic papules, known as weathering nodules, are seen on the helices of Caucasian men who have a history of significant cumulative sun exposure. The largest series published to date is that of Kavanagh et al.[74]; all of their patients were Caucasian men who had significant outdoor sun exposure either at work or with hobbies. The median age was 79 years (range 44–91). A survey of 100 geriatric male inpatients in the same geographic area revealed that four had similar lesions.

Pathogenesis

Although the precise pathogenesis is unknown, the consistent history of sun exposure and the presence of actinic damage suggest a role for UV light.

Clinical features

Weathering nodules are white or skin-colored, and are present along the free margin of the helix (Fig. 88.13). They are bilateral and multiple in most patients. Multiple lesions create a scalloped appearance to the helical rim. Individual lesions are 2 to 3 mm in diameter and slightly elevated. Patients generally have significant actinic damage elsewhere[74].

Pathology

Epidermal atrophy, solar elastosis and telangiectasias occur over the nodule. The nodule itself is a fibrous tissue spur with cartilage metaplasia extending upward from disrupted perichondrium. The spur is connected to the underlying cartilage. No inflammation or epidermal disruption are noted[74].

Differential diagnosis

Alternative diagnostic considerations include CNH, elastotic nodules, amyloidosis, gouty tophi, calcinosis cutis, granuloma annulare and rheumatoid nodules. Chondrodermatitis occurs in a similar clinical setting, but can be distinguished by the presence of ulceration and tenderness clinically, and marked inflammatory changes histologically. Elastotic nodules of the ear occur more often on the anterior ear or antihelix. They are waxy, firm, mildly tender nodules. Microscopically, these lesions exhibit thick coalescing elastic fibers and amorphous basophilic masses. No cartilaginous changes are seen. The deposits of amyloid, uric acid and calcium have distinctive appearances and staining characteristics[74,75]. Granuloma annulare and rheumatoid nodules consist of necrobiotic granulomas.

Treatment

Treatment is unnecessary, but Kavanagh et al.[74] note that two of their patients had received cryosurgery, with no local recurrence of the nodules.

Traumatic Auricular Hematoma

Synonyms: ■ Cauliflower ear ■ Wrestler's ear

Key features

- Trauma to the pinna avulses the anterior perichondrium from the underlying cartilage, then a subperichondrial hematoma can develop
- Drainage and replacement of the perichondrium can prevent development of fibroneocartilage

Introduction

Blunt trauma to the auricle can create a subperichondrial hematoma. If not corrected quickly, the hematoma will organize into a permanent disfiguring nodularity known as cauliflower ear. Therefore, early surgical correction is crucial.

History

Ancient Greek wrestlers were recognized by the stigma of a misshapen, thickened ear, the wrestler's "ear-mark". Similar ear injuries also are seen in boxers, rugby players, and piano movers. Early twentieth century Hong Kong opium dens produced a similar finding as opium abusers slept for long periods on the wooden pillows. Although past generations of wrestlers lined up after competition to have their ears "needled", soft plastic protective headgear has been available for several decades[76].

Epidemiology

Traumatic auricular hematoma is seen almost exclusively in male athletes who participate in wrestling, boxing or rugby. Piano movers are at risk as well, due to pressure on the ear while lifting.

Pathogenesis

A glancing blow or twisting movement against the anterolateral pinna avulses the anterior perichondrium from the underlying cartilage. Adhesion between skin structures and perichondrium is apparently stronger than between perichondrium and cartilage. These shearing forces rupture vessels that then bleed into the subperichondrial or intracartilaginous space, creating the auricular hematoma[76]. Regardless of the location of the hematoma, there is agreement that, if left untreated, the hematoma will organize into a solid mass with subsequent production of fibroneocartilage. Fibroneocartilage formation begins 7–10 days after injury. Calcification may also ensue. Repeated injury produces the multinodular deformity known as cauliflower ear[77].

Clinical features

A painless to slightly tender swelling appears on the upper anterior aspect of the pinna in the scaphoid or triangular fossa. If left untreated, the swelling persists and becomes firmer with time. The color varies from skin-colored to slightly bluish. No epidermal change is noted. Older lesions may feel soft and cystic or very firm[76,77].

Pathology

Histopathologic examination reveals a hematoma with fibrosis and foci of new cartilage formation. Older lesions may exhibit calcification and even ossification within the hematoma[76].

Differential diagnosis

The history of trauma and characteristic presentation readily aid in establishing the diagnosis. Other considerations include relapsing polychondritis, auricular pseudocyst and epidermoid cyst. Polychondritis should produce painful inflammatory episodes unrelated to trauma. Histologic features would confirm the inflammatory nature, even in the quiescent phase with thickening of the perichondrium. Auricular pseudocysts and epidermoid cysts are discussed in Chapter 110.

Treatment

Goals of treatment for auricular hematomas are evacuation of the hematoma, prevention of fluid reaccumulation, and maintenance of function and cosmesis. There is general consensus that treatment needs to proceed within 7 days (preferably the first 72 hours). Treatment modalities include aspiration, incision and drainage (with or without cartilage removal), and splinting to prevent recurrence[77]. Cochrane database investigators were unable to find controlled randomized or cohort studies to determine the best modality. Their conclusion was that there are no good data defining a best treatment, or even whether post-drainage treatment is needed[78].

SPORTS-RELATED DERMATOSES

Variants: ■ Tennis toe ■ Jogger's toe ■ Turf toe ■ Surfer's nodules ■ Surfer's knots ■ Jogger's nipple

Key features

- Cutaneous trauma produces abrasions, blistering, ecchymoses, callosities and unique sport-specific stigmata
- Allergic contact dermatitis in athletes is often due to rubber antioxidants and adhesives
- Cutaneous bacterial, viral and fungal infections occur more often in those engaged in sports with close physical contact
- Existing dermatoses may be exacerbated by sports participation

Introduction

Participation in sports may be associated with many types of cutaneous injuries or infections. Most of these problems are minor inconveniences. The following discussion will be organized into: mechanical trauma (acute, chronic); exposure-related dermatoses; infections; and exacerbation of existing conditions.

History

Cutaneous injury has been an accepted consequence of athletic activity at least since Ancient Greece. Stigmata such as the wrestler's "earmark" have been viewed as marks of athletic prowess.

Epidemiology

Sports participation has shown a steady increase over the past 30 years. Along with the gain in popularity of athletic activity has come an increase in sports-related dermatoses and infections. For example, herpes simplex viral infections were seen in 2.6% of high school and 7.6% of collegiate wrestlers in the 1984 season, and a third of wrestlers in a wrestling camp in 1989[79,80]; wrestlers are also at risk of developing tinea corporis gladiatorum[81]. More recently, cutaneous infections with community acquired MRSA have been observed among athletes, in particular football players and wrestlers[82,83]. Risk factors include frictional injuries, weight, poor hygiene, and sharing clothing and towels with team members.

Pathogenesis

The types of frictional and mechanical trauma that can lead to dermatoses in athletes are summarized in Table 88.13. For example, acne mechanica is thought to occur when the local microenvironment of the skin is altered by a combination of pressure, heat, moisture (perspiration), friction and occlusion[84].

Exposure to heat and cold are discussed in other sections of this chapter. The pathogenetic mechanisms underlying pre-existing dermatoses that may be aggravated by athletic activity are discussed in the respective sections.

Clinical features

Acute or chronic mechanical trauma during sports activity creates unique cutaneous lesions summarized in Table 88.13.

In some patients, chronic friction on extensor extremities during the summer is thought to produce frictional lichenoid dermatitis (summertime pityriasis). This malady affects prepubertal children (mostly boys) and is characterized by irregular clusters of pale to skin-colored, flat-topped, lichenoid papules on the elbows, knees, dorsal metacarpophalangeal and interphalangeal joints, and extensor shins and forearms. Mild pruritus may develop, although most children are asymptomatic[87].

Another common finding in athletes is the presence of striae distensae, or stretch marks. These are most common in sports that emphasize strength training by weightlifting, such as body builders, football players, wrestlers and gymnasts. Striae are also seen in non-athletic settings such as Cushing's syndrome, obesity, pregnancy and overuse of corticosteroids. In addition, striae are thought to occur in 70% of adolescent girls and 40% of adolescent boys[84].

Environmental exposure creates additional challenges for the sports enthusiast, especially with activity during temperature extremes. Summer heat poses risks such as heat exhaustion and heat stroke (see above). Mountain climbers, skiers (downhill and Nordic), biathletes, winter hikers and others are at risk for cold injury (see above). Water exposure in swimming, diving, snorkeling and scuba diving has intrinsic risks as well. Overhydration of the stratum corneum increases susceptibility to blisters, skin breakdown and cutaneous infection.

Allergic contact dermatitis is likely to be as common among athletes as the general population, but specific situations may make contact dermatitis more apparent due to the use of specialized equipment. Erythema in the distribution of a swimmer's goggles or scuba mask ("mask burn") may be seen, and individuals with more severe reactions can also develop vesiculation, weeping, crusting, pruritus and pain. Rubber antioxidant allergy is known to occur in this setting, with mercaptobenzothiazole, tetramethylthiuram and paraphenylenediamine derivatives being the major allergens. Rubber compounds in athletic

FRICTIONAL AND MECHANICAL DERMATOSES IN ATHLETES				
Condition	**Clinical features**	**Sports**	**Etiology/pathogenesis**	**Prevention/treatment**
Friction blisters* (see Ch. 33)	Bullae and superficial erosions	Any	Friction or tangential impact to foot while in warm moist shoes	Frequent drying of feet, lubrication, proper shoe fit, drain blisters/leave roof
Contusion*	Ecchymosis	Any	Perpendicular mechanical trauma producing vascular damage	Padding
Subungual hematoma*		Running, tennis, basketball	Sudden impact of toe tip with end of shoe	Enlarged shoe toe box with proper arch and metatarsal support, drainage of hematoma may be needed
Black heel*	See text			
Turf toe*	Painful, erythematous, edematous hallux	Football, soccer	Acute dorsal and plantar tendonitis	Rest
Jogger's nipple*	Pain, erythema, fissuring, occasional bleeding	Running	Repeated friction of rough shirt fabric	Woman: jogging bra Man: taping, lubrication, semisynthetic or silk shirt
Callosities	See text	Many		
Tennis toe	Toe tip callus, nail thickening, subungual hyperkeratosis (Fig. 88.14)	Tennis, running	Repeated trauma of longest toe against inside of toe box	Proper shoe fit, enlarged toe box, improved arch support
Nail dystrophy	Onycholysis, hematoma, subungual hyperkeratosis, paronychia	Many	Repeated trauma to nails	Keeping nails trimmed
Fibrotic nodules (e.g. surfer's knots)	Thick fibrotic nodules on knees, knuckles, dorsal feet	Surfing, boxing, football, marbles	Chronic pressure over bony prominences	Padding, position change, prone rather than kneeling on surfboard
Piezogenic papules	Multiple asymptomatic to tender yellowish outpouchings on the medial and lateral aspects of the heels when standing (Fig. 88.15)	Distance running, high-impact sports	Herniation of subcutaneous fat through small tears in plantar fascia	None known
Runner's rump	Small ecchymoses in upper gluteal cleft	Running	Constant friction with each stride	Lubrication
Alopecia and hypertrichosis	Transient alopecia on forearms followed by hypertrichosis	Gymnastics	Frictional alopecia, compensatory regrowth	
Swimmer's shoulder	Erythematous plaque on shoulder	Swimming	Friction of unshaven beard against the shoulder during the swim stroke	More frequent shaving

*Acute injury.

Table 88.13 Frictional and mechanical dermatoses in athletes[84–86].

Fig. 88.14 Chronic "tennis toe". Chronic and repeated trauma of the longer second toe against the end of the tennis shoe toe box during sudden stops creates the distal callus formation and nail plate thickening known as tennis toe.

Fig. 88.15 Piezogenic papules. Yellowish outpouchings on the heel represent herniation of subcutaneous fat through the plantar fascia in this sometimes painful condition.

shoes pose risks to individuals with contact sensitivity, particularly with thiourea, mercaptobenzothiazole and thiuram antioxidants. The resulting erythema, desquamation, vesiculation, fissuring, pain and pruritus of the feet can prove quite disabling for the athlete, particularly when alternative footwear without rubber (e.g. soccer cleats, baseball cleats) is not readily available. However, the development of polyurethane shoes by a few manufacturers offers an alternative for runners allergic to rubber components. Adhesives in tape, benzoin, topical antiseptics and antibiotics, dyes and leather tanning agents also may be problematic in several groups of athletes[84,86].

Acne mechanica occurs commonly in athletes in whom occlusive uniforms or protective gear create the right microenvironment. Football players flare during the August pre-season practice with follicular

papules, pustules and nodules on the forehead, preauricular areas, chin and shoulders, corresponding to forehead and ear pads of the helmet, chin strap and shoulder pads, respectively. Acne keloidalis of the lower occiput may be aggravated by the helmet as well. Other sports in which protective headgear may create acne mechanica include hockey, lacrosse and wrestling. Occlusive synthetic clothing of dancers and gymnasts, plastic benches of weight lifters, the golf bag shoulder strap, and the cradling of the shot against the neck in shot putters may also produce acne mechanica[84].

Heat, moisture, friction, and contact with other athletes or various surfaces increase the risk of some infectious conditions (Table 88.14). Several common monikers attest to the frequent association, such as "jock itch", "herpes gladiatorum", "athlete's foot" and "swimmer's ear". A report that evaluated the risk of staphylococcal infections in football players within a professional team noted that weight and turf injuries were risk factors and, therefore, linemen were more prone to developing this infection. However, practices of the trainers and the use of whirlpool equipment also pointed to risks associated with poor hygienic practices[82].

The final issue of sports-related skin disease is aggravation of pre-existing conditions. Psoriasis, vitiligo and lichen planus may exhibit a Koebner phenomenon, flaring in areas of skin injury such as abrasions. Epidermolysis bullosa simplex of the Weber–Cockayne type is worsened by friction on the feet and hands, particularly in warm summer months (see Ch. 32). Photosensitive dermatoses may be exacerbated by outdoor sun exposure (see Ch. 87). Both cholinergic and exercise-induced urticaria may worsen with heavy physical exertion[88] (see Ch. 18). Vibratory angioedema has also been reported with bicycling, walking, and jogging[90]. The reader is referred to The American Academy of Pediatrics guide for further information on medical conditions affecting sports participation[91].

Pathology

Many of the friction-induced conditions discussed here have histologic features similar to callosities (see above). Surfer's nodules show hyperkeratosis and mild acanthosis of the epidermis with increased numbers of normal-appearing collagen bundles. The overall histologic appearance is similar to that of a collagenoma[92]. The infectious processes are covered in detail in their respective chapters, as are the existing dermatoses aggravated by sports participation.

Treatment

Therapy for the non-infectious conditions discussed in this section is based primarily upon anecdotal reports and small series, and is

CUTANEOUS INFECTIONS IN ATHLETES

Condition	Common name	Clinical features	Organisms	Typical sport
Impetigo		Small vesicles to large bullae on glistening erythematous bases; honey-colored crusts	*Staphylococcus aureus*, β-hemolytic streptococci	Wrestling, European football (soccer), American football, swimming, gymnastics
Folliculitis		Erythematous follicular papules and pustules	*S. aureus*	Most sports
Hot tub folliculitis		Markedly erythematous, edematous follicular papulopustules, few in number, often involving axillae, breasts, pubic area and buttocks	*Pseudomonas aeruginosa*	Swimming; use of whirlpool, hot tub or Jacuzzi
Pseudomonas hot-foot syndrome		Tender nodules on soles	*P. aeruginosa*	Use of wading pool
Furuncles	Boils	Tender warm red nodules or abscesses on trunk or extremities	*S. aureus* (including MRSA)	Football, wrestling, basketball, swimming
Erythrasma		Reddish-brown dry patches in axillae, groin or toe webs	*Corynebacterium minutissimum*	Most sports, especially with occlusive clothing
Pitted keratolysis	Toxic sock syndrome	Malodorous feet with plantar 1–3 mm punched-out erosions extending only through the stratum corneum of overhydrated skin	*Corynebacterium* spp., *Micrococcus (Kytococcus) sedentarius*	Running, tennis, basketball
Otitis externa	Swimmer's ear	Pruritus may be followed by pain, discharge, tenderness of the pinna, sensation of fullness and reduced hearing	*P. aeruginosa* most common; also streptococci, diphtheroids and staphylococci	Swimming, diving (atopics at risk)
Swimming pool granuloma		Firm acral red papules	*Mycobacterium marinum*	Swimming
Verruca vulgaris	Warts	Verrucous, keratotic papules and plaques	Human papillomavirus	Any that use locker-room showers or public pools
Herpes simplex viral infection	Herpes gladiatorum	Clustered vesicles on erythematous bases at point of skin-to-skin contact	Herpes simplex virus	Wrestling
Molluscum contagiosum		Shiny, umbilicated 2–3 mm papules at the skin contact site	Parapoxvirus	Wrestling, swimming
Tinea pedis	Athlete's foot	Maceration, scaling, pruritus in toe webs; or diffuse plantar erythema and scale	*Trichophyton rubrum, T. mentagrophytes, Epidermophyton floccosum*	Any sport
Tinea cruris	Jock itch	Annular to polycyclic erythema with scaly, active borders, perifollicular papules or pustules; favors upper inner thighs	Same as tinea pedis	Any sport
Tinea corporis	Tinea gladiatorum	Except for location, the same as tinea cruris	*Trichophyton* spp.	Wrestling
Seabather's eruption	Sea lice	Pruritic papules on areas covered by bathing suit	*Edwardsiella lineata, Linuche unguiculata*	Salt water swimming
Swimmer's itch	Cercarial dermatitis	Pruritic erythematous papules on exposed skin	Duck schistosome cercaria	Fresh water pond and lake swimming and wading

Table 88.14 Cutaneous infections in athletes[79,80,82,84,88,89].

DERMATOLOGIC CONDITIONS IN LIMB AMPUTEES			
Physical/mechanical effects	**Allergic contact dermatitis (most common allergens)**	**Infections**	**Exacerbation of pre-existing condition**
• Callus • Verrucous hyperplasia • Hypertrichosis • Erythema • Blisters • Ulceration • Folliculitis (normal flora) • Inclusion cyst	• Para-phenylenediamine (PPD) • Formaldehyde • Epoxy resin • Mercapto mix • Fragrance mix	• Group A β-hemolytic *Streptococcus* – impetigo, cellulitis • *Staphylococcus aureus* – impetigo, cellulitis, folliculitis • *S. epidermidis* • Dermatophytes • *Candida* spp.	• Psoriasis • Eczema • Pyoderma gangrenosum

Table 88.15 Dermatologic conditions in limb amputees[93]. Localized pemphigoid of the stump has also been reported.

summarized in Table 88.13. Frictional lichenoid dermatitis responds to friction avoidance, the use of clothing to protect extensor surfaces, and moderate-potency topical corticosteroids[84,86–88]. Education and changes in practice behavior might aid in the prevention of infections in athletes.

AMPUTEE-RELATED DERMATOSES

Whether amputation is due to traumatic injuries (vehicular accidents, war-related, sports-related), environmental exposure, or a chronic medical condition (e.g. diabetes mellitus), skin disorders are a frequent complication, with reported incidences ranging from 35% to 75%. Table 88.15 lists dermatologic conditions observed in amputees. Implicated factors include higher level of amputation, higher activity level, and soft socket (as opposed to silicone) prostheses[93].

MUSICAL INSTRUMENT-RELATED DERMATOSES

Variants: ■ Cellist's chest or knee ■ Clarinetist's cheilitis ■ Drummer's digit ■ Fiddler's neck ■ Flautist's chin ■ Garrod's pads ■ Guitar nipple ■ Harpist's fingers

Key features

- Cutaneous disorders in musicians include frictional injury, irritant and allergic contact dermatitis, hyperhidrosis, acne mechanica and vascular compromise
- Dermatoses tend to be recurrent unless the posture, use or contact can be avoided
- Identification of the mechanism of injury is critical for successful therapy

Introduction

Musicians have unique cutaneous reactions related to countless hours of practice and performance required to master their art. Skin and associated soft tissue and musculoskeletal changes are therefore not uncommon. The major categories of injury in musicians are contact dermatitis, repetitive motion injury and dysautonomia.

History

One of the first reports of an occupational dermatosis is reputed to be the recognition of fiddler's neck in 1713. About the same time, Italian physician Bernadino Ramazzizi noted the peculiar distension and soft tissue laxity of the cheeks in horn players, and summarized the occupational problems of musicians[94].

Epidemiology

The injuries discussed below all require considerable devotion of time to practice and performance of the chosen instruments. Some of these conditions are considered marks of virtuosity, such as cellist's thumb. The impact of these conditions is greatest on professional musicians, although amateurs, and even beginners, may be afflicted[95].

Pathogenesis and clinical features

The clinical features and pathogenesis of dermatoses caused by musical instruments are summarized in Table 88.16.

Another common dermatosis that may occur in musicians is "lip licker's" dermatitis, characterized by erythema, fissuring and scaling in wind instrument players. Intraoral hyperkeratosis of the lip or shallow erosions may develop in patients with dental irregularities or orthodontic appliances. Salivary abnormalities may interfere with performance with wind instruments. Xerostomia is devastating to the wind player (especially brass), while increased salivation is problematic for the recorder player. Sialolithiasis has been seen in association with fiddler's neck.

Sharing of mouthpieces may increase the risk of transmission of infections such as herpes simplex virus, EBV, cytomegalovirus, and hepatitis A and B. Latent herpes simplex may be reactivated by the frictional trauma of wind instruments, with brass players tending to have upper lip lesions and woodwind players having lower lip lesions[96].

Hyperhidrosis of the palms may lead to corrosion of metal instruments or the inability to maintain proper contact with instrument keys or strings[97].

Allergic contact dermatitis associated with musical instruments is summarized in Table 88.17.

Pathology

Diagnosis of most of these conditions does not require histologic evaluation. However, fiddler's neck has been shown to exhibit epidermal hyperplasia with elongation of the rete ridges, follicular plugging, folliculitis and perifolliculitis, and epidermoid cyst formation[96].

Differential diagnosis

Fiddler's neck needs to be distinguished from localized cervical lymphadenitis, an inflamed epidermoid cyst, draining dental abscess, and acne mechanica from other causes (e.g. telephone, headset). Clinical history should suffice, along with the characteristic location and clinical features. For example, a dental abscess, scrofuloderma or cervical actinomycosis with fistula formation often leaves the area indented and bound to underlying structures.

Treatment

Discontinuation of the instrument is curative in almost all cases, but usually quite impractical. Professional musicians, in particular, need other options. Frictional injuries may be addressed with padding, or change in position of the instrument. Fiddler's neck, for example, seems less common if the dropping neck position is avoided. Anecdotal

DERMATOSES CAUSED BY MUSICAL INSTRUMENTS			
Condition (synonym)	**Clinical features**	**Pathogenesis**	**Associated instruments**
Acne mechanica (fiddler's neck, clarinetist's cheilitis, flautist's chin)	Follicular papules and pustules, lichenification, hyperpigmentation	Repetitive friction and pressure, coupled with occlusion and moisture (sweat, saliva)	Violin, viola, clarinet, saxophone, flute
Cellist's chest	Sternal skin tenderness, erythema, edema, hyperpigmentation	Pressure and friction	Cello
Cellist's knee	Erythema, scale, callus and hyperpigmentation of left medial knee	Friction callus	Cello
Finger calluses	Hyperkeratotic callosities on fingertip pads	Repetitive friction	All strings
Drummer's digit	Vesicle or erosion on the radial aspect of the left ring finger distal and middle phalanx, followed by callus formation	Friction from holding left drumstick in classical position	Drums
Garrod's pads (violinist's pads)	Calluses on dorsal aspect of proximal interphalangeal joints of left index and middle fingers	Repeated extension and flexion of extensor tendon over tightly flexed joint	Violin, viola
Guitar nipple	Unilateral mastitis with erythema, edema, pain	Pressure and friction of guitar sound box pressed against chest	Guitar
Paronychia, onycholysis, subungual hemorrhage		Repeated trauma to nail apparatus	Piano, strings (especially playing pizzicato), harp, guitar

Table 88.16 Dermatoses caused by musical instruments[94–96].

ALLERGIC CONTACT DERMATITIS ASSOCIATED WITH MUSICAL INSTRUMENTS		
Sensitizer/contactant	**Skin distribution**	**Instrument**
Rosin/colophony (abietic acid)	Hands, face, neck	Violin, viola, cello, double bass
Rosewood	Lips, chin, cheek	Strings, reeds
Makassar ebony	Chin	Violin
Cocobolo wood	Lips	Recorder
African blackwood	Lips	Recorder, oboe
Nickel	Chin	Violin
	Fingers, hands	Cello, sitar
	Lips, chin	Flute, brass
Reed (perhaps only irritant)	Lips	Saxophone, clarinet
