Key features

- Melanoma represents a malignant tumor that arises from melanocytes, and, due to its metastatic potential, leads to >75% of skin cancer deaths
- The incidence rates of melanoma have increased over the past four decades by three- to five-fold, whereas mortality rates began to stabilize in the early 1990s
- *In situ* and early invasive cutaneous melanoma can be subtle in appearance but dermoscopy has led to an improvement in diagnostic accuracy
- Early-stage melanomas are often curable by surgical excision
- For metastatic melanoma, immunotherapies (e.g. ipilimumab) and targeted therapies (e.g. vemurafenib) can be tried

INTRODUCTION

Melanoma is a malignant tumor that arises from melanocytes and is most commonly cutaneous in origin. It can also arise on mucosal surfaces (e.g. oral, conjunctival, vaginal) and within the uveal tract of the eye as well as the leptomeninges. While the majority of melanomas are brown-black in color due to melanin deposition, some are skin-colored to pink-red, i.e. amelanotic.

Rising incidence rates of cutaneous melanoma have been observed worldwide over the past four decades in white populations[1–3]. While mortality rates increased slightly in the US and Europe during the 1970s and 1980s, a stabilization of mortality rates was observed in a number of countries during the 1990s, due primarily to the early detection of thinner cutaneous melanomas. Melanoma is also one of the most common forms of cancer in young adults[4]. It therefore represents a significant public health problem, especially with respect to years of life lost.

MOLECULAR PATHOGENESIS

There are several hallmarks of cancer, including self-sufficiency with regard to growth signals, insensitivity to antigrowth signals, evasion of apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis[5,6]. As depicted in Figures 107.3 and 107.4, this set of properties can be acquired by the activation of oncogenes or the inactivation of tumor suppressor genes via molecular mechanisms such as point mutations, deletions and translocations as well as epigenetic mechanisms such as microRNA expression and promoter methylation. Genome-wide analysis of genetic aberrations has revolutionized our understanding of the complex interplay of signaling pathways, including in melanoma[7].

Carcinomas usually develop through a stepwise, evolutionary process. Tumor progression involves both genetic instability[8] and selective growth of cells with advantageous mutations[9]. Additional factors include genetic predisposition, mutagenic environmental events, and antitumor host response. For example, melanomas from different body sites and from locations with different amounts of ultraviolet radiation (UVR) damage also differ genetically (Fig. 113.1). Based upon different patterns of DNA copy number changes and varying frequencies of oncogene mutations, the molecular classification of melanoma was thus redefined[10], providing a rationale for targeted therapy.

Cellular Signaling Pathways in Melanoma

Genetic aberrations in melanoma frequently affect signaling pathways that play an essential role in normal melanocyte biology. Discovery of specific sites of dysfunction within these pathways has led to the era of targeted therapies, e.g. the use of vemurafenib in patients with a somatic mutation in *BRAF* that leads to substitution of glutamic acid (E) for valine (V) at codon 600 (i.e. V600E) and subsequent activation of the mitogen-activated protein kinase (MAPK) pathway.

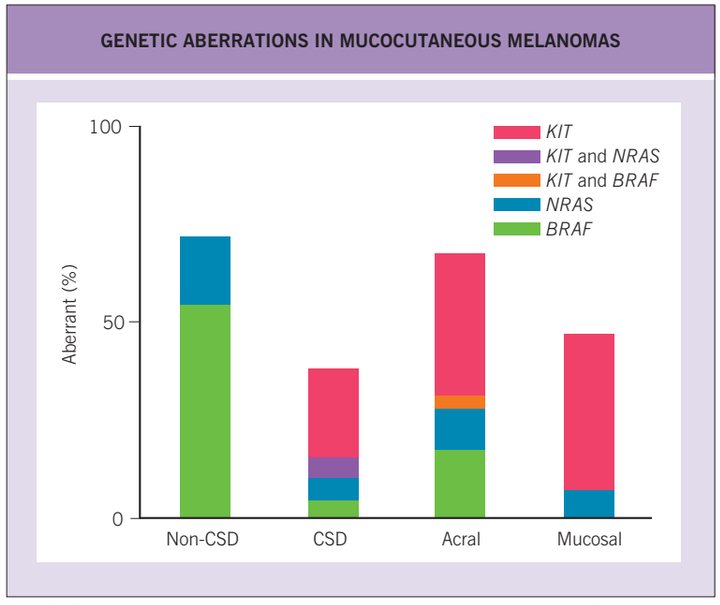

Fig. 113.1 Genetic aberrations in mucocutaneous melanomas. CSD, skin with chronic sun-induced changes such as marked solar elastosis; non-CSD, skin without chronic sun-induced damage. *From Curtin JA, Busam K, Pinkel D, Bastian BC. J Clin Oncol. 2006;24:4340–6.*

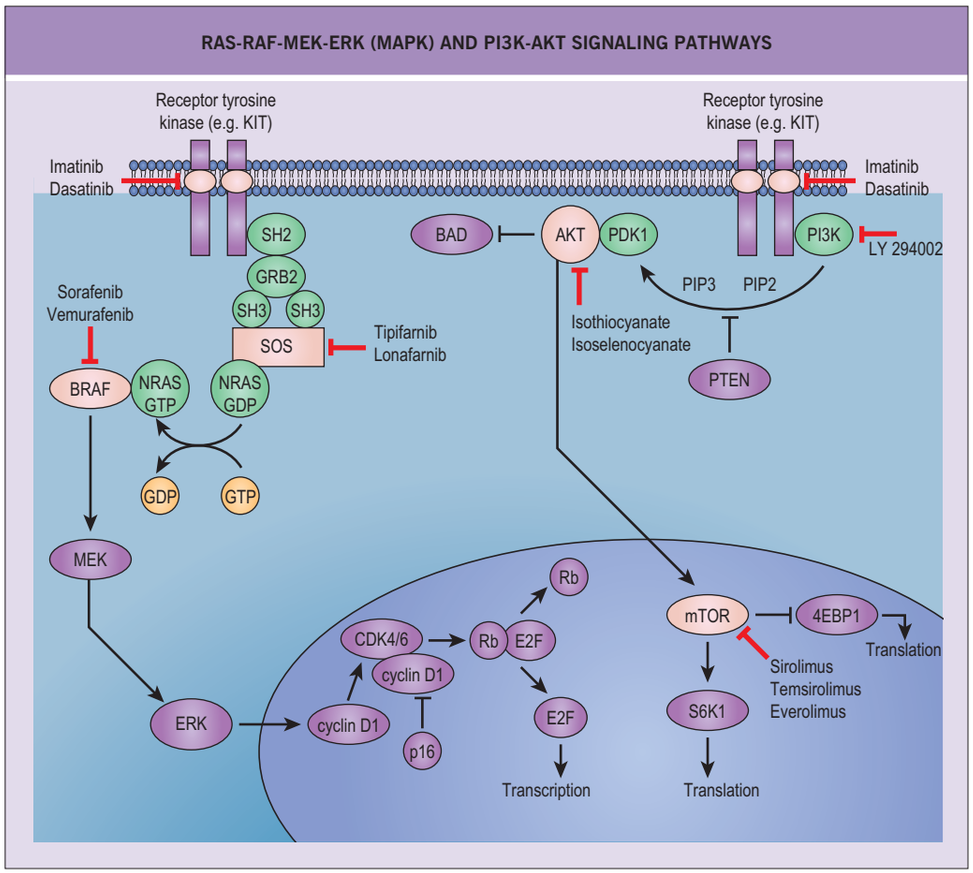

Fig. 113.2 RAS-RAF-MEK-ERK (MAPK) and PI3K-AKT signaling pathways The mitogen-activated protein kinase (MAPK) pathway is physiologically activated by growth factor binding to receptor tyrosine kinases. The stimulus is relayed to the nucleus via the GTPase activity of NRAS and the kinase activity of BRAF, MEK and ERK. Within the nucleus, this results in increased transcription of genes involved in cell growth, proliferation, and migration. The central role of this pathway in melanocytic neoplasia is highlighted by the fact that either *NRAS* or *BRAF* is mutated in approximately 80% of all cutaneous melanomas and melanocytic nevi. The PI3K-AKT pathway is another important regulator of cell survival, growth, and apoptosis. A key inhibitor of this pathway is PTEN and inactivation of the gene that encodes PTEN via mutations, deletions or promoter methylation also occurs in cutaneous melanomas. As a result, there is increased activity of the PI3K-AKT signaling pathway. 4EBP1, eIF-4E binding protein 1 (inhibits translation); CDK, cyclin-dependent kinase; E2F, transcription factor that controls transcription of cyclins; GDP, guanosine-5′-diphosphate; GRB2, growth factor receptor-bound protein 2, an adaptor protein that contains one Src homology 2 (SH2) domain and two SH3 domains; GTP, guanosine-5′-triphosphate; MEK, MAPK kinase; mTOR, mammalian target of rapamycin (aka sirolimus); PDK1, phosphoinositide-dependent kinase-1; PI3K, phosphoinositide 3-kinase; PIP2, phosphatidylinositol 4,5-bisphosphate; PIP3, phosphatidylinositol 3,4,5-triphosphate; PTEN, phosphatase and tensin homolog; Rb, retinoblastoma protein; S6K1, S6 kinase 1; SOS, son of sevenless.

MAPK signaling

The MAPK pathway regulates cellular proliferation, growth and migration. Via this pathway, interactions between growth factors (mitogens) and receptor tyrosine kinases (RTKs) such as the KIT receptor on the cell surface eventually lead to changes in the activity of transcription factors and gene expression within the nucleus (Fig. 113.2)[11]. Upon ligand binding, RTKs dimerize and become activated by autophosphorylation of intracellular tyrosine residues. The phosphorylation of tyrosine residues creates binding sites for adaptor proteins (e.g. GRB2, SOS) and initiates a signaling cascade that requires the GTPase activity of NRAS and the kinase activity of BRAF, MEK and ERK. Phosphorylated ERK activates nuclear cyclin D1 and a complex between cyclin D1 and cyclin-dependent kinases 4 and 6 (CDK4/6) is formed that phosphorylates retinoblastoma tumor suppressor protein (Rb), resulting in release of E2F from the Rb–E2F complex (see Fig. 107.1)[12]. E2F represents a family of transcription factors that play an important role in the regulation of cell cycle progression. An important tumor suppressor is p16, encoded by the *CDKN2A* gene. By binding to CDK4/6, p16 prevents the formation of the cyclin D1–CDK4/6 complex and as a result prevents Rb activation and E2F release.

The key role of the MAPK pathway in melanoma is highlighted by the high frequency of mutations in the genes that encode its components and its downstream targets. With regard to RTKs, 30% to 40% of acral and mucosal melanomas as well as melanomas from chronically sun-exposed skin harbor activating mutations or copy number amplifications of the *KIT* gene[13]. In addition, constitutively activating mutations are present in the *NRAS* gene (15–20% of melanomas overall)[10,14] and the *BRAF* gene (50–60%)[15,16] (Table 113.1). Of note, the frequency of *BRAF* mutations is high in melanomas from skin intermittently exposed to UV, yet low in melanomas with histopathologic evidence of significant UV damage[10,17], i.e. with increasing cumulative amounts of mutagenic UV radiation, the *BRAF* mutation frequency declines. MAPK pathway activation in melanoma can also be induced by inherited mutations in the *CDKN2A* gene that underlie familial melanoma[18], as well as by acquired inactivating mutations and deletions of *CDKN2A*[19].

PI3K signaling

Phosphoinositide 3-kinases (PI3Ks) are enzymes that regulate cell growth, proliferation, differentiation, motility and survival (see Fig. 113.2). PI3Ks are activated by RTKs and phosphorylate PIP2 (phosphatidylinositol 4,5-bisphosphate) to PIP3 (phosphatidylinositol 3,4,5-triphosphate). PIP3 then acts as a second messenger and AKT is activated via phosphorylation[20]. It is important to note that by converting PIP3 back to PIP2, AKT activation can be inhibited by PTEN[21]. Activated phospho-AKT inhibits apoptosis by phosphorylating BAD which leads to its loss of pro-apoptotic function (see Fig. 107.5), enhances survival by increasing the transcription of survival genes, and accelerates cell growth via mTOR (see Fig. 113.2)[22].

PI3K signaling is activated in a high percentage of melanomas by multiple mechanisms. Frequent activating events include inactivation of the gene that encodes the inhibitor PTEN via mutations, deletions or promoter methylation[23], activating mutations of *NRAS*[10], and overexpression of AKT[23]. However, direct activation of the PI3K pathway by activating mutations in the genes that encode PI3K subunits occurs infrequently[24].

WNT signaling

As a group, WNT signaling proteins are involved in cellular processes such as differentiation, migration, proliferation, and stem cell maintenance. When Frizzled (FZ)/LRP receptor complexes are *not* bound by ligand, the "destruction complex" that contains the adenomatous polyposis coli (APC) tumor suppressor protein phosphorylates β-catenin (Fig. 113.3). Phosphorylated β-catenin is ubiquitinated and as a result targeted by the proteasome for rapid destruction. Once bound by extracellular WNT, the FZ/LRP coreceptor complex activates dishevelled (DSH) which inhibits the β-catenin destruction complex, leading to the stabilization of β-catenin. Beta-catenin then translocates to the nucleus and promotes the transcription of WNT target genes via the TCF/LEF family of transcription factors[25–27].

The role of WNT signaling in melanoma is complex, as WNT signaling is tightly regulated. In melanoma, mutations that stabilize β-catenin

NEWER THERAPEUTIC APPROACHES TO MELANOMA		
IMMUNOTHERAPY		
Treatment rationale	**Clinical indication**	**Drug**
CTLA-4 inhibition	Unresectable or metastatic melanoma	• Ipilimumab: 3 mg/kg IV infusion (over 90 minutes) every 3 weeks for 4 total doses
MUTATED-ONCOGENE TARGETED THERAPY		
Mutated oncogene*	**Clinical associations**	**Drug (inhibitor)**
c-*KIT*	Found in site-specific melanomas: • Mucosal (~40%) • Acral (~35%) • Chronically sun-damaged skin (25-30%)	• Imatinib • Nilotinib • Dasatinib • Sunitinib
NRAS	Found in ~15–20% of melanomas Most often seen in later age-at-onset melanomas	• R115777
BRAF	Found in ~40–60% of melanomas Most often seen in younger age-at-onset melanomas Most common in melanomas arising in intermittently sun-exposed, non-chronically sun damaged skin	Non selective: • Sorafenib • XL-281 • RAF-265
BRAF (V600E)	Of melanomas with *BRAF* mutations, ~80% are of the V600E subtype	Selective for V600E: • Vemurafenib (PLX4032) • GSK2118436
GNAQ	Uveal melanomas (45%); "malignant" blue nevi (melanoma arising within a cellular blue nevus)	
CDK4	Germline in a few families with inherited melanoma	• PD0332991
ERBB4	Found in ~20% of melanomas	• Lapatinib
MEK	Can be seen in patients who develop resistance to vemurafenib	• AZD6244 • GSK1120212 • PD0325901
PI3K		• GDC0941 • XL147
AKT		• MK-2206 • GSK690693

*Somatic (acquired) unless other noted under clinical associations. IV, intravenous.

Table 113.1 Newer therapeutic approaches to melanoma. Ipilimumab has also been administered intravenously at 10 mg/kg for four doses and once every 12 weeks as maintenance therapy. Side effects, related to autoimmunity, include enterocolitis, hypophysitis, thyroiditis, primary adrenal insufficiency, dermatitis (sometimes severe) and toxic epidermal necrolysis. The mechanism of action of ipilimumab is depicted in Fig. 128.8E. Use of targeted therapies has followed the discovery of mutations in the genes that encode the components of several signal transduction pathways including RAS-RAF-MEK-ERK (MAPK) and PI3K-AKT (see Fig. 113.2). Mechanisms of resistance to BRAF inhibitors include mutational activation of MEK (downstream of BRAF in the MAPK pathway), overexpression of COT which leads to an increase in MEK activity, and expression of truncated forms of BRAF (which can dimerize and activate the MAPK pathway) in addition to overexpression of platelet-derived growth factor. As a result, in the future, multi-drug regimens will be utilized from the onset and include inhibitors of BRAF and MEK as well as inhibitors of the PIP3/AKT pathway. One possible explanation for the induction of cutaneous keratoacanthomas and squamous cell carcinomas by BRAF inhibitors such as vemurafenib is the presence of *RAS* mutations plus wild-type BRAF (leading to activation of the MAPK pathway) in the keratinocytes of sun-damaged skin. Figure 107.1 illustrates the role of CDK4 in cell cycle regulation.

and increase intracellular β-catenin have been described[28]. However, β-catenin and *APC* mutations are rare events in melanoma[29,30]. The controversial role of β-catenin signaling in melanoma is highlighted by the observation that gene silencing of β-catenin in melanoma cells slows their growth but promotes the formation of pulmonary metastases in mice[31]. In sum, WNT signaling can promote tumor growth by activating proliferation and cell migration, but it can also inhibit tumor growth by inducing cell differentiation and acting as a tumor suppressor[32].

MC1R-MITF signaling

The melanocortin 1 receptor (MC1R) is a G-protein-coupled receptor that is activated by melanocortins (ACTH, α-MSH; see Table 65.4). MC1R is one of the key receptors involved in regulating skin and hair color[33]. When bound to its ligands, MC1R activates adenylate cyclase and cAMP is formed as a second messenger (see Fig. 65.15). cAMP activates protein kinase A (PKA) and PKA activates the cAMP response-element binding protein (CREB); the latter is a transcription factor that enhances expression of microphthalmia-associated transcription factor (MITF; see Fig. 65.4)[34,35]. MITF is also a transcription factor and it regulates expression of a number of melanocyte lineage specific genes that encode enzymes of the melanin biosynthetic pathway (e.g. tyrosinase, tyrosinase-related proteins) as well as other genes such as *CDK2*, *CDKN2A* and *BCL2*. MITF signaling is also tightly linked and regulated by MAPK and WNT signaling.

MCIR variants have been associated with a red hair/fair skin phenotype, and independent of phenotype, have been found to be a risk factor for the development of cutaneous melanoma (see Fig. 65.14 and Table 65.5)[37]. In addition, MITF has been shown to be an oncogene amplified in melanoma[38]. However, MITF can also act as an antiproliferative transcription factor by inducing cell cycle arrest[39,40]. Interestingly, mutant oncogenic BRAF can regulate MITF expression to ensure that its protein levels are compatible with proliferation and survival of melanoma cells[41].

Better understanding of the molecular mechanisms of melanoma development will hopefully translate into improvements in melanoma risk assessment, prevention, diagnosis, and molecularly targeted therapies.

HOST IMMUNE RESPONSE TO MELANOMA

Clinical observations such as incomplete or complete regression of melanoma (Fig. 113.4), associated development of vitiligo-like depigmentation and halo nevi, and a higher incidence of melanoma in immunosuppressed patients point to the fact that melanoma is an immunogenic tumor[42]. Numerous melanoma antigens recognized by autologous T cells or antibodies have been described including: (1) mutant tumor antigens (e.g. mutant p16 [*CDKN2A*]); (2) shared tumor-specific antigens of the cancer/testis family (e.g. MAGE-1, MAGE-3, NY-ESO-1); and (3) cell type-specific differentiation antigens (e.g. tyrosinase, gp100/Pmel17, Melan-A/MART-1). These proteins are processed and presented on the melanoma cell surface as MHC/peptide complexes. $CD8^+$ cytotoxic T cells recognize these antigens and, if appropriately activated, are able to kill tumor cells. In addition to $CD8^+$ T cells, $CD4^+$ helper T cells as well as antibodies also play a critical role.

Activation of melanoma-specific $CD8^+$ T cells is dependent on the migration of tumor antigen-loaded dendritic cells to a draining lymph node. Here, melanoma antigens are presented to $CD8^+$ T cells in the

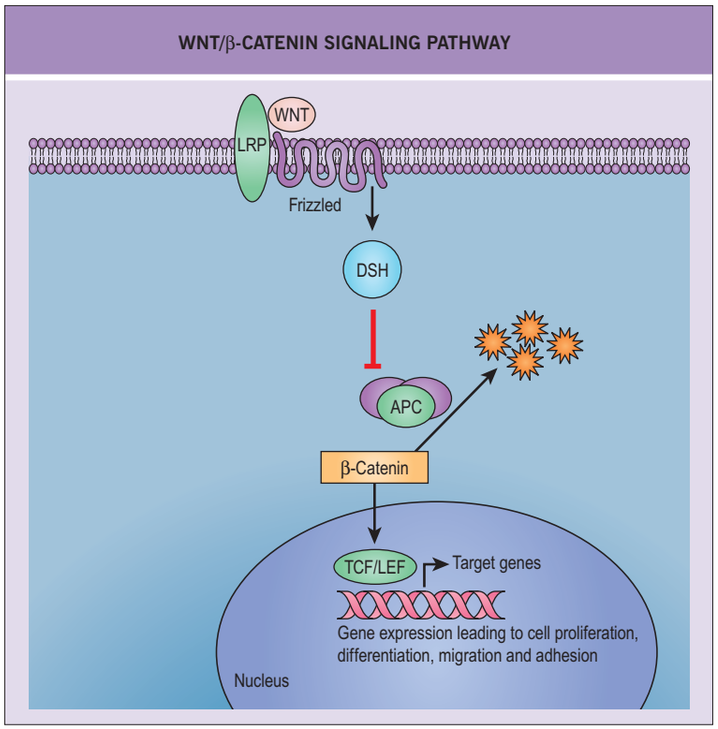

Fig. 113.3 WNT/β-catenin signaling pathway. When extracellular WNT binds to the Frizzled/LRP receptor complex, the cytosolic protein dishevelled (DSH) is activated and can inhibit the "destruction complex". The latter complex contains the adenomatous polyposis coli (APC) tumor suppressor protein and it can phosphorylate β-catenin. Phosphorylated β-catenin becomes ubiquitinated and then is targeted by the proteosome for destruction. Therefore, when DSH is activated by WNT binding, β-catenin is not phosphorylated and it accumulates and is translocated to the nucleus. There, it induces the transcription of target genes via the T-cell factor/lymphoid enhancer factor (TCF/LEF) family of transcription factors. LRP, low-density lipoprotein-receptor-related protein.

presence of a costimulatory signal provided by the binding of B7 on the antigen-presenting cell to CD28 on the T cell (see Ch. 4). Cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) is an inhibitory homologue of CD28 that is upregulated following T-cell activation and acts as natural inhibitor of T-cell activation by removing the costimulatory signal. Recently, immunotherapy based upon CTLA-4 blockade was introduced for the treatment of melanoma (see below).

Fig. 113.4 Cutaneous melanoma with regression. An asymmetric, irregularly pigmented melanocytic lesion. The central depigmented zone is due to tumor regression and histopathologically, an inflammatory infiltrate can be seen.

A variety of immune escape mechanisms may be found in advanced tumors, including melanoma. These include loss of tumor-specific antigens, loss of MHC class I molecules, and secretion of immunoinhibitory cytokines such as interleukin (IL)-10 and TGF-β[43]. Downregulation of a melanoma-specific immune response might also involve naturally occurring $CD4^+/CD25^+$ regulatory T cells, inducible IL-10-producing regulatory T cells, or negative signals delivered via cell surface CTLA-4[44]. New insights into mechanisms of melanoma-specific host immune responses and immune escape will hopefully lead to more successful immunotherapy, including more effective vaccines.

EPIDEMIOLOGY

Over the past several decades, the incidence rates of cutaneous melanoma have increased significantly (Fig. 113.5)[2,45,47]. It develops almost exclusively in Caucasian populations, with its incidence remaining very low amongst darkly pigmented populations of African, Asian and Hispanic origin[46].

The annual increase in melanoma incidence varies depending upon the populations, but in general it has been estimated to be between 3% and 7%[48–53]. These estimates predict a doubling of rates every 10–20 years, making cutaneous melanoma the most rapidly increasing cancer in white populations. For example, in the US, over a period of 30 years, an increase in incidence rates of at least three-fold was observed[49,54,55] (see Fig. 113.5). Cohort studies from several countries indicate that the trend of increasing incidence rates will continue for at least the next two decades.

Based upon data from the Surveillance Epidemiology and End Results (SEER) database, an estimated 62 480 men and women in the US were expected to be diagnosed with melanoma in 2008 and an estimated 8420 were expected die from melanoma that same year[55]. In Europe, the highest incidence rates were noted in Scandinavian countries[48,56,57], while the lowest incidence rates were observed in Mediterranean countries[58,59]. One explanation for this North–South gradient is a darker skin phototype (types III–IV) in the Mediterranean populations. Worldwide, the highest incidence rates have been reported in Australia and New Zealand, with 30 to 60 cases per 100 000 inhabitants per year. Within Australia, the highest incidence rates were found in the northern equatorial regions of the country (e.g. Queensland)[60].

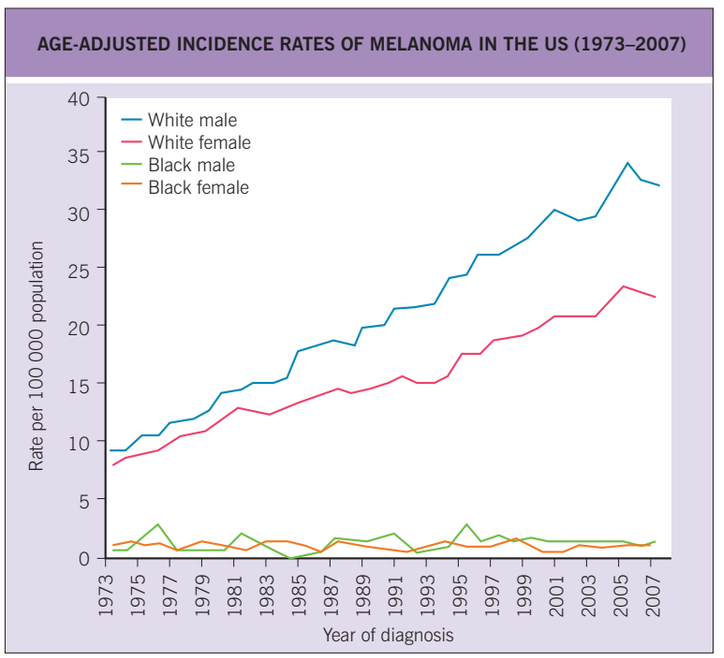

Fig. 113.5 Age-adjusted incidence rates of melanoma in the US (1973–2007). The incidence has increased in the male and female Caucasian populations over the past three decades and this trend has not yet stopped. The African-American population shows a constant low incidence, mostly caused by acral and mucosal melanomas. *Data from the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute.*

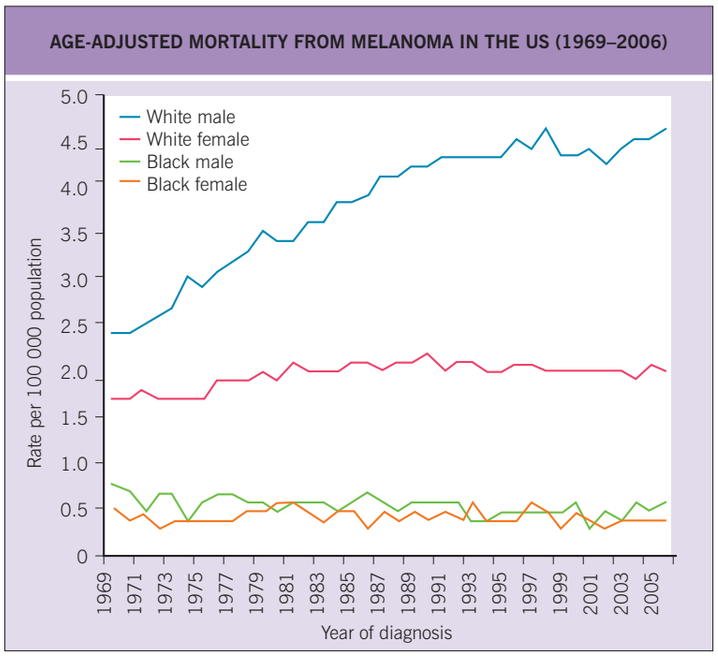

Fig. 113.6 Age-adjusted mortality from melanoma in the US (1969–2006). The mortality has increased, especially for the male Caucasian population, over the past three decades. For females, the increase was less pronounced and has leveled off since the 1980s. *Data from the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute.*

RISK FACTORS FOR THE DEVELOPMENT OF CUTANEOUS MELANOMA
GENETIC FACTORS
• Family history of cutaneous melanoma • Lightly pigmented skin • Tendency to burn, inability to tan • Red hair color • DNA repair defects (e.g. xeroderma pigmentosum)
ENVIRONMENTAL FACTORS
• Intense intermittent sun exposure • Chronic sun exposure • Residence in equatorial latitudes • PUVA (possible) • Tanning bed use, especially under the age of 35 years • Iatrogenic or acquired immunosuppression
PHENOTYPIC EXPRESSIONS OF GENE/ENVIRONMENT INTERACTIONS
• Melanocytic nevi and solar lentigines: – Increased total number of acquired melanocytic nevi (MN) >100 MN, relative risk ~ 8–10-fold increased – Atypical melanocytic nevi (AMN) > 5 AMN, relative risk ~ 4–6-fold increased – Multiple solar lentigines (SL) Multiple SL, relative risk ~3–4-fold increased Relative risks (RR) are multiplicative: e.g. a person with >100 MN + >5 AMN + multiple SL has a relative risk ~ 10 × 5 × 3 = 150-fold • Personal history of cutaneous melanoma

Table 113.2 Risk factors for the development of cutaneous melanoma.

Mortality rates from melanoma increased throughout the 1980s in most European countries[1,47,52,61], as well as in North America (Fig. 113.6), Australia and New Zealand[4,62,63]. Mortality rates peaked around 1988–1990. Subsequently, trends have been less uniform, with mortality rates still rising in several European countries among middle-aged adults, but with more favorable trends in women and some stabilization in young adults; rates have remained relatively constant among men[64].

The vertical tumor thickness (Breslow depth) is the most important local prognostic factor in primary cutaneous melanoma[65–67]. Therefore, tumor thickness serves as an indicator of the effectiveness of early detection of melanoma[68,69]. In a number of countries, there is an ongoing trend for the diagnosis of thinner melanomas[68,70,71]. For example, in Germany, such a trend has been observed since the 1980s, with the median tumor thickness decreasing from 1.81 mm (1980s) to 0.53 mm (2000). The percentages of *in situ* and level II melanoma also increased[68]. The diagnosis of thinner tumors should translate into stable or decreasing mortality rates, despite the increase in incidence rates.

The tumor thickness at the time of primary diagnosis is also age-dependent. In general, there are significantly fewer melanomas ≤1.0 mm in older age groups. As a corollary, the percentage of thick melanomas increases significantly with age and reaches 20% by age 80 years in both genders[72].

RISK FACTORS FOR CUTANEOUS MELANOMA

Recognition of risk factors for the development of melanoma is important from a public health and a clinical care perspective (Table 113.2). Identification of high-risk cohorts improves the efficiency and efficacy of public health efforts. Individual risk assessment influences clinical decision-making including the threshold for performing a biopsy, prevention counseling, and surveillance. Risk factors may be divided into three categories: (1) genetic factors, (2) phenotypic manifestations of gene–environment interactions, and (3) environmental factors.

Genetic Risk Factors

Germline genetic mutations and polymorphisms can predispose individuals to melanoma. The genes involved range from the rare high-penetrance genes responsible for some familial clustering of melanoma to the very common pigmentation genes responsible for the relative propensity for fair-skinned individuals to develop melanoma[73].

The major high-penetrance susceptibility gene locus associated with familial melanoma is *CDKN2A*. Approximately 2% of cutaneous melanomas can be specifically attributed to pathogenic germline mutations in *CDKN2A*[74]. This locus encodes two distinct protein products, p16 and $p14^{ARF}$, with the latter via an alternative reading frame, hence the designation ARF. p16 and $p14^{ARF}$ exert regulatory effects on cell cycle progression through the retinoblastoma protein (Rb) and p53 pathways, respectively (see Fig. 107.1)[75,76]. Germline *CDKN2A* mutations are observed in ~25% of familial melanoma kindreds[77]. The penetrance of *CDKN2A* mutations is modified by germline variants of other genes, including *MC1R*[78,79]. In some families, carriers of germline *CDKN2A* mutations are also at increased risk of developing pancreatic cancer[80].

While assays for these *CDKN2A* mutations have been commercialized and have been advocated by some in the field, it is the recommendation of the International Melanoma Genetics Consortium that at present genetic testing for *CDKN2A* mutations be done only as part of research protocols[81]. However, a recent study suggested that individuals with three or more primary invasive melanomas or families with at least one invasive melanoma and two or more other diagnoses of invasive melanoma or pancreatic cancer among first- or second-degree relatives (on the same side of the family) were appropriate candidates for referral for genetic consultation and possible testing[74].

Among pigmentation genes, specific germline variants of the melanocortin 1 receptor (*MC1R*) gene have been found to correlate with melanoma risk above and beyond clinically apparent skin phenotype[82]. Recently, a strong association between *MC1R* as a susceptibility gene and risk of developing *BRAF*-mutant melanomas was observed. While the risk of developing any cutaneous melanoma lies between 1.5-fold and 3-fold for individuals with *MC1R* variants, the risk of developing *BRAF*-mutant melanomas was as high as 17-fold for those with two *MC1R* germline variants[83,84]. In addition to *MC1R*, single nucleotide polymorphisms in the tyrosinase (*TYR*) gene, the tyrosinase-related protein 1 (*TYRP1*) gene, and the *SLC45A2* gene are significantly associated with melanoma risk (see Table 65.5)[85].

Phenotypic Risk Factors Reflecting Gene/Environment Interactions

The strongest independent risk factors for the development of cutaneous melanoma are those that reflect both genetic susceptibility and environmental exposure: melanocytic nevi, atypical melanocytic

nevi[86,87], ephelides and solar lentigines. Both an increased number of common melanocytic nevi and the presence of atypical melanocytic nevi are independent risk factors for melanoma, as is the presence of solar lentigines. Acquired melanocytic nevi play a dual role as a risk factor: (1) they are indicators of UV exposure and DNA damage; and (2) they can be formal precursors of melanoma. However, remnants of benign melanocytic nevi are found in only a minority of melanomas[88,89]. Based on epidemiologic data, the risk of malignant transformation in an individual melanocytic nevus has been estimated to be one melanoma in hundreds of atypical nevi and one in thousands of common nevi[90,91]. Consequently, prophylactic removal of clinically unsuspicious melanocytic nevi is not justified.

Common melanocytic nevi

Although performed on populations from different regions and with varying skin phototypes, studies have consistently reported a continuous and almost linear increase in melanoma risk with greater numbers of common melanocytic nevi[92–98] (Fig. 113.7). It has been speculated that the increased risk may be attributed to higher numbers of melanocytes in patients with numerous common nevi or with large congenital melanocytic nevi[99].

Light-skinned populations have higher melanocytic nevus counts than do darker-skinned populations. The relative melanoma risk for greater than 50 common melanocytic nevi has ranged from 6.9 in southern Spain[97] to 53.9 in Scotland[100]. Nonetheless, the dose-dependent relationship between number of common melanocytic nevi and risk of cutaneous melanoma holds true for all Caucasian populations.

The association of increased nevus counts and melanoma risk is strongest for superficial spreading melanoma and nodular melanoma, in contrast to lentigo maligna melanoma which is highly correlated with skin type and hair color[100,101]. This suggests there are additional genetic susceptibility factors and molecular mechanisms involved in the formation of melanoma in chronically versus intermittently sun-exposed skin (see Fig. 113.1). Melanoma at a particular anatomic site is more strongly related to the number of melanocytic nevi at that respective site than to the number of nevi in other body sites[97,100], highlighting the key role of local mutagenic effects of UV radiation in addition to genetic susceptibility.

Atypical melanocytic nevi

Since the original description of BK-mole syndrome in 1978[86], several definitions of atypical melanocytic nevi and of the atypical mole syndrome have been published[93,102–104]. A relative risk of up to 500-fold for developing cutaneous melanoma has been described for specific subgroups of the atypical mole syndrome[105]. However, sporadic atypical melanocytic nevi are often diagnosed in "normal" individuals outside of the setting of the atypical mole syndrome. One possible explanation for the range of estimates of risk is the use of different definitions of clinically "atypical" melanocytic nevi by various investigators.

Several studies have found clinically atypical nevi to be associated with increased melanoma risk outside of the context of familial melanoma[92–95,98,106,107] (Fig. 113.8). The maximum reported relative risk for developing melanoma was as high as 32-fold when there were 10 or more atypical melanocytic nevi[98]. The consistency of these findings among multiple studies and across geographic locations supports the significance of atypical melanocytic nevi as an independent risk marker for sporadic melanoma.

In contrast to the continuous increase in melanoma risk with greater numbers of common melanocytic nevi, for atypical melanocytic nevi a threshold level of five or more such lesions was associated with a clearly higher relative risk in several studies; however, there was no significant increase in the risk beyond this number[93]. This finding suggests that at least five atypical melanocytic nevi are needed to establish the diagnosis of atypical mole syndrome. In patients with familial melanoma, atypical melanocytic nevi are an indicator of a markedly elevated melanoma risk[108,109].

Ephelides and solar lentigines

Ephelides (freckles) have been reported to be a risk factor independent of numbers of common melanocytic nevi[106,110,111]. The independence of freckling and common melanocytic nevi indicates that these cutaneous findings represent separate host characteristics, both of which are related to sun exposure[112]. Additional studies found that solar lentigines were a risk factor for the development of cutaneous melanoma, independent of the number of common melanocytic nevi[93].

Environmental Risk Factors

Ultraviolet radiation

It is widely believed that the total risk for developing melanoma is determined by the interplay between genetic factors and exposure to UVR[113]. Approximately 80% of cutaneous melanomas develop in intermittently sun-exposed regions, and both intermittent sun exposure and sunburn history have been identified as risk factors in epidemiologic studies[2,114].

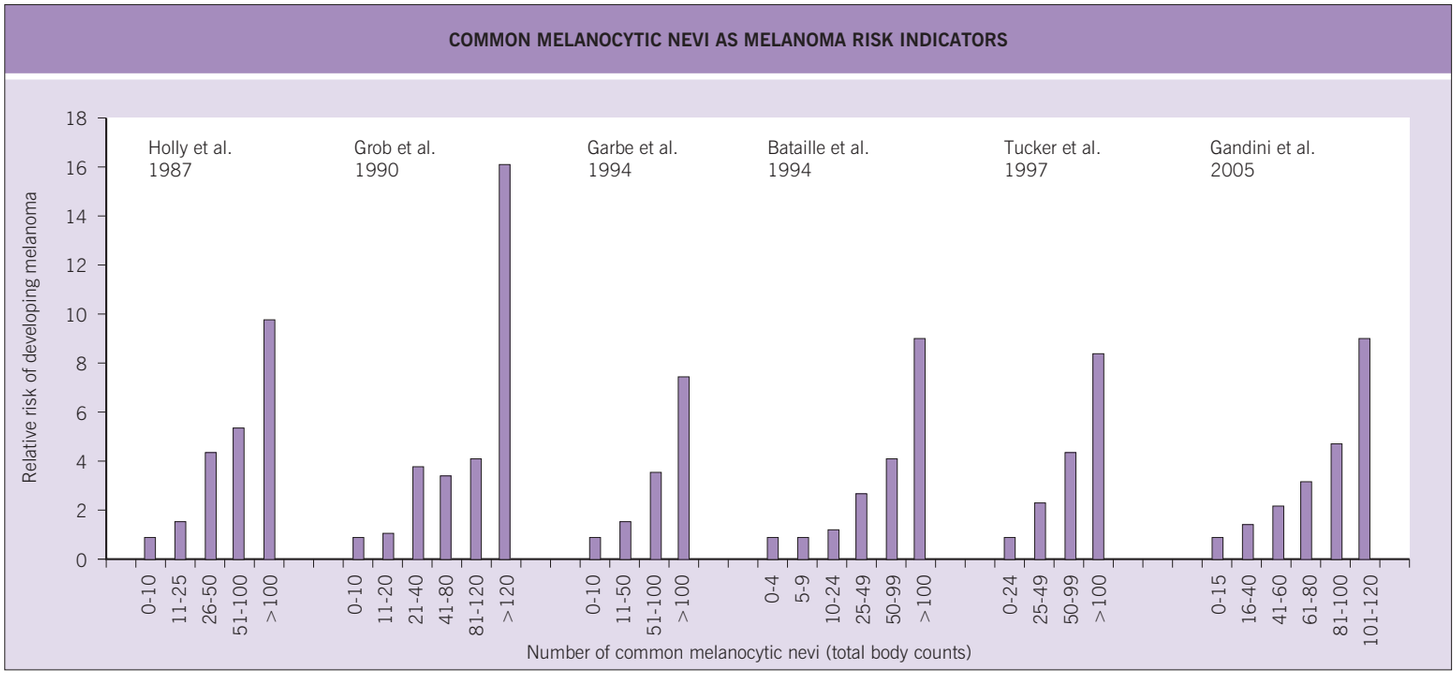

Fig. 113.7 Common melanocytic nevi as melanoma risk indicators. Relative risk of developing melanoma for a given number of common melanocytic nevi (total body counts) as determined by five epidemiologic studies and one meta-analysis (Gandini et al.). Melanoma risk increases almost linearly with the number of common melanocytic nevi, rendering common nevi valuable as risk indicators.

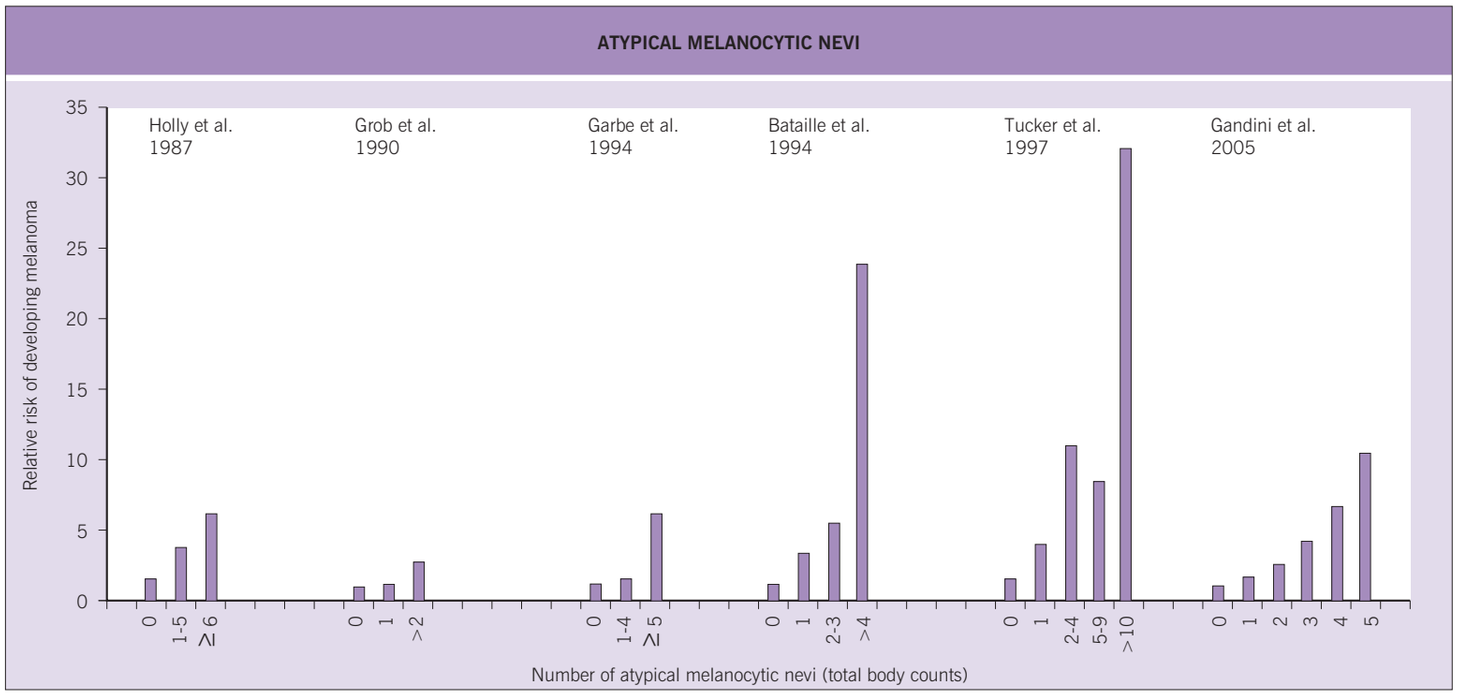

Fig. 113.8 Atypical melanocytic nevi as melanoma risk indicators. Relative risk of developing melanoma for a given number of atypical melanocytic nevi (total body counts) as determined by five epidemiologic studies and one meta-analysis (Gandini et al.). An elevated risk is associated with relatively small numbers of atypical nevi. The relative risk as indicated by the number of atypical nevi is independent from the total number of melanocytic nevi, and it is related in a multiplicative fashion to the risk based on the total number of nevi. In other words, the individual risk for developing melanoma is calculated by multiplying the risk related to the total number of nevi times that due to the number of atypical nevi (see Table 113.2).

The role of sunlight in melanoma development has been a matter of debate for decades, in part because the etiologic role of sunlight is far less clear than in other tumors such as cutaneous squamous cell carcinoma (SCC)[115,116]. Also, melanoma is clearly a multi-factorial disease and forcing an all-or-none stance regarding sun exposure represents an erroneous oversimplification. That said, the following clinical and epidemiologic features have raised doubts regarding the impact of sunlight on melanoma development:

- With the exception of lentigo maligna melanoma, the anatomic distribution of melanoma does not closely match sites of greatest cumulative sun exposure as in cutaneous SCC.
- Melanoma most commonly develops in middle-aged adults, not the elderly with the greatest cumulative sun exposure.
- In most of the reported case-control studies, neither greater cumulative sun exposure during adulthood nor sunburns during the preceding years was associated with an elevation in melanoma risk.

Initial indications of an etiologic role for sunlight came from the observation that melanoma incidence was increased in white populations living closest to the equator. This was most striking when melanoma incidence and mortality rates in Europe versus Australia were compared, with both variables being 5–10 times higher in Australia[117,118]. Furthermore, case–control studies demonstrated that melanoma risk was closely associated with the number of melanocytic nevi and with the occurrence of sunburns in childhood[112,119,120]. Interestingly, sunburns during childhood and adolescence significantly elevated the risk for melanoma development, but additional sunburns during adulthood did not contribute to any further risk elevation. This was in agreement with previous findings that melanoma risk is mainly acquired during childhood.

The total number of melanocytic nevi has been identified as the most important risk factor for cutaneous melanoma, and as the number of melanocytic nevi increases, the melanoma risk increases nearly linearly (see Fig. 113.7)[93,95,121]. Therefore, to gain more insight into the relationship between sun exposure and nevus development, epidemiologic studies have been performed in young children. With exposure to intense UVR, children in Australia developed melanocytic nevi early in life and in large numbers[122]; of note, duration of sun exposure was a stronger risk factor than the occurrence of sunburns. In a study of 1812 German nursery school children, high nevus counts in children were preferentially associated with the number of weeks on sunny holidays and with outdoor activities at home that were linked to moderate sun exposure[123,124]. These findings suggested that sunburns were not required and that moderate sun exposure appeared to be sufficient for the induction of melanocytic nevi in children.

A possible explanation for the differences in the epidemiology of melanoma as compared with non-melanoma skin cancer involves apoptosis[125]. After exposure to UVR, the most severely damaged keratinocytes undergo apoptosis (sunburn cells), with the less damaged keratinocytes upregulating their DNA-repair capacities and undergoing nearly perfect DNA repair. As a result, the development of non-melanoma skin cancer would favor elderly adults. In contrast, melanocytes do not undergo apoptosis as readily. Their function is to provide protective melanin to the surviving cells and so they are retained within the epidermis, even with damage. In addition, some UVR-induced mutations are thought to enable melanocytes to proliferate and give rise to junctional nevi. Subsequently, melanoma could arise in anatomic sites with intermittent sun exposure, with the sites of melanoma development reflecting the distribution pattern of melanocytic nevi[126,127]. This hypothesis might also explain why melanomas tend to develop in a younger age group (i.e. middle-aged adults).

Both UVB and UVA radiation are thought to be associated with the development of cutaneous melanoma, with UVB believed to be the stronger risk factor. Data supporting UVB as a causative factor come from: (1) animal studies in which UVB was shown to induce melanoma in susceptible mice and in xenografted human skin engineered to express melanocytic growth factors[128,129]; and (2) the fact that there is a higher incidence of cutaneous melanoma in equatorial regions where UVB is most intense. Data implicating UVA in the development of cutaneous melanoma derive from: (1) animal studies in which UVA was shown to initiate melanoma (fish) and melanocytic hyperplasia (pigmented opossums)[130–133]; and (2) recent studies showing an increased incidence of melanoma developing in users of tanning beds and perhaps recipients of PUVA. In 2009, the World Health Organization (WHO)

International Agency for Research on Cancer (IARC) categorized tanning beds as a human carcinogen. Of note exposure to tanning beds before the age of 35 years has a statistically significant association with melanoma development.

Sun protection

With regard to sun protection, there is a significant misunderstanding by the public that avoidance of sunburns and use of sunscreens is sufficient to prevent skin cancer. It is well established that sub-erythemal doses of UVR cause DNA mutations. Chronic irradiation with 10–20% of the minimal erythema dose of UVB induced DNA damage in mouse skin and this damage persisted in the dermis and epidermis for several weeks following discontinuation[134]. Therefore, low-dose UVB exposure in a repeated fashion could cause skin cancer.

Regular use of sunscreen has been shown to decrease the development of actinic keratoses and cutaneous SCCs, but evidence regarding its ability to prevent cutaneous melanoma has been controversial to non-existent, until recently (see Ch. 132). In 2010, a randomized sunscreen trial in Australia found that the regular application of SPF 15+ sunscreen in 1621 adults over 5 years reduced the incidence of new primary cutaneous melanoma, even 10 years after completion of the trial. Whether or not the regular use of sunscreen in children, when sun exposure is thought to be critical for the development of cutaneous melanoma, will be beneficial is less clear[135].

There are additional sun-protective measures that should be encouraged, including physical means of blocking the sun (e.g. non-transparent clothing, hats[136]) and reducing UVR exposure (e.g. shade coverings, limiting outdoor activities between the hours of 10:00 AM and 4:00 PM).

TYPES OF PRIMARY MELANOMAS

Until the 1960s, melanoma was regarded as a large black nodule that, as a rule, metastasized and caused death. Therefore, the recognition of early-stage melanoma was a major advancement. Four major subtypes (growth patterns) of primary cutaneous melanoma have been described[137] (Table 113.3). These different growth patterns characterize the early phase of development, but do not predict the prognosis.

DIFFERENT TYPES OF PRIMARY CUTANEOUS MELANOMA			
Clinico-histopathologic subtype	**Abbreviation**	**Percentage**	**Median age**
Superficial spreading melanoma	SSM	57.4%	51 years
Nodular melanoma	NM	21.4%	56 years
Lentigo maligna melanoma	LMM	8.8%	68 years
Acral lentiginous melanoma	ALM	4%	63 years
Unclassifiable melanoma	UCM	3.5%	54 years
Others		5%	54 years

Table 113.3 Different types of primary cutaneous melanoma. Data from the German Central Malignant Melanoma Registry (N = 30 015).

Fig. 113.9 Superficial spreading melanoma (SSM). Note asymmetry, irregular borders, variation in colors, scar-like regression zones, and an inferior pink papule, indicating vertical growth phase.

Superficial Spreading Melanoma

Superficial spreading melanoma (SSM) is the most common type of cutaneous melanoma in fair-skinned individuals (Fig. 113.9) and it is diagnosed most frequently between the ages of 40 and 60 years. It accounts for approximately 60–70% of all melanomas and occurs at any site, but is most frequently seen on the trunk of men and the legs of women. It begins as an asymptomatic brown to black macule with color variations and irregular, notched borders (Fig. 113.10). SSM can arise *de novo* or in a pre-existing nevus (Fig. 113.11). When *in situ*, the melanoma is usually macular with an irregular outline and variable pigmentation (Fig. 113.12). SSMs may have a diameter ≤5 mm (Fig. 113.13). After a typically slow horizontal (radial) growth phase limited to the epidermis or focally within the papillary dermis, a more rapid vertically oriented growth phase, which presents clinically with the development of a papule or nodule, can then occur. In up to two-thirds of tumors, regression (visible as gray, hypo- or depigmentation) of part of the lesion is observed, reflecting the interaction of the host immune system with the progressing tumor. About half of SSMs arise in a pre-existing nevus[138], although the likelihood of an individual nevus progressing to melanoma is exceedingly low.

Nodular Melanoma

Nodular melanoma is the second most common type of cutaneous melanoma in fair-skinned individuals and is diagnosed most frequently in patients in their sixth decade of life. It accounts for approximately 15% to 30% of all melanomas and occurs at any body site, but is most frequently seen on the trunk, head and neck. Nodular melanomas are observed more frequently in men than in women. They usually present as a blue to black, but sometimes pink to red, nodule which may be ulcerated or bleeding and in some patients have developed rapidly over months (Fig. 113.14). Nodular melanoma is believed to arise as a *de novo* vertical growth phase tumor without the pre-existing horizontal growth phase that characterizes the other histologic types. These melanomas tend to be diagnosed at a thicker, more advanced stage, with an associated poorer prognosis. The incidence of nodular melanoma has remained fairly stable in recent decades[139].

Lentigo Maligna Melanoma

Lentigo maligna melanoma (LMM) represents a minority of cutaneous melanomas (around 10%) and it is diagnosed most frequently during the seventh decade of life. It occurs in chronically sun-damaged skin, most commonly on the face, with a preference for the nose and cheek. LMM usually develops as a slowly growing, asymmetric, brown to black macule with color variation and an irregular, indented border (Fig. 113.15). Invasive LMM arises in a precursor lesion termed lentigo maligna (*in situ* melanoma in sun-damaged skin). It has been estimated that 5% of lentigo maligna lesions progress to invasive melanoma[140]. Because lentigo maligna typically arises within a background of severely sun-damaged skin, it can be difficult to histologically distinguish lentigo maligna from the atypical melanocytic hyperplasia seen in severely sun-damaged skin[141](see Fig. 150.5).

Lentigo maligna displays characteristic features on dermoscopic examination (Fig. 113.16). Hyperpigmented follicular openings of the facial skin (circle in a circle), are slowly overgrown by irregular pigmented dots around the follicles (annular granular pattern)[142,143] Rhomboidal structures can also be seen (see Table 0.13).

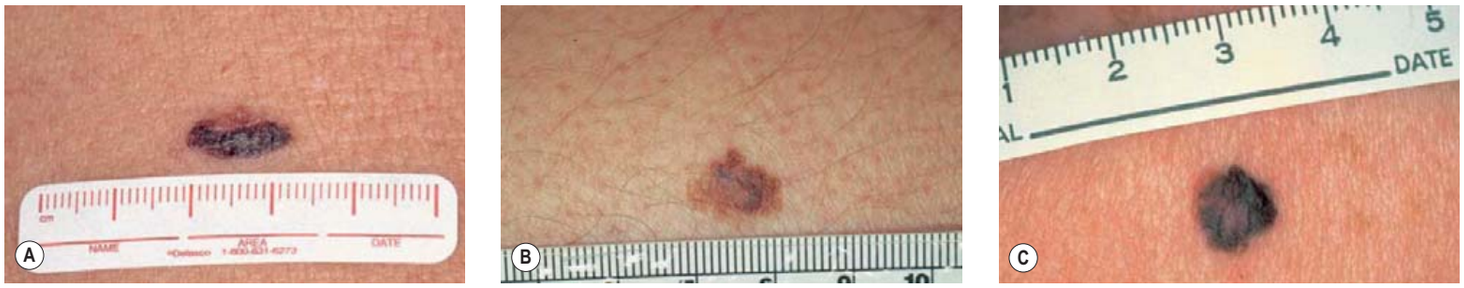

Fig. 113.10 Early superficial spreading melanomas. All of these lesions demonstrate asymmetry due to variation in color and irregularity in outline. In addition, there is pink discoloration in **C**. **A,B** were less than 0.5 mm in thickness and **C** was 0.8 mm. *A, Courtesy, Kalman Watsky MD. B & C, Courtesy, Jean L Bolognia, MD.*

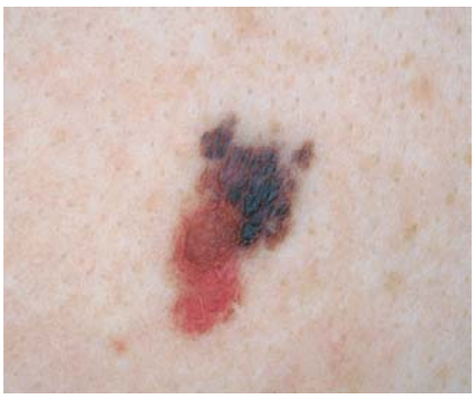

Fig. 113.11 Superficial spreading melanoma (SSM) arising in a pre-existing nevus. Note the irregular outline and variable pigmentation.

Fig. 113.12 Melanoma *in situ*. A Note the asymmetry, border irregularity, color variation, and erythema ("Little Red Riding Hood" sign). **B** The dermoscopic findings include a broadened network, dots and some globules inside this asymmetric lesion.

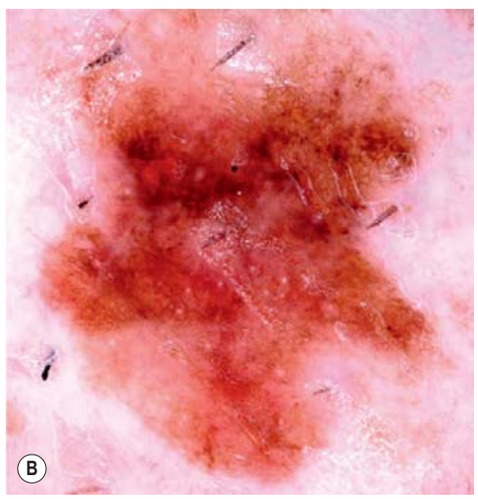

Fig. 113.13 Melanoma *in situ*. This melanoma *in situ* measured less than 3 mm in diameter. Small melanomas can be easily overlooked, especially if they are less heavily pigmented. This lesion was the "ugly duckling" of all of this patient's nevi. Dermoscopy assists in making an earlier diagnosis.

Acral Lentiginous Melanoma

Acral lentiginous melanoma (ALM) is a relatively uncommon type of cutaneous melanoma and is diagnosed most frequently in the seventh decade of life. It typically occurs on the palms and soles or in and around the nail apparatus. ALM accounts for approximately 5% of all melanomas and the incidence of ALM is similar across all racial and ethnic groups. As more darkly pigmented Africans and Asians do not typically develop sun-related melanomas, ALM represents a disproportionate percentage of melanomas diagnosed in blacks (up to 70%) and Asians (up to 45%)[144].

ALM typically presents as an asymmetric, brown to black macule with color variation and irregular borders (Fig. 113.17). A disproportionate percentage of ALMs are diagnosed at an advanced stage. This is likely the result of the difficulty of clinically distinguishing many ALMs from benign lesions and traumatic skin changes, as well as an elevated threshold for biopsy due to the morbidity associated with surgery at acral sites. Primary misdiagnosis of ALM occurs in about one-third of all patients and leads to substantial delay in establishing the correct diagnosis[145].

Melanoma of the nail matrix can present as longitudinal melanonychia (Fig. 113.18) or as hyperpigmentation extending onto the hyponychium or beyond the lateral or proximal nail fold (Hutchinson sign) (see Ch. 71). The possibility of melanoma should be considered for all pigmented nail bands in fair-skinned individuals, especially if they are darkly pigmented, have irregular pigmentation and/or have a width ≥3 mm.

Fig. 113.14 Nodular melanoma (NM). Rapidly growing black nodule that was >15 mm in diameter on the back of a male patient.

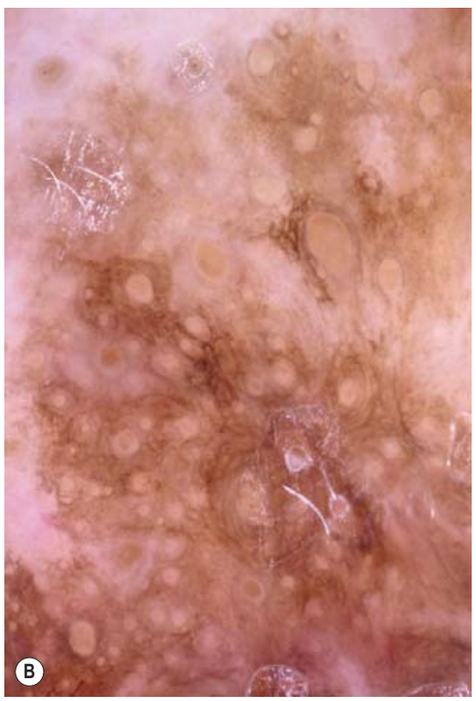

Fig. 113.16 Lentigo maligna melanoma (LMM). A A pigmented lesion on the dorsal nose, with irregular borders, light to dark brown pigmentation and marked asymmetry. **B** Dermoscopy demonstrating annular structures corresponding to follicular openings surrounded by melanoma cells ("circle in a circle").

Fig. 113.15 Lentigo maligna versus lentigo maligna melanoma. A Large-sized brown patch with mild variation in color representing lentigo maligna. **B** Similarly sized lesion, but with marked variation in color and topography. There was invasion to a depth of 1.1 mm within the blue-gray papules.
B, Courtesy, Kalman Watsky, MD.

ALM is a genetically distinct subtype of melanoma and clearly differs from the other types of cutaneous melanoma. It harbors more and different genetic changes than the other types and can display activating *KIT* mutations in exons 11, 13 and 17, which can make the tumor sensitive to KIT-inhibiting drugs (e.g. imatinib; see Table 113.1)[10,146].

OTHER MELANOMA VARIANTS

There are cutaneous melanomas that may present with unusual manifestations. Some of these are defined by clinical features, others by histologic findings.

Amelanotic Melanomas

Fortunately, the overwhelming majority of melanomas are pigmented, aiding visual diagnosis. Melanomas lacking clinically evident pigment are termed "amelanotic" (Fig. 113.19). All four histologic subtypes of melanoma discussed above can occur as amelanotic variants that largely defy clinical diagnosis. Amelanotic SSMs, nodular melanomas and LMMs are often biopsied due to clinical suspicion of basal cell carcinoma. Amelanotic ALMs are especially challenging and may be mistaken for warts or squamous cell carcinoma. Amelanotic melanomas do not differ from pigmented melanomas in terms of prognosis or therapy.

Fig. 113.17 Acral lentiginous melanoma (ALM). Irregularly pigmented lesion on the plantar surface of the foot. These tumors may become amelanotic and are then easily overlooked or misdiagnosed as verrucae or other benign lesions, often resulting in a significantly delayed diagnosis.

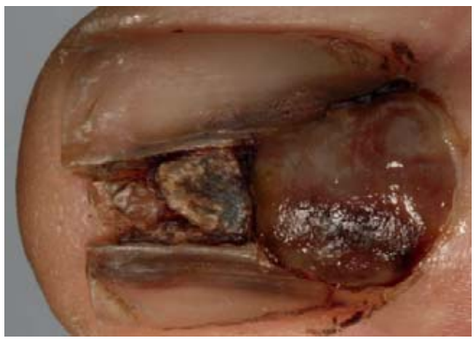

Fig. 113.18 Melanoma of the nail matrix. Ulcerated tumor destroying the nail plate. The longitudinal pigmentation of the nail plate adjacent to the nodular portion is a clue to the diagnosis of melanoma.

Fig. 113.19 Amelanotic melanoma. A, B Skin-colored to light pink nodule on the right scapula of a female patient. Pathology revealed an amelanotic nodular melanoma with a tumor thickness of 4 mm.

Melanoma with Features of a Spitz Nevus ("Spitzoid" Melanoma)

This variant shows histologic features suggestive of Spitz nevus (Fig. 113.20) with overall symmetry and a dermal nodule of epithelioid melanocytes that do not mature with progressively deeper dermal extension. Other important histologic clues that point to the diagnosis of melanoma are sheets of atypical melanocytes in the dermis and mitotic figures at the base of the lesion. While several approaches have been taken to distinguish spitzoid melanomas from benign Spitz nevi (e.g. immunohistochemistry, fluorescence in situ hybridization [FISH], comparative genomic hybridization [CGH] analysis), some of these lesions continue to defy definitive histologic diagnosis[147].

Desmoplastic Melanoma

While this type of melanoma is histologically defined, the typical clinical lesion consists of a skin-colored, red or brown–black nodule or plaque, usually in sun-exposed sites. It may develop *de novo*, but more commonly arises in conjunction with a lentigo maligna, ALM or mucosal radial growth phase melanoma. Deep tissue samples are necessary to establish the diagnosis (Fig. 113.21), as superficial portions of the tumor show subtle or non-diagnostic findings which may be mistaken for the fibrosis of a scar or other spindle cell neoplasms. Metastasis to lymph nodes is uncommon, but the tumor is highly infiltrative and, thus, locally aggressive, with recurrence being common after incomplete excision. While these tumors do have significant potential for distant metastasis, conventional T staging tends to overestimate the likelihood for metastasis of these tumors, which are typically quite deep at the time of diagnosis[148,149].

Clear Cell Sarcoma: Melanoma of Soft Parts

Clear cell sarcoma most often presents on the distal extremities of adolescents and young adults. The tumors usually arise in association with tendons and aponeuroses, and they are composed of nests and fascicles of oval to spindled cells with vesicular nuclei, basophilic nucleoli, and eosinophilic to clear cytoplasm. Multinucleated giant cells and melanin can frequently be seen. Despite its unique clinical and histologic presentation, several lines of evidence, including immunohistochemical studies, presence of melanosomes on electron microscopy, and gene profiling, support the classification of clear cell sarcoma as a subset of melanoma[150,151]. Clear cell sarcoma pathogenesis differs from that of other melanoma subtypes by a frequent and characteristic reciprocal translocation t(12;22)(q13;q12) that results in fusion of the *EWS* and *ATF1* genes[150]. The clinical course of these lesions resembles that of other soft tissue sarcomas, with a high likelihood of regional and distant metastasis.

Malignant Blue Nevus

Malignant blue nevus is a rare dermal tumor of melanocytes, most commonly located on the head and particularly the scalp (Fig. 113.22). It appears as a blue–black, deeply situated nodule, generally >1 cm in diameter. Histologically, elements of a benign cellular blue nevus are associated with nodular areas of atypical spindle-shaped and bipolar dendritic melanocytes, mitotic figures, necrosis and melanophages[152].

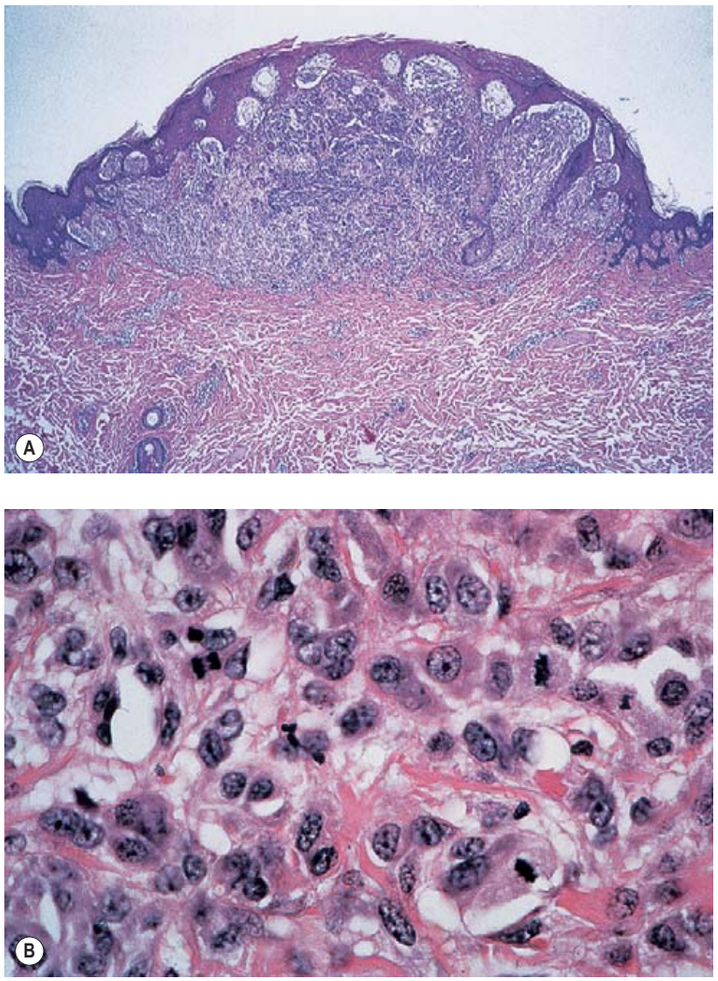

Fig. 113.20 Histopathology of "spitzoid" melanoma, histopathologically simulating a Spitz nevus. This neoplasm could be misdiagnosed as a Spitz nevus because the lesion is symmetrical and well circumscribed (**A**). This is a melanoma because: nests of melanocytes have become confluent with formation of sheets; there is no distinct maturation of melanocytes; nuclei of melanocytes are atypical; and melanocytes are in mitosis at the base of the neoplasm (**B**). *Courtesy, Helmut Kerl, MD.*

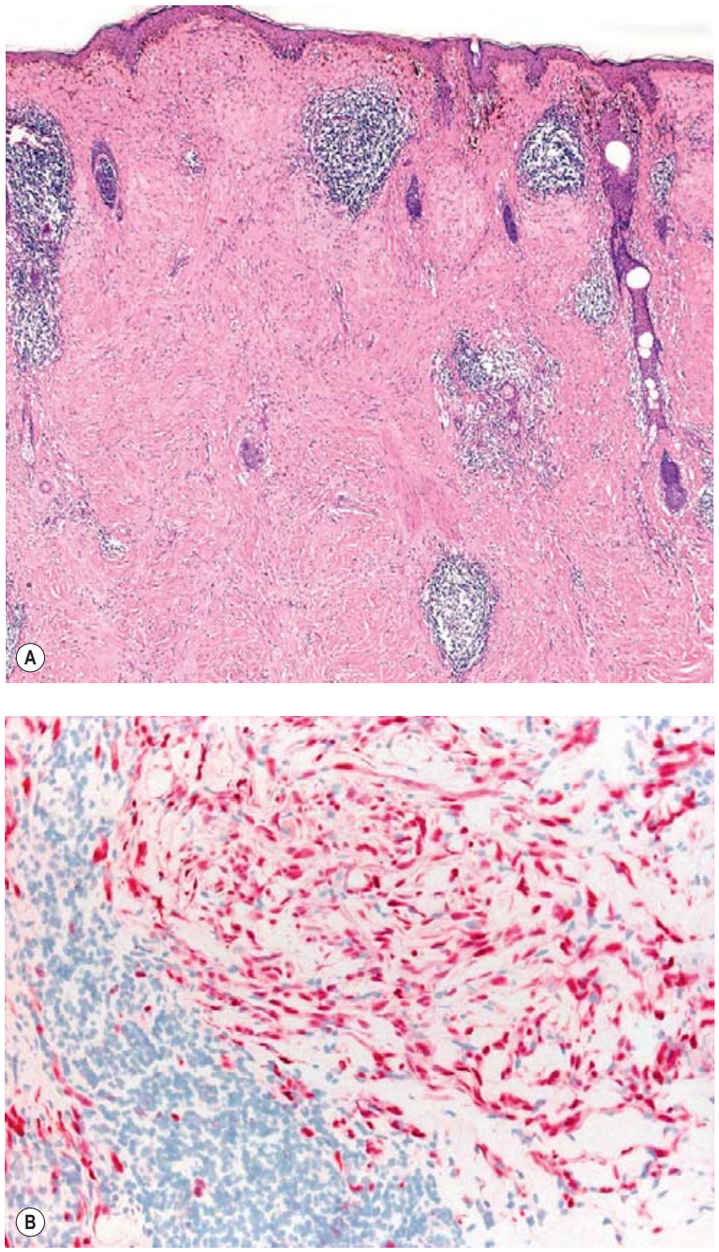

Fig. 113.21 Histopathology of desmoplastic melanoma. A Loosely textured spindle cells within fibroblastic stroma. In the epidermis and follicular epithelium, there are changes of melanoma *in situ* with proliferation of atypical melanocytes. Note the lymphoid infiltrates. **B** S100-positive spindle cells within the dermis. *Courtesy, Lorenzo Cerroni, MD.*

The clinical course is characterized by a high rate of recurrence and metastasis.

Ocular Melanoma

Primary ocular melanomas, which are relatively rare (5% of all melanomas), can be divided into conjunctival melanomas and uveal melanomas (iris, choroidal and ciliary body melanomas). Uveal melanomas frequently (80–85%) harbor somatic activating mutations in *GNA11* or *GNAQ*. These genes encode members of the q class of G protein α-subunits. Heterotrimeric G proteins are involved in mediating signals between G-protein-coupled receptors (GPCRs) and downstream effectors (see Fig. 65.15)[153]. Of note, *GNAQ* (more frequently than *GNA11*) mutations have been detected in blue nevi but not in cutaneous melanomas. Chromosomal changes of prognostic significance in ocular melanoma have been described and include monosomy 3 and alterations of 8q and 6p. Monosomy 3 reduces the 5-year survival from approximately 100% to less than 50%. A particularly poor outcome has been associated with combined abnormalities in chromosomes 3 and 8[154]. The management of uveal melanoma has shifted to eye-sparing approaches without significant impact on patient survival. Radiotherapy with proton beams has replaced eye enucleation as the standard treatment for uveal melanoma[155].

Mucosal Melanoma

Mucosal melanomas are rare lesions that may occur in the mouth, nasopharynx, larynx, vagina and anus. They tend to occur near the mucocutaneous junctions of squamous and columnar epithelia and account for ~1% of melanomas. As many as 35% of mucosal melanomas are reportedly amelanotic, further complicating a difficult clinical diagnosis[156]. Not surprisingly, these tumors tend to be diagnosed at a locally advanced stage with associated poor prognosis. Similar to ALM, mucosal melanomas are a genetically distinct subtype of melanoma. They harbor more and different DNA copy number changes than do cutaneous melanomas and they can harbor activating *KIT* mutations, which can make the tumor sensitive to KIT-inhibiting drugs (e.g. imatinib; see Table 113.1)[10,146].

MELANOMA AND PREGNANCY

During pregnancy, levels of hormones and growth factors that stimulate melanocytes are elevated and increased pigmentation occurs in some women. More than 10% of women experience darkening of melanocytic nevi during the first 3 months of pregnancy[157]. However, an association

Fig. 113.22 Melanoma in association with a cellular blue nevus (malignant blue nevus). Satellite metastases are also present. *Courtesy, Frank Nestlé, MD.*

between hormonal changes during pregnancy and development of melanoma or worsening of the prognosis of an existing melanoma has not been demonstrated[158]. Transplacental metastases are very rare in pregnant women with melanoma and only a limited number of cases have been described in the literature[159]. Surgical excision and sentinel lymph node biopsy (if chosen by the patient) are performed as indicated, based upon stage of disease and current recommendations (see below). In more advanced stages, the advantages and disadvantages of immunotherapy and chemotherapy should be discussed with the patient. Ultrasound and magnetic resonance imaging can be performed in pregnant patients, but computerized tomography (CT) scans should be avoided. In women with a history of high-risk melanoma, it may be reasonable to wait 2 years after diagnosis before becoming pregnant again, because two-thirds of recurrences occur within this period. Lastly, there have been no studies demonstrating an adverse effect of hormonal contraception on melanoma development[160].

CHILDHOOD MELANOMA

Childhood melanoma is very rare. Approximately 2% of melanomas occur in patients younger than 20 years of age, and 0.3% in those younger than 14 years[161]. The risk factors for melanoma in children parallel those in adults. The exceedingly rare conditions of xeroderma pigmentosum and giant congenital melanocytic nevi contribute minimally to the prepubertal incidence of melanoma. Histologically, melanomas in children may resemble those of adults, but melanomas with features of Spitz nevus are reported to be more common in this age group[162]. As noted above, the differentiation of melanoma from atypical Spitz nevus and from deep penetrating nevus remains a major challenge, and overdiagnosis of childhood melanoma may result from this uncertainty[163,164]. Overall survival and prognosis appears to be stage-dependent and similar to that in adults[165]. Treatment follows the same rationale as in adults.

DIAGNOSIS

Early detection is a key factor in improving survival in patients with melanoma. The clinical diagnosis of cutaneous melanoma continues to be based on visual inspection and dermoscopy. A history of change in the color, shape or size of a pigmented skin lesion over the course of months or years is the most sensitive clinical sign for melanoma, and may be detected by the patient himself or by serial screening examinations based on dermoscopy with image storing or on lesional or total body photography[166,167].

Public awareness campaigns have highlighted the ABCD's of melanoma: **A**symmetry, **B**order irregularity, **C**olor variegation, and **D**iameter greater than 5 mm. However, the ABCD rule widely overlaps with the definition of benign atypical melanocytic nevi[168]. Furthermore, it has been shown that patients recognize a melanoma by the development of a new pigmented lesion or by an increase in size or change in color of a pre-existing lesion instead of by the ABCD features[169]. Thus, an '**E,**' for **E**volving, has been added to highlight the importance of a changing lesion.

Dermatologists seem to unconsciously rely on cognitive (overall pattern) and comparative (ugly duckling sign) processes rather than an algorithm of morphologic criteria (ABCD)[170]. A diagnostic clue is the so-called *"ugly duckling" sign*, which focuses on the morphologic differences between a single striking lesion and the surrounding benign "signature" nevi[171]. There is a good inter-observer reproducibility of this sign[172].

Two other helpful clinical clues are the *"Little Red Riding Hood" sign* and the *"EFG" rule*. The former represents the finding of erythema or inflammation that at times will surround a cutaneous melanoma. "EFG" stands for an **E**levated, **F**irm, or **G**rowing lesion and is helpful to keep in mind for accurately diagnosing an amelanotic or nodular melanoma.

It is important to keep in mind that not all cutaneous melanomas present with these typical clinical clues. Diagnostic accuracy for the clinical diagnosis of melanoma does not exceed 75% and may be increased to up to 90% with the use of dermoscopy by experts. However, 10–25% of melanomas may still be missed despite all these diagnostic efforts. The term "featureless melanoma" has been coined for early and difficult-to-diagnose melanomas and may partially explain this statistic[173,174]. Sometimes, patients are the first to recognize these featureless cutaneous melanomas and infrequently patients are very suspicious about a single such skin lesion. Therefore, the following principle for the management of skin cancer patients is suggested, which may be called "Garbe's rule": *If a patient is worried about a single skin lesion, do not ignore their suspicion and have a low threshold for performing a biopsy.*

Differential Diagnosis

A variety of conditions may simulate melanoma, either clinically or histopathologically, or both. Awareness of these simulators is of great practical importance in order to avoid misdiagnosis or overdiagnosis of melanoma[175]. Tables 113.4 and 113.5 list several melanocytic and non-melanocytic lesions that can mimic melanomas. Occasionally, a primary melanoma arising in the dermis with no epidermal component is diagnosed as a dermal metastasis of melanoma.

Dermoscopy

Dermoscopy, also known as skin surface microscopy or epiluminescence microscopy (ELM), is a helpful non-invasive tool for diagnosing pigmented skin lesions and for recognizing cutaneous melanoma (Fig. 113.23)[176]. Clinical diagnostic sensitivity is significantly enhanced by the use of dermoscopy and the correct diagnosis of melanoma is improved by nearly 50% by utilizing this diagnostic technique[177].

In one form of dermoscopy, a magnifying lens system is combined with a fluid interface in order to eliminate skin surface reflection. Hand-held lenses or cameras equipped with lenses and coupled with digital imaging systems are used. A glass plate makes direct contact with the skin and for the fluid interface, ultrasound contact gel or a disinfectant spray can be used. Morphologic structures within the epidermis, the dermal–epidermal junction and the superficial dermis can be visualized with this technique. An alternative form of dermoscopy employs polarized light to eliminate the surface reflection so that neither a liquid interface nor direct skin contact is required. The magnifications of these instruments range from 6- to 100-fold, but the most widely used dermoscope provides a 10-fold magnification, which is sufficient for routine assessment of pigmented skin lesions.

The dermoscopic evaluation of cutaneous pigmented lesions involves a two-step algorithm. First, the observer determines whether the lesion under investigation is of melanocytic origin or not. For a lesion to be considered melanocytic, it needs to have at least one of the following dermoscopic structures/features: pigment network, streaks, aggregated globules, homogeneous blue pigment, or parallel pattern (acral lesions). If the lesion does not possess one of the aforementioned melanocytic features, then it needs to be evaluated further to determine if it has any dermoscopic characteristics consistent with other entities such as a seborrheic keratosis, dermatofibroma or pigmented basal cell carcinoma (see Ch. 0). However, if the lesion does not have any features of

MELANOCYTIC LESIONS THAT SIMULATE MELANOMAS
CLINICAL SIMULATORS
• Acral nevi • Atypical (dysplastic, Clark's) nevi • Black (hypermelanotic) nevi • Blue nevi and variants • Combined nevi • Congenital nevi • Halo nevi • Longitudinal melanonychia • Melanosis of mucosal regions • Nevi and lentigines in genital regions • Nevi in patients with epidermolysis bullosa • Pigmented streaks in melanoma scars • Recurrent nevi • Reticulated (ink-spot) lentigo • Spitz nevi and variants
HISTOPATHOLOGIC SIMULATORS
• Acral nevi • Ancient nevi • Atypical (dysplastic, Clark's) nevi • Atypical Spitz nevi and variants • Congenital nevi biopsied shortly after birth • Deep penetrating nevi • Hyperplasia of melanocytes in sun-damaged skin • Melanocytic proliferation overlying a benign neoplasm • Nevi arising within areas of lichen sclerosus • Nevi exposed to UV radiation • Nevi in genital regions (including milk-line nevi and flexural nevi) • Nevi in patients with epidermolysis bullosa • Nevi on or around the ear • Pigmented streaks in melanoma scars • Proliferating nodules in giant congenital nevi in neonates • Recurrent nevi

Table 113.4 Melanocytic lesions that simulate melanomas.

NON-MELANOCYTIC CLINICAL SIMULATORS OF MELANOMA
SIMULATING SUPERFICIAL SPREADING MELANOMA
• Seborrheic keratosis • Thrombosed hemangioma, angiokeratoma • Pigmented basal cell carcinoma • Pigmented actinic keratosis • Extramammary Paget's disease • Bowen's disease including pigmented variant
SIMULATING NODULAR MELANOMA
• Seborrheic keratosis • Pyogenic granuloma • Dermatofibroma • Thrombosed hemangioma, angiokeratoma • Pigmented basal cell carcinoma • Pigmented poroma and pigmented porocarcinoma • Pigmented pilomatricoma • Pigmented dermatofibrosarcoma protuberans (Bednar tumor)
SIMULATING LENTIGO MALIGNA MELANOMA
• Macular seborrheic keratosis • Solar keratosis, including the pigmented variant • Pigmented basal cell carcinoma
SIMULATING ACRAL LENTIGINOUS MELANOMA OF THE PALMS AND SOLES
• Black heel (hemorrhage in stratum corneum caused by trauma) • Plantar warts • Trophic ulcers • Plantar callosity • Tinea nigra
SIMULATING SUBUNGUAL ACRAL LENTIGINOUS MELANOMA
• Subungual hematoma • Bowen's disease • Verruca • Paronychia • Drug-induced nail pigmentation
SIMULATING AMELANOTIC MELANOMA
• Superficial basal cell carcinoma • Bowen's disease • Benign lichenoid keratosis • Isolated patch of psoriasis

Table 113.5 Non-melanocytic clinical simulators of melanoma.

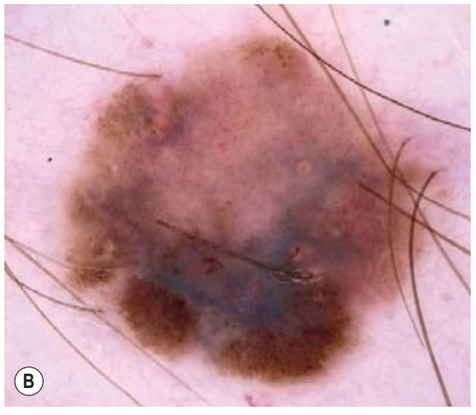

Fig. 113.23 Illustration of dermoscopy. This pair of images illustrates the clinical appearance (**A**), and the same lesion viewed with dermoscopy (**B**). Greater detail can be appreciated at 10- to 20-fold magnification. This lesion is an early invasive melanoma with sharp demarcation, asymmetry, and a central blue-whitish veil.

a melanocytic lesion *and* it does not have any features of a non-melanocytic tumor, then, by default, the lesion is considered to be of melanocytic origin.

Once a lesion is deemed to be of melanocytic origin, the second step of the algorithm is to differentiate between benign melanocytic nevi and melanoma. To this end, multiple algorithms have been created, including pattern analysis, the ABCD rule, Menzies method, and the 7-point checklist, among others, which assist the clinician in deciding which lesions require a biopsy (see Tables 0.15–0.18)[142].

The major dermoscopic criteria for melanoma can be broken down into global features, patterns and local features (Fig. 113.24). Global features of melanoma include dermoscopic asymmetry and the presence of multiple colors. Patterns seen by dermoscopy include reticular, globular, reticular–globular, homogeneous, reticular–homogeneous, and starburst. In melanoma, the most common patterns are the multi-component pattern (three or more dermoscopic structures distributed asymmetrically), asymmetric starburst pattern, and nonspecific pattern (does not fit one of the known benign patterns). Lastly, the presence of any of the following local features should raise concern for melanoma: atypical network, streaks, atypical dots or globules, irregular blood vessels, regression structures and blue-white veil (Table 113.6).

Over the past several years, dermoscopy has been further refined in order to recognize difficult-to-diagnose melanomas such as ALMs and subungual melanomas[178–180]. Additionally, diagnostic clues for early nodular melanomas and for amelanotic melanomas have been described, as these melanomas do not display the classic features (see above)[181,182].

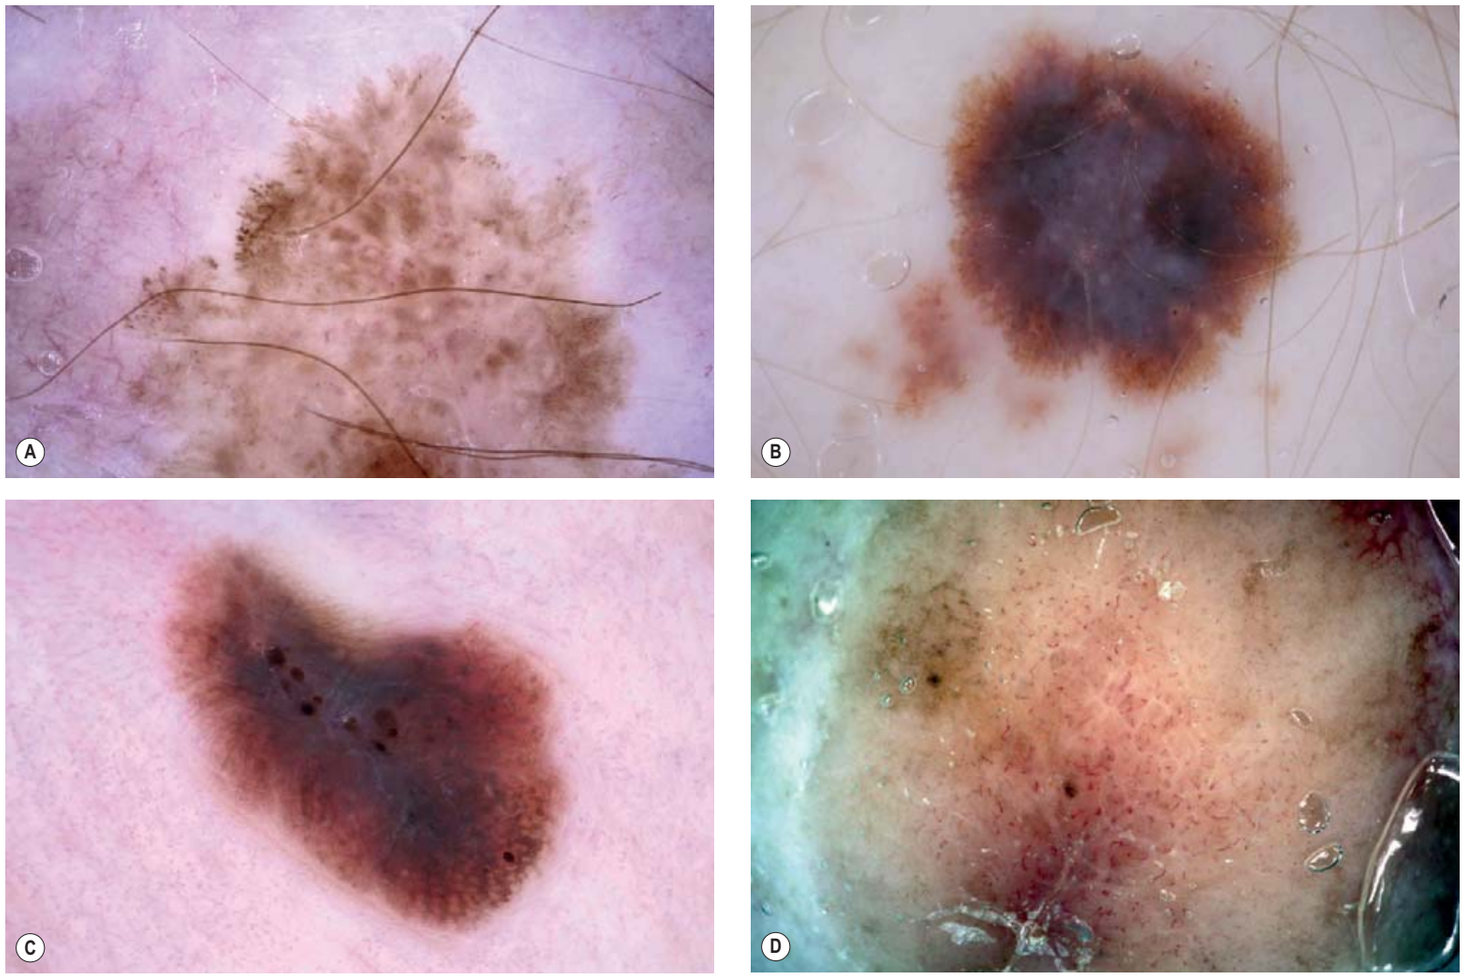

Fig. 113.24 Dermoscopic appearance of primary cutaneous melanomas. A Superficial spreading melanoma (SSM) with striking asymmetry, and streaks at the periphery. The latter have also been called radial streaming and pseudopods. **B** SSM with streaks and blue-whitish veil. **C** SSM with streaks, blue-whitish veil, and irregular blotches. **D** Dermoscopy of a clinically amelanotic melanoma (Fig. 113.19) reveals some pigmented globules that allow one to identify the tumor as a melanocytic lesion. Dotted, point and linear-irregular vessels are suggestive of melanoma.

It is noteworthy that not all melanomas can be clearly recognized by dermoscopy and that "featureless" melanomas exist[174].

Photography

In high-risk patients, especially those with complex mole patterns, baseline photographs can be a helpful adjunct in the identification of new and changing lesions[183]. The advent of digital photography and computerized image archives has improved the practicality of this approach. The availability of baseline images for comparison, including dermoscopic images, permits the detection of melanomas that are growing or changing without manifesting obvious clinical characteristics, while simultaneously avoiding the excision of stable, albeit clinically concerning, atypical nevi[184].

HISTOPATHOLOGY

Histopathology remains the gold standard for melanoma diagnosis. While most melanomas are readily distinguished from melanocytic nevi based on standard criteria (Table 113.7), some melanocytic lesions remain diagnostically challenging despite the advent of immunohistochemical and molecular techniques. There is significant variability in the application of diagnostic criteria for thin and *in situ* melanomas among pathologists[185].

It has been proposed that melanomas progress through two phases[186]. The first is the *r*adial (horizontal) *g*rowth *p*hase (RGP), characterized by centrifugal spread of neoplastic melanocytes within the epidermis and infiltration of the papillary dermis by single cells or small nests. The second, *v*ertical *g*rowth *p*hase (VGP), is characterized by the presence of dermal nests/nodules of atypical melanocytes that are larger than and/or cytologically distinct from their intraepidermal counterparts. It has been further postulated that the RGP lacks metastatic potential even in the presence of dermal invasion, whereas the VGP correlates with the capacity for metastasis. The major histologic types of melanoma described above differ with regard to the presence and morphology of the RGP.

Typically, cutaneous melanoma (Fig. 113.25)[137,187] is asymmetric, poorly circumscribed, and characterized by nests of melanocytes within the epidermis that are not equidistant from one another, vary in size and shape, and focally become confluent. Within the epidermis, solitary melanocytes predominate over nests. Some solitary melanocytes and nests of melanocytes are found well above the dermal–epidermal junction, at times extending into the upper epidermis, even the cornified layer. These findings define melanoma *in situ* (Fig. 113.26). One element of this histologic asymmetry is the extension of the intraepidermal tumor cells far from the invasive intradermal component. Similar findings are present in the adnexal epithelium of pilosebaceous units and eccrine ducts. Within the dermis, nests of melanocytes do not become smaller with progressive descent (absence of maturation). In parallel, nuclei of melanocytes do not become smaller in deeper portions of the tumor.

Lentigo maligna melanoma differs from the prototypic melanoma by its presence within sun-damaged skin, and the tendency to have little pagetoid spread within the epidermis. Tumor cells show lentiginous spread, i.e. solitary tumor cells predominate over tumor cell nests within the epidermis (Fig. 113.27). The atypical melanocytes are commonly present within the epithelium of adnexal structures, especially

DERMOSCOPIC CRITERIA AND THEIR CORRESPONDING HISTOPATHOLOGIC FEATURES			
Criterion	**Morphologic definition**	**Associated histopathologic changes**	**Diagnosis**
Pigment network	Network of brownish lines over a diffuse tan background	Pigmented rete ridges	Melanocytic lesion
Typical network	Brown-colored, regularly meshed and narrowly spaced network	Regular and elongated rete ridges	Benign melanocytic lesion
Atypical network	Black, brown or gray network with irregular meshes and thick lines	Irregular and broadened rete ridges	Melanoma
Dots/globules	Black, brown and/or gray, round to oval, variably sized structures regularly or irregularly distributed within the lesion	Pigment aggregates within the stratum corneum, epidermis, dermal–epidermal junction or papillary dermis	If regular: benign melanocytic lesion; if irregular: melanoma
Streaks	Irregular, linear structures not clearly combined with pigment network lines at the margins	Confluent junctional nests of melanocytes	Melanoma
Blue-whitish veil	Irregular, confluent, gray–blue to whitish-blue diffuse pigmentation	Acanthotic epidermis with focal hypergranulosis above sheets of heavily pigmented melanocytes in the dermis	Melanoma
Blotches	Black-, brown- and/or gray-colored areas with regular or irregular shape/distribution	Hyperpigmentation throughout the epidermis and/or upper dermis	If regular: benign melanocytic lesion; if irregular: melanoma
Regression structures	White (scar-like) areas, blue (pepper-like) areas or combinations of both	Thickened papillary dermis with fibrosis and/or variable amounts of melanophages	Melanoma
Milia-like cysts	White-yellowish, roundish dots	Intraepidermal horn globules, also called horn pseudocysts	Seborrheic keratosis (occasionally observed in papillomatous melanocytic nevi)
Comedo-like openings	Brown-yellowish, round to oval or even irregularly shaped, sharply circumscribed structures	Keratin plugs situated within dilated follicular openings	Seborrheic keratosis
Leaf-like areas	Brown–gray to gray–black patches revealing a leaf-like configuration	Pigmented, solid aggregations of basaloid cells in the papillary dermis	Basal cell carcinoma
Red–blue lacunas	Sharply demarcated, roundish to oval areas with a reddish, red-bluish, or red–black color	Dilated vascular spaces situated in the upper dermis	Vascular lesion
Vascular structures	Comma-like vessels Arborizing vessels Hairpin vessels Dotted or irregular vessels		Benign melanocytic lesion Basal cell carcinoma Seborrheic keratosis Melanoma

Table 113.6 Dermoscopic criteria and their corresponding histopathologic features. *With permission from Argenziano & Soyer, Lancet Oncol. 2001;2:443–9. © 2001 Elsevier.*

CRITERIA FOR THE HISTOPATHOLOGIC DIAGNOSIS OF MELANOMA
ARCHITECTURAL PATTERN
• Asymmetry • Poor circumscription of intraepidermal melanocytic component • Silhouette of tumor base is uneven (except in nevoid melanoma) • No maturation of melanocytes with progressive descent into the dermis • Nests of melanocytes within the epidermis are not equidistant from one another • Nests of melanocytes vary in size and shape • Some nests of melanocytes become confluent • Scatter of melanocytes above the dermal–epidermal junction • Melanocytes arranged as solitary units predominate over nests within the epidermis • Melanocytes in some nests are not cohesive • Melanocytes extend down adnexal epithelium • Sheets of melanocytes within the dermis • Nests at the base of lesions are occasionally large
CYTOMORPHOLOGY
• Atypical melanocytes (with pleomorphic nuclei) • Mitotic figures • Necrotic melanocytes
OTHER FEATURES
• Signs of regression • Actinic elastosis • "Dusty" melanin within tumor cells • Melanin is not distributed in a uniform fashion • Plasma cells at the base of the lesion

Table 113.7 Criteria for the histopathologic diagnosis of melanoma. *Adapted from Ackerman A, Cerroni L, Kerl H. Pitfalls in Histopathologic Diagnosis of Malignant Melanoma. Philadelphia: Lea & Febiger, 1994.*

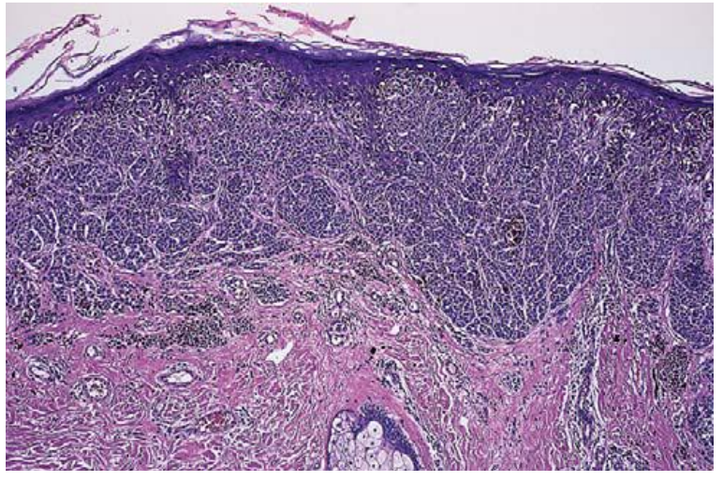

Fig. 113.25 Histopathology of a typical melanoma. Pagetoid melanocytes organized as solitary units and nests varying in size and shape are present throughout the entire epidermis. Neoplastic melanocytes extend into the dermis. There is absence of maturation at deeper levels of the dermis. *Courtesy, Helmut Kerl, MD.*

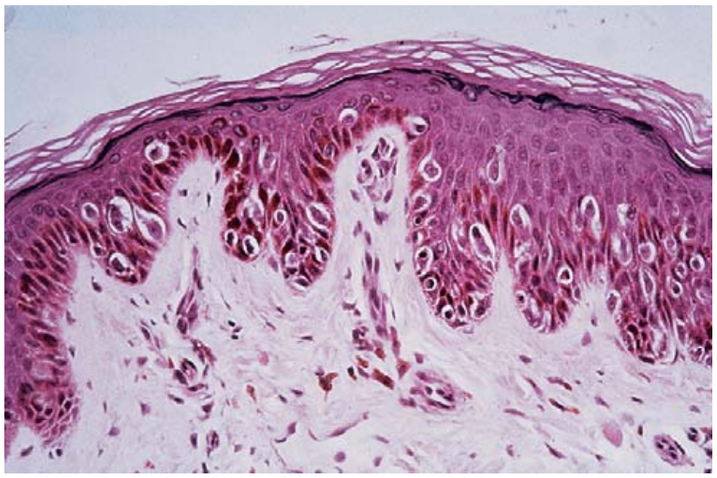

Fig. 113.26 Histopathology of a melanoma *in situ*. Increased number of melanocytes with atypical nuclei not only in the basal zone, but also at the upper levels of the epidermis. *Courtesy, Helmut Kerl, MD.*

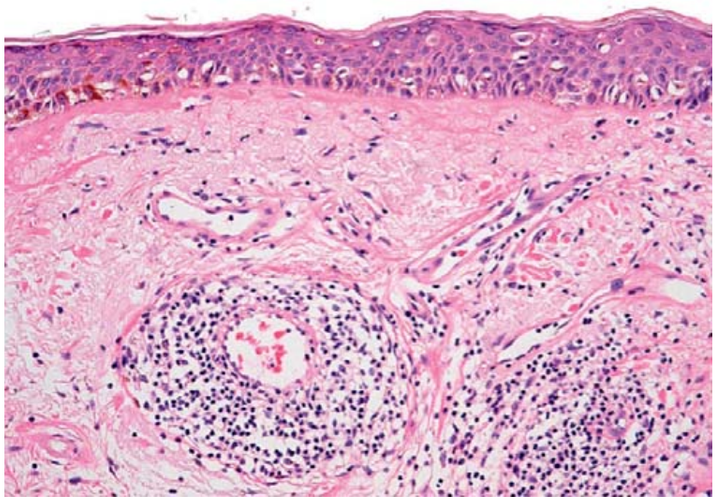

Fig. 113.27 Histopathology of a lentigo maligna melanoma. Proliferation of atypical melanocytes within the epidermis, with single cells predominating over nests. Note the flattened appearance of the epidermis and the solar elastosis in the dermis. *Courtesy, Lorenzo Cerroni, MD.*

along the outer root sheath of hair follicles. The invasive component is more often composed of spindle cells. Desmoplastic stromal change and neurotropism of tumor cells are additional findings. Epidermal atrophy and signs of solar elastosis are often observed in the upper dermis.

ALM often has a proliferation of atypical melanocytes within the basal layer of a hyperplastic epidermis, i.e. a lentiginous spread of single melanoma cells. Atypical melanocytes are arranged singly and in irregularly shaped nests at all levels of the epidermis ("pagetoid scatter"), with predominance of single cells. In the cornified layer, numerous melanocytes and melanin granules are found in a diffusely scattered distribution (Fig. 113.28). Notably, melanomas in volar and subungual sites display strikingly dendritic melanocytes.

Microstaging

Of the histologic features of a primary cutaneous melanoma, the Breslow depth or tumor thickness (depth of invasion) is the strongest predictor of survival. Melanoma thickness is measured in millimeters from the top of the granular cell layer of the epidermis (or the base of an ulcer) to the deepest point of tumor penetration, using an ocular micrometer (Fig. 113.29). In addition to tumor thickness, a number of other histologic features should be noted (Table 113.8)[188]. Tumor thickness, ulceration, and mitoses/mm^2 are major determinants of T stage

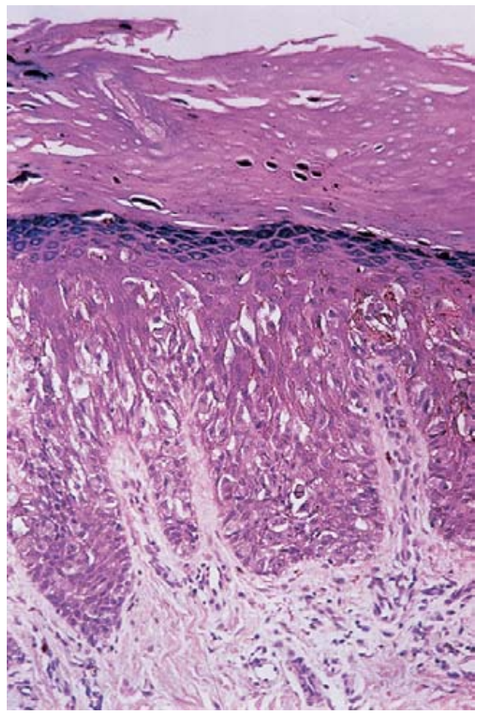

Fig. 113.28 Histopathology of an acral melanoma. Atypical melanocytes are scattered throughout the hyperplastic epidermis including the cornified layer. Note the presence of dendritic melanocytes. *Courtesy, Helmut Kerl, MD.*

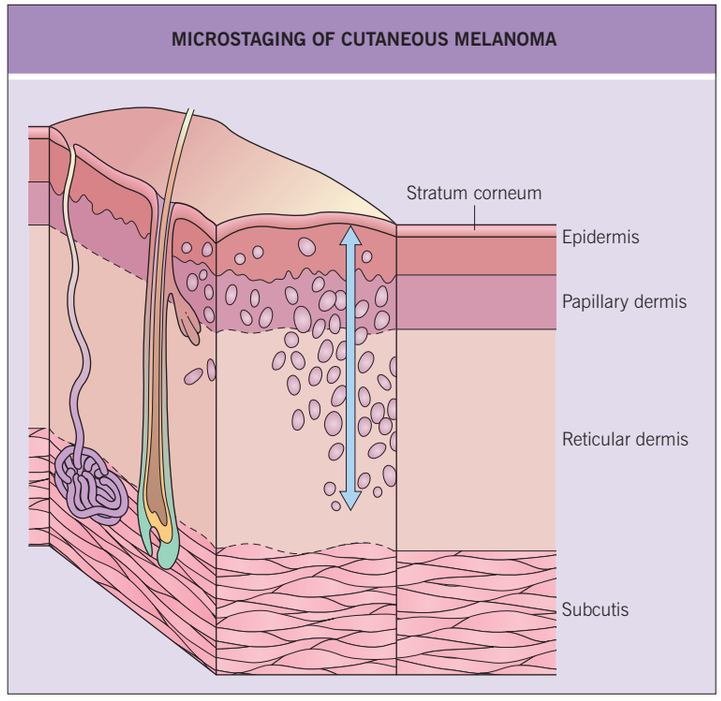

Fig. 113.29 Microstaging of melanoma: Breslow tumor thickness. Breslow method: measure from the granular layer of the epidermis to the deepest part of the tumor.

in the current staging system, with ulceration defined as the absence of an intact epidermis overlying a major portion of the primary tumor, based on microscopic examination.

Immunohistopathology

Immunohistochemical studies can be helpful in the assessment of diagnostically difficult cases of primary melanoma as well as in the assessment of metastatic tumors of unknown origin (see Table 0.11). However, the diagnosis of cutaneous melanoma is made on the basis of routine H&E staining, as no immunostaining pattern exists which on its own allows a clear differentiation between benign and malignant

lesions. A wide range of melanoma-associated antigens have been identified for which immunohistochemical stains are available. Melanocyte differentiation antigens, e.g. gp100 (HMB45), tyrosinase and Melan-A/MART-1, are useful for distinguishing cells of melanocytic lineage from other tumor types, for visualizing the full extent of tumor cells of a primary melanoma, and for the identification of minute foci of melanoma in sentinel lymph node biopsies. Staining for S100, a calcium-binding protein, has high sensitivity for melanocytes and melanoma, but this protein is also expressed by Langerhans cells, other dendritic cells, eccrine glands, Schwann cells, chondrocytes and adipose tissue. Of note, S100 is the most reliable marker for identifying the spindled component of a melanoma. HMB45, which recognizes the melanosome-specific glycoprotein gp100/Pmel17, has high specificity for melanocytes and nevus cells, but its utility is limited by its heterogeneous staining pattern and limited sensitivity. Staining for MITF expression can assist in distinguishing solar lentigo from lentigo maligna. The use of panels of these antibodies improves sensitivity and specificity, but remains diagnostically imperfect[189].

CUTANEOUS MELANOMA – COMPONENTS OF THE HISTOPATHOLOGIC REPORT
MANDATORY
Diagnosis of malignant melanoma
Thickness (Breslow depth)
Ulceration
Mitoses/mm^2 (for melanomas ≤ 1 mm)
Margins
DESIRABLE
Histopathologic subtype of melanoma
Level of invasion (Clark), if mitotic rate can not be determined (T1 melanomas)
Regression, tumor-infiltrating lymphocytes, presence of plasma cells
Vascular invasion
Microscopic satellites
Associated nevus

Table 113.8 Cutaneous melanoma – components of the histopathologic report.

Molecular Analysis

Some cutaneous melanomas are very difficult to diagnose, and the differentiation between atypical Spitz nevus and spitzoid melanoma or between deep penetrating blue nevus and melanoma can be difficult based upon histopathology. It has been suggested that these lesions be called melanocytic tumors of uncertain malignant potential (MELTUMP)[190]. In such cases, comparative genomic hybridization and fluorescence *in situ* hybridization may be helpful[147].

Comparative genomic hybridization (CGH) is a method for the genome-wide assessment of DNA copy number changes in tumor cells[191]. Fluorescence-labeled tumor DNA and reference DNA from a healthy donor are hybridized onto metaphase chromosomes or on arrays of oligonucleotides (array-CGH) (Fig. 113.30). From the relative fluorescence copy number, gains or losses within the tumor can be calculated (see Ch. 3). The oligonucleotide spots on the array can be mapped to the respective position within the human genome. CGH analysis of benign melanocytic nevi typically shows no clonally expanded chromosomal aberrations, while in the vast majority of melanomas, gains and losses of particular segments of chromosomes or entire chromosomes are found. As an exception, ~20% of Spitz nevi show an increase in copy number of chromosome 11p, an aberration not found in melanoma. CGH can be used as an adjunct for the difficult-to-diagnose melanocytic tumors described above.

Fluorescence *in situ* hybridization (FISH) can also assist in differentiating between benign and malignant melanocytic tumors. FISH assays focus on chromosomal loci that are frequently affected by copy number changes in melanoma. Studies have shown that a FISH assay that targets 6p25, 6q23, 11q13 and CEP6 (centromere of chromosome 6) discriminates between benign nevi and melanoma with high sensitivity and specificity[192,193]. The disadvantage of this approach is that only gains and losses involving two chromosomes are detected, whereas CGH examines the entire genome.

STAGING

Prior staging systems categorized melanoma into local, regional or distant disease, which strongly correlates with survival. The present

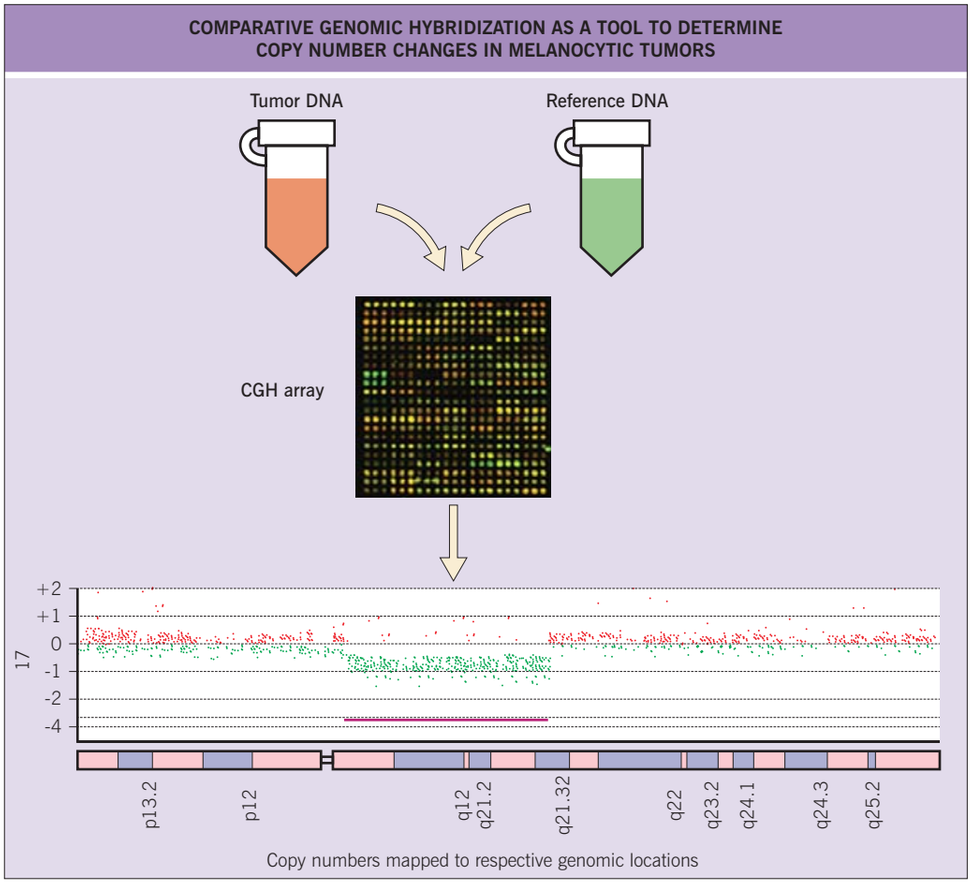

Fig. 113.30 Comparative genomic hybridization (CGH) as a tool to determine copy number changes in melanocytic tumors. Total genomic DNA is isolated from the tumor and from healthy reference samples, and labeled with fluorescent dyes. The mixture of test and reference DNA is hybridized onto a genome-wide microarray of oligonucleotides. Tumor and reference DNA bind to the complementary oligonucleotides and the ratio of their fluorescence intensities is approximately proportional to the ratio of the copy numbers of the corresponding DNA sequences in the tumor and reference genomes. The copy number ratio can be mapped to the genomic location of the array element.

MELANOMA TNM CLASSIFICATION		
T classification	**Thickness**	**Ulceration status/ Mitoses**
Tis	NA	NA
T1	≤1.0 mm	a: Without ulceration and mitosis <1/mm^2 b: With ulceration or mitoses ≥1/mm^2
T2	1.01–2.0 mm	a: Without ulceration b: With ulceration
T3	2.01–4.0 mm	a: Without ulceration b: With ulceration
T4	>4.0 mm	a: Without ulceration b: With ulceration
N classification	**Number of metastatic nodes**	**Nodal metastatic mass**
N0	0	NA
N1	1 node	a: Micrometastasis* b: Macrometastasis†
N2	2–3 nodes	a: Micrometastasis* b: Macrometastasis† c: In-transit met(s)/ satellite(s)‡ without metastatic node(s)
N3	4 or more metastatic nodes, matted nodes, or in-transit met(s)/satellite(s)‡ with metastatic node(s)	
M classification	**Site**	**Serum lactate dehydrogenase**
M0	No distant metastases	NA
M1a	Distant skin, subcutaneous or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases Any distant metastasis	Normal Elevated

*Micrometastases are diagnosed after sentinel or elective lymphadenectomy.
†Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.
‡In-transit metastases are >2 cm from the primary tumor but not beyond the regional lymph nodes, while satellite lesions are within 2 cm of the primary.

Table 113.9 Melanoma TNM classification. For defining T1 melanomas, Clark level of invasion is used as default criterion only if mitotic rate cannot be determined. Histologic evaluation of lymph nodes must include at least one immunohistochemical marker (e.g. HMB45, Melan-A/MART-1). NA, not applicable. *Adapted from Balch CM, Gershenwald JE, Soong SJ, et al. Final version of 2009 AJCC melanoma staging and classification. J Clin Oncol. 2009;27: 6199–6206. Reprinted with permission from the American Society of Clinical Oncology.*

STAGE GROUPINGS FOR CUTANEOUS MELANOMA							
	Survival (%)*	**Clinical staging†**			**Pathologic staging‡**		
		T	**N**	**M**	**T**	**N**	**M**
0		Tis	N0	M0	Tis	N0	M0

III§		Any T	N1 N2 N3	M0			
IIIA	78				T1-4a T1-4a	N1a N2a	M0
IIIB	59				T1-4b T1-4b T1-4a T1-4a T1-4a	N1a N2a N1b N2b N2c	M0
IIIC	40				T1-4b T1-4b T1-4b Any T	N1b N2b N2c N3	M0
IV	9–27‖	Any T	Any N	Any M1	Any T	Any N	Any M1

*Approximate 5-year survival (%), modified from Balch et al.[194]
†Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.
‡Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception.
§There are no stage III subgroups for clinical staging.
‖Higher survival rate associated with normal serum LDH levels and lower rate with elevated LDH levels.

Table 113.10 Stage groupings for cutaneous melanoma. *Adapted from Balch CM, Gershenwald JE, Soong SJ, et al. Final version of 2009 AJCC melanoma staging and classification. J Clin Oncol. 2009;27:6199–6206. Reprinted with permission from the American Society of Clinical Oncology.*

tumor–node–metastases (TNM) staging system was introduced by the American Joint Committee on Cancer (AJCC) in 2000, and then revised in 2009 (Table 113.9)[66,194].

The three main factors that determine the **T** classification are: (1) Breslow depth; (2) primary tumor mitotic rate; and (3) histopathologic evidence of ulceration. The **N** classification is determined by the extent of tumor within the regional lymph node basin. The most important prognostic factors in the **N** classification are: (1) the number of metastatic lymph nodes; (2) the presence of microscopic versus macroscopic nodal tumor burden; and (3) the presence or absence of satellite or in-transit metastases. The **M** classification refers to metastatic disease and is based on two important features: (1) the anatomic site of the distant metastases; and (2) the serum lactate dehydrogenase (LDH) level. When the **T**, **N**, **M** classifications are combined, placement into one of the four stages in the current AJCC staging system can be accomplished (Table 113.10; www.cancerstaging.org/staging/index.html) and then treatment can be determined and survival predicted (Fig. 113.31).

Stage 0 represents melanoma *in situ*. Stages I and II represent localized disease, but a distinction is often made between low-risk stage I patients (Breslow depth <1 mm) and higher-risk stage II patients (>2 mm or >1 mm plus ulceration). Stage III represents regional nodal and/or intralymphatic metastases. Stage IV represents distant metastases.

PROGNOSIS

The prognosis of a patient with melanoma depends upon the stage at diagnosis. Prognosis for patients with localized primary cutaneous melanoma and no nodal or distant metastases (stage I or II) is generally favorable. Patients with stage IA melanoma have a 10-year survival expectancy of >95%, whereas patients with thick (>4 mm) melanoma and ulceration (T4b) have a 10-year survival rate of ~50%. In addition to the microstaging variables discussed above, clinical variables with prognostic significance in stage I/II disease include sex, age and anatomic site[65,195,196] (Table 113.11). For example, women with stage I/II disease tend to have a better survival rate than men. Location of the primary melanoma on the trunk, head or neck portends a poorer prognosis than when located on the extremities.

Stage III melanoma patients are a heterogeneous group with respect to their risk for distant metastases and melanoma-specific mortality.

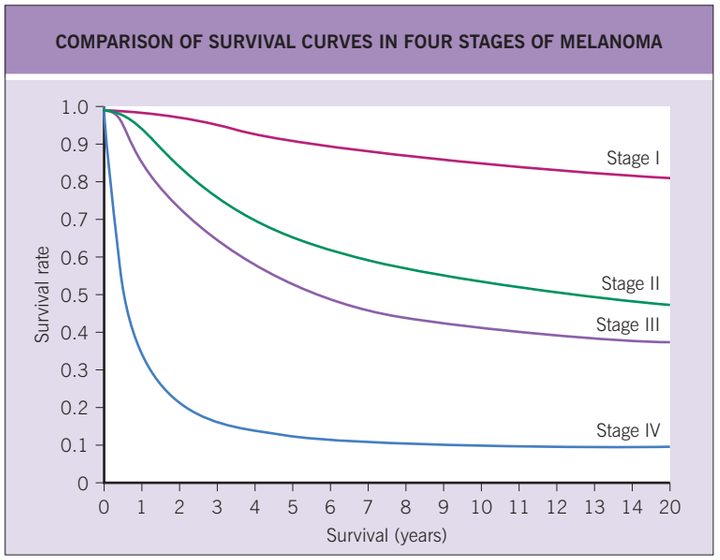

Fig. 113.31 Comparison of survival curves in four stages of melanoma.
Redrawn from Balch CM. Melanoma of the skin. In: Edge SB, Byrd DR, Compton CC, et al., eds. AJCC Cancer Staging Manual, 7th edn. New York: Springer Verlag, 2009.

MAJOR INDEPENDENT PROGNOSTIC FACTORS FOR SURVIVAL IN MULTIVARIATE ANALYSES

Prognostic factor	Commentary
Tumor thickness	≤1 mm, low risk; >1 mm, higher risk melanoma
Ulceration	Worse prognosis with ulceration
Mitotic rate	Worse prognosis with ≥1 mitoses/mm^2
Age	Worse prognosis with higher age
Sex	Men have poorer prognosis (only for localized disease)
Anatomic site	Trunk, head and neck associated with poorer prognosis than extremities
Number of involved lymph nodes	Cut-off points: 1, 2–3, 4 or more lymph nodes (see Table 113.9)
Regional lymph node tumor burden	Macroscopic (palpable) nodal metastases with poorer prognosis than microscopic (non-palpable) nodal metastases
Site of distant metastases	Visceral metastases associated with poorer prognosis than non-visceral metastases (skin, subcutaneous, distant lymph nodes)

Table 113.11 Major independent prognostic factors for survival in multivariate analyses.

The 5-year survival rates range from 70% for patients with non-ulcerated melanomas and a single nodal micrometastasis (T1–4N1aM0), to a low of 39% for patients with ulcerated primary melanomas and four or more lymph nodes with clinically apparent metastases (T1–4N3M0)[65]. Major prognostic factors in this group are the number of metastatic lymph nodes and the tumor burden. Tumor burden is reflected by whether the nodal metastases are clinically occult (micrometastases, as detected by sentinel or elective lymph node dissection) or clinically palpable (macrometastases).

In stage IV patients, the major prognostic factor is the site of distant metastases, with a poorer prognosis for visceral than for non-visceral (e.g. skin, subcutaneous, and distant lymph node) metastases. The median survival time for stage IV patients is 9 months, and the estimated 5-year survival rate is 10% when the serum LDH level is abnormally elevated. The main variables that predict survival are initial site of metastasis, disease-free interval before distant metastases, and stage of disease preceding distant metastases.

EVALUATION OF A PATIENT WITH SUSPECTED MELANOMA

Medical History

A thorough medical history should be taken, focusing especially on risk factors for the development of melanoma (see above), such as a personal or family history of melanoma, skin phototype I/II, extensive tanning bed use or PUVA treatment, childhood history of sunburns, genetic syndromes with skin cancer predisposition (e.g. xeroderma pigmentosum), and iatrogenic or acquired immunosuppression (e.g. solid organ transplant recipients, HIV infection). A detailed history of the specific lesion in question should be obtained. Was the lesion present at birth? Did the lesion develop in a pre-existing mole? Did it change in size or shape? Did it change in color or ulcerate? Was there itching or bleeding? What is the time course of change? Are there systemic symptoms such as weight loss, fatigue, headache or cough?[197] Other family members should be screened if either melanoma or atypical melanocytic nevi are present. All individuals at risk should be educated about the clinical features of melanoma and about sun protection measures.

Skin Investigation and Clinical Diagnosis

A total body skin examination (TBSE) has to be performed. An estimation of the total number of melanocytic nevi and of the number of clinically atypical melanocytic nevi should be noted, as well as the presence of congenital nevi. Atypical pigmented lesions should be examined by dermoscopy. Any lesion suspected of being melanoma should undergo biopsy. Excisional biopsy with narrow 1–2 mm margins is the preferred method of biopsy, as it prevents sampling error (e.g. missing a focus of melanoma arising in a precursor benign lesion) and enables the pathologist to assess the overall architecture of the lesion and accurately microstage the tumor. Superficial shave biopsies should be avoided, but deeper saucerization biopsies may be used for flat lesions or if the clinical suspicion of cutaneous melanoma is not high. The specimen should be sent to an individual experienced in the diagnosis of melanocytic tumors. A second opinion is sometimes necessary for difficult cases. Examination of lymph node basins should also be routinely performed.

Laboratory Investigations and Imaging

The evidence-based clinical practice guidelines (2008) for the management of melanoma in Australia and New Zealand had the following recommendation: following the diagnosis of localized primary cutaneous melanoma (stages I, II), routine laboratory investigations and imaging (e.g. chest radiography) are not required for asymptomatic patients. Additional investigators noted that such tests have limited, if any, value in the initial evaluation of asymptomatic patients with primary cutaneous melanoma 4 mm or less in thickness[198]. An American Academy of Dermatology task force recommended that initial imaging studies and blood work should be optional and most appropriately directed based on findings of a thorough medical history and physical examination[199]. In a study involving more than 200 asymptomatic patients with localized melanomas initially examined with chest radiography, the true-positive radiograph rate for lung metastases was 0%, with a false-positive rate of 7%[198].

A simple and effective examination technique which was first introduced in Europe is lymph node ultrasound[200]. The scar of the primary cutaneous melanoma, the lymphatic drainage areas, and the regional lymph node basin are examined by ultrasound with a 7.5–10 MHz probe. In one-third of patients, metastases can be detected before they become palpable with this technique. In some European countries, lymph node ultrasound is recommended for staging and follow-up of patients with melanomas >1 mm in thickness[201,202].

Serum markers for metastatic melanoma have been examined and the two most frequently employed markers are protein S100B and melanoma inhibitory activity (MIA). Comparative studies found a higher diagnostic sensitivity for protein S100B than for MIA[203]. A large US study found that for patients with surgically resected high-risk melanoma, a high baseline or increasing serum S100B level was an independent prognostic marker of risk for mortality[204]. Primarily in Europe, protein S100B is currently the most widely used serum marker

SYMPTOMS AND DIAGNOSTIC TESTS FOR METASTATIC MELANOMA		
Metastatic site (TNM)	**Symptoms**	**Diagnostic tests***
Skin, soft tissue metastasis (TxNxM1a), in-transit metastasis (TxN2cM0)	Papules or nodules that vary in color from skin-toned to pink–red to blue, brown or black; secondary ulceration or bleeding	Histopathologic examination
Brain metastasis (TxNxM1c)	Headache, nausea, seizures, focal weakness, visual disturbance, paresthesias	MRI, CT or PET-CT
Lung metastasis (TxNxM1b)	Chest pain, dyspnea, cough, hemoptysis	Chest radiograph, CT or PET-CT
Gastrointestinal or liver metastasis (TxNxM1c)	• GI: abdominal pain, signs of anemia (e.g. fatigue, chest pain), vomiting, constipation, melena • Liver: abdominal pain, jaundice	• CBC, CT or PET-CT; colonoscopy • Liver function tests, LDH; CT, PET-CT or MRI
Bone metastasis (TxNxM1c)	Pain, spontaneous fractures	Bone scan or PET-CT

*Always include a thorough medical history and physical examination as well as complete blood count (CBC) and blood chemistry including lactate dehydrogenase (LDH). Special procedures such as detection of soluble melanoma markers (e.g. S100, melanoma inhibitory activity [MIA] protein) are performed at selected melanoma referral centers, especially in Europe.

Table 113.12 Symptoms and diagnostic tests for metastatic melanoma. CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

SURGICAL TREATMENT OF PRIMARY CUTANEOUS MELANOMA		
Tumor thickness	**Excision margins (cm)**	**Comments**
In situ	0.5	Lentigo maligna of the face may be excised with 1 cm margins (especially when lesions are >1.5–2 cm in diameter) or treated by Mohs micrographic surgery or radiotherapy; postoperative topical imiquimod is often used
≤1 mm	1.0	Mohs micrographic surgery may be necessary in acral and facial melanomas
1.01–2 mm	1.0–2.0	
>2 mm	2.0	

Table 113.13 Surgical treatment of primary cutaneous melanoma. Evidence from available randomized trials is insufficient to address the optimal margins for the excision of primary cutaneous melanoma, but multiple expert international committees have produced fairly consistent guidelines, as summarized here. Of note, further investigative efforts will likely alter the standards of care over time. *Adapted from Sladden MJ, et al. Surgical excision margins for primary cutaneous melanoma. Cochrane Database Syst Rev. 2009;(4):CD004855.*

for the detection of melanoma metastasis, both at the time of staging and in conjunction with surveillance examinations, in patients with elevated risk for recurrence[201,202]. Of note, detection of circulating melanoma cells in the blood by tyrosinase/MART-1 reverse transcription–polymerase chain reaction (RT-PCR) was found by several investigators to have no predictive value.

Investigation of stage III/IV melanoma patients may include radiologic investigations such as CT of the chest, abdomen and pelvis and CT or MRI of the brain as well as positive emission tomography (PET)-CT (Table 113.12). For routine examinations and staging, CT remains the imaging technique of choice. Whereas CT is the most sensitive technique for the detection of lung metastases, intra-abdominal and soft tissue metastases are better detected by MRI, and the latter is often chosen for special clinical situations such as deciding on the operability of soft tissue metastases[205]. A significant advance in imaging for metastasis detection is PET scanning using 18F-fluorodeoxyglucose (FDG)[206]. It is based on the assumption that melanoma metastases have a higher metabolic rate than does normal tissue and utilize more glucose. PET is now being combined with CT technology and whole body PET-CT is the most sensitive technique for the detection of melanoma metastasis[207]. As PET-CT is an expensive examination technique, it should not be used indiscriminately.

MANAGEMENT

Management of the Primary Melanoma (Stage I and II)

Following histologic diagnosis, the primary cutaneous melanoma site should be re-excised with an appropriate margin determined by the Breslow depth (Table 113.13). The rationale for excisional margins is based on the capacity of melanoma cells to migrate away from the tumor origin, i.e. melanoma may extend wider or deeper than is visibly apparent. The major goal is to prevent local recurrence or persistent disease.

Excisional margins for primary cutaneous melanoma have changed remarkably over the past several decades. Until the 1980s, melanoma was often excised with a margin of 5 cm, independent of its tumor thickness. A WHO randomized trial demonstrated that 1 cm excisional margins were safe and effective for melanomas with a Breslow depth <1 mm[208]. A randomized trial focusing on intermediate-thickness melanoma (1 to 4 mm in depth) found that 2 cm margins were as effective as 4 cm margins in preventing local recurrences[209]. While current randomized trial evidence is insufficient with regard to optimal excisional margins, expert international committees have produced fairly consistent guidelines, as summarized in Table 113.13[202,210,211].

Margins of excision are also limited by surgically difficult anatomic sites such as the distal extremities, the mucous membranes and the face. Often, an individualized surgical approach must be undertaken[212]. For instance, lentigo maligna melanoma on the face may necessitate narrower margins and Mohs micrographic control of excisional margins may be employed to conserve anatomic structures. Lentiginous acral and mucosal melanomas are often poorly defined and multifocal with discrepancies between the clinically visible and histopathologic margins. As a result, local recurrences are more frequent in these types of melanoma. Therefore, removal can be achieved with increased safety margins (at least 1 cm) or by narrow margins with micrographic control (e.g. in subungual melanoma)[213,214,215].

Treatment of lentigo maligna with topical imiquimod rather than surgical excision is an area of debate. While some clinicians limit its use as a primary therapy to elderly patients with serious comorbidities or facial lesions whose surgical removal would lead to mutilation, others use it more routinely. Initial case series reported histologic clearance rates of 80-90%, but a recent study from Australia observed histologic clearance in only 53% of patients (20/38) when used for 12 weeks following excision of lentigo maligna with 5 mm margins[215a].

Local Recurrences

Local recurrence is defined as any recurrence within 2 cm of the scar from the primary melanoma excision[66] (Fig. 113.32). Recurrence results from extension of the primary tumor or intralymphatic spread. The overall risk of recurrence is approximately 4%, and is increased in thicker or ulcerated tumors as well as melanomas located on the head and neck or distal lower extremity[216]. Local recurrence is strongly associated with the development of in-transit, regional and distant metastases but it is not an independent prognostic indicator of survival in multivariate analysis[216]. There is evidence that patients with local recurrence, satellites and in-transit metastases have similar outcomes[217]. There is no evidence that patient survival is adversely affected if local recurrence results from incomplete excision of the primary melanoma (i.e. persistent disease), provided that the residual tumor is *in situ* or in a radial growth phase, is promptly re-excised, and there is no distant disease at the time of re-excision[218].

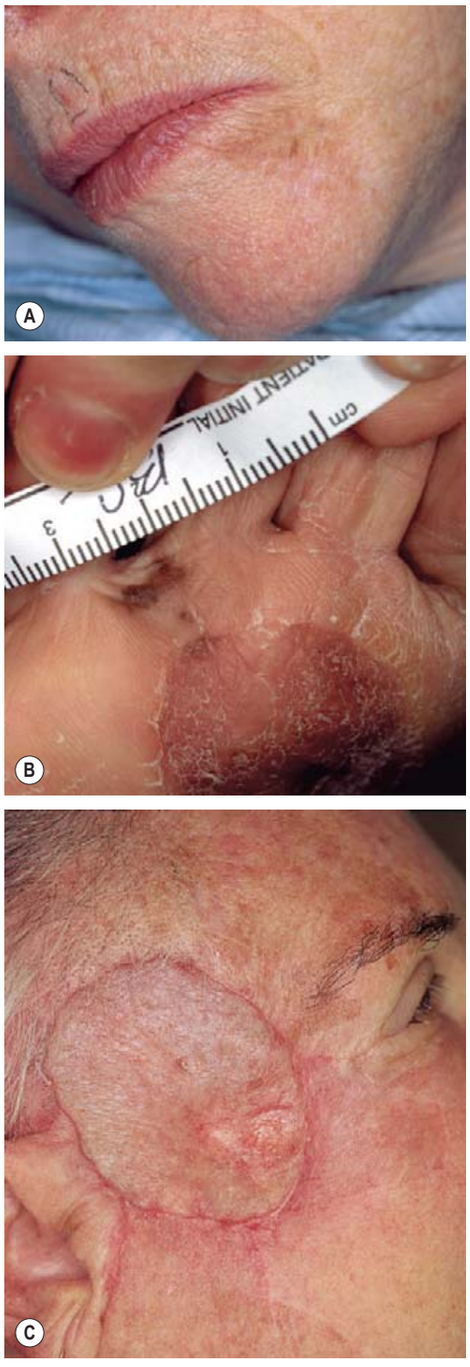

Fig. 113.32 Local recurrence of cutaneous melanoma. A Recurrent lentigo maligna along the upper lateral margin of the excision of the chin; inked lesion on the central upper lip is an actinic keratosis. **B** Recurrent *in situ* acral lentiginous melanoma at the 10 o'clock position on the split-thickness skin graft. **C** Amelanotic nodular recurrence of a desmoplastic melanoma within the skin graft. *Courtesy, Jean L Bolognia, MD.*

Management of Regional Metastatic Melanoma (Stage III)

Metastatic spread of melanoma is primarily regional in about 70% of patients, i.e. confined to the site of the primary melanoma and its draining lymph nodes. For example, metastasis may manifest as a clinically occult lymph node micrometastasis, as a rapidly growing clinically evident lymph node macrometastasis, or as in-transit metastasis.

Elective lymph node dissection and sentinel lymph node biopsy

Approximately 20% of patients with a cutaneous melanoma >1 mm in depth, plus no evidence (clinically or radiologically) of detectable nodal disease at presentation, will have microscopic lymph node involvement[219]. On the basis of a presumed migration of melanoma cells in an orderly fashion towards the draining lymph node, surgical resection of regional lymph nodes in all patients with intermediate- and high-risk tumors was previously recommended and was referred to as "elective lymph node dissection (ELND)". However, four multicenter, randomized, prospective trials in patients with primary melanoma did not show a survival benefit for patients treated with ELND plus wide re-excision as compared to wide re-excision alone[220–223].

As a consequence, a less traumatic procedure to identify regional metastatic disease was introduced, called the sentinel lymph node biopsy (SLNB)[224]. SLNB is based on the finding that the cutaneous site of the melanoma drains to one or more lymph node basins and particularly to one (or two but rarely more) lymph node, the sentinel node, which is the first site of deposition of metastatic cells. The draining lymph node basins for a given melanoma site and the approximate location of the sentinel node within that basin are identified and marked on the overlying skin preoperatively during lymphoscintigraphy performed in the nuclear medicine department. Intraoperatively, typically in conjunction with the wide local excision[206], technetium sulfur colloid and blue dye are injected into the skin surrounding the melanoma biopsy site. A small incision is made at the previously marked site overlying the sentinel node and a hand-held gamma counter and visual inspection are used to identify the "hot, blue" sentinel node(s), which is selectively biopsied and examined by serial sectioning using H&E stains combined with immunohistochemistry (S100, HMB45). If melanoma micrometastasis is identified, then a complete regional lymph node dissection is normally recommended. As the therapeutic benefit of complete lymphadenectomy after positive sentinel node(s) has not been demonstrated in clinical trials (as often the remainder of the lymph nodes have no evidence of metastasis), two large multicenter trials are presently being conducted to compare complete lymphadenectomy versus observation with lymph node ultrasound examinations in patients with lymph node micrometastasis.

Sentinel lymph node biopsy, followed by complete lymphadenectomy in the case of positive sentinel node(s), has meanwhile become a standard procedure in the staging and prognostication of primary cutaneous melanoma ≥1 mm in thickness. Numerous publications have identified the status of the sentinel lymph node as a strong prognostic factor for survival and recurrence[225–227], and the AJCC included it in the latest staging system for cutaneous melanoma (see Tables 113.9 & 113.10)[194]. In 2006, the randomized Multicenter Selective Lymphadenectomy Trial (MSLT-1) confirmed the prognostic value of SLNB, and found improved disease-free survival for the SLNB group and improved survival for SLNB-positive patients with complete lymphadenectomy as compared to patients developing macroscopic nodal metastasis in the control group, but no difference in overall survival[228].

Thus, based upon current data, SLNB is useful as a diagnostic and prognostic tool, but its usefulness as a therapeutic modality has not been established. Also, given the potential morbidity (chronic lymphedema) associated with the completion lymphadenectomy that is usually performed if the SLNB is positive, the question arises as to why SLNB should even be performed. There are basically four reasons to proceed with a SLNB in a person with a primary cutaneous melanoma >1 mm thick who has no clinically involved lymph nodes: (1) to obtain the most complete and accurate diagnostic and staging information possible for a patient who desires such data; (2) to institute early therapeutic complete lymph node dissection if there is evidence of micrometastases, providing improved disease-free survival but not overall survival; (3) to offer adjuvant therapy (interferon-α may slightly improve overall survival in selected patients); and (4) to gain entry into a clinical trial for new adjuvant therapies. Reasons *not* to proceed with SLNB include: (1) the patient is not interested in a complete lymphadenectomy or adjuvant therapy; and (2) he or she is content not knowing whether micrometastases exist.

Skin satellite and in-transit metastases

Satellite and in-transit metastases are recurrences that generally occur in the lymphatic vessels more proximally relative to the primary cutaneous melanoma and toward the regional lymph nodes. Patients generally have a poorer prognosis with frequent development of distant metastasis. However, occasionally, despite the development of numerous in-transit metastases, the disease remains localized to a lower extremity for years. The goal of treatment is maintenance of local control.

The treatment of choice for skin metastases is surgical, but systemic therapies should be considered if numerous or extensive lesions are not

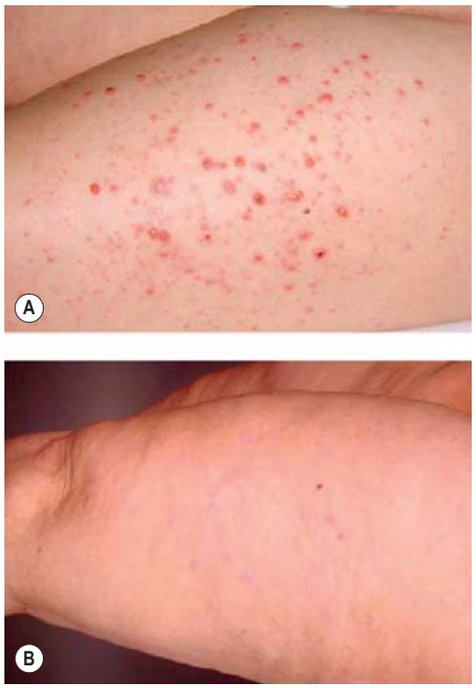

Fig. 113.33 Intralesional interleukin-2 (IL-2) treatment. A Multiple in-transit metastases were treated with intralesional low-dose IL-2 for 6 weeks. **B** Complete remission after 1 year, which persisted during the follow-up period of 7 years.

DOSAGE SCHEDULES FOR ADJUVANT THERAPY WITH INTERFERON-α

Schedule	Dose	Frequency	Duration	Indication
Low-dose	3 million IU sc	Days 1, 3 & 5 every week	18 months	Stage II–III
High-dose				
– Initiation	20 million IU/m^2 IV rapid infusion	Days 1–5 every week	4 weeks	Stage III
– Maintenance	10 million IU/m^2 sc	Days 1, 3 & 5 every week	11 months	Stage III
Pegylated				
– Initiation	6 mcg/kg body weight sc	Day 1 every week	8 weeks	Stage III
– Maintenance	3 mcg/kg body weight sc	Day 1 every week	Total 5 years	Stage III

Table 113.14 Dosage schedules for adjuvant therapy of melanoma with interferon-α. IV, intravenous; sc, subcutaneous.

amenable to surgery. For multiple lesions on a limb, isolated limb perfusion with melphalan, with or without tumor necrosis factor (TNF), has palliative value[229,230]. In stage III patients with satellite/in-transit metastases, the procedure may be curative, as indicated by reported 5- and 10-year survival rates of 40% and 30%, respectively. Alternative options include cryotherapy, laser therapy, and experimental approaches such as intralesional/topical IL-2 (Fig. 113.33), electrochemotherapy, miltefosine, interferon-α and imiquimod[231].

Clinically identified lymph node metastases

If lymph node metastasis is diagnosed clinically or by imaging techniques, complete lymph node dissection is considered standard therapy, which consists of an anatomically complete dissection of the involved nodal basin[202,210,211]. The extent of complete lymph node dissection is often modified according to the anatomic area of lymph node involvement, e.g. in the setting of inguinal lymphadenopathy, a deep groin dissection is recommended if the PET or pelvic CT scan reveals iliac and/or obturator lymphadenopathy.

Adjuvant therapy

The goal of adjuvant therapy is the elimination of clinically unapparent micrometastases. The major target population for adjuvant therapy is patients with resected high-risk stage II or III melanoma. Some trials have also targeted resected stage IV patients. A number of postsurgical adjuvant approaches have been tested, including systemic chemotherapy and immunotherapy using microbial agents such as bacille Calmette-Guérin (BCG) or *Corynebacterium parvum*[232]. None of these approaches were successful in randomized controlled trials.

The current recommendation is to include appropriate patients in well-controlled clinical studies in order to obtain valid data leading to recommendations regarding future adjuvant therapies. Currently, the major candidates for adjuvant therapy are recombinant biological response modifiers, in particular the intensively studied IFN-α. IFN-α is a type I member of the interferon family of proteins and has pleiotropic functions including induction of MHC class I expression, activation of natural killer (NK) cells and the maturation of dendritic cells; some of its activities may have direct or indirect antitumor effects[233]. It is important to distinguish high-dose IFN-α therapy with the aim of reaching maximally tolerated dosage (20 MIU/m^2 intravenously 5 days per week during the initiation phase, followed by 10 MIU/m^2 subcutaneously three times per week) from low-dose IFN-α therapy which is much better tolerated in terms of side effects (typically 3 MIU subcutaneously three times per week). Treatment regimens with pegylated IFN-α have also been established, which because of its prolonged half-life is given once weekly (Table 113.14).

High-dose IFN-α has demonstrated an improvement in relapse-free and overall survival compared to controls in two studies (ECOG 1684 and ECOG 1694). However, a beneficial effect on overall survival was not seen in a third high-dose IFN-α study (ECOG 1690). A recent study noted the association of the appearance of autoantibodies or clinical manifestations of autoimmunity during IFN-α-2b treatment with significant improvements in relapse-free survival and overall survival[234].

Toxicities from high-dose IFN-α include constitutional (flu-like) symptoms and neuropsychiatric (depression, suicidal intention), hematologic and hepatic side effects[235]. These toxicities have a major impact on the patient's quality of life and lead to dose modifications in two-thirds of patients during the first month of high-dose IFN-α therapy. IFN-α and now pegylated IFN-α are the only FDA-approved adjuvant therapies for melanoma in the US. The use of high-dose IFN-α adjuvant therapy has been questioned, especially in Europe, due to the inconsistent reports of its impact on overall survival and the considerable dose-dependent toxicity. For low-dose IFN-α, randomized studies have consistently reported a benefit with regard to relapse-free survival – and, in one trial, for overall survival – compared to untreated controls[236–238].

The large number of clinical trials with variations in dosage, schedule and duration of IFN-α administration, as well as different patient populations, has prompted several attempts to consolidate and review the available outcome data. A large meta-analysis of the available published data of 6067 patients from randomized clinical trials was reported in 2007, summarizing event-free survival (over 3700 events) and overall survival (over 3000 events) in patients with high-risk melanoma treated with IFN-α adjuvant therapy[239]. Clinical data were sorted by IFN dose: high (20 MIU/m^2), intermediate (5–10 MIU/m^2), low (3 MIU/m^2), and very low (1 MIU/m^2) doses. Groups were also stratified by duration of treatment (<6 months, 12–18 months, or >24 months). Although there was a statistically significant overall survival benefit for treatment of patients with IFN-α ($p = 0.008$), this assimilation did not find evidence of a clear difference in overall survival with different dose levels ($p = 0.8$) or durations of treatment ($p = 0.9$). Thus, adjuvant IFN improves overall survival of patients with stage II/III melanoma, though the absolute benefit in terms of survival rate at 5 years was small (~3%; 95% CI 1%–5%). In summary, there is a clear benefit for recurrence-free survival and a small benefit for overall survival with adjuvant IFN-α treatment regardless of dose, schedule, duration, or formulation (pegylation).

In spite of more than 20 years' experience with adjuvant IFN-α in melanoma, there are still some unanswered questions. *First*, the optimal dose remains unclear. It has been claimed that high-dose IFN-α leads to a higher rate of durable responses; however, this has

not been convincingly demonstrated. In the only randomized trial comparing high-dose versus low-dose IFN-α adjuvant treatment, improvement of recurrence-free survival was nearly identical for both regimens, and improvement of overall survival was not achieved by either regimen[240]. An initiation phase with modified high-dose IFN-α for 1 month followed by 18 months of low-dose IFN-α did not improve outcomes[241]. *Secondly*, the optimal treatment duration is unknown. The prolongation of low-dose IFN-α adjuvant treatment from 18 to 60 months was not associated with a survival benefit in a large randomized trial[242]. Interestingly, 1 month of treatment with a modified high-dose IFN-α regimen was not inferior as compared to a 1-year modified high-dose IFN-α treatment regimen in a randomized trial[243]. Presently, a large ECOG trial is looking at the reduction of high-dose IFN-α adjuvant treatment from 1 year to 1 month. *Thirdly*, the role of the pegylated formulation of IFN-α is not yet clear. A large EORTC trial tested pegylated IFN-α versus observation and found a benefit for disease-free but not for overall survival[244]. No superiority of pegylated IFN-α over classic IFN-α would be expected based on these results. Two large randomized multicenter trials in Europe are currently addressing this question. *Fourthly*, the optimal patient profile to benefit from adjuvant IFN-α therapy has not been clearly defined. Micrometastases in sentinel nodes and ulceration of the primary tumor were unequivocally associated with increased benefit in two large adjuvant IFN-α trials of the EORTC[244,245]. Therefore, patients fulfilling these criteria should be specifically offered adjuvant IFN-α treatment.

Management of Distant Metastases (Stage IV)

Despite new treatment options, the prognosis for patients with distant metastatic melanoma has not changed significantly over the past several decades, with 5-year survival rates of ~10% and a median survival time of around 9 months, with considerable inter-individual variation[246]. Differential survival is observed within the AJCC substages, that is soft tissue metastases only (M1a) versus lung metastasis (M1b) versus other visceral metastasis (M1c). For each of these disease sites, an abnormal LDH level is associated with a poorer prognosis (upstaging to M1c). By multivariate analysis, more than one metastasis, more than one organ involved, and older age at diagnosis are independently associated with poorer survival[246]. In a certain percentage of patients with few metastases and only one or two organs involved, surgical or other ablative treatment strategies with curative intent may be considered. When patients have failed to respond to previous therapies, a discussion regarding the option of enrolling in clinical trials is appropriate. In some patients, however, the focus is on palliative therapy with special emphasis on quality of life.

Surgery

Despite the well-known ability of melanoma to disseminate to multiple organs, resection of metastases may provide excellent palliation and, in selected patients, long-term survival[247]. Numerous studies have demonstrated clear and durable survival advantages for patients undergoing complete resection of metastatic melanoma. Factors that positively influence prognosis are isolated non-visceral metastasis and complete resection with free surgical margins. For certain indications, such as isolated lung metastases, median 5-year survival can approach 30% after surgical treatment. Patients rarely survive long-term with brain metastases but surgical resection may extend median survival to about 10 months, with a significant improvement in quality of life[248].

Radiation therapy

The efficacy of radiotherapy for melanoma is often understated due to unfavorable clinical results observed in early studies[249]. Radiotherapy can be administered to patients with unresectable disease, yielding relatively favorable results. Furthermore, radiotherapy is used successfully as a palliative maneuver for symptoms related to distant metastases in patients with incurable disease. Specific indications include pain control and stabilization of bones affected by metastases, spinal cord compression, brain metastases and local control of cutaneous disease. Studies do not support the administration of adjuvant radiotherapy following resection of regional lymph node metastases[250].

Whole brain radiotherapy combined with surgical resection has been the mainstay for treating cerebral metastases. This approach results in a median survival of about 10 months[251]. A newer development, providing at least similar results, is stereotactic radiosurgery utilizing either the so-called "Gamma Knife" or a linear accelerator. Up to five cerebral metastases can be treated, and the median survival was found to be 11.1 months from time of diagnosis. One-year and 2-year survival was 48% and 18%, respectively[252]. A benefit of radiosurgery is the virtual absence of perioperative complications, with a reduced adverse impact on quality of life compared to surgery or whole brain radiotherapy.

Systemic therapy

The mainstay of therapy in patients with distant metastases is systemic therapy. The systemic agents that have been used include chemotherapy, immunotherapy and combination biochemotherapy. A recent and very promising development has been the introduction of molecularly targeted therapy (see Table 113.1)[253,254]. Especially in the past, the overall results with many of these therapies have been sufficiently disappointing such that participation in clinical trials should be considered, if not encouraged, for this patient population.

Chemotherapy

Over the past four decades, cytotoxic chemotherapy has had a low but reproducible level of activity against metastatic melanoma (Table 113.15). Drugs employed include dacarbazine (DTIC)/temozolomide, carboplatin/cisplatin, vindesine/vinblastine, BCNU/fotemustine and paclitaxel/docetaxel[202]. Unfortunately, despite the identification of multiple chemotherapeutic agents with activity against melanoma as demonstrated *in vitro* and in phase I/II clinical trials[255,256], this has not translated into a significant impact on survival.

The most widely used single chemotherapeutic agent remains dacarbazine (DTIC). It has shown the greatest effectiveness as a single agent in most trials and was equally effective when combined with IFN-α or tamoxifen. With DTIC as a single agent, an approximately 10–15% response rate can be achieved with a median response duration of 5 to 6 months. The oral alkylating agent temozolomide (a prodrug of MTIC, the active metabolite of DTIC) has some efficacy in CNS metastasis and equal efficacy to DTIC[257,258]. Fotemustine is a member of the nitrosourea family and has some efficacy in melanoma, including brain metastases[259].

Combination chemotherapy regimens like CVD (cisplatin, vinblastine, DTIC) and BOLD (bleomycin, vincristine, lomustine, DTIC) have induced responses in metastatic lesions typically unresponsive to DTIC alone, including in the liver, bone and brain, but have failed to improve overall patient survival[260]. Another approach is chemohormonal therapy using tamoxifen in addition to chemotherapy. The four-drug combination cisplatin, carmustine (BCNU), DTIC and tamoxifen, also referred to as the "Dartmouth regimen", achieved high response rates in earlier trials (up to 55%), but a phase III trial did not show a statistical survival benefit compared to DTIC alone[261]. Therefore, DTIC remains the reference standard for chemotherapy in stage IV melanoma.

Immunotherapy

Immunotherapy builds on the concept that the immune system is able to fight cancer and melanoma is one of the prototypic immunogenic cancers. Therefore, a therapeutic effect might be achieved by infusing effectors of the immune system such as cytokines, killer cells or antibodies. Presently, high-dose IL-2 treatment, CTLA-4 blockade, cancer vaccination and adoptive T-cell transfer are the most promising strategies.

High-dose interleukin-2 treatment

High-dose recombinant IL-2 received US FDA approval for the treatment of metastatic melanoma in 1998. An objective response rate of approximately 16% was observed in phase II trials in patients with metastatic melanoma[262,263]. The inpatient high-dose regimen consisted of 600 000 U/kg of IL-2 every 8 hours for up to 14 doses. A small percentage of patients (~5%) experienced long-term, durable complete responses, which has been interpreted as potential cure. However, this therapy has not been shown to improve overall survival and has never been evaluated in a phase III setting. In addition, IL-2 treatment-related toxicity is severe and requires inpatient intensive care. A recent study combined a gp100 peptide vaccine with high-dose IL-2 and both the

MEDICAL TREATMENT OPTIONS FOR METASTATIC MELANOMA		
Medication	**Dose**	**Objective response rates***
	SINGLE AGENTS	
Dacarbazine (DTIC), 5 days	250 mg/m^2 IV daily for 5 days every 3–4 weeks	12–17%
Dacarbazine (DTIC), 1 day	800–1200 mg/m^2 IV on one day every 3–4 weeks	5–23%
Temozolomide	150–200 mg/m^2 po daily for 5 days every 4 weeks	13–21%
Fotemustine	100 mg/m^2 IV on days 1, 8 and 15; then 5-week pause, then repeat single dose every 3 weeks	7–24%
Vindesine	3 mg/m^2 IV every 14 days	12–26%
Interferon-α	9–18 million IU/m^2 sc 3× weekly	(13–25%)
Interleukin-2	600 000 IU/kg as 15-min infusion IV every 8 hours for 5 days (total of 14 doses). Repeat every 2 weeks, depending upon response and toxicity	(16–21%)
	COMBINED REGIMENS	
DTIC (or temozolomide) + interferon-α	DTIC 850 mg/m^2 IV day 1 (or temozolomide 150 mg/m^2 po days 1–5); interferon-α-2a/b 3 million IU/m^2 sc days 1–5, then 5 million IU/m^2 sc 3× weekly in weeks 2–4; repeat every 4 weeks	14–28%
Vindesine + interferon-α	Vindesine 3 mg/m^2 IV day 1; interferon-α-2a/b 5 million IU/m^2 sc 3× weekly; repeat every 2 weeks	24%
BHD	BCNU 150 mg/m^2 IV day 1 in every other cycle; hydroxyurea 1500 mg/m^2 po days 1–5; DTIC 150 mg/m^2 IV days 1–5 every 4 weeks	13–30%
BOLD	Bleomycin 15 mg IV days 1+4; vincristine 1 mg/m^2 IV days 1+5; CCNU 80 mg/m^2 po day 1; DTIC 200 mg/m^2 IV days 1–5; repeat every 4–6 weeks	20–40%
DVP	DTIC 250 mg/m^2 IV days 1–5; vindesine 3 mg/m^2 IV day 1; cisplatin 100 mg/m^2 IV day 1; repeat every 3–4 weeks	30–45%
DVP	DTIC 450 mg/m^2 IV days 1+8; vindesine 3 mg/m^2 IV days 1+8; cisplatin 50 mg/m^2 IV days 1+8; repeat every 3–4 weeks	25%
DBCT	DTIC 220 mg/m^2 IV days 1–3; BCNU 150 mg/m^2 IV day 1 of every other cycle; cisplatin 25 mg/m^2 IV days 1–3; tamoxifen 2 × 10 mg po daily; every 3–4 weeks	20–30%
CarboTax	Carboplatin AUC6 IV day 1, after four cycles reduce to AUC4; paclitaxel 225 mg/m^2 IV day 1 every 3 weeks, after four cycles reduce to 175 mg/m^2	12% (second line)

*Objective response rates were ascertained from randomized controlled clinical trials, or, if not available, from phase II trials or retrospective studies (in brackets). For details, see Garbe et al.[202,254a].

Table 113.15 Medical treatment options for metastatic melanoma. See Table 113.1 for newer therapeutic approaches to melanoma. IV, intravenous; po, orally; sc, subcutaneous.

response rates and progression-free survival were significantly improved[264].

Cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) blockade

Seemingly one of the most potent immunotherapeutic approaches in melanoma is CTLA-4 blockade[265,266]. Full T-cell activation requires stimulation through the T-cell receptor as well as a costimulatory signal provided by the binding of B7 on an antigen-presenting cell to CD28 on the T cell. CTLA-4 is a homologue of CD28 and is an inhibitory T-cell receptor that is upregulated following T-cell activation. The normal function of CTLA-4 is to compete with CD28 to bind B7 in order to downregulate T-cell activation, acting as a natural "brake" by removing the costimulatory signal. The CTLA-4–B7 interaction can be blocked with an anti-CTLA-4 monoclonal antibody, which has a higher affinity for CTLA-4 than B7. Thus, the inhibitory signal is prevented and the "brake" on T-cell activation released. Two fully human anti-CTLA-4 monoclonal antibodies (mAbs) have been investigated, tremelimumab and ipilimumab, with the latter recently receiving US FDA approval for the treatment of metastatic melanoma[266a,266b]. As a single agent, objective response rates vary from 7–15%, with a median duration of 20 months. At three years, the survival rate for ipilimumab plus dacarbazine was 20.8% versus 12.2% for dacarbazine alone. Although responses to anti-CTLA-4 mAbs are durable, they may take as long as 12 weeks or even longer to develop[267]. Side effects with CTLA-4 blockade are autoimmune-related, but less acute than those observed with high-dose IL-2 therapy and are manageable. Presently, studies are ongoing to combine CTLA-4 blockade with vaccination treatments[268] and radiotherapy.

Cancer vaccines

Cancer vaccines have been pursued in hopes of enhancing immune recognition and effector antitumor immune responses via improved antigen presentation and the ability to elicit effector memory T-cell responses that are durable[269,270]. Increased knowledge of the relevant antigenic epitopes capable of eliciting antitumor immunity has prompted a variety of vaccine approaches. Although vaccines are well tolerated, they rarely have been monitored with methods that are now recognized to be critical for detecting whether or not the vaccine induced an immune response. Not surprisingly, the large phase III trials of older crude tumor cell vaccines have not demonstrated robust clinical evidence of antitumor activity either in advanced disease or in the adjuvant setting.

Peptide vaccines are a promising vaccine category. Peptide vaccines have been studied in large, multicenter ECOG trials in the US[271]. These studies in patients with advanced metastatic melanoma revealed the induction of immune responses, e.g. more than a third of vaccinated patients had increased T-cell production of IFN-γ as detected by ELISPOT. Of interest, those patients who demonstrated immune response to the triple peptide (gp100, MART-1/Melan-A, and tyrosinase HLA-A2 epitopes) had significantly improved survival that was nearly double that of patients who did not develop immunity to one or more of the peptide vaccine epitopes.

Adoptive cell therapy

To date, adoptive cell therapy has yielded some of the most dramatic responses among patients with metastatic melanoma. Objective response rates in a highly selected patient population have been stated to range between 49% and 72%[272,273]. Adoptive cell therapy as

undertaken by the group based at the National Cancer Institute is complex and costly, involving multiple steps: first, specifically sensitized antitumor lymphocytes must be isolated from the patient's tumor or stimulated *in vitro* with autologous melanoma cells. For this purpose, tumor-infiltrating lymphocytes are cultured *in vitro* in IL-2-containing media, exhibiting MHC-restricted recognition of the autologous melanoma cells. Secondly, the antitumor lymphocytes have to be expanded *in vitro* to large numbers as the efficacy of adoptive cell therapy depends on the presence of large numbers of antitumor lymphocytes capable of recognizing the melanoma cells and destroying the cancer cells *in vivo*. The ideal number for the adoptive transfer is more than 10^{11} cells. Because objective clinical responses have been associated with cells that were cultured for shorter time periods (14 days), a protocol for rapid expansion has been developed[274], utilizing IL-2, anti-CD3 antibodies, and irradiated allogeneic feeder cells.

The third step entails lymphodepletion which is performed to prepare the patient for adoptive cell transfer. Seven days before the adoptive transfer, a non-myeloablative lymphodepleting regimen consisting of cyclophosphamide and fludarabine is administered[272]. It has been suggested that this be supplemented with total body irradiation in single fractions of 2 Gy or with 12 Gy administered as 2 Gy twice a day for 3 days[273]. Fourthly, the adoptive cell transfer, accompanied by treatment with high-dose IL-2 for 3 days, is performed. The tumor-infiltrating lymphocytes are administered as a bolus intravenous infusion over 0.5–1 hours and the high-dose IL-2 treatment is then started within 24 hours. Patients who received total body irradiation additionally received autologous cryopreserved $CD34^+$ hematopoietic stem cells previously obtained from a granulocyte colony-stimulating factor-mobilized apheresis. After non-myeloablative but lymphodepleting chemotherapy, adoptive cell transfer therapy (n = 35) resulted in objective response rates of 51%[121]. By intensifying the lymphodepleting therapy through the addition of total body irradiation with a total dose of 12 Gy (n = 25), the response rate could be increased to 72%[273].

It is important to mention that this therapeutic approach is not generally available. It is performed primarily at the National Cancer Institute in the US and only a few other institutions in the world have developed these protocols[275–277]. The procedure is very complex and has several critical steps, such as the isolation of the tumor-infiltrating lymphocytes and their *in vitro* expansion, which is labor-intensive as well as costly. Finally, the patients must have an excellent performance status with no other severe co-morbidities. Therefore, only a few patients per year have been included in phase II studies, and, to date, no phase III study has been initiated.

Molecularly targeted therapy

As described above, ongoing molecular studies have identified the signaling pathways involved in melanoma progression and the genes that encode their components. These studies have provided molecular targets for melanoma therapy (see Table 113.1)[16,278,279].

Tumor genotyping indicates that between 50% and 60% of melanomas harbor activating mutations in *BRAF*, leading to constitutive activation of the RAS/RAF/MEK/ERK (MAPK) signaling pathway that regulates cell proliferation (see Fig. 113.2). A specific point mutation in *BRAF*, which leads to the substitution of glutamic acid (E) for valine (V) at codon 600, hence V600E, accounts for 90% of these mutations. Oral small molecule inhibitors that selectively target the mutant BRAF kinase have been developed and vemurafenib (PLX4032) was recently approved by the FDA based upon the results of a phase III clinical trial comparing it to DTIC[16,280,281,281a]. In patients with metastatic melanoma carrying the V600E mutation who received vemurafenib at the maximum tolerated dose of 960 mg twice daily, a 50% response rate was reported. Tumor responses were rapid with onset seen by PET scan as early as 2 weeks into treatment. Other similar compounds are under development by different pharmaceutical companies (see Table 113.1)[16,280], but there are issues with drug resistance due to alternative activation of the signaling pathway and the development of keratoacanthoma- and cutaneous SCC-like lesions.

For a smaller subgroup of melanoma patients, mutations in the KIT receptor gene represent another promising target for systemic melanoma therapy. Based on one analysis, KIT mutations and/or amplifications were found in about 30–40% of patients with chronic sun-damaged, mucosal or acral lentiginous melanomas (see Fig. 113.1)[273,282]. Anecdotal reports indicate that inhibitors of KIT, including imatinib, dasatinib and nilotinib, may benefit these patients who can be identified using commercially available assays. This hypothesis is currently being tested in several ongoing clinical trials.

In the further development of systemic targeted therapies for melanoma, combinations of selective BRAF inhibitors plus other targeted agents that inhibit downstream or parallel signaling molecules such as MEK, PI3 kinase, AKT and mTOR are considered the most promising at this time[283,284](see Fig. 113.2). It is very likely that combined treatments targeting several molecules simultaneously will be the treatment strategy in the future. Also, combinations of targeted molecules with cytotoxic agents is possible. Interestingly, blockade of the MAPK pathway did not show synergistic actions with cytotoxic drugs, whereas inhibition of the PI3K/AKT pathway appeared to lead to increased chemosensitivity[285,286].

MELANOMA SURVEILLANCE

Protocols for the longitudinal care of melanoma patients vary worldwide and there are no generally accepted guidelines. The primary objectives are to identify potentially curable locoregional recurrences and to identify additional primary cutaneous melanomas. Lifelong follow-up of these patients is important because of: (1) the significant risk of second primary cutaneous melanomas (3.5–4.5%); (2) the risk of local recurrence (~4%; greatest in the first 2–5 years after initial diagnosis and in thicker/ulcerated tumors and those on the head/neck/distal legs); (3) the risk of ultra-late recurrence (>15 years), which is unpredictable but does occur; and (4) the increased risk of other cutaneous and non-cutaneous malignancies.

Most stage I/II cutaneous melanomas will present with locoregional recurrence, while stage III/IV patients most often present with systemic metastases. The latter group is also typically followed by an oncologist. Recommendations for the frequency of dermatologic visits varies internationally and amongst practitioners. As 90% of all recurrences occur during the first 5 years following primary diagnosis (with the greatest risk in the first 2 years), most experts recommend dermatologic visits one to four times per year for 2 years after diagnosis (depending on risk factors and frequency of oncologic visits) and then every 6 to 12 months thereafter for life. The frequency is also influenced by the number of melanocytic nevi, common and atypical, and the number of primary cutaneous melanomas.

Dermatologic visits should include: (1) updates on the medical history; (2) review of systems (e.g. any new or changing lesions; new "lumps or bumps," weight loss, fatigue, headache or cough); (3) TBSE; (4) examination and palpation of the melanoma scar/excision site and surrounding area for local recurrences or in-transit metastases; (5) examination of lymph nodes; (6) laboratory and radiologic tests as indicated by signs and symptoms. Patients should be counseled to adhere to sun-protective measures; perform skin self-examinations at home; and to take an oral vitamin D supplement. Family members should also be encouraged to undergo TBSEs.

Although there has been an ongoing debate regarding the value of follow-up examinations[287] (some authors doubt that early detection of metastases has a beneficial effect on patient survival and that it may only prolong the patient's period of suffering), a review of the literature on early detection and on resection of melanoma metastases demonstrates the following[288]:

- For in-transit metastases and regional lymph node metastases, the tumor volume of the metastatic nodules at the time of diagnosis has prognostic significance. Either the number of nodes involved or the diameter of the largest node has demonstrated prognostic importance. Therefore, early detection appears to affect the cure rate in stage III disease.
- With distant metastases, surgical resection of all recognizable metastases (if possible) prolongs survival.

Therefore, early detection of melanoma metastases may contribute to prolongation of survival. Lastly, in a prospective follow-up study of more than 2000 patients, recurrences were classified as diagnosed in either an early or a late phase of development, and patients diagnosed in an early phase had significantly more favorable odds of recurrence-free and overall survival than those in a late phase[289,290].

Vascular Neoplasms and Neoplastic-like Proliferations

114

Paula E North and Jay Kincannon

Chapter Contents

Benign vascular neoplasms and reactive hyperplasias *1915*
Borderline and low-grade malignant vascular neoplasms *1928*
Malignant vascular neoplasms *1935*
Perivascular neoplasms and neoplastic-like proliferations *1937*

INTRODUCTION

In this chapter we use the term *neoplasm* synonymously with *tumor* in a general, albeit imperfect[1], sense, consistent with its common usage: *an abnormal proliferation ("new growth") of cells that appears to be relatively autonomous (i.e. not reactive)*. Of note, common infantile hemangiomas are discussed separately (see Ch. 103) as are telangiectatic lesions (see Ch. 106) and vascular malformations (see Ch. 104); the latter, however, may be associated, in some patients, with a number of the cellular vascular proliferations discussed herein. Several entities with established or suspected features of reactive processes that mimic neoplasms are included in this chapter (Table 114.1) as is Kaposi sarcoma, a virus-associated and possibly virus-induced process of as-yet-uncertain position on the hyperplasia–neoplasia spectrum, but with an associated mortality rate. Two benign vascular proliferations of more seemingly straightforward infectious etiology (bacillary angiomatosis and verruga peruana) are covered elsewhere (see Ch. 74). With these caveats in mind, a broad working classification of vascular neoplasms and neoplastic-like conditions is presented in Table 114.1. Vascular neoplasms with classic associations with syndromes or laboratory findings appear in Figure 114.1.

BENIGN VASCULAR NEOPLASMS AND REACTIVE HYPERPLASIAS

Intravascular Papillary Endothelial Hyperplasia (PEH)

Synonyms: ■ Masson's lesion ■ Masson's pseudoangiosarcoma ■ Masson's tumor ■ Masson's hemangio-endotheliome vegetant intravasculaire

Key features

- Not a specific disease entity, but rather a distinct histopathological pattern that can be confused with angiosarcoma
- The primary or "pure" form is not associated with a pre-existing vascular anomaly and appears as a solitary, slowly growing, often painful nodule located within a dilated dermal, subcutaneous or submucosal vein
- Secondary forms are associated with venous malformations and other vascular anomalies prone to thrombosis
- Rare forms are extravascular, probably arising within hematomas
- Thought to represent an unusual, exuberant response of endothelial cells to organizing thrombus

Introduction

Masson first described this process in 1923 in hemorrhoidal veins, terming it *hemangio-endotheliome vegetant intravasculaire*, and interpreted it as a neoplastic process mimicking angiosarcoma. In 1932, Henschen re-interpreted the process as reactive, and in 1971 Kauffman and Stout noted its occurrence not only in thrombosed vessels but also in a hematoma, further demonstrating the potential for confusion with soft tissue angiosarcoma. A lymphatic vessel counterpart of Masson's lesion was reported in 1979 in a cystic lymphatic malformation[2].

Epidemiology

Papillary endothelial hyperplasia (PEH) shows a slight female predominance, most pronounced for the rare extravascular examples[3]. Although lesions can occur at any age, most are in adults, with an average age of 34 years. A history of trauma was elicited in a small minority of patients[3].

Pathogenesis

Areas of papillary endothelial hyperplasia can, in most cases, be seen to merge with definitive thrombus material, in support of the notion that they represent an unusual form of thrombus organization.

Clinical features

Primary lesions of superficial tissues appear as solitary, firm masses, often with red or blue discoloration of the overlying skin or mucosa. The history is typically one of slow growth over a period of several months or years. These occur most commonly within veins of the head and neck and, interestingly, the fingers, but they may also arise elsewhere[3]. In a study of 314 cases, 56% were of the primary form, 40% were associated with other vascular lesions, and 4% appeared extravascularly[3]. Clinical features of the secondary forms are those of the underlying vascular anomaly.

Pathology

Intravascular examples may be limited to the confines of a single thin-walled vein or may arise, often multifocally, within pre-existing vascular lesions such as venous malformations, glomuvenous malformations (glomangiomas), spindle cell hemangiomas and pyogenic granulomas (Fig. 114.2). Foci of intravascular papillary endothelial hyperplasia are extremely common in venous malformations and serve to distinguish these low-flow lesions from high-flow arteriovenous malformations. Rarely, the involved vessel wall is ruptured, allowing the proliferative vascular process to spill out into the adjacent stroma. Extravascular examples that on serial sectioning show no evidence of a surrounding blood vessel wall may have arisen within an organizing hematoma[3].

Early lesions show growth of endothelial sprouts into fibrinous thrombus material, dividing it into papillary fronds lined by a single layer of plump endothelial cells with minimal mitotic activity and no significant cytologic atypia (Fig. 114.2, insert). The early fibrin cores of the papillae become collagenized and hyalinized with time, and the endothelial lining becomes thin and attenuated. Lesional papillae may fuse to form an anastomosing meshwork of vessels separated by connective tissue stroma that mimics angiosarcoma. However, the relatively high mitotic rate, striking pleomorphism and necrosis that characterize angiosarcoma are lacking[4].

Differential diagnosis

The clinical appearance of these lesions is nonspecific, and diagnosis relies on microscopic examination. The most important differential diagnostic consideration for the pathologist is well-differentiated angiosarcoma.

A WORKING CLASSIFICATION OF VASCULAR TUMORS AND ANOMALIES
REACTIVE CONDITIONS
• ***Intravascular papillary endothelial hyperplasia***
• ***Reactive angioendotheliomatosis***
– ***Intravascular reactive angioendotheliomatosis***
– ***Diffuse dermal angiomatosis***
• Eruptive pseudoangiomatosis (self-limited exanthem of bright-red angioma-like lesions, originally described in children)
VASCULAR AND LYMPHATIC MALFORMATIONS (see Ch. 104)
• Capillary malformation (port-wine stain)
• Venous malformation
• Lymphatic malformation (microcystic and macrocystic)
• Mixed capillary/venous/lymphatic malformation ("lymphangioma")
• Arteriovenous malformation
• Verrucous "hemangioma"
TELANGIECTASIAS (see Ch. 106)
• Generalized essential telangiectasia
• Unilateral nevoid telangiectasia
• Hereditary hemorrhagic telangiectasia
• Hereditary benign telangiectasia
• Angioma serpiginosum
• Spider nevus
• Venous lake
• ***Angiokeratoma*** (exception is angiokeratoma circumscriptum, which represents a capillary/lymphatic or capillary malformation)
BENIGN VASCULAR NEOPLASMS
• Infantile hemangioma (see Ch. 103)
• Congenital hemangioma (see Ch. 103)
• ***Cherry angioma***
• ***Sinusoidal hemangioma***
• ***Hobnail hemangioma (targetoid hemosiderotic hemangioma)***
• ***Tufted angioma***
• ***Multifocal lymphangioendotheliomatosis with thrombocytopenia***
• ***Glomeruloid hemangioma****
• ***Microvenular hemangioma****
• ***Angiolymphoid hyperplasia with eosinophilia (ALHE)****
• ***Pyogenic granuloma (lobular capillary hemangioma)****
• ***Spindle cell hemangioma***†
• Epithelioid angiomatous nodule (debate as to whether it is a variant of epithelioid hemangioma or ALHE)
• Papillary hemangioma
• Acquired elastotic hemangioma (hobnail endothelial pattern in association with solar elastosis)
• Cutaneous pseudoangiomatous stromal hyperplasia (primarily encountered in the breast)
BORDERLINE AND LOW-GRADE MALIGNANT VASCULAR NEOPLASMS
• ***Kaposiform hemangioendothelioma***
• ***Dabska-type hemangioendothelioma (papillary intralymphatic angioendothelioma [PILA])***
• ***Retiform hemangioendothelioma***
• ***Epithelioid hemangioendothelioma***
• ***Kaposi sarcoma***
MALIGNANT VASCULAR NEOPLASMS
• ***Angiosarcoma***
PERIVASCULAR NEOPLASMS AND NEOPLASTIC-LIKE CONDITIONS
• ***Glomus tumor (proper)***
• ***Glomuvenous malformation ("glomangioma")***
• ***Infantile-type hemangiopericytoma/myofibromatosis***
• Adult-type hemangiopericytoma
• Glomangiopericytoma
• Myopericytoma
• PEComa (*p*erivascular *e*pithelioid *c*ell tumor)‡
*Also viewed as a reactive condition.
†Also viewed as a vascular malformation.
‡A spectrum of mesenchymal tumors that includes clear cell "sugar" tumor of the lung, angiomyolipoma, lymphangiomyomatosis, clear cell myomelanocytic tumor, and the rare *cutaneous* tumors with a similar morphology and phenotype.

Table 114.1 A working classification of vascular tumors and anomalies. Entities covered in this chapter are in bold italics.

Treatment

Surgical excision is usually curative. Local recurrences may occur when the lesion is superimposed on a vascular malformation that may generate new foci of endothelial hyperplasia.

Reactive Angioendotheliomatosis

Key features

- Rare, self-limited process occurring exclusively in the skin and characterized histologically by a dense proliferation of small capillaries
- The most common form is predominantly intravascular, resulting in luminal obliteration of pre-existing dermal vessels; many of these patients have vaso-occlusive disorders or systemic infections
- Should be distinguished from *intravascular large cell lymphoma (B or NK/T)*, an angiotropic lymphoma erroneously termed *malignant angioendotheliomatosis* prior to the advent of discriminating immunohistochemistry

Introduction

Angioendotheliomatosis has historically been considered to be a single disease entity, divided into benign and malignant variants. As such, the large pleomorphic cells found within blood vessels in malignant angioendotheliomatosis were thought to be transformed endothelial cells. More recently, immunohistochemical studies have convincingly demonstrated that these cells are neoplastic lymphocytes. Accordingly, *malignant angioendotheliomatosis* has been renamed *intravascular large cell lymphoma (B or NK/T)* (see Ch. 119). The benign form is a true angioendotheliomatosis and is considered reactive.

Epidemiology

Reactive angioendotheliomatosis is rare and although it can occur at any age, the age of onset often reflects that of any associated systemic disorder. While many cases are idiopathic, this vascular proliferation is frequently associated with systemic disorders such as bacterial endocarditis, monoclonal gammopathies (including type I cryoglobulinemia), antiphospholipid syndrome, renal transplantation, hepatic disease and rheumatoid arthritis. The diffuse dermal angiomatosis variant, whether on the leg or the breast[5], is associated with atherosclerosis and cigarette smoking.

Pathogenesis

Reactive angioendotheliomatosis is a benign self-limited process. Its frequent association with various systemic conditions has led some investigators to propose that the capillary proliferation may be caused by a circulating angiogenic factor[6]. However, the fact that many of the disorders associated with this process cause vascular occlusion or tissue ischemia suggests that a local, hypoxia-induced increase in vascular endothelial growth factor (VEGF) may be playing a role. In addition, immunological factors may contribute to the proliferative process.

Clinical features

Although erythematous nodules or plaques, often with superimposed petechiae or ecchymoses, are the characteristic primary lesions, the spectrum ranges from erythematous macules to tumor-like masses. Sites of involvement can vary, but the most common is the lower extremities. Focal ulceration may be evident, especially in the diffuse dermal angiomatosis variant.

Pathology

In this predominantly dermal, but also occasionally subcutaneous, process, there is a poorly marginated proliferation of closely packed capillaries lined by plump endothelial cells rimmed by small numbers of pericytes. The pattern of proliferation is highly variable both within and between lesions and is typically described as diffuse and/or lobular[7]. Focally, more dilated capillaries may be present and foci of hemosiderin

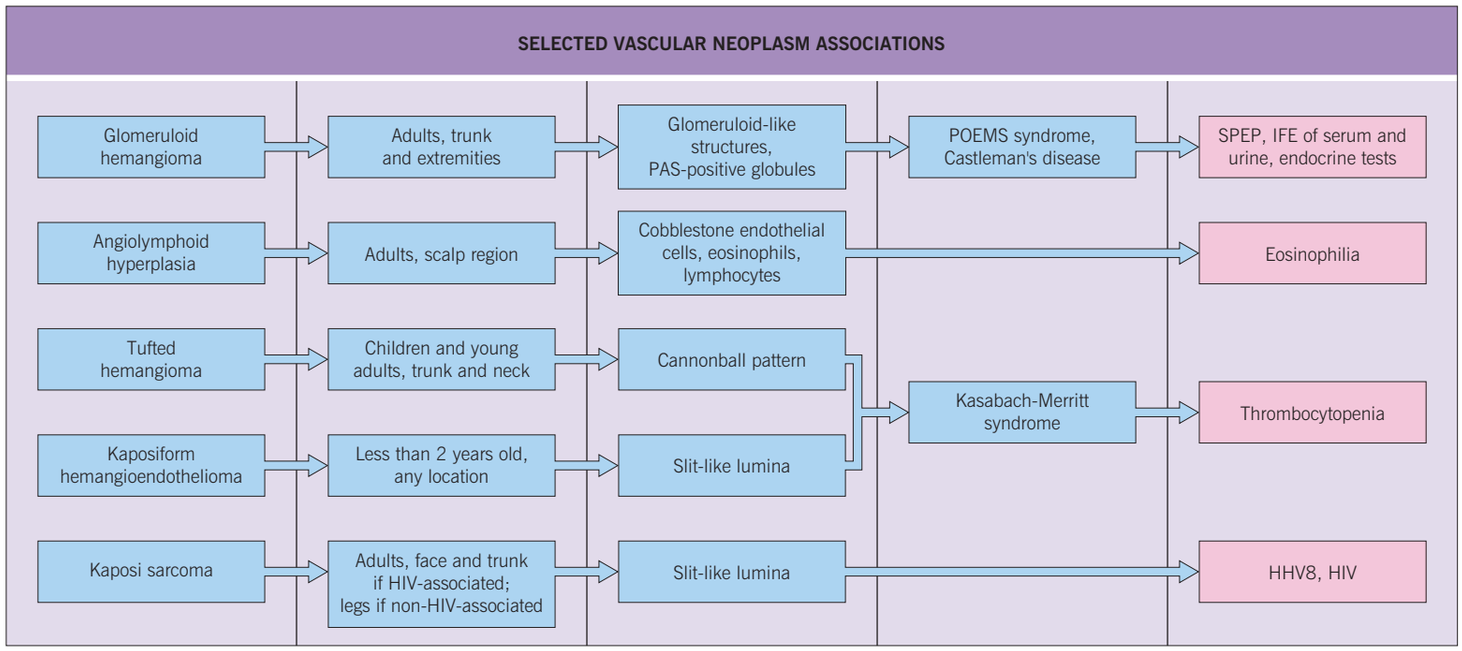

Fig. 114.1 Selected vascular neoplasm associations. IFE, immunofixation electrophoresis; SPEP, serum protein electrophoresis. HHV8, human herpesvirus 8; HIV, human immunodeficiency virus, PAS, periodic acid-Schiff stain.

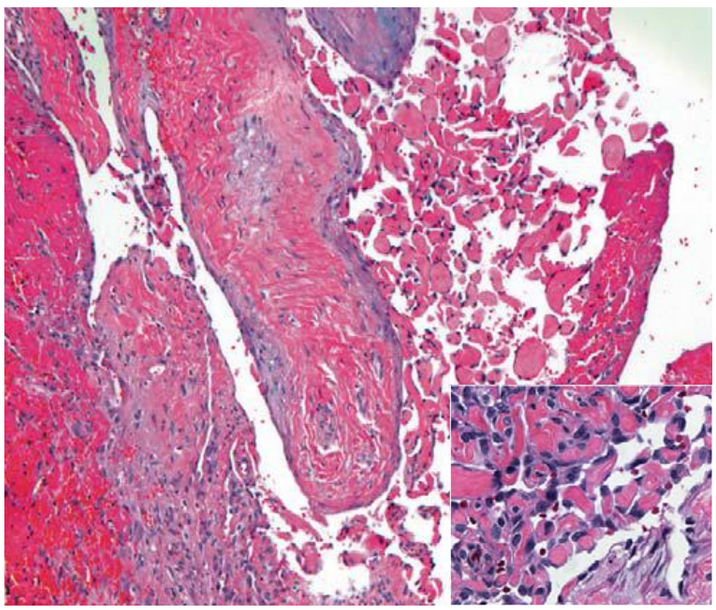

Fig. 114.2 Histology of papillary endothelial hyperplasia. Hyperplastic endothelial cells line stromal papillae formed within organizing thrombus material. Complex networks of recanalizing thrombus may mimic angiosarcoma (insert).

deposition, fibrin microthrombi and/or mild chronic inflammation are relatively common. Immunohistochemical positivity for endothelial markers such as CD31 and von Willebrand's factor, and focally for pericyte/smooth muscle-associated actins, confirms the cellular composition. Cytologic atypia is absent and mitotic figures are rare to absent.

The capillary lumina are small and may be occluded by fibrin thrombi and bulging endothelial cells (Fig. 114.3A). In many cases, the proliferating capillaries appear to be contained within a larger, pre-existing vessel, obliterating its lumen, but sometimes the proliferation extends directly between collagen bundles (Fig. 114.3B). Cases associated with cryoglobulinemia typically show intraluminal and intracellular eosinophilic globules, but this finding can also be seen in the absence of cryoglobulinemia.

Differential diagnosis

The clinical differential diagnosis includes vascular tumors (e.g. Kaposi sarcoma, angiosarcoma) as well as other causes of ulceration (see Fig. 105.1). Histologically, one must consider other forms of intravascular endothelial proliferation, including intravascular pyogenic granuloma, Dabska's tumor and intravascular papillary endothelial hyperplasia.

Treatment

Evaluation for known associated systemic disorders is important because lesions may regress upon resolution of the underlying condition, e.g. revascularization of an ischemic limb. In case reports, oral isotretinoin has led to improvement, possibly due to its antiangiogenic properties[8].

Glomeruloid Hemangioma

Key features

- A histologically distinct type of hemangioma that occurs in patients with POEMS syndrome
- In POEMS syndrome, presents as multiple, small, firm, angiomatous papules scattered primarily on the trunk and proximal extremities
- Characterized histologically by nests of capillaries within dilated dermal vessels, resembling renal glomeruli
- May be induced by increased circulating levels of vascular endothelial growth factor

Introduction and history

The term *glomeruloid hemangioma* was coined by Chan et al.[9] in 1990 to describe a distinctive vascular proliferation that occurs in patients with POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy, and *s*kin lesions), sometimes in association with multicentric Castleman's disease. Although there is some overlap with reactive angioendotheliomatosis, it is discussed separately because of its highly distinctive histologic features and well-recognized clinical association.

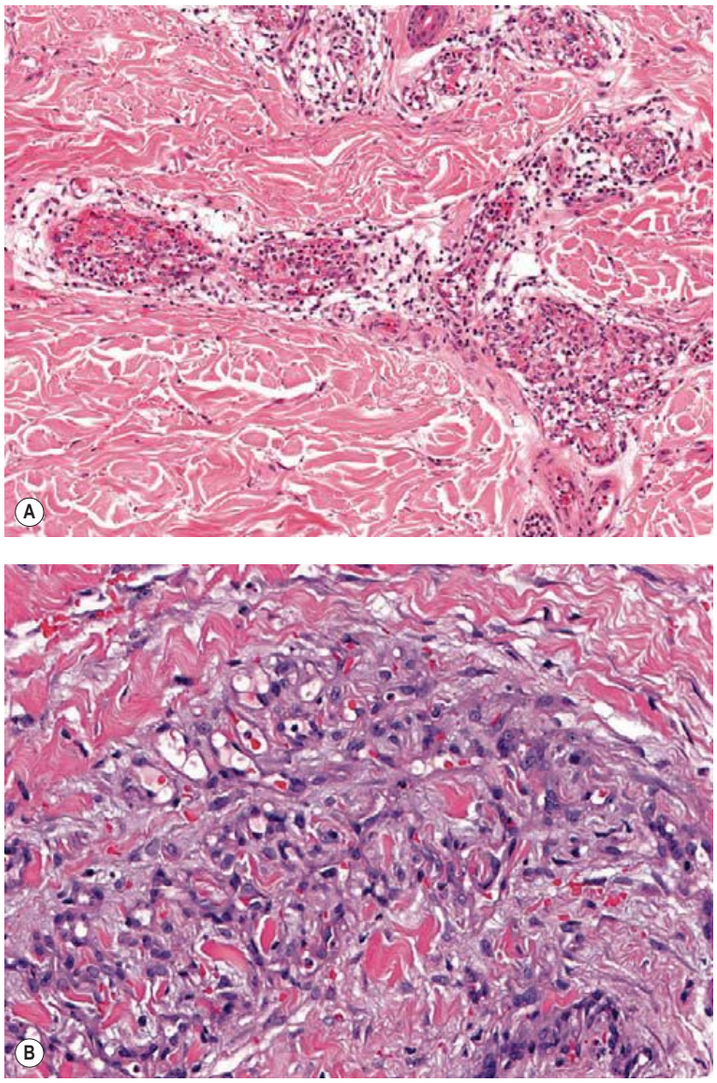

Fig. 114.3 Reactive angioendotheliomatosis. A Intravascular variant with proliferation of grouped capillaries along the course of a dermal blood vessel. The endothelial cells lack atypia and within several capillaries there is an intraluminal proliferation of endothelial cells admixed with erythrocytes occluding the lumina. **B** Diffuse dermal angiomatosis variant with proliferation of hyperplastic endothelial cells without atypical features infiltrating the dermis and forming small vascular lumina. *A, Courtesy, Heinz Kutzner, MD; B, Courtesy, Lorenzo Cerroni, MD.*

POEMS SYNDROME – CLINICAL CRITERIA, CUTANEOUS FINDINGS AND ASSOCIATED VASCULAR LESIONS
DIAGNOSTIC CRITERIA
***M*onoclonal plasmaproliferative disorder** – *and* – **Sensorimotor *p*olyneuropathy** *plus at least one other major and one minor criterion*
Major criteria
• Sclerotic bone lesions • Castleman's disease • Increased circulating levels of VEGF
Minor criteria
• Extravascular volume overload (peripheral edema, pleural effusions, ascites) • Thrombocytosis • Papilledema • *O*rganomegaly (hepatosplenomegaly) or lymphadenopathy • *E*ndocrinopathy (e.g. adrenal, pituitary, gonadal, parathyroid) • *S*kin changes (characteristic)
CUTANEOUS FINDINGS
• More common: diffuse hyperpigmentation, induration, hypertrichosis, hyperhidrosis • Less common: clubbing, livedo reticularis, acrocyanosis, flushing
TYPES OF VASCULAR LESIONS
• Cherry hemangiomas • Glomeruloid hemangiomas • Other: reactive angioendotheliomatosis, intravascular papillary endothelial hyperplasia, lobular capillary hemangiomas, microvenular hemangiomas

Table 114.2 POEMS syndrome – clinical criteria, cutaneous findings and associated vascular lesions. VEGF, vascular endothelial growth factor. *Adapted from Dispenzieri A. Blood Rev. 2007;21:285–99.*

Clinical features

The reported incidences of angiomas in patients with POEMS syndrome range from 25% to 45%. These appear as multiple, firm, dome-shaped, red to purple papules ranging in diameter from a few millimeters to a few centimeters and are scattered predominantly over the trunk and proximal extremities (see Ch. 53). Additional cutaneous manifestations of POEMS syndrome are outlined in Table 114.2, as are the types of vascular lesions that occur in these patients. True glomeruloid hemangiomas appear to be fairly specific for POEMS syndrome, although rarely they may appear years prior to recognition of the syndrome[10]. In addition, there are reports of a solitary variant that is not associated with POEMS syndrome.

Pathogenesis

Glomeruloid hemangiomas are thought to be reactive, rather than neoplastic. Patients with POEMS syndrome often have increased circulating levels of VEGF[11] such that this elevation represents a major diagnostic criterion (see Table 114.2). Most cases of POEMS syndrome associated with multicentric Castleman's disease (~90%) have evidence of human herpesvirus-8 (HHV-8) infection by PCR. It is suspected that viral interleukin (IL)-6 produced by the HHV-8 may indirectly promote angiogenesis by inducing VEGF expression[12].

Pathology

Most of the angiomas seen in patients with POEMS syndrome are found upon histologic examination to be consistent with common cherry angiomas, with numerous dilated dermal capillaries lined by flattened endothelial cells (see below). Only a few demonstrate the distinctive features of glomeruloid hemangioma. These consist of dilated dermal vessels filled by small, well-formed capillary loops that lead to structures reminiscent of renal glomeruli (Fig. 114.4).

The capillaries comprising these glomeruloid formations are lined by flat endothelial cells surrounded by an outer layer of pericytes and are separated by a scant stroma containing large cells with lightly eosinophilic cytoplasm and multiple eosinophilic globules. The latter are PAS-positive, diastase-resistant, and immunopositive for polytypic immunoglobulin, presumably derived from the associated paraprotein[9]. Of note, these interstitial, immunoglobulin-containing cells are of endothelial derivation. Lastly, since many POEMS syndrome patients have both cherry angiomas and glomeruloid hemangiomas, and the cherry angiomas may display focal glomeruloid formation, it is likely that these two histologic subsets reflect different stages of the same process[9].

Differential diagnosis

The clinical differential diagnosis includes other vascular proliferations and tumors (see Table 114.1) while the histologic differential diagnosis of glomeruloid hemangioma is essentially that described above for reactive angioendotheliomatosis. A more recently described entity, *papillary hemangioma*, also enters the histologic differential diagnosis[13]. The latter is characterized by intravascular papillary growths of capillaries, pericytes and stromal cells within ectatic dermal vessels, accompanied by hyaline globules (features reminiscent of glomeruloid hemangioma), but it differs by being solitary, being confined to the head and neck region, and having neither a true glomeruloid architecture nor an association with POEMS syndrome.

Treatment

Treatment is not required, although shave excision, cryosurgery, electrodesiccation, or pulsed dye laser surgery will remove the vascular tumors.

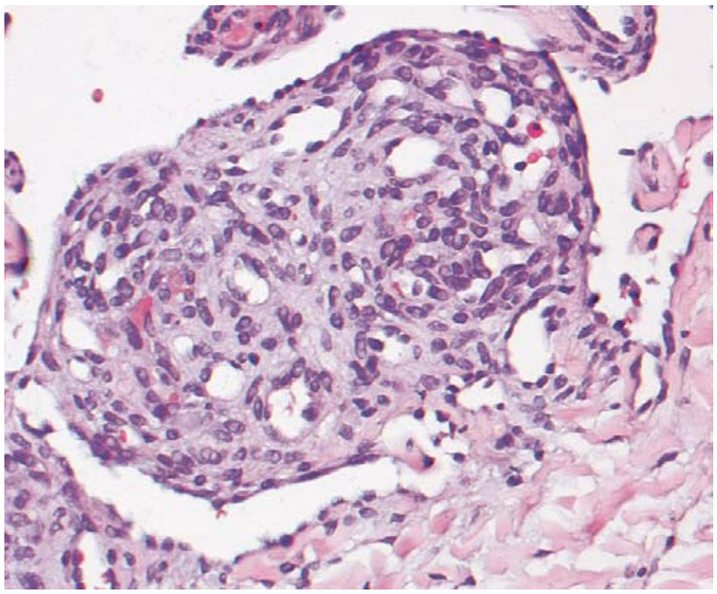

Fig. 114.4 Histology of a glomeruloid hemangioma in a patient with POEMS syndrome. Dilated dermal vessels are filled with congeries of small capillaries reminiscent of renal glomeruli.

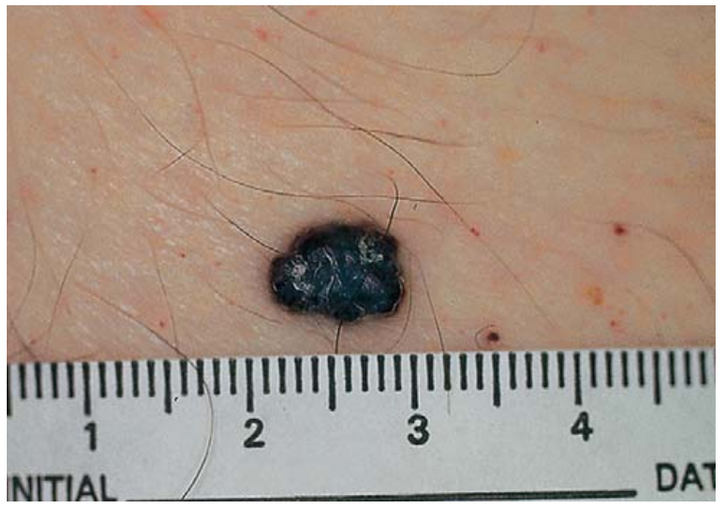

Fig. 114.5 Solitary angiokeratoma. Because of their dark color, these lesions may resemble cutaneous melanoma. Dermoscopy will readily distinguish between these two entities. *Courtesy, Jean L Bolognia, MD.*

Fig. 114.6 Scrotal angiokeratomas. These lesions typically arise along superficial vessels.

Angiokeratomas

Key features

- Small, dark, vascular and variably keratotic lesions that result from dilation of superficial vessels
- Angiokeratoma circumscriptum is a capillary–lymphatic or capillary malformation
- Angiokeratoma corporis diffusum results from several lysosomal storage disorders and is associated with systemic manifestations

Introduction

Angiokeratomas are well-circumscribed vascular lesions consisting of superficial vascular ectasia and hyperkeratosis. Five variants have been recognized. With the exception of angiokeratoma circumscriptum (which represents a capillary–lymphatic or capillary malformation), angiokeratomas result from ectatic dilation of pre-existing vessels in the papillary dermis.

Clinical features

Solitary or multiple angiokeratomas

Most commonly, they present as a small, warty, black papule on the lower extremities, but may occur anywhere on the body (Fig. 114.5). The lesions are thought to result from injury/trauma to or chronic irritation of the wall of a venule in the papillary dermis. Solitary lesions may be confused with melanoma due to their dark color. Dermoscopy will readily distinguish between these two entities (see Ch. 0).

Angiokeratomas of the scrotum and vulva

Synonym: ■ Angiokeratoma of Fordyce

These angiokeratomas may arise in the second or third decade but are most commonly seen in older age groups. The lesions are red-purple to black in color, may be single or multiple, and arise along superficial vessels (Fig. 114.6). In some patients, they may be associated with thrombophlebitis, varicoceles and inguinal hernias. Vulvar lesions may be associated with vulvar varicosities, hemorrhoids, oral contraceptive use, or increased venous pressure during pregnancy.

Angiokeratoma corporis diffusum

This disorder is characterized by the development of multiple, often clustered angiokeratomas, usually in a bathing trunk distribution. Lesions vary in number (from only a few to numerous) and usually begin to appear during late childhood or adolescence. X-linked recessive Fabry disease is the best known entity with this clinical presentation and results from a deficiency of the lysosomal enzyme α-galactosidase A (see Ch. 63). This leads to the accumulation of the neutral glycolipid ceramide trihexidose within lysosomes of multiple cell types. Other enzyme deficiencies associated with angiokeratoma corporis diffusum are outlined in Table 63.6.

Angiokeratoma of Mibelli

Lesions usually develop between the ages of 10 and 15 years and are most commonly situated on the dorsal and lateral aspects of the fingers and toes. They may also occur on the dorsa of the hands and feet and rarely on the elbows and knees. Angiokeratoma of Mibelli may be associated with chilblains and acrocyanosis. In rare instances, ulceration of the fingertips can occur. There is a familial predisposition and the disorder may be transmitted in an autosomal dominant fashion with variable penetrance.

Fig. 114.7 Angiokeratoma circumscriptum. These grouped red–violet papules had been present since childhood. *Courtesy, Jean L Bolognia, MD.*

Angiokeratoma circumscriptum

This entity usually develops during infancy or childhood as either a plaque of multiple discrete papules (Fig. 114.7) or hyperkeratotic papules and nodules that often become confluent. They occur on the trunk, arms or legs and are unilateral in most patients. There is a female predominance.

Pathology

Marked dilatation of the papillary dermal vessels is seen in association with an acanthotic, variably hyperkeratotic epidermis. Elongated rete ridges may partially or completely enclose vascular channels, and a collarette may be present at the margin of the lesions. In Fabry disease, vacuoles can be detected within endothelial cells and pericytes. The amount of glycolipid is small and may be difficult to detect in routinely prepared sections. However, the deposits are PAS-positive and Sudan black-positive and these stains can therefore assist in diagnosis. They can also be demonstrated by electron microscopy.

Differential diagnosis

Angiokeratomas should be distinguished from other vascular lesions. In particular, darkly colored or thrombosed angiokeratomas may resemble cutaneous melanoma.

Treatment

Patients may request removal for cosmetic reasons. This may be achieved by shave excision, diathermy or laser therapy, the choice of which would largely depend on the size of the lesion.

Microvenular Hemangioma

Synonym: ■ Microcapillary hemangioma

Key features

- An uncommon, acquired, slowly growing, benign vascular tumor of young to middle-aged adults of both genders
- Presents as a small, usually solitary, sharply circumscribed red papulonodule or plaque on the trunk or extremities, with a predilection for the forearms
- Consists of small branching capillaries and venules with collapsed lumina and conspicuous pericytes infiltrating the full thickness of the reticular dermis
- May be subject to hormonal influences in some women

Introduction and history

Microvenular hemangioma was first described by that name in 1991 by Hunt, Santa Cruz and Barr[14], although cases reported as microcapillary hemangiomas are probably identical.

Epidemiology

Reported cases have been in young and middle-aged adults of both sexes. Some cases in women have been temporally related to pregnancy or oral contraceptive use, although this has not been widely corroborated.

Pathogenesis

Microvenular hemangiomas have been reported in patients with POEMS syndrome[15], suggesting that these lesions, like glomeruloid hemangiomas, may be of reactive etiology. Observations that some microvenular hemangiomas affecting women present in association with pregnancy or oral contraceptive use arguably suggest a hormonal influence.

Clinical features

Microvenular hemangioma typically presents as a solitary, purple to red, slowly enlarging papule, plaque or small nodule on the trunk or extremities (rarely the face). There appears to be a particular predilection for the forearms, and most lesions are less than 2 cm in diameter[15]. Although the majority are asymptomatic, mild erythema and tenderness have been reported.

Pathology

Histologically, lesions are poorly circumscribed proliferations of small, relatively monomorphous, branching capillaries and venules involving the full thickness of the reticular dermis. Unlike port-wine stains, in which vascular ectasia is prominent, the vascular lumina of this tumor are inconspicuous and often collapsed. Cells lining the vessels show no atypia and are strongly positive for endothelial markers and are associated with smooth muscle actin-positive pericytes. The vessels are not as delicate or angulated as the lymphatic-like vessels of Kaposi sarcoma or vessels of microcystic lymphatic malformations and often contain red blood cells. The pericytic component is obvious even in routine H&E-stained sections.

Differential diagnosis

The major histologic differential diagnostic consideration for these acquired lesions is patch-stage Kaposi sarcoma. Kaposi sarcoma differs by the presence of delicate lymphatic-like vessels, plasma cells, eosinophilic globules, and interstitial fascicles of spindle cells.

Treatment

Surgical excision has been effective in reported cases.

Angiolymphoid Hyperplasia with Eosinophilia (AHE)

Synonyms: ■ Epithelioid hemangioma ■ Pseudopyogenic granuloma ■ Inflammatory angiomatous nodule ■ Papular angioplasia ■ Inflammatory arteriovenous hemangioma ■ Intravenous atypical vascular proliferation ■ Nodular angioblastic hyperplasia with eosinophilia and lymphofolliculosis ■ Histiocytoid hemangioma[16]

Key features

- Benign angiomatous nodules or plaques, often multiple and grouped, usually located in the head and neck region, especially around the ears
- May be painful, pruritic or pulsatile, and often recur after excision
- Characterized histologically by proliferations of capillary-sized vessels with epithelioid endothelial cells surrounding larger, thick-walled vessels, accompanied by eosinophils and lymphocytes
- May be associated with arteriovenous shunts
- Kimura's disease now thought to be a separate clinicopathological entity

Introduction and history

Angiolymphoid hyperplasia with eosinophilia (AHE) was first described in 1969 by Wells and Whimster[17]. They considered AHE to be a late stage of Kimura's disease, described in the Japanese literature in 1948. It is now generally accepted that these are two separate entities[18].

Epidemiology

AHE occurs in young to middle-aged adults without gender predilection. Previous reports of a female predominance are not supported by more recent series. A history of trauma can be elicited in some patients[19].

Pathogenesis

The frequent presence of mural damage or rupture in intralesional large vessels of AHE has suggested a role for trauma or arteriovenous shunting in its pathogenesis[19]. Cases have been described in association with arteriovenous fistulas and malformations. These findings suggest that in some patients AHE may be reactive, rather than neoplastic, especially in those with this latter type of lesion.

Clinical features

AHE typically presents as papules or nodules that are tan, brown, pink or dull red in color and are located predominantly in the head and neck region, especially around the ears and on the forehead and scalp (Fig. 114.8). Less commonly, lesions have been observed in the mouth and on the trunk, distal extremities, vulva and penis. Most papulonodules are dermal in location, but some are subcutaneous; occasionally, AHE involves deeper soft tissues or arises from vessels[4]. Approximately half of patients have multiple lesions, generally in a clustered pattern[4]. AHE can be either asymptomatic or painful, pruritic or pulsatile[19]. Some patients have regional lymph node enlargement and peripheral eosinophilia.

Fig. 114.8 Angiolymphoid hyperplasia with eosinophilia. Multiple pink papulonodules are often seen on the scalp.

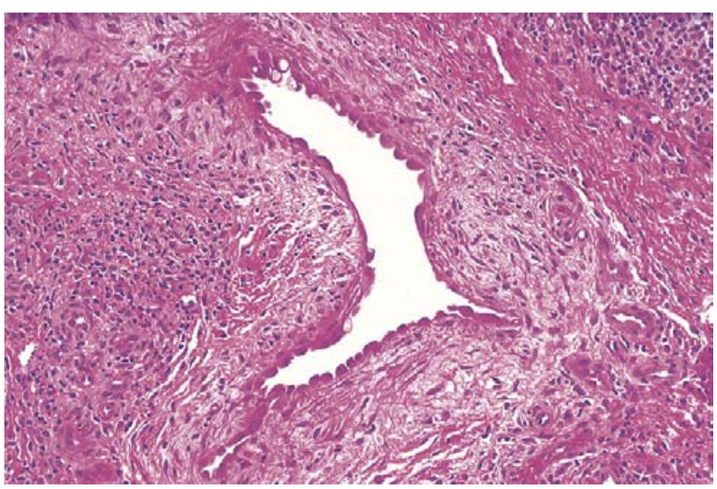

Fig. 114.9 Histology of angiolymphoid hyperplasia with eosinophilia. Enlarged endothelial cells protrude into the lumen of the central blood vessel, producing a scalloped or "cobblestone" appearance. An infiltrate of lymphocytes and eosinophils surrounds the vessel. *Courtesy, Ronald P Rapini, MD.*

Pathology

Typical lesions involving the dermis and subcutaneous tissue are well circumscribed and show vaguely lobular proliferations of capillary-sized vessels surrounding larger central blood vessels, with a variably dense perivascular inflammatory infiltrate rich in lymphocytes and eosinophils (Fig. 114.9). Scattered ectatic lymphatic vessels are variably present. Mast cells and plasma cells are usually also present, and nodular lymphoid aggregates, with or without germinal centers, may be prominent in subcutaneous lesions. The stroma is fibrous, and the larger vessels have thick walls with prominent myxoid degeneration.

Many of the vessels, particularly the larger ones, are lined by enlarged endothelial cells that protrude into the lumen, producing a scalloped or "cobblestone" appearance. These epithelioid endothelial cells are responsible for the synonym *epithelioid hemangioma*. Inflammatory infiltration of medium- to large-sized arteries, with variable luminal occlusion, damage to elastic laminae, and even mural rupture, is common. In older lesions, fibrosis is more prominent, with a reduction in the inflammatory and vascular elements.

Differential diagnosis

AHE may resemble cutaneous lymphoid hyperplasia, lymphoma cutis, sarcoidosis, angiosarcoma, Kimura's disease, and richly vascularized metastatic tumors. Angiosarcoma lacks the eosinophils and is usually cytologically more atypical and hemorrhagic. Although AHE was previously postulated to be a variant of Kimura's disease, current opinion is that these represent distinct entities. Kimura's disease has much larger lymphoid follicles and is usually located on the posterior neck.

Treatment

Although rare instances of spontaneous regression have been reported, surgical excision is generally required. About one-third of lesions recur after excision[4], sometimes due to incomplete excision of an underlying nidus of arteriovenous (AV) shunting (e.g. an AV malformation, an acquired AV fistula). Intraoperative bleeding can be problematic. Various lasers (e.g. CO_2, pulsed dye, copper vapor) have been used with variable success. In a small case series, treatment with polidocanol sclerotherapy (for the deep vascular component) plus radiofrequency ablation was reportedly successful[20].

Spindle Cell Hemangioma

Synonym: ■ Spindle cell hemangioendothelioma

Key features

- Blue–red nodules that typically appear in the dermal and subcutaneous tissue of the distal extremities of young adults and children and tend to multiply locally
- Composed of thin-walled cavernous veins containing organizing thrombi, interspersed with fascicles of spindle cells resembling Kaposi sarcoma
- Originally interpreted as a low-grade angiosarcoma (*spindle cell hemangioendothelioma*), but now viewed as a benign lesion without metastatic potential (*spindle cell hemangioma*)
- Currently viewed by many as a vascular malformation complicated by thrombosis and irregular vascular collapse
- Tends to recur following resection

Introduction and history

This entity was first described by Weiss and Enzinger in 1986 as *spindle cell hemangioendothelioma* in order to recognize its spindle cell morphology and the fact that one case from their series of 26 had metastasized to a regional lymph node[21]. Results of larger studies with

extended follow-up have led to the current view that this tumor has no inherent malignant potential[4,22]. Based on these observations, Perkins and Weiss suggested in 1996 that the entity be renamed *spindle cell hemangioma*[22].

Epidemiology

Spindle cell hemangiomas usually occur in children and young adults, although in a series of 78 cases compiled by Perkins and Weiss[22], patient ages ranged from 8 to 78 years, with a median age of 32 years. However, those presenting during late adulthood appear to represent previously occult, longstanding lesions. There is no gender predilection. Spindle cell hemangiomas are occasionally associated with Maffucci syndrome[21–23], Klippel–Trenaunay syndrome[23], congenital lymphedema[21,23], and, rarely, epithelioid hemangioendothelioma.

Pathogenesis

This vascular proliferation[23–25] is thought to probably be a vascular malformation altered by thrombosis and irregular vascular collapse[4,22]. The typical development of multiple nodules over time within a given anatomic region may represent intravascular propagation[22].

Clinical features

Most spindle cell hemangiomas begin as a solitary, firm, red–blue nodule in the subcutaneous tissue and dermis of the distal upper or lower extremity, then slowly develop multifocally within a localized area (Fig. 114.10). Rarely there is involvement of skeletal muscle and occasionally tumors develop on the trunk, head and neck, or proximal limbs. Spindle cell hemangiomas are largely asymptomatic, but ~60% recur following resection[22].

Fig. 114.10 Spindle cell hemangioma. Clustered blue–red multifocal nodules are typical.

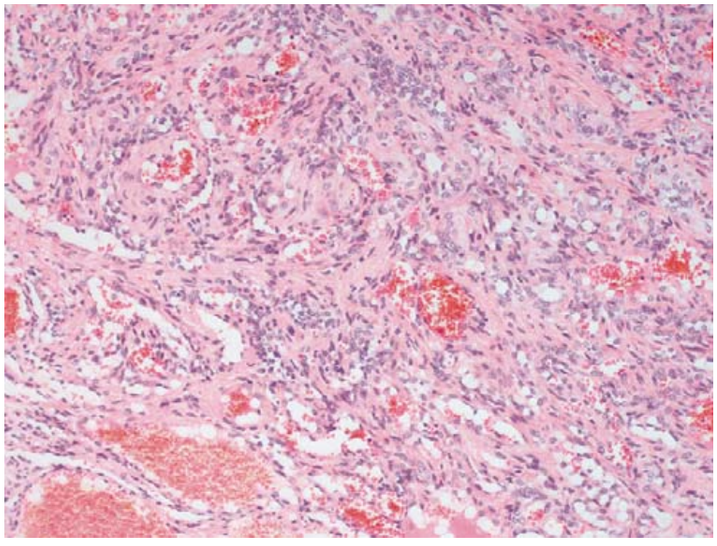

Fig. 114.11 Histology of spindle cell hemangioma. Collapsed veins containing organizing thrombi alternate with more cellular spindled areas and occasional vacuolated epithelioid cells.

Pathology

Hemorrhagic, often multiple, nodules are see within the dermis and subcutaneous tissue and are composed of two basic histologic elements (in variable combinations): (1) thin-walled, cavernous spaces containing organizing thrombi; and (2) more cellular areas containing spindle cells and occasional aggregates of vacuolated epithelioid cells (Fig. 114.11). The spindled areas stain focally for actin, form slit-like vascular spaces, and appear to consist of fibroblastic cells, pericytes and collapsed vessels[4]. The epithelioid interstitial cells, as well as the flattened cells lining the cavernous spaces, immunoreact positively for endothelial markers[23]. Cavernous vessels may show foci of intravascular papillary endothelial hyperplasia consistent with the presence of organizing thrombus material (see above). Frequently, remnants of residual vascular walls rim the lesion, suggesting intravascular development.

Differential diagnosis

These tumors may resemble nodular lesions of Kaposi sarcoma, but the latter lack cavernous vascular spaces and vacuolated epithelioid endothelial cells. The frequent presence of foci of intravascular papillary endothelial hyperplasia (Masson's lesion) within a spindle cell hemangioma may lead to misdiagnosis. A primary Masson's lesion is solitary and lacks epithelioid endothelial cells.

Treatment

Based upon the large series of Perkins and Weiss[22], simple surgical excision is successful in some patients (approximately 40%). The frequent local recurrences may reflect the inherent multifocality, with growth within vessels leading to discontinuous locoregional sites[22]. There is one report of the successful use of intralesional and intra-arterial IL-2, with no signs of recurrence at 24 months[26].

Pyogenic Granuloma

Synonyms: ■ Lobular capillary hemangioma ■ Granuloma pyogenicum ■ Tumor of pregnancy ■ Eruptive hemangioma ■ Granulation tissue-type hemangioma

Key features

- Rapidly growing, friable, red papule or polyp of skin or mucosa that frequently ulcerates; most common in children and young adults
- Examples arising on the gingiva of pregnant women (*granuloma gravidarum*) are considered a separate subgroup, but are histologically indistinguishable
- Consist of lobules of small capillaries set in a fibromyxoid matrix, often distinctly exophytic and bounded by collarettes of hyperplastic epithelium
- Occasionally found in subcutaneous or intravascular locations
- Neither infectious in etiology nor granulomatous histologically; often considered a reactive vascular hyperplasia rather than a neoplasm

Introduction and history

Poncet and Dor are credited with the initial description in 1897, and they believed the cause was a *Botryomyces* infection. The term *granuloma pyogenicum* was coined in 1904 by Hartzell to describe four similar cases that he thought represented a nonspecific granulation tissue-type response to any type of pyogenic agent[27]. Although the etiology of these common lesions remains uncertain today, the term *pyogenic granuloma* is clearly a misnomer. There is no evidence to

implicate any infectious agent, and the histologic appearance is not granulomatous.

Epidemiology

Pyogenic granulomas can develop at any age but are more common in children and young adults. There may be a slight male predominance, but no racial or familial predisposition. Gingival lesions are relatively common during pregnancy.

Pathogenesis

Pyogenic granulomas exhibit a number of clinical features suggestive of reactive neovascularization, including a common association with a pre-existing injury or irritation, limited capacity for growth, and a propensity for multiple eruptions that may be localized or disseminated. The occasional eruption of pyogenic granulomas within pre-existent port-wine stains[28] and other vascular malformations suggests that abnormalities in blood flow may be etiologically important in some cases.

Clinical features

The lesion presents as a solitary red papule or polyp that grows rapidly over the course of several weeks or months, stabilizes and then may decrease in size (Fig. 114.12). Its final size is rarely >1 cm, and it may persist indefinitely if not removed. Approximately one-third develop following minor trauma. In one series of 289 cases, the most common sites, in decreasing order of frequency, were the gingiva, fingers, lips, face and tongue[29]. They are extremely friable, frequently ulcerate and may bleed profusely with minor trauma. Multiple satellite lesions occasionally develop near a primary pyogenic granuloma, usually after destruction of that lesion[30]. Rarely, pyogenic granulomas arise within the subcutis, develop intravascularly or erupt in a disseminated fashion[31]. Pyogenic granulomas have been reported in association with systemic retinoids[32], indinavir, and EGFR inhibitors, but in some cases this may represent excessive granulation tissue.

Pathology

The quintessential lesion is a well-circumscribed, exophytic, sometimes pedunculated, proliferation of small capillaries, often arranged in a lobular pattern (Fig. 114.13). Lesional capillaries are lined by flattened to slightly plump endothelial cells, rimmed by pericytes, and surrounded by a variably edematous fibromyxoid interstitial stroma containing fibroblasts. Endothelial and stromal cell mitotic activity is highly variable and depends on the stage of growth; a scant infiltrate of lymphocytes, plasma cells and mast cells may be present. Capillary lumina within the lobules vary from small and angular to branching and ectatic, and foci of thrombosis and intravascular papillary endothelial hyperplasia may be present. A few larger vessels with smooth muscle walls, usually venous (but often including a small ascending arterial feeder), are frequently present at the base of the lesion. Thick, intervening bands of dense fibrous tissue sharply define the lobularity and help distinguish pyogenic granuloma from other lobular forms of capillary proliferation such as infantile hemangioma.

The lateral margins are often defined by prominent epithelial "collarettes" resulting from peripheral adnexal hyperplasia or, in some cases, from downward growth of rete ridges, bridged by flattened epidermis. The histology of many early lesions is altered by ulceration and secondary inflammatory change, leading to an appearance similar to granulation tissue, with radially oriented capillaries, fibrin deposition and a loss of lobularity. Intravascular and subcutaneous forms demonstrate features similar to superficial lesions, but without the inflammatory complications. Late-stage lesions are characterized by increased *intra*lobular and *inter*lobular fibrosis, as well as quiescent, flattened capillary endothelia.

Differential diagnosis

The diagnosis of pyogenic granuloma can be made clinically if the red, bleeding papule is coupled with the characteristic location and history. Otherwise they can be easily confused with amelanotic melanoma and, in the immunosuppressed patient, bacillary angiomatosis or Kaposi sarcoma. Glomus tumors, hemangiomas, and irritated melanocytic nevi and warts can all mimic pyogenic granulomas. Histologic conformation is always helpful in cases where the diagnosis is in question.

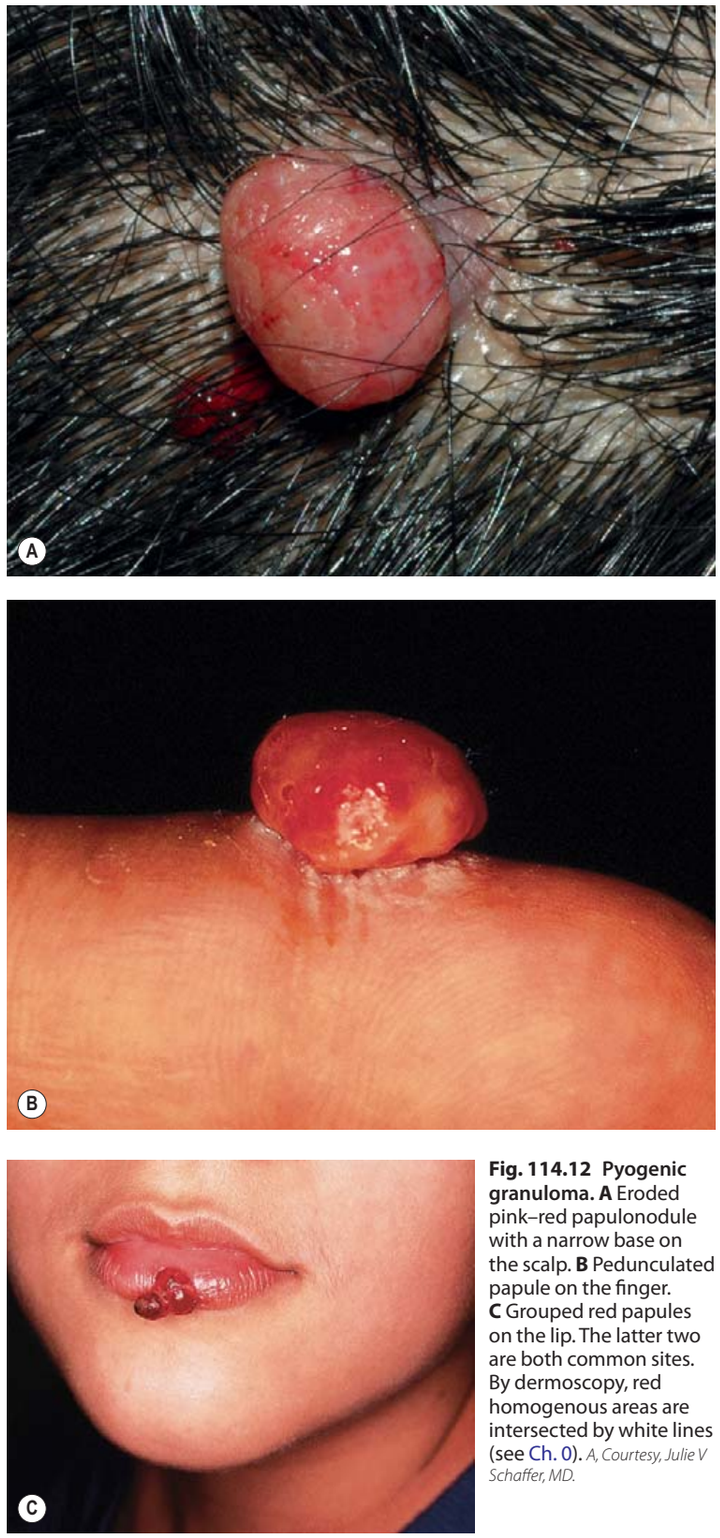

Fig. 114.12 Pyogenic granuloma. A Eroded pink–red papulonodule with a narrow base on the scalp. **B** Pedunculated papule on the finger. **C** Grouped red papules on the lip. The latter two are both common sites. By dermoscopy, red homogenous areas are intersected by white lines (see Ch. 0). *A, Courtesy, Julie V Schaffer, MD.*

Treatment

Shave excision followed by electrosurgery of the base under local anesthesia is sufficient for most lesions. Patients and parents should be alerted to the possibility of recurrence after removal. Excision with suturing may result in less postoperative bleeding and a lower recurrence rate.

Pulsed dye laser has also been shown to be a safe and effective treatment for small pyogenic granulomas and may be particularly useful in children[33]. There is a report of successful sclerotherapy in nine patients using monoethanolamine oleate, with inconspicuous scar formation and no recurrence[34].

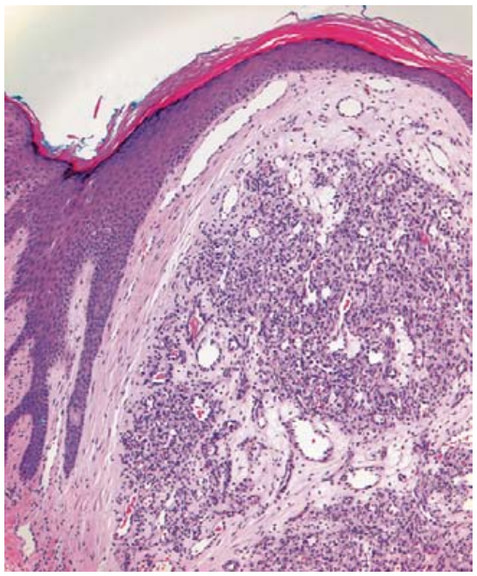

Fig. 114.13 Histology of pyogenic granuloma. Proliferating capillaries are often grouped into lobules by dense fibrous bands, hence the synonym lobular capillary hemangioma. The lesion is often clutched by an epithelial collarette.

Cherry Angioma

Synonyms: ■ Cherry hemangioma ■ Senile angioma ■ Campbell–De Morgan spot

Key features

- Bright red, dome-shaped to polypoid papules up to several millimeters in diameter that begin appearing during adult life, most commonly on the trunk and upper extremities
- A common, benign lesion found in most individuals by the age of 60 years, often in large numbers
- Consist of dilated, congested capillaries and postcapillary venules within the papillary dermis

Introduction and history

Cherry angiomas are the most common of the acquired cutaneous vascular proliferations. They can be unattractive and rarely when eruptive herald an underlying systemic abnormality.

Epidemiology

Both sexes are affected equally. Although they may occasionally develop during adolescence, cherry hemangiomas usually first appear during the third decade of life or later, and then increase in number over time. Most people over 60 years of age have one or more such lesions.

Pathogenesis

An increased number of cherry angiomas often appear during pregnancy and may involute in the postpartum period, suggesting that hormonal factors may be important in their pathogenesis. Two women with hundreds of eruptive cherry hemangiomas, both of whom had increased serum levels of prolactin, have also been reported[15]. Most angiomas that appear in the setting of POEMS syndrome are cherry angiomas, often in association with glomeruloid hemangiomas.

Clinical features

Cherry angiomas are round to oval, bright red, dome-shaped papules ranging in size from barely visible to several millimeters in diameter (Fig. 114.14). Well-developed lesions may be polypoid. They most commonly develop on the trunk and proximal extremities and are rare on the hands, feet and face. It is not unusual for elderly adults to have 50–100 cherry angiomas on their trunk. Patients are usually aware of the benign nature of these extremely common lesions and bring them to a physician's attention only when concerned about their appearance. They are generally asymptomatic, but may occasionally bleed when traumatized.

Pathology

Histologically, congested, ectatic capillaries and postcapillary venules are seen within the papillary dermis and superficial reticular dermis (Fig. 114.14, insert). Early lesions are characterized by small lumina and plump endothelial cells. With maturation, the vessels dilate and the endothelial cell cytoplasm flattens, often producing slightly hobnailed nuclei. Vessel diameter decreases with descent into the reticular dermis. There is loss of epidermal ridges centrally and peripherally adnexal epithelial collarettes are seen.

Differential diagnosis

The distinctive clinical and dermoscopic finding (see Ch. 0) limit other diagnostic considerations. Glomeruloid hemangiomas, although similar in clinical appearance, can be distinguished histologically. Tiny cherry angiomas may resemble petechiae.

Treatment

Patients may request removal of cosmetically undesirable or chronically traumatized cherry angiomas. This can be accomplished by shave excision, electrodesiccation or laser ablation, with recurrences unusual.

Sinusoidal Hemangioma

Synonyms: ■ Variant sinusoidal hemangioma ■ Sinusoidal venous malformation

Key features

- Relatively rare, small, well-demarcated acquired lesion most commonly seen in the subcutis of middle-aged women and traditionally described as a variant of "cavernous hemangioma" (venous malformation)
- Probably malformative with a delayed presentation, rather than neoplastic or reactive in etiology
- Histologically distinguished by dilated, interconnecting venous channels exhibiting a prominent sieve-like or sinusoidal pattern
- Similar sinusoidal patterns are seen focally in many venous malformations
- May be confused with well-differentiated angiosarcoma, but distinguished from the latter by lack of significant cytologic atypia, infiltrative growth and endothelial multilayering

Introduction and history

In 1991, sinusoidal hemangioma was described as a distinctive subset of so-called "cavernous hemangioma" (historic term as now recognized to be a venous malformation)[35]. In contrast to typical venous malformations of childhood, sinusoidal hemangiomas presented during adulthood and had an unusually prominent sinusoidal or sieve-like histologic pattern.

Epidemiology

These adult-onset lesions have most commonly been observed in middle-aged women and are relatively rare. Their not uncommon occurrence in breast subcutaneous tissue has emphasized the need to differentiate these lesions from angiosarcoma.

Pathogenesis

Because of the typical presentation during adulthood, a neoplastic or reactive etiology has been suggested. However, the strong histologic parallels with venous malformations of childhood suggests that these mitotically quiescent vascular lesions are probably congenital developmental disorders that become evident later in life due to remodeling, thrombosis, recanalization and progressive vascular dilation. Focal sinusoidal patterns have also been described in congenital venous malformations.

Clinical features

Sinusoidal hemangiomas, as traditionally defined, are relatively well-demarcated, solitary, deep dermal or subcutaneous papulonodules that are freely mobile. The color varies from red (superficial lesions) to bluish or skin-colored (subcutaneous lesions). They most commonly develop in adult women and favor the arms and torso (including the breast). Longitudinal studies have revealed no evidence of metastasis or of local recurrence following resection.

Pathology

Generally well-defined lobules of dilated, thin-walled veins with scant mural smooth muscle form characteristic interconnected, "emphysematous", sieve-like spaces. Lining endothelial cells are flattened, single-layered, and mitotically inactive. Organizing thrombi are common, with occasional superimposed changes of papillary endothelial hyperplasia. There is no significant cytologic atypia. Central infarction and necrosis have been reported.

Differential diagnosis

Given the typical presentation during adulthood and anastomosing vascular pattern, the most clinically significant simulant is well-differentiated angiosarcoma. The latter is distinguished by a more infiltrative pattern, endothelial multilayering, mitotic activity and cytologic atypia.

Treatment

Complete surgical resection, which is facilitated by the typical well demarcation, is curative.

Hobnail Hemangioma

Synonym: ■ Targetoid hemosiderotic hemangioma

Key features

- Uncommon, acquired, benign vascular lesion that usually presents as a red–blue or brown papule on the trunk or extremities of children and young to middle-aged adults
- The papule is sometimes surrounded by a pale ring and then an ecchymotic halo
- Biphasic pattern of dilated, thin-walled vessels with hobnail endothelial cells in the superficial dermis, transitioning to smaller, slit-like vessels in the deeper dermis
- Lesional endothelial cells strongly express the lymphoendothelial marker podoplanin and poorly express CD34, suggesting lymphatic differentiation

Introduction and history

The original description in 1988 coined the term *targetoid hemosiderotic hemangioma* to emphasize the targetoid clinical appearance and hemosiderin deposition seen in a series of eight cases. Since then it has become apparent that only a minority of these lesions demonstrate the ecchymotic halo and hemosiderin deposition is variable. The term *hobnail hemangioma* has been proposed to encompass lesions with the characteristic biphasic growth pattern and marked hobnail endothelial morphology, with or without a targetoid clinical appearance and/or marked hemosiderin deposition[36,37]. More than 100 cases have now been reported[37,38], and all have had a benign clinical course.

Epidemiology

There is an equal male : female distribution[37]. In the largest series to date (62 cases), patients ranged in age from 6 to 72 years (median, 32 years)[38].

Pathogenesis

It has been proposed that this tumor represents the benign end of a spectrum of vascular tumors with hobnail endothelial cells that also includes Dabska's tumor and retiform hemangioendothelioma[36]. However, recent demonstration of markers of lymphatic derivation in hobnail hemangioma and Dabska's tumor, but not retiform hemangioendothelioma, suggests that the underlying pathogenesis of this histologic spectrum is not uniform. Trauma may stimulate the appearance of a hobnail hemangioma, and microshunts between small lesional blood vessels and adjacent lesional lymphatic vessels may explain the presence of erythrocytes within lymphatic vessels and hemosiderin deposits[39].

Clinical features

Most lesions are asymptomatic, solitary, well-circumscribed, red–blue to brown papules that are initially 2 to 3 mm in diameter and then slowly increase in size. In some cases, the papule is surrounded by a thin, pale area and then an ecchymotic ring (Fig. 114.15). The ecchymotic halo may fade and eventually disappear over time, and some lesions have been reported to undergo cycles of spontaneous regression and recurrence[31]. Favored sites, in decreasing order of frequency, are the lower extremities, upper extremities, back, buttock and hip, and chest wall. Lesions have also been reported on the tongue and gingiva[37].

Pathology

A biphasic histologic pattern is observed, consisting of a superficial dermal complement of dilated, thin-walled vessels containing small numbers of red blood cells and lined by prominent hobnail endothelial cells, which then merge with smaller, more slit-like vessels that dissect between collagen bundles in deeper areas of the dermis (Fig. 114.16). Extravasated red blood cells and hemosiderin deposits are common, but may be absent. Although the superficial vessels occasionally show delicate intraluminal papillary fronds, the more complex, multilayered endothelial tufts of Dabska's tumor are lacking. The endothelial cells of both the dilated and slit-like vessels immunoreact positively for the lymphoendothelial markers VEGF-3 and podoplanin (see Ch. 102), but show little, if any, reactivity for the blood vascular marker CD34[38,39].

Fig. 114.15 Hobnail hemangioma (targetoid hemosiderotic hemangioma). Note the target-like appearance. *Courtesy, Ronald P Rapini, MD.*

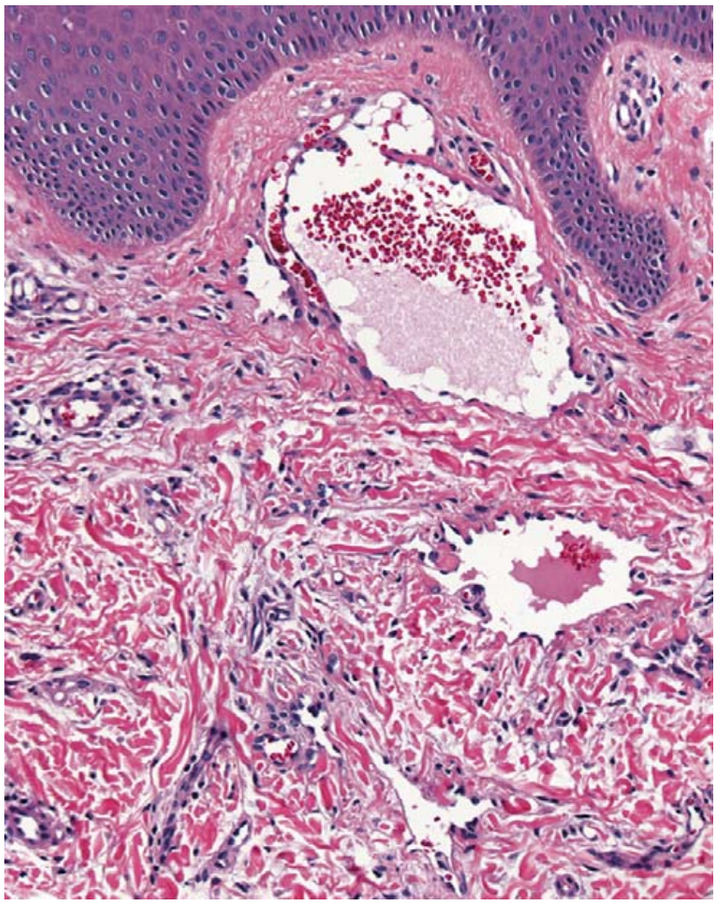

Fig. 114.16 Histology of hobnail hemangioma. Dilated superficial dermal vessels lined by hobnailed endothelial cells, merging with smaller slit-like vessels in the lower dermis.

Differential diagnosis

Hobnail hemangiomas are benign in clinical appearance and may resemble a melanocytic nevus or a sclerosing hemangioma as well as other benign vascular proliferations[37]. The histopathologic differential diagnosis is much more complex and includes patch-stage and lymphangioma-like variants of Kaposi sarcoma, well-differentiated angiosarcoma, retiform hemangioendothelioma, Dabska's tumor and microcystic lymphatic malformation.

Treatment

Hobnail hemangioma is successfully treated by simple excision. Longitudinal evaluation of 35 patients, ranging from 1 to 4 years, revealed no local recurrence or systemic metastasis[38].

Tufted Angioma

Synonyms: ■ Acquired tufted angioma ■ Angioblastoma of Nakagawa ■ Tufted hemangioma ■ Hypertrophic hemangioma ■ Progressive capillary hemangioma

Key features

- Inhomogeneous pink to red patches and plaques with superimposed papules that spread slowly, often to involve large areas, then stabilize; rarely may regress
- Most commonly located on neck or trunk
- Usually presents as an acquired lesion in children and young adults, but may be congenital or appear late in life
- When congenital, may be associated with Kasabach–Merritt phenomenon
- Characterized histologically by tightly packed tufts of tiny capillaries distributed within the dermis and subcutis in a "cannonball" pattern; foci of spindled endothelial cells may also be present

Introduction

Tufted angioma has often been lumped erroneously with infantile hemangioma under the generic term "capillary hemangioma". However, a distinction is important given its association with Kasabach–Merritt syndrome in some infants. In older children and adults, it may clinically mimic Kaposi sarcoma. Current opinion is that it represents a mild, superficial form of kaposiform hemangioendothelioma (KHE).

History

Tufted angioma was first described in 1989 by Wilson-Jones and Orkin[40]. Apparently identical lesions had been described many years previously as angioblastoma[41] and progressive capillary hemangioma[42]. The association of tufted angioma with Kasabach–Merrit phenomenon, shared by KHE, has relatively recently been recognized[43].

Epidemiology

Most lesions occur in young adults and children, many during the first year of life. Over 50% present before 5 years of age[40], and approximately 15% are congenital[40]. Rarely, lesions appear late in life[44]. Although one family with several affected family members has been reported[45], the vast majority of cases are sporadic.

Pathogenesis

Tufted angioma and KHE have a significant degree of overlap in histologic features, with resection specimens of KHE often demonstrating dermal changes that would have been interpreted in small biopsy specimens as tufted angioma. In light of the virtually exclusive association of these two entities with Kasabach–Merritt phenomenon, this histologic overlap suggests that tufted angioma may represent a more superficial, milder form of KHE[43,46,47].

Clinical features

Tufted angiomas appear as mottled red patches or plaques with superimposed angiomatous papules, typically on the neck, trunk or shoulders, that grow slowly by lateral extension over a period of 5 months to 10 years[40] (Fig. 114.17). Occasionally, lesions have an associated growth of lanugo hair or port-wine-like stain[48]. Platelet trapping (Kasabach–Merritt phenomenon) may develop in congenital cases, although less commonly than in KHE. Lesions eventually stabilize in size, then may persist unchanged, shrink or leave a fibrotic residuum. Rarely, complete spontaneous regression has been observed[48]. Occasional lesions are painful, and this may be exacerbated during periods of uncontrolled platelet trapping[49].

Pathology

Tufted angiomas are characterized by multiple discrete lobules of capillaries set within the dermis and often the subcutis in a so-called "cannonball" pattern (Fig. 114.18). Borders of the area of tissue involvement are poorly defined. Dermal collagen and subcutis separating capillary lobules may be histologically normal, but are often fibrotic. The lobules are composed of tiny capillaries with pinpoint lumina, occasionally containing fibrin microthrombi, tightly packed together without intervening stroma and frequently bulging into peripherally placed thin-walled vessels. Mitotic figures are rare.

Foci of spindled endothelial cells that coexpress the lymphatic markers podoplanin, LYVE-1 and Prox1, in addition to the blood vascular marker CD34, may be present within the tumor lobules, but this feature is typically not prominent[50]. Of note, the endothelial cells of tufted angioma do not immunoreact for infantile hemangioma-associated antigens such as GLUT-1 and Lewis Y antigen[51]. Ultrastructural studies have demonstrated classical Weibel-Palade bodies. In cases

Fig. 114.17 Tufted angioma. A Mottled red patches and superimposed papules are typical clinical features. **B** Dark-red to violet plaque in an infant.

associated with Kasabach–Merritt phenomenon, platelet trapping has been confirmed with CD61 immunoreaction[52].

Differential diagnosis

Congenital tufted angiomas must be differentiated from infantile hemangiomas, the most common tumors of infancy (see Ch. 103). The latter are positive for placental capillary-associated endothelial markers (e.g. GLUT-1) and show more rapid growth (without lateral extension) during the first year of life, followed by spontaneous, slow involution[51]. Infantile hemangiomas are transiently positive for the lymphatic-associated marker LYVE-1 early in their course, presumably as an expression of their embryonic, cardinal vein-type endothelial phenotype[50], but lack the definitive mixed lymphatic–blood endothelial phenotype described above[53,54].

Other entities that may mimic the clinical appearance of tufted angioma include pyogenic granuloma arising within a vascular malformation and Kaposi sarcoma. Pyogenic granuloma can be distinguished histologically by its characteristic edematous stroma, granulation tissue-type changes, lack of association with lymphatic markers, and generally larger, more loosely packed lesional vessels. Kaposi sarcoma differs in its lack of tufting, presence of a plasma cell infiltrate and prominence of fascicles of spindle cells forming slit-like spaces. KHE, although overlapping in histology and likely in pathogenesis, is traditionally described as a more bulky, deeply seated lesion that tends to infiltrate across multiple tissue planes and has more prominent spindled endothelial cells[50].

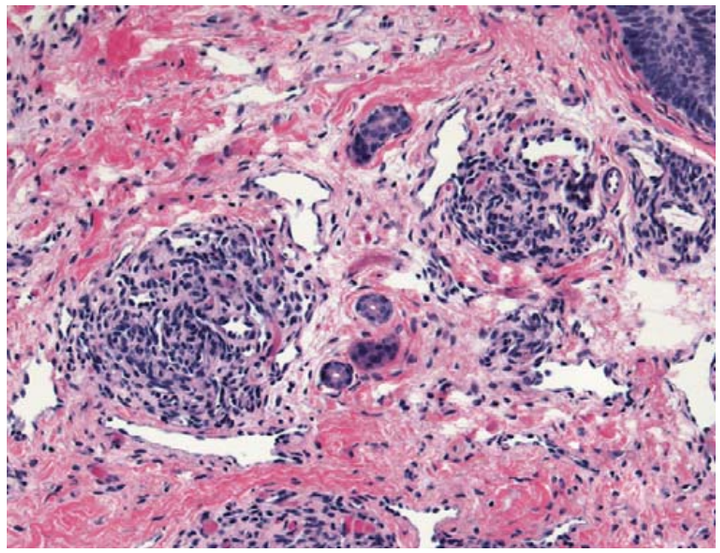

Fig. 114.18 Histology of tufted angioma. A cannonball distribution of dense capillary lobules in the dermis is classic.

Treatment

Complete surgical excision is the treatment of choice for small tufted angiomas, although recurrence is common. Use of the pulsed dye laser has been ineffective[49,55], although the argon tunable dye laser has been used successfully but with the risk of scarring. Both aggravation and improvement have been reported with the Nd:YAG laser. High-dose systemic corticosteroids may be useful[56], and interferon-α has produced partial regression (for side effects, see Ch. 103)[55]. Currently, vincristine is the preferred treatment for Kasabach–Merritt syndrome[57]. Aspirin may help control the platelet interaction, pain and growth of tufted angiomas that develop this complication[49].

Multifocal Lymphangioendotheliomatosis with Thrombocytopenia

Synonyms: ■ Congenital cutaneovisceral angiomatosis with thrombocytopenia

Key features

- Multiple congenital and progressive vascular lesions involving the skin and viscera, complicated by chronic mild to moderate thrombocytopenia
- Skin lesions consist of red–brown plaques and they may be numerous
- Clinically significant gastrointestinal bleeding appears universal and may be life-threatening
- Distinctive histopathological features that resemble benign lymphangioendothelioma, with variable expression of lymphatic-associated immunohistochemical markers (e.g. LYVE-1, podoplanin)

Introduction and history

This distinctive, but only recently recognized, clinicopathological entity was first described in 2004 by North et al.[58] as *multifocal lymphangioendotheliomatosis with thrombocytopenia* (MLT), based upon the highly characteristic histology, multifocal tissue involvement, and consistent expression of the lymphatic-associated marker LYVE-1. An equivalent series of cases was reported by Prasad et al.[59] in 2005 using the term *congenital cutaneovisceral angiomatosis with thrombocytopenia* (CCAT).

Epidemiology

Most cases are evident at birth, although many lesions are slowly progressive and increase in number with time. No clear racial or sexual predilections have emerged.

Pathogenesis

Reported cases are sporadic and it is not yet clear if the lesions are best considered tumors or malformations. Lesional endothelial cells coexpress CD34 and LYVE-1 and may focally express podoplanin, making blood-vascular versus lymphatic-vascular differentiation ambiguous[60]. The association with selective thrombocytopenia draws parallels with KHE and tufted angioma – two vascular entities uniquely linked to the Kasabach–Merritt phenomenon that also express mixed blood vascular and lymphatic endothelial markers[43,47,58].

Clinical features

Cutaneous lesions, often numbering in the hundreds at birth, are flat or indurated red–brown to burgundy plaques or papules, often with central pallor and occasionally central scar-like areas. Slow progression of pre-existing lesions and progressive appearance of new lesions is typical, without evidence of regression. Similar lesions in the gastrointestinal tract cause severe gastrointestinal bleeding beginning in infancy. Some patients have extensive pulmonary involvement complicated by hemoptysis; rarely, other sites are affected (e.g. muscle, synovium)[47,48,58,59,61]. Thrombocytopenia is mild to moderate, chronic and fluctuating, with essentially normal prothrombin time (PT), partial thromboplastin time (PTT) and serum fibrinogen levels.

Pathology

Lesions are composed of thin-walled vessels scattered throughout the dermis and subcutis and lined by a monolayer of slightly hobnailed endothelial cells that focally form papillary projections (Fig. 114.19). Some of the papillary formations are complex and appear to float in the luminal plane of section (Fig. 114.19, insert). Many vessel lumens, especially the smaller ones, are largely devoid of red blood cells. Endothelial cells show strong immunopositivity for CD31, CD34, and LYVE-1, light to absent positivity for D2-40 (podoplanin), and negativity for GLUT-1[58]. Mitotic figures are rare or absent.

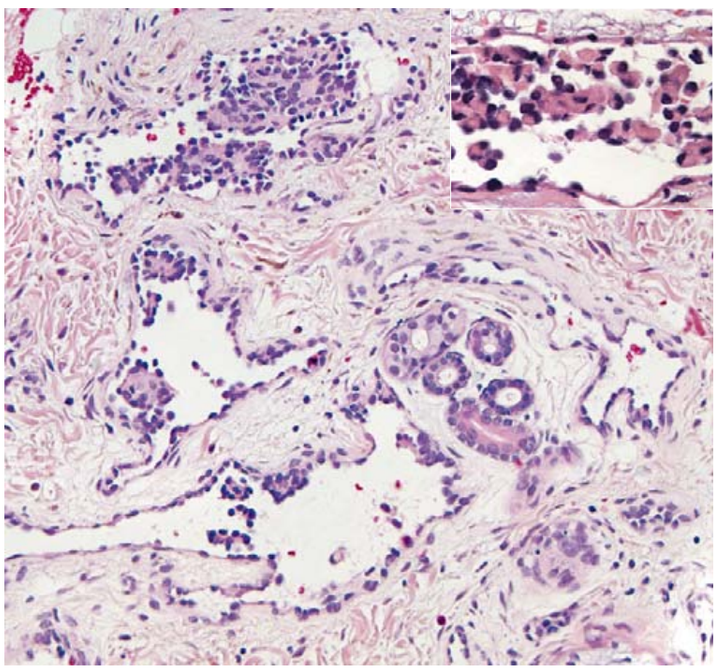

Fig. 114.19 Histology of multifocal lymphangioendotheliomatosis with thrombocytopenia. Thin-walled vessels focally forming intraluminal papillary projections scattered throughout the dermis and subcutis. Complex papillary projections lined by endothelium may appear to float in the lumen (insert).

Differential diagnosis

This entity must be differentiated from other multifocal vascular skin disorders presenting during infancy or childhood, including diffuse neonatal hemangiomatosis, blue rubber bleb nevus syndrome, glomuvenous malformations (glomangiomas), and Maffuci syndrome. The differential diagnosis also includes other causes of a "blueberry muffin baby", such as extramedullary hematopoiesis and leukemia cutis (see Table 121.4). The skin lesions of MLT, however, are unique in their clinical and histologic appearance, and are far more numerous than would be typical for any of the other vascular conditions except diffuse neonatal hemangiomatosis.

Treatment

Gastrointestinal bleeding may spontaneously stabilize or require colectomy for effective control. Corticosteroids, interferon-α, thalidomide and bevacizumab have been reported to be of possible value in some, but not all, cases[58,59,62].

BORDERLINE AND LOW-GRADE MALIGNANT VASCULAR NEOPLASMS

Kaposiform Hemangioendothelioma

Synonyms: ■ Infantile kaposiform hemangioendothelioma ■ Kaposi-like infantile hemangioendothelioma

Key features

- A rare vascular tumor of childhood that presents as an ill-defined violaceous plaque and in some patients is associated with a life-threatening platelet-trapping syndrome (Kasabach–Merritt phenomenon)
- Locally aggressive and occasionally multifocal along lymphatic pathways, but thought not to truly metastasize
- Classically, a deeply seated, infiltrative tumor that crosses tissue planes and may involve the skin and subcutaneous as well as deep soft tissues, bone and even viscera
- Overlapping histologic features (e.g. expression of mixed blood vascular and lymphatic endothelial markers) and likely synonymous in pathogenesis with tufted angioma, with the latter being more superficial in location
- Unlike common infantile hemangioma, does not spontaneously involute
- Complete surgical excision is recommended where feasible

Introduction and history

Kaposiform hemangioendothelioma (KHE) was described as such by Zukerberg et al.[46] in 1993, although equivalent lesions had been previously reported as "hemangioma with Kaposi's sarcoma-like features"[63] and "Kaposi-like infantile hemangioendothelioma"[64]. Many lesions of this type were previously misdiagnosed as infantile hemangioma.

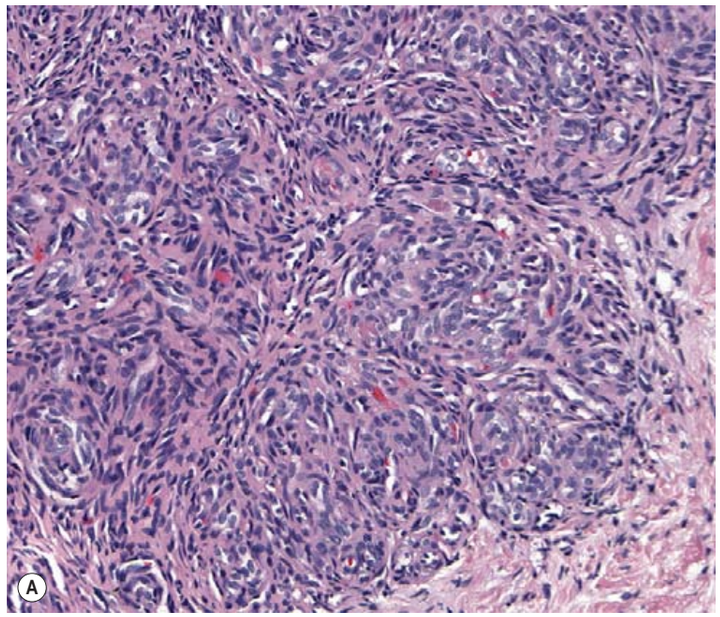
Epidemiology

Most tumors present in children less than 2 years of age, and some are congenital. Occasionally they have been reported in adults, all to date without evidence of Kasabach–Merritt syndrome[65]. There is no gender predilection.

Pathogenesis

Recent studies have demonstrated expression of several lymphatic endothelium-associated antigens (including the master regulator of lymphatic differentiation Prox1) in KHEs, supporting the concept that these tumors, like tufted angioma, Kaposi sarcoma and a subset of angiosarcomas, have at least a partial lymphatic endothelial phenotype[50,66]. Coexpression of the blood vascular marker CD34 with these

Fig. 114.20 Kaposiform hemangioendothelioma complicated by Kasabach–Merritt phenomenon. A large red–purple mass on the upper flank of an infant.



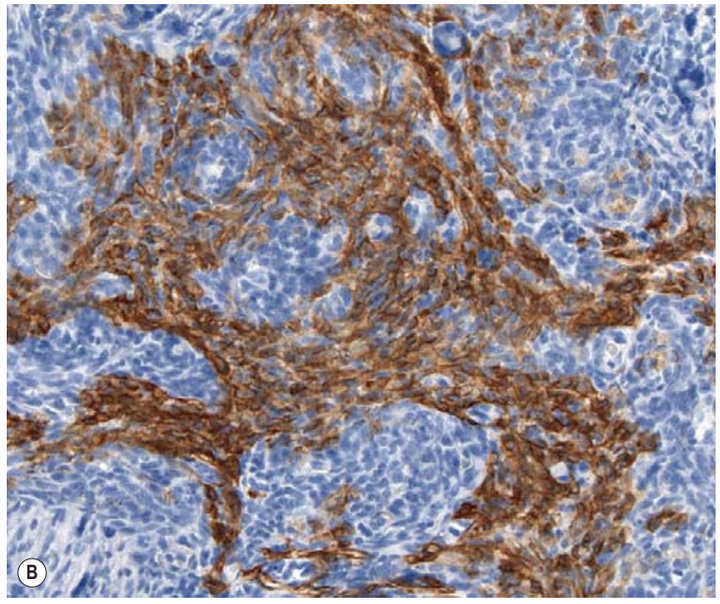


Fig. 114.21 Histology of kaposiform hemangioendothelioma. A Fascicles of spindled endothelial cells forming slit-like lumina surround nests of more epithelioid areas rich in pericytes. **B** The endothelial cells show evidence of lymphatic differentiation, here evidenced by positivity for podoplanin.

lymphatic markers in both KHE and tufted angioma, together responsible for the vast majority of cases of Kasabach–Merritt phenomenon, suggests that this aberrant, ambiguous lymphatic–blood vascular phenotype (at least when present in infants) may promote intratumoral platelet trapping[58].

Although platelet transfusions may be necessary for acute management, they have in some patients paradoxically worsened the coagulopathy[43,67]. Based on these observations plus the rapid tumor shrinkage that can follow pharmacologic control of platelet trapping, it has been suggested that intratumoral platelet activation may "add fuel to the fire" by stimulating vascular proliferation[43], presumably by the release of angiogenic agonists such as platelet-derived growth factor. A self-sustaining cycle of platelet trapping and tumor growth may thus be important for development of the full-blown Kasabach–Merritt phenomenon.

Histologic and immunohistochemical similarities between Kaposi sarcoma and KHE suggested that these entities might be etiologically related. However, HHV-8 sequences have not been identified in KHE[68], and children with coincident KHE and HIV infection have not been reported.

Clinical features

Cutaneous forms present as locally infiltrative vascular macules or plaques that may develop nodules. Deeper soft tissue lesions may present as bulging, indurated masses (Fig. 114.20) or be undetected on physical examination. Untreated lesions do not appear to regress, and patients with tumors complicated by Kasabach–Merritt phenomenon often have purpura and ecchymoses. In a compilation of reported cases with skin involvement[68], the initial average age at presentation was 43 months, which is significantly later than that of classic infantile hemangioma. More deeply seated tumors, particularly those in the retroperitoneum, are more likely to cause Kasabach–Merritt phenomenon[68].

The two most common causes of death from KHE are complications of thrombocytopenia and direct tumor infiltration[68]. No distant metastases have been reported to date, although one patient had spread to regional lymph nodes[69]. Clinical evaluation of suspected cases, for instance new-onset vascular tumors in children >3 months of age[68], should include magnetic resonance imaging (MRI), a complete blood cell count, coagulation studies to detect coexistent Kasabach–Merritt phenomenon, and, if not prohibited by severe thrombocytopenia, biopsy for histopathologic diagnosis. MRI typically shows ill-defined tumor margins with the involvement of multiple tissue layers.

Pathology

Kaposiform hemangioendotheliomas are characterized by ill-defined, frequently coalescing nodules composed of fascicles of moderately plump spindled endothelial cells with eosinophilic to clear cytoplasm and bland nuclei that form elongated, slit-like lumina containing erythrocytes, reminiscent of Kaposi sarcoma (Fig. 114.21A). The spindle cells often encompass nests of more epithelioid endothelial cells and pericytes that are surrounding platelet-rich microthrombi (highlighted by CD61 immunostaining). At the margin of the lesion, the spindle cells may infiltrate into the surrounding adipose tissue and between collagen bundles, or they may be encased by desmoplastic stroma. The spindle cells are strongly immunoreactive for the pan-endothelial marker CD31, the blood vascular marker CD34, and the lymphatic endothelial markers podoplanin (Fig. 114.21B), LYVE-1, VEGFR-3 and Prox1[50].

Mitotic activity is variable, but generally low. Focally, lobules of small, rounded capillaries lined by flat endothelia merge with the spindled areas. Extravasated erythrocytes and hemosiderin granules are typically present, and tumor cells may contain intracytoplasmic erythrocyte fragments and hyaline globules. Often there is a prominent component of dilated vessels with a lymphatic morphology that intermingles with the tumor lobules, but these vessels are often most obvious within the marginal soft tissues. Residual KHE, i.e. remaining after successful

medical treatment, represents a dormant, often sclerotic, version of the original disease process.

Differential diagnosis

The most important differential considerations are common infantile hemangioma, tufted angioma and Kaposi sarcoma. Infantile hemangiomas, unlike KHE, express an unusual and complex endothelial phenotype shared only by placental capillaries, most commonly manifested by immunohistochemical staining for GLUT-1[51,70]. Infantile hemangiomas also lack both fascicles of spindle cells and foci with a mixed lymphatic–blood vascular phenotype. Tufted angioma is thought to be a milder, more superficial form of KHE that is distinguished by a relative scarcity of endothelial spindling and an absence of pericyte-rich epithelioid nodules. Kaposi sarcoma, which is rare in children (outside of Africa), lacks the lobularity of KHE and characteristically contains plasma cell infiltrates.

Treatment

Tumors that are localized and superficial can be cured by wide local excision. However, tumors in the mediastinum or retroperitoneum are often large and unresectable. Evidence-based treatment regimens for unresectable tumors with associated Kasabach–Merritt syndrome are not available. Based upon case series, the following, alone or in combination[71], may be helpful therapeutically: interferon-α-2a[72], vincristine[73], radiation therapy, and aspirin plus ticlopidine, as well as chemotherapeutic regimens (e.g. cyclophosphamide, vincristine and actinomycin D)[74]. Currently, vincristine is the recommended first-line treatment for associated Kasabach–Merritt syndrome[57]. Corticosteroids alone do not appear to be effective[68].

Dabska-type Hemangioendothelioma

Synonyms: ■ Papillary intralymphatic angioendothelioma (PILA) ■ Dabska tumor ■ Endovascular papillary angioendothelioma ■ Malignant endovascular papillary angioendothelioma ■ Hobnail hemangioendothelioma

Key features

- Rare neoplasm of at least partial lymphatic differentiation and very low metastatic potential that occurs primarily in children
- Enlarging dermal or subcutaneous mass or plaque, primarily in children and often on distal extremities
- Histologically defined by prominent papillary intralymphatic growth and peculiar rosette-like clusters of hobnail, columnar endothelial cells
- Arguably related to retiform hemangioendothelioma, a histologically similar tumor occurring mainly in adults

Introduction and history

Maria Dabska first described tumors of this type as *malignant endovascular papillary angioendothelioma* in 1969 based on a series of six cases, all in children. Two patients in this original series had lymph node metastases, and one of these later developed distant metastases and died[75]. Subsequently reported cases have behaved in a benign fashion, although follow-up for some has been limited[76]. Based on the prominent presence of lymphatic vessels, the tentative potential for malignant or borderline clinical behavior, and the defining presence of papillary intravascular proliferation, another designation for this tumor is *papillary intralymphatic angioendothelioma* (PILA)[76]; this latter term has been adopted by the WHO[77]. Because of their shared hobnail endothelial morphology, lymphatic differentiation and similar biologic behavior, Weiss and Goldblum[4] have suggested that the term *hobnail hemangioendothelioma* be used to embrace both Dabska-type hemangioendothelioma and retiform hemangioendothelioma. However, detection of lymphatic differentiation in retiform hemangioendothelioma has been inconsistent, bringing into question the relatedness of these two entities[78–80].

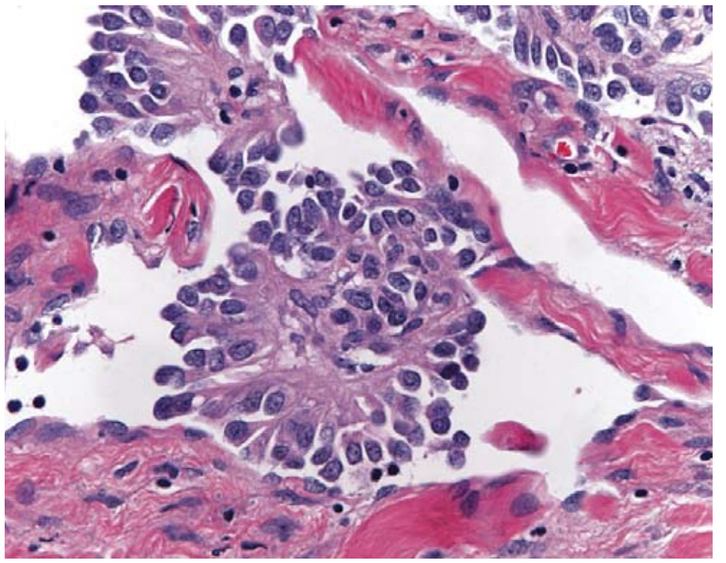

Fig. 114.22 Histology of Dabska-type hemangioendothelioma. Rosette-like intravascular clusters of hobnailed, columnar endothelial cells.

Epidemiology

Compilations of reported cases have shown no clear gender predilection, with approximately 75% of patients being children and the remainder primarily young adults. Tumors may be present at birth. A more recent series of 12 patients in which the mean age was 30 years suggests a wider age range for Dabska-like hemangioendotheliomas[76].

Clinical features

Most of these tumors originate within the soft tissues of an extremity and rarely other sites such as bone or spleen. Lesions can present as either enlarging, diffuse, firm swellings of skin and subcutaneous tissue or as soft intradermal plaques; sometimes there is also a pink or blue discoloration of the skin. The size range is wide (up to 40 cm)[76]. A number of cases appear to have arisen within pre-existing lymphatic malformations ("lymphangiomas"). Involvement of superficial tissues has been observed on the extremities, head and neck, and trunk. Local recurrences are relatively common (about 40%).

Pathology

The unifying microscopic feature is a presence within the dermis and/or subcutis of intercommunicating, thin-walled vessels lined by hobnail endothelial cells, with the latter forming characteristic intraluminal papillary projections that focally assume a rosetting or matchstick-like pattern (Fig. 114.22). Lesional vessels are variable in size. Hyaline papillary stromal cores are immunoreactive for collagen type IV, and, in some cases, focal actin-positive pericytes may be present within the papillary projections[76]. Lymphocytes may cluster along the endothelial lining of the vessels and infiltrate into the surrounding stroma; large lymphoid aggregates are common. Recent studies have shown strong endothelial immunopositivity for VEGFR-3 and podoplanin in the hobnail endothelial proliferations of these tumors[52,62,66,76,77], indicative of lymphatic differentiation. CD34 expression is low.

Differential diagnosis

Dabska-type hemangioendotheliomas must be differentiated histologically from other entities with hobnail endothelial architecture, including hobnail hemangioma (targetoid hemosiderotic hemangioma), retiform hemangioendothelioma, and well-differentiated angiosarcoma. Hobnail hemangioma is a smaller, more superficial dermal process, without exuberant papillary tufts. Retiform hemangioendotheliomatosis usually occurs in adults and intravascular papillary tufts are infrequent and poorly developed. Of note, regional lymph node disease has been documented in both Dabska-type and retiform hemangioendothelioma. Angiosarcoma, even when well differentiated, may display intravascular papillary growths that suggest Dabska-type

hemangioendothelioma, but classic hobnail endothelial cells are absent. Angiosarcomas are extremely uncommon in children and are usually visceral (especially cardiac or pericardial).

Treatment

Dabska tumors are rare, typically indolent lesions with rare examples of regional lymph node spread. Optimal therapy is relatively conservative surgical excision with clear margins, supplemented by close follow-up.

Retiform Hemangioendothelioma

Synonym: ■ Hobnail hemangioendothelioma

Key features

- Rare neoplasm with very low metastatic potential that occurs primarily in adults
- Presents as a slow-growing exophytic tumor or plaque on the trunk or extremities, especially the distal lower extremities
- Characterized histologically by a diffuse infiltration of the dermis and/or subcutis by elongated vessels with hobnail endothelial cells arborizing in a pattern similar to that of the normal rete testis
- Local recurrence following excision occurs in about 60% of cases but regional lymph node spread is rare
- Proposed, but still unclear, relationship to Dabska-type hemangioendothelioma, a histologically similar tumor occurring mainly in children

Introduction and history

Retiform hemangioendothelioma was first described as an entity in 1994 by Calonje et al.[36] based on a series of 15 cases, and was interpreted as a low-grade angiosarcoma. Fewer than a dozen additional cases have subsequently been reported. Similarities in histology and clinical behavior to Dabska-type hemangioendothelioma, a tumor mainly affecting children, have led to a proposal that these two entities be jointly described by the term *hobnail hemangioendothelioma*[4], not to be confused with hobnail hemangioma discussed previously. However, reported cases of retiform hemangioendothelioma, unlike hobnail hemangioma and Dabska-type hemangioendothelioma which show clear lymphatic differentiation, have shown variable expression of lymphatic markers[78–80].

Epidemiology

Men and women are equally affected. The patient age range for reported cases is 9 to 78 years.

Clinical features

The clinical appearance of retiform hemangioendothelioma is not specific and its vascular nature may not be suspected clinically. Lesions present as solitary, slowly growing plaques, exophytic masses or dermal/subcutaneous nodules, and they most commonly develop on the extremities. In the series of Calonje et al.[36], nearly 60% of cases recurred locally, and 1 of 14 patients followed longitudinally developed lymph node involvement. To date, there have been no tumor-related deaths.

Pathology

Retiform hemangioendothelioma is one of a small group of vascular tumors that also includes hobnail hemangioma and Dabska's tumor which is characterized by endothelial cells with a so-called hobnail appearance. Overall, there is a diffuse infiltration of the reticular dermis and/or subcutis by an arborizing network of elongated, thin-walled vessels forming a pattern reminiscent of normal rete testis. The margins are ill defined. Higher magnification of the lesional vessels reveals a lining of bland endothelial cells with prominent apical nuclei that protrude into the lumina in a hobnail or "matchstick" fashion. Mitotic figures are rare, and cytologic atypia is minimal, or rarely, mild. Solid foci of spindle cells expressing endothelial markers are often present, as are occasional intravascular papillae. The cavernous lymphatic-like vessels and prominent intravascular proliferations characteristic of Dabska-type hemangioendothelioma tumor are absent. Most, but not all, cases of retiform hemangioendothelioma that have been assessed for markers of lymphatic endothelial differentiation (e.g. VEGFR-3, podoplanin) have proved to be negative[66,76,78,79].

Differential diagnosis

The most important entity to exclude is well-differentiated angiosarcoma, which is distinguished by cytologic atypia, multilayed endothelial cells, increased mitotic activity, and lack of hobnail endothelial cells.

Treatment

Wide excisional biopsy with follow-up is appropriate.

Epithelioid Hemangioendothelioma

Key features

- Vascular tumor of adults with intermediate malignant potential
- Skin involvement is uncommon and is usually associated with more deeply seated disease, often associated with a vein
- Characterized histologically by cords and nests of epithelioid endothelial cells in a myxoid or hyalinized background
- Approximately 30% of patients develop metastases within regional nodes, lung, liver or bone
- Fewer than 50% of patients with metastases die of their disease

Introduction and history

Epithelioid hemangioendothelioma is a low-grade angiosarcoma (hemangioendothelioma) first described by Weiss and Enzinger in 1982. It has more metastatic potential than other lesions classified as hemangioendotheliomas[81]. Most arise within deep soft tissues, but lesions can occur in the skin, viscera and bone. Since its original description, approximately 20 cutaneous cases have been reported in the literature[81,82].

Epidemiology

Epithelioid hemangioendothelioma typically occurs in adults. There is no gender predilection.

Pathogenesis

Epithelioid hemangioendotheliomas are clonal neoplastic proliferations of endothelial cells with low to intermediate potential to metastasize. Chromosomal translocation has been reported[83].

Clinical features

Most tumors present as a solitary, slightly painful, soft tissue mass. Skin involvement is often associated with an underlying soft tissue or bone tumor, but purely cutaneous examples also occur[81]. The most frequently reported sites of cutaneous involvement are the extremities. Some cases are closely associated with or arise from a vessel, usually a vein[84]. Occlusion of that vessel may cause secondary symptoms, such as edema or thrombophlebitis. Overall, approximately 30% of patients develop metastatic disease involving regional nodes, lung, liver or bone, and fewer than 50% of these patients with metastases have died of their disease[84]. One study of 30 patients suggested that dermal tumors may have a better prognosis than more deeply seated lesions[76].

Pathology

Like their more common counterparts involving soft tissue and bone, epithelioid hemangioendotheliomas involving the skin show an infiltrative growth pattern of epithelioid tumor cells with eosinophilic cytoplasm that form poorly canalized nests and cords within a distinctive myxohyaline stroma. An important clue to their endothelial origin is the presence of small intracytoplasmic vacuoles containing red blood cells (Fig. 114.23). Nuclei are vesicular with little or no atypia and

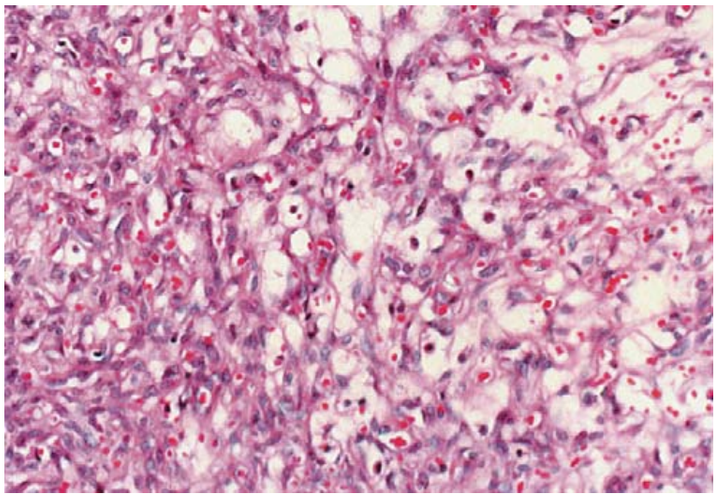

Fig. 114.23 Histology of epithelioid hemangioendothelioma. Poorly canalized cords and nests of endothelial cells in a myxoid background form small intracytoplasmic vacuoles containing red blood cells.

contain small, inconspicuous nucleoli. An angiocentric growth pattern may be present, but is less commonly observed in cutaneous tumors. Unlike epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia), inflammation is sparse. Mitotic rate is variable and only weakly correlated with clinical outcome[81].

Differential diagnosis

The differential diagnosis is wide and includes epithelioid sarcoma, metastatic carcinoma, melanoma and epithelioid angiosarcoma. An essential criterion for diagnosis of epithelioid hemangioendothelioma is immunohistochemical evidence of endothelial differentiation[81]. Differentiation from epithelioid angiosarcomas may be problematic and relies upon recognition of the typical architectural pattern of epithelioid hemangioendothelioma throughout the lesion.

Treatment

Appropriate therapy involves wide local excision without adjuvant chemotherapy or radiotherapy, given the typically low-grade nature of these tumors. Regional lymph nodes should be evaluated since these represent a common metastatic site. In case reports, stabilization of disease has been observed with antiangiogenic agents such as interferon, celecoxib and thalidomide[85].

Kaposi Sarcoma

Key features

- It is controversial whether Kaposi sarcoma (KS) represents neoplasia or hyperplasia; all clinical variants are viewed as a virally induced disease, with human herpesvirus-8 (HHV-8) the implicated agent
- A multifocal systemic disease with four principal clinical variants: (1) chronic or classic KS; (2) African endemic KS, including a fulminant lymphadenopathic type; (3) KS due to iatrogenic immunosuppression; and (4) AIDS-related epidemic KS
- Cutaneous lesions can vary from pink patches to dark violet plaques, nodules or polyps, depending on clinical variant and stage
- The histologic features of KS do not vary significantly between clinical subtypes, but do vary with stage of the lesion
- Most cases in children, with or without HIV infection, are of the lymphadenopathic type and are rapidly fatal due to visceral dissemination
- Because of multifocality, treatment with chemotherapy and/or radiation is favored over surgery

EPIDEMIOLOGIC ASPECTS OF THE FOUR MAJOR TYPES OF KAPOSI SARCOMA
CLASSIC
• Predominantly in individuals of Jewish (Ashkenazi) descent and/or of Mediterranean/Eastern European descent • Male : female (M : F) ratio varies from 15 : 1 (older literature) to 3 : 1 or 1 : 1 (more recent observations) • Two-thirds of patients develop disease after the age of 50 years
AFRICAN ENDEMIC
• Incidence amongst black Africans ranges from 1% to 10%, with a clear male predominance • Accounts for up to 9% of all reported cancers in equatorial Africa • The lymphadenopathic variant affects primarily children, with a M : F ratio of approx. 1 : 1
DUE TO IATROGENIC IMMUNOSUPPRESSION
• Individuals are immunosuppressed secondary to systemic medications, e.g. calcineurin inhibitors, prednisone, cytotoxic agents • Cyclosporine is associated with a higher incidence and more rapid onset of disease • Lesions can regress following cessation of immunosuppressive therapy • Estimated incidences of post-transplantation KS in Western countries and the Near East are <1% and 4%, respectively • Men are slightly more often affected than women
AIDS-RELATED EPIDEMIC
• Occurs primarily in men who have sex with men • To a lesser degree, seen in female partners of affected men and in women from certain regions of Africa and the Caribbean who became HIV-infected via heterosexual contact • Up to 40% of men who have AIDS and became HIV-infected via homosexual contact can develop KS, compared with <5% in other risk groups and 4% in children

Table 114.3 Epidemiologic aspects of the four major types of Kaposi sarcoma (KS).

Introduction and history

In 1872 Moritz Kaposi described five men with an unusual multifocal sarcoma of the skin which he termed "idiopathic multiple pigmented sarcoma of the skin". This disease entity became known as *Kaposi sarcoma* and historically has been considered a chronic, protracted disease primarily affecting elderly men, generally Jewish (Ashkenazi) or of Mediterranean/Eastern European descent. Despite occasional reports regarding its occurrence in organ transplant recipients and its endemic form in Africa, KS received little attention until it became epidemic among men who have sex with men and was recognized as a sign of acquired immunodeficiency syndrome (AIDS). A new human herpesvirus (HHV-8) was recognized as the probable inductive agent of all clinical variants of KS. The mechanisms that control the clinical variability of KS are likely to involve a number of interrelated factors modulated by the patient's immune status and have yet to be fully defined.

Epidemiology

The epidemiologic aspects of the four major types of Kaposi sarcoma are outlined in Table 114.3.

Pathogenesis

Immunohistochemical and ultrastructural studies have firmly established the endothelial nature of KS, but it remains controversial whether this endothelial phenotype is vascular, lymphatic or perhaps a composite of both. Moreover, many, if not most cells forming the substance of a plaque or nodule of KS are spindled cells distinctly unlike normal endothelial cells in morphology, although expressing pan-endothelial markers like CD31. These spindled cells also coexpress markers of blood vascular differentiation (CD34) and lymphatic differentiation (VEGFR-3[66,86], podoplanin[87] and LYVE-1[88]). A seminal discovery was that, *in vitro*, HHV-8 can infect both lymphatic and blood vascular endothelial cells and induce transcriptional reprogramming, leading to expression of lymphangiogenic molecules in infected blood vascular endothelial cells[89] and a more blood vascular profile in infected

Fig. 114.24 Classic Kaposi sarcoma. Red macules and patches on the plantar surface of the foot, with violaceous plaques on the ankle.

Fig. 114.25 Kaposi sarcoma in a patient with AIDS. Violet–red papules or nodules are often oval to lanceolate and are usually more widely distributed than in classic KS.

lymphatic endothelial cells[90]. This potentially explains the mixed lymphatic/blood vascular phenotype of KS, but also emphasizes the difficulty in precisely assigning endothelial cell derivation based solely on marker studies[91].

It also remains unclear whether KS is essentially hyperplastic or neoplastic in nature. While some studies employing X-chromosome inactivation (methylation) patterns have supported singular, presumably disseminated, clones[92], others utilizing the same methodology in examining sets of multiple lesions from single patients have found either oligoclonal composition within a given lesion or dissimilar, presumably independently developing, clones[93].

Despite these lingering uncertainties about endothelial phenotype and clonality, it is noteworthy how much compelling molecular, clinical and epidemiological evidence has accumulated to confirm that infection with HHV-8 causes, or at least strongly influences, the development of KS[94]. This virus was first identified in KS cells of a patient with AIDS and now is known to be present in most patients with all clinical types of KS. Seroreactivity to HHV-8 is not present to a significant degree in the normal population. The HHV-8 genome, when detected in the blood of HIV-positive men, strongly predicts their subsequent development of KS. HHV-8 contains homologues of cellular genes that can stimulate cell proliferation, inflammation and angiogenesis and perhaps inhibit apoptosis[95]. The host immune response and cytokines (particularly fibroblast growth factor) released by the virally infected cells may further support tumor growth in an autocrine and paracrine manner[77,78,96,97]. The role of inflammation in KS is supported by the observation that in patients with AIDS, pre-existing KS can get worse, at least transiently, in the setting of the immune reconstitution inflammatory syndrome (IRIS; see Ch. 78)[98].

Clinical features

Classic KS typically presents as slowly growing, pink to red–violet macules on the distal lower extremities that may coalesce to form large plaques (Fig. 114.24), or develop into nodules or polypoid tumors. Initially unilateral lesions progress to a more widely disseminated multifocal pattern. Early lesions may regress, while others evolve, leading to lesions of different stages at the same time. Patients with longstanding KS may have lesions in the mouth and gastrointestinal tract that are usually asymptomatic.

African endemic KS can be classified into four subgroups: nodular, florid, infiltrative and lymphadenopathic. The nodular variant resembles classic KS in course and appearance, whereas the florid and infiltrative types are more biologically aggressive. The lymphadenopathic type is notably different in several regards: it predominantly affects children, the primary tumors involve the lymph nodes (although skin and mucosal lesions may also be present), and its course is fulminant and fatal.

KS due to iatrogenic immunosuppression (transplantation-associated KS) is generally clinically similar to classic KS. It may resolve completely upon removal of immunosuppressive therapy. KS associated with prolonged high-dose immunosuppression may behave in a more aggressive fashion, causing death in patients who develop internal involvement.

AIDS-related epidemic KS most commonly affects HIV-infected patients with advanced immune impairment and $CD4^+$ T cell counts of fewer than 500 cells per cubic millimeter[99]. Clinical features of KS in the HIV-infected patient are protean. While some patients experience only a single lesion, others have disseminated cutaneous disease. Individual lesions range from faint erythematous macules, papules and plaques, to purple–black tumors and nodules. Macules and plaques are frequently oval to lanceolate and may array along lines of cleavage of the skin (Fig. 114.25). Coalescing papules and plaques occasionally form extensive armor-like constricting plaques that may impair the function of extremities and cause lymphedema.

While any skin surface may be involved, the trunk and midface (particularly the nose) are common sites, causing significant cosmetic disfigurement (see Ch. 78) . Bluish to violaceous macules, plaques and tumors can arise intraorally. Plaques and tumors at any site may ulcerate and become secondarily infected. KS frequently involves the viscera, including the gastrointestinal tract, lymph nodes and lungs. The prognosis of pulmonary disease is grave.

Pathology

The histologic appearance of KS does not vary significantly between the different clinical subtypes, but does vary with stage of the lesion. The *patch* stage is characterized by a superficial dermal proliferation of small, angulated vessels lined by inconspicuous endothelial cells, suggestive of lymphatics (Fig. 114.26). These delicate but "jagged" vessels tend to separate collagen bundles and are accompanied by a sparse infiltrate of lymphocytes and plasma cells as well as small numbers of spindle cells expressing endothelial markers. In the more advanced *plaque* stage, the vascular proliferation extends to include the deeper dermis and may involve the subcutis. The spindled endothelial cell population also expands among the ramifying small vessels.

In the *nodular* phase, there is replacement of dermal collagen by these spindled endothelial cells. Pleomorphism and significant numbers of mitotic figures are absent. The spindle cells form intersecting fascicles and are separated by characteristic slit-like spaces containing erythrocytes (Fig. 114.27). The resulting sieve-like pattern of vascular spaces is highly characteristic of KS. Intracellular and extracellular hyaline globules are thought to represent degenerated erythrocytes[4]. The tumor nodules are often rimmed by ectatic or crescentic vessels, hemosiderin

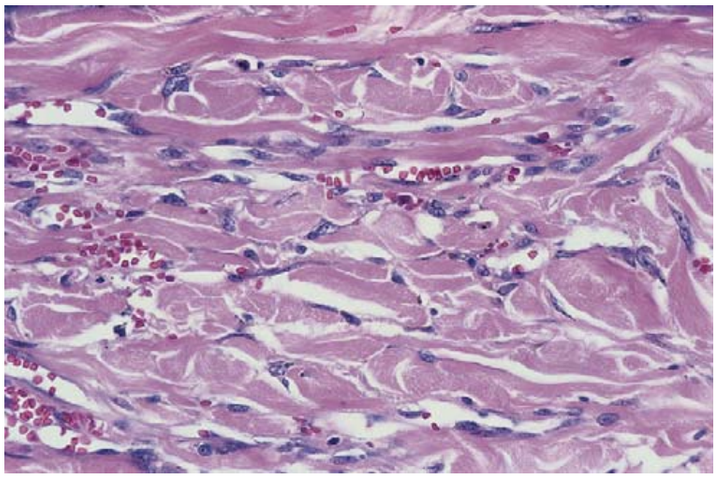

Fig. 114.26 Histology of Kaposi sarcoma – patch stage. Slit-like vascular spaces are present. *Courtesy, Ronald P Rapini, MD.*

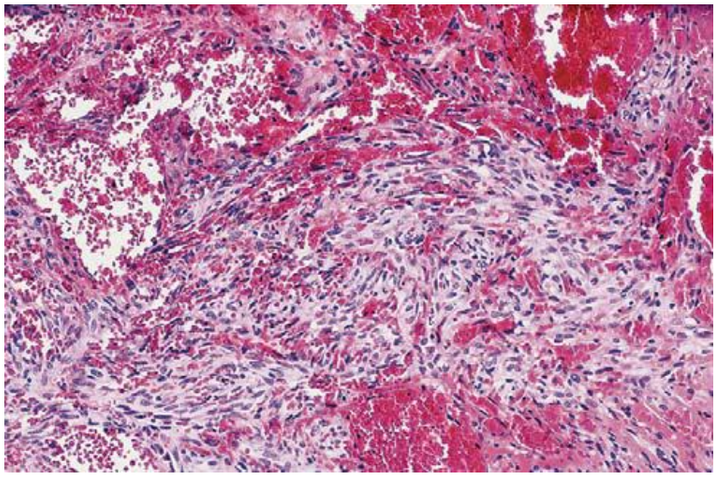

Fig. 114.27 Histology of Kaposi sarcoma – nodular stage. Dilated blood vessels and solid areas of bland spindle cells, slit-like spaces, and hemorrhage.

deposits, lymphocytes and plasma cells, and may be compartmentalized by fibrous bands. Some tumors contain prominent ectatic meshworks of vessels and have been referred to as "lymphangioma-like" KS. Tumors with a frankly sarcomatous appearance, nuclear pleomorphism and brisk mitotic activity may occur either as a late stage within previously indolent lesions or as an initial presentation, the latter most commonly in African endemic cases.

Demonstration of expression of the latency-associated nuclear antigen (LANA-1) of HHV-8 has proved in a number of studies to be a highly sensitive and specific marker of KS and other HHV-8-associated disorders such as multicentric Castleman's disease and primary effusion lymphoma in both HIV-positive and HIV-negative patients (see Ch. 80)[100,101]. Immunohistochemical detection of this antigen in vascular tumors is more diagnostically useful than detection of the HHV-8 genome by PCR since a few non-KS vascular tumors in both immunocompromised and immunocompetent patients have been found to be positive for HHV-8 by PCR, but not by LANA-1 immunohistochemistry, presumably due to detection of HHV-8 within blood cells circulating through the tumors[100].

Differential diagnosis

Lesions of KS may resemble a number of other diseases clinically and histologically, especially early and late stage lesions. The clinical differential for macular stage KS includes well-differentiated angiosarcoma, capillary malformation, microvenular hemangioma and hobnail hemangioma. These can be distinguished histologically, with the plasma cell-rich infiltrate of KS being an important discriminating factor.

The most important differential diagnostic considerations in nodular stage KS are KHE, spindle cell hemangioma and moderately differentiated angiosarcoma. Although KS and spindle cell hemangioma are both characterized by proliferations of spindle cells, KS lacks the cavernous spaces of the latter. KHE is almost exclusively a disease of infancy and childhood and is distinguished from KS by a strongly lobular architecture and lack of plasma cell infiltrates. Angiosarcoma is characterized by endothelial atypia and mitotic activity, both absent in KS.

Late stage KS may both clinically and histologically resemble acroangiodermatitis of chronic venous insufficiency and Stewart–Bluefarb syndrome (pseudo-Kaposi sarcoma). These reactive, hyperplastic entities differ from KS in that the hyperplasia can be seen to derive from pre-existing vasculature. Late stage KS lesions can also be confused histologically with a number of non-vascular spindle cell sarcomas such as fibrosarcoma and leiomyosarcoma. In these cases, demonstration of CD31 immunoreactivity helps confirm the vascular differentiation of KS.

Other entities that can mimic KS clinically but which can be easily distinguished on the basis of histologic features include cutaneous metastases, leukemia or lymphoma cutis, venous and lymphatic malformations, and the cutaneous manifestations of polyarteritis nodosa and erythema elevatum diutinum.

Treatment

In many patients with KS, obtaining a complete cure may be an unrealistic expectation, since recurrence rates are high. Treatment of visible lesions, even in HIV-positive patients with widely disseminated disease, improves appearance, heightens self-esteem and provides patients with a sense of control in an otherwise difficult situation. In older immunocompetent patients with static disease, observation and close follow-up is an option. Surgery is only useful for tissue diagnosis and removal of solitary lesions. Cryotherapy, laser surgery, photodynamic therapy and topical alitretinoin have been used to treat superficial macules and plaques. Freezing must usually be sufficiently vigorous to cause epidermal ulceration, and the resulting scar seems to replace the vascular proliferation of KS. Extensive, multifocal disease often requires chemotherapy.

Radiation therapy is a treatment option for the patient presenting with multifocal but relatively localized KS. Regimens reported to be successful include single-dose radiation (8 to 12 Gy) delivered to an extended field and total body electron beam therapy (4 Gy) once a week for 6 to 8 weeks. Radiation therapy clearly plays a role in the treatment of localized cutaneous and oral KS, but may have a briefer effect in AIDS-related KS than in classic KS[102].

Rapidly progressive KS (defined by development of 10 or more new cutaneous lesions per month), pulmonary KS, symptomatic visceral involvement and lymphedema are indications for systemic chemotherapy. Doxorubicin, vincristine, etoposide and bleomycin are administered singly or in combination[103], with liposomal preparations of anthracyclines employed to try to reduce side effects. The taxanes paclitaxel and docetaxel are used for the treatment of disseminated KS not responsive to anthracyclines and, depending upon comorbitities, may be used initially. Gemcitabine, an analogue of deoxycytidine, has shown some promise in the treatment of classic KS, with limited side effects[104].

For treatment of individual lesions, intratumoral vinblastine (0.1 mg/ml) or vincristine (0.001 mg/ml)[105] causes a slow fading of erythema and thickness. High concentrations or volumes of injection may cause ulceration of the overlying epidermis, but lesions still resolve with adequate cosmesis.

Interferon-α is a biological response modifier that has been proven effective as a systemic therapy for KS. It is administered either intravenously or as daily subcutaneous injections, with the dose required to achieve success in the treatment of disseminated KS approaching 30 million units per day. However, patients may not tolerate the interferon, given its multiple side effects at this dose[106].

Systemic therapies that inhibit angiogenesis or target HHV-8 are also being investigated. These include thalidomide, bevacizumab (anti-VEGF), the matrix metalloproteinase inhibitor COL-3, and TNP-470 (fumagillin analogue)[83,84]. Additional potential therapies are tyrosine kinase inhibitors (imatinib, sorafenib, gefitinib), pentosan polysulfate, IL-12 and topical halofuginone[104,107,108]. Antiretroviral therapy has clearly helped to alleviate AIDS-related KS, probably indirectly by

decreasing viral load and by increasing the CD4 count, but the exact mechanism is unclear. As noted previously, flares of KS can occur as a manifestation of IRIS (see Ch. 78), but this does not necessarily translate into a poor prognosis.

Organ transplant patients with KS pose a particular therapeutic challenge, that of balancing the risk of graft rejection with the benefit of improvement in KS. In addition to reduction of immunosuppression[109], substitution of sirolimus (rapamycin; mTOR inhibitor) for cyclosporine can also lead to clinical improvement of KS. In 15 renal transplant recipients, this substitution led to resolution of all of the KS lesions in all of the patients, both clinically (by 3 months) and histologically (by 6 months). The authors observed neither episodes of rejection nor changes in kidney graft function[110]. This observation has been independently corroborated by additional studies, albeit not always with equally impressive response rates[111]. It is not yet clear if the beneficial effect of sirolimus reflects lessened immunosuppression or possibly a more direct antitumor effect related to inhibition of HHV-8-induced effects (e.g., PI3K and AKT phosphorylation)[91]. Organ transplant patients with KS also respond to conventional local and systemic therapies used in other forms of KS. There are few published studies on the treatment of African endemic KS.

MALIGNANT VASCULAR NEOPLASMS

Angiosarcoma

Synonyms: ■ Malignant hemangioendothelioma ■ Hemangiosarcoma ■ Lymphangiosarcoma

Key features

- Uncommon malignant neoplasm of endothelium, accounting for <1% of all sarcomas
- Unlike most sarcomas, has a predilection for skin and superficial soft tissue
- Most commonly affects the scalp and face of the elderly and areas of chronic lymphedema or radiodermatitis; rare in children
- Cutaneous forms are usually well to moderately differentiated lesions composed of anastomosing vessels that dissect between bundles of collagen
- Approximately 50% of cases express markers of lymphatic differentiation
- Prognosis is extremely poor, with fewer than 15% of patients surviving 5 years
- Most long-term survivors received early radical ablative surgery

Introduction and history

The term *angiosarcoma* is traditionally used to denote all biologically high-grade malignant neoplasms of endothelial derivation, regardless of the evidence of lymphatic or blood vascular differentiation. Endothelial tumors of low or intermediate malignant potential are designated *hemangioendotheliomas*, although in the past these borderline tumors were often referred to as *low-grade angiosarcomas*. An exception to this rule is KS, a virus-associated disease of highly variable behavior that maintains a controversial place on the spectrum between neoplasia and hyperplasia. Angiosarcomas were first described systematically by Caro and Stubenrauch in 1945. Only 3 years later, Stewart and Treves described the association between angiosarcoma and post-mastectomy lymphedema[112]. The cutaneous form of angiosarcoma that primarily affects the face and scalp of the elderly was characterized by Wilson-Jones in 1964[113].

Epidemiology

Angiosarcomas are unusual neoplasms that occur primarily in adults. Those rare examples that occur during childhood or adolescence are more likely to arise within viscera (especially the heart or pericardium)[114] or in association with other disease states[115], including chronic or congenital lymphedema, chronic radiodermatitis and immunosuppression. Among elderly patients with angiosarcomas of the face and scalp, there is a strong predilection for Caucasians compared to individuals of African or Asian descent, and approximately a 2:1 male:female ratio[116].

Pathogenesis

Angiosarcomas are clonal proliferations of malignantly transformed cells expressing endothelial differentiation. Mechanisms of the association between chronic lymphedema and angiosarcoma remain uncertain. Theories include induction of neoplastic change by unknown carcinogens in accumulated lymphatic fluid[112] and the idea that areas with chronic lymphedema are "immunologically privileged sites" due to loss of afferent lymphatic connections. Although angiosarcomas arising in the setting of chronic lymphedema have often been presumed to originate from lymphatics, this has not been definitively proven. In one series in which cases associated with lymphedema and prior irradiation were excluded, expression of the lymphatic endothelium-associated antigen VEGFR-3 was observed in 8 of 16 angiosarcomas[66]. Another series found VEGFR-3 positivity in only 1 of 2 spindled angiosarcomas and in 0 of 4 epithelioid angiosarcomas[76]. Most angiosarcomas in a third series were found to coexpress podoplanin and podocalyxin, thought to be markers of lymphatic and vascular endothelium, respectively[87]. In sum, this suggests that many angiosarcomas are of mixed lineage. Until this issue is further clarified, use of the more generic term *angiosarcoma,* rather than *lymphangiosarcoma* or *hemangiosarcoma*, seems prudent.

Radiotherapy has been shown to be an independent risk factor for angiosarcoma development, best exemplified in breast cancer patients (see below). Gene amplification of *MYC* and *FLT4* has been implicated in the pathogenesis of secondary angiosarcoma, but not other types[117,118]. Environmental chemical exposures linked to angiosarcoma, particularly of the liver, include vinyl chloride, thorium dioxide, arsenic, radium, and anabolic steroids[119]. Lastly, neither HHV-8 infection nor cumulative sun exposure appears to be associated with angiosarcoma.

Clinical features

The most common form of angiosarcoma is cutaneous angiosarcoma (without lymphedema) in the elderly. Approximately 70% of these tumors occur in patients over 40 years of age, with the highest incidence in those >70 years of age. About 50% involve the head and neck (Fig. 114.28). Lesions typically present as a deceptively benign-appearing bruise-like patch on the central face, forehead or scalp. Facial swelling and edema may be present. More advanced lesions are violaceous, elevated nodules that bleed easily. Ulceration may be present. The area of involvement spreads centrifugally, eventually covering large portions of the head and neck. The prognosis is invariably poor, with a less than 15% survival over a 5-year period[116].

Fig. 114.28 Angiosarcoma. Erythematous and purple hemorrhagic plaques as well as grouped vesicles with clear or hemorrhagic fluid (reminiscent of microcystic lymphatic malformation) are present. There is also induction and a pink hue to the left side of the face in addition to evidence of previous excisions and radiotherapy. *Courtesy, Lorenzo Cerroni, MD.*

Angiosarcomas that arise in the setting of chronic lymphedema present as firm, coalescing violaceous nodules or an indurated plaque on a background of brawny, non-pitting edema. More than 90% of all angiosarcomas associated with lymphedema arise after mastectomy and lymph node dissection (Stewart–Treves syndrome). In these cases, the inner aspect of the upper arm is the most common site of involvement. Other forms of chronic lymphedema are associated with angiosarcoma, including congenital, filarial, traumatic and idiopathic. The duration of lymphedema prior to appearance of angiosarcoma ranges from 4 to 27 years.

Even though the incidence is very low (<0.05% in a recent survey of breast cancer patients)[120], the greater use of breast-sparing surgery paired with irradiation has translated into an increase in post-irradiation sarcomas. The latter arise within breast parenchyma and overlying skin, with an average post-treatment interval of 6 years. Post-irradiation angiosarcomas appear as infiltrative plaques or nodules in or near the area of tissue irradiated and share the poor prognosis of all forms of angiosarcoma. These are aggressive, infiltrative, multicentric tumors that enlarge incessantly. Local recurrence and metastasis to regional lymph nodes and lung are common.

Angiosarcomas of skin and soft tissue have also been reported in association with benign and malignant nerve sheath tumors[121], defunctionalized arteriovenous shunts in renal transplant patients[122], long-term exposure to various foreign materials[123], xeroderma pigmentosum[124] and bilateral retinoblastoma[125]. MRI, which shows a nonspecific decreased or variable signal intensity in T1 images, an increased signal in T2 images, and enhancement with gadolinium, is more useful than CT in accurately delineating the extent of local disease, including involvement of neurovascular structures and joints. It is also the imaging modality of choice for evaluating tumor response to preoperative radiation or chemotherapy.

Pathology

Angiosarcomas involving the skin, although highly variable in degree of endothelial differentiation both between and within individual tumors, do not vary in histology as a class between those of the "usual type" not associated with lymphedema, those associated with chronic lymphedema, and those associated with chronic radiodermatitis. Well-differentiated areas display an anastomosing network of sinusoidal vessels, often bloodless, lined by a single layer of endothelial cells of slight to moderate nuclear atypia. These exhibit a highly infiltrative pattern, splitting apart collagen bundles and groups of adipose cells (Fig. 114.29). In less well-differentiated areas, the endothelial cells with more pronounced nuclear pleomorphism and mitotic activity pile up and form papillary projections. In poorly differentiated areas, luminal formation may be non-apparent and mitotic activity may be high, mimicking other high-grade sarcomas, carcinoma or melanoma. Hemorrhage and blood-filled cavities may be present.

In tumors associated with chronic lymphedema, networks of small lymphatics lined by endothelial cells with hyperchromatic nuclei may ramify through adjacent soft tissues and have been interpreted as premalignant change. Angiosarcomas developing in this setting may retain lymphatic characteristics (Fig. 114.30). Most angiosarcomas immunoreact positively for CD31 and CD34, with CD31 being the more sensitive and endothelium-specific of the two. Immunohistochemical detection of factor VIII-related antigen, although highly specific for endothelial cells, lacks sensitivity for vascular neoplasms and is negative or very weak even in well-differentiated angiosarcomas. Highly aggressive angiosarcomas with an epithelioid appearance occasionally occur in the skin[126], although this variant is more common in deep soft tissues. These so-called "epithelioid angiosarcomas" consist of large rounded cells with prominent eosinophilic nucleoli in which the only morphologic evidence of vascular differentiation may be the presence of occasional intracytoplasmic vacuoles. Cytokeratin positivity is present in about one-third of epithelioid angiosarcomas[127,128], making distinction from carcinoma problematic. Fortunately, this distinction can be accomplished by demonstration of coexistent CD31 expression.

Differential diagnosis

Early recognition and histologic diagnosis are crucial in the treatment of angiosarcoma. Well-differentiated angiosarcomas, which display only slight cytologic atypia despite their high-grade biologic behavior, may closely resemble microcystic lymphatic malformation. Other vascular neoplasms that must be distinguished from angiosarcoma histologically include Dabska-like and retiform hemangioendothelioma, epithelioid hemangioendothelioma and tufted angioma. Intravascular proliferation of atypical endothelial cells is not a feature of KS.

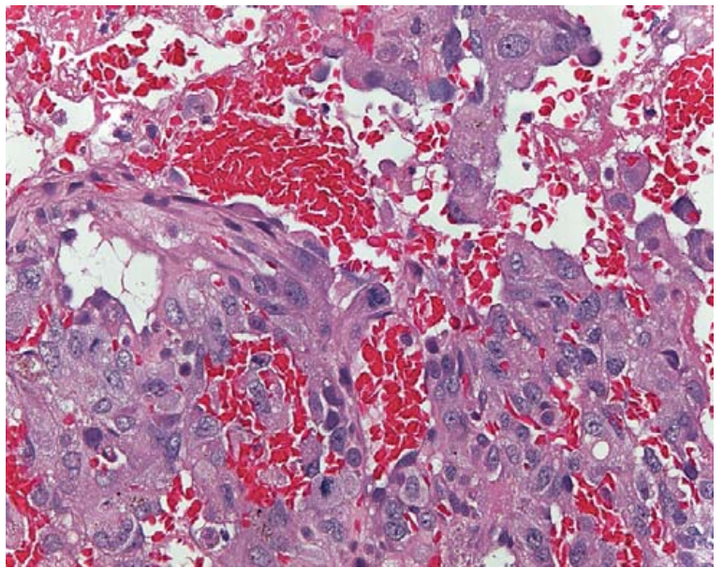

Fig. 114.29 Histology of angiosarcoma. Infiltration of the dermis by ill-defined vascular spaces lined by atypical, piled-up endothelial cells.

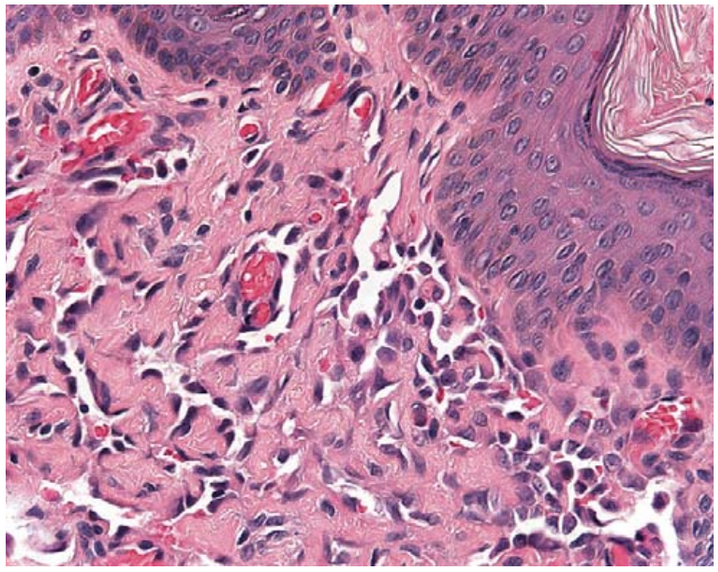

Fig. 114.30 Histology of angiosarcoma with lymphatic characteristics ("lymphangiosarcoma"). Some of the vascular channels are angular and lack erythrocytes. Also note the hyperchromatic atypical endothelial cells.

Treatment

Surgical excision with wide margins is indicated. Even with negative margins by histologic examination, the recurrence rate and chance of metastatic disease are high. This may in part reflect the tendency for multifocality. In a recent retrospective review, 10 of 13 patients showed a response to weekly paclitaxel versus 14 of 27 for non-paclitaxel regimens, but the difference was not statistically significant (p=0.18)[129]. There are also isolated reports of successful thalidomide therapy. Radiotherapy may be palliative, but does not improve survival.

PERIVASCULAR NEOPLASMS AND NEOPLASTIC-LIKE PROLIFERATIONS

Glomus Tumors and Glomuvenous Malformations (Glomangiomas)

Synonyms: ■ Glomus tumor: solitary glomus tumor, solid glomus tumor ■ Glomuvenous malformation: glomangioma, infiltrating glomus tumor, multiple glomus tumors

Key features

- A heterogeneous group of benign tumors and malformations characterized by presence of glomus cells
- The two major subgroups are *glomus tumor* and *glomuvenous malformation (glomangioma)*
- The glomus tumor typically presents in young adults, is a *solitary*, *painful* papule or nodule on the extremities with a predilection for subungual sites, and consists of a relatively *solid proliferation of glomus cells* associated with *small vessels*
- The less common glomuvenous malformation ("glomangioma") typically presents in infancy or childhood, is often *multiple* and *asymptomatic* and histologically resembles a venous malformation in which *dilated vessels* are rimmed by a *few glomus cells*
- Histologic variants in which glomus cells merge with well-differentiated smooth muscle cells are referred to as glomangiomyomas
- Extremely rare atypical and malignant forms have been described

Introduction

Tumors distinguished by the presence of benign glomus cells have been subclassified in the past into a number of descriptive types, such as solid, solitary, multiple, adult, pediatric and diffuse. Current evidence supports division of these tumors into two major disparate categories: (1) the glomus tumor proper, a cellular lesion that tends to be well circumscribed, solitary and subungual; and (2) the glomuvenous malformation, a frequently multifocal lesion, traditionally termed a "glomangioma", that most commonly presents in infants or children and histologically resembles a venous malformation in which lesional vessels are rimmed by glomus cells.

Epidemiology

Solitary glomus tumors can occur at any age, but are most common in young adults. Although these tumors in general show no gender predilection, subungual lesions are more common in women. Glomuvenous malformations are less common (accounting for 10–20% of all glomus cell lesions) and typically present in children; many are congenitally evident.

Pathogenesis

The fact that the most common site of occurrence of glomus tumors (the subungual region of the finger) corresponds to one of the densest areas of distribution of the normal glomus body suggests that many glomus tumors represent neoplastic proliferations originating from pre-existing normal glomus cell populations. However, the occasional occurrence of glomus tumors at sites where normal glomus bodies may not be found, including bone, gastrointestinal tract, trachea and nerve, suggests that some glomus tumors may arise from pluripotent mesenchymal cells or even ordinary smooth muscle cells.

Despite their shared compliment of benign glomus cells, glomus tumors and glomuvenous malformations differ widely in clinical and histopathologic features and are likely unrelated in pathogenesis. The resemblance to venous malformations plus the early presentation of glomuvenous malformations strongly supports their now widely accepted malformative etiology, thus the recent abandonment of the traditional term *glomangioma*. Although a number of glomuvenous malformations are sporadic, a recent large cohort study found that approximately two-thirds of cases are familial[130], with an autosomal dominant pattern of inheritance[131,132]. Multiple loss-of-function mutations in the glomulin gene (*GLMN*) have been identified in patients with familial glomuvenous malformations[133–135].

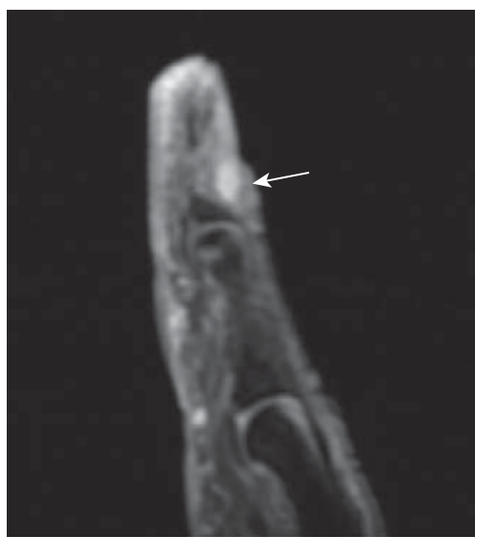

Fig. 114.32 MRI of a glomus tumor located in the proximal portion of the nail bed and matrix. While there was a low signal lesion noted in T1-weighted images of the left index finger, the lesion was very bright in T2-weighted images with diffuse homogeneous enhancement with gadolinium (arrow). *Courtesy, Kalman Watsky, MD.*

Clinical features

The glomus tumor is a benign lesion that usually presents in young adults (20–40 years of age) as a small (<2 cm), blue–red papule or nodule in the deep dermis or subcutis of the distal upper or lower extremities. They are tender to touch, and may be associated with severe paroxysmal pain in response to temperature changes and pressure. The hand, especially the nail beds and palm, is most commonly affected (Fig. 114.31), but lesions can also occur at other cutaneous locations. Unusual extracutaneous glomus tumors have been reported in the gastrointestinal tract, bone, mediastinum, trachea, mesentery, cervix and vagina. Extremely rare instances of malignant transformation within glomus tumors, with documented metastasis, have been described[136]. Radiographs are of limited usefulness in diagnosis, but subungual tumors often show bony erosion and may show increased distance between the nail and the dorsum of the phalanx. MRI is frequently the primary diagnostic imaging modality of choice (Fig. 114.32), followed by contrast-enhanced CT. Glomus tumors are strongly enhancing masses by both CT and MRI.

Glomuvenous malformations arise in children and adolescents and tend to be multiple. They are generally asymptomatic lesions that appear either as multiple, soft, red to blue nodules that may be widely distributed or confluent, or as pink to deep blue plaque-like lesions (Figs 114.33 & 114.34), also multifocal. Although they clinically

Fig. 114.33 Glomuvenous malformation ("glomangioma"). Note the cluster of slightly compressible blue papules.

Fig. 114.34 Glomuvenous malformation ("glomangioma"). Large cluster of blue papulonodules becoming confluent centrally.

resemble venous malformations, glomuvenous malformations differ in appearance from the latter in a number of aspects[137]: they tend to be more nodular or cobblestone-like in appearance, more blue and less compressible, and they do not swell with exercise or dependency. Lesions typically thicken and become more blue in color with time. Although less painful than the glomus tumor, glomuvenous malformations may be tender to palpation, and attacks of pain may occur in association with menstruation and pregnancy. All reported cases have behaved in a benign fashion.

Pathology

The common glomus tumor is a generally well-circumscribed proliferation of solid sheets and clusters of uniform glomus cells focally clustering around a variable complement of capillary-sized, endothelium-lined vessels (Fig. 114.35). The stroma is typically myxoid or hyalinized and may contain numerous small nerve twigs. A dense fibrous pseudocapsule may be present. The glomus cells are distinctive in their uniformly rounded or polygonal shape, centrally placed, rounded nuclei, and pale eosinophilic cytoplasm. PAS staining reveals basement membrane material around individual tumor cells. Mitotic figures may be present, but are normally configured. The ultrastructural features of these cells are consistent with modified smooth muscle cells, replete with relatively abundant myofilaments that focally condense to form dense bodies and pinocytotic vesicles[138]. Immunohistochemical studies have revealed consistent expression of vimentin and muscle actin isoforms, and variably reported expression of desmin. Examples demonstrating gradual transition from rounded glomus cells to elongated, well-differentiated smooth muscle cells have been termed glomangiomyomas[139].

Although the great majority of glomus tumors display no significant cytologic atypia, some have atypical or frankly malignant features.

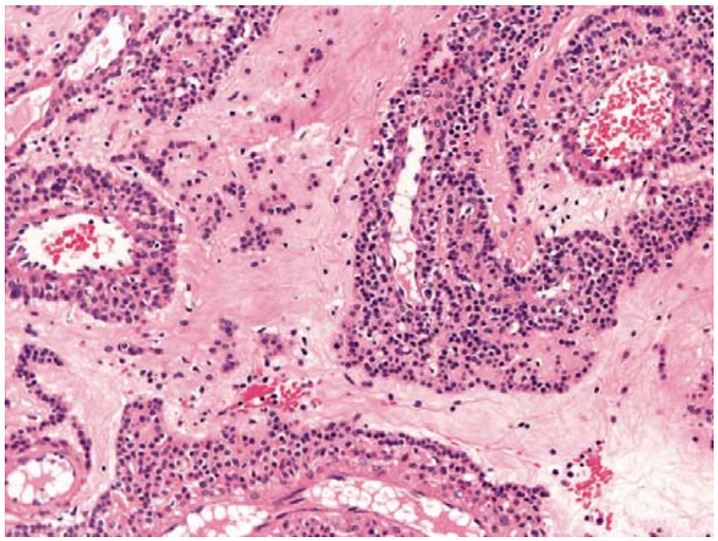

Fig. 114.35 Histology of glomus tumor. Proliferation of rounded, homogeneous, hyperchromatic glomus cells surrounding vascular lumina. *Courtesy, Lorenzo Cerroni, MD.*

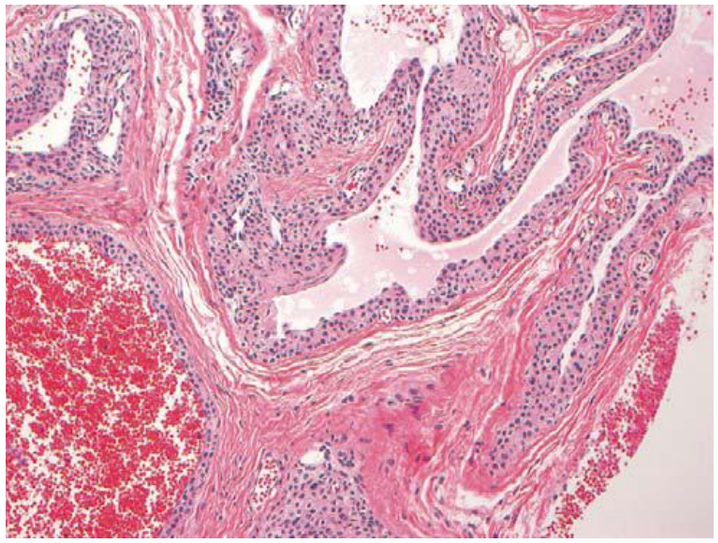

Fig. 114.36 Histology of glomuvenous malformation ("glomangioma"). One or more, often incomplete, layers of glomus cells rim abnormal venous channels that are otherwise histologically consistent with a venous malformation.

Based on an analysis of 53 atypical and malignant glomus tumors[140], a histopathologic classification of glomus tumors with unusual features has been proposed, with malignant glomus tumors defined as those of large size (>2 cm) and deep location, or those with marked atypia and a high mitotic rate (≥5/50 HPF), or those with atypical mitotic figures. Malignant examples show a compressed rim of benign glomus tumor around the malignant areas in about one-half of cases, consistent with malignant transformation from a pre-existing benign tumor.

Glomuvenous malformations consist of large, dilated, thin-walled veins in the dermis and subcutaneous tissue, histologically equivalent to those comprising venous malformations, but surrounded by one or more layers of uniform, cuboidal glomus cells (Fig. 114.36). Some microscopic fields may lack the glomus cells and be indistinguishable from common venous malformations. They are less circumscribed than solitary glomus tumors and may be distributed as separate nodules in the same anatomic area. Like venous malformations without glomus cells, many glomuvenous malformations contain organizing thrombi or phleboliths.

Differential diagnosis

Solitary glomus tumors may clinically be confused with other painful nodules such as eccrine spiradenomas and leiomyomas which can readily be distinguished from glomus tumors histologically and immunohistochemically. From a histologic point of view, solid forms of hidradenoma may closely resemble glomus tumors, especially when sweat ducts acquire erythrocytes, but can be distinguished by their keratin expression. Cellular glomus tumors are occasionally mistaken for pseudoangiomatous intradermal nevi, but the latter are positive for S100.

Glomuvenous malformations must be distinguished from ordinary venous malformations that lack glomus cells by histologic examination, although several clinical features of these lesions help make this distinction (see section above). It is likely that many cases of the so-called blue rubber bleb nevus syndrome, a familial disorder characterized by multiple venous malformations, actually represent examples of multiple glomuvenous malformations (glomangiomatosis).

Treatment

Solitary glomus tumors can be treated successfully by local surgical excision. Other options include electrodesiccation and sclerotherapy.

Glomuvenous malformations are less amenable to surgery than are common glomus tumors, due to their more extensive and multifocal nature. In a series of large facial "glomangiomas"[137], MRI was the best modality for definition of the extent of the lesions and their relationship to other anatomic structures. In this same series, surgical resection reduced the area of discoloration and improved facial contour, while sclerotherapy was less effective than for venous malformations[137]. Laser surgery employing CO_2, KTP, Nd:YAG and pulsed dye lasers may also be helpful. Residual lesions following subtotal resections may slowly re-expand[137].

Infantile Hemangiopericytoma

Synonym: ■ Congenital hemangiopericytoma

Key features

- Benign neoplasm of perivascular myoid differentiation that usually presents at birth or in the first years of life
- Clinical appearance is that of single or multiple dermal and subcutaneous nodules that may be alarmingly large at birth or grow rapidly
- Differs in both histology and clinical behavior from adult-type hemangiopericytoma, which rarely involves the skin
- Multilobulated tumor with cellular areas of spindle cells and antler-like branching blood vessels, merging with less cellular areas containing plump myofibroblasts
- Closely related to infantile myofibromatosis
- Behaves in a benign fashion, despite frequent focal necrosis and increased mitotic activity

Introduction and history

The concept of hemangiopericytoma as an entity has been controversial since these tumors were described in 1942 by Stout and Murray, who considered them to be composed mainly of pericytes. Congenital or infantile hemangiopericytoma was recognized as a separate entity from adult-type hemangiopericytoma in 1976 by Enzinger and Smith[141] in consideration of its distinguishing clinical and histologic features. Classic adult-type hemangiopericytomas will not be discussed here because of their extreme rarity in superficial tissues.

Epidemiology

Infantile hemangiopericytomas are uncommon tumors that typically appear in the first year of life and are usually congenital. There is a male predominance by approximately 2 : 1. Examples in older children have occasionally been reported.

Pathogenesis

The frequent zonal pattern of myofibroblastic differentiation in infantile hemangiopericytomas has led to the proposal that infantile hemangiopericytoma and infantile myofibromatosis may lie upon a continuous spectrum of myofibroblastic lesions[142]. A family of adult tumors with perivascular myoid differentiation has been described that overlaps histologically with infantile myofibromatosis and includes two newer entities, termed *glomangiopericytoma* and *myopericytoma*. Granter et al.[143], in support of similar observations by Requena and colleagues[144], have proposed that this widening spectrum of tumors and their distinctive cellular components might be better explained by derivation from a pluripotent periendothelial cell capable of differentiating along smooth muscle, pericytic and glomus cell lines, rather than from myofibroblasts.

Clinical features

Infantile hemangiopericytomas are nodules that primarily occur in the subcutaneous and dermal tissues of the head and neck. Congenital examples may be alarming in size at birth or grow rapidly thereafter. Multicentric cases have been reported and have in some instances been misinterpreted as examples of distant metastasis. Although benign behavior appears to be the rule, large tumors may be problematic if they hemorrhage or threaten vital structures. Lesions in deeply seated sites, such as the tongue, mediastinum and abdomen, have been reported. Rare multisystemic forms in neonates may be lethal. Local recurrence after excision is common, although spontaneous tumor regression has also been documented.

Pathology

Infantile-type hemangiopericytomas, unlike the adult type, are usually dermal or subcutaneous in location and are often multilobulated. They typically show a biphasic growth pattern in which primitive, hemangiopericytomatous areas resembling the adult tumors (short spindle cells arranged around thin-walled, branching vessels) blend with less cellular areas containing plump, myofibroblast-like cells set within a collagenous matrix. Focal necrosis and significant mitotic activity may be present, but are not indicative of poor prognosis.

Differential diagnosis

Infantile hemangiopericytomas demonstrate nonspecific clinical and radiologic features and require histologic examination for definitive diagnosis. They may be confused clinically with an infantile hemangioma due to rapid postnatal growth, and large congenital lesions may suggest a rapidly involuting congenital hemangioma or infantile fibrosarcoma. Further diagnostic considerations include infantile myofibromatosis and subcutaneous pyogenic granuloma.

Treatment

Conservative treatment following establishment of the diagnosis via histologic examination is generally recommended given the potential for spontaneous regression. Complete surgical resection is a reasonable option in some cases, although there appears to a conflicting tendency of these tumors to both locally recur and spontaneously regress.

Chapter Contents

Classification, terminology and histogenesis *1943*
Neuromas *1944*
Schwannoma *1948*
Neurofibroma *1949*
Nerve sheath myxoma and cellular neurothekeoma *1951*
Granular cell tumor *1952*
Perineurioma *1953*
Malignant peripheral nerve sheath tumor *1953*
Merkel cell carcinoma *1954*
Heterotopic neuroglial tissue *1955*
Heterotopic meningeal tissue *1957*
Heterotopic neuroblastic tissues and their tumors *1957*

For decades, neural tumors were often misdiagnosed histopathologically because of confusing classifications; as a result, their clinical relevance was poorly understood. Clinically, cutaneous neural tumors often look alike and most of them are benign. However, their correct diagnosis can be helpful in recognizing important clinical syndromes and can contribute to better patient management. Moreover, with the advancement of immunohistochemistry, new variants of cutaneous neural neoplasms have been described[1].

CLASSIFICATION, TERMINOLOGY AND HISTOGENESIS

Cutaneous neural tumors can be classified into two major groups: those derived from peripheral nerves and those derived from ectopic or heterotopic neural tissue (Table 115.1). The former group is often subdivided into true nerve sheath neoplasms and hamartomatous tumors, although this classification may not be universally accepted[2].

Cutaneous neural tumors either arise from or differentiate toward one or more elements of the nervous system. During their differentiation, neural neoplasms often recapitulate to varying degrees the morphogenesis of normal peripheral nerves. Therefore, knowledge of the organization of the normal peripheral nerve is crucial to understanding the histogenesis of tumors that arise from it[3]. The peripheral nerve can be compared to a conventional telephone cable, in which each axon and its surrounding Schwann cell layer correspond to a telephone wire and its insulation, respectively (Fig. 115.1).

The basic units of a peripheral nerve are nerve fibers, composed of axons and the surrounding Schwann cells. These fibers form nerve fascicles and are held together by a sheath of specialized cells, which is called the perineurium. The space between the individual nerve fibers is called the endoneurium. As in a telephone cable system where the smaller cable units are separated, protected and held together by an outer wrapping, bundles of nerve fascicles are also encased in a supportive fibrous sheath that is called the epineurium. To a variable extent, this architectural arrangement is recognizable in many cutaneous neural neoplasms.

The most important constituent cells are the Schwann cell, the perineurial cell, and the various nonspecific mesenchymal cells, such as fibroblasts and mast cells. These cells are capable of proliferation and malignant transformation. Other elements of the peripheral nerve, which are cell parts or products (i.e. axons and myelin), cannot duplicate. Schwann cells are derived from the neural crest, and there is evidence that perineurial cells are modified fibroblasts of mesodermal origin. This difference in histogenesis is also reflected in the distinct antigenic expression of these cells. Schwann cells express S100 protein but not epithelial membrane antigen, whereas perineurial cells stain for epithelial membrane antigen but not for S100 protein. Axons contain a specific type of intermediate filament called neurofilament, and myelinated axons contain myelin basic protein, both of which can be detected by immunohistochemistry. These and other immunohistochemical markers often can help to establish the correct diagnosis.

In the following sections, each clinically relevant neural neoplasm is discussed (Tables 115.2–115.4; Fig. 115.2).

CLASSIFICATION OF CUTANEOUS NEURAL TUMORS

Peripheral nerve sheath tumors	Neural heterotopias
Hamartomas	**Meningeal**

• Neuromas
  • Traumatic (amputation)
  • Spontaneous
  • Solitary, palisaded encapsulated
  • Multiple, non-encapsulated
  • Variants
	• Meningocele
	• Rudimentary meningocele
	• Meningioma

	Neuroglial
	• Nasal glioma
True nerve sheath neoplasms	**Neuroblastic/ganglionic**

• Schwannomas
  • Common, solitary
  • Ancient
  • Cellular
  • Plexiform
  • Variants
• Neurofibromas
  • Superficial/solitary
  • Deep
  • Diffuse
  • Pigmented
  • Plexiform
  • Variants
• Nerve sheath myxoma
• Cellular neurothekeoma
• Perineurioma
• Malignant peripheral nerve sheath tumor
	• Neuroblastoma
	• Primary primitive neuroectodermal tumor
	• Ganglioneuroma

	Miscellaneous
	• Pigmented neuroectodermal tumor of infancy
Miscellaneous	
• Neuroendocrine carcinoma of the skin (Merkel cell carcinoma) • Granular cell tumor

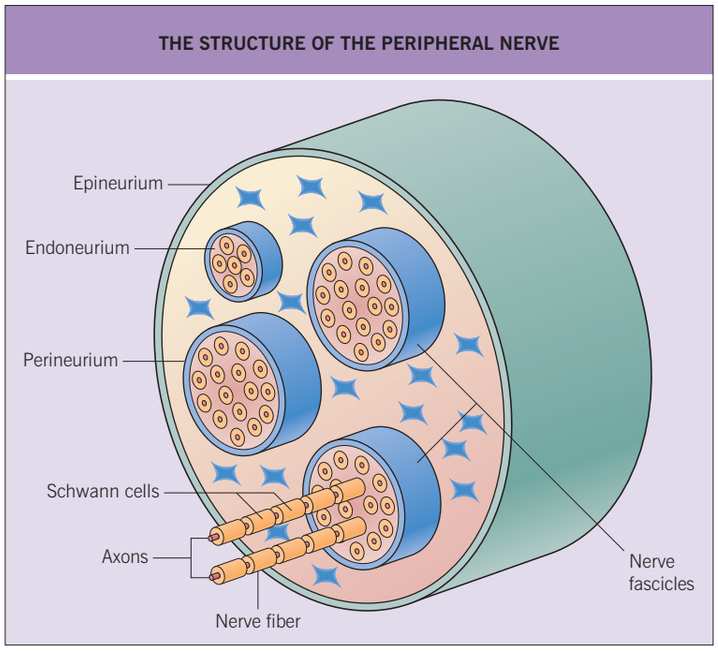

Fig. 115.1 The structure and components of the peripheral nerve.

NEUROMAS

Key features

Traumatic neuroma

- At the site of previous trauma
- Skin-colored papule or nodule
- Often painful or sensitive
- Circumscribed histologically, but not encapsulated
- Regenerative proliferation of axons and Schwann cells with fibrous tissue

Palisaded encapsulated neuroma (PEN)

- Usually on the face of adults
- Solitary
- Skin-colored papule or nodule
- Circumscribed histologically; partly or completely encapsulated
- Compactly arranged fascicles of spindle cells with vague palisading of nuclei

Introduction

Neuromas are proliferations of neural tissue in which Schwann cells and axon components are found in roughly equal numbers. There are two major subtypes: *traumatic* or *amputation neuroma* and *palisaded encapsulated neuroma* (PEN). Traumatic or amputation neuromas are complex regenerative proliferations of nerve fibers secondary to injury. Palisaded encapsulated or solitary circumscribed neuromas are complex hamartomatous proliferations of nerve fibers without apparent previous tissue injury.

History

The current view of traumatic neuroma was introduced by Huber and Lewis based on the concept of Wallerian degeneration[4]. PEN was described by Reed and co-workers in 1972[5].

Epidemiology

Traumatic neuromas are relatively uncommon but can occur at any age and in either sex. They are more prevalent in professions with a high probability of physical injuries. The solitary form of PEN develops spontaneously and gradually without evidence of obvious previous trauma. These tumors appear during adulthood (mean age, 45.5 years) with about equal occurrence in men and women[5]. With the solitary form, there is no specific association with neurofibromatosis or multiple endocrine neoplasia syndrome type 2B (MEN 2B).

Pathogenesis

Any extrinsic damage to nerve fibers can cause a traumatic neuroma. Amputation neuroma is considered the most common form and represents an attempted, but failed, regeneration of nerve fibers following transection. After transection, the distal segments of the nerve fibers degenerate, whereas the proximal segments regenerate in an attempt to reunite with the distal portion of the transected nerve fibers[6]. In cases of severe trauma, this regenerative process is unsuccessful and the growing nerve fibers form a tangle of fascicles within fibrotic tissue. Despite marked variations in arrangement, size and shape of the regenerating fascicles, in traumatic neuromas the constituent fibers have a Schwann cell to axon ratio close to normal (1 : 1), which helps to distinguish true neuromas from other nerve sheath neoplasms[7].

In PEN there is an overgrowth of axons and their sheath cells within the confinement of the perineurium. This benign tumor most likely represents a hamartomatous growth in which there is a close reduplication of the normal axon to Schwann cell ratio[5]. The cause of the overgrowth of neurites is unknown. Although minor tissue injury such as inflammation induced by acne has been suggested as a cause, to date a definite traumatic origin has not been established[7].

Clinical Features

Traumatic neuromas are usually solitary, skin-colored or reddish purple, firm papules or nodules at sites of wounds, surgical scars and amputations[8,9] (Fig. 115.3). On the lower extremities they tend to be multiple[8]. Early lesions are asymptomatic, but after a few months they gradually become painful, frequently with a lancinating character. Variable tingling and itching can be associated with the pain.

In neonates and young infants, lesions may be located on the lateral surface of a normal digit, most commonly the ulnar side of the fifth digit. Here, they represent amputation neuromas secondary to amputation *in utero* of supernumerary digits[10] (see Ch. 64). These tumors are occasionally referred to as "rudimentary supernumerary digits"; however, on histologic examination, they do not contain either normal or rudimentary elements of a digit.

In the solitary form of PEN, the individual lesions are asymptomatic, rubbery, firm, skin-colored to pink papules or nodules ranging in size from 0.2 to 0.6 cm in diameter[5]. Approximately 90% are located on the face, primarily around the nose, but they also occur on the cheek, chin and lips[11]. The remaining 10% occur elsewhere, including the trunk and extremities.

In MEN 2B, also referred to as multiple mucosal neuroma syndrome or MEN type 3, numerous soft, skin- or mucosa-colored papules and nodules appear on the lips, tongue and conjunctivae, as well as in the nasal and laryngeal mucosa. Patients also develop pheochromocytomas, medullary carcinoma of the thyroid, and gastrointestinal ganglioneuromas (see Table 63.2); therefore, early recognition of this syndrome can be life-saving. Multiple mucocutaneous neuromas with a predilection for the face and distal extremities can also be a manifestation of the PTEN hamartoma tumor syndrome, which includes Cowden disease and Bannayan–Riley–Ruvalcaba syndrome (see Table 63.3).

Pathology

Traumatic or amputation neuromas are usually well-circumscribed nodules located at any level of the dermis or the subcutis. They are encased by a fibrous sheath, although the distal end can be poorly defined. The proliferation is composed of a chaotic, poorly organized tangle of fascicles of various sizes and shapes (Fig. 115.4). Between the fibers are variable amounts of fibrous tissue with or without inflammatory cells or mucin[7]. The constituent cells are Schwann cells and perineurial cells with spindle-shaped nuclei and cytoplasm (Fig. 115.5). Special stains show many axons in an irregular, haphazard pattern[1,5].

Solitary PENs are well-circumscribed, ovoid or round tumors located in the mid dermis, although some lesions may extend into the subcutis. The tumor appears encapsulated by a thick condensation of collagen

CLINICAL FEATURES OF BENIGN NEURAL NEOPLASMS							
	Traumatic neuroma	**Palisaded encapsulated neuroma (PEN)**	**Schwannoma (neurilemmoma)**	**Neurofibroma**	**Nerve sheath myxoma***	**Cellular neurothekeoma***	**Granular cell tumor**
Incidence	Uncommon	Rare	Uncommon	Very common	Rare	Rare	Rare
Age	Any	Adults (mean age, 45.5 years)	Adults (20–50 years)	Adults (20–60 years)	Adults (mean age, 48 years)	Early adulthood (mean age, 24 years)	Adults (30–50 years)
Gender	Any	M:F = 1:1	F > M	M:F = 1:1	M:F = 1:2	F > M	M:F = 1:3
Number	Usually solitary	Usually solitary	Usually solitary (>90%)	Usually solitary	Usually solitary	Usually solitary	Usually solitary
Location	At sites of trauma, surgical scars, amputations	90% face, 10% elsewhere	Flexor aspect of an extremity, head	Trunk, head (solitary type)	Head and upper extremities	Predominantly on head, but also elsewhere	30% tongue, 70% elsewhere, mainly head and neck
Size	0.5–2.0 cm	0.2–0.6 cm	0.5–3.0 cm	0.2–2.0 cm	0.5–1.0 cm	0.5–3.0 cm	0.5–3.0 cm
Clinical appearance	Skin-colored to reddish purple, firm papule or nodule	Skin-colored or pink, rubbery, firm papule or nodule	Soft, skin-colored to pink or yellow, smooth-surfaced nodule or tumor	Skin-colored, soft or rubbery papule or nodule, sometimes pedunculated	Soft, skin-colored papule or nodule	Pink, red or brown, firm papule or nodule	Skin-colored to brownish red, firm papulonodule; may have ulceration or verrucous surface
Symptoms	Variable; tingling, pruritus, lancinating pain	Asymptomatic	Asymptomatic; occasionally painful or tender; rarely paresthetic; occasionally freely movable	Asymptomatic; "buttonhole" sign may be present	Asymptomatic	Usually asymptomatic, rarely sore or pruritic	Asymptomatic or occasionally tender or pruritic
Association	NA	Multiple (non-encapsulated) neuromas in MEN 2B (mucosal) and PTEN hamartoma tumor syndrome (mucocutaneous)	Neurofibromatosis (primarily type 2)	If multiple, may be sign of one of the various forms of neurofibromatosis (see Ch. 61)	NA	NA	10% multiple; predilection for blacks; rare in children
Clinical differential diagnosis	Hypertrophic scar, dermatofibroma, foreign body granuloma, granular cell tumor, neurothekeoma	Basal cell carcinoma, adnexal tumor, IDN, neurofibroma, schwannoma, nerve sheath myxoma	Neurofibroma, lipoma, angiolipoma, cyst (epidermoid, pilar, dermoid, ganglion), IDN, adnexal tumor (including sebaceous), PEN, leiomyoma	IDN, soft fibroma, schwannoma, fibrolipoma, PEN, nerve sheath myxoma, anetoderma, lipoma, cyst (epidermoid, pilar)	IDN, neurofibroma, schwannoma, lipoma, cyst (myxoid, ganglion, epidermoid, pilar)	Dermatofibroma (including sclerosing hemangioma variant), adnexal tumor, hypertrophic scar, keloid, granular cell tumor, PEN, fibrosed dermal or compound melanocytic nevus, pyogenic granuloma	Tongue: irritation (traumatic) fibroma, verruca, SCC Elsewhere: dermatofibroma, regressing verruca, adnexal tumor, prurigo nodularis, fibrosed melanocytic nevus, SCC
Other	"Rudimentary supernumerary digit" is considered a variant	May be induced by minor trauma	May be multiple; "schwannomatosis"	Plexiform variant is pathognomonic for neurofibromatosis type 1			Visceral forms occur; malignant transformation may occur (3%)

*Some authors view as ends of a spectrum.

Table 115.2 Clinical features of benign neural neoplasms. NA, not applicable; IDN, intradermal melanocytic nevus; MEN 2B, multiple endocrine neoplasia, type 2B; SCC, squamous cell carcinoma.

fibers that surround it, and there is often some clefting from the adjacent dermis[5] (Fig. 115.6). The parenchyma is composed of interwoven fascicles of spindled cells. The fascicles are compactly and relatively uniformly arranged, separated only by clefts. There is no evidence of extensive fibrosis, inflammation, granulation tissue, degenerative changes or foreign bodies, in contrast to traumatic neuromas[7].

The nuclei of the spindle-shaped tumor cells are elongated and wavy with tapered ends, and have an evenly basophilic chromatin pattern. Occasionally, a parallel arrangement of the nuclei is present, but, despite its name, distinct palisading or Verocay body formation is rare[12–14]. There is no appreciable nuclear pleomorphism, and mitotic figures are scant or absent. Special stains show abundant axons in a variable pattern[12]. The tumors of MEN 2B may be considered to be a variant of PEN but are not encapsulated and are multiple.

Differential Diagnosis

The diagnosis of traumatic neuroma is usually suspected by the history of a painful or symptomatic papulonodule at a site of injury and is confirmed by pathologic examination.

A PEN can resemble a BCC, adnexal tumor, intradermal melanocytic nevus or neurofibroma (see Table 115.2). The diagnosis is seldom made clinically and depends upon histologic examination (see Table 115.3).

Treatment

Surgical excision of traumatic neuromas is recommended, with an attempt to reposition the proximal nerve stump into a scar-free area[8].

PENs are easily excised, and some can even be enucleated from the surrounding dermis or subcutaneous tissue[5].

HISTOLOGIC DIFFERENTIAL DIAGNOSTIC FEATURES OF COMMON CUTANEOUS NEURAL NEOPLASMS				
	Traumatic neuroma	**Palisaded encapsulated neuroma**	**Schwannoma**	**Neurofibroma**
Location in the skin	Any level of dermis or subcutis	Mid dermis, occasionally extending into subcutis	Deep dermis or subcutis	Any location in the dermis
Growth pattern	Usually well circumscribed but may be poorly defined at the distal end	Well circumscribed, nodular, rarely plexiform	Well circumscribed, nodular or ovoid	Poorly to well circumscribed
Encapsulation	Usually encased by a fibrous sheath	Yes, by perineurium	Yes, by perineurium	Not encapsulated in the dermis
Architecture	Chaotic, poorly organized tangle of fascicles of various sizes and shapes	Compactly arranged fascicles; frequent clefts between fascicles	Hypercellular areas (Antoni A), fascicles in various patterns, hypocellular areas (Antoni B), edematous, myxoid	Fine fibrillary lattice of haphazardly arranged spindle cells in variably dense matrix
Constituent cell types	Schwann cells, fibroblasts, perineurial cells, inflammatory cells, macrophages	Schwann cells (99%), perineurial cells (in capsule only)	Schwann cells (99%), perineurial cells (in capsule only)	Schwann cells, perineurial cells, fibroblasts, mast cells
Cytologic features	Spindle cells with indistinct cytoplasmic contours and tapered slender nuclei	Spindle cells with indistinct cytoplasmic contours and tapered slender nuclei	Spindle cells with indistinct cytoplasmic contours and slender nuclei	Spindle cells with slender nuclei, plump fibroblasts
Nuclear palisading	None	Usually present, but indistinct	Yes, prominent in Antoni A areas	Rarely
Verocay bodies	None	None	Often	None
Nerve fibers (axons)	Yes; abundant, irregular pattern	Yes; abundant, often in a parallel arrangement	None or only at the site of the connecting nerve	Yes; rare, scattered
Other important features	Nerve of origin frequently present, extensive fibrosis	Nerve of origin frequently present, no fibrosis	Mast cells; may have extensive degenerative changes (e.g. hyalinization, hemorrhage) in Antoni B areas ("ancient changes")	Variable fibrosis and myxoid changes, mast cells, occasional blood vessels
Histopathologic differential diagnosis	Hypertrophic scar, neurofibroma, schwannoma	Traumatic neuroma, schwannoma, angioleiomyoma, myofibroma	Palisaded encapsulated neuroma, angiomyoma, fibrous histiocytoma	Neural nevus, dermatofibroma, hypertrophic scar, dermatofibrosarcoma protuberans, traumatic neuroma

Table 115.3 Histologic differential diagnostic features of common cutaneous neural neoplasms.

TUMORS AND TUMOR-LIKE CONDITIONS OF ECTOPIC AND HETEROTOPIC NEURAL TISSUE INVOLVING THE SKIN				
	Nasal glioma*	**Rudimentary meningocele**	**Cutaneous meningioma (Types II and III)**	**Peripheral neuroblastoma**
Incidence	Rare	Rare	Extremely rare	Extremely rare
Age	Neonates	Neonates or infants	Usually adults	Late adulthood
Location	Most commonly near the root of the nose but can be intranasal	Scalp, forehead, paravertebral area	Scalp	Head and trunk
Size	1.0–3.0 cm	0.5–3.0 cm	0.5–4.0 cm	0.5–5.0 cm
Clinical appearance	Firm, smooth, skin-colored to red–purple nodule	Soft to firm nodule, often with alopecia or the "hair collar" sign; occasionally cystic; blue–red hue common	Soft to firm nodule, often with alopecia	Soft, skin-colored to red, often ulcerated nodule
Clinical differential diagnosis	Infantile hemangioma, nasal polyp, juvenile xanthogranuloma, dermoid cyst	Membranous aplasia cutis, heterotopic brain tissue, dermoid cyst, infantile hemangioma	Epidermoid or pilar cyst, adnexal tumor, cutaneous metastasis	Adnexal tumor, lymphoma, soft tissue sarcoma, cutaneous metastasis
Associations	Intracranial connection in ~20% ("atretic" encephalocele)	An intracranial connection may be present ("atretic" meningocele)	May be associated with neurofibromatosis (types I and II)	NA
Other	NA	NA	Metastasis of CNS meningioma must be excluded	Metastasis of ganglionic or adrenal neuroblastoma and extension of olfactory neuroblastoma must be excluded, especially in children
Histopathologic features	Lobulated neural tissue (glial cells, astrocytes, rarely true neurons)	Cystic or cavernous spaces, scattered meningothelial cells, pseudovascular pattern, psammoma bodies	Solid nests and strands, whorls of epithelioid or spindle cells, psammoma bodies	Rosette-like (Homer Wright type) structures of small, round, blue cells, extensive infiltration and necrosis
Biologic course	Benign	Benign	Locally aggressive and destructive	Extremely malignant with widespread metastases
*Heterotopic brain tissue can also be located in the midline scalp, orbit, lip and oropharynx.

SCHWANNOMA

Synonyms: ■ Neurilemmoma ■ Neurolemmoma ■ Schwann cell tumor ■ Acoustic neuroma

Key features

- Solitary papulonodule that usually appears on the flexural aspect of an extremity, along a peripheral nerve
- Occasionally painful or tender
- Deep dermal or subcutaneous location
- Histologically, there is an encapsulated spindle cell proliferation with biphasic Antoni A and B areas, palisading of nuclei, and Verocay bodies; axons are usually absent

Fig. 115.7 Solitary schwannoma. Skin-colored nodule on the plantar surface of the great toe. *Courtesy, Julie V Schaffer, MD.*

Introduction

Schwannomas are benign true nerve sheath neoplasms composed entirely of a Schwann cell proliferation.

History

Stout coined the term "neurilemoma", referring to the closely applied sheath and covering of the tumor[15]. Verocay suggested nerve sheath tumor as a general classification[16]. Because nearly the entire tumor is composed of Schwann cells, the designation "schwannoma" is now preferred.

Epidemiology

Schwannomas are relatively uncommon tumors that can occur at any age, but they are seen most often in adults and slightly more frequently in women than in men. Approximately 90% of schwannomas are solitary and not associated with any specific syndrome[2]. That said, schwannomas are seen in patients with neurofibromatosis (primarily type 2) and therefore can be associated with bilateral acoustic neuromas and meningiomas (see Table 61.5)[2]. Rare cases of multiple schwannomas have been referred to as "neurilemmomatosis" or "schwannomatosis"; sometimes there is a familial occurrence[17,18] or features that overlap with neurofibromatosis type 2 (NF2)[19,20]. Germline mutations in *INII/SMARCB1* have been described in familial schwannomatosis[21].

Pathogenesis

Schwannomas are derived from a proliferation of periaxonal or endoneurial Schwann cells. As a result of the Schwann cell proliferation, the remaining normal nerve fibers are displaced to the periphery of the tumor, creating an absence of the other components of a peripheral nerve[2]. Only after careful dissection can the attached nerve trunk be demonstrated. Since only the Schwann cells proliferate, the neoplasm remains within the confines of the perineurium, forming an encapsulated tumor. The exact cause of the exclusive Schwann cell proliferation is unknown, but in some patients it is related to mutations in both alleles of *NF2*[22].

Clinical Features

Schwannomas present as a solitary, soft, skin-colored to pink or yellow, smooth-surfaced dermal or subcutaneous papulonodule (Fig. 115.7). In general, their size ranges between 0.5 and 3.0 cm in diameter[23]. They are most commonly found on the flexor aspect of an extremity along a larger nerve trunk, followed by the head and neck region[24,25]. The tumors are usually asymptomatic, but occasionally pain and tenderness occur, in particular if the tumor is forcefully moved and the attached nerve is placed under tension. Motor disturbances and paresthesias are extremely rare[26].

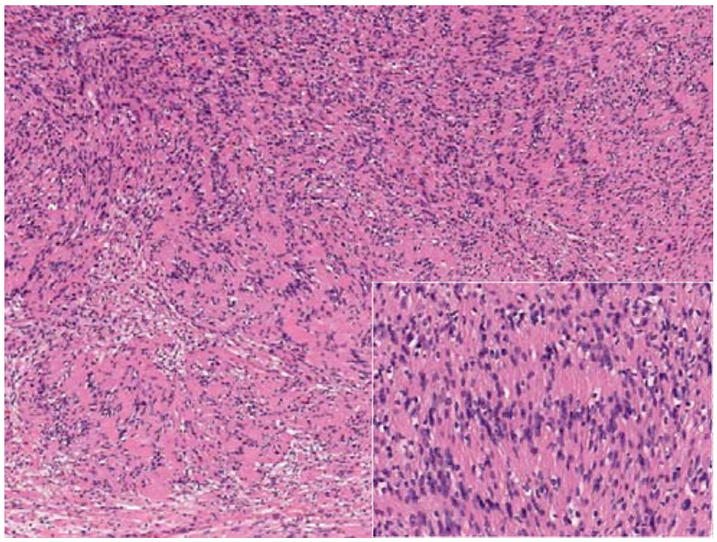

Fig. 115.8 Solitary cutaneous schwannoma. Hypercellular areas often show nuclear palisading and Verocay bodies. Detail of Verocay bodies (insert). *Courtesy, Lorenzo Cerroni, MD.*

Pathology

Schwannomas are well-circumscribed, nodular or ovoid tumors located in the deep dermis or subcutis. They are almost always encapsulated. The tumors are composed of hypercellular (also called Antoni A-type tissue) and hypocellular (Antoni B-type tissue) areas[2]. The hypercellular areas show proliferation of spindle cells with indistinct cytoplasmic contours and uniform nuclei[27]. Nuclear palisading and arrangement of palisaded nuclei in double rows, so-called "Verocay bodies", are characteristic features of these tumors[15,28] (Fig. 115.8). Mitotic figures are absent or rare.

The hypocellular areas show variable degrees of degeneration, including cystic, edematous, mucinous, fibrotic and vascular changes. Degenerative changes are often associated with some degree of cytologic atypia. These so-called *ancient schwannomas* should not be confused with the more specific entity of cellular schwannomas, which may display similar degenerative changes but rarely occur in the skin[29]. As a general rule, schwannomas are devoid of axons or the latter can only be detected at the site at which they are attached to a nerve[2]. There are additional less common subtypes of schwannomas, e.g. plexiform (no association with neurofibromatosis), pigmented, epithelioid and glandular[2,30–34].

Differential Diagnosis

The clinical differential diagnosis includes neurofibroma, lipoma, angiolipoma, adnexal tumor, cyst (epidermoid, pilar, dermoid, ganglion), and intradermal melanocytic nevus. The diagnosis is made by histopathologic examination.

Treatment

This tumor is benign and a simple excision is curative. If the clinical diagnosis is suspected, the lesion should be removed by enucleation, preserving normal nerve function.

NEUROFIBROMA

Variants/synonyms: ■ Solitary neurofibroma – sporadic neurofibroma, solitary nerve sheath tumor ■ Deep neurofibroma – subcutaneous neurofibroma ■ Plexiform neurofibroma

Key features

Solitary type

- Skin-colored to tan–violet papule or nodule
- May be pedunculated or have the "buttonhole" sign
- Predilection for the trunk and head
- Spindle cell proliferation with variable mixture of the components of the peripheral nerve, including residual axons
- Fibrosis and mucinous changes are common

Plexiform type

- Pathognomonic of NF1
- Large, occasionally pigmented, bag-like mass
- Favors the trunk and proximal extremities
- The plexiform variant has similar cytologic constituents as the solitary or sporadic type

Introduction

Neurofibromas are benign tumors composed of a complex proliferation of neuromesenchymal tissue (Schwann cells, perineurial cells, fibroblasts and mast cells), with residual nerve fibers (axons)[2]. Cutaneous neurofibromas are common, especially as solitary lesions. The presence of multiple neurofibromas raises the possibility of one of the several types of neurofibromatosis (including the mosaic form; see Ch. 61). Plexiform neurofibromas are seen in patients with neurofibromatosis type 1 (NF1).

History

Neurofibromas were originally described as fibrous tumors by von Recklinghausen. Subsequently, a neuroectodermal origin was suggested by Verocay[35], which was eventually confirmed by immunohistochemical and ultrastructural studies.

Epidemiology

Solitary cutaneous neurofibromas are relatively common, especially in adults, and have no gender preferences. The presence of a plexiform neurofibroma almost always indicates that the patient has NF1.

Pathogenesis

Neurofibromas differ from schwannomas in that several cell types are involved in their histogenesis. Regardless of the various histologic subtypes of neurofibromas (e.g. solitary, diffuse, combined, plexiform), the basic process is proliferation of the entire "neuromesenchyme", which includes Schwann cells, endoneurial fibroblasts, perineurial cells, mast cells, and cell types with intermediate features[2]. Since the extent of proliferation of each cell line often differs, the resultant histologic composition and architecture will vary. As stated earlier, axons do not duplicate; therefore, the relative ratio of axons to Schwann cells will be less than 1:1. Studies in patients with NF1 indicate that their mutations lead to inactivation of one copy of *NF1* (i.e. haploinsufficiency); however, tumorigenesis requires a somatic mutation that inactivates the remaining allele, i.e. a "second hit" leading to loss of heterozygosity (see Ch. 54). While nullizygosity ($NF^{-/-}$) of Schwann cells is necessary, it may not be sufficient for neurofibroma formation; the latter may require an $NF^{+/-}$ environment, in particular $NF^{+/-}$ mast cells (see Ch. 61). The pathogenesis of isolated solitary neurofibromas is unclear.

Clinical Features

Neurofibromas are usually solitary, skin-colored, soft or rubbery papulonodules. They range in size from 0.2 to 2.0 cm and may become pedunculated[2]. They grow slowly and are asymptomatic. The "buttonhole" sign is often present[2], i.e. the tumor is easily invaginated. Approximately 10% of patients with common neurofibromas will have multiple lesions, and some of these patients have one of the several types of neurofibromatosis (see Ch. 61). There are several clinical and pathologic subtypes of neurofibroma, such as diffuse, pigmented and

Fig. 115.9 Plexiform neurofibroma in a child with neurofibromatosis. Bag-like mass with overlying patches of hyperpigmentation.

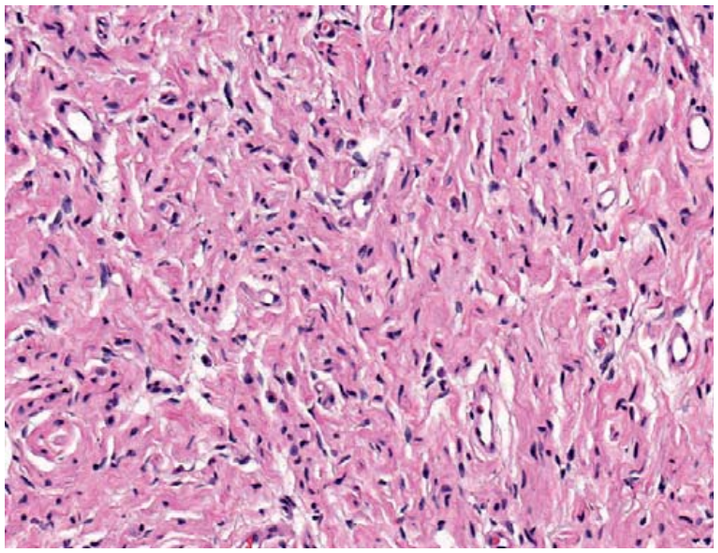

Fig. 115.10 Neurofibroma. The tumor contains a diffuse proliferation of spindle cells with slender, ovoid nuclei in a fibrillary matrix. Note several mast cells. *Courtesy, Lorenzo Cerroni, MD.*

plexiform variants. The diffuse and pigmented subtypes may present as indurated or soft nodules and plaques, with or without hyperpigmentation. Except for the plexiform variant, these subtypes of neurofibromas rarely undergo malignant change.

The plexiform neurofibroma is especially important because it is considered pathognomonic of von Recklinghausen disease (NF1) and carries a higher probability of malignant transformation[2]. Typically, these tumors are baggy or pedunculated dermal and subcutaneous masses that can feel rope-like on palpation and are sometimes hyperpigmented (Fig. 115.9). Recognition and correct patient management is crucial in these cases, especially in subtle forms of NF1, where the other cutaneous stigmata may not be obvious[36]. The exact incidence of malignant transformation of plexiform neurofibromas is not known; it ranges from 2% to 13% (the lower percentage cited more recently).

Pathology

Neurofibromas are poor- to well-circumscribed, usually nonencapsulated, nodular or oblong tumors that can be located anywhere within the dermis and subcutis[2,37]. The common solitary variant is usually present in the superficial dermis, creating a dome-shaped or polypoid elevation of its surface. The tumor is composed of a fine fibrillary lattice of haphazardly arranged slender spindle cells[38] (Fig. 115.10). The stroma can be variably vascular, fibrotic, edematous or myxomatous. In addition to Schwann cells and perineurial cells, plump fibroblasts and mast cells are present. Palisading of nuclei can occur, but true Verocay body formation is rare[37,38]. Mitotic figures are absent or rare. The diffuse form has an essentially similar cytology, but lacks a well-defined growth pattern as it infiltrates adjacent structures. Atypical forms of neurofibromas have been described[39].

As opposed to superficial, solitary and diffuse forms, neurofibromas which are seated within the deep dermis, subcutis and other deep soft tissues are usually encapsulated by perineurium or epineurium and may show a plexiform growth pattern (Fig. 115.11)[2]; the latter is defined as irregularly expanded, twisted and interconnected nerve fascicles arranged in lobular structures. Variants with a combined diffuse and plexiform growth pattern usually occur in NF1. By utilizing special stains, rare scattered axons can be demonstrated in both the superficial and deep variants of neurofibroma.

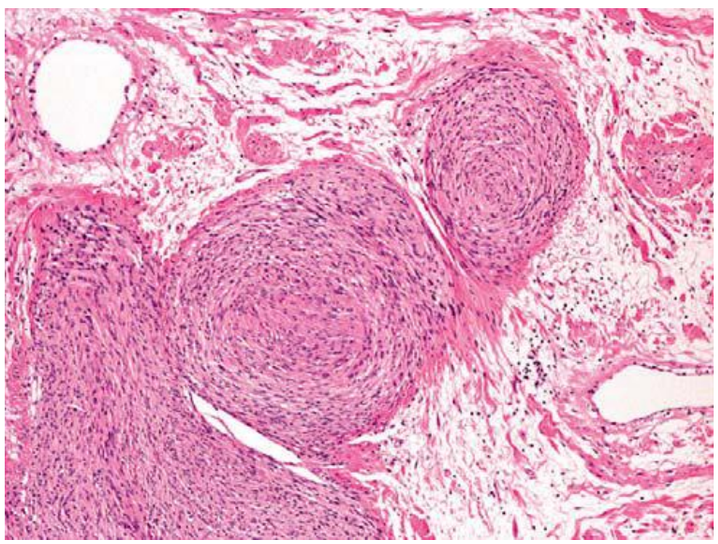

Fig. 115.11 Plexiform neurofibroma. Irregularly expanded, twisted nerve fascicles arranged in lobular structures. *Courtesy, Lorenzo Cerroni, MD.*

Differential Diagnosis

The clinical differential diagnosis of a solitary neurofibroma includes a dermal melanocytic nevus, schwannoma, soft fibroma and fibrolipoma (see Table 115.2). The majority of solitary or sporadic neurofibromas have similar clinical and histologic features as the multiple papular neurofibromas seen in patients with NF1. Plexiform neurofibromas with overlying hyperpigmentation and hypertrichosis can resemble congenital melanocytic nevi. As the latter can undergo neurotization, examination of the patient for Lisch nodules, axillary freckling and café-au-lait macules is essential. Histologically, a plexiform neurofibroma must be differentiated from other plexiform tumors, including a plexiform schwannoma.

Treatment

Neurofibromas are usually treated by simple excision. The evaluation and management of plexiform neurofibromas and neurofibromatosis is discussed in Chapter 61.

NERVE SHEATH MYXOMA AND CELLULAR NEUROTHEKEOMA

Synonyms: ■ Neurothekeoma ■ Myxoma of the nerve sheath

Key features

- Occurs most commonly in young and middle-aged women
- A skin-colored to red–brown papule or nodule with a predilection for the head and neck region
- Histologically, a lobular and fascicular pattern with a lack of axons
- There is a hypocellular myxomatous pattern as well as a cellular type with scant mucin
- Benign behavior, but local recurrences may occur

Introduction

Nerve sheath myxoma and cellular neurothekeoma refer to a spectrum of neuromesenchymal tumors that are characterized by the proliferation of nerve sheath cells in a variably myxomatous stroma. Nerve sheath myxomas have been traditionally classified into a *classic myxoid type* and a *cellular type* (cellular neurothekeoma)[40,41], based on the degree of cytologic differentiation and the relative amount of myxomatous stroma. Nevertheless, recently there has been a growing body of evidence that there are myxoid variants of cellular neurothekeoma which are histogenetically different from nerve sheath myxoma[42].

History

Nerve sheath myxoma was first described as a specific entity by Harkin and Reed in 1969[43]. The term "cellular neurothekeoma" was coined by Rosati et al. in 1986[44].

Epidemiology

The classic or myxoid type of nerve sheath myxoma occurs commonly in middle-aged adults (mean age, 48 years) with an approximate 1:2 male–female ratio[45,46].

The cellular form of nerve sheath myxoma (cellular neurothekeoma) is also a tumor of adulthood, but it usually affects younger adults (mean age, 24 years) and is also more common in women[47,48].

Pathogenesis

Both Schwann cells and perineurial cells are present in a classic nerve sheath myxoma[40,41]. The reason for extreme mucin production is unknown, although mucin is part of the normal endoneurium. Some authors speculate that a nerve sheath myxoma could represent a variant of neurofibroma with extreme myxoid degeneration[45]. This degeneration may explain the virtual lack of axons in these tumors. The available immunohistochemical and ultrastructural data support nerve sheath differentiation in the classic myxoid variant. The cellular neurothekeoma has a controversial histogenesis. Despite its having some similarities to the mucin-rich variant of a classic nerve sheath myxoma, only partial or indirect markers of neural differentiation are detected in a cellular neurothekeoma[42,49].

Clinical Features

A classic nerve sheath myxoma is a soft, skin-colored papule or nodule, generally 0.5 to 1.0 cm in diameter and typically located on the head and upper extremities[45].

Although cellular neurothekeomas also favor the head, cases from a variety of anatomic sites have been reported. These tumors are described as firm papulonodules that are pink, red or brown in color and range in size from 0.5 to 3.0 cm (Fig. 115.12). Symptoms are nonspecific and seem to relate to the size and firmness of the tumor[47,48].

Fig. 115.12 Cellular neurothekeoma of the scalp, presenting as an erythematous, firm papule.

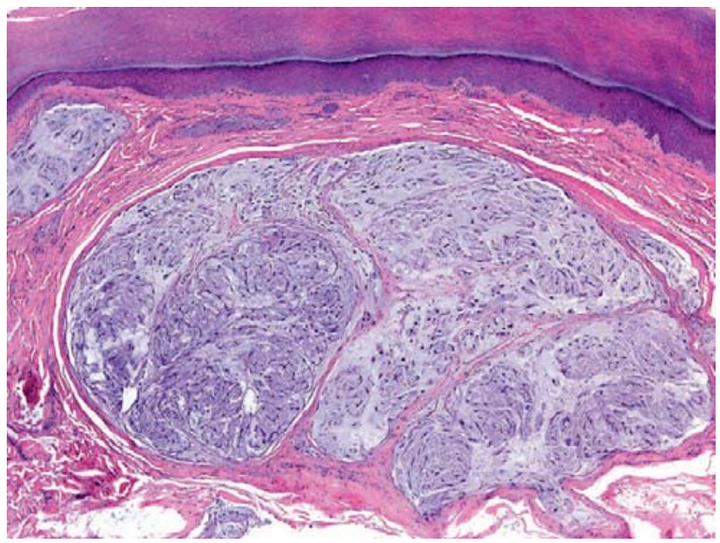

Fig. 115.13 Nerve sheath myxoma. Well-defined fascicles with myxoid stroma. *Courtesy, Lorenzo Cerroni, MD.*

Pathology

The classic myxoid type of nerve sheath myxoma is a well-defined, lobular or plexiform neoplasm that is usually located in the reticular dermis (Fig. 115.13). It often appears encapsulated by a compression of the surrounding fibrous tissue[40]. There is a hypocellular myxoid stroma with rare, scattered, spindled, stellate or dendritic cells. The cells usually have scant, pale cytoplasm with indistinct cytoplasmic contours and hyperchromatic, ovoid or angulated nuclei[40,45]. Nucleoli are small and mitotic figures are rare or absent. On occasion, multinucleated giant cells with eosinophilic cytoplasm can be identified. Histochemically, the myxoid stroma stains strongly positive for acidic mucopolysaccharides (see Ch. 46)[45]. While entrapped nerves in and around the tumor can be identified, the presence of scattered axons or direct continuity of axons with tumor cells has not been established[40,41]. The tumor cells are positive for S100 protein and collagen type IV and the capsule can express epithelial membrane antigen (EMA).

A cellular neurothekeoma is composed of ill-defined multilobular masses or fascicles in the reticular dermis[40] (Fig. 115.14). In some cases, the growth pattern can be frankly infiltrative or dissecting without any hint of a residual capsule, and there may be involvement of the superficial subcutis[7]. Cytologically, the predominant cell types are epithelioid or polygonal cells with ample eosinophilic cytoplasm and round nuclei with an open chromatin pattern[48,50]. Many cells have prominent nucleoli. Less often, the constituent cells are spindle-shaped with hyperchromatic nuclei, as are seen in the classic form of nerve sheath myxoma. Mitotic figures are often present but are usually normal morphologically. Rare cases with increased mitotic figures and cytologic atypia have been reported[51]. The stroma can be markedly fibrotic or even hyalinized. An obvious direct connection with peripheral nerves has not been established, but branches of pre-existing nerve

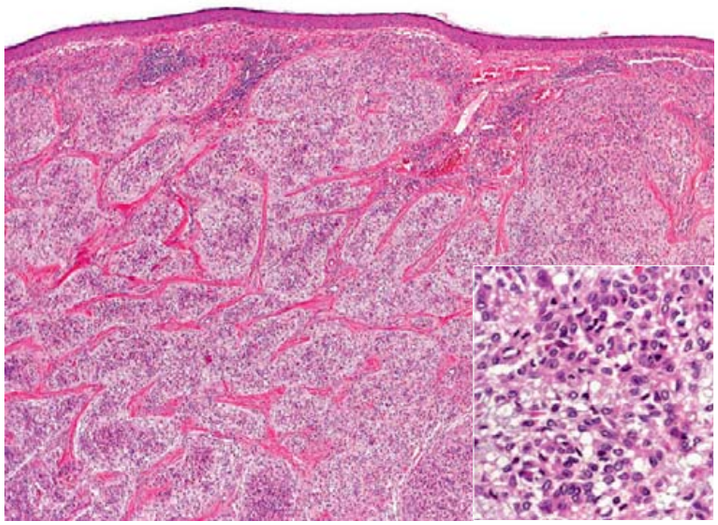

Fig. 115.14 Cellular neurothekeoma. Epithelioid nests are dispersed in a hyalinized stroma. Whorl-like arrangement of epithelioid cells with nuclear pleomorphism (insert). *Courtesy, Lorenzo Cerroni, MD.*

fibers can be demonstrated by special stains. The tumor does not have a consistent immunohistochemical profile, with NKI/C3, PGP9.5 (neuron-specific peptide), microphthalmia transcription factor (see Ch. 65), and smooth muscle-specific actin the most commonly expressed markers. While the lack of S100 protein expression can help to differentiate it from a classic nerve sheath myxoma, S100A6 may be expressed[52].

Differential Diagnosis

A nerve sheath myxoma is usually asymptomatic and clinically is often mistaken for a dermal melanocytic nevus, neurofibroma, lipoma or cyst (e.g. myxoid, ganglion) (see Table 115.2). Clinically, a cellular neurothekeoma usually resembles a dermatofibroma (including the sclerosing hemangioma variant), hypertrophic scar, keloid or granular cell tumor.

Treatment

These lesions are usually treated by simple excision; however, if incompletely removed, a nerve sheath myxoma may recur. There have been a few case reports of atypical variants of cellular neurothekeoma with postulated uncertain behavior, in which case complete excision is recommended.

GRANULAR CELL TUMOR

Synonym: ■ Abrikossoff's tumor

Key features

- Seen more commonly in adults, women and darkly pigmented individuals of African descent
- Predilection for the tongue, but can occur anywhere, including the viscera
- Malignant transformation is rare and usually occurs with deep-seated lesions
- Histologically, an ill-defined, infiltrative tumor, often with associated pseudoepitheliomatous hyperplasia
- Large polygonal cells with finely granular eosinophilic cytoplasm; the granules are PAS-positive, diastase-resistant

Introduction

Granular cell tumor is a descriptive term for a heterogeneous group of neoplasms composed of cells with granular cytoplasm due to the accumulation of lysosomal granules. Most cutaneous granular cell neoplasms are of neural origin, but granular cell change occurs in a variety of neoplasms (see below).

History

This tumor was originally thought by Abrikossoff to be derived from muscle, who used the term "granular cell myoblastoma"[53]. Feyrter first suggested a neural origin[54].

Epidemiology

Granular cell tumor is a relatively rare tumor that occurs primarily in adults (age 30–50 years) with a 1 : 3 male–female ratio. The tumor is characteristically solitary, and 70% of them are located in the head and neck region, including 30% on the tongue[53]. Other common locations are the breast (5–15%) and the proximal extremities. Rare visceral lesions have also been reported. In approximately 10% of patients, the lesions are multiple, especially in darkly pigmented individuals of African descent.

Pathogenesis

The neural origin of this tumor has been a subject of controversy, and it was originally based on the observation that granular cells are sometimes intimately associated with nerves and other neural tumors[55–57]. In addition, granular cells express S100 protein and CD57 (a neuronally expressed adhesion molecule), as do many Schwann cell tumors[58]. However, the classic form of this tumor does not resemble any other type of peripheral nerve sheath tumor. More recent immunohistochemical studies suggest that this tumor is neural crest-derived with peripheral nerve-related cellular differentiation[59]. Despite the controversy regarding its histogenesis, the granular cell tumor is histologically distinct and rarely presents a diagnostic problem.

Clinical Features

A granular cell tumor presents as an asymptomatic or occasionally tender or pruritic, skin-colored to brownish-red, firm dermal or subcutaneous papulonodule, ranging in size from 0.5 to 3.0 cm in diameter. Occasionally, the surface will be ulcerated or verrucous. Granular cell tumors are slowly growing and in general have a benign behavior. In approximately 3% of cases, malignant behavior may ensue (local infiltration or metastasis), usually when the tumor arises from a visceral or deep location.

Pathology

The dermis contains a poorly circumscribed nodule composed of polygonal, pale-staining cells that may infiltrate into the adjacent dermis. The cells have abundant, granular, faintly eosinophilic cytoplasm with round, dark nuclei (Fig. 115.15)[60]. Characteristic larger cytoplasmic granules are called pustulo-ovoid bodies. With the PAS reaction, the granules are positive, but they are diastase-resistant. Occasionally, a perineurial growth pattern is present; however, the tumor is devoid of axons. Increased numbers of mast cells are present in some lesions[55]. The overlying epidermis is frequently acanthotic. Rarely, a plexiform growth pattern has been described[61]. Histologic criteria that can prospectively identify the rare aggressive tumors are not well established[62]. The presence of necrosis, an increased mitotic rate, and spindling of the cells has been suggested as predictive of aggressive behavior[63].

Differential Diagnosis

The clinical differential diagnosis of lingual lesions includes an irritation fibroma, verruca and squamous cell carcinoma (SCC). Elsewhere, this tumor may resemble a dermatofibroma, regressing verruca or adnexal neoplasm (see Table 115.2). Granular cell tumors can induce considerable pseudocarcinomatous hyperplasia of the overlying epithelium, and superficial biopsy samples have been mistaken for SCC, especially on the tongue[64]. A variety of epithelial and mesenchymal neoplasms can show granular cell change, including BCCs, leiomyomas and leiomyosarcomas[60,65].

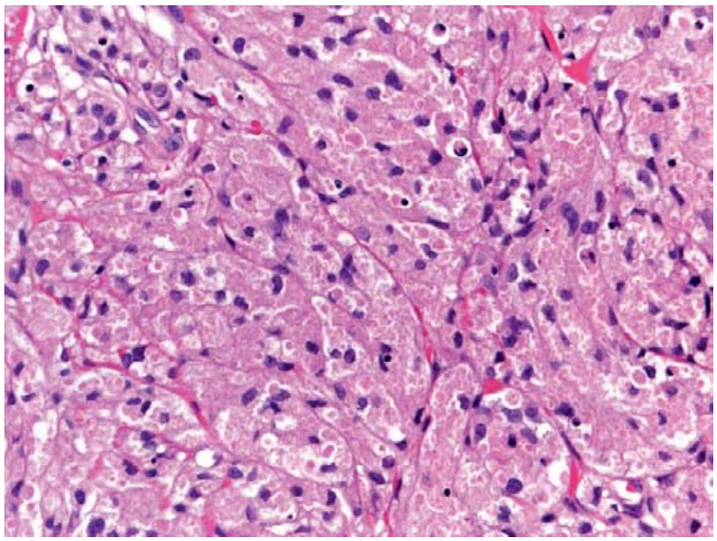

Fig. 115.15 Granular cell tumor. The tumor may show a nodular or infiltrative growth pattern. The large polygonal cells have finely granular cytoplasm and round nuclei. *Courtesy, Lorenzo Cerroni, MD.*

Treatment

The treatment is complete excision. If incompletely excised, this tumor has a high local recurrence rate, due to the plexiform or perineurial growth pattern.

PERINEURIOMA

Synonyms ■ Storiform perineurial fibroma ■ Fibrolamellar nerve sheath tumor ■ Localized hypertrophic neuropathy

Introduction

Perineuriomas represent a proliferation of perineurial cells, with both intraneural and extraneural growth patterns. Because of their rarity, only the extraneural variants that are pertinent to dermatologists are summarized in Table 115.5.

PERINEURIOMAS – KEY FEATURES OF EXTRANEURAL VARIANTS OF INTEREST TO DERMATOLOGISTS
CLINICAL FEATURES
• Solitary, non-descript, skin-colored, soft tissue mass • Occurs primarily on the trunk and extremities of adults, with the sclerosing type favoring the hands of young men
HISTOPATHOLOGIC FEATURES
• Predominant cell type is the perineurial cell, with an admixture of fibroblasts • The two most common variants are: "soft tissue" and "sclerosing type" • In the "soft tissue" variant, there is a well-circumscribed (but non-encapsulated) proliferation of slender, elongated spindle cells within the dermis and/or subcutis; the latter form tightly woven fascicles (sometimes with a lamellar or storiform pattern; Fig. 115.16) and the intertwining stroma can be hyalinized or myxoid • In the "sclerosing type", there may be epithelioid cells alternating with spindle cells, intermixed with thick collagen bundles • No significant atypia or mitotic activity
IMMUNOHISTOCHEMISTRY
• Cells stain positively for EMA, claudin 1, type IV collagen and laminin
CLINICAL DIFFERENTIAL DIAGNOSIS
• Benign soft tissue tumors (e.g. lipoma) and soft tissue sarcomas
HISTOLOGIC DIFFERENTIAL DIAGNOSIS
• Neurofibromas with extensive fibrosis (S100-positive and NF-positive), DFSP (EMA-negative; CD34-positive), sclerosing fibroma (EMA-negative)
TREATMENT
• Complete excision – biologic behavior usually benign, rarely malignant

Table 115.5 Perineuriomas – key features of extraneural variants of interest to dermatologists. Based upon refs 66 & 67. DFSP, dermatofibrosarcoma protuberans; EMA, epithelial membrane antigen; NF, neurofilament. Claudin-1 is a tight junction-associated protein.

MALIGNANT PERIPHERAL NERVE SHEATH TUMOR

Synonyms: ■ Neurosarcoma ■ Malignant schwannoma

The term "malignant peripheral nerve sheath tumor" is preferable to the widely used but confusing synonyms above. This is because any cellular component of the peripheral nerve can give rise to these tumors. In the majority of cases, perineurial or endoneurial fibroblasts (rather than Schwann cells) form the bulk of the tumor[68–70].

Malignant peripheral nerve sheath tumor is a tumor of deep soft tissues and rarely involves the skin. A definitive diagnosis requires histologic examination, usually in conjunction with immunohistochemistry and molecular biologic analysis. Histologically, in the most common form, there is a proliferation of atypical spindle cells, often arranged in a "herring-bone" pattern. There is variable cytologic atypia, numerous abnormal mitotic figures, and areas of necrosis and hemorrhage (Fig. 115.17)[69–71]. Despite its rarity,

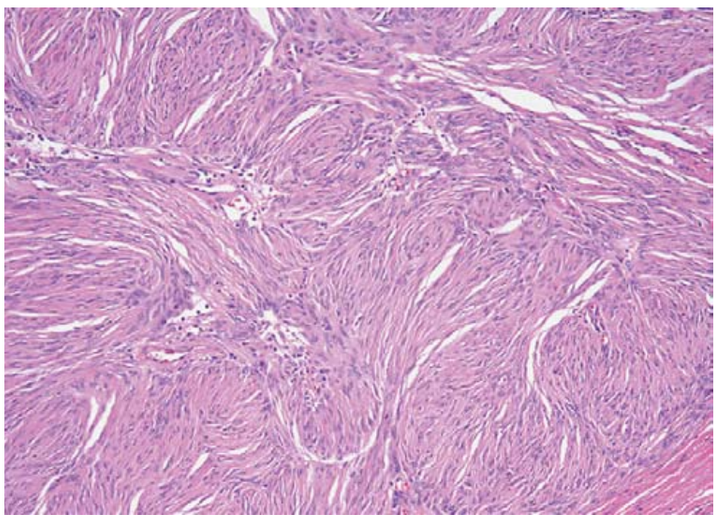

Fig. 115.16 Soft tissue perineurioma. Compact proliferation of spindle cells with lobular and storiform pattern.

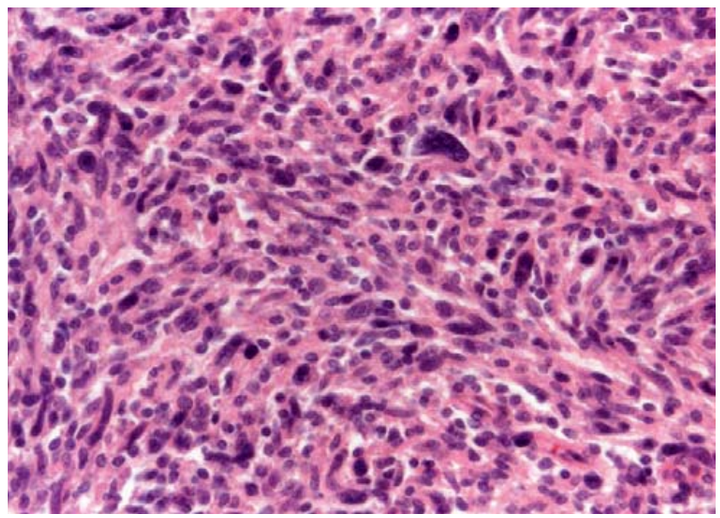

Fig. 115.17 Malignant peripheral nerve sheath tumor. Marked cellular pleomorphism with cytologic atypia and mitotic activity. Overall, the intersecting fascicles create a "herring-bone" pattern.

malignant peripheral nerve sheath tumor has clinical relevance for the dermatologist, because this malignancy develops within 2–13% of plexiform neurofibromas, which are associated with neurofibromatosis[71] (Ch. 61).

MERKEL CELL CARCINOMA

Synonyms: ■ Primary neuroendocrine carcinoma of the skin ■ Trabecular carcinoma of the skin ■ Primary small cell carcinoma of the skin ■ Cutaneous apudoma

Key features

- Predilection for the head and neck region of older adults
- Solitary, rapidly growing nodule
- Histologically, tumor is composed of small, round blue cells, often with a nested or trabecular growth pattern
- High mitotic rate, frequent single-cell necrosis, and often zonal necrosis
- Aggressive, malignant behavior

Introduction

Merkel cell carcinoma is a malignant proliferation of highly anaplastic cells which share structural and immunohistochemical features with various neuroectodermally derived cells, including cutaneous Merkel cells. These tumors display nonspecific clinical features and highly aggressive behavior. Early recognition and adequate therapy are therefore critical.

History

This tumor was originally described by Toker and given the name "trabecular carcinoma" based on its lattice-like and infiltrative growth pattern[72]. Subsequently, the neuroendocrine nature of this tumor was recognized, with similarities to the normal Merkel cell of the skin[73].

Epidemiology

Merkel cell carcinoma most commonly occurs in the elderly, and it is slightly more prevalent in women[74].

Pathogenesis

Although the cells of this tumor and the normal Merkel cell, which is a specialized receptor cell of touch located in the basal layer of the epidermis, share several morphologic, immunohistochemical and ultrastructural features, there is little evidence for a direct histogenetic relationship between the two[73]. Furthermore, extracutaneous neuroendocrine tumors display similar features. Therefore, the conceptually more unifying term "primary neuroendocrine carcinoma of the skin" (PNECS) is preferred by pathologists over Merkel cell carcinoma[4], as it indicates the tumor's relationship with neuroendocrine tumors of other origins. Clinicians seem to prefer the shorter term Merkel cell carcinoma, which appears entrenched in the lexicon.

In 2008, the first report appeared of the association of polyomavirus and PNECS[75]. This polyomavirus, now referred to as Merkel cell polyomavirus, infects approximately 80% of these carcinomas[76]. Notably, there is monoclonal integration of viral DNA into the host genome (rather than existing as a plasmid), suggesting that this is an early event. Inhibition of viral oncoproteins in polyomavirus-infected tumor cells leads to their death while this has no effect on uninfected tumor cells, pointing to a causal relationship.

Clinical Features

The tumor favors the head and neck region, followed by the extremities and the buttocks. It usually presents as a pink–red to violaceous, firm, dome-shaped, solitary nodule that has grown rapidly (Fig. 115.18)[74]. Ulceration can occur. Overall, the behavior is that of an aggressive tumor, with significant risk of recurrence after excision.

Tumor diameter at the time of diagnosis influences prognosis, with lesions >2 cm having a 51% relative survival rate at 5 years (compared to 66% for tumors ≤2 cm; Table 115.6)[77]. In a series of 5823 prospectively enrolled patients followed for a median of 64 months[77], 27% had lymph node involvement and 7% had distant metastatic disease at the time of presentation.

A Nodular infiltrate of basaloid cells with focally small "trabecular" structures within the entire dermis and superficial subcutis. **B** Small, round to ovoid basaloid cells with vesicular nuclei and small nucleoli; note several necrotic (apoptotic) cells and a mitotic figure (arrow). **C** Immunohistochemical stain for cytokeratin 20 demonstrates a characteristic perinuclear dot pattern. *Courtesy, Lorenzo Cerroni, MD.*

Pathology

The tumor appears as a poorly defined dermal mass, frequently infiltrating the subcutaneous fat, fascia and muscle. While it may show various growth patterns, a sheet-like growth pattern is seen most commonly, followed by nested and trabecular patterns (Fig. 115.19A)[78]. Characteristically, the edge of the tumor shows a trabecular infiltrating pattern[72]. The tumor is composed of monotonously uniform, small, round to oval cells that are about two to three times larger than mature lymphocytes[72,73]. The nuclei of these cells are ovoid with a finely dispersed chromatin pattern and distinct nuclear membranes (Fig. 115.19B). Nucleoli are usually not prominent. Mitotic figures are abundant. The cytoplasm is scant and faintly amphophilic. Extensive areas of necrosis, individual cell necrosis and characteristic crush artifact are common[78].

Various types of differentiation have been described in Merkel cell carcinoma, including rosette-like structures resembling Homer Wright rosettes of neuroblastoma, epidermotropic involvement with pagetoid spread, and eccrine and squamoid differentiation[79,80]. Immunohistochemically, there is a characteristic perinuclear globule upon staining for low-molecular-weight cytokeratins (CK) such as CK20, CK5/6 and CK7 (Fig. 115.19C). This corresponds to the ultrastructural distribution of paranuclear whorls of intermediate filaments[78,79]. In addition, there is positive staining for various neuroendocrine markers, including chromogranin, synaptophysin, somatostatin, calcitonin and vasoactive intestinal peptide[79]. These peptides are associated with ultrastructurally demonstrable, membrane-bound, dense-core secretory granules. The tumor also expresses neuron-specific enolase and, occasionally, neural filaments and CD56; however, immunostaining for S100 protein is characteristically negative[79]. Likewise, a negative reaction for thyroid transcription factor 1 (TTF-1) helps to differentiate Merkel cell carcinoma from cutaneous metastases of other small cell carcinomas (pulmonary and extrapulmonary); the latter are characteristically positive for this marker[79]. Recent recognition of Merkel cell polyomavirus, which can be detected by immunohistochemical (e.g. T antigen) and molecular biologic methods[81], provides an additional tool for diagnosis; however, false-positive PCR results are possible given the ubiquitous nature of the virus. For prognostication, increased p63 expression may portend a clinically aggressive behavior[82].

Differential Diagnosis

Common clinical diagnoses are BCC, SCC, amelanotic melanoma and adnexal tumor. Due to the violaceous, sometimes hemorrhagic, appearance of some tumors, the differential diagnosis also includes pyogenic granuloma, abscess, angiosarcoma and lymphoma. Histologically, there is a broad spectrum of small, round, blue cell tumors of diverse histogenesis that can be confused with PNECS[79]. These include metastatic neuroendocrine carcinoma of the lung (small cell or oat cell carcinoma), poorly differentiated eccrine carcinoma, lymphoma, metastatic neuroblastoma, primary peripheral primitive neuroectodermal tumor, Ewing's sarcoma, melanoma, and poorly differentiated SCC[78,79].

Treatment

Surgery is the primary approach. However, owing to the aggressive nature of this tumor, adjuvant chemotherapy and radiation therapy are often administered simultaneously[83]. To aid in treatment decisions and for prognosis, sentinel lymph node mapping has been recommended[84,85] (Fig. 115.20).

TUMORS AND TUMOR-LIKE CONDITIONS OF ECTOPIC AND HETEROTOPIC NEURAL TISSUE OF THE SKIN

These rare lesions develop from embryologically misplaced neural tissue within the skin. They range from benign malformations to cellular proliferations with potential for metastasis. There are three major clinicopathologic manifestations of neural heterotopias in the skin: (1) neuroglial; (2) meningeal; and (3) neuroblastic/ganglionic abnormalities.

HETEROTOPIC NEUROGLIAL TISSUE

Synonyms: ■ Nasal glioma ■ Brain-like heterotopia ■ Glial hamartoma

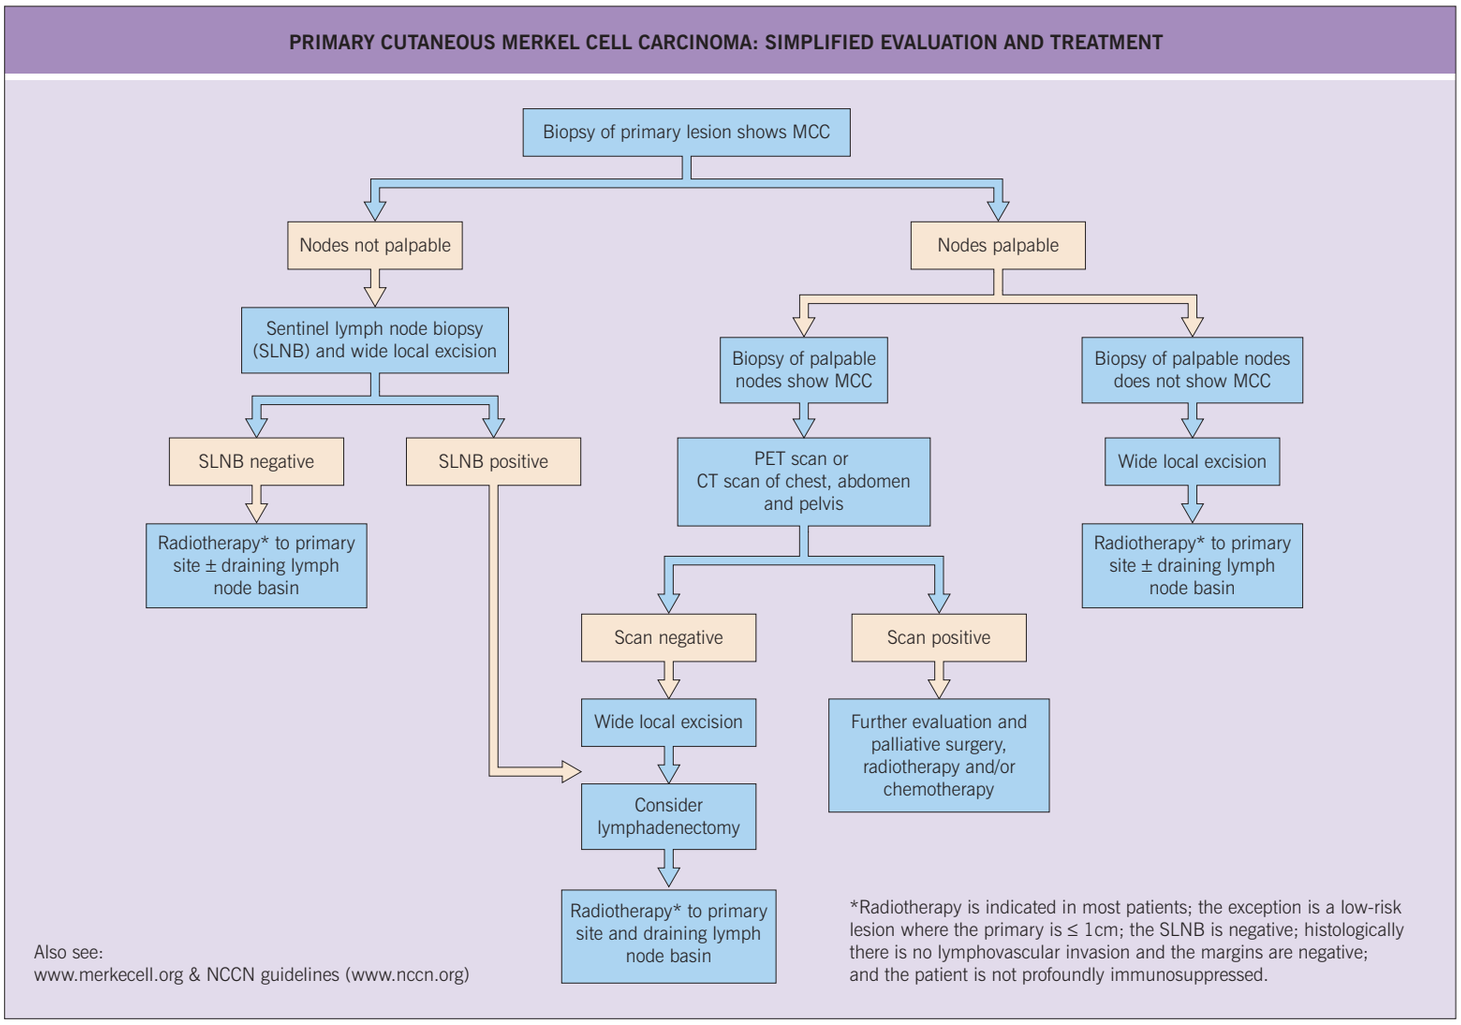

Fig. 115.20 Primary cutaneous Merkel cell carcinoma (MCC): simplified evaluation and treatment algorithm. NCCN, National Comprehensive Cancer Network; PET, positron emission tomography. *Courtesy, Paul Nghiem, MD PhD. Based upon: Gupta SG, Wang LC, Penas PF, et al. Sentinel lymph node biopsy for evaluation and treatment of patients with Merkel cell carcinoma: The Dana-Farber experience and meta-analysis of the literature. Arch Dermatol. 2006;142:685–90.*

Key features

- Rare, benign, congenital lesion
- Most common near the root of the nose, but can be intranasal
- Solitary, firm, smooth, skin-colored to red–purple papulonodule
- May be associated with an encephalocele
- Microscopically, lobulated neuroglial tissue

History

The term "nasal glioma" was introduced by Schmidt in 1900[86].

Epidemiology

These tumors are rare and usually manifest at the time of birth.

Pathogenesis

A nasal glioma is the result of embryologic displacement of brain tissue, usually along the cranial closure lines and without apparent communication with underlying structures[87]. It has a predilection for the perinasal area; therefore, it is commonly referred to as a nasal glioma. As this is not a true neoplasm, the term is misleading[88].

Clinical Features

Nasal gliomas are firm, smooth-surfaced, skin-colored to red–violet papulonodules that may have obvious telangiectasias and range in size from 1 to 3 cm. Approximately 60% are located on the bridge of the nose (Fig. 115.21), with the remainder usually located intranasally or in both locations[88,89].

Pathology

In a nasal glioma, an ill-defined, non-encapsulated neuropil-like mass is seen within the dermis and subcutis. The neuropil-like tissue is composed of nests and strands of pale-staining, finely vacuolated or fibrillary matrix in which various types of astrocytes can be found[87]. Gemistocytic astrocytes, with polygonal, eosinophilic cytoplasm and eccentric nuclei, as well as multinucleated giant cells, are relatively common. Mature neurons are present in variable numbers[88]. Occasionally, residual meningoendothelial cells, ependymal cells, choroid plexus-like structures and pigmented cells can be identified[89]. No mitotic activity or aggressive growth pattern has been described.

Differential Diagnosis

Clinically, the lesion must be differentiated from other facial midline lesions (see Ch. 64)[88,90] as well as an infantile hemangioma, juvenile xanthogranuloma, dermoid cyst and nasal polyp.

Treatment

Most cutaneous neural malformations can be effectively treated by excision. Cranial imaging is recommended before these lesions are biopsied or removed[91], because nasal gliomas can communicate with the intracranial space, and cerebrospinal fluid leakage and subsequent

Fig. 115.21 Nasal glioma in a newborn. Pink to violet soft nodule.

meningoencephalitis and other neurologic damage may occur after biopsy[88].

HETEROTOPIC MENINGEAL TISSUE

Synonyms: ■ Cutaneous meningioma ■ Rudimentary meningocele

Key features

- Rare disorder that usually presents in neonates and infants and favors the scalp, forehead and paravertebral region
- Soft to firm, skin-colored nodule, often with partial alopecia or the "hair collar" sign
- Can be associated with neurofibromatosis or other developmental anomalies
- Histologically, solid nests and strands, whorls of epithelioid or spindle cells, and psammoma bodies

History

The rare cutaneous presentation of meningioma was first reported by Winkler[92] in 1904, and the concept of rudimentary meningocele was introduced by Lopez et al.[93].

Epidemiology

Meningeal heterotopias are rare lesions, usually apparent at or shortly after birth[93].

Pathogenesis

Rudimentary meningoceles are thought to result from herniation of the meningeal lining into the skin and subcutaneous tissues during embryologic development, usually with no residual communication with the CNS (see Ch. 64)[94]. Cutaneous meningiomas have three major forms of histogenesis[93]. In type I, the tumors are composed of arachnoid lining cells that were misplaced during embryogenesis. These lesions are usually congenital, and considering their non-neoplastic nature, they are better classified as rudimentary meningoceles[94]. In type II, the tumors develop along the course of the cranial nerves. Type III lesions represent cutaneous "metastasis" or direct extension of primary meningiomas of the arachnoid lining[95,96].

Clinical Features

Rudimentary meningoceles most commonly present on the scalp of neonates and infants at the sites of cranial closure. Less often they occur on the forehead (midline) or in a paravertebral location. Skin-colored papules or nodules on the scalp are often associated with alopecia or the "hair collar" sign[95]. Type II and type III meningiomas usually develop on the head of adults[93]. Their clinical appearance is similar to rudimentary meningoceles. Cutaneous meningioma has been reported in association with neurofibromatosis[97].

Pathology

A rudimentary meningocele is an ill-defined mass of cavernous, pseudovascular spaces embedded in a markedly collagenous stroma[94,98]. The spaces may be lined by elongated meningoendothelial cells characterized by eosinophilic cytoplasm, round or ovoid nuclei, and a fine chromatin pattern. Similar cells dissect or wrap around collagen fibers, producing "collagen bodies". No significant cytologic atypia or mitotic activity is present. Focal calcification and psammoma bodies (eosinophilic laminated and whorled structures with variable calcification) may occur.

A cutaneous meningioma is composed of a multinodular mass in the deep dermis or subcutis, often with an infiltrative growth pattern[99–101]. Depending on their histogenesis, the cells may show a variable degree of differentiation. In the most common form, the spindle cells show a concentric, whorl-like arrangement[99]. The cells have oval nuclei with a vesicular chromatin pattern. Mitotic figures are rare in type II and variably increased in type III. Psammoma bodies are often present[99–101].

Differential Diagnosis

Rudimentary meningoceles must be distinguished from "atretic" meningoceles (an intermediate form with an intracranial connection), membranous aplasia cutis congenita, heterotopic brain tissue, dermoid cysts and infantile hemangiomas. Clinically, cutaneous meningiomas may resemble cysts and other adnexal neoplasms as well as metastatic tumors.

Treatment

As with heterotopic neuroglial tissue (nasal glioma), imaging studies are required prior to biopsy or excision. The latter is usually performed by neurosurgeons.

HETEROTOPIC NEUROBLASTIC TISSUES AND THEIR TUMORS

Synonyms: ■ Neuroblastoma (primary or metastatic) ■ Primitive neuroectodermal tumor ■ Neuroepithelioma

Key features

- The third most common malignant neoplasm in children
- Cutaneous metastases (children) are seen more frequently than primary cutaneous tumors (adults)
- Cutaneous metastases present as multiple, blue to purple dermal nodules in association with elevated serum and urine catecholamines
- Histologically, small, round, blue cells in a nested or infiltrative growth pattern, with formation of Homer Wright rosettes
- Prognosis depends on the patient's age, clinical stage and specific genetic abnormalities (e.g. *MYCN* oncogene amplification)

Introduction

Neuroblastic–ganglionic tumors are derived from the germinal neuroepithelium and/or from the neural crest. They display a wide spectrum of clinicopathologic features based on their relative degree of differentiation, ranging from very primitive neuroectodermal tumors to more mature forms such as neuroblastomas.

History

The concept of neuroectodermal tumors was introduced by Stout in 1918[102]. Since then, different terms have been used for tumors with cytologically similar features, reflecting the controversy regarding this entity. Dehner performed a comprehensive review of the nosology of this diverse group of lesions, suggesting the term "primitive neuroectodermal tumors" (PNET)[103].

Epidemiology

Neuroblastoma is the third most commonly observed childhood malignancy, and cutaneous metastases are frequent[3]. Most neuroblastomas develop as sporadic tumors, although familial cases have been reported. Primary cutaneous PNETs are tumors of adulthood (mean age, 40 years) and are exceedingly rare[3].

Pathogenesis

PNETs of the skin either represent metastases from a PNET of the adrenals and/or ganglionic chain (traditionally designated as neuroblastomas) or develop *de novo* from heterotopic neural crest cells[3]. In the latter case, they are referred to as peripheral PNETs or as peripheral neuroblastomas. Recent studies have implicated the anaplastic lymphoma kinase gene in the tumorigenesis of many familial and some sporadic cases of neuroblastoma. In addition, specific genetic abnormalities, such as *MYCN* oncogene amplification or aberrations of chromosomes 1p or 11q, influence prognosis[104].

Clinical Features

In children, the cutaneous metastases of neuroblastoma often manifest as multiple, blue to purple, dermal papules or nodules that resemble the "blueberry muffin" lesions seen with congenital infections or hematologic disorders[5] (see Ch. 121). These nodules may blanch upon stroking and develop an erythematous halo[105,106]. Serum and urine catecholamine levels are typically elevated. Spontaneous regression has been described in stage IV-S[7], but rarely occurs in other stages.

In adults, PNETs are rapidly growing dermal or subcutaneous nodules that favor the trunk or head. Ulceration is common. These highly aggressive neoplasms have an almost invariably fatal outcome[107].

Pathology

In metastatic neuroblastoma, an ill-defined or infiltrative mass is present in the dermis and/or the subcutis. However, when smaller and more superficial, deposits are more well defined. The tumor mass is composed of atypical, small, dark cells with scant cytoplasm[3,103]. The cells have larger nuclei than mature lymphocytes (with a coarse chromatin pattern) and they form irregular nests, cords or poorly cohesive sheets. Rosette formation, by concentrically arranged tumor cells in double or multiple circles, is common. The center of the rosettes contains converging fine fibrillary material characteristic of Homer Wright-type rosettes[3] (Fig. 115.22). Mitotic activity is high, and abnormal mitoses are abundant. Extensive areas of necrosis and hemorrhage are common.

As the tumor differentiates, the relative proportion of neuroblastoma components decreases, and the ganglioneuromatous elements increase. Eventually, the tumor may become a ganglioneuroma[107]. Immunohistochemically, the cells react variably with neural and neuroendocrine markers, depending on their state of differentiation. These markers include neuron-specific enolase, S100 protein, neurofilaments, synaptophysin, chromogranin and CD99 (see Ch. 0)[104].

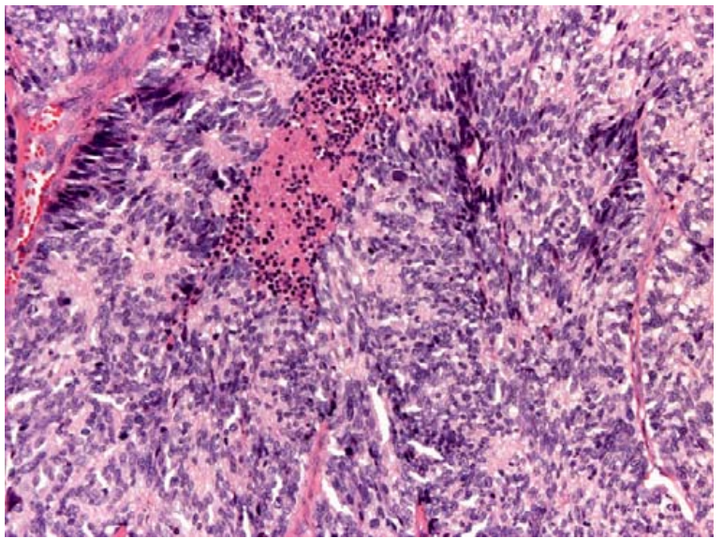

Fig. 115.22 Cutaneous neuroblastoma. The tumor is composed of small cells with small, round to ovoid nuclei that can be arranged in rosettes. The fibrillary material in the center of Homer Wright-type rosettes is characteristic. *Courtesy, Lorenzo Cerroni, MD.*

Primary PNETs have similar histopathologic features to those of the classic neuroblastoma, but ganglionic or neuromatous differentiation is not characteristic. PNET and classic neuroblastoma also share major immunohistochemical features. However, MIC-2(013) is commonly expressed by PNETs, but not by neuroblastomas, facilitating their distinction[104,108–111].

Differential Diagnosis

In children, the clinical differential diagnosis includes other types of cutaneous metastasis, extramedullary hematopoiesis and mastocytosis, whereas in adults it includes adnexal tumors, lymphoma and soft tissue sarcomas. Histologically, both metastatic neuroblastoma and primary cutaneous neuroectodermal tumor must be differentiated from other rosette-forming small, round, blue cell tumors that may involve the skin[109–111] (see Merkel cell carcinoma).

Treatment

The effective treatment of neuroblastoma requires an interdisciplinary team that includes oncologists, surgeons and radiation therapists. The overall prognosis of localized tumor involvement has recently improved with combined surgical excision, multiagent chemotherapy, differentiating agents (e.g. 13-cis-retinoic acid), radiopharmaceuticals, and small molecule inhibitors of signal transduction pathways[104]. Important prognostic factors include the age, stage, histologic differentiation, specific genetic abnormalities (e.g. *MYCN* oncogene amplification, 11q aberration), and response to initial chemotherapy[3].

Key features

- Fibrous and fibrohistiocytic proliferations of the skin and tendons are common lesions that include both neoplastic and "reactive" processes
- Common benign fibrous and fibrohistiocytic proliferations, some of their atypical variants that could be misdiagnosed as malignant tumors, and corresponding malignant neoplasms are reviewed
- These tumors are composed of fibroblasts, myofibroblasts, histiocytes, dermal dendritic cells, collagen fibers, elastic fibers and connective tissue mucin, each present in variable proportions depending upon the particular lesion
- Immunohistochemical stains for vimentin (for nonspecific mesenchymal components); factor XIIIa and CD34 (for dermal dendritic cells); CD68 and α1-antichymotrypsin (for histiocytes); and muscle-specific actin (for myofibroblasts) are helpful in evaluating these lesions

SKIN TAGS

Synonyms: ■ Acrochordons ■ Fibroepithelial polyps ■ Soft fibromas

Clinical Features

Skin tags are very common, presenting as soft, skin-colored to slightly hyperpigmented, pedunculated papules that favor the neck, axilla and groin (Fig. 116.1). They may be single or multiple and vary from 1–2 mm papules on the eyelids to 1–2 cm baggy polyps on the trunk. Skin tags are usually asymptomatic, but can become painful secondary to irritation or infarction.

Clinically, they can resemble intradermal melanocytic nevi, neurofibromas and pedunculated seborrheic keratoses.

Epidemiology

The incidence increases with age. Men and women are equally affected, and close to 50% of all individuals have at least one skin tag[1]. Although skin tags were once thought to be associated with colonic polyps, more recent studies have not confirmed this relationship[2]. Skin tags have also been reported as a cutaneous marker for diabetes mellitus[3].

Pathology

Histologically, skin tags are polypoid with loose to dense collagenous stroma and thin-walled blood vessels. The overlying epidermis may be hyperpigmented and hyperplastic. Adipocytes are sometimes seen within larger skin tags (lipofibroma or fibroma molle). The histopathologic differential diagnosis includes seborrheic keratosis, nevus lipomatosus superficialis, and angiofibroma.

In Birt–Hogg–Dubé syndrome and Cowden syndrome, patients can have typical skin tags, but sometimes the "skin tags" represent fibrofolliculomas, trichodiscomas or perifollicular fibromas, versus sclerotic fibromas, respectively[4].

Treatment

Unless irritated or infarcted, skin tags are more of a cosmetic issue than a clinical concern and can be removed by scissor excision.

CUTANEOUS ANGIOFIBROMA

Synonyms: ■ Fibrous papule ■ Pearly penile papule ■ Periungual fibroma

Cutaneous angiofibroma is a descriptive term for a group of lesions with different clinical presentations and implications, but similar histologic findings.

Clinical Features

Fibrous papules are solitary, dome-shaped and shiny, skin-colored to reddish papules located on the face of adults, most commonly on the nose (Fig. 116.2)[5]. Clinically, they can mimic small intradermal melanocytic nevi, basal cell carcinomas (BCCs) or adnexal tumors. They are often sampled to exclude a BCC. Removal consists of shave excision and electrodesiccation.

Pearly penile papules are pearly, white, dome-shaped, closely aggregated small papules located on the glans penis, commonly in a multilayered and circumferential manner on the corona (Fig. 116.3). They are found in up to 30% of young postpubertal adults, and are more common in uncircumcised men[6]. They can be mistaken for condyloma acuminata or hypertrophied sebaceous glands. They are sometimes of significant cosmetic concern to the patient, but no treatment is needed, only reassurance.

Fig. 116.1 Multiple skin tags in the axilla. The lesions are skin-colored, soft and pedunculated.

Fig. 116.2 Fibrous papule of the nose. A smooth, dome-shaped, skin-colored papule.

Fig. 116.3 Pearly penile papules. Multiple small white papules along the corona of the glans penis. Note the multilayered distribution. *Courtesy, Kalman Watsky, MD.*

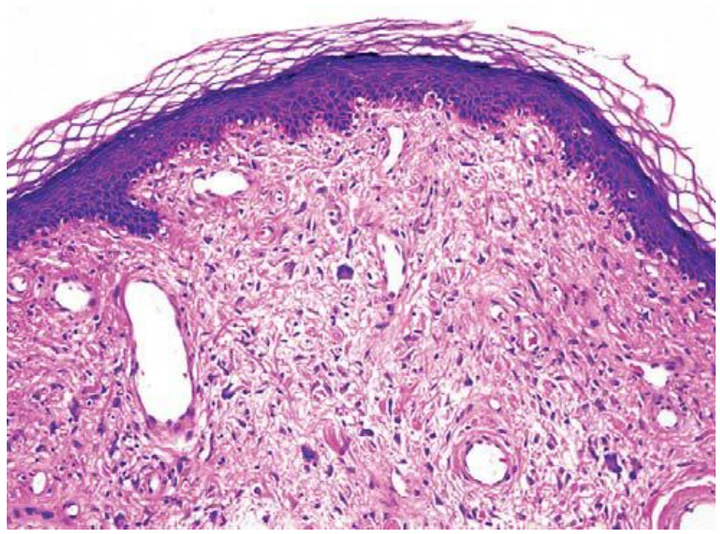

Fig. 116.4 Angiofibroma. Dermal fibroplasia with dilated, thin-walled vessels and large stellate fibroblasts is seen.

Multiple facial angiofibromas are seen in tuberous sclerosis (TS), multiple endocrine neoplasia type 1 and Birt–Hogg–Dubé syndrome[7] (see Ch. 61). They are usually distributed bilaterally on the cheeks, nasolabial folds, nose and chin. In TS, facial angiofibromas usually appear during early to mid childhood, with 75% of individuals eventually developing these lesions. Patients with TS can also have multiple *periungual angiofibromas*; they are less common in children but increase in incidence with age to 40% in adults. Both facial and periungual angiofibromas represent major diagnostic criteria for TS (see Table 61.8).

Pathology

All angiofibromas are dome-shaped lesions composed of a dermal proliferation of fibroblasts in a collagenous stroma with an increase in the number of thin-walled, dilated blood vessels (Fig. 116.4). The collagen fibers can be arranged in a concentric fashion around hair follicles and blood vessels (a variant known as perifollicular fibroma). Elastic fibers are decreased in number. Some fibroblasts are stellate in shape and can be multinucleated. By immunohistochemistry, these cells are positive for factor XIIIa and negative for S100 protein. The overlying epidermis is sometimes slightly atrophic. The histopathologic differential diagnosis includes skin tags and intradermal melanocytic nevi.

DERMATOFIBROMA

Synonyms: ■ Fibroma simplex ■ Benign fibrous histiocytoma ■ Nodular subepidermal fibrosis ■ Histiocytoma ■ Sclerosing hemangioma ■ Dermal dendrocytoma

Clinical Features

Dermatofibromas are the second most common fibrohistiocytic tumor of the skin (after skin tags). They are seen primarily in adults and favor the lower extremities. They are firm, minimally elevated to dome-shaped papules that usually measure from a few millimeters to 1 cm in diameter, but occasionally are up to 2 cm in size. The lesions are commonly hyperpigmented (Fig. 116.5), but in patients with lightly pigmented skin may appear tan to pink. On palpation, they may seem attached to the subcutaneous tissue; pinching the lesion gently usually results in apparent downward movement of the tumor, also known as the "dimple sign".

Although some dermatofibromas are thought to arise at sites of trauma or arthropod bites, their precise etiology is not known. Multiple eruptive dermatofibromas have been observed in patients with autoimmune disorders (e.g. lupus erythematosus), atopic dermatitis and in the

Fig. 116.5 Dermatofibroma. Hyperpigmented firm papule on the lower extremity. *Courtesy, Jean L Bolognia, MD.*

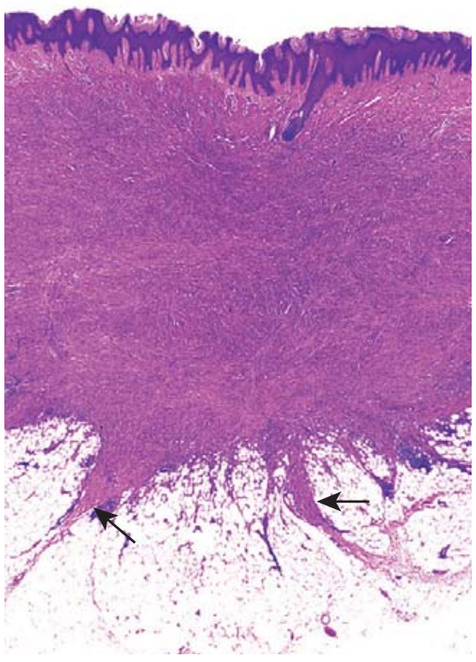

Fig. 116.6 Dermatofibroma. There is a nodular proliferation of spindled fibroblasts and histiocytes in the reticular dermis, with hyperplasia and hyperpigmentation of the overlying epidermis. Extension into the subcutaneous tissue occurs in a radial pattern (arrows).

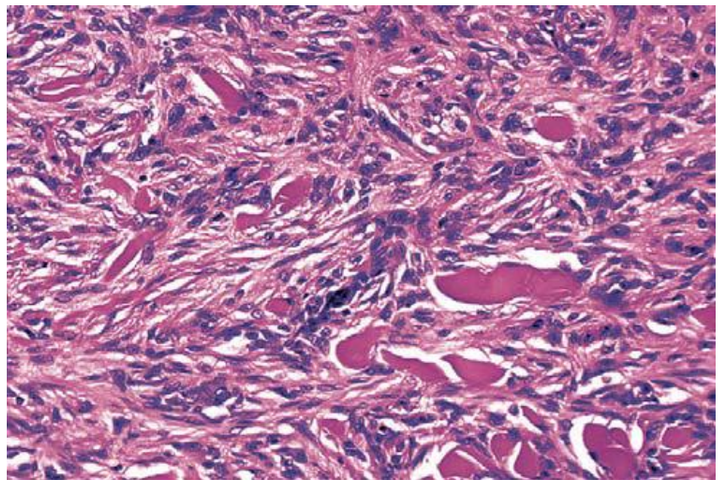

Fig. 116.7 Dermatofibroma. The fibroblasts are arranged in broad intersecting fascicles with entrapment of thick collagen bundles.

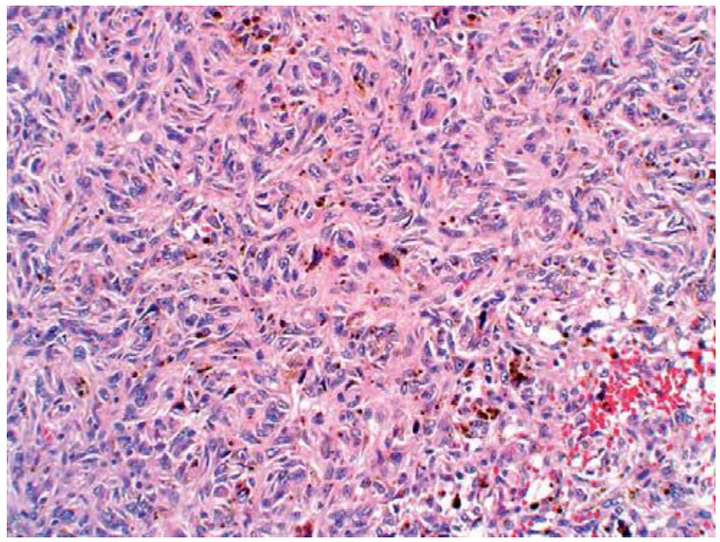

Fig 116.8 Dermatofibroma, sclerosing hemangioma pattern. In addition to plump fibroblasts and blood vessels, there are extravasated red blood cells and abundant hemosiderin pigment.

setting of immunosuppression (e.g. HIV infection)[8]. Clinically, dermatofibromas can be confused with cysts or melanocytic nevi, especially those with fibrosis. In the case of larger lesions, the possibility of dermatofibrosarcoma protuberans (DFSP), which is less well defined and multilobulated, may be considered.

Pathology

Dermatofibromas are characterized by a nodular dermal proliferation, predominantly of spindle-shaped fibroblasts and myofibroblasts arranged as short intersecting fascicles (Fig. 116.6). The fibroblasts and myofibroblasts have plump oval nuclei with small nucleoli; mitoses may be present. There may be a component of mono- or multinucleated histiocytes with vacuolated (xanthomatous) cytoplasm (hence the synonym benign fibrous histiocytoma). "Keloidal" collagen bundles, which are refractile with polarized light, are seen at the periphery (Fig. 116.7). An increased number of small blood vessels and a perivascular infiltrate of lymphocytes and plasma cells may be present. Hemorrhage into a dermatofibroma (sclerosing hemangioma) explains the common finding of hemosiderin (Fig 116.8).

The overlying epidermis is usually hyperplastic with flat confluent rete ridges and hyperpigmentation of the basal layer (so-called "dirty fingers"). Adnexal structures are usually absent at the center of the lesion; however, very often, small follicular or sebaceous structures are connected to the epidermis. Sometimes there are aggregates of basaloid cells with follicular differentiation emanating from the epidermis, which may be confused with a superficial BCC. There are, however, a few reported cases of true BCCs evolving within longstanding dermatofibromas[9]. Histologic variants of dermatofibroma are listed in Table 116.1.

MAJOR HISTOLOGIC VARIANTS OF DERMATOFIBROMA
With atypical ("monster") cells*
Atrophic
Extending into the subcutaneous tissue (deep dermatofibroma)
Palisading
Aneurysmal (hemosiderotic sclerosing hemangioma)
With osteoclast-like cells
Ossifying
Clear cell
Xanthomatous†
With granular cells
Cellular
Myxoid
*Also referred to as atypical (pseudosarcomatous) cutaneous histiocytoma.
†May be yellow in color.

Table 116.1 Major histologic variants of dermatofibroma.

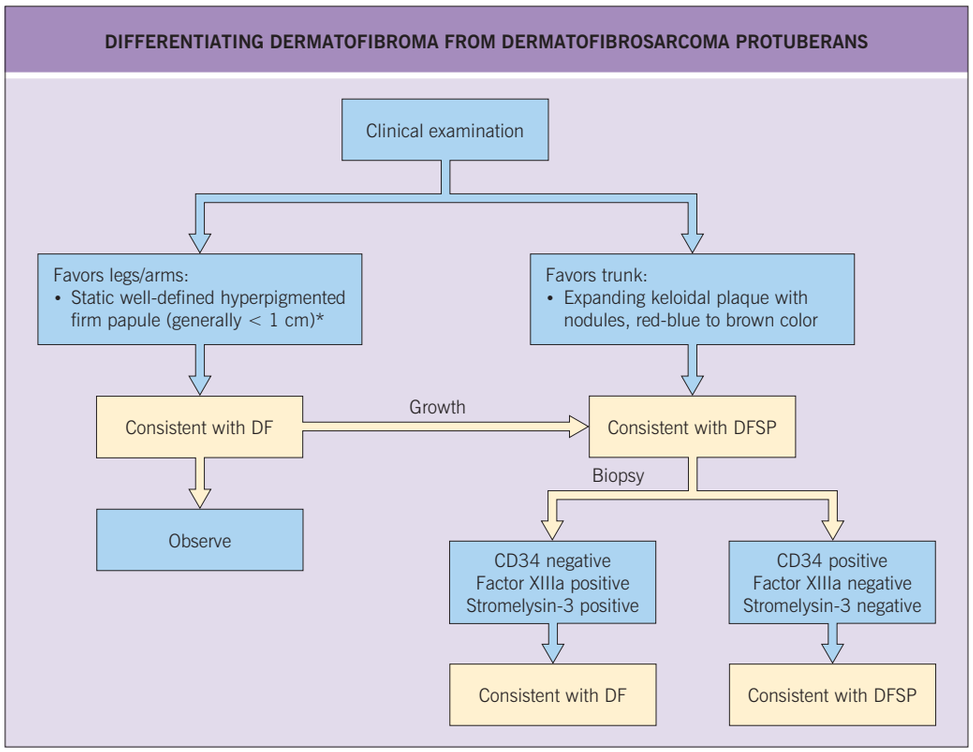

Fig. 116.9 Differentiating dermatofibroma (DF) from dermatofibrosarcoma protuberans (DFSP). At the periphery of dermatofibromas, there may be an increased number of CD34-positive cells, most likely representing pre-existing dendritic cells that were displaced by the cells of the dermatofibroma. *In patients with skin phototype I, it may be pink in color.

Positive immunohistochemical reactions for vimentin, factor XIIIa[10–12], stromelysin-3[13], muscle-specific actin, and CD68, as well as a negative reaction for CD34, support a diagnosis of dermatofibroma (Fig. 116.9). The histologic differential diagnosis includes keloid, scar, dermatomyofibroma, DFSP ($CD34^+$) and nodular Kaposi sarcoma. Whether dermatofibromas are reactive or neoplastic has been an area of controversy. More recent studies have reported evidence of clonality in dermatofibromas, supporting the neoplastic nature of this tumor[14,15].

Treatment

Dermatofibromas may be biopsied or excised to exclude a melanocytic proliferation, a fibrosed cyst or other mesenchymal neoplasm. Excision for cosmetic purposes is of questionable value, as the resultant scar is sometimes more noticeable than the original lesion, especially on the legs. However, some patients find the lesions bothersome or may wish to have histologic confirmation of the diagnosis. Undisturbed, dermatofibromas usually persist, but with time may undergo partial regression, especially centrally.

Histologic Variants of Dermatofibroma (Table 116.1)

Dermatofibroma with atypical cells

Dermatofibromas with atypical cells usually present in middle-aged adults and are slightly larger than 1 cm in diameter. Clinical follow-up in three studies showed no evidence of recurrence after simple excision[16–18].

Dermatofibromas with atypical cells have the architectural pattern and components of common dermatofibromas. In addition, they have atypical mono- and multinucleated cells with large pleomorphic and hyperchromatic nuclei, some of which have prominent nucleoli (Fig. 116.10). The cells have abundant vacuolated cytoplasm, often with hemosiderin deposits. Mitotic figures are rare, and atypical mitoses are not seen. The histopathologic differential diagnosis includes atypical fibroxanthoma and pleomorphic fibroma.

Deep dermatofibroma extending into the subcutaneous tissue

Deep dermatofibromas are usually seen on the trunk and proximal extremities of young to middle-aged patients and tend to be larger than the common variety, measuring 1–2 cm in diameter. The skin surface may be depressed, flat or dome-shaped, and on palpation the tumor is attached to the underlying subcutaneous tissue. The clinical differential diagnosis includes a cyst, lipoma and DFSP.

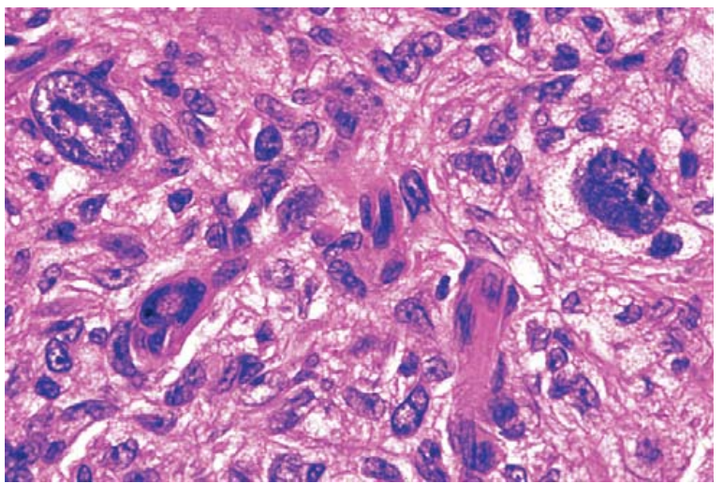

Fig. 116.10 Dermatofibroma with atypical cells. There are histiocyte-like cells with large hyperchromatic nuclei as well as scattered fibroblasts.

The deep variant has histopathologic features similar to those of the common dermal dermatofibroma, but with extensions into the subcutaneous tissue in two main patterns[19]. In approximately 70% of cases, the dermatofibroma extends in a vertical or radial fashion, predominantly along the septae, which have a wedge-shaped appearance (see Fig. 116.6). In approximately 30% of cases, the base is well circumscribed, with a smooth deep margin. All the components present within the dermis extend into the subcutaneous tissue. These patterns are different from the multilayered and "honeycomb" patterns characteristic of DFSP. The histologic differential diagnosis includes DFSP and malignant fibrous histiocytoma.

ACRAL FIBROKERATOMA

Synonym: ■ Acquired digital fibrokeratoma

Fig. 116.11 Acral fibrokeratoma. A light pink exophytic papule arising from the dorsal surface of the finger.

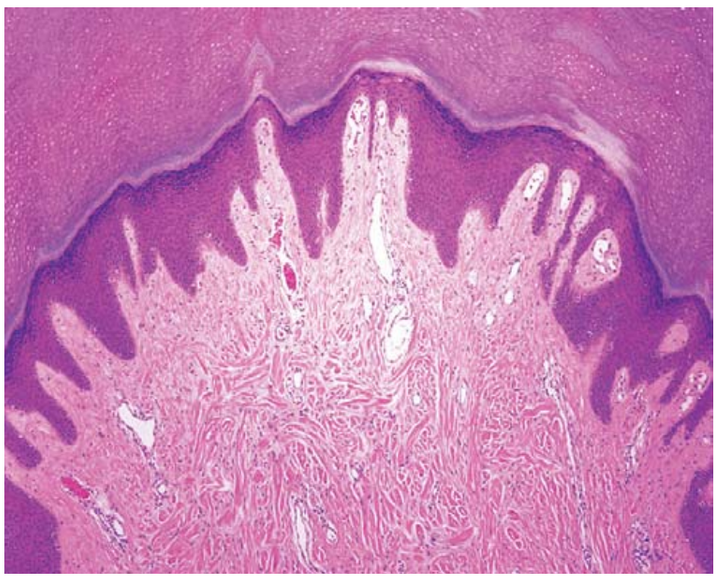

Fig. 116.12 Acral fibrokeratoma. There is a digitated fibrovascular core with vertically arranged collagen bundles lined by epidermal hyperplasia. Note the thick stratum corneum.

Clinical Features

These uncommon lesions present as a solitary, skin-colored to pink, slightly keratotic, exophytic papulonodule with a collarette of elevated skin (Fig. 116.11). Acquired fibrokeratomas usually occur in middle-aged adults and the most common site is the finger[20]. Clinically, they can resemble a supernumerary digit (see Ch. 64), periungual fibroma or verruca. Fibrokeratomas are benign and can be removed by shave excision.

Pathology

Acral fibrokeratomas are composed of thick collagen bundles surrounded by blood vessels, oriented perpendicularly to the epidermis. There is orthokeratosis with variable epidermal hyperplasia, and elastic fibers are decreased (Fig. 116.12)[21]. The histopathologic differential diagnosis includes periungual fibroma and supernumerary digit[22].

SUPERFICIAL ACRAL FIBROMYXOMA

Clinical Features

Superficial acral fibromyxoma is a rare tumor of acral sites, first described by Fetsch et al.[23] in 2001. There is a 2:1 male:female ratio, with a broad range for age of onset. The tumor presents as a slowly enlarging mass, attaining an average size of 2 cm. It usually develops on the toes or fingers, with two-thirds of tumors occurring close to or involving the nail bed. Less common sites include the palm or heel[24]. The clinical differential diagnosis includes periungual fibroma, verruca, giant cell tumor of the tendon sheath, squamous cell carcinoma (SCC), glomus tumor and pyogenic granuloma.

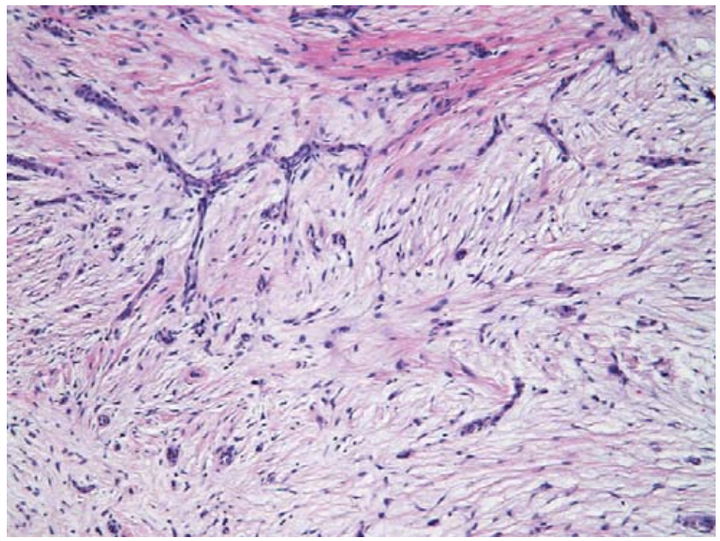

Fig. 116.13 Superficial acral fibromyxoma. The lesion is composed of spindled and stellate cells arranged in a loose storiform pattern with a myxoid collagenous matrix. *Courtesy, Shane Meehan, MD.*

Pathology

Superficial acral fibromyxomas are located within the dermis with extension into the subcutis. There are non-encapsulated masses composed of spindled to stellate cells arranged in a vague storiform or fascicular pattern (Fig. 116.13). The stroma is myxoid to fibromyxoid with prominent blood vessels and frequent mast cells. Mitotic figures are rare and necrosis is not seen. In cases involving the nail bed, there is often papillary hyperplasia of the nail bed epithelium[24].

The majority of these tumors stain strongly for CD34 and frequently for CD99, with focal expression of epithelial membrane antigen[24]. The histologic differential diagnosis includes myxoid neurofibroma, superficial angiomyxoma, DFSP and acral myxoinflammatory fibroblastic sarcoma.

Treatment

These tumors follow a benign course with only rare recurrences after complete excision. Malignant transformation has not been reported.

SCLEROTIC FIBROMA OF THE SKIN

Clinical Features

This distinct, very collagenous variant of fibroma was originally reported as a component of Cowden disease (PTEN hamartoma tumor syndrome). However, a sporadic solitary form has also been described[25].

In Cowden disease, the sclerotic fibromas can be solitary or multiple. They appear on the skin and/or mucous membranes as pearly papules or nodules that measure from a few to up to 10 mm in diameter. Sclerotic fibromas usually develop during adulthood, and there is no gender predominance. In the sporadic form, there is no predilection for any particular anatomic site.

Pathology

Sclerotic fibromas are well-circumscribed, dome-shaped, dermal hypocellular nodules composed predominantly of sclerotic thick collagen bundles arranged as short intersecting stacks in a parallel arrangement and separated by spaces containing connective tissue mucin (plywood-like or whorl-like pattern; Fig. 116.14). Between the collagen bundles, there are thin spindled cells with scanty cytoplasm and small

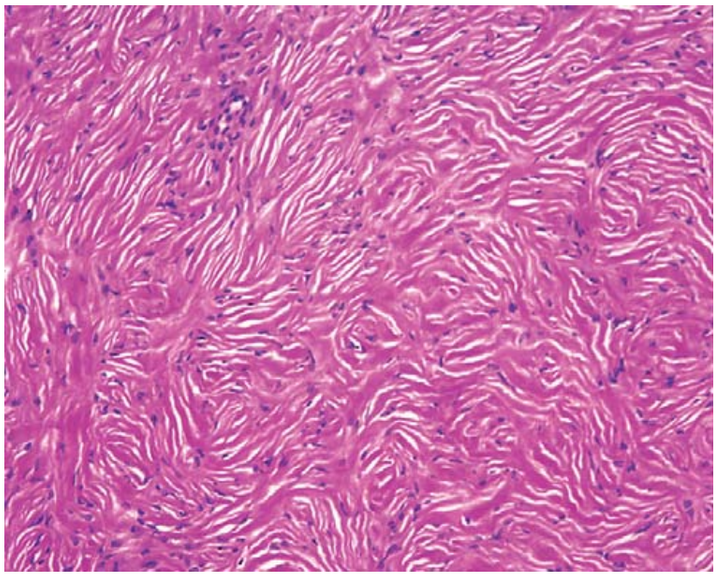

Fig. 116.14 Sclerotic fibroma. The collagen bundles in this hypocellular tumor are arranged in short parallel bundles, leading to a laminated or "plywood" appearance.

nuclei. The blood vessels are inconspicuous, and the overlying epidermis is usually thin. The spindle cells react positively for vimentin, muscle-specific actin, and CD34[26]. Positivity for CD34 may result in the misdiagnosis of early DFSP. The differential diagnosis includes keloid and early DFSP.

PLEOMORPHIC FIBROMA OF THE SKIN

Clinical Features

This unusual variant of a fibroma was described by Kamino et al.[27] in 1989. Pleomorphic fibromas of the skin usually present in adults, with a slight preponderance in women. They favor the extremities and appear as asymptomatic, solitary, skin-colored, dome-shaped or polypoid papules which measure from a few millimeters to nearly 2 cm in diameter. Clinically, they resemble skin tags, neurofibromas or intradermal melanocytic nevi. Treatment is simple excision, and to date there have been no reports of recurrence.

Pathology

Pleomorphic fibromas are polypoid or dome-shaped, well-circumscribed dermal lesions characterized by low cellularity with a predominance of thick collagen bundles in a haphazard array. There are scattered spindled cells and irregularly shaped multinucleated cells with scanty cytoplasm, indistinct cellular borders, and large pleomorphic and hyperchromatic nuclei. Some of the multinucleated cells have multilobed nuclei (Fig. 116.15). Mitotic figures are rare. In some cases, moderate amounts of connective tissue mucin and scattered adipocytes are present. The overlying epidermis is thinned.

The spindle-shaped cells and the irregularly shaped, multinucleated cells are positive for vimentin and CD34[28], and the spindle-shaped cells react positively for muscle-specific actin. The differential diagnosis includes dermatofibroma with atypical cells, atypical fibroxanthoma, and neurofibroma with atypical cells.

EPITHELIOID FIBROUS HISTIOCYTOMA

This benign epithelioid cell mesenchymal neoplasm was originally described as epithelioid cell histiocytoma by Wilson Jones and co-workers in 1989[29].

Clinical Features

Epithelioid fibrous histiocytomas commonly present in adults during the fifth decade of life, with a slight predominance in women. They

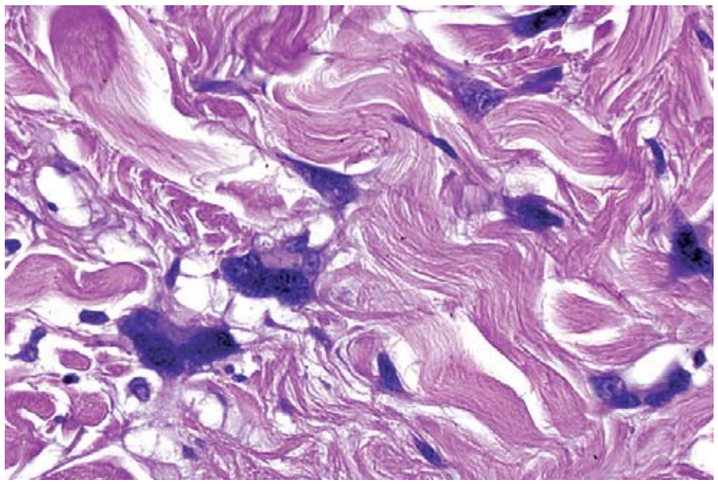

Fig. 116.15 Pleomorphic fibroma. There are interwoven coarse collagen bundles with a few interspersed large mono- and multinucleated atypical fibroblasts.

favor the extremities, and the thigh is the most frequent location. They are firm, sessile or polypoid papules or nodules measuring 0.5–1.5 cm in diameter. Because this neoplasm can be vascular in appearance, common clinical diagnoses are pyogenic granuloma and dermatofibroma (sclerosing hemangioma). The treatment consists of simple excision.

Pathology

Epithelioid fibrous histiocytomas are dome-shaped or polypoid dermal nodules with a well-demarcated base and a collarette of epithelium at their periphery. They are cellular lesions comprised of a monomorphous population of large, epithelioid stellate and triangular cells with angulated borders. The cells have abundant eosinophilic cytoplasm and oval nuclei with small nucleoli; some cells have two or more nuclei. Mitotic figures are rare. The cells are separated by delicate collagen fibers and variable amounts of connective tissue mucin, with no evidence of nesting. A proliferation of small blood vessels can be seen.

The neoplastic cells react positively for vimentin and factor XIIIa[29,30]. Most of the epithelioid cells are negative for CD68 and α_1-antichymotrypsin. The differential diagnosis includes intradermal Spitz nevus and cellular neurothekeoma.

MULTINUCLEATE CELL ANGIOHISTIOCYTOMA

Clinical Features

The typical clinical presentation of multinucleate cell angiohistiocytomas is that of slowly growing, multiple, discrete but grouped, red to violaceous papules, usually on the lower extremities (Fig. 116.16) or the dorsal aspect of the hands. The lesions may be unilateral or bilateral, and typically affect women over 40 years of age[31]. A generalized form has also been described in a young man[32]. Clinically, lesions may resemble Kaposi sarcoma, granuloma annulare or sarcoidosis.

Pathology

These lesions are composed of a proliferation of dilated capillaries and small venules in the superficial to mid dermis within thickened collagen bundles. The characteristic cell is a multinucleated giant cell, sometimes with peripheral palisading of the nuclei within eosinophilic cytoplasm (Fig. 116.17). By immunohistochemistry, these cells are positive for vimentin and factor XIIIa and negative for S100 protein. Mast cells and a mixed inflammatory cell infiltrate can also be seen. The overlying epidermis may be hyperplastic, with hyperpigmentation and orthokeratosis. The histopathologic differential diagnosis includes dermatofibroma, angiofibroma, hemangioma and interstitial granuloma annulare.

Treatment

These lesions are benign and can be removed by simple excision. If left untreated, most cases progress slowly without evidence of spontaneous resolution.

Fig. 116.16 Multinucleate cell angiohistiocytoma. Grouped erythematous macules and papules on the thigh. Hemorrhagic crust represents biopsy site.

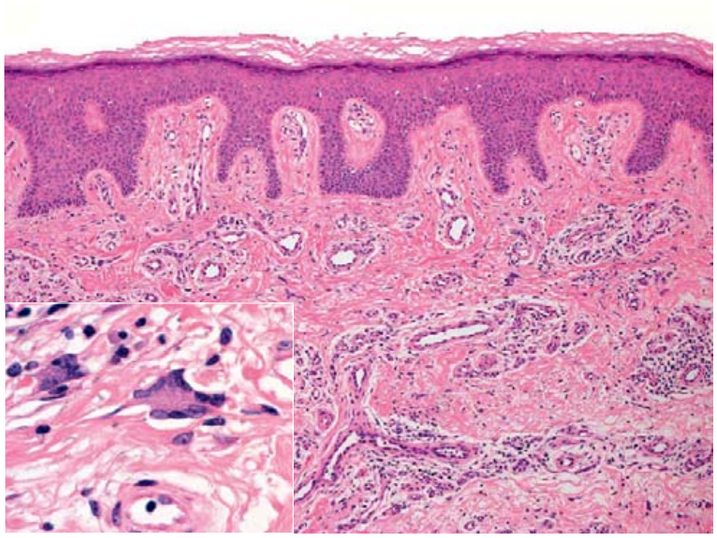

Fig. 116.17 Multinucleate cell angiohistiocytoma. There is a proliferation of dilated blood vessels with a sparse inflammatory infiltrate, an increase in fibroblasts, and the presence of angulated multinucleated giant cells (insert). *Courtesy, Lorenzo Cerroni, MD.*

DERMATOMYOFIBROMA

This tumor was described as plaque-like dermal fibromatosis in 1991 by Hugel[33] and as dermatomyofibroma by Kamino et al.[34] the following year.

Clinical Features

Dermatomyofibromas are lesions predominantly of young women and usually involve the shoulder area, axilla, upper arm and neck. Occasionally, these tumors arise during childhood. They are asymptomatic, well-circumscribed, oval or annular, skin-colored to red–brown plaques measuring 1–2 cm in greatest diameter, with a smooth skin surface. The clinical differential diagnosis includes dermatofibroma, fibrosed cyst, granuloma annulare, pseudolymphoma and DFSP.

Pathology

Dermatomyofibromas are well-circumscribed plaques involving the reticular dermis and the upper portion of the subcutaneous septae; they are composed of well-defined, long fascicles of spindle-shaped cells parallel to the skin surface (Fig. 116.18). The cells have a very uniform appearance, with elongated nuclei having rounded or pointed ends and one or two small nucleoli. There is no evidence of nuclear atypia, and mitoses are rare. The cells are separated by thin collagen fibers and elastic fibers are preserved. The fascicles, spindle-shaped cells, collagen fibers and elastic fibers may have a wavy appearance. The adnexal structures are spared.

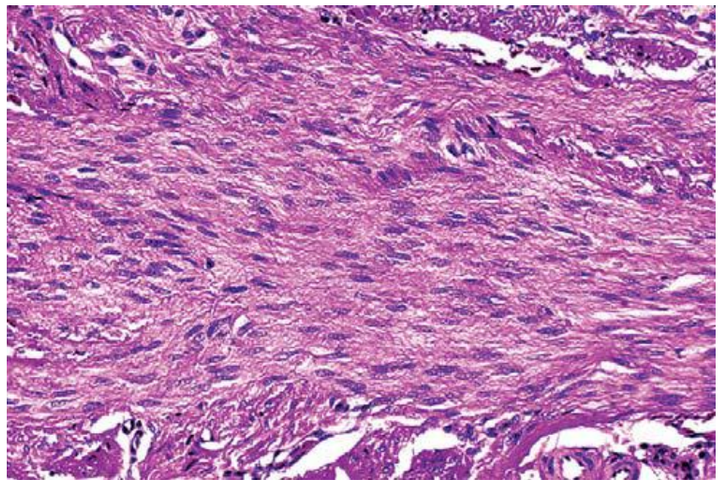

Fig. 116.18 Dermatomyofibroma. The myofibroblasts are arranged in long intersecting fascicles that are parallel to the skin surface.

Masson's trichrome stain highlights the presence of thin collagen fibers between the spindle cells. With Verhoeff–van Gieson's stain, the elastic fibers appear slightly increased in number compared with the surrounding uninvolved dermis. The spindle-shaped cells react positively for vimentin and muscle-specific actin. They are variably positive for smooth muscle actin and negative for desmin, factor XIIIa and CD34. These results support a fibroblastic–myofibroblastic differentiation rather than smooth muscle differentiation[33,34]. On electron microscopy, the myofibroblasts contain prominent rough endoplasmic reticulum and intracytoplasmic myofilaments[34]. The histologic differential diagnosis includes dermatofibroma, leiomyoma and neurofibroma.

Treatment

The treatment is simple excision. Recurrence is uncommon even when marginally or incompletely excised[35].

GIANT CELL TUMOR OF TENDON SHEATH

Synonyms: ■ Localized nodular tenosynovitis ■ Giant cell synovioma ■ Pigmented villonodular synovitis

Clinical Features

This tumor usually presents as a firm nodule on the hand or finger (Fig. 116.19), but can also occur on the toes and other periarticular sites. It is typically slow growing and fixed to subcutaneous structures without attachment to the overlying skin, except on the distal fingers and toes. Although usually asymptomatic, there can be pain, numbness or stiffness of the affected digit.

Giant cell tumor of tendon sheath is the most common tumor of the hand and can present at any age, but usually appears in adults 30 to 50 years of age and is more common in women than in men[36]. The clinical differential diagnosis is broad and includes rheumatoid nodule, ganglion cyst, subcutaneous granuloma annulare, fibroma of tendon sheath, and the rare entity epithelioid sarcoma.

Pathology

These tumors have a lobular outline and are attached to the tendon sheath. They have a biphasic appearance, with moderately cellular areas of rounded to polygonal cells blending into hypocellular collagenized areas with spindle cells. The characteristic multinucleated giant cells are scattered throughout the tumor in variable densities.

Fig. 116.19 Giant cell tumor of tendon sheath. A skin-colored nodule on the lateral aspect of the index finger.

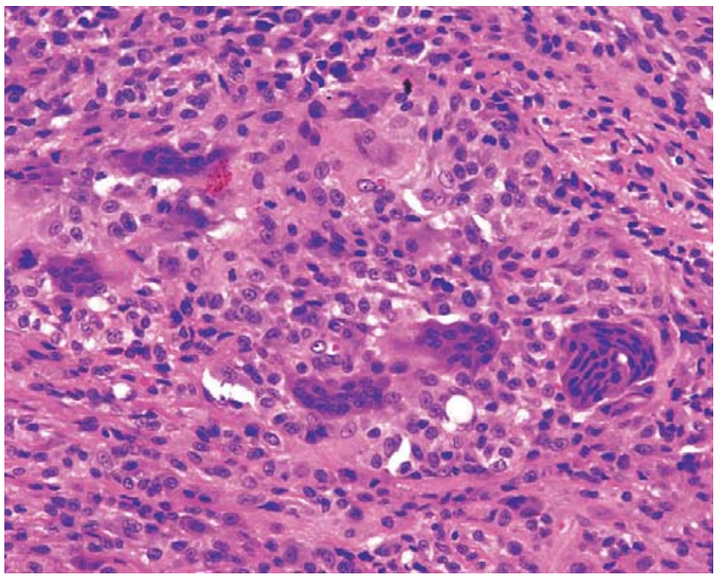

Fig. 116.20 Giant cell tumor of tendon sheath. The tumor is composed of sheets of epithelioid histiocytes with a variable number of the characteristic multinucleated osteoclast-like giant cells. Some of the histiocytes may have pale foamy cytoplasm. *Courtesy, Jacqueline M Wharton, MD.*

These cells have eosinophilic cytoplasm and from a few to 50 nuclei (Fig. 116.20). There are also mononucleated histiocytes with abundant vacuolated cytoplasm containing variable amounts of hemosiderin deposits. Stromal clefts, mitotic figures, and, rarely, vascular involvement may be observed. The histologic differential diagnosis includes subcutaneous granuloma annulare, rheumatoid nodule, epithelioid sarcoma, synovial sarcoma, deep dermatofibroma, fibroma of tendon sheath, and foreign body granuloma.

Treatment

This tumor is benign, with a local recurrence rate of 30%. It can be treated by a simple excision[36]. Whether this tumor is reactive or neoplastic in nature remains controversial. Although karyotypic abnormalities have been reported by some, others have found that the tumors are polyclonal[37].

FIBROMA OF TENDON SHEATH

Clinical Features

This benign tumor presents as a small subcutaneous nodule. It is most frequently found on the hands and feet, with the thumb being the most common site of involvement. They are usually asymptomatic, but there can be limitation in the range of motion of involved joints[38].

The usual age of presentation is between 20 and 50 years. Men develop these tumors three times more often than women. The clinical differential diagnosis includes giant cell tumor of tendon sheath, neuroma, ganglion cyst, rheumatoid nodule and subcutaneous granuloma annulare.

Pathology

The tumor has a well-circumscribed lobular appearance and is attached to a tendon sheath. It is composed of dense hyalinized collagen with scattered spindle-shaped fibroblasts and stromal clefts. There are occasional giant cells and foci of myxoid change. The histopathologic differential diagnosis includes giant cell tumor of tendon sheath, fibromatosis, nodular fasciitis, benign fibrous histiocytoma, synovial sarcoma and fibrosarcoma.

Treatment

This tumor is benign, with a recurrence rate of about 25%. Treatment is usually simple excision. Some authors believe that this tumor may represent a sclerotic end-stage of giant cell tumor of tendon sheath[39].

NODULAR FASCIITIS

Synonyms: ■ Subcutaneous pseudosarcomatous fibromatosis ■ Pseudosarcomatous fasciitis

Clinical Features

Nodular fasciitis is a benign reactive process seen in young to middle-aged adults. The upper extremity is the most common site. In children, the head and neck region is the most frequent location[40]. There is no gender predominance. Nodular fasciitis presents as a rapidly growing (but self-limited) subcutaneous nodule measuring from 1 to 5 cm in diameter, which may be tender. Some lesions are triggered by trauma.

Pathology

There is a well-circumscribed subcutaneous, fascial or intramuscular nodule with a stellate appearance. Dermal and intravascular variants have been reported[41]. A proliferation of plump spindle and stellate fibroblasts and myofibroblasts with oval nuclei that have a fine chromatin pattern and prominent nucleoli is seen. In early lesions, the cells are loosely arranged in an edematous, myxomatous stroma imparting a "feathered" appearance (Fig. 116.21), with a proliferation of small

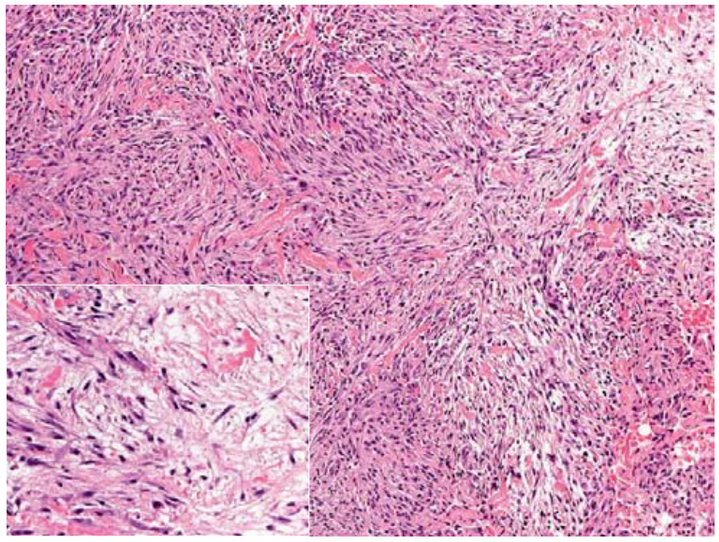

Fig. 116.21 Nodular fasciitis. Proliferation of spindle-shaped and plump fibroblasts arranged in a haphazard array with focally myxoid stroma. The plump and spindle-shaped fibroblasts within the myxoid stroma have a vague "tissue culture-like" appearance (insert). *Courtesy, Lorenzo Cerroni, MD.*

blood vessels, scattered lymphocytes and extravasated erythrocytes. Mitoses are frequent. Occasionally, clusters of siderophages may be present. Older lesions show hyalinized collagen bundles.

The fibroblasts and myofibroblasts react positively for vimentin and muscle-specific actin and, to a lesser degree, for smooth muscle actin. Some cells are positive for CD68[42]. The histologic differential diagnosis includes fibrosarcoma and malignant fibrous histiocytoma.

Treatment

Nodular fasciitis is treated with a conservative excision. The recurrence rate is approximately 1%[43].

CONNECTIVE TISSUE NEVUS

Synonyms: ■ Collagenoma ■ Elastoma ■ Shagreen patch (tuberous sclerosis) ■ Dermatofibrosis lenticularis disseminata (Buschke-Ollendorf syndrome)

Clinical Features

Connective tissue nevi are firm, solitary or multiple, skin-colored papules, nodules or plaques that usually present at birth or arise during childhood (Fig. 116.22). A linear arrangement occasionally occurs. These nevi may represent hamartomas rather than neoplasms. Clinically and histologically, they may be subtle and even resemble normal skin. There are several variants, including the shagreen patch of tuberous sclerosis (see Ch. 61), which most commonly presents as a pebbly plaque with a "pigskin" appearance on the lower back.

In the Buschke–Ollendorf syndrome, multiple skin-colored or slightly yellowish papules are seen and are referred to as dermatofibrosis lenticularis disseminata. The disease is due to loss-of-function mutations in the *LEMD3* gene which then lead to loss of antagonism of the TGF-β and bone morphogenic protein signaling pathways[44]. The disorder is inherited in an autosomal dominant pattern and the papules begin at an early age. In radiograms, a characteristic stippled appearance to the bone is seen, called osteopoikilosis (Fig. 116.23). This abnormality is asymptomatic.

Connective tissue nevus is a specific criterion (category A) for Proteus syndrome. The nevi occur most commonly on the plantar surface and acquire a cerebriform appearance, but can be seen elsewhere (e.g. hands, abdomen).

Pathology

There is usually a poorly demarcated area of increased dermal collagen bundles (some of which are oriented perpendicular to the skin surface), without an apparent increase in fibroblasts. These lesions are designated collagenomas. A variant with increased elastic fibers has been called elastoma. Many of the cutaneous lesions in Buschke–Ollendorf syndrome tend to have increased elastic fibers, but some appear to be primarily collagenous. Elastoma should not be confused with elastofibroma, which is a large mass in the deep subcutaneous tissue or fascia of the infrascapular area that is rarely treated by dermatologists. In many examples of connective tissue nevi, the connective tissue alterations may not be readily apparent unless the surrounding normal skin is examined histologically for comparison or special stains are performed (e.g. Verhoeff–van Gieson).

Fig. 116.22 Connective tissue nevus. Coalescence of multiple tan papules and plaques on the lower back. The lesion was firm to palpation and histologically had increased collagen.

Fig. 116.23 Osteopoikilosis. In this radiograph, multiple asymptomatic round to oval areas ("islands") of increased bone density are seen in the tibia. *Courtesy, Jean L Bolognia, MD.*

Differential Diagnosis

Although the differential diagnosis includes fibromatoses, fibrous hamartoma of infancy, infantile myofibromatosis and dermatofibromas, clinicopathologic correlation usually establishes the diagnosis fairly easily.

INFANTILE DIGITAL FIBROMA

Synonyms: ■ Recurring digital fibrous tumor of childhood ■ Inclusion body fibromatosis

Clinical Features

Infantile digital fibromas commonly present as multiple, firm, smooth, skin-colored, dome-shaped nodules on the dorsolateral aspects of the fingers and toes (Fig. 116.24). They can be up to several centimeters in diameter, and tend to spare the thumb and great toe.

Almost all cases occur in infants under 1 year of age, and boys and girls are equally affected. Rare adult cases of a histologically similar tumor have been reported at extradigital sites[45]. The smaller tumors can resemble acral fibrokeratomas, periungual fibromas and supernumerary digits.

Pathology

Infantile digital fibromas are poorly circumscribed proliferations of spindle-shaped myofibroblasts, arranged as interwoven fascicles with a collagenous stroma within the dermis or subcutaneous tissue. The cells have uniform spindle-shaped wavy nuclei without nuclear atypia or mitoses. The pathognomic feature is the presence of eosinophilic intracytoplasmic inclusions (Fig. 116.25), which are often perinuclear. These inclusions stain red with Masson's trichrome and purple with

Fig. 116.24 Infantile digital fibroma. Firm skin-colored nodule on the dorsolateral aspect of the second toe in a young child.

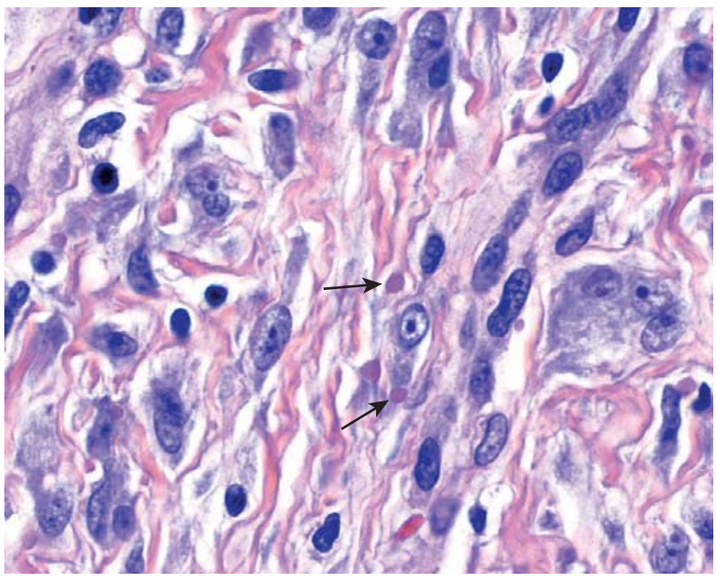

Fig. 116.25 Infantile digital fibroma. Myofibroblasts have pathognomonic cytoplasmic eosinophilic hyalin globules (arrows).

phosphotungsten acid–hematoxylin (PTAH). Ultrastructurally, the inclusions are composed of bundles of actin-like filaments. The histopathologic differential diagnosis includes scar, dermatofibroma, angiofibroma, neurofibroma and angiofibromatous verruca vulgaris.

Treatment

In general, the clinical course is benign, although functional impairment is possible. Spontaneous regression within 2–3 years is the usual natural history[46]. Contractures can be problematic. Recommended treatment options include conservative excision or observation (after histologic confirmation), with additional surgery as necessary for recurrences[47].

INFANTILE MYOFIBROMATOSIS

Synonyms: ■ Congenital multicentric fibromatosis ■ Congenital generalized fibromatosis

Fig. 116.26 Infantile myofibromatosis. Multiple firm violaceous papulonodules on the scalp.

Clinical Features

Although this entity is rare, it is the most common of the juvenile fibromatoses. Clinically, it presents as one or more, firm to rubbery, skin-colored to purple, dermal or subcutaneous nodules, commonly located in the head and neck region (Fig. 116.26) or on the trunk. Skeletal involvement in the form of lytic metaphyseal lesions occurs in half of the patients, and the tumors can involve multiple internal organs, including the gastrointestinal tract, kidneys, lungs and heart.

Approximately 50% of patients have lesions present at birth, with more appearing during the first 2 years of life. Familial cases have been reported, but with an unclear inheritance pattern, and female infants have a greater tendency for visceral involvement[48]. When there are multiple myofibromas, the clinical differential diagnosis includes multiple juvenile xanthogranulomas (JXG), hemangiomatosis, mastocytomas, and cutaneous metastases; when the lesion is solitary, it may resemble a mastocytoma, nodular JXG, nasal glioma, soft tissue sarcoma (e.g rhabdomyosarcoma), or vascular tumor (e.g. infantile hemangiopericytoma).

Solitary myofibromas may also develop in older children or adults and have a good prognosis[49].

Pathology

These tumors are composed of circumscribed nodules with a biphasic appearance. Areas of plump spindle-shaped myofibroblasts, with abundant cytoplasm arranged in fascicles within a collagenous stroma, blend with more cellular areas of smaller, rounder cells having less cytoplasm and an associated stag-horn pattern of dilated branching blood vessels. Mitotic figures, necrosis, intravascular growth and stromal hyalinization can be present.

Immunohistochemically, the spindle and rounded cells are positive for vimentin and actin, with negative staining for desmin, as is seen in myofibroblasts. The histologic differential diagnosis includes infantile hemangiopericytoma (which some authors suggest exists on a continuum with myofibromatosis), fibrosarcoma, leiomyosarcoma, leiomyoma, juvenile hyaline fibromatosis, nodular fasciitis and fibrous hamartoma of infancy.

Treatment

Patients with only soft tissue and bony involvement have a good prognosis, as the tumors regress spontaneously within months via massive apoptosis[50]. Those with visceral involvement have a high mortality rate within the first 4 months owing to the compromise of vital organ function (e.g. cardiopulmonary failure). However, if patients survive beyond this period to when the tumors begin to regress, the prognosis is much improved. Because the tumors tend to regress, debulking surgery is recommended only for symptomatic lesions. Combination chemotherapy has been used in severe cases[48].

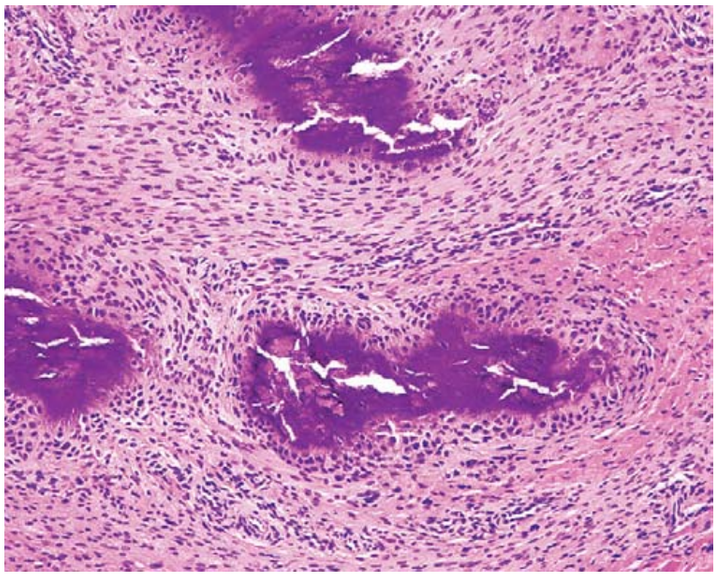

Fig. 116.27 Calcifying aponeurotic fibroma. Islands of calcification are surrounded by palisaded and osteoclast-like fibroblasts. In between these areas are sheets of spindled and epithelioid fibroblasts in a collagenous stroma.

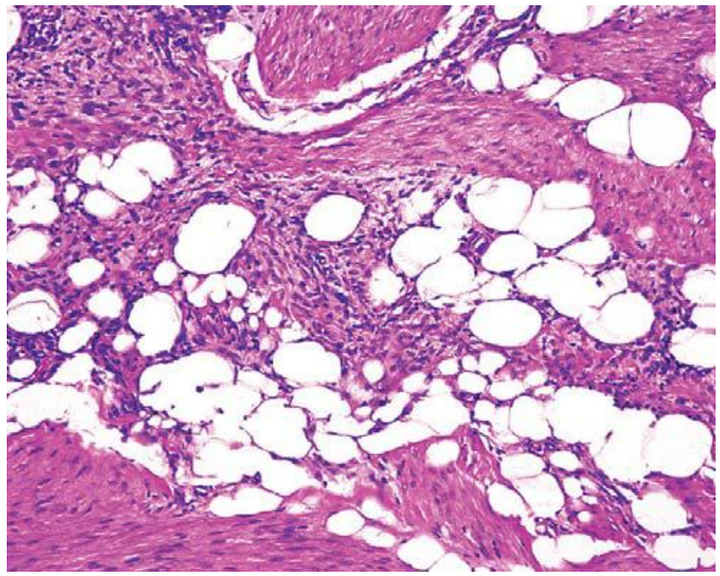

Fig. 116.28 Fibrous hamartoma of infancy. It is composed of a mixture of elongated bundles of spindle-shaped myofibroblasts, clusters of smaller immature mesenchymal cells in a myxoid stroma, and mature adipocytes.

CALCIFYING APONEUROTIC FIBROMA

Synonyms: ▪ Juvenile aponeurotic fibroma ▪ Calcifying fibroma ▪ Cartilage analogue of fibromatosis

Clinical Features

This is a very rare entity that presents as a slowly growing, asymptomatic, solitary, firm, subcutaneous nodule that is usually fixed to underlying structures. It occurs primarily on the hands, and sometimes on the feet. A characteristic radiologic finding is the presence of stippled calcifications. Most cases occur in young children and adolescents, and boys are affected more frequently than girls[51]. The clinical differential diagnosis includes giant cell tumor of tendon sheath, fibroma of tendon sheath, neuroma and rheumatoid nodule.

Pathology

The tumor is poorly circumscribed with an infiltrating border. It is composed of sheets of spindled and epithelioid fibroblasts with parallel nuclei in a collagenous stroma. There are characteristic islands of calcifications surrounded by palisaded epithelioid fibroblasts (Fig. 116.27). In older lesions, these areas of calcification can undergo chondroid and osseous metaplasia. Occasional multinucleated giant cells may also be present. The histopathologic differential diagnosis includes palmar and plantar fibromatosis, chondroma and pseudogout.

Treatment

These tumors are benign, with a local recurrence rate of ~50%[51]. Treatment consists of local excision, with re-excision for recurrences.

FIBROUS HAMARTOMA OF INFANCY

Synonym: Subdermal fibromatous tumor in infancy

Clinical Features

This tumor typically presents as a painless, solitary, skin-colored, subcutaneous nodule. It favors the axilla, shoulder and upper arm, although it can appear in other sites such as the groin[52,53]. There is a variable rate of growth, and the fibrous hamartoma can become quite large. Fixation to underlying structures may be observed. Occasionally, hypertrichosis is present[54].

Most of these tumors appear within the first year of life, but some are congenital. Boys are affected three times as often as girls[52,55]. They may mimic other subcutaneous malignancies of infancy such as rhabdomyosarcoma and cutaneous metastases (e.g. neuroblastoma, leukemia) as well as other fibromatoses and subcutaneous fat necrosis.

Pathology

This tumor is not well circumscribed, and it is composed of three distinctive elements in variable proportions: (1) a proliferation of spindle-shaped myofibroblasts arranged as broad fascicles within a collagenous stroma; (2) nests and aggregates of smaller, round to plump, spindle-shaped, immature mesenchymal cells within a myxoid matrix; and (3) mature adipocytes (Fig. 116.28). The histopathologic differential diagnosis includes infantile myofibromatosis, embryonal rhabdomyosarcoma, neurofibroma, early calcifying aponeurotic fibroma, fibrolipoma and lipoblastoma.

Treatment

Fibrous hamartoma is benign and the usual treatment is local excision, with recurrence being fairly uncommon[55]. If left untreated, the tumor continues to grow and stabilizes in size by mid-childhood.

FIBROMATOSES

Synonyms/subtypes:
- Superficial fascial fibromatosis:
  - palmar fibromatosis (Dupuytren's disease)
  - plantar fibromatosis (Ledderhose's disease)
  - penile fibromatosis (Peyronie's disease)
  - knuckle pads (holoderma)
  - pachydermodactyly
- Deep musculoaponeurotic fibromatosis:
  - desmoid tumor (extra-abdominal)

Clinical Features

Fibromatoses are slowly growing tumors. The superficial variants may reach up to several centimeters in greatest diameter[56]. They appear as firm nodules, plaques, or cord-like tumors along the flexor tendons (see Ch. 98).

Palmar and plantar fibromatoses usually appear during adulthood and the incidence increases with age. Flexion contractures, especially of the fourth and fifth fingers, can result. Penile fibromatosis is more common

Fig. 116.29 Knuckle pads. Note the localization to the skin overlying the knuckles. *Courtesy, Ronald P Rapini, MD.*

Fig. 116. 30 Pachydermodactyly. A form of digital fibromatosis characterized by soft tissue swelling of the lateral aspects of the fingers, usually in the area of the proximal interphalangeal joints of the second to fourth fingers. *Courtesy, Julie V Schaffer, MD.*

in middle-aged to elderly men; pain and erectile dysfunction are common.

Knuckle pads affect the extensor surfaces of the interphalangeal and metacarpophalangeal joints (Fig. 116.29) and may be associated with palmar and plantar fibromatosis. While often idiopathic, they may also be a reflection of trauma. In Bart–Pumphrey syndrome, knuckle pads are seen in association with palmoplantar keratoderma, hearing loss and leukonychia (see Ch. 58).

Pachydermodactyly is an uncommon form of digital fibromatosis. It typically presents in adolescent boys as soft tissue swelling of the lateral aspects of the proximal interphalangeal joints of the second to fourth fingers (Fig. 116.30). This disorder may be related to mechanical trauma[57].

Deep musculoaponeurotic fibromatoses or desmoid tumors are usually rather large – up to 25 cm in diameter. There are abdominal and extra-abdominal variants. They may present after pregnancy in the abdominal wall, in postsurgical scars, and as mesenteric fibromatosis in Gardner syndrome (see Ch. 63). Trauma and cytogenetic

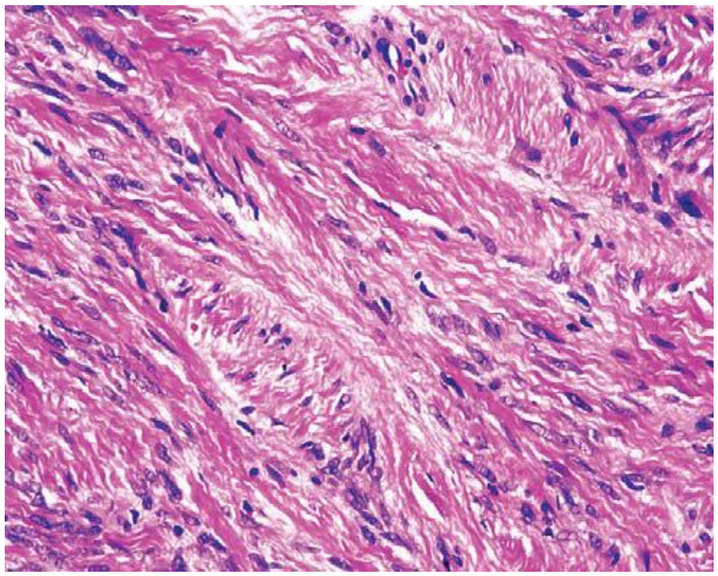

Fig. 116.31 Fibromatosis. Slender spindle-shaped fibroblasts and collagen strands are arranged in broad sweeping fascicles.

abnormalities, including trisomies of chromosomes 8 and 14 (in plantar fibromatosis), may play a role in the pathogenesis of these tumors[58].

Pathology

Fibromatoses consist of large, poorly circumscribed, dermal and subcutaneous plaques and nodules composed of long fascicles of monomorphous fibroblasts and myofibroblasts (Fig. 116.31); the nuclei are elongated with a fine chromatin pattern and small nucleoli. Mitotic figures are rare. There are cellular foci in which the cells are scattered between thin collagen fibers. In hypocellular areas, the cells are separated by thick collagen fibers. The neoplastic cells usually infiltrate the adjacent aponeurosis, fascia and skeletal muscle. The histopathologic differential diagnosis includes fibrosarcoma, dermatomyofibroma, DFSP and keloid.

Cytogenetic abnormalities have been identified less frequently in superficial fibromatoses as compared to their deep counterparts, and, in the former, usually exhibit simple numerical changes, especially gains of chromosome 8[59].

Treatment

Surgical excision with fasciectomy is standard therapy for palmar and plantar fibromatosis, with the goal of reducing functional impairment rather than complete disease removal. More recently, injectable collagenase (from *Clostridium histolyticum*) was approved by the FDA for the treatment of Dupuytren's contractures, based upon response rates of 45–65%[60]. Penile fibromatoses may resolve spontaneously in approximately a third of patients[61]. Therefore, a waiting period is recommended before surgical excision or laser treatment. The deep musculoaponeurotic fibromatoses have a higher recurrence rate and appropriate treatment of these is beyond the scope of this book.

PLEXIFORM FIBROHISTIOCYTIC TUMOR

Clinical Features

A plexiform fibrohistiocytic tumor typically presents as a slowly growing, firm, painless mass in a child or young adult[62]. It is usually less than 3 cm in diameter and favors the wrists and hands; there is a striking female predominance. This tumor is regarded as being of intermediate malignancy, with a tendency to recur locally but only rarely metastasizing.

Pathology

Within the dermis and subcutaneous fat, a multinodular mass is seen composed of nodules of histiocytes and fascicles of spindled cells intersecting the stroma in a plexiform pattern. Multinucleated giant cells

are frequently present. Mitotic figures and mild nuclear pleomorphism may be seen. Immunohistochemical and ultrastructural studies confirm histiocytic and myofibroblastic differentiation. The histopathologic differential diagnosis includes cellular dermatofibroma, dermatomyofibroma, fibromatoses, and nodular fasciitis; the latter lacks a plexiform pattern. Based on shared morphologic and phenotypic features, there is growing evidence to suggest that cellular neurothekeoma and plexiform fibrohistiocytic tumor exist on a continuum[63].

Treatment

These tumors are locally aggressive with high rates of recurrence, requiring excision with wider margins and long-term evaluation[64].

ATYPICAL FIBROXANTHOMA

Synonym: ■ Superficial variant of malignant fibrous histiocytoma

Clinical Features

Atypical fibroxanthoma is a low-grade sarcoma that occurs in the sun-damaged skin of the head and neck in elderly patients. It usually presents as a rapidly growing, dome-shaped nodule that measures from 1 to 2 cm in diameter (Fig. 116.32). Secondary changes include serosanguineous crusts and ulceration[65]. A few cases have been reported in children with xeroderma pigmentosum[66], and a rare variant can develop in non-sun-damaged skin of the trunk or extremities in younger patients. The clinical differential diagnosis includes BCC, SCC, amelanotic melanoma, Merkel cell carcinoma, and cutaneous metastasis.

Pathology

A thin epidermis covers a dome-shaped nodule composed of both atypical spindle-shaped cells with moderate amounts of cytoplasm and large atypical cells with abundant pale-staining vacuolated cytoplasm. The cells have large pleomorphic and hyperchromatic nuclei and some of them are multinucleated (Fig. 116.33). There are numerous typical and atypical mitotic figures. A rare variant with scattered osteoclast-like multinucleated giant cells has been reported[67].

Both the spindle-shaped cells and the histiocyte-like cells react positively for vimentin. The spindle-shaped cells are positive for muscle-specific actin, while the large histiocyte-like cells react positively for α_1-antichymotrypsin, CD68 and CD10[68]. The differential diagnosis includes spindle cell SCC, spindle cell melanoma, dermatofibroma with atypical cells, and pleomorphic fibroma. Atypical fibroxanthoma is considered to be a superficial form of malignant fibrous histiocytoma, which typically presents as a deep subcutaneous or visceral mass that regularly metastasizes.

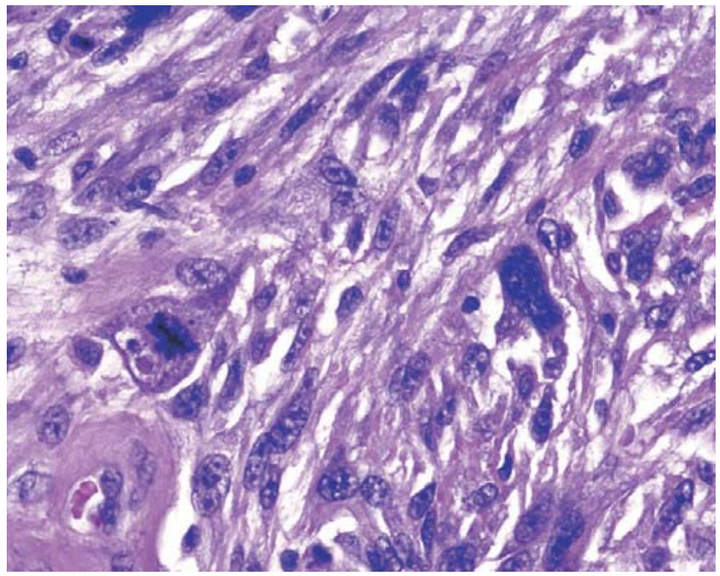

Fig. 116.33 Atypical fibroxanthoma. The spindled cells have pale foamy cytoplasm and hyperchromatic nuclei with small nucleoli. There is also a large atypical giant cell with darker nuclear chromatin as well as a cell in atypical mitosis.

Treatment

Atypical fibroxanthoma is a low-grade superficial sarcoma that usually is cured by complete excision. It has a very low incidence of local recurrence, and metastases are rare[68].

DERMATOFIBROSARCOMA PROTUBERANS

Clinical Features

Dermatofibrosarcoma protuberans (DFSP) is a locally aggressive sarcoma of intermediate malignancy that favors young to middle-aged adults. Lesions that are present at birth or with an onset during childhood have also been reported. DFSP occurs on the trunk in 50–60% of patients, the proximal extremities in 20–30%, and the head and neck in 10–15%. There is a predilection for the shoulder or pelvic region. Initially, it presents as a slowly growing, asymptomatic, skin-colored, indurated plaque that eventually develops violaceous to red–brown nodules measuring from one to several centimeters in diameter (Fig. 116.34)[69]. On palpation, the lesion is firm and attached to the subcutaneous tissue. There are reports of accelerated growth during pregnancy[70].

Fig. 116.32 Atypical fibroxanthoma. A red, dome-shaped nodule on the nose of an elderly man. *Courtesy, Lorenzo Cerroni, MD.*

Fig. 116.34 Dermatofibrosarcoma protuberans. A broad, pink–brown, multinodular, firm plaque on the back.

The early plaque stage may be misdiagnosed as a benign tumor and incompletely excised. Moreover, superficial samples may not yield diagnostic material. The clinical differential diagnosis includes keloid, large dermatofibroma, dermatomyofibroma and morphea. Congenital and childhood-onset DFSP (and occasionally early lesions in adults) may have an atrophic appearance and/or hypopigmented to blue–red color, with the latter potentially leading to misdiagnosis as a vascular malformation or tumor.

Pathology

Early plaque lesions are characterized by a flat surface and low cellularity and are comprised of slender spindle-shaped cells arranged as long fascicles parallel to the skin surface. The cells are scattered between thin collagen fibers and infiltrate thick collagen bundles which appear cellular and wavy. Nuclear atypia is minimal and mitotic figures are rare. Adnexal structures are infiltrated and obliterated. The spindle cells infiltrate into the subcutaneous tissue, very often in a multilayered pattern (Fig. 116.35)[19].

In the nodular stage, the tumor becomes more cellular, with the cells arranged as short fascicles in a "storiform" or mat-like arrangement (Fig. 116.36). The cells infiltrate the subcutaneous tissue in a "honeycomb" pattern. Nuclei are hyperchromatic, and mitotic figures are easily identified. The nodules may develop myxomatous areas, characterized by more rounded to stellate cells in a highly vascular myxomatous stroma. Less differentiated fibrosarcomatous foci have a more cellular appearance, with intersecting fascicles in a "herringbone" pattern, with increased cytologic atypia and frequent mitoses.

Less than 5% of DFSPs contain melanin-producing cells with schwannian differentiation, and they are referred to as Bednar tumors[71].

In plaque-stage tumors, the spindle-shaped cells are strongly positive for CD34[10,72,73] (see Fig. 116.9). The reaction is stronger within the plaque areas than in the nodular foci[74]. Plaque and nodular areas are negative for factor XIIIa[10]. The general immunostaining pattern of DFSP – CD34-positive, factor XIIIa-negative – serves to distinguish it from large and/or highly cellular dermatofibromas, which are CD34-negative and factor XIIIa-positive.

Unique cytogenetic abnormalities have been reported, such as reciprocal t(17;22) translocations (see below) and supernumerary ring chromosomes containing sequences from chromosomes 17 and 22[75]. Overexpression of *p53* has been found in the fibrosarcomatous foci of DFSP that have higher proliferative activity and aneuploidy[76].

The pathologic differential diagnosis of the plaque stage of DFSP includes atrophic dermatofibroma, dermatomyofibroma and neurofibroma. For the nodular stage, it includes deep dermatofibroma extending to the subcutaneous tissue, fibrosarcoma and malignant peripheral nerve sheath tumor. Incisional biopsy specimens, including ample subcutaneous tissue, are optimal for diagnosis.

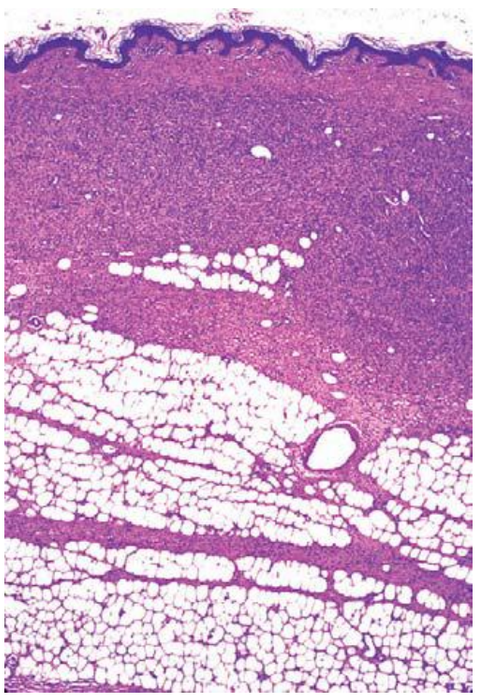

Fig. 116.35 Dermatofibrosarcoma protuberans, plaque stage. Characteristic mutilayered pattern of infiltration into the subcutaneous tissue.

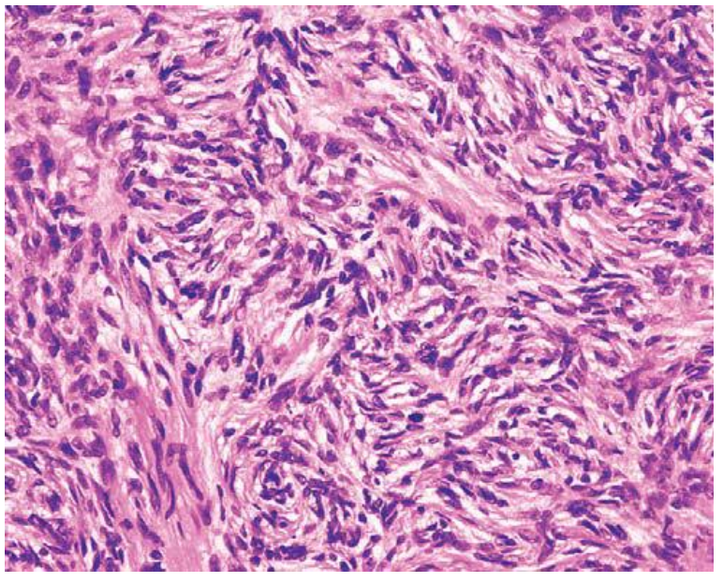

Fig. 116.36 Dermatofibrosarcoma protuberans, nodular stage. The spindle-shaped cells are arranged in a "storiform" pattern.

Treatment

Complete surgical excision, including Mohs micrographic surgery, is the standard treatment for DFSP[77]. This tumor is characterized by its local invasion and tendency to recur. In rare cases, recurrent tumors with fibrosarcomatous areas have metastasized to the lungs[78]. Because the translocation (17;22) places the platelet-derived growth factor (PDGF) β-chain gene under the control of the collagen 1A1 promoter, imatinib mesylate (which targets the PDGF receptor [as well as other proteins with tyrosine kinase activity, e.g. KIT and BCR-ABL]), was tried in patients with DFSP. It is currently FDA-approved for adults with unresectable, recurrent and/or metastatic DFSP (800 mg daily). In two phase II trials with a total enrollment of 24 patients with DFSP, there was a partial response in 46% of individuals[79].

GIANT CELL FIBROBLASTOMA

Clinical Features

This is a rare, solitary, slow-growing, asymptomatic, skin-colored, dermal or subcutaneous nodule involving the neck, trunk or groin. It usually appears during early childhood, with a strong predilection for boys[80]. Clinically, these tumors can mimic cystic hygromas, lipomas or other juvenile subcutaneous tumors (see fibrous hamartoma of infancy section).

Pathology

This lesion is composed of diffusely infiltrating sheets of spindle-shaped fibroblasts and multinucleated cells with hyperchromatic nuclei within a slightly myxoid matrix. Irregular "angiectoid" or pseudovascular spaces lined by multinucleated giant cells are present throughout the tumor (Fig. 116.37). These giant cells do not react with markers for endothelial differentiation, but do react with anti-CD34 antibodies[81]. Similar-appearing giant cells can also be seen in the solid portions of the tumor. On occasion, some tumors have hypercellular spindle cell areas with a storiform pattern similar to that seen in DFSP[81], and some authors consider giant cell fibroblastoma to be the juvenile form of DFSP[82]. More recent molecular studies have revealed that giant cell fibroblastoma and DFSP share the same t(17;22) chromosomal translocation which places the PDGF β-chain gene under the control of the promoter of the collagen 1A1 gene[83].

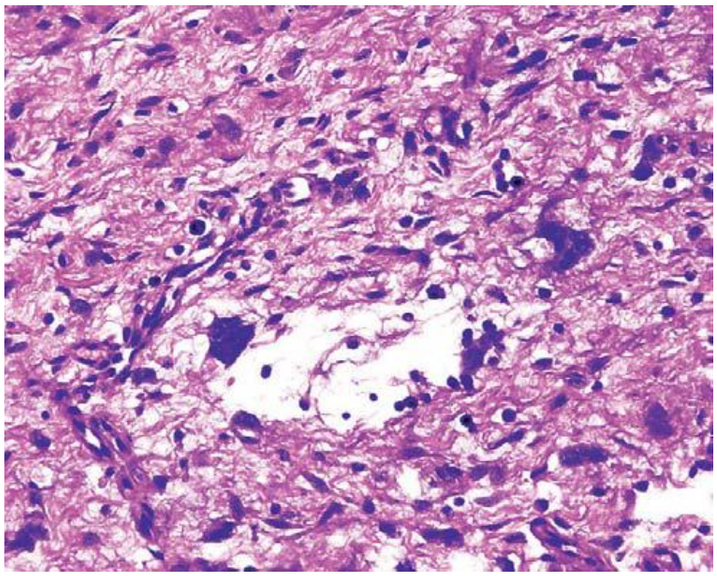

Fig. 116.37 Giant cell fibroblastoma. This pseudovascular or "angiectoid" space lined by giant cells with hyperchromatic nuclei is characteristic of this tumor.

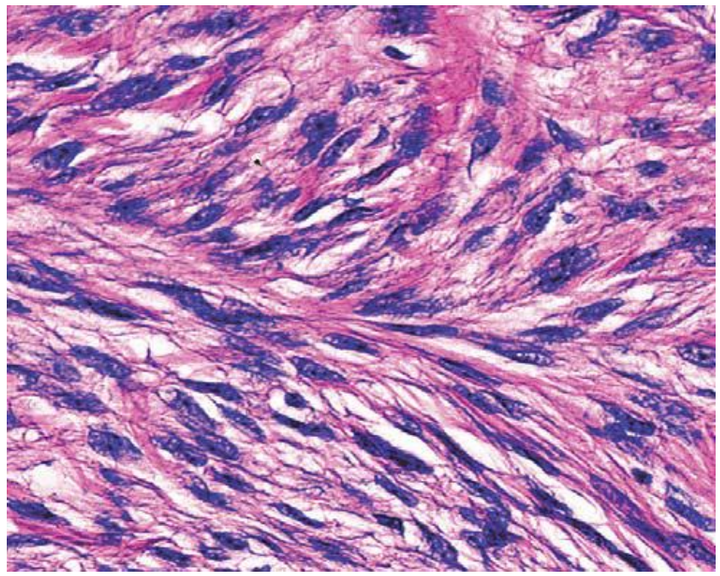

Fig. 116.38 Fibrosarcoma. Cellular fascicles of atypical spindle-shaped fibroblasts with coarse nuclear chromatin are arranged in a "herringbone" pattern.

Treatment

Giant cell fibroblastoma is a low-grade sarcoma with occasional recurrences following local excision[80].

FIBROSARCOMA

Clinical Features

Fibrosarcoma usually affects young to middle-aged adults. The most common location is the lower extremities, followed by the upper extremities, trunk, and head and neck region. This is a neoplasm predominantly of the deep soft tissues, with secondary involvement of the overlying subcutis and skin. Fibrosarcoma is a slowly growing tumor that measures from 1 to 10 cm in diameter and is usually diagnosed when it becomes a palpable painful nodule[84]. They may appear in old burn scars and in areas of prior irradiation[85].

Pathology

The tumor is composed of a proliferation of atypical spindle-shaped cells arranged as intersecting fascicles in a "herringbone" pattern (Fig. 116.38). There are thin collagen bundles between the cells which have scanty cytoplasm and elongated hyperchromatic nuclei. Mitotic figures are easily identified and myxomatous foci may be present. A sclerosing epithelioid variant that simulates an infiltrating carcinoma has been described[86]. High-grade fibrosarcomas are characterized by increased cellularity with more atypical nuclei, a higher mitotic rate, foci of necrosis, and a less distinct "herringbone" pattern. In most cases, the constituent cells only react positively for vimentin (nonspecific) and, to a lesser degree, for muscle-specific actin.

The histopathologic differential diagnosis includes nodular fasciitis, fibromatoses, DFSP, malignant fibrous histiocytoma, and malignant peripheral nerve sheath tumor (see Ch. 115).

Treatment

The treatment for fibrosarcoma is wide excision. When wide free margins cannot be achieved, adjuvant radiation therapy and amputation are additional options. In high-grade fibrosarcomas, adjuvant systemic chemotherapy is given. Hematogenous metastases to the lung, and, less often, to the bones, develop in patients with high-grade or poorly differentiated fibrosarcomas. The overall 5-year survival rate is approximately 40%[84]. There are rare cases of congenital or infantile fibrosarcomas that tend to be less aggressive[87].

EPITHELIOID SARCOMA

Synonym: ■ Epithelioid cell sarcoma

Clinical Features

This rare tumor presents as a slow-growing, firm, subcutaneous nodule of the distal extremities, usually the hands and fingers. There may be associated ulceration if the tumor involves the dermis. Advanced disease can present as a linear arrangement of ulcerated nodules extending from distal to proximal sites on affected extremities. If there is involvement of a large nerve, associated pain, paresthesias and muscle wasting can occur[88].

The majority of patients are between 20 and 40 years of age, and men are affected twice as often as women. Hand and finger lesions may resemble giant cell tumor of tendon sheath, fibroma of tendon sheath, nodular fasciitis, subcutaneous granuloma annulare, rheumatoid nodule or ganglion cyst. Penile lesions can mimic Peyronie's disease[88].

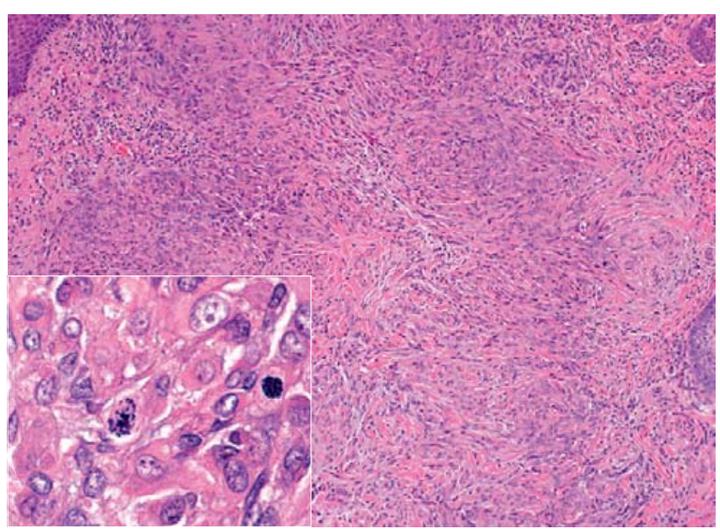

Fig. 116.39 Epithelioid sarcoma. Palisading of atypical epithelioid cells. Pleomorphism and mitoses are present (insert). *Courtesy, Lorenzo Cerroni, MD.*

Pathology

The tumor is composed of a nodular proliferation of spindle-shaped to round or polygonal cells with abundant eosinophilic cytoplasm and small uniform nuclei without prominent nucleoli (Fig. 116.39). The tumor is frequently associated with fascia, periosteum, tendons and nerves. The larger tumor nodules have zones of central necrosis surrounded by palisaded tumor cells and a mixed chronic inflammatory cell infiltrate. Distinction from other tumors usually requires immunohistochemical analysis. The tumor cells are positive for both keratins (hence "epithelioid") and vimentin (hence "sarcoma"). They are also positive for epithelial membrane antigen and negative for S100, HMB45 and CD31. The histopathologic differential diagnosis includes granuloma annulare, necrobiosis lipoidica, rheumatoid nodule, infectious granuloma, giant cell tumor of tendon sheath, SCC, fibrosarcoma, melanoma, synovial sarcoma, epithelioid angiosarcoma, epithelioid hemangioendothelioma, and malignant fibrous histiocytoma.

Treatment

Epithelioid sarcoma tends to be multifocal, with an infiltrating growth pattern along tendons, nerves and fascia. Although earlier therapeutic approaches involved radical surgery, including amputation, there has been a movement toward more conservative surgery with adjuvant radiation therapy[89]. Local recurrences are frequent, as are pleuropulmonary metastases (seen in 50% of patients)[88]. The 5-year survival rate is 50%, and metastases can present as late as two decades after the initial diagnosis[88,90].

Muscle, Adipose and Cartilage Neoplasms 117

Steven Kaddu and Sabine Kohler

In this chapter, benign and malignant neoplasms of muscle, adipose tissue and cartilage will be reviewed (Fig. 117.1). The entities include:

- leiomyoma
- leiomyosarcoma
- smooth muscle hamartoma
- lipoma
- angiolipoma
- spindle cell/pleomorphic lipoma
- hibernoma
- nevus lipomatosus superficialis
- lipoblastoma/lipoblastomatosis
- liposarcoma/atypical lipomatous tumor
- extraskeletal chondroma

TUMORS OF SMOOTH MUSCLE

Leiomyoma

Synonyms: ■ Superficial leiomyoma ■ Leiomyoma cutis ■ Superficial benign smooth muscle tumor

Key features

- Three distinct variants: piloleiomyoma, genital leiomyoma and angioleiomyoma
- A solitary or multiple clustered (piloleiomyomas) papules or nodules in an adult
- Piloleiomyomas may be painful
- Multiple piloleiomyomas may be a manifestation of Reed syndrome (multiple cutaneous and uterine leiomyomatosis)
- Smooth muscle cells (myocytes) are fusiform cells with centrally located, cigar-shaped nuclei

Introduction

Superficial (cutaneous) leiomyomas represent benign smooth muscle tumors that can arise from arrector pili muscles, the dartoic, vulvar or mammary smooth muscles, or the muscles enveloping dermal blood vessels. Thus, they are subclassified into piloleiomyomas (solitary or multiple), leiomyomas of the external genitalia, and angioleiomyomas. Some authors categorize vulvar and scrotal leiomyomas separately, based upon distinctive clinical and histologic features[1].

History

In an early review article, Arthur Purdy Stout[2] cites an 1854 publication of Rudolf Virchow as the first case report of multiple leiomyomas involving the skin near the areola in a 32-year-old man.

Epidemiology

Cutaneous leiomyomas are relatively uncommon neoplasms, but their exact incidence is not known[3]. Angioleiomyomas appear to be more common than piloleomyomas[4], with genital leiomyomas the least common variant.

Pathogenesis

The exact pathogenesis of superficial leiomyomas has yet to be determined. Piloleiomyomas are thought to arise from the smooth muscle cells within the arrector pili muscle of the pilosebaceous unit. Leiomyomas of the external genitalia are probably derived from the network of smooth muscles in the external genitalia (e.g. scrotum, vulva) and areolae. Angioleiomyomas are believed to originate from the smooth muscle within the walls of arteries and veins.

Multiple piloleiomyomas may occur sporadically or they may be inherited in an autosomal dominant manner (with variable penetrance) as a component of the multiple cutaneous and uterine leiomyomatosis syndrome, also referred to as Reed syndrome[5] (Table 117.1). Although the molecular basis of Reed syndrome is known (mutations in the gene that encodes fumarate hydratase), how this translates into smooth muscle tumors is not understood.

Clinical features

Piloleiomyomas can be solitary or multiple, and in an occasional patient may even number in the hundreds. They present as firm, reddish-brown to skin-colored papules or nodules. Solitary piloleiomyomas develop primarily during adulthood and there is an approximately equal sex distribution[6]; rare congenital or pediatric cases have been reported. When multiple, the distribution pattern is most often clustered (Fig. 117.2), linear or along Blaschko's lines, but widespread lesions are observed occasionally. Most piloleiomyomas measure 1–2 cm in diameter, and they usually develop on the extremities and trunk (especially the shoulder), with solitary lesions favoring the limbs and multiple lesions the trunk[6]. Piloleiomyomas are often associated with spontaneous or induced pain, e.g. following cold exposure, but the explanation is still unclear[6].

Genital leiomyomas are most often solitary and painless. They can develop on the vulva, penis, scrotum, nipple or areola and usually measure less than 2 cm in diameter. Occasionally, lesions are pedunculated.

Angioleiomyomas most commonly present as a solitary, firm subcutaneous nodule on the lower extremity. They often develop in women during the fourth to sixth decades of life[4]. Approximately 50% of angioleiomyomas are painful.

Pathology

Piloleiomyomas are typically centered within the reticular dermis, with focal extension into the subcutaneous fat in some cases. They are composed of interlacing fascicles of relatively bland smooth muscle cells (myocytes) which peripherally tend to ramify between surrounding dermal collagen bundles (Fig. 117.3); often there is a close relationship to hair follicles[4]. Occasionally, the overlying epidermis is hyperplastic. Smooth muscle cells have abundant brightly eosinophilic cytoplasm and blunt-ended, cigar-shaped nuclei.

Mitotic figures are rare. In the presence of bland cytology, one or two morphologically normal mitotic figures per 10 high-power fields may be seen, which does not signify aggressive behavior. Cases with nuclear pleomorphism and atypical nuclei, but without mitotic activity (symplastic leiomyomas), have also been described[7].

In leiomyomas, smooth muscle differentiation is usually obvious in H&E-stained sections. Sometimes, special stains for smooth muscle cells are utilized, including Masson's trichrome stain (cells stain red) and immunohistochemical stains for smooth muscle actin and desmin (cells are consistently positive). Other smooth muscle-associated markers include smooth muscle myosin (SMS), calponin and h-caldesmon, but the first two markers in particular may also be expressed in other spindle cell tumors[8]. In contrast to uterine leiomyomas, smooth muscle tumors of the skin do not express receptors for estrogen or progesterone[9].

Genital leiomyomas of the scrotum or vulva tend to be larger and better circumscribed than piloleiomyomas. Scrotal leiomyomas are

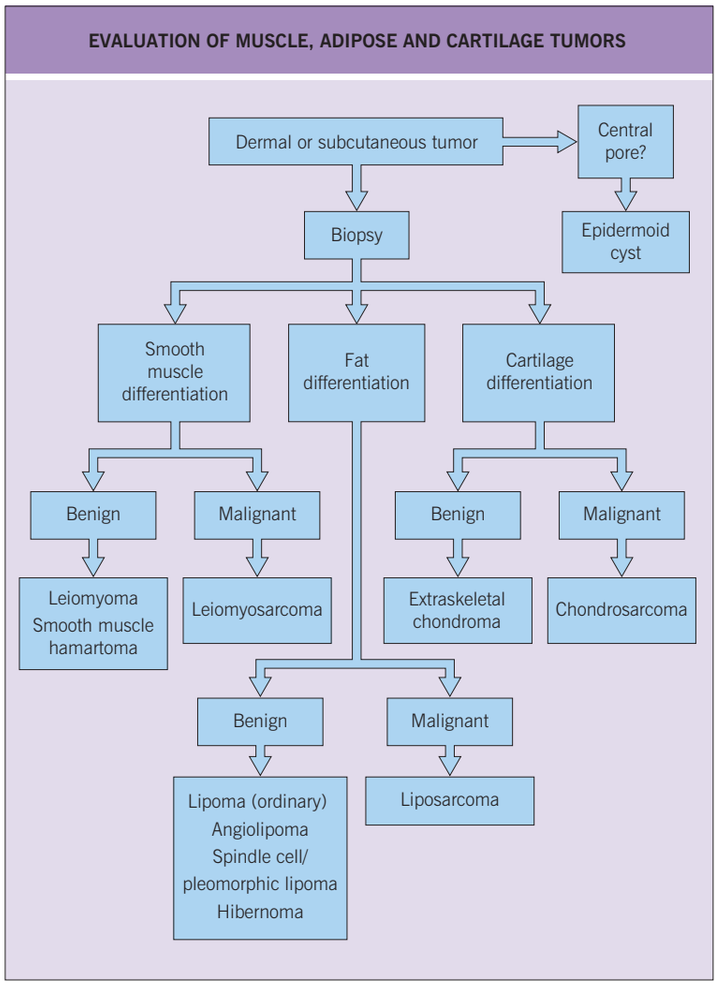

Fig. 117.1 Evaluation of muscle, adipose and cartilage tumors.

CLINICAL FEATURES OF MULTIPLE CUTANEOUS AND UTERINE LEIOMYOMATOSIS (REED SYNDROME)	
Genetic aspects	• Autosomal dominant • Mutations in the gene that encodes fumarate hydratase, an enzyme in the mitochondrial Krebs cycle
Clinical features	• Cutaneous leiomyomas: appear during the second to fourth decade and multiple painful, grouped, skin-colored to red-brown papules during the second to fourth decades • Uterine leiomyomas: >90% of affected women; menorrhagia and pelvic pressure or pain • Renal cell cancer: 1–17% of families with syndrome; most commonly type II papillary renal cell carcinomas that are often early-onset and aggressive (metastases in >50% of patients)
Screening of individuals with multiple cutaneous leiomyomas	• Abdominal and pelvic ultrasound (or CT scan) • Complete history and physical examination, including pelvic examination in women • Genetic testing for mutations in the fumarate hydratase gene
Patients with confirmed Reed syndrome	• Complete history and physical examination yearly, including pelvic examination in women • Repeat abdominal and pelvic ultrasound (or CT scan or MRI) every 2 years • Complete physical examination (including pelvic examination in women) of first-degree family members and other family members as indicated; abdominal and pelvic ultrasound as indicated

Table 117.1 Clinical features of multiple cutaneous and uterine leiomyomatosis (Reed syndrome). Other reported features that may not be directly related to the syndrome include tumors of the breast, prostate, bladder and testis, Leydig cell tumors, adrenal gland adenomas, ovarian and kidney cysts, and cerebral cavernomas.

Fig. 117.2 Clustered piloleiomyomas on the back. The trunk is a common location for multiple piloleiomyomas. Patients with this clinical presentation need to be evaluated for the possibility of Reed syndrome (see Table 117.1).

usually homogeneous spindle cell tumors, while vulvar lesions may demonstrate an epithelioid cytology, myxoid changes, and/or hyalinization[1]. Leiomyomas of the nipple closely resemble piloleiomyomas.

Angioleiomyomas are usually well-circumscribed tumors centered within the superficial subcutis. They are composed of bland smooth muscle cells compactly arranged into bundles and whorls around thick-walled vascular channels[4] (Fig. 117.4). Degenerative changes including hyalinization, focal thrombosis, myxoid changes, dystrophic calcification, pyknotic nuclear atypia and fat foci may be present.

Differential diagnosis

For single lesions, the clinical differential diagnosis includes other dermal nodules such as a dermatofibroma, adnexal tumor or fibrosed epidermoid inclusion cyst and the diagnosis is based upon histologic findings. When a lesion is painful or there is clustering of multiple red–brown papulonodules, the diagnosis may be strongly considered prior to biopsy.

Histopathologically, leiomyomas need to be distinguished from other spindle cell tumors with fibrohistiocytic or peripheral nerve sheath differentiation. The differences between leiomyomas and leiomyosarcomas are discussed below.

Treatment

Simple excision is usually curative for solitary or limited tumors. For those tumors that are not amenable to surgery because of their number or location, treatment with gabapentin, medications that reduce smooth muscle contraction (e.g. nifedipine, nitroglycerin, doxazosin), cryotherapy or CO_2 laser ablation may provide relief from pain[10,11]. The experience with mitotically active leiomyomas is very limited. There are no definitive criteria for distinguishing mitotically active leiomyomas from leiomyosarcomas and there is significant overlap between these two entities. It would, therefore, appear prudent to completely excise mitotically active leiomyomas.

Leiomyosarcoma

Synonyms: ■ Superficial leiomyosarcoma ■ Superficial malignant smooth muscle tumor

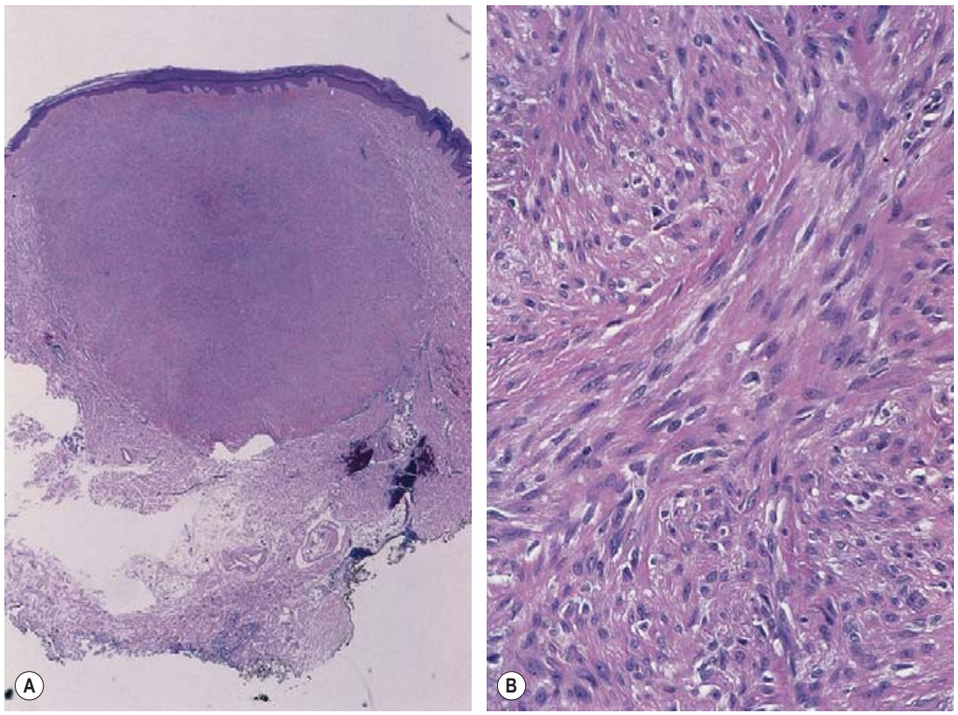

Fig. 117.3 Piloleiomyoma. A Piloleiomyoma centered in the reticular dermis forming a nodule with fascicles of myocytes interdigitating between collagen bundles at its periphery. **B** The center of the lesion shows intersecting fascicles of smooth muscle cells which have eosinophilic cytoplasm and elongated nuclei. The latter are described as cigar-shaped.

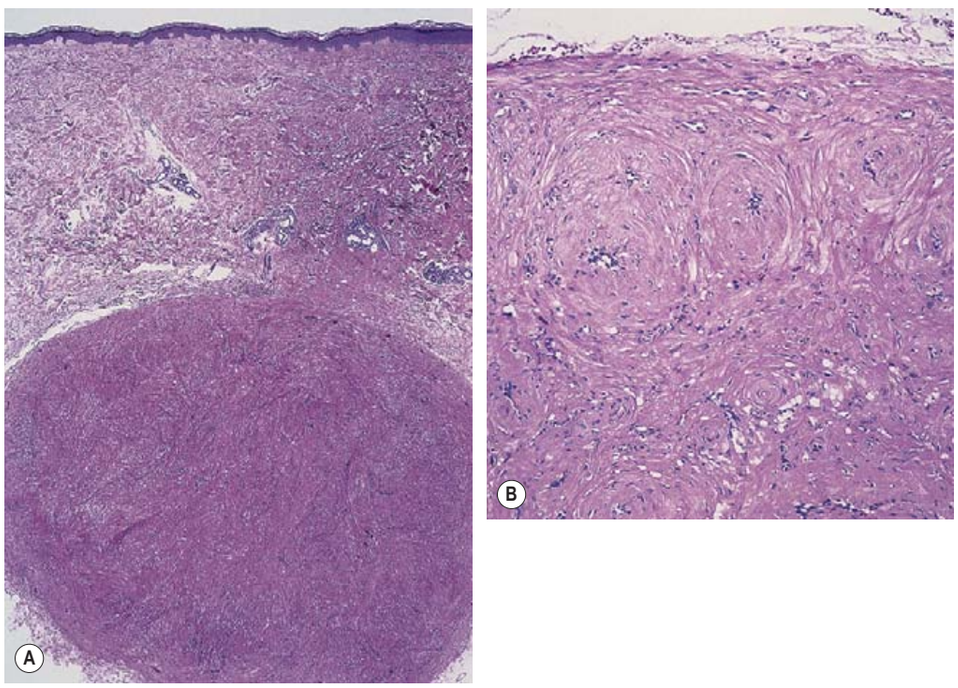

Fig. 117.4 Angioleiomyoma. A Angioleiomyomas are well circumscribed and often located in the deep dermis, extending into the subcutis. **B** At higher magnification, thick-walled vessels are surrounded by bundles of smooth muscle cells.

Key features

- Malignant smooth muscle neoplasms
- Occur primarily in adults older than 50 years of age
- Most commonly located on the extremities, in particular the lower leg
- *Dermal* leiomyosarcomas are typically cured by simple excision and rarely metastasize; *subcutaneous* leiomyosarcomas require wide excision and have a 25–40% risk of metastasis

Introduction

For management and prognostic reasons, it is important to differentiate between "superficial leiomyosarcomas" that are limited to the dermis, and lesions that primarily arise in or extensively involve the subcutis. The former have a favorable prognosis, can recur, but very rarely metastasize. Subcutaneous leiomyosarcomas, in contrast, metastasize in approximately 25–40% of cases[12,13].

Epidemiology

Cutaneous and subcutaneous leiomyosarcomas are rare neoplasms, comprising only 4.0–6.5% of soft tissue sarcomas[14,15].

Pathogenesis

Dermal leiomyosarcomas are thought to arise from either arrector pili or genital smooth muscles. Subcutaneous leiomyosarcomas probably originate from vascular smooth muscle. Anecdotal reports describe a rare association with trauma and radiation[15,16].

Clinical features

Cutaneous and subcutaneous leiomyosarcomas classically present as a solitary, firm, skin-colored to red–brown nodule or plaque. Dermal tumors range from 0.5 to 4 cm in diameter[17], while subcutaneous lesions tend to be larger. Sometimes the tumors are painful or become ulcerated. Leiomyosarcomas favor the extremities, in particular the lower leg of older adults (Fig. 117.5)[4,17,18]. There is a slight male preponderance[4]. Patients with multiple tumors should be evaluated to exclude the possibility of metastases due to a primary retroperitoneal or visceral leiomyosarcoma.

Pathology

The histopathologic features of leiomyosarcomas span a morphologic continuum that, at the well-differentiated end, demonstrates an overlap with leiomyomas, while poorly differentiated lesions closely resemble atypical fibroxanthomas or "malignant fibrous histiocytomas". Leiomyosarcomas of moderate differentiation are comprised of cells that cytologically resemble normal smooth muscle cells. Compared with leiomyomas, malignant smooth muscle tumors are more cellular, exhibit cytologic atypia, and contain easily identifiable mitotic figures (Fig. 117.6). At least focally, the spindle cells are arranged in fascicles. Cytologically, poorly differentiated leiomyosarcomas may resemble myofibroblastic or fibrohistiocytic tumors. Notably, the degree of differentiation may vary within a single tumor.

While a leiomyoma is usually recognized morphologically, the diagnosis of leiomyosarcoma often requires adjuvant special stains and/or immunohistochemical studies to support the cell lineage. Historically, red staining of the cytoplasm on Masson's trichrome stain was used to support smooth muscle differentiation. Nowadays, immunophenotypic studies with antibodies to smooth muscle actin and desmin represent the standard of care. Of the two markers, actin is more sensitive and desmin is somewhat more specific. Unfortunately, neither of these markers is entirely specific for smooth muscle differentiation, and reactivity (especially for actin) may also be observed in myofibroblasts and fibroblasts. However, negative staining with an antibody to smooth muscle actin would strongly argue against smooth muscle differentiation. Additional smooth muscle-associated markers include smooth muscle myosin (SMS), calponin and h-caldesmon, but the first two markers in particular may also be expressed in myofibroblastic tumors[8,17]. Careful consideration of morphologic features and use of multiple immunohistochemical stains are essential for the diagnosis of leiomyosarcoma.

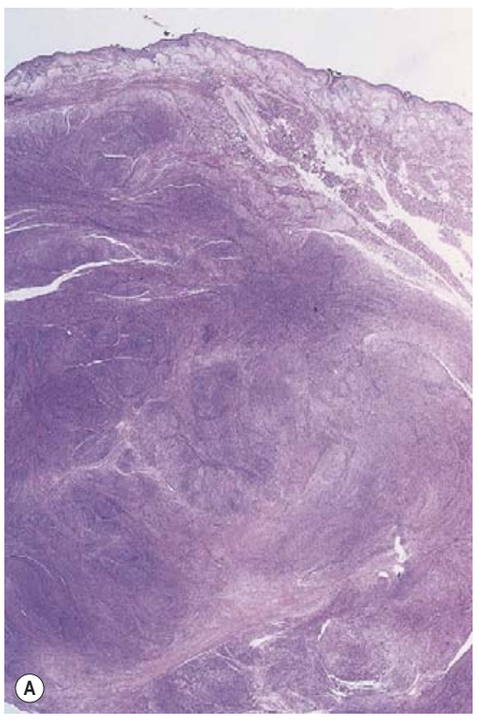
Rarely, leiomyosarcomas have an epithelioid cytology[19]. These neoplasms are usually actin-positive and desmin-negative, but they seem to possess a clinical behavior similar to that of ordinary leiomyosarcomas.

By definition, dermal leiomyosarcomas are superficial malignant smooth muscle neoplasms with at least 90% of the tumor confined to the dermis[20]. They are usually poorly circumscribed and are composed of spindle cells; the latter are focally arranged in fascicles that infiltrate between adjacent collagen bundles. In comparison, subcutaneous leiomyosarcomas tend to be better circumscribed and may be surrounded by a pseudocapsule of compressed tissue.

Fig. 117.5 Leiomyosarcoma. Two hyperpigmented tumor nodules on the lower extremity. *Courtesy, Lorenzo Cerroni, MD.*

Differential diagnosis

Because the clinical features are not unique, the differential diagnosis includes a number of tumors that can present as a solitary firm nodule or plaque (e.g. dermatofibrosarcoma protuberans, other soft tissue



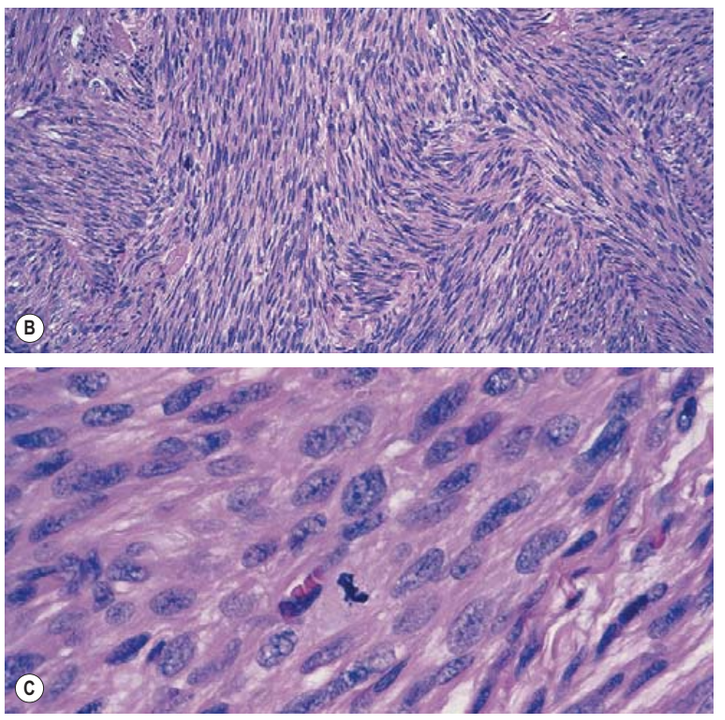


Fig. 117.6 Leiomyosarcoma. A A large tumor extending from the upper reticular dermis deep into the subcutis. **B** At higher magnification, this neoplasm is more cellular than a leiomyoma. The nuclei are pleomorphic, more hyperchromatic, and have coarse chromatin. **C** Mitotic figures are numerous and are easily identified.

IMMUNOHISTOCHEMICAL FINDINGS IN LEIOMYOSARCOMA RELATIVE TO OTHER SPINDLE CELL TUMORS					
	Leiomyosarcoma	SCC	Melanoma	Nerve sheath tumors	AFX/MFH
Actin	+	–	–	–	±
Desmin	±	–	–	–	–
Cytokeratin	–	+	–	–	–
S100 protein	–	–	+	+	–
CD68	–	–	±	–	±

Table 117.2 Immunohistochemical findings in leiomyosarcoma relative to other spindle cell tumors. AFX, atypical fibroxanthoma; MFH, malignant fibrous histiocytoma; SCC, spindle cell squamous carcinoma. CD68 is a glycoprotein expressed by monocytes and macrophages.

sarcomas), a fibrosed epidermoid inclusion cyst, and, less often, panniculitis (e.g. lipodermatosclerosis).

The histopathologic differential diagnosis usually raises two problems: the differentiation of leiomyosarcoma from leiomyoma and its delineation from other spindle cell neoplasms. Traditionally, the number of mitotic figures is used as the most reliable diagnostic criterion when trying to predict clinical behavior. In the presence of cytologic atypia, a mitotic rate of one or more mitotic figures per high-power field is generally considered to be indicative of malignancy[14]. It is important to remember, however, that the prognosis of leiomyosarcomas appears to depend more on the depth of involvement (dermal vs subcutaneous), and that the extent of mitotic activity is probably more important in subcutaneous lesions. Necrosis and angiolymphatic invasion are generally not useful for predicting prognosis of patients with dermal and subcutaneous leiomyosarcomas.

The distinction of leiomyosarcoma from other dermal spindle cell neoplasms nearly always requires immunophenotyping. This is best approached by using a panel of antibodies that examine the neoplasm for its line of differentiation (Table 117.2). A standard panel consists of antibodies to actin, desmin, keratin, S100 protein and CD68. Leiomyosarcoma will usually be actin-positive and desmin-positive, but negative for keratin, S100 protein and CD68. Other dermal and subcutaneous spindle cell neoplasms that are often in the differential diagnosis include spindle cell squamous carcinoma (keratin-positive), spindle cell and desmoplastic melanoma (S100-positive), nerve sheath tumors (S100-positive), atypical fibroxanthoma (AFX)/malignant fibrous histiocytoma (MFH), and nodular fasciitis. It is important to remember that cutaneous leiomyosarcomas can rarely express cytokeratins[4].

Treatment

Wide excision with meticulous examination of all surgical margins is crucial in order to prevent recurrence. Recurrent tumors tend to infiltrate more deeply, and they are often less well differentiated. They are more difficult to treat and carry a higher risk of metastasis. Several authors have reported successful treatment with Mohs micrographic surgery[15], allowing for complete margin control.

Complete surgical excision of a primary dermal leiomyosarcoma can be curative. Local recurrences, due to incompletely excised tumors, are unusual and metastases rarely, if ever, develop. Recently, some authors have even suggested using the term "atypical intradermal smooth muscle neoplasm".[20a] Subcutaneous leiomyosarcomas metastasize in 25–40% of patients. The risk of metastasis appears to be related to size, as metastasis is unlikely in tumors <5 cm in diameter. Metastatic spread occurs hematogenously to the lung and, less often, other visceral organs, or via the lymphatics to regional lymph nodes[16,20].

Smooth Muscle Hamartoma

Key features

- Congenital or acquired skin-colored to hyperpigmented plaque on the trunk or proximal extremities
- Commonly exhibit follicular prominence and/or hypertrichosis
- Clinical and histopathologic overlap with Becker's nevus (melanosis)

Fig. 117.7 Smooth muscle hamartoma. This infant presented with a firm plaque on the thigh. *Courtesy, Ronald P Rapini, MD.*

Introduction

Hamartoma is derived from the Greek word *hamartanein*, which means "to err" or "to fail". Hamartomas are defined as lesions that are: (1) most commonly present at birth, but can also be acquired; and (2) are composed of aberrant mature or nearly mature structures. The term hamartoma is synonymous with "nevus", for example, nevus sebaceus, apocrine nevus, eccrine nevus. A smooth muscle hamartoma may be congenital or acquired and may be associated with a Becker's nevus (melanosis).

History

The first description of a smooth muscle hamartoma is attributed to Stokes in 1923[21].

Epidemiology

The estimated incidence ranges from 1 : 1000 to 1 : 27 000 live births.

Clinical features

Smooth muscle hamartomas not associated with a Becker's nevus present as firm, skin-colored or hyperpigmented plaques, most commonly located on the trunk, buttocks or proximal extremities (Fig. 117.7). Surface changes may be present in the form of small follicular papules or hypertrichosis. Lesions with hypertrichosis and hyperpigmentation overlap with a Becker's nevus (see Ch. 112). These hamartomas are most often solitary, but may be multiple. Extensive lesions can present as large areas of hypertrichotic skin with dimpling (accentuated upon exposure to cold) and/or folding, and generalized involvement may produce a "Michelin tire baby" phenotype (see Table 97.6)[22]. Rubbing of the plaque may result in a pseudo-Darier's sign, consisting of transient induration of the affected area.

Pathology

Well-defined and thickened bundles of smooth muscle are haphazardly distributed throughout the dermis. Connections with hair follicles may

be present. The epidermis is often acanthotic and has hyperpigmentation of the basal layer.

Differential diagnosis

Clinically and histologically, smooth muscle hamartomas demonstrate overlap with Becker's nevus, and the two lesions possibly represent a spectrum of phenotypic expression of the same process. Leiomyomas usually present as papulonodules rather than plaques. Additional entities in the clinical differential diagnosis are congenital melanocytic nevus and neurofibroma. Histologically, the smooth muscle fibers in a piloleiomyoma aggregate to form dermal tumors with irregular margins, but they are not haphazardly scattered throughout the dermis as in a smooth muscle hamartoma.

Treatment

Therapy may be indicated for cosmetic reasons. A small lesion may be amenable to excision. Treatment of Becker's nevi with lasers that target melanin (e.g. Q-switched ruby laser) lead to modest, if any, improvement[23].

Fig. 117.8 Familial multiple lipomatosis. Several discrete lipomas are present on the forearm.

TUMORS OF FAT

Lipoma

Key features

- Common benign tumor of mature fat
- Asymptomatic, soft, subcutaneous nodule arising at any site
- Multiple lipomas are seen in familial multiple lipomatosis, Madelung's disease, adiposis dolorosa, Gardner syndrome, Bannayan–Riley–Ruvalcaba syndrome and Proteus syndrome

Introduction

(Ordinary) lipomas are benign tumors composed of mature lipocytes. They are among the most common neoplasms in humans, and they represent the most common mesenchymal neoplasm[24]. Lipomas are often solitary, but 5–10% of patients have multiple lipomas, usually in the setting of a lipomatosis or less often a multisystem syndrome.

Epidemiology

Lipomas develop at any age, but they usually become clinically apparent between the fourth and sixth decades of life. Most studies report the incidence of lipomas to be slightly higher in men than in women[24].

Pathogenesis

Little is known about the pathogenesis of lipomas and the vast majority represent an incidental finding. Of note, the incidence of lipomas is increased in overweight individuals, diabetics, and patients with elevated serum cholesterol[24]. In familial multiple lipomatosis, there is clearly a genetic component.

Clonal chromosomal aberrations are found within lipomas in approximately two-thirds of patients. The abnormalities are heterogeneous and most commonly consist of translocations between 12q13–15 and various other chromosomes. This 12q13–15 region contains the gene *HMGA2* (*HMGIC*) which encodes a transcriptional regulatory factor that is a member of the *h*igh-*m*obility *g*roup (non-histone chromosomal) protein family[25]; of note, this region is amplified in well-differentiated liposarcomas.

Clinical features

Classically, lipomas present as solitary, painless, soft (to rubbery), mobile, subcutaneous nodules, with a normal overlying epidermis[4]. They are often oval in shape and may feel multilobular. Most lipomas measure a few centimeters in diameter, but occasionally reach over 10 cm in size. Although lipomas may develop within any fatty tissue, sites of predilection are the neck, proximal extremities, forearms and buttocks; lipomas also occur on the trunk, but are very rarely seen on the hands and feet. They present primarily in adults over the age of 30 years.

Lipomas usually exhibit an initial slow growth phase, then remain stable in size with no tendency to involute. The rate of growth may accelerate during periods of weight gain, but weight loss, even when extreme, does not seem to affect their size. Weight loss, however, may result in lipomas becoming more clinically apparent.

Multiple lipomas may be observed in patients with a lipomatosis or in the setting of a multisystem syndrome, such as Proteus syndrome.

Infiltrating or diffuse lipomatosis is characterized by non-encapsulated mature fat infiltrating subcutaneous tissue, muscle, skin, and, at times, even fascia and bone. This entity usually occurs before 30 years of age and is rarely congenital. Diffuse lipomatosis has been described in association with tuberous sclerosis (see Ch. 61) and paralytic poliomyelitis[26–28]. The lower extremities are most commonly affected, but involvement of the head, neck, face and upper extremities have all been reported. Pelvic involvement may lead to urinary tract, intestinal, and even vena caval obstruction[29].

Familial multiple lipomatosis is also known as familial multiple lipomas, multiple circumscribed lipomas, hereditary multiple lipomas, and discrete lipomatosis (Fig. 117.8). This disorder is characterized by multiple lipomas occurring in several members of one kindred. In contrast to benign symmetric lipomatosis (Madelung's disease), the tumors are discrete, mobile, and surrounded by a capsule, as opposed to the diffuse and infiltrative tumor growth observed in Madelung's disease[30]. Favored sites include, but are not limited to, forearms and thighs. The neck and shoulders are generally spared.

Proteus syndrome is a complex disorder due to mosaicism for an activating mutation in the **AKT1** oncogene. It is characterized by asymmetric, disproportionate (i.e. progressive and distorting) overgrowth of multiple tissues and multiple hamartomatous malformations (see Ch. 62). Although this syndrome has a highly variable phenotype[31], clinical criteria include a mosaic distribution of lesions, progressive course, and sporadic occurrence. The tissue overgrowth is progressive until after adolescence, but then seems to plateau.

Lipomatosis arising in the setting of Proteus syndrome is associated with overgrowth of multiple tissues in a mosaic pattern, and this can lead to partial gigantism of the head or limbs, vascular malformations and skeletal deformities as well as areas of lipoatrophy[32]. Connective tissue nevi (particularly cerebriform lesions on the palms and soles) and epidermal nevi are also commonly observed in these patients.

Hemihyperplasia–multiple lipomatosis syndrome is a related but distinct condition characterized by multiple lipomas in association with asymmetric (but non-progressive and non-distorting) overgrowth, mild macrodactyly, cutaneous capillary malformations, and thickened plantar skin with prominent creases. Additional entities with lipomatosis include **CLOVE syndrome**, which is characterized by *c*ongenital *l*ipomatous *o*vergrowth (typically not progressive), *v*ascular malformations and *e*pidermal nevi, and individuals with Proteus-like features who have germline mutations in *PTEN* (plus a second hit in affected

Fig. 117.9 Benign symmetric lipomatosis (Madelung's disease). Large symmetric fatty deposits in the supraclavicular region, lateral chest, and abdomen.

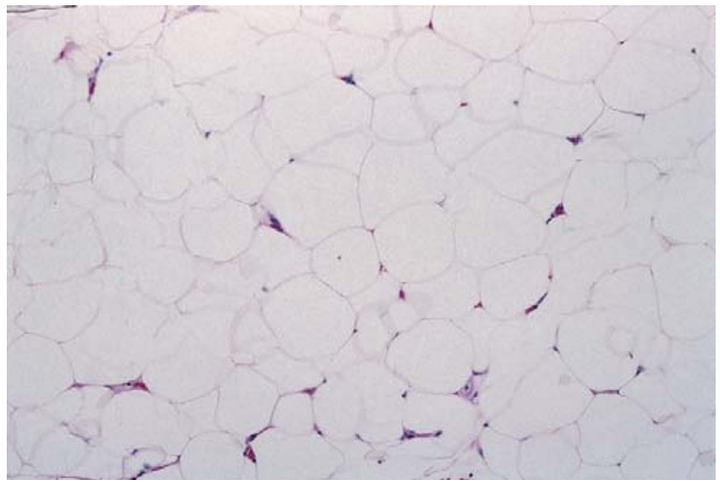

Fig. 117.10 Lipoma (ordinary). A uniform population of mature adipocytes with small and eccentric nuclei is seen.

tissues) and develop *s*egmental *o*vergrowth, *l*ipomatosis, *a*rteriovenous *m*alformations, and *e*pidermal *n*evi (**SOLAMEN**)[33].

Benign symmetric lipomatosis is also known as Madelung's disease in the American literature[34] and as benign symmetric lipomatosis of Launois–Bensaude in the European literature[35]. It consists of extensive symmetric fat deposits in the head, neck, and shoulder girdle area (Fig. 117.9). When the mediastinum is involved, complications related to a space-occupying mass may ensue. Most patients are men, and a high percentage suffer from alcoholism; this may account for several disorders reported in association with benign symmetric lipomatosis, such as peripheral neuropathy, squamous cell carcinomas of the head and neck, and macrocytic anemia. Mutations in the mitochondrial tRNA lysine gene (which also result in neuropathy) have been described in a subset of patients with benign symmetric lipomatosis.

Multiple painful lipomas are present primarily on the arms, trunk, and in the periarticular soft tissue in **adiposis dolorosa (Dercum disease)**. This disease most commonly affects postmenopausal women, and it is associated with weakness and psychiatric symptoms such as depression[36]. Pain is intermittent, but it may be debilitating, necessitating sophisticated pain management. Pain is caused by lipomas compressing adjacent nerves. Lipomas may be part of **Gardner syndrome**. This syndrome consists of polyposis of the colon (eventuating in colonic carcinoma unless there is surgical intervention), odontomas, multiple epidermoid cysts, osteomas, leiomyomas and desmoid fibromatosis (see Ch. 63). Congenital hypertrophy of the retinal pigment epithelium (CHRPE) is an early characteristic finding in Gardner syndrome. Mutations in the *APC* gene are responsible for this syndrome as well as familial adenomatous polyposis.

Multiple lipomas are also seen in **Bannayan–Riley–Ruvalcaba syndrome**, an autosomal dominantly inherited hamartoma syndrome. The characteristic constellation of findings has been described under at least five different eponyms, including Riley–Smith syndrome (1960), Bannayan–Zonana syndrome (1971), Ruvalcaba–Myre syndrome (1980) and Bannayan–Riley–Ruvalcaba syndrome (1980). Cutaneous manifestations include pigmented macules on the penis, multiple acrochordons, multiple lipomas, and "hemangiomas" (which actually represent vascular anomalies)[37,38].

Bannayan–Riley–Ruvalcaba syndrome and Cowden disease are allelic genetic disorders. Both are due to mutations in the tumor suppressor gene *PTEN* (*p*hosphatase and *ten*sin homolog deleted from chromosome 10). As outlined in Table 63.3, these two disorders have overlapping features, including lipomas, and exist along a disease spectrum[27]. Nowadays they are often referred to as the PTEN hamartoma tumor syndrome.

Pathology

Lipomas are composed of a uniform population of mature fat cells with small, uniform and eccentric nuclei (Fig. 117.10). The fat cells are arranged in lobules with capillaries scattered throughout the lesion. Mitotic figures are absent. Microscopically, lipomas may be indistinguishable from mature adipose tissue. Some lipomas contain lipocytes with intranuclear vacuoles that need to be distinguished from lipoblasts. Fibrolipoma and myxolipoma represent lipomas with an admixture of significant amounts of fibrous tissue and myxoid stroma, respectively. Occasionally, foci of cartilaginous tissue and osseous metaplasia may be present. Secondary changes, due primarily to trauma, include focal fat necrosis and/or aggregates of foamy macrophages and these changes may pose diagnostic difficulties.

Differential diagnosis

Clinically, lipomas may be mistaken for epidermoid cysts, hibernomas, and other special variants of benign fatty tumors. On the forehead, for example, a subfrontalis lipoma is often misdiagnosed as an epidermoid inclusion cyst. As lipomas are histologically indistinguishable from normal fat, a definitive diagnosis may not be possible in some patients.

Treatment

Small solitary lipomas are usually cured by simple excision. Local recurrence after excision is more common with larger-sized lipomas. Larger lesions, or systemic lipomatoses, may be amenable to liposuction.

Angiolipoma

Key features

- Soft subcutaneous nodule, usually less than 2 cm in diameter
- Typically located on the forearms of young adults
- More often painful than ordinary lipomas
- Well-circumscribed lesion composed of mature fat cells intermingled with small, focally thrombosed vessels

Introduction

Angiolipomas are benign subcutaneous tumors composed of mature fat and a vascular component.

Epidemiology

Patients with angiolipomas are typically young adults in their late teens or early twenties. About 5% of cases are familial.

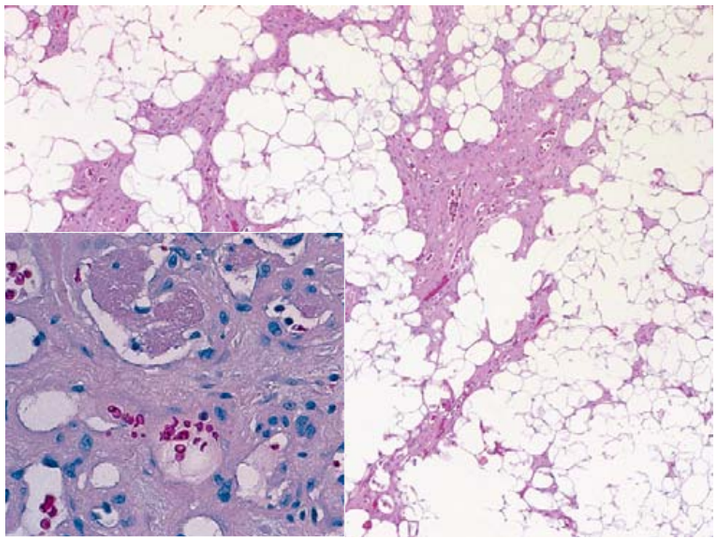

Fig. 117.11 Angiolipoma. In angiolipomas, mature fat is admixed with a variable number of small vessels. Occasional vessels are occluded by fibrin thrombi (insert).

Pathogenesis

The pathogenesis of angiolipomas is not known. A small number of cases are familial, thus suggesting a genetic component. Unlike lipomas, hibernomas and many other fatty tumors, angiolipomas have a normal karyotype.

Clinical features

Angiolipomas usually measure less than 2 cm in diameter and are clinically similar to ordinary lipomas. However, they may be painful. In approximately two-thirds of patients, the tumors are found on the forearms. Other, less common, sites include the trunk and upper arms. An estimated two-thirds of patients have multiple tumors[24].

Pathology

On cut sections, angiolipomas are well-circumscribed or encapsulated yellow tumors with a reddish tinge. Histologically, mature adipose tissue is admixed with a variable number of small vessels (Fig. 117.11). Occasional blood vessels are occluded by fibrin thrombi. The degree of vascularity varies among different lesions and within different areas of the same tumor. Tumors with a predominantly vascular component may be difficult to distinguish from a vascular neoplasm. There is a cellular variant which is characterized by dense cellular angiomatous tissue with a prominent number of spindle cells. Mast cells are more numerous than in ordinary lipomas, and older lesions may contain areas of fibrosis.

Differential diagnosis

Clinically, angiolipomas cannot be reliably distinguished from other benign fatty tumors, although the presence of pain may hint towards a diagnosis of angiolipoma. The histopathologic differential diagnosis includes ordinary lipoma, and no lower threshold exists for the minimal number of vessels required to warrant the diagnosis of angiolipoma. The identification of thrombosed vessels may be helpful in this situation, as they are usually not seen in ordinary lipomas. Highly vascular or cellular angiolipomas may be difficult to distinguish from Kaposi sarcoma, spindle cell lipoma and spindle cell hemangioendothelioma.

Treatment

Surgical excision is curative and, to date, no malignant transformation has been reported. Angiolipomas tend to be more circumscribed than ordinary lipomas and are therefore more readily excised *in toto*.

Spindle Cell/Pleomorphic Lipoma

Key features

- Solitary, subcutaneous nodule on the upper back of middle-aged to older men
- Histologic triad of spindle cells, mature fat cells, and strands of dense collagen
- Pleomorphic lipomas also contain an admixture of floret-like cells

Introduction

Spindle cell and pleomorphic lipomas represent a group of histologically distinct tumors composed of mature fat cells, a population of spindle cells, and strands of dense collagen. Pleomorphic lipomas also contain an admixture of bizarre, often multinucleated cells ("floret-like cells"). Not only do spindle cell and pleomorphic lipomas share common karyotypic abnormalities (rearrangements of 13q and 16q), but tumors with intermediate histopathologic features (between classic spindle cell lipoma and pleomorphic lipoma) are sometimes observed. Spindle cell/pleomorphic lipomas usually develop on the posterior neck, upper back and shoulders of middle-aged and older men, and their clinical appearance is similar to other fatty tumors.

History

Spindle cell lipoma was first described by Enzinger and Harvey in 1975[39].

Epidemiology

Although these tumors have occasionally been reported in women and young men, the vast majority of spindle cell and pleomorphic lipomas have been observed in middle-aged to older men[39].

Pathogenesis

The pathogenesis of spindle cell and pleomorphic lipomas is unknown. Only a small fraction of cases occurs in a familial setting. The spindle cells in spindle cell and pleomorphic lipomas probably represent undifferentiated mesenchymal cells. The causal relationship between the chromosomal abnormalities and tumor formation is not known.

Clinical features

A spindle cell/pleomorphic lipoma presents as a solitary, slowly growing, mobile and painless subcutaneous nodule without epidermal changes. The most common locations are the posterior neck, upper back and shoulders, but these tumors can develop in other sites, including the breast, upper aerodigestive tract, and orbit[24]. Multiple spindle cell lipomas and familial cases are rare.

Pathology

Histopathologically, the diagnosis of spindle cell lipoma requires the presence of three components, admixed in varying proportions: (1) mature fat cells; (2) small, uniform spindle cells; and (3) strands of dense, eosinophilic ("ropey") collagen[40] (Fig. 117.12). In some tumors, variable myxoid areas are seen, whereas in others, spindle cells may predominate; mature fat cells may even be inconspicuous or absent. The spindle cells have bland, uniform nuclei and pale eosinophilic "bipolar" cytoplasm. Other possible histologic features include foci with nuclear palisading, cleft-like spaces and numerous mast cells.

Pleomorphic lipomas are characterized by the presence of mature adipocytes admixed with a variable number of bizarre, multinucleated cells ("floret-like cells") and occasional lipoblasts (Fig. 117.13). By immunohistochemistry, the spindle cells in both spindle cell and pleomorphic lipomas are CD34-positive and rarely S100-positive.

Differential diagnosis

Clinically, spindle cell/pleomorphic lipomas are indistinguishable from other benign superficial lipomatous tumors, with anatomic location being the most characteristic finding. The histopathologic appearance

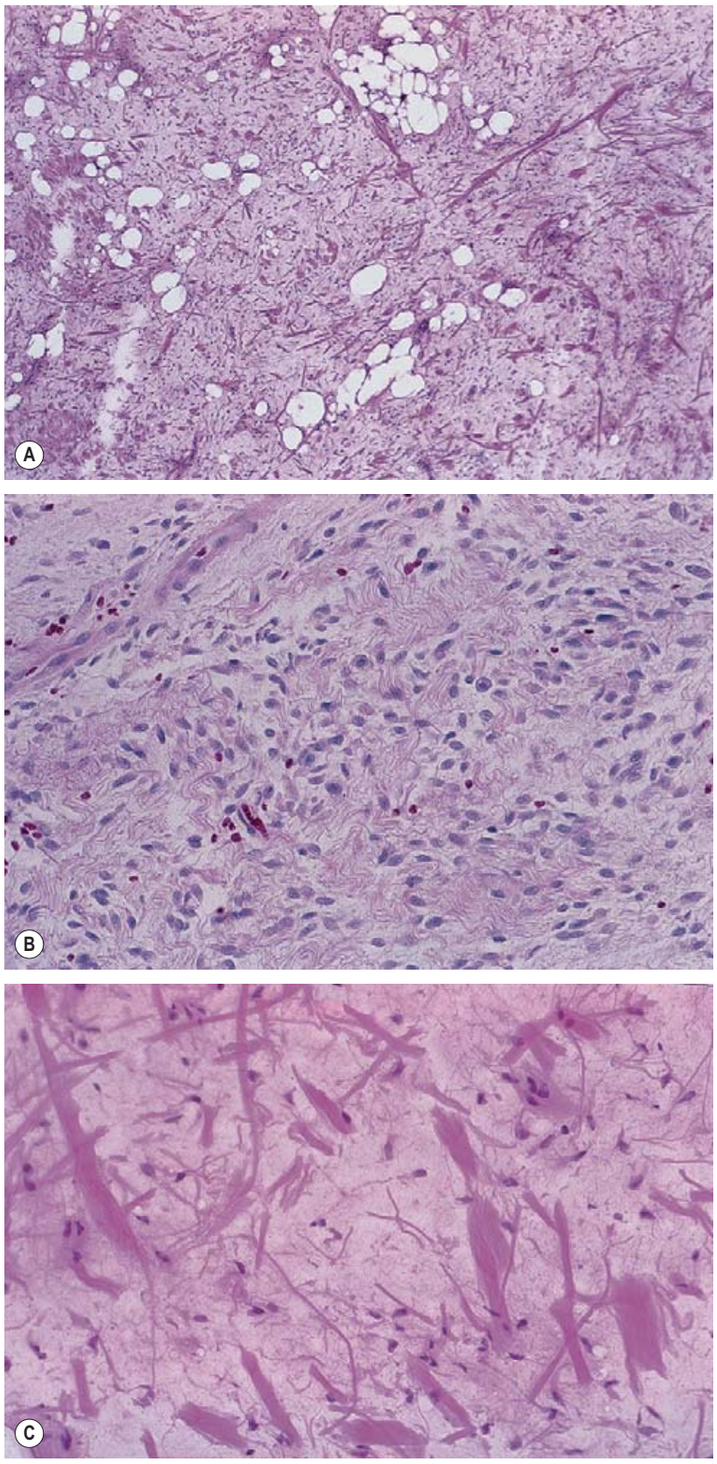

Fig. 117.12 Spindle cell lipoma. A This low-power photomicrograph shows all three components of a spindle cell lipoma – spindle cells, mature fat cells, and "ropey" collagen. **B** The spindle cells are small, uniform, bland, and have inconspicuous cytoplasm. **C** High magnification of thick, "ropey" collagen.

is characteristic, and diagnostic problems should arise only when the spindle cell population is predominant. In the latter situation, immunophenotyping may be helpful. Nodular fasciitis is actin-positive and CD34-negative. Neurofibroma and schwannoma are also in the differential diagnosis, but these tumors are S100-positive.

Treatment

Surgical excision is curative for this benign tumor. It is rare for spindle cell lipomas to recur after complete excision.

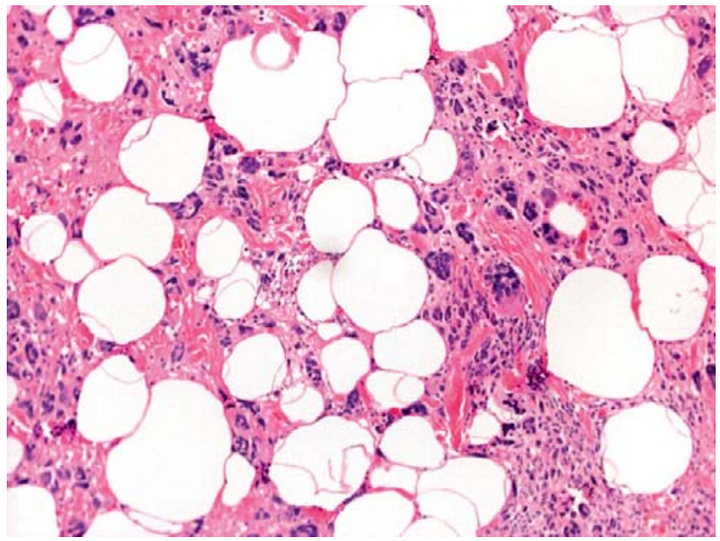

Fig. 117.13 Pleomorphic lipoma. Numerous floret-like multinucleate cells are present in this tumor. Sometimes only a few floret-like multinucleate cells are seen and the majority of cells are mature adipocytes.

Hibernoma

Synonyms: ■ Lipoma of immature adipose tissue ■ Lipoma of embryonic fat ■ Fetal lipoma

Key features

- Rare benign fatty tumor derived from brown fat
- Except for a larger average size, clinically indistinguishable from a lipoma
- The most common locations are the interscapular area, thighs, neck and chest

Introduction

A hibernoma is a rare benign tumor that is derived from brown fat. Brown fat is prominent in hibernating animals, but it is also found in humans. Brown fat first appears in the human fetus and persists into childhood. In children, brown fat is most prominent in the interscapular area, neck, mediastinum, anterior abdominal wall, and around some of the intraperitoneal and retroperitoneal organs. Brown fat gradually disappears with increasing age, and, in adults, it only persists in the neck and around the kidneys, adrenal glands and aorta. The main function of brown fat is heat production.

History

This neoplasm was first described in 1906 by Merkel[41] as a pseudolipoma of the breast. The term hibernoma was first introduced by Gery in 1914[42].

Epidemiology

Hibernomas occur primarily in adults. Individuals who develop these tumors are younger than patients with ordinary lipomas, and are typically in their thirties. In a series of 170 hibernomas, patient ages ranged from 2 to 75 years, with a mean age of 38 years. The series included nine children[43].

Pathogenesis

Little is known about the pathogenesis of hibernoma. Characteristic clonal chromosomal abnormalities consist of structural rearrangements of 11q13 and 11q21.

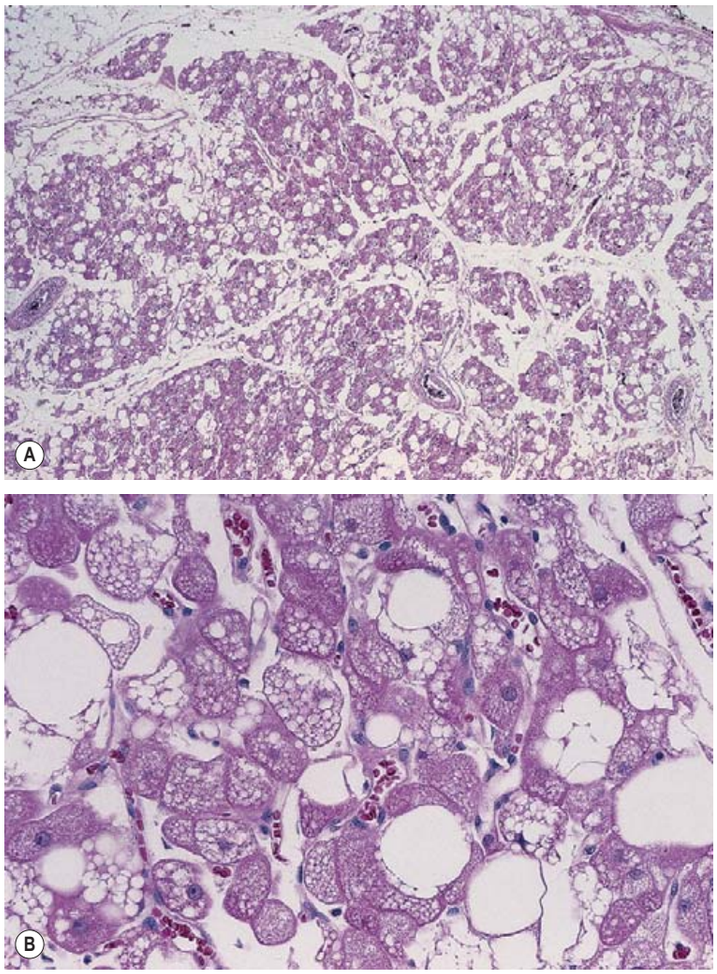

Fig. 117.14 Hibernoma. A Hibernoma with characteristic lobulation. **B** The cytoplasm of hibernoma cells ranges from multivacuolated to granular.

Clinical features

Hibernomas are slow-growing tumors located in the subcutis or, occasionally, within skeletal muscle. On examination, they are indistinguishable from a lipoma, i.e. they consist of a soft, mobile, round to oval subcutaneous nodule. The most common anatomic locations are the interscapular area, thighs, shoulder, neck, chest, arms and abdominal cavity/retroperitoneum. They can measure up to 25 cm in diameter, with an average size of 10 cm[43].

Pathology

On cut section, hibernomas have a characteristic tan to deep red–brown color. Histologic examination shows pronounced lobulation. Highly vascular interlobular septa surround individual lobules (Fig. 117.14). Common to hibernomas are the characteristic brown fat cells with a small central nucleus and multivacuolated to granular eosinophilic cytoplasm. The cellular membrane is distinct. These typical hibernoma cells are admixed with variable numbers of mature fat cells and pale multivacuolated cells. Rare cases have a myxoid stroma or have features of both spindle cell lipoma and hibernoma[43].

Differential diagnosis

Except for a larger average size, hibernomas are clinically indistinguishable from lipomas. However, their histopathologic features are characteristic.

Treatment

Surgical excision is curative. In a clinicopathologic study of 66 cases, none recurred after complete excision[43].

Nevus Lipomatosus Superficialis

Synonym: ■ Nevus lipomatosis of Hoffman and Zurhelle

Key features

- Grouped soft papulonodules on the hips and upper thighs
- Hamartomatous lesion with onset during the first two decades of life
- Mature fat cells in the dermis are the defining histopathologic feature

Introduction

Nevus lipomatosus superficialis of Hoffman and Zurhelle is a connective tissue nevus or hamartoma that is characterized by grouped soft papulonodules. It is most commonly located on the buttocks or upper thighs.

History

Nevus lipomatosus was first described by Hoffman and Zurhelle in 1921[44].

Epidemiology

This rare hamartoma develops shortly after birth or during the first two decades of life, and no gender preference has been observed.

Pathogenesis

The pathogenesis of nevus lipomatosus superficialis is unknown. There is speculation that precursor cells around dermal blood vessels give rise to mature fat cells in a mosaic pattern.

Clinical features

Nevus lipomatosus superficialis consists of soft, clustered papulonodules that are usually present at birth, or appear during childhood or adolescence. Initial presentation in adults has been described. The lesions consist of soft, yellow to skin-colored papules or nodules that are clustered, do not cross the midline, and may follow Blaschko's lines (Fig. 117.15A). Individual lesions may be sessile or pedunculated, and they have a smooth or cerebriform surface. The pelvic girdle area and upper thighs are the most common locations.

Pathology

The defining histopathologic feature consists of mature fat cells in the dermis (Fig. 117.15B). Skin appendages are not displaced.

Differential diagnosis

A solitary acquired papilloma that contains fat cells but no adnexal structures in the dermis is a variant of a skin tag known as a lipofibroma, not a nevus lipomatosus superficialis. The congenital circumferential folds of excess skin in patients with the "Michelin tire baby" phenotype can have the histologic findings of nevus lipomatosus superficialis (see Table 97.6)[45]. In focal dermal hypoplasia (Goltz syndrome), the dermis is either absent and completely replaced by fat cells, or significantly thinned. Adnexal structures are missing. Clinically, agminated neurofibromas may be mistaken for nevus lipomatosus.

Treatment

Most lesions are amenable to excision.

Lipoblastoma/Lipoblastomatosis

Synonym: ■ Embryonic lipoma

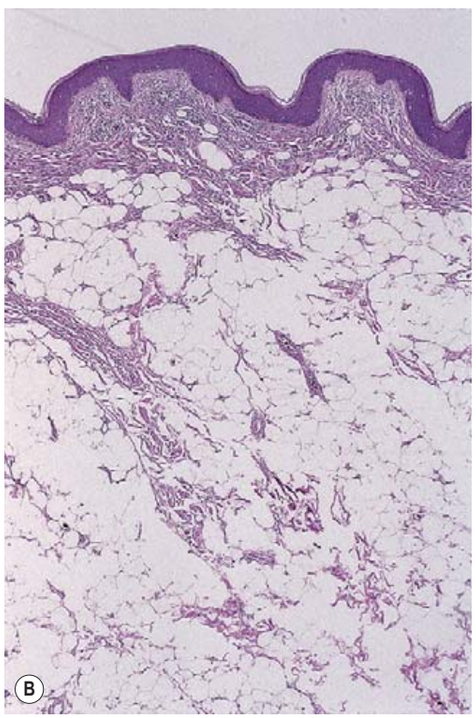

Fig. 117.15 Nevus lipomatosus superficialis. A This hamartoma is characterized by grouped, soft, pedunculated, skin-colored tumors; a partial resection had been performed. **B** Histopathologically, mature fat cells seen in the dermis are pathognomonic. *A, with permission from Kopf AW and Bart RS. J Dermatol Surg Oncol 9:279–281, 1983.*

Key features

- Benign neoplasm of immature fat cells that arises primarily on the extremities of children
- The circumscribed form is termed lipoblastoma, and the diffuse form is termed lipoblastomatosis
- Histopathologically, indistinguishable from myxoid liposarcoma

Introduction

This is a rare variant of lipoma, and it represents a benign tumor of immature fat cells that occurs almost exclusively in children. When circumscribed, this neoplasm is termed lipoblastoma, and, when diffuse, it is known as lipoblastomatosis.

History

The term lipoblastoma was coined by Vellios et al.[46] in 1958 when they reported a case of lipoblastomatosis.

Epidemiology

Lipoblastoma and lipoblastomatosis are tumors of infancy. Occasionally, these neoplasms are described in older children, or even teenagers, but the majority occur before the age of 3 years. Congenital tumors have been observed. Boys are affected twice as often as girls.

Pathogenesis

Lipoblastomas are neoplasms of immature white fat, and they probably represent residual areas of immature fat. The latter is suggested by sequential biopsies showing maturation to mature fat and by the almost exclusive occurrence in infancy and childhood. On the other hand, the presence of chromosomal rearrangements affecting chromosome 8q argues for a clonal neoplasm.

Clinical features

The majority of lipoblastomas present before the age of 3 years, and they are twice as common in boys as in girls. The upper and lower extremities are the sites of predilection. Most tumors are circumscribed and limited to the subcutis, and hence represent lipoblastomas. In addition to the extremities, lipoblastomas may be found in the head and neck region as well as on the trunk. These superficial lesions clinically simulate ordinary lipomas, presenting as slow-growing, soft, mobile, painless nodules, measuring 3–5 cm in diameter.

Lipoblastomatosis affects the deeper soft tissue and often diffusely infiltrates adjacent skeletal muscle. This process can occur in the mediastinum, mesentery and retroperitoneum. Rare tumors weigh up to 1 kg. Depending on the location, the tumor may result in symptoms of local obstruction or compression.

Pathology

Grossly, lipoblastomas are paler than ordinary lipomas, and they have a myxoid quality. Histologically, it is a lobulated neoplasm. The stroma is often myxoid, contains a plexiform vascular network, and is divided into lobules by connective tissue septa. Deep-seated tumors often lack the lobulation, and they may grow in a diffuse pattern. The tumors are composed of fat cells spanning the range of maturation from immature stellate and spindled mesenchymal cells, to lipoblasts with a single cytoplasmic vacuole that indents a peripherally located nucleus, to small and mature adipocytes. Lipoblastomas are paucicellular, cytologically bland, and lack mitotic activity. Serial biopsies of a lipoblastoma may show gradual maturation to a mature fatty tumor.

Differential diagnosis

Histopathologically, lipoblastoma and myxoid liposarcoma can be indistinguishable. Clinical parameters that aid in the differential diagnosis are the age of the patient and the location of the tumor. Myxoid liposarcomas almost always develop in individuals older than 20 years of age, and they are located in the deep soft tissue, rather than the subcutis. Nevertheless, in a child, an immature fat tumor that contains areas of marked cellularity, loss of lobulation, and mitotic figures should raise concern for a myxoid liposarcoma.

Treatment

Lipoblastoma, if treated with complete excision, rarely recurs. Unusual cases of spontaneous resolution without treatment exist[47]. In a series of 14 patients with lipoblastomas/lipoblastomatosis, 22% recurred after excision[48]. Wide excision is the therapy of choice for the diffuse form of the disease.

Liposarcoma/Atypical Lipomatous Tumor

Synonym: ■ Atypical lipoma

Key features

- Sarcoma of deep soft tissue that is only rarely limited to the skin
- Five major histologic subtypes, ranging from locally aggressive tumors without metastatic potential to malignant neoplasms with a significant risk of metastatic dissemination
- Cutaneous involvement may represent superficial extension of a deeply situated tumor

Fig. 117.16 Liposarcoma. Note the large mass in the right buttock. *Courtesy, Ronald P Rapini, MD.*

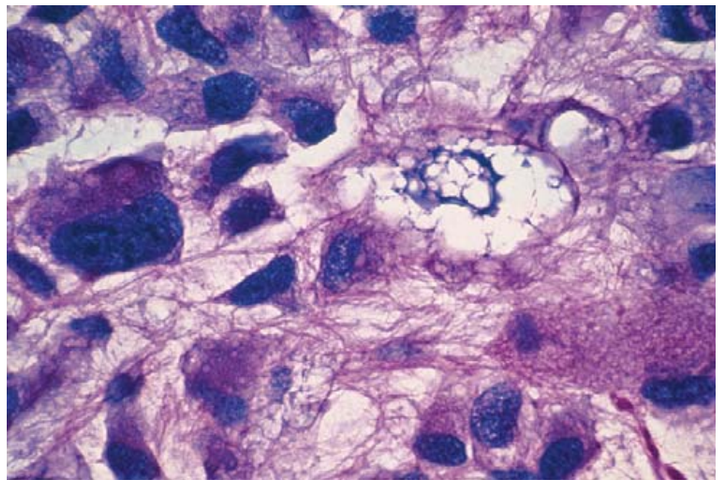

Fig. 117.17 Liposarcoma. Lipoblasts are immature fat cells, with a hyperchromatic nucleus that is scalloped by cytoplasmic fat vacuoles. Their presence is mandatory for a diagnosis of liposarcoma. *Courtesy, Richard Kempson, MD.*

Introduction

Liposarcoma is the second most common soft tissue sarcoma after malignant fibrous histiocytoma. Five histopathologic subtypes are recognized by the World Health Organization (WHO), with important prognostic, cytogenetic, molecular and epidemiologic differences. The biologic behavior of the subtypes ranges from locally aggressive tumors without metastatic potential to highly malignant neoplasms with a significant risk of systemic spread. There is considerable controversy among soft tissue pathologists regarding the nomenclature of this tumor. Some experts prefer the term atypical lipomatous tumor for all liposarcomas in the subcutis, because these tumors recur but have virtually no metastatic potential[49,50]. Others prefer to retain the term liposarcoma because histologically and cytogenetically these tumors are the same, regardless of location, and also because these tumors carry a small risk for dedifferentiation, which confers metastatic potential[51].

Epidemiology

The annual incidence of all types of soft tissue liposarcoma is estimated at 2.5 per million, based on a Swedish study. The average age at presentation is 50 years. Rare cases arise in children older than 10 years of age, but virtually never in children younger than 10 years of age.

Pathogenesis

It appears that liposarcomas arise *de novo*, rather than from preexisting lipomas. A reciprocal translocation between chromosomes 12 and 16 is consistently present in myxoid and round cell liposarcomas, and this results in expression of the TLS/FUS-DDIT3 fusion protein; the latter plays an important role in oncogenesis. Well-differentiated liposarcomas have giant and ring chromosomes that are derived from chromosome 12 and can result in amplification of the 12q13–15 region. Unlike for other soft tissue sarcomas, radiation does not appear to play a role in their pathogenesis.

Clinical features

Liposarcoma is a tumor primarily of the deep soft tissue of the extremities and retroperitoneum. Legs and buttocks are more frequently affected than the upper extremities (Fig. 117.16). It originates in, and is limited to, the dermis or subcutis only in exceptional circumstances[52,53]. Primary cutaneous liposarcomas are described as dome-shaped or polypoid, and they measure between 1 and 20 cm[53]. If a liposarcoma presents in the subcutis, this will often be due to direct extension from an underlying sarcoma of the deep soft tissue.

Tumors limited to the dermis or subcutis can recur, but they do not metastasize or cause patient death. Liposarcomas of the deep soft tissue and retroperitoneum are malignant neoplasms, capable of recurrence, metastasis, and causing patient death. The prognosis depends on the location, degree of differentiation, and the histopathologic subtype.

Pathology

The *sine qua non* for the diagnosis of liposarcoma is the presence of lipoblasts. Lipoblasts are immature fat cells, characterized by a hyperchromatic nucleus that is indented or scalloped by cytoplasmic fat vacuoles (Fig. 117.17). However, the lipoblasts need to be present in the appropriate histopathologic context, as they are not specific for liposarcomas, but can also be found in lipoblastomas and pleomorphic lipomas, or can closely resemble histiocytes found in fat necrosis or fat atrophy.

The histopathologic appearance is highly variable and depends on the particular subtype (Fig. 117.18). A **well-differentiated** liposarcoma consists of mature fat with a variable number of lipoblasts and cells with hyperchromatic nuclei. **Myxoid** liposarcoma resembles immature fat and can be histologically indistinguishable from a lipoblastoma. Small and uniformly bland spindle cells are set in a myxoid matrix with plexiform vessels. In the more cellular areas, myxoid liposarcoma merges with **round cell** liposarcoma, which is characterized by sheets of primitive round cells. Several classification schemes recognize round cell liposarcoma as a part of the spectrum of myxoid liposarcoma. **Pleomorphic** liposarcoma is the least common subtype; it exhibits an extreme degree of nuclear pleomorphism and resembles a malignant fibrous histiocytoma. **Dedifferentiated** liposarcoma is a biphasic tumor comprised of areas of well-differentiated liposarcoma/atypical lipomatous tumor and areas of a non-lipogenic sarcoma.

Differential diagnosis

Liposarcomas of the skin and superficial subcutaneous tissue are exceedingly rare, and they should be diagnosed only after histopathologic mimics, metastases, and direct extension from a deep soft tissue sarcoma have been excluded. In addition, these tumors need to be distinguished from a spindle cell/pleomorphic lipoma, a benign lipomatous tumor that commonly arises on the upper back and posterior neck of older men and is characterized histopathologically by the presence of a variable number of floret-like cells and occasional lipoblasts, admixed with mature adipocytes.

Myxoid liposarcoma can be histologically indistinguishable from lipoblastoma and lipoblastomatosis. This differential diagnosis relies on clinical parameters and is discussed above under lipoblastoma.

Treatment

Wide excision is the treatment of choice. Tumors limited to the dermis and subcutis may be treated by dermatologists. The treatment of most liposarcomas, however, will require an oncologic soft tissue surgeon. It is not uncommon for liposarcomas to have a multinodular growth pattern and extend into muscle and fascial planes. Excision needs to be carefully planned using MRI and radiographic information.

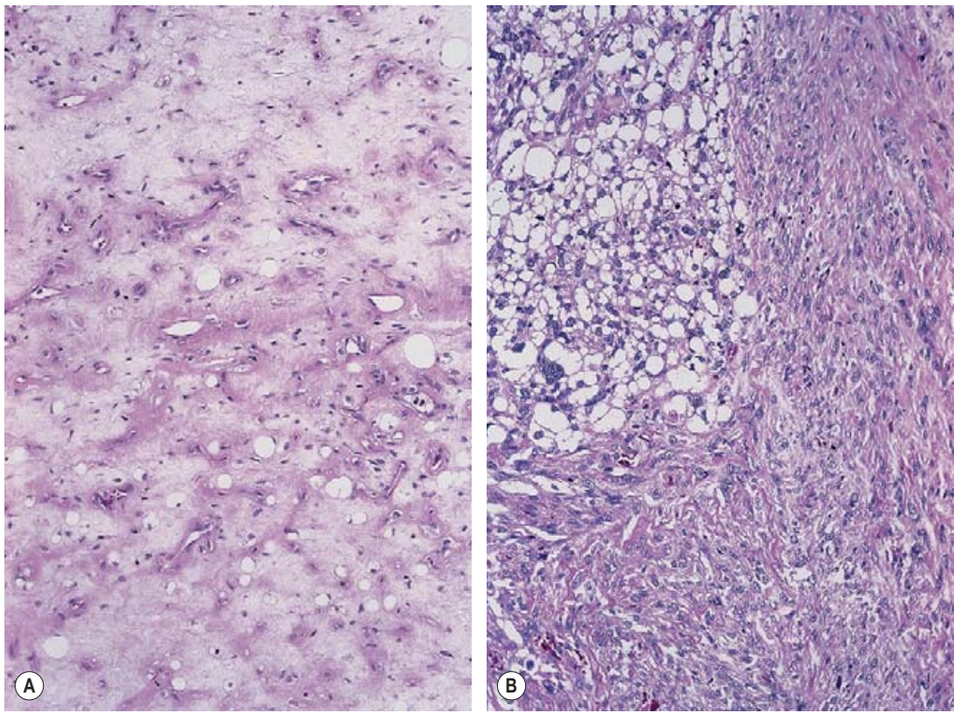

Fig. 117.18 The varied histopathologic features of liposarcoma. A Myxoid liposarcoma – without the clinical context, this tumor can be indistinguishable from lipoblastoma. Bland spindle cells occur in a myxoid matrix with plexiform vessels. **B** Pleomorphic liposarcoma – anaplastic and cellular neoplasm. Lipoblasts may be difficult to find.

TUMORS OF CARTILAGE

Extraskeletal Chondroma

Synonym: ■ Chondroma of soft parts

Key features

- Rare benign tumor of mature cartilage
- Most commonly located near the small joints of the hands and feet

Introduction

Cartilage can be found in the skin as a result of metaplasia, as a component of chondroid syringomas, and as the exclusive component of extraskeletal chondromas. By definition, extraskeletal chondromas are not attached to bone and occur outside the synovial space. With the exception of two clinical series[54,55], most of the experience with extraskeletal chondromas is in the form of case reports.

Epidemiology

Extraskeletal chondromas are rare tumors that occur in children as well as adults, but most patients are beyond their third decade.

Clinical features

Extraskeletal chondromas present as solitary painless nodules on the hands and feet and, most frequently, on the fingers. They grow slowly and are often associated with tendons. Other, rare locations include the trunk, head, neck, oropharynx and larynx.

Pathology

On gross examination, chondromas are sharply circumscribed and often lobulated. Most measure less than 2 cm, but larger lesions can occur. Histopathologically, they consist of hyaline cartilage that may be admixed with variable amounts of fibrous tissue or myxoid stroma. The cartilage may compose only a small portion of the tumor. Mature hyaline cartilage displays a dense basophilic matrix with nuclei in lacunae. Calcification is common, preferentially affecting the center of the tumor, and it may be extensive. Like normal chondrocytes, the lesional cells of chondroma are reactive for S100 protein.

Differential diagnosis

Synovial chondromatosis consists of multiple discrete osteocartilaginous nodules and favors the large joints, such as the knee, hip and elbow. Histologic differentiation from grade I chondrosarcoma or myxoid chondrosarcoma may be difficult, but chondrosarcomas rarely affect hands and feet, and they are in continuity with bone and cartilage.

Treatment

Local excision is usually curative. Up to 20% of extraskeletal chondromas may recur. To the best of our knowledge, malignant transformation to chondrosarcoma does not occur.

118 Mastocytosis

Michael D Tharp

Key features

- The onset of mastocytosis can occur from birth to adulthood and may involve only the skin (most children and some adults) or multiple organs such as the bone marrow, liver, spleen and/or lymph nodes (primarily adults)
- Childhood disease is more common and often presents with one or more tan to brown papules or plaques *(urticaria pigmentosa)* that frequently resolve during late adolescence or early adulthood
- Mastocytomas are thicker plaques or nodules that occur primarily in children
- Adults with mastocytosis may or may not have cutaneous lesions; when present, they appear as 2–5 mm red–brown macules or papules. Adult disease persists throughout life
- Stroking of lesions of mastocytosis often causes urtication (Darier's sign), which is more pronounced in children due to a higher density of mast cells
- Activating mutations in codon 816 of c-*KIT* are detected in the majority of adults and up to 40% of children with mastocytosis; extracellular domain mutations occur more frequently in childhood-onset disease
- Patients may be asymptomatic or have accompanying symptoms of mast cell mediator release such as pruritus, flushing, headaches, abdominal pain, diarrhea and syncope

INTRODUCTION

Mastocytosis represents a spectrum of clinical disorders with a common phenotype of tissue mast cell hyperplasia. Patients with this disorder were initially thought to have only cutaneous disease, but it was then discovered that mastocytosis patients could have involvement of multiple organs. Although the clinical aspects of the disorder have been well documented for decades, the last 10 years have brought significant advances in understanding its pathogenesis. Nonetheless, explanations for the differences in clinical presentations and course between childhood-onset and adult-onset disease (Fig. 118.1) are still needed. Therapy for mastocytosis currently centers on inhibiting the effects of secreted mast cell mediators, with cladribine reserved for advanced systemic disease. Only a small subgroup of patients responds to the tyrosine kinase inhibitor imatinib.

HISTORY

The original description of mastocytosis was by Nettleship and Tay, who reported on a 2-year-old girl with hyperpigmented papules that spontaneously urticated[1]. Eight years later, in 1877, Paul Ehrlich formally discovered the mast cell. The next year, Sangster suggested the name "urticaria pigmentosa"[2]. Unna was the first to demonstrate that mast cells were responsible for the cutaneous eruption in mastocytosis patients.

EPIDEMIOLOGY

Mastocytosis can present in neonates or develop any time thereafter into late adulthood. Childhood mastocytosis is defined as that with an onset before puberty. Approximately 55% of mastocytosis patients develop their disease by 2 years of age, and another 10% experience disease onset between the ages of 2 and 15 years. This disorder has no gender preference, and it has been reported in all races[3]. While most patients with mastocytosis have no family history of the disorder, to date there have been approximately 70 familial cases of mastocytosis reported, including at least 15 sets of monozygotic twins (although several monozygotic twin pairs discordant for mastocytosis have also been described). Familial mastocytosis has been documented in three generations of a single kindred[4].

PATHOGENESIS

Mast cells are derived from pluripotent $CD34^+$ precursors in the bone marrow and circulate in the peripheral blood as agranular, monocytic-appearing cells. After migrating into tissues, these immature mast cells assume their typical granular morphology (see Ch. 18). Circulating mast cell precursors express CD34, the tyrosine kinase KIT (CD117), and IgG receptors (FcγRII), but not high-affinity IgE receptors (FcεRI)[5]. KIT is the protein product of the proto-oncogene c-*KIT* located on chromosome 4q12, and it belongs to the type III receptor tyrosine kinase subfamily. KIT is expressed on mast cells, melanocytes, primitive hematopoietic stem cells, primordial germ cells, and interstitial cells of Cajal. Activation of KIT induces cellular growth and extends cell survival by preventing apoptosis. The ligand for KIT is stem cell factor (SCF), which is an important growth factor for mast cells. The gene for SCF is located on chromosome 12, and encodes a protein that localizes to the cell membrane. A membrane-bound and a soluble form of SCF exist, and both induce KIT activation; the latter is thought to arise via enzymatic cleavage of the former[6]. SCF is produced by bone marrow stromal cells, fibroblasts, keratinocytes, endothelial cells, and reproductive Sertoli and granulosa cells. Peripheral blood mast cell precursors cultured in the presence of SCF and other cytokines (e.g. interleukin [IL]-3, -4, -6, -9) become $KIT^+/CD34^-/Fc\gamma RII^-/Fc\varepsilon RI^+$ and develop characteristic cytoplasmic mast cell granules, as seen in mature tissue mast cells[5,7].

Alterations in KIT structure and activity are central to the pathogenesis of several forms of mastocytosis. *Somatic* mutations involving codon 816 of the c-*KIT* gene represent the most common genetic abnormality in patients with sporadic mastocytosis. The result is a substitution of the amino acid aspartic acid (D) with valine (V) or another amino acid; examples include D816V, D816Y, D816F and D816H (Fig. 118.2). These particular mutations are activating mutations and lead to constitutive ligand-independent activation of the receptor. Additional, less common mutations that have been identified in children and adults with mastocytosis are outlined in Table 118.1[4,8]. As noted, non-D816 mutations can also be activating and there are examples of dominant inactivating mutations (e.g. E839K).

In a recent study of 50 children (0–16 years of age) with mastocytosis in whom the entire c-*KIT* sequence was analyzed, activating mutations were found in 86% of the patients – 42% in codon 816 and the remainder elsewhere, in particular within the portion of the gene that encodes the proximal extracellular region (fifth immunoglobulin-like domain)[8]. Examples of the latter are del419 and K509I (see Fig. 118.2). The majority of the children in this study had urticaria pigmentosa and the results have led to a shift in thinking about the basis for spontaneously resolving childhood-onset mastocytosis. For example, functional studies have been designed and differences in signaling properties between extracellular domain mutations and phosphotransferase domain mutations (i.e. D816) have been observed[9]. Lastly, in a study of 114 adults with childhood-onset mastocytosis in whom seven exons of c-*KIT* were sequenced, 42% had D816 mutations while 23% had other activating mutations[10]. Further insights will surely emerge from long-term studies of children with known mutations.

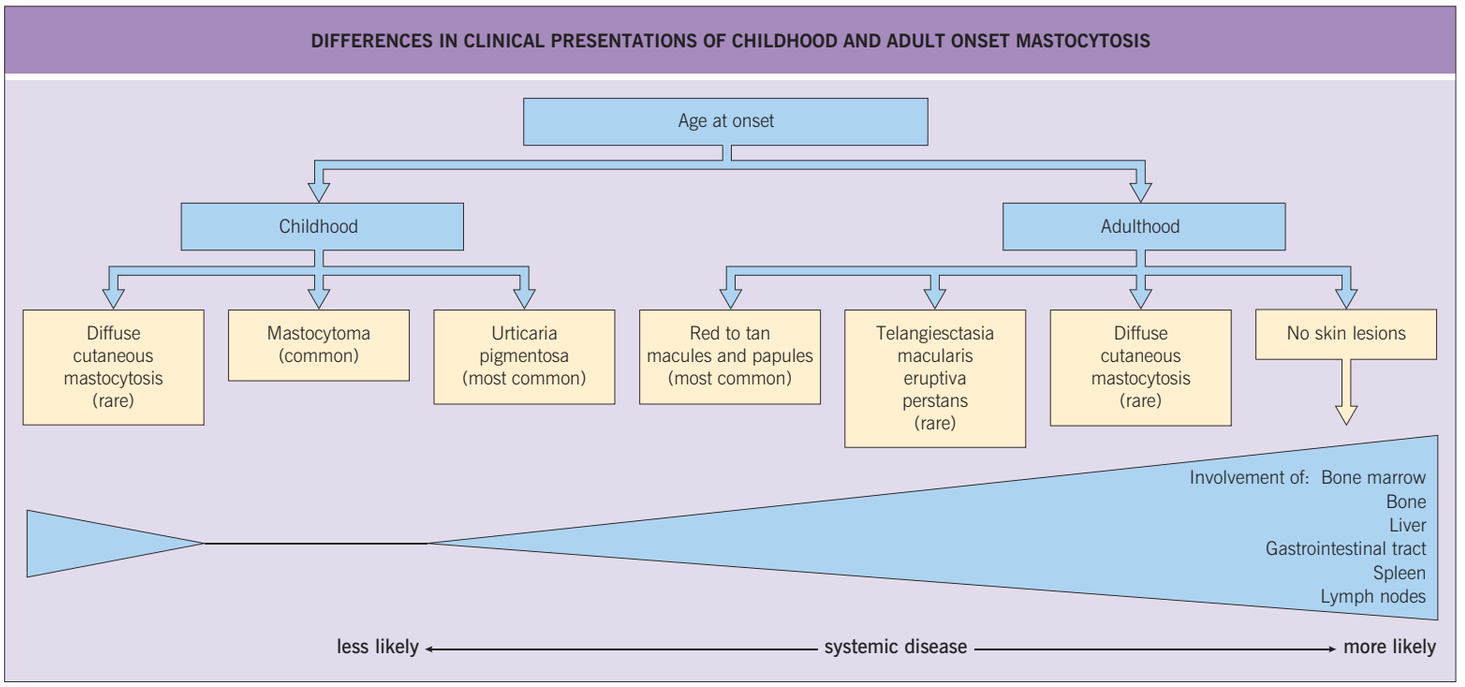

Fig. 118.1 Differences in clinical presentations of childhood and adult-onset mastocytosis. Based upon the WHO classification scheme (see Tables 118.2 & 118.3), most children and some adults have cutaneous mastocytosis. Those with indolent systemic mastocytosis and smoldering systemic mastocytosis often have cutaneous lesions, while individuals with systemic mastocytosis with associated clonal hematological non-mast cell-lineage disease, aggressive mastocytosis or mast cell leukemia often do not have cutaneous lesions. Only a few children with TMEP have been reported. In general, children have a more benign course with a tendency for spontaneous remission of cutaneous and extracutaneous disease.

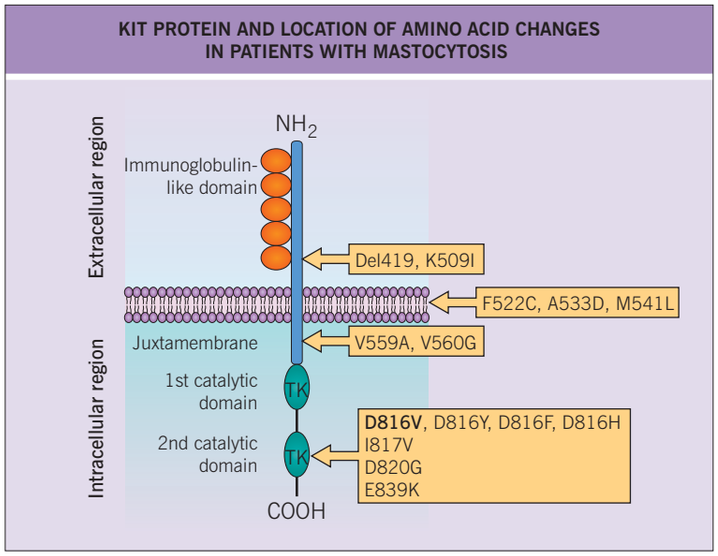

Fig. 118.2 KIT receptor and location of amino acid changes (due c-*KIT* mutations) in patients with mastocytosis. For example, D816V means that because of a mutation in codon 816, valine (V) has replaced aspartic acid (D). The plasma membrane-bound KIT receptor is composed of three distinct regions: (1) the extracellular region (five immunoglobulin-like repeats [orange]); (2) the transmembrane region; and (3) the intracellular region (two tyrosine kinase domains [green]). The most common site for activating mutations is exon 17, which contains codon 816. The result is constitutive ligand-independent activation of the receptor (see Table 118.1). TK, tyrosine kinase domain (one binds ATP and the other has phosphotransferase activity).

MUTATIONS IN c-*KIT* IN PATIENTS WITH MASTOCYTOSIS
CHILDHOOD-ONSET DISEASE
No activating mutation (minority*) Activating mutations (majority*; e.g. D816V†, del419‡, K509I‡, A533D) Inactivating mutations (rare; e.g. E839K) Other mutations (rare; e.g. M541L‡)
ADULT-ONSET DISEASE
D816 activating mutations (most; D816V†, D816Y, D816F, D816H) Activating mutations, non-D816 (few; e.g. V560G‡, del419‡, K509I‡, D820G) Other mutations, some of which are activating (rare; e.g. F522C‡, V533D, V559A‡, I817V, E839K)
FAMILIAL DISEASE
No activating or inactivating mutation (some) Other mutations (few; e.g. del419‡, K509I‡, F522C‡, A533D)
FAMILIAL GASTROINTESTINAL STROMAL TUMORS (GISTS) PLUS HYPERPIGMENTATION OR MAST CELL DISEASE
Examples: deletion of V559 & V560; V559A‡; L576_P577insQL; del419‡)
*In one series of 50 children and adolescents (the majority of whom had urticaria pigmentosa or diffuse cutaneous disease), 86% had an activating mutation[8]. †For example, when it leads to an Asp/Val substitution, the abbreviation is D816V, and when it leads to an Asp/Phe substitution, D816F. ‡Disease responsive to imatinib.

Table 118.1 Mutations in c-*KIT* in patients with mastocytosis.

Recently, a transgenic mouse model of mastocytosis was developed via the expression of human activated (D816V) c-*KIT*[11]. Among the 28 genetically identical animals studied, only eight had clinical findings of mastocytosis, and the disease ranged from indolent mast cell hyperplasia to an invasive mast cell tumor. This diverse phenotypic expression of mastocytosis in genetically identical animals, along with the finding of inactivating or no c-*KIT* mutations in some patients with mastocytosis, especially children, points to additional factors beyond an abnormal KIT receptor.

CLINICAL FEATURES

Signs and Symptoms

Many children and adults have few, if any, symptoms. When symptoms do occur, they are due to the diverse physiologic effects of secreted mast cell mediators, such as histamine, eicosanoids and cytokines

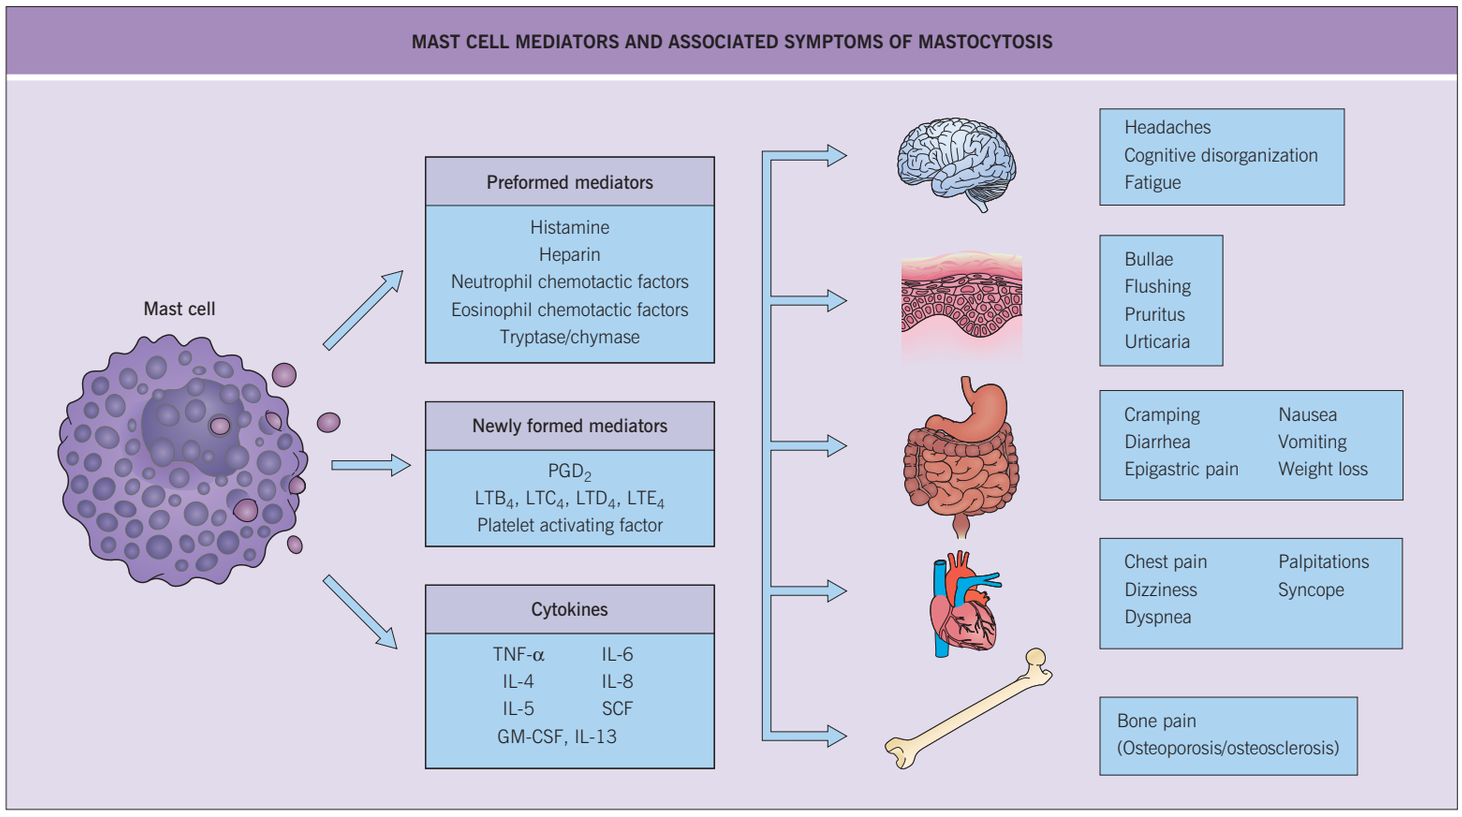

Fig. 118.3 Mast cell mediators and associated symptoms of mastocytosis. GM-CSF, granulocyte–macrophage colony-stimulating factor; IL, interleukins; LT, leukotrienes; PGD_2, prostaglandin D_2; SCF, stem cell factor; TNF, tumor necrosis factor.

(Fig. 118.3). These complaints and findings may range from pruritus and flushing to abdominal pain and diarrhea to palpitations, dizziness and syncope. Of interest is the relative absence of pulmonary symptoms in mastocytosis. Complaints of fever, night sweats, malaise, weight loss, bone pain, epigastric distress, and problems with mentation (cognitive disorganization) often signal the presence of extracutaneous disease. Deaths associated with extensive mast cell mediator release also are rare, but have been reported in both children and adults. Symptoms of mastocytosis can be exacerbated by exercise, heat, or local trauma to skin lesions. In addition, alcohol, narcotics, salicylates and other nonsteroidal anti-inflammatory drugs (NSAIDs), polymyxin B, and anticholinergic medications have been implicated in precipitating symptoms of mastocytosis. Some systemic anesthetic agents may precipitate anaphylaxis (see Treatment).

Cutaneous Lesions

The two common clinical presentations of **childhood mastocytosis** are a solitary tan, yellow–tan or brown plaque or nodule (mastocytoma; Fig. 118.4) and variable numbers of tan to brown macules or papules (urticaria pigmentosa, UP; Fig. 118.5). Mastocytomas may be present at birth or may appear during infancy, and they favor the distal extremities[12]. An estimated 10–35% of patients with childhood-onset mastocytosis have mastocytomas while ~65% have UP. The lesions of UP usually develop during early childhood and most commonly appear on the trunk, classically sparing the central face, scalp, palms and soles.

While telangiectatic macules (telangiectasia macularis eruptiva perstans, TMEP) are a rare manifestation of mastocytosis in children, at least three children have been reported with this type of lesion. A form of childhood mastocytosis with little clinical resemblance to lesions of UP or TMEP is diffuse cutaneous mastocytosis. The skin of patients with this form of mastocytosis has numerous erythematous to yellow–tan papules and plaques with areas of confluence that have a leathery texture. Some infants and children with UP and diffuse cutaneous mastocytosis develop non-scarring vesicles or bullae (Fig. 118.6; see Ch. 34). Bullous lesions of mastocytosis usually resolve by 3 to 5 years of age, and are believed to result from the release of mast cell serine proteases.

Fig. 118.4 Mastocytoma in an infant. Note the leathery appearance of the skin and the two erosions.

Skin lesions in **adult mastocytosis** patients differ significantly from those in children. The most common cutaneous lesions of mastocytosis in adults are reddish-brown macules and papules that measure 1 cm or less in diameter (Fig. 118.7), and in patients with skin type I, they may be pink to red in color. These lesions are most numerous on the trunk and proximal extremities and appear less frequently on the face, distal extremities or palms and soles. Individual lesions can resolve, but the total number usually increases over time. Close inspection reveals variable hyperpigmentation and fine telangiectasias.

A more rare form of adult cutaneous mastocytosis is TMEP, which is characterized by macules and patches composed of telangiectasias without significant hyperpigmentation (Fig. 118.8). While there have been several reports of mastocytomas in adults, these are extremely rare. Diffuse cutaneous mastocytosis has also been documented in adults. The skin of these patients has a doughy consistency, and the presence of numerous, confluent, yellow–tan papules has led to the descriptive term xanthelasmoidal mastocytosis. In more advanced stages, skin folds of patients with diffuse disease become markedly thickened and can distort facial features. Another rare variant, nodular mastocytosis, was recently described in an adult who had red–purple

Fig. 118.5 Urticaria pigmentosa in children. Both papular (**A**) and papulonodular (**B**) lesions are seen. As in mastocytomas, the degree of associated hyperpigmentation can vary. *A, Courtesy, Julie V Schaffer, MD.*

Fig. 118.6 Diffuse cutaneous mastocytosis in infants. A Diffuse infiltration with multiple erosions. **B** Spontaneous blister superimposed on a plaque; note the leathery appearance of the lesions on the shin.

nodules of the axillae and inguinal region; the mast cells had the V560G c-*KIT* mutation[13].

The presence of mast cell hyperplasia in the skin of mastocytosis patients can be confirmed clinically by firmly rubbing a characteristic lesion. The formation of an urticarial wheal (Darier's sign; Fig. 118.9) at the lesion site is indicative of mast cell mediator release. Darier's sign is readily demonstrated in mastocytomas and childhood UP lesions, whereas it may be less apparent in common adult mastocytosis lesions and barely detectable in TMEP. This can be explained from studies quantifying mast cells in the skin of children and adults with mastocytosis. Mast cell concentrations in mastocytomas and childhood UP have been reported to be 150-fold and 40-fold greater than normal skin, respectively, whereas the mast cell content of lesional skin in adult mastocytosis patients was only 8-fold greater than normal skin[14].

Systemic Manifestations

Skeletal lesions are detected more commonly in adult patients with mastocytosis and are reported as rare in children[12]. In one study of 142 adults with mastocytosis, 40% had skeletal involvement, with a similar frequency in those with childhood-onset and adult-onset disease[10]. Bony lesions may appear as radio-opacities, radiolucencies, or a mixture of the two. The skull, spine and pelvis are most commonly involved. In an earlier study of 58 adult systemic mastocytosis patients, 57% had diffuse bone involvement, whereas only 2% had focal lesions. Demineralization was the most common change in patients with diffuse skeletal disease, followed by osteosclerosis and mixed lesions of osteosclerosis and osteoporosis[15]. Patients can complain of skeletal pain.

Undecalcified iliac crest biopsies from adult mastocytosis patients have demonstrated increased numbers of mast cells and evidence of

Fig. 118.7 Adult mastocytosis – typical reddish-brown macules and papules.

Fig. 118.8 Telangiectasia macularis eruptiva perstans. Multiple lesions composed of telangiectasias are present.

Fig. 118.9 Darier's sign in mastocytosis. An infant with extensive cutaneous involvement (**A**) and an adult with macular and papular lesions (**B**). *A, Courtesy, Julie V Schaffer, MD. B, Courtesy, Thomas Horn, MD.*

enhanced cortical and trabecular bone turnover. These observations have led to the hypothesis that mast cells and their mediators are directly responsible for the associated skeletal changes. For example, mast cell-derived heparin and SCF have been implicated in promoting osteoporosis via stimulation of osteoclastic activity. Osteoclasts have been shown to express KIT on their surface and to be activated by SCF. Mast cell histamine, however, is capable of promoting bone sclerosis through activation of fibroblasts, and mast cell-derived IL-6 appears to induce both bone resorptive and fibrotic activities[16,17].

The bone marrow is commonly involved in adult patients with mastocytosis. In a report of 71 adults with mastocytosis, 90% had increased numbers of spindle-shaped bone marrow mast cells with focal perivascular, peritrabecular and/or intertrabecular accumulations[18]. Of the 114 patients with adult-onset mastocytosis in the previously cited study[10], 70% had bone marrow involvement. When bone marrow biopsies were performed in 19 children with mastocytosis, only focal perivascular mast cell aggregates were observed in 10 of the patients. Eight of the remaining nine children had normal marrow cellularity, and the ninth child had hypocellular changes[18a]. These and similar observations have led to the recommendation that bone marrow biopsies should not be routinely performed in children with mastocytosis. Also, in patients with indolent mastocytosis and normal hematologic parameters, especially those with limited cutaneous disease, bone marrow biopsies are not required (in the opinion of the author and editors). Of note, some groups have recommended performing a bone marrow biopsy in all adult mastocytosis patients as well as anyone with a serum tryptase level >100 ng/ml (including children)[20].

Splenomegaly, detected either clinically or by CT scan, has been reported in 50% to 60% of adult systemic mastocytosis patients[18,19]. However, in two recent larger studies, each with over 140 adult mastocytosis patients, splenomegaly was observed in only 8–9% of individuals[10,21]. Increased numbers of mast cells and eosinophils are frequently observed in the spleen, as are various degrees of fibrosis and hematopoiesis. Lymph node enlargement is uncommon in most mastocytosis patients, but occurs in patients with more advanced systemic disease. Among 58 systemic mastocytosis patients, 26% had peripheral lymphadenopathy, whereas 19% had central nodal disease[22]. Histologically, early involvement of lymph nodes often consists of only clusters of mast cells, while in more advanced disease, mast cell infiltrates involve the paracortex, and are often accompanied by eosinophils[18,22].

Gastrointestinal (GI) symptoms that are due to mast cell mediator release, such as abdominal pain, diarrhea, nausea and vomiting, may occur spontaneously or may be precipitated by alcohol, aspirin, NSAIDs or certain foods[15,18,20]. Diarrhea in patients with mastocytosis is usually episodic; it can result from malabsorption, increased motility and/or acid hypersecretion, with the former due to infiltration and the latter two probably a result of the release of mast cell histamine and prostaglandins. GI hemorrhage has been reported in some patients with systemic mastocytosis and is often secondary to gastritis or peptic ulcers. A number of radiographic changes in the GI tract have been described and they include urticaria-like lesions and thickened gastric, duodenal and jejunal folds, as well as mucosal nodules and/or peptic ulcers. Biopsies of mucosal nodules have demonstrated numerous mast cells with varying numbers of eosinophils. Hepatomegaly has also been documented in several large series of systemic mastocytosis patients, ranging from 12% to 40%; however, abnormal liver function tests were detected less frequently[10,19,21].

A mixed organic brain syndrome with a constellation of symptoms – including irritability, fatigue, headache, poor attention span and motivation, limited short-term memory, inability to work effectively, and difficulty in interacting with other people – has been described in patients with mastocytosis[23]. It has been hypothesized that these symptoms may be secondary to released mast cell mediators. Electroencephalographic studies in these patients range from normal to changes consistent with a toxic or metabolic process.

Classification of Mastocytosis

In 2001, the World Health Organization (WHO) proposed a classification scheme, with seven disease variants (Table 118.2)[24]. *Cutaneous mastocytosis* represents the largest group and includes children and some adults. Most children with cutaneous mastocytosis have a limited course, with approximately 50% experiencing resolution of their disease by adolescence and the remainder noting a marked reduction in lesion number[3,12]. With the discovery of c-*KIT* mutations in the majority of children with urticaria pigmentosa or diffuse mastocytosis[8], there has been a change in thinking about why most patients experience

WHO CLASSIFICATION OF MASTOCYTOSIS	
Variants (abbreviation)	**Subvariants**
Cutaneous mastocytosis (CM)	Urticaria pigmentosa (maculopapular), diffuse, mastocytoma
Indolent systemic mastocytosis (ISM)	Smoldering systemic mastocytosis (SSM), isolated bone marrow mastocytosis
Systemic mastocytosis with *a*ssociated clonal *h*ematological *n*on-*m*ast cell-lineage *d*isease (AHNMD)*	Associated with myeloproliferative disorder, CMML, myelodysplastic disorder, AML, non-Hodgkin lymphoma, HES†
Aggressive systemic mastocytosis (ASM)	Lymphadenopathic with eosinophilia‡
Mast cell leukemia (MCL)	Aleukemic
Mast cell sarcoma (e.g. larynx, colon, brain)	
Extracutaneous mastocytoma (e.g. lung)	

*Some patients have *JAK2* V617F mutations.
†Myeloproliferative form of HES characterized by *FIP1L1/PDGFRA* fusion gene (see Ch. 25).
‡Some patients have *FIP1L1/PDGFRA* fusion gene.

Table 118.2 WHO classification of mastocytosis. Patients with disorders in shaded boxes often do not have cutaneous lesions. While both are extremely rare, mast cell sarcomas have a poor prognosis while extracutaneous mastocytomas appear to have a good prognosis. AML, acute myelogenous leukemia; CMML, chronic myelomonocytic leukemia; HES, hypereosinophilic syndrome. From ref. 24.

WHO CRITERIA FOR THE DIAGNOSIS OF SYSTEMIC MASTOCYTOSIS
Requires either the major criterion plus one minor criterion* or *three minor criteria
MAJOR CRITERION
• Multifocal dense infiltrates of mast cells (aggregates of ≥15 mast cells) in bone marrow or extracutaneous tissues
MINOR CRITERIA
• >25% of mast cells in bone marrow samples or extracutaneous tissues are spindle-shaped or otherwise atypical • Extracutaneous mast cells (CD117⁺) express CD2, CD25 or both (often bone marrow; determined via flow cytometry) • Presence of c-*KIT* codon 816 mutation in blood, bone marrow or extracutaneous tissues • Serum total tryptase level is persistently >20 ng/ml (unless there is an associated clonal myeloid disorder, in which case this parameter is not valid)

Table 118.3 WHO criteria for the diagnosis of systemic mastocytosis. From ref. 24.

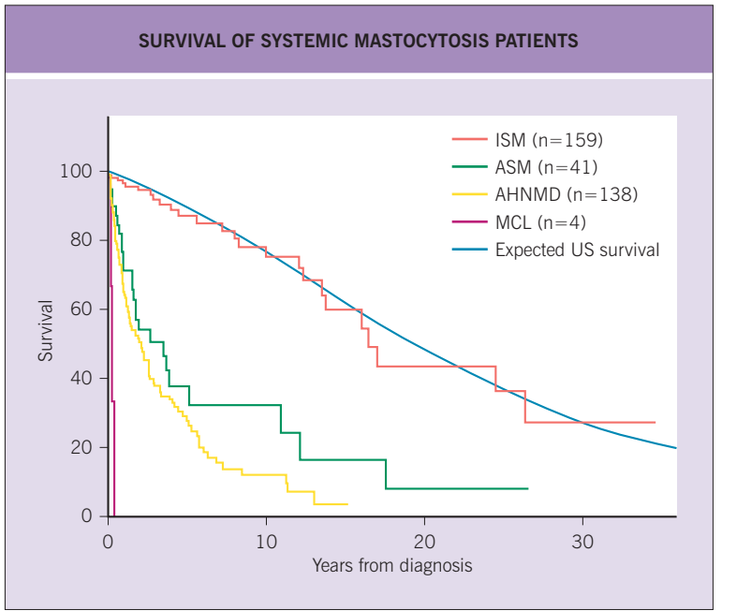

Fig. 118.10 Survival of systemic mastocytosis patients. The life expectancy of patients with indolent systemic mastocytosis (ISM) was not significantly different from the age- and sex-matched US population from the appropriate time period, and leukemic transformation rarely occurred. Based upon these data, the authors recommended that, in general, therapy for ISM should be symptom-directed with avoidance of potentially leukemogenic and immunosuppressive therapies. ASM, aggressive systemic mastocytosis; AHNMD, systemic mastocytosis with *a*ssociated clonal *h*ematological *n*on-*m*ast cell-lineage *d*isease; MCL, mast cell leukemia. *From Lim K-H, Tefferi A, Lasho TL, et al. Systemic mastocytosis in 342 consecutive adults: survival studies and prognostic factors. Blood. 2009;113:5727–36.*

spontaneous resolution of childhood-onset mastocytosis and the disease persists into adulthood in only 10–15% (see above).

The WHO has also established criteria for the diagnosis of systemic mastocytosis (SM; Table 118.3)[20,24]. From a dermatologic perspective, appreciation of indolent and smoldering SM is important as these patients frequently have cutaneous lesions. Although mast cell infiltrates can be detected in multiple organs (e.g. bone marrow, liver, spleen and/or lymph nodes) in patients with *indolent SM* (ISM), organ impairment is usually absent and they have few, if any, systemic symptoms. Progression to more severe forms of SM appears to be limited; in a study of 145 adults with ISM, the cumulative probabilities of disease progression to aggressive SM at 10 and 25 years were 1.7% and 8.4%, respectively[21].

Compared to those individuals with ISM, patients with *smoldering SM* (SSM) have more disease burden, e.g. hepatosplenomegaly, lymphadenopathy, serum tryptase levels >200 ng/ml. The overall prognosis for SSM patients is unknown, but they do have the potential to progress to aggressive SM[24]. Recently, a revised classification system was proposed for SM: indolent, smoldering, aggressive, and associated with an unclassifiable myeloproliferative neoplasm (with mast cell leukemia classified under acute leukemias)[25]. The distinction between the first two categories (ISM vs SSM) was based upon the absence or presence, respectively, of "B" symptoms.

Patients with *SM-AHNMD* (systemic mastocytosis-associated clonal hematological non-mast cell-lineage disease) often do not have cutaneous lesions, but they may have liver, spleen and/or lymph node involvement, in addition to the associated hematologic disorder (see Table 118.2). The overall prognosis of SM-AHNMD patients appears directly dependent upon the severity of the hematologic disease[20,24].

Patients with *aggressive SM* have symptomatic disease due to mast cell infiltrates in the liver (hepatomegaly, functional impairment), bone (pain, pathologic fractures), gastrointestinal tract (malabsorption) and spleen (hypersplenism), in addition to cytopenias, leukocytoses (eosinophilia, basophilia, monocytosis) and thrombocytosis as a reflection of bone marrow involvement and abnormal myelopoiesis. The serum tryptase level is often high, reflecting a significantly increased total body mast cell burden. The overall prognosis appears to be dependent upon the response to treatment[20,21,24], and in one study, the median survival was 3.5 years (Fig. 118.10)[26].

Mast cell leukemia (MCL) is rare. Diagnosis requires the peripheral blood nucleated cell population to be composed of at least 10% mast cells and bone marrow smears to contain at least 20% mast cells[20,21,24]. However, because mature mast cells are rarely observed in the peripheral blood of normal individuals, their presence should raise the suspicion of MCL. Most patients do not have cutaneous lesions, but frequently experience recurrent fever, weight loss, abdominal pain, diarrhea, nausea and vomiting. Multiorgan failure, including the bone marrow, often occurs over weeks to a few months. Prognosis is extremely poor, with an expected survival of a year or less from the time of diagnosis[20,24].

With the detection of c-*KIT* mutations (see Table 118.1), an alternative classification for childhood, adult-onset, and familial mastocytosis may become more clinically relevant (e.g. D816 mutations versus extracellular domain mutations). However, in a recent study of 165 adults with systemic mastocytosis, the presence of the D816V mutation did not correlate with survival, but it did correlate with mast cell burden[26].

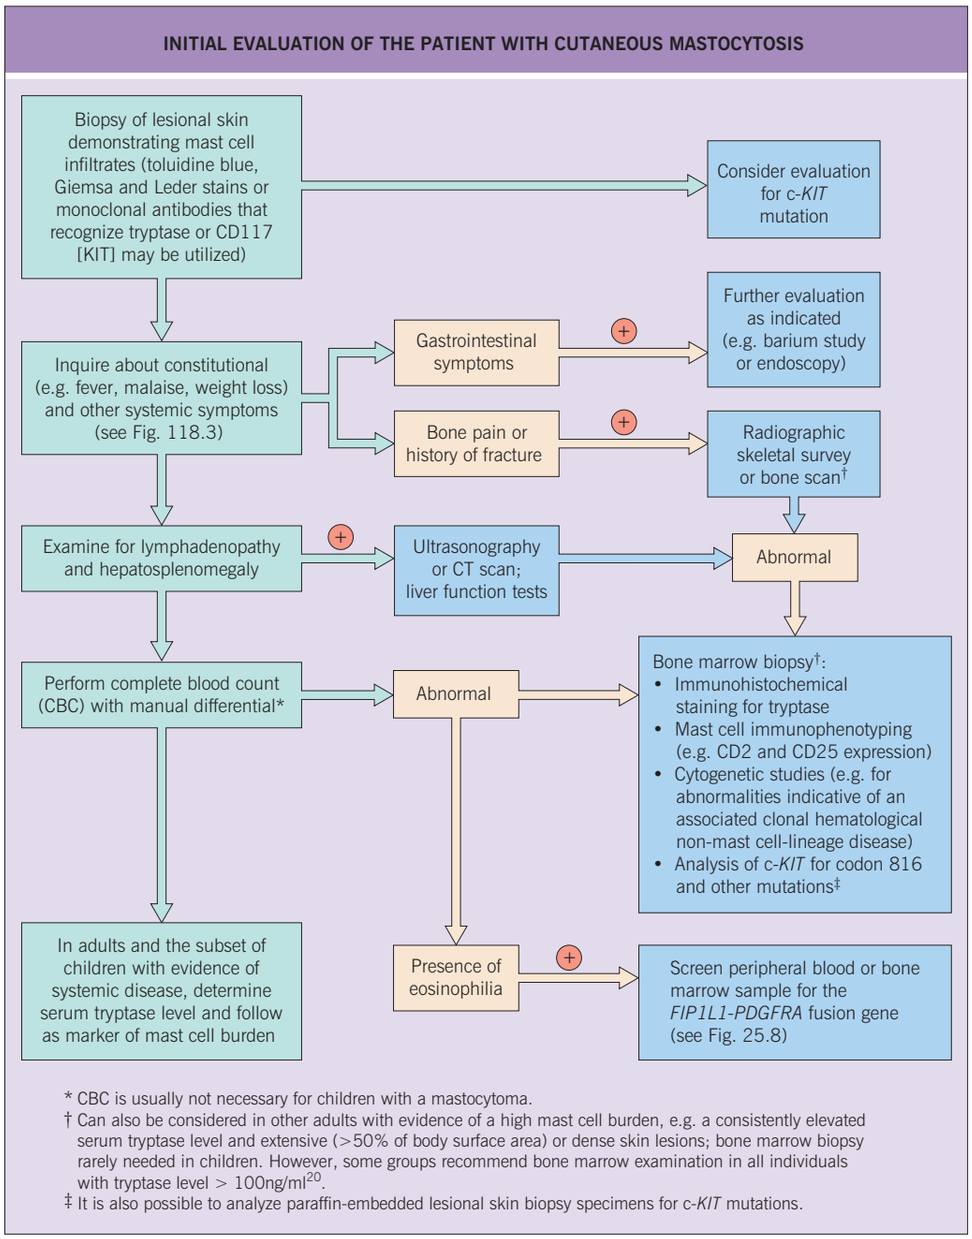

Fig. 118.11 Initial evaluation of the patient with cutaneous mastocytosis. A proposed scheme for the diagnosis of mastocytosis of the skin requires one major criterion (typical skin lesions clinically) plus one or two minor criteria. The minor criteria are: (1) monomorphic mast cell infiltrate that consists of either large aggregates of tryptase-positive mast cells (>15 cells/cluster) or scattered mast cells exceeding 20 cells per microscopic high power field (40×); and (2) detection of a c-*KIT* mutation at codon 816 in lesional skin[20].

Interestingly, patients with familial disease often lack c-*KIT* mutations. The clinical course and overall prognosis of familial disease appears good, but is less well defined.

An approach to the initial evaluation of a patient with mastocytosis is presented in Figure 118.11.

PATHOLOGY

Direct Studies

The diagnosis of mastocytosis is established by demonstrating characteristic mast cells in one or more organs. For patients with cutaneous lesions, mast cell infiltrates can be demonstrated in a biopsy of lesional skin (Fig. 118.12). Eosinophils are also commonly found within the dermis and hyperpigmentation of the basal layer of the epidermis is often seen, especially in lesions of urticaria pigmentosa. Special stains, such as toluidine blue, Giemsa and Leder, or monoclonal antibodies that recognize tryptase or CD117 (KIT) are helpful for identifying tissue mast cells (Fig. 118.13). Mast cells in nodular, papular and macular lesions (including TMEP) of mastocytosis have been quantified using a morphometric technique and shown to contain mean mast cell densities of 63.2% (± 8.2% SEM), 16.1% (± 4.8% SEM) and 3.5% (± 1.8% SEM), respectively[27]. In contrast, the mast cell content of normal skin

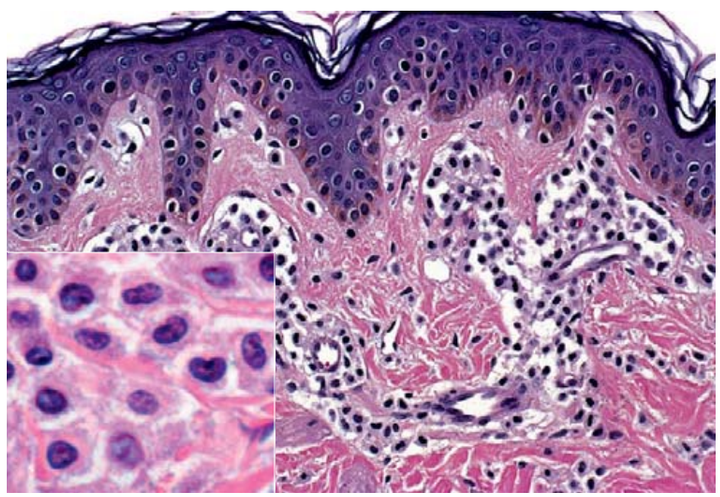

Fig. 118.12 Cutaneous mastocytosis – histologic features. Mast cells within the dermis have a "fried egg" appearance. Granules are seen within the amphophilic cytoplasm (insert). *Courtesy, Lorenzo Cerroni, MD.*

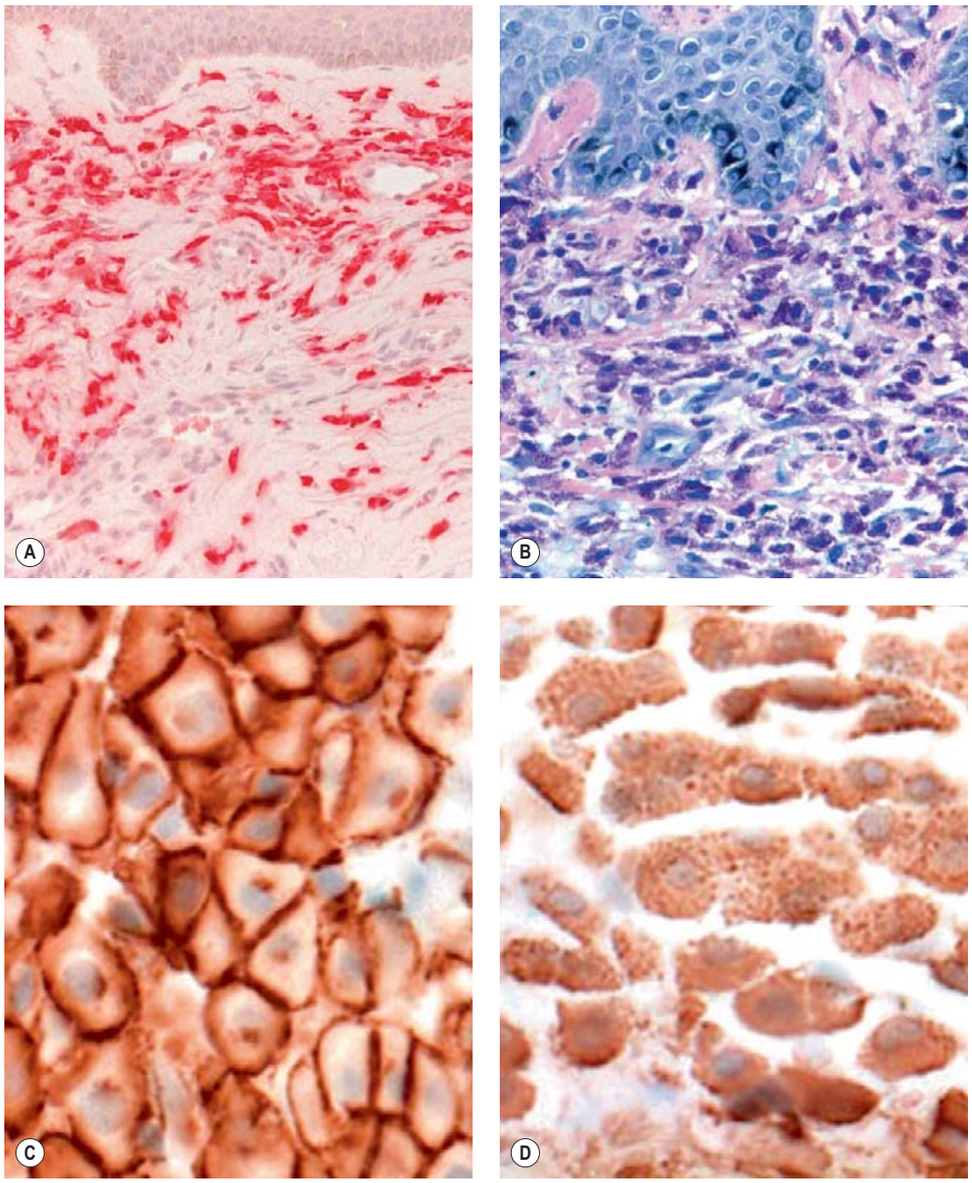

Fig. 118.13 Special stains to detect dermal mast cells. A The Leder method utilizes naphthol AS-D chloroacetate esterase and the mast cell granules appear red. **B** With the Giemsa stain, the mast cell granules stain metachromatically purple. Immunohistochemical staining with monoclonal antibodies that recognize CD117/KIT receptor (**C**) or tryptase (**D**) can also be employed. *A,B, Courtesy, Lorenzo Cerroni, MD. C,D, Courtesy, Antonio Subtil, MD.*

was reported to be 0.4% (± 0.1% SEM). In cases of adult mastocytosis with cutaneous lesions that contain only borderline numbers of mast cells, molecular diagnostic studies for c-*KIT* mutations may help confirm or establish a diagnosis. However, these studies are not routinely available. Immunohistochemical staining for CD117 (KIT) can prove helpful in establishing the diagnosis in more subtle forms of mastocytosis[20,28].

Biopsy specimens of normal-appearing skin from patients with mastocytosis have normal concentrations of mast cells, and thus are not helpful in establishing the diagnosis. A biopsy of the bone marrow or GI tract may be indicated for patients in whom the diagnosis of SM is a possibility, but who lack skin lesions. Increased mast cell numbers in association with variable numbers of eosinophils are observed in these tissue specimens. In addition, the combination of monoclonal antibodies against CD117 (KIT) and tryptase may be particularly useful for identifying atypical mast cells in various tissues[20,28]. WHO criteria for the diagnosis of SM are listed in Table 118.3.

Indirect Studies

Detection of circulating mast cell mediators and/or their metabolites can offer indirect evidence of mastocytosis. Two forms (α and β) of mast cell tryptase have been identified[29]. Alpha-tryptase is elevated in patients with SM, regardless of whether or not they are experiencing acute symptoms, and therefore may be useful in assessing total body mast cell burden. Beta-tryptase, however, is often detected both in mastocytosis patients and in patients without mastocytosis who are experiencing anaphylactic symptoms. Total (α and β) serum tryptase levels have been correlated with the extent of mast cell disease. Fifty percent of patients with total serum tryptase levels between 20 and 75 ng/ml had evidence of SM, whereas all patients with levels >75 ng/ml had proven systemic involvement. Of note, a total serum tryptase level >20 ng/ml represents one of the minor criteria for SM[24] (see Table 118.3).

Urinary histamine and its metabolites have also been measured in mastocytosis patients. In many instances, unmetabolized urinary histamine levels may be normal in asymptomatic SM patients, whereas the major metabolite of histamine, 1,4-methylimidazole acetic acid (MeImAA), is often persistently elevated. When urinary MeImAA levels were correlated with the extent of mast cell disease, patients with widespread systemic involvement had the highest concentrations, and patients with only cutaneous disease had normal or only slightly elevated MeImAA[30]. It is important to note that certain foods with high histamine content, such as spinach, eggplant, cheeses (Parmesan, Roquefort and blue) and red wines, can artificially elevate the levels of urinary histamine and its metabolites.

The urinary excretion of the major urinary metabolite of prostaglandin D_2 (PGD_2), 9α,11β-dihydroxy-15-oxo-2,3,18,19-tetranorprost-5-ene-1,20-diolic acid (PGD_2M), has also been reported to be increased in some systemic mastocytosis patients[31]. In one study of 17 patients with mastocytosis, the levels of PGD_2M were compared to urinary

methylhistamine concentrations. In all patients, urinary PGD_2M levels were increased to a greater extent than those of methylhistamine, and markedly elevated PGD_2M levels were detected in four patients with a normal concentration of urinary methylhistamine. Urinary PGD_2M levels have not been compared to urinary MeImAA or serum α-tryptase determinations, and as a result it is unclear whether measuring PGD_2M offers any advantage over obtaining commercially available urinary MeImAA or serum tryptase levels. Plasma levels of IL-6 have also been shown to be elevated in patients with mastocytosis, correlating with severity of bone marrow pathology, organomegaly and extent of skin involvement[32].

DIFFERENTIAL DIAGNOSIS

The lesions of childhood and adult mastocytosis are so characteristic that they are only occasionally confused with other skin disorders. Childhood lesions of UP may spontaneously urticate and thus may be mistaken for urticaria. However, lesions of urticaria last only a few hours and do not have the associated hyperpigmentation seen in UP. Some childhood mastocytosis patients may develop bullae. Therefore, the differential diagnosis for blisters in these children includes bullous arthropod bites, bullous impetigo, herpes simplex viral infection, linear IgA bullous dermatosis and, less often, other autoimmune bullous dermatoses. In addition, children with diffuse cutaneous mastocytosis may develop widespread blisters early in their course, which may be mistaken for epidermolysis bullosa or toxic epidermal necrolysis. Demonstration of increased mast cells in either the blister fluid or skin biopsy of the mastocytosis patient helps to establish the correct diagnosis. Rarely, nodular scabies has been misdiagnosed as mastocytosis. Lastly, if mast cells are not readily detected due to the presence of other leukocytes within the dermis, the patient may be misdiagnosed as having a histiocytic disorder or vasculitis[33].

Skin lesions of adult mastocytosis patients may at first glance appear as lentigines or melanocytic nevi, but mastocytosis lesions usually have an associated erythema. Mastocytomas in children may be confused with café-au-lait macules, arthropod bites, Spitz or congenital melanocytic nevi, pseudolymphomas and juvenile xanthogranulomas.

TREATMENT

Treatment of patients with mastocytosis is directed primarily at alleviating symptoms, since there is no cure for this disorder. Many patients with CM and ISM have few, if any, symptoms, and therefore require little or no therapy. Mastocytosis patients should be cautioned to avoid potential mast cell degranulating agents and environmental triggers (Table 118.4). A number of systemic anesthetic agents that have been directly or indirectly implicated in precipitating anaphylactoid reactions in mastocytosis patients are listed in Table 118.4. In contrast to systemic anesthetics, local injections of lidocaine can be used safely in these patients, and recent reports indicate that fentanyl, sufentanil, remifentanil, midazolam, propofol, ketamine, desflurane, sevoflurane, cisatracurium, pancuronium and vecuronium bromide are safe alternative systemic anesthetics for patients with mastocytosis. It has been recommended that mastocytosis patients undergoing general anesthesia be monitored postoperatively for at least 24 hours since delayed anaphylaxis has occurred hours after surgery in some of these patients[34,35].

Histamine type 1 (H_1) receptor antagonists, or combined H_1 and H_2 receptor antagonists, are often helpful in controlling many of the symptoms associated with mastocytosis. The second-generation antihistamines cetirizine, loratadine and fexofenadine have distinct advantages over first-generation antihistamines because they have longer half-lives and are more specific H_1 antagonists. In some instances, the addition of an H_2 antagonist (cimetidine, ranitidine, famotidine or nizatidine) may prove beneficial, especially in patients with gastric acid hypersecretion. Oral cromolyn sodium (disodium cromoglycate; 400–800 mg/day) may alleviate GI, cutaneous and CNS symptoms associated with mastocytosis.

Psoralen plus UVA (PUVA) therapy given up to four times a week can help to control the pruritus and cutaneous whealing in patients with mastocytosis[36,37]. While PUVA is capable of reducing skin mast cell histamine content, it does not permanently eliminate cutaneous mast cell infiltrates.

THERAPEUTIC LADDER FOR MASTOCYTOSIS
AVOIDANCE OF POTENTIAL MAST CELL STIMULI
Alcohol Anticholinergic medications Aspirin Nonsteroidal anti-inflammatory drugs Heat Friction Narcotics (e.g. morphine, codeine) Polymyxin B sulfate Systemic anesthetics, including lidocaine, d-tubocurarine, metocurine, etomidate, thiopental, succinylcholine hydrochloride (suxamethonium chloride), enflurane, isoflurane (see text for alternatives)
LOCAL THERAPY FOR SYMPTOM CONTROL
Potent and superpotent topical corticosteroids, including under occlusion (2) Intralesional corticosteroids (3)
SYSTEMIC THERAPY FOR SYMPTOM CONTROL
Oral H_1 and H_2 receptor antagonists (2) Oral cromolyn sodium (1) Oral PUVA [psoralens plus ultraviolet A] (2) Oral corticosteroids (3) UVA1 (3) Pre-measured epinephrine with auto-injector (EpiPen®) (3)
SYSTEMIC THERAPY FOR AGGRESSIVE/SEVERE MASTOCYTOSIS
Interferon-α-2b (2; limited success) Cladribine (2) Imatinib mesylate or other KIT inhibitors, depending upon type of mutation (3)

Table 118.4 Therapeutic ladder for mastocytosis. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

Potent topical corticosteroids under occlusion for 6 weeks or more eliminate pruritus and cutaneous whealing and reduce histamine levels and the number of lesional skin mast cells, but they can lead to skin atrophy[38]. Intralesional injections of triamcinolone acetonide have also been successful in clearing mast cell infiltrates in the skin of mastocytosis patients. The use of systemic corticosteroids in SM patients has been anecdotal, but relief of both cutaneous and GI symptoms has been reported using prednisone, alone or in combination with cyclosporine, for more severe disease[39,40].

Some patients with systemic mastocytosis may experience recurrent, life-threatening episodes of hypotension following mast cell mediator release, and therefore should be provided with a premeasured epinephrine (adrenaline) preparation (EpiPen®) for emergency use. In some instances, these patients may experience recurrent similar attacks within hours of the initial event; when this occurs, prednisone (20–40 mg/day for 2–4 days) should be initiated, since it often suppresses these recurrent reactions.

Interferon-α-2b has been used with limited success in patients with aggressive forms of mastocytosis. Of the various chemotherapeutic agents that have been tried for severe mastocytosis, intravenous cladribine (2-chlorodeoxyadenosine [2-CDA]) has been shown to effectively eliminate skin lesions and markedly reduce the number of bone marrow mast cells in patients with advanced SM, including those with the D816 c-*KIT* mutation. Because this latter group of patients does not respond to imatinib mesylate (see below), for them 2-CDA represents first-line therapy[41,42]. For patients with SM-AHNMD, chemotherapy should be directed at treating the associated hematologic disorder. Local radiation therapy (approximately 20 to 40 Gy over a 7- to 14-day period) may benefit patients with bone pain. Splenectomy may be indicated for mastocytosis patients with hypersplenism who experience significant cytopenia, and it appears to improve survival in patients with more aggressive disease. Non-myeloablative allogeneic hematopoietic stem cell transplantation for life-threatening disease is still under investigation.

Imatinib mesylate is a tyrosine kinase inhibitor that can inhibit the KIT and PDGF receptors, as well as the BCR-ABL oncoprotein

associated with chronic myelogenous leukemia. However, the active site for imatinib within the KIT receptor is at a distance from the location of the amino acid substitutions that result from the most common mutation, D816 (see Table 118.1), and the latter are thought to hamper the binding ability of imatinib. As a result, imatinib does not alter the clinical course of patients with mutations at this codon[43]. On the other hand, it does appear to alleviate the signs and symptoms of mastocytosis in patients with rare c-*KIT* mutations (e.g. del419, V560G, F522C and K509I; see Fig 118.2)[43–45], in addition to those with the *FIP1L1-PDGFRA* fusion gene who are D816-negative[46]. Dasatinib, a dual SRC/ABL kinase inhibitor, reduces the proliferation of D816V-expressing mastocytosis mast cell lines *in vitro*; however, this agent does not appear to be effective as monotherapy for mastocytosis patients who have this mutation[47].

B-Cell Lymphomas of the Skin 119

Lorenzo Cerroni

Synonyms: ■ Cutaneous B-cell lymphomas ■ *S*kin-*a*ssociated *l*ymphoid *t*issue (SALT)-related B-cell lymphomas

Key features

- Cutaneous B-cell lymphomas represent a group of lymphomas whose primary site is the skin; they are derived from B lymphocytes in different stages of differentiation. The skin can also be the site of secondary involvement by extracutaneous (usually nodal) B-cell lymphomas
- Most primary cutaneous B-cell lymphomas (>80%) are low-grade malignancies, and they are characterized by indolent behavior and a good prognosis
- The widespread use of immunohistochemical and molecular genetic techniques has shown that many of the cases previously classified as cutaneous B-cell pseudolymphomas actually represent low-grade malignant B-cell lymphomas of the skin
- Precise classification can be achieved only after a complete synthesis of clinical, histopathologic, immunophenotypic and molecular features. The WHO-EORTC and new WHO classifications provide the basis for a consistent classification of patients
- Treatment options for low-grade types include primarily "watchful waiting" and local radiotherapy; when solitary lesions are present, surgical excision is an option. Systemic or intralesional anti-CD20 antibody may be used in some patients, while systemic chemotherapy is usually required in only a small proportion of patients with high-grade tumors

INTRODUCTION

Although B-cell lymphomas represent the majority of non-Hodgkin lymphomas arising within lymph nodes, they represent only a minority of the non-Hodgkin lymphomas whose primary site is the skin. In the classification of cutaneous lymphomas published by the World Health Organization (WHO) and the European Organization for Research and Treatment of Cancer (EORTC) Cutaneous Lymphoma Project Group (Table 119.1), B-cell lymphomas represented 22.5% of all cutaneous lymphomas[1]. A similar figure was derived from a large series of patients observed in Graz between 1960 and 1999, in which B-cell lymphomas represented 26.4% of all cases of primary cutaneous lymphoma[2]. The WHO-EORTC classification has been integrated with only minor changes into the new WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues published in 2008 (see Table 119.1)[3].

Primary cutaneous lymphomas are defined as *malignant lymphomas confined to the skin at presentation after complete staging procedures*[1,4]. In general, most patients with primary cutaneous B-cell lymphoma are diagnosed by dermatologists, as extracutaneous symptoms and signs are observed only very rarely at the onset of the disease. Consequently, dermatologists should be conversant with the clinicopathologic features of this group of diseases, in order to be able to establish the diagnosis in its early stages. Additionally, as aggressive treatment modalities are needed only in selected cases, these patients should be managed primarily in dermatology departments with special expertise in cutaneous lymphomas.

HISTORY

In the past, cutaneous B-cell lymphomas were thought to be invariably secondary, that is, due to dissemination of extracutaneous (usually nodal) B-cell lymphomas to the skin. In recent years, it was recognized that B-cell lymphomas whose primary site is the skin, i.e. primary cutaneous B-cell lymphomas (pCBCLs), represent a distinct and very important group of extranodal lymphomas[4]. The widespread use of immunohistochemical and molecular genetic techniques that can establish clonality has shown that many of the cases previously classified as cutaneous B-cell pseudolymphomas actually represent low-grade malignant B-cell lymphomas of the skin[4,5].

The WHO-EORTC and WHO 2008 classification schemes provide a valid basis for a uniform classification of pCBCLs and should be used consistently, in order to allow comparison of data amongst different centers.

EPIDEMIOLOGY

Although reports of single cases or small series of pCBCL have been published from around the world, there are only a few studies of large series of patients. Consequently, epidemiologic data are still fragmentary and are based primarily on the experience of two major centers in the Netherlands and Austria[1,2].

pCBCLs may occur more frequently in specific regions of the world. For example, analysis of data from four academic centers in the US showed that they represented only 4.5% of all the cases of primary cutaneous lymphoma registered in those centers[6]. In contrast, pCBCL represented 22.5% of all the cases of primary cutaneous lymphoma in the Dutch and Austrian registries for cutaneous lymphomas[1].

Regional variations have also been observed with regard to the incidence of specific types of pCBCL. In the two largest series published to date, the relative frequencies of follicle center lymphoma and marginal zone lymphoma varied considerably. For example, follicle center lymphoma represented 71% of all pCBCLs in the Netherlands, but only 41% in Graz; conversely, marginal zone lymphoma represented 42% of all cases of pCBCL in Graz, but only 10% in the Netherlands. On the other hand, the relative frequency of the third most common type of pCBCL, the diffuse large B-cell lymphoma, leg type, was similar in the two series (~15%), indicating that, in these two series, differences in the relative frequencies were confined to B-cell lymphomas characterized by an indolent behavior. This suggests that these variations may be due, at least in part, to a different classification of patients in different centers.

Although variations in the relative frequency of pCBCLs, and of specific subtypes, may be explained by differences in diagnostic and classification standards, true regional variations in the incidence of special types of pCBCL may be due to the presence of different etiologic factors. For example, the association between pCBCL and infection with specific *Borrelia* species in endemic areas has been known for many years (see Ch. 74). This association may explain, in part, regional differences in the incidence of pCBCLs, but the relatively low percentage of such cases (even in countries with endemic *Borrelia* infections) suggests that other etiologies are also involved in regional variations.

pCBCL affects adults of both sexes. In a study of 147 patients, there was a slight predominance of men (male : female = 1.1 : 1)[2]. With the exception of precursor B lymphoblastic lymphoma/leukemia (which

only rarely represents an example of true pCBCL), only a few cases have been observed in patients less than 20 years of age.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of pCBCL is unknown. In contrast to the many nodal B-cell lymphomas that have been linked to specific genetic alterations (e.g. nodal follicular lymphomas and interchromosomal 14;18 translocations), there are relatively limited data on the specific genetic features of pCBCLs, especially for low-grade subtypes (for details see below).

Some similarities to the clinicopathologic features observed in B-cell lymphomas arising in the gastric mucosa (so-called *mucosa-associated lymphoid tissue* [MALT] lymphomas) led to the hypothesis that pCBCLs are caused by longstanding antigenic stimulation, possibly due to chronic infection with specific microorganisms. In fact, it has been long established that MALT lymphomas originating in the stomach are linked to chronic antigenic stimulation due to infection with *Helicobacter pylori*. As previously mentioned, *Borrelia* spp. are thought to play a role in the etiology of a minority of cases of pCBCL, particularly in Europe. In patients from a region in Austria with endemic *Borrelia* infections, specific DNA sequences of *Borrelia* were detected in 18% of all cases of pCBCL[7]; similar findings have been reported from Scotland[8].

At present, no other microorganism has been convincingly linked to the development of pCBCL. However, it should be noted that pCBCLs have been described in patients with AIDS, and reversible pCBCLs have been observed in patients undergoing therapy with methotrexate (in particular those with rheumatoid arthritis), thus suggesting that immune dysregulation may play a role in the development of this disease[9,10].

CLINICAL FEATURES

In the WHO-EORTC 2005 classification scheme, pCBCLs have been divided into four major types (see Table 119.1)[1]; these subtypes are also included in the WHO 2008 classification scheme. Follicle center lymphoma and marginal zone B-cell lymphoma are characterized by an indolent clinical behavior, whereas diffuse large B-cell lymphoma, leg type, and intravascular diffuse large B-cell lymphoma have a more aggressive clinical behavior. It must be emphasized that, in addition to pCBCLs, the skin can be a site of secondary involvement for practically all types of extracutaneous (usually nodal) B-cell lymphomas and leukemias. Consequently, complete staging must be performed in all patients with a confirmed diagnosis of B-cell lymphoma involving the skin. This includes a complete blood examination, flow cytometry of peripheral blood, and CT examination of the chest, abdomen and pelvis. Gallium scans have been replaced by positron emission tomography (PET). Bone marrow biopsy (with flow cytometry of the aspirate) is recommended in follicle center lymphoma, diffuse large B-cell lymphoma, leg type, and intravascular diffuse large B-cell lymphoma, but seems to be of limited value in cutaneous marginal zone lymphoma[11].

In the following two sections, the clinicopathologic features of the main types of pCBCL will be discussed. In addition, the cutaneous manifestations of precursor B lymphoblastic lymphoma/leukemia will be presented.

Primary Cutaneous Follicle Center Lymphoma

*P*rimary *c*utaneous *f*ollicle *c*enter *l*ymphoma (PCFCL) is defined as a neoplastic proliferation of germinal center cells confined to the skin. It represents a common subtype of pCBCL.

Clinically, patients present with solitary or grouped, pink- to plum-colored papules, plaques or tumors, which, especially on the trunk, can be surrounded by patches of erythema (Figs 119.1 & 119.2). Ulceration is uncommon. Preferential locations are the scalp and forehead or the back. In the past, lesions located on the back were referred to as Crosti's lymphoma or reticulohistiocytoma of the dorsum[12]. The skin lesions are usually asymptomatic, and, as a rule, symptoms are rare. The serum level of lactate dehydrogenase (LDH), which is a powerful prognostic factor in systemic lymphomas, is within normal limits.

The prognosis is favorable[1,13,14]. Recurrences are observed in up to 50% of patients, but dissemination to lymph nodes or internal organs is rare.

Primary Cutaneous Marginal Zone B-Cell Lymphoma

*P*rimary *c*utaneous *m*arginal *z*one B-cell *l*ymphoma (PCMZL) has been recognized as a distinct variant of low-grade malignant pCBCL[5,15]. In the WHO classification of 2008[3], it has been grouped with other extranodal marginal zone lymphomas of *m*ucosa-*a*ssociated *l*ymphoid *t*issue

Fig. 119.1 Cutaneous follicle center lymphoma. Large ulcerated tumors on the scalp surrounded by infiltrated erythematous nodules and plaques.

Fig. 119.2 Cutaneous follicle center lymphoma. Large ulcerated tumor on the back. Note surrounding erythematous papules, patches and plaques (Crosti's lymphoma).

(i.e. MALT lymphomas). Of note, cases classified in the past as *primary cutaneous immunocytoma* or *primary cutaneous plasmacytoma* represent examples of PCMZL with prominent lymphoplasmacytic or plasmacytic differentiation, respectively, and the terms cutaneous immunocytoma and cutaneous plasmacytoma are not used in the WHO-EORTC and WHO 2008 classification schemes[1,3].

Clinically, patients present with recurrent pink–violet to red–brown papules, plaques and nodules localized preferentially on the extremities (upper more so than lower) or trunk (Figs 119.3 & 119.4). Generalized lesions can be observed in a small number of patients. Ulceration rarely, if ever, occurs and skin lesions are usually asymptomatic. As a rule, systemic signs and symptoms, such as fever, night sweats, weight loss and malaise (B-symptoms), are not present. The serum level of LDH is within normal limits. In some instances, resolution of lesions may be accompanied by secondary anetoderma due to loss of elastic fibers in the area of the tumor infiltrate.

The prognosis of PCMZL is excellent. In a study of 32 patients with PCMZL, none of them developed lymph node or internal involvement during a mean follow-up of more than 4 years[5].

Fig. 119.3 Cutaneous marginal zone B-cell lymphoma. Two well-circumscribed, erythematous nodules on the shoulder.

Fig. 119.4 Cutaneous marginal zone B-cell lymphoma. Dome-shaped erythematous nodule with smooth surface. The surrounding area shows features of acrodermatitis chronica atrophicans. This tumor, which demonstrated prominent lymphoplasmacytic differentiation histologically, was classified as cutaneous immunocytoma in the past.

Of note, PCMZL can arise in areas affected by acrodermatitis chronica atrophicans (see Fig. 119.4), and it may be linked to infection by *Borrelia* spp. more frequently than are other types of pCBCL, particularly in Europe[7].

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

Primary cutaneous *d*iffuse *l*arge *B-c*ell *l*ymphoma, *l*eg *t*ype (DLBCLLT), represents a form of pCBCL that is characterized by a predominance of large round cells (centroblasts, immunoblasts) positive for Bcl-2, MUM1 (*mu*ltiple *m*yeloma oncogene *1* or interferon regulatory factor 4 [expressed by germinal center B cells and plasma cells]) and FOX-P1[1]. It has an intermediate prognosis and occurs almost exclusively in elderly patients, predominantly women[16].

Clinically, patients present with solitary or clustered erythematous to red–brown nodules, located primarily on the distal aspect of one leg (Fig. 119.5). In some patients, lesions may arise on both lower extremities contemporaneously or within a short interval of time. Ulceration may occur. Small erythematous papules can be seen adjacent to larger nodules. It must be emphasized that in approximately 20% of patients, tumors with similar morphologic and phenotypic features can arise in areas other than the lower extremities[17].

The prognosis of DLBCLLT is less favorable than that of other types of pCBCL, with a 5-year survival rate of approximately 50%[1,2]. In the past, the prognosis of cutaneous diffuse large B-cell lymphomas had been linked to several factors, including Bcl-2 expression, morphology of the cells, number of lesions at presentation, and location on the legs[18,19]. A large study, however, demonstrated that accurate classification based upon the WHO-EORTC categories was the single most important prognostic criterion, and other features were of little or no relevance when patients were stratified into these specific categories[17]. Recent data revealed that 9p21 deletions, possibly due to loss of function of *CDKN2A* (encodes p16 and $p14^{ARF}$), are associated with a worse prognosis[20,21].

It must be stressed that some patients with nodal large B-cell lymphoma can present with secondary cutaneous lesions located exclusively on the legs, underlying the need for complete staging investigations before a diagnosis of DLBCLLT can be established. The addition of PET scans to CT studies is a useful way of discovering evidence of systemic disease.

Intravascular Diffuse Large B-Cell Lymphoma

*I*ntra*v*ascular *d*iffuse *l*arge *B-c*ell *l*ymphoma (IVDLBCL) is a malignant proliferation of large B lymphocytes within blood vessels[22]. Most patients have a B-cell phenotype, but a T-cell variant has been reported. In occasional patients, the skin may be the only affected site, although more often there is systemic involvement (including the CNS) from the

Fig. 119.5 Cutaneous diffuse large B-cell lymphoma, leg type. Multiple red–brown papulonodules and tumor on the lower leg.

onset. Clinically, patients present with indurated, erythematous or violaceous patches and plaques, preferentially located on the trunk and thighs. The clinical appearance is not typical of cutaneous lymphoma, and it may sometimes suggest a diagnosis of panniculitis or vascular tumors. Interestingly, IVDLBCL has been observed to be confined to cherry angioma lesions[23]. The prognosis of IVDLBCL limited to the skin has been reported to be better than that of the systemic (disseminated) form, but only a limited number of cases have been studied.

Precursor B Lymphoblastic Lymphoma/Leukemia

B-cell lymphoblastic lymphomas/leukemias are malignant proliferations of precursor B lymphocytes. Reports of patients whose primary site is the skin have been rare. It should be emphasized, however, that all patients should be assumed to have, and treated for, systemic disease, even in the absence of documented systemic involvement at the time of presentation.

In contrast to the other cutaneous B-cell lymphomas, this disease shows a clearcut predilection for children and young adults[24,25]. Clinically, patients present with solitary large erythematous tumors, commonly located on the head (Fig. 119.6) and neck. Patients with primary skin disease often have asymptomatic lesions of a few weeks' duration. Those with secondary skin lesions may have systemic symptoms (e.g. weight loss, fever, fatigue, malaise, night sweats). The serum level of LDH is often elevated, reflecting the aggressive and often systemic nature of the disease. The disease is highly aggressive, and the prognosis of untreated patients is poor.

Other Cutaneous B-Cell Lymphomas

Rare cases of pCBCL do not fit within the subtypes reviewed above. They are therefore placed in the category of primary cutaneous large B-cell lymphoma, other (WHO-EORTC classification)[1]. In the new WHO 2008 classification, these patients are divided amongst several categories, including (but not limited to) large B-cell lymphomas arising in the setting of immune suppression, EBV-associated diffuse large B-cell lymphoma of the elderly, and diffuse large B-cell lymphoma, NOS[3].

Plasmablastic lymphoma is a rare lymphoma that usually arises within the oral cavity in patients with severe immunosuppression, especially HIV-related. It is often associated with infection by human herpesvirus-8 (HHV-8) and EBV. EBV-associated diffuse large B-cell lymphoma of the elderly is an aggressive large B-cell lymphoma occurring in patients >50 years of age[26]. The disease is commonly extranodal, including the skin as the primary site, but prognosis is poor irrespective of the primary site.

Fig. 119.6 Precursor B lymphoblastic lymphoma/leukemia. Large erythematous tumor on the face of a small child.

PATHOLOGY

Primary Cutaneous Follicle Center Lymphoma

In PCFCL, nodular or diffuse infiltrates are seen within the entire dermis, often extending into the subcutaneous fat (Fig. 119.7A)[3]. The epidermis is usually spared. A clearcut follicular pattern with formation of neoplastic germinal centers was observed in only a minority of cases (25%) in the series from Graz[2,13]. However, a higher percentage of cases may show at least some follicular architecture. In those with a follicular pattern, the neoplastic follicles show morphologic features of malignancy, including the presence of a reduced or absent mantle zone, the lack of tingible body macrophages, and a monomorphism of the follicles – so-called "dark" and "clear" areas are no longer recognizable (Fig. 119.8)[13].

In both the follicular and diffuse variants, centroblasts (large, noncleaved follicle center cells with prominent nucleoli) and centrocytes (small to large, cleaved follicle center cells) predominate within the neoplastic infiltrate, admixed with a variable number of immunoblasts, small lymphocytes, histiocytes, and, in some cases, eosinophils and plasma cells (see Fig. 119.7B). On a cytomorphologic basis, some cases of PCFCL with a diffuse pattern of growth have the appearance of a large cell lymphoma, but the prognosis of these cases is similar to that of lesions without the large cell morphology[1,17]. An accompanying infiltrate of small T lymphocytes and histiocytes/macrophages is usually present, and, in some instances, these cells can be predominant.

In addition to cases characterized by numerous large cells, other morphologic variants of PCFCL include those with a predominant

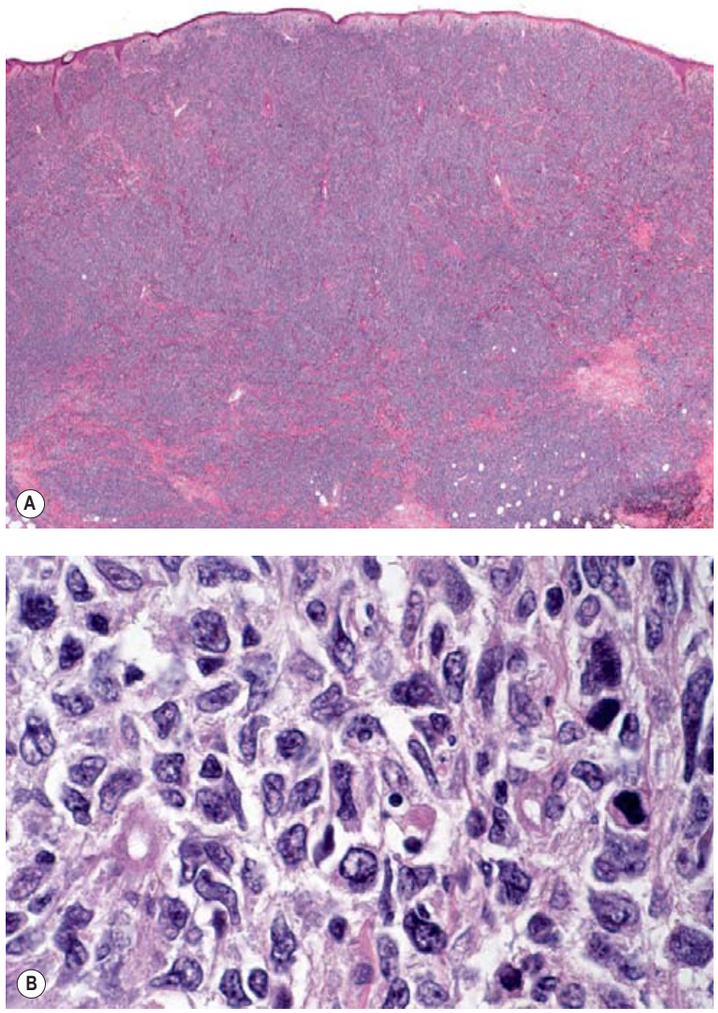

Fig. 119.7 Cutaneous follicle center lymphoma, diffuse type. A Diffuse infiltrate without follicular pattern. **B** Centroblasts and medium- and large-sized centrocytes (cleaved cells) predominate.

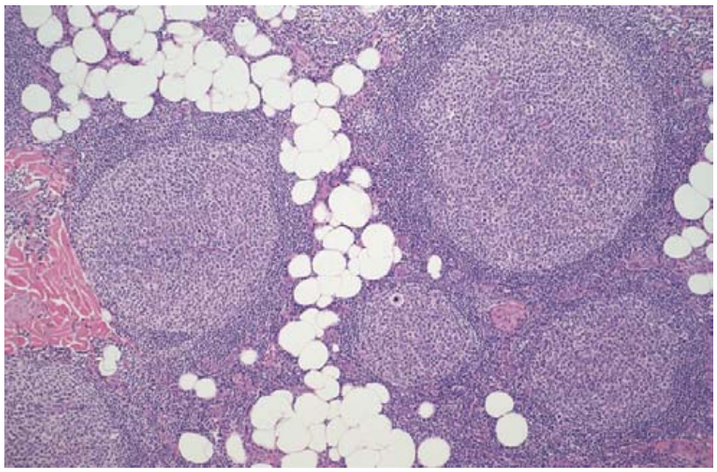

Fig. 119.8 Cutaneous follicle center lymphoma, follicular type. Neoplastic follicles with monomorphous morphology.

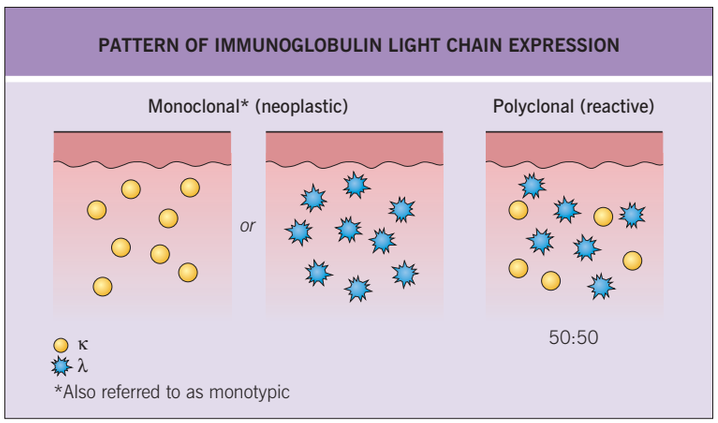

Fig. 119.9 Pattern of immunoglobulin light chain expression.

spindle cell morphology, which can simulate sarcomas or other spindle cell tumors histopathologically, thus representing a diagnostic pitfall[27]. Lesions in which a few B-cell blasts are admixed with numerous T lymphocytes have been classified as "T-cell/histiocyte-rich B-cell lymphomas", and in the skin probably represent another rare morphologic variant of PCFCL[3].

The tumor cells express monotypic surface immunoglobulins (e.g. all the neoplastic cells stain positively for either κ or λ light chains; Fig. 119.9) as well as B-cell-associated antigens (CD20, CD79a); they are $CD5^-$ and $CD43^-$ (see Table 0.11 for the specificities of CD markers). When follicles are present, they are characterized by an irregular network of $CD21^+$ follicular dendritic cells. Bcl-6 (a marker of germinal center cells and other blastic cells) is positive in virtually all cases, irrespective of the pattern of growth. In all cases with a follicular growth pattern, and in a minority of those with a diffuse growth pattern, neoplastic cells also stain positively for CD10. The presence of small clusters of $Bcl\text{-}6^+$ cells outside the follicles is considered strongly suggestive of a diagnosis of PCFCL[13].

In the overwhelming majority of cases, staining for the protein product of *bcl-2* (Bcl-2) yields negative results, representing a major difference from follicular lymphomas arising within lymph nodes[28]. A useful, though somewhat counterintuitive, distinguishing immunohistochemical feature is the *lower* degree of proliferative activity within *malignant* follicles as detected by the MIB-1 antibody (which detects the Ki-67 antigen expressed by proliferating cells), in contrast to the strong MIB-1-positivity in *reactive* follicles[13,29]. In cases with large cell morphology (predominance of large cleaved cells), immunohistochemical staining for MUM1 is usually either negative or is positive in a minority of neoplastic cells (in contrast to strong expression of MUM1 by DLBCLLT; see below)[1,17].

The interchromosomal 14;18 translocation, typically found in *nodal* follicular lymphomas, is present in a minority of PCFCLs[28]. Therefore, the presence of the 14;18 translocation and/or expression of Bcl-2 should raise suspicion that the patient has a systemic lymphoma involving the skin. Analysis of the genes that encode the joining segment (J_H) and other regions of the immunoglobulin heavy chain (IGH) reveals the presence of a monoclonal rearrangement in the majority of patients (60–70%). In cases of PCFCL with a follicular growth pattern, monoclonality of the follicular structures has been proven by PCR analysis of J_H gene rearrangements after microdissection of the follicular cells[15]. When gene expression in PCFCLs was analyzed via cDNA microarrays, a germinal center cell signature pattern was observed.

Analysis of morphologic, immunohistochemical and molecular data suggests that follicular lymphomas originating in the lymph nodes and the skin, although characterized by a similar morphologic pattern, have different pathogenic mechanisms.

Primary Cutaneous Marginal Zone B-Cell Lymphoma (Extranodal Marginal Zone Lymphoma of the Mucosa-Associated Lymphoid Tissue – MALT Lymphoma)

Histology of PCMZL shows a patchy, nodular or diffuse infiltrate involving the dermis and subcutaneous fat. The epidermis is spared. A characteristic pattern can be observed at scanning magnification: nodular infiltrates (sometimes containing reactive germinal centers) are surrounded by a pale-staining population of small- to medium-sized cells with indented nuclei, inconspicuous nucleoli and abundant pale cytoplasm (Fig. 119.10A) – variously described as marginal zone cells, centrocyte-like cells or monocytoid B cells (Fig. 119.11A)[3,5]. In addition, plasma cells (at the margins of the infiltrate), lymphoplasmacytoid cells, small lymphocytes and occasional large blasts are observed. Eosinophils are also a common finding. In some patients, there may be a granulomatous reaction with epithelioid and giant cells. Cases with a predominance of lymphoplasmacytoid lymphocytes were once classified as cutaneous immunocytomas[30], but are now considered variants of PCMZL. PAS-positive intranuclear inclusions (Dutcher bodies) are sometimes observed and represent a valuable clue to the diagnosis (Fig. 119.11B). Occasionally, the predominant cell type is a plasma cell (Fig. 119.11C), and although such cases used to be classified as primary cutaneous plasmacytomas, they are now also considered to be variants of PCMZL[1].

The centrocyte-like cells stain positively for CD20, CD79a and Bcl-2, and they are negative for CD5, CD10 and Bcl-6. In the overwhelming majority of cases, intracytoplasmic monotypic expression of immunoglobulin light chains (either κ or λ, but not both) can be observed (see Fig. 119.9). The monoclonal population of B lymphocytes is often characteristically arranged at the periphery of the cellular aggregates (Fig. 119.10B). Staining for proliferation markers also shows increased positivity at the periphery of the nodules (Fig. 119.10C). Monoclonal rearrangement of the *IGH* genes can be observed in the majority of cases (60–80%).

PCMZLs express class-switched immunoglobulins[31] (class-switching allows a B lymphocyte to change antibody production from one class to another, e.g. from an IgG to an IgM isotype; after class-switching, the cell retains affinity for the same antigen, but can interact with different effector molecules) and are characterized by aberrant somatic hypermutations[32]. A particular translocation, t(14;18)(q32;21), that involves the *IGH* and *MALT1* genes has been detected recently in a subset of PCMZL as well as MALT lymphomas arising in organs other than the skin. In gene expression studies utilizing cDNA microarrays, PCMZLs had a plasma cell signature pattern. Other genetic aberrations include trisomy 3 and rarely an 11;18 or a 3;14 translocation. However, in more than 50% of patients, no molecular abnormalities have been found.

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

In DLBCLLT, a dense diffuse infiltrate is seen within the dermis and subcutis. The infiltrate usually involves the entire papillary dermis

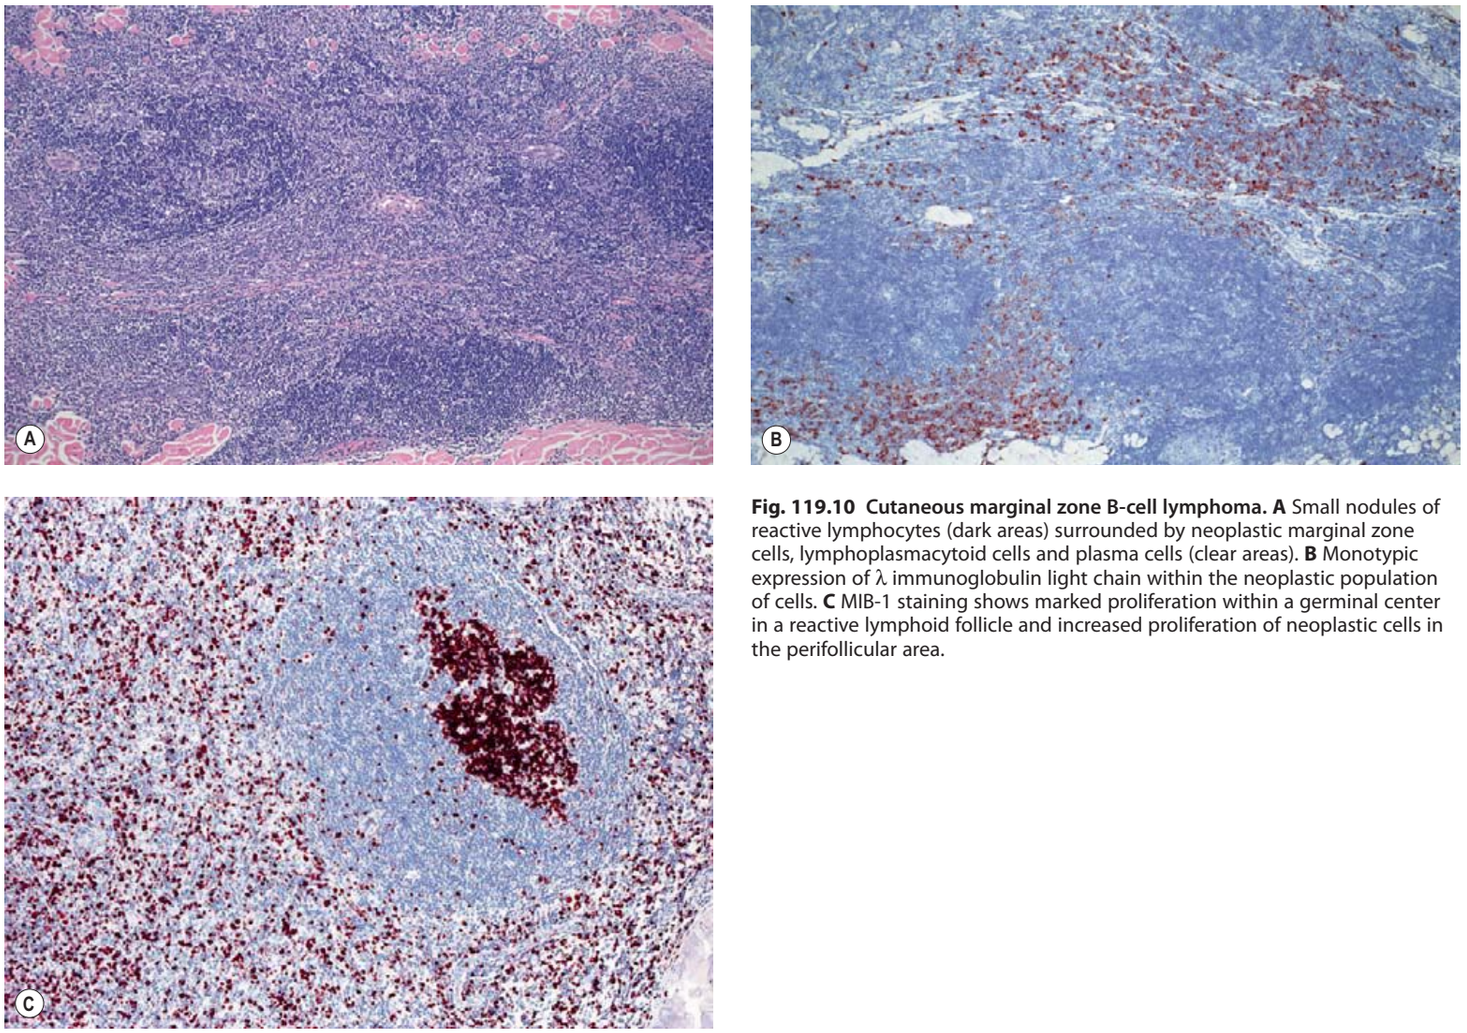

Fig. 119.10 Cutaneous marginal zone B-cell lymphoma. A Small nodules of reactive lymphocytes (dark areas) surrounded by neoplastic marginal zone cells, lymphoplasmacytoid cells and plasma cells (clear areas). **B** Monotypic expression of λ immunoglobulin light chain within the neoplastic population of cells. **C** MIB-1 staining shows marked proliferation within a germinal center in a reactive lymphoid follicle and increased proliferation of neoplastic cells in the perifollicular area.

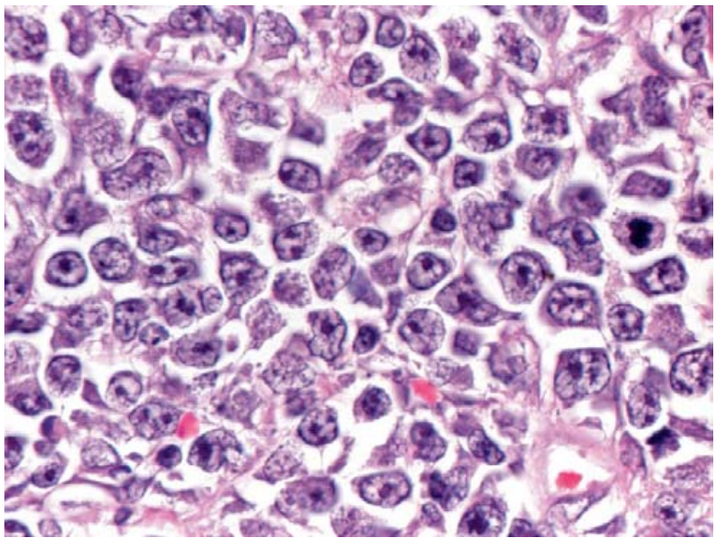

Fig. 119.12 Cutaneous diffuse large B-cell lymphoma, leg type. Large cells with a round morphology (mainly immunoblasts) predominate.

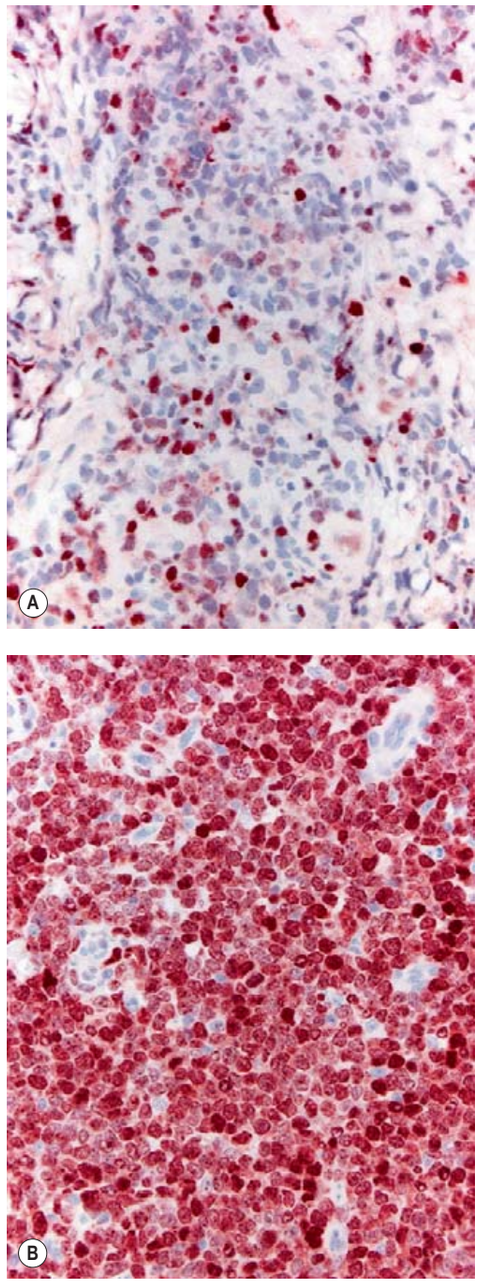

Fig. 119.13 Immunohistochemical staining with the anti-MUM1 antibody. **A** Only a minority of cells are positive in primary cutaneous follicle center lymphoma, diffuse type. **B** Virtually all tumor cells are positive in primary cutaneous diffuse large B-cell lymphoma, leg type.

extending to the dermal–epidermal junction. Involvement of the epidermis by clusters of large atypical cells, simulating the Pautrier's microabscesses found in cutaneous T-cell lymphoma, can be observed in some cases (B-cell epidermotropism), representing a potential diagnostic pitfall[3]. The neoplastic infiltrate consists predominantly of immunoblasts (large round cells with abundant cytoplasm and prominent nucleoli) and centroblasts (Fig. 119.12). Of note, cases of diffuse large B-cell lymphoma with a predominance of large cleaved cells are classified among the PCFCLs[1]. Reactive small lymphocytes are few or absent, and mitoses are frequent. Based on the common finding of immunoglobulin gene hypermutations, it has been proposed that most cases of DLBCLLT represent large cell lymphomas originating from lymphocytes of the germinal center.

Neoplastic cells express monoclonal surface immunoglobulins and/or cytoplasmic immunoglobulins. They are positive for B-cell markers (CD20, CD79a), but there can be (partial) loss of antigen expression. MUM1 (see above) and FOX-P1 are strongly expressed by neoplastic cells in most patients[1,17]. These markers are useful in the differential diagnosis of DLBCLLT from PCFCL, diffuse type; in the latter, MUM1 and FOX-P1 are usually either negative or expressed by a small minority of cells (Fig. 119.13). The tumors demonstrate monoclonal rearrangement of the *IGH* genes. The interchromosomal 14;18 translocation is not present. Staining for Bcl-2 is positive in all patients with primary cutaneous DLBCLLT, and an algorithmic approach to the diagnosis of cutaneous diffuse large B-cell lymphomas is provided in Figure 119.14.

Rare cases of otherwise typical cutaneous DLBCLLT show expression of CD30 by neoplastic cells[17]. In contrast to cutaneous T-cell lymphomas, prognosis in large B-cell lymphomas (both cutaneous and extracutaneous) is not related to CD30 expression. Hypermethylation of the genes that encode p15 and/or p16 (*CDKN2B*, *CDKN2A*), resulting in decreased expression of these proteins, has been observed in some patients. 9p21 deletions, possibly due to loss of function of *CDKN2A*, are associated with a worse prognosis[21]. However, 9p21 deletions may not be detected by some of the standard fluorescent *in situ* hybridization (FISH) probes[33].

Genetic data obtained by FISH or microarray chip technologies have confirmed that DLBCLLTs show clear molecular differences from PCFCL, diffuse type, confirming the need of classifying these cases separately[34,35]. Some of the aberrations found in DLBCLLT are similar to those observed in diffuse large B-cell lymphomas of the lymph nodes.

Intravascular Diffuse Large B-Cell Lymphoma

IVDLBCL is characterized by a proliferation of large atypical lymphocytes that fills dilated blood vessels within the dermis and subcutaneous tissues (Fig. 119.15A). The malignant cells are large with scanty cytoplasm and often have prominent nucleoli. They are positive for B-cell-associated markers (Fig. 119.15B) as well as for Bcl-2, MUM1 and FOX-P1. Staining with endothelial cell-related antibodies (e.g. CD31, CD34) highlights the characteristic intravascular location of the cells (Fig. 119.15C). Molecular analysis shows monoclonal rearrangement of the *IGH* genes.

Precursor B Lymphoblastic Lymphoma/Leukemia

Histologically, precursor B lymphoblastic lymphoma/leukemia shows a monomorphous proliferation of medium-sized cells with scanty cytoplasm and round or convoluted nuclei with fine chromatin (Fig. 119.16). A "starry sky" pattern is commonly seen at low power, due to the presence of macrophages with inclusion bodies ("tingible bodies"). Another characteristic feature is the arrangement of neoplastic cells in a "mosaic-stone" pattern. Mitoses and necrotic cells are abundant. It must be stressed that histologic features alone do not allow differentiation of lymphoblastic lymphomas of B-cell phenotype from those of T-cell

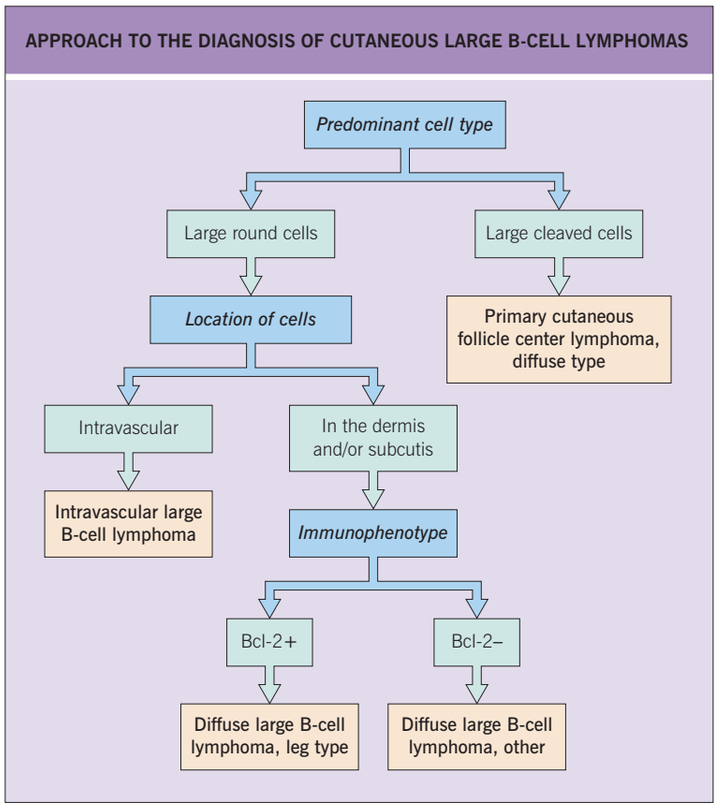

Fig. 119.14 Approach to the diagnosis of cutaneous large B-cell lymphomas. In most patients with primary cutaneous diffuse large B-cell lymphoma, leg type, the neoplastic cells strongly express MUM1 and FOX-P1, whereas in primary cutaneous follicle center lymphoma, diffuse type, these stains are usually either negative or expressed by a small minority of cells.

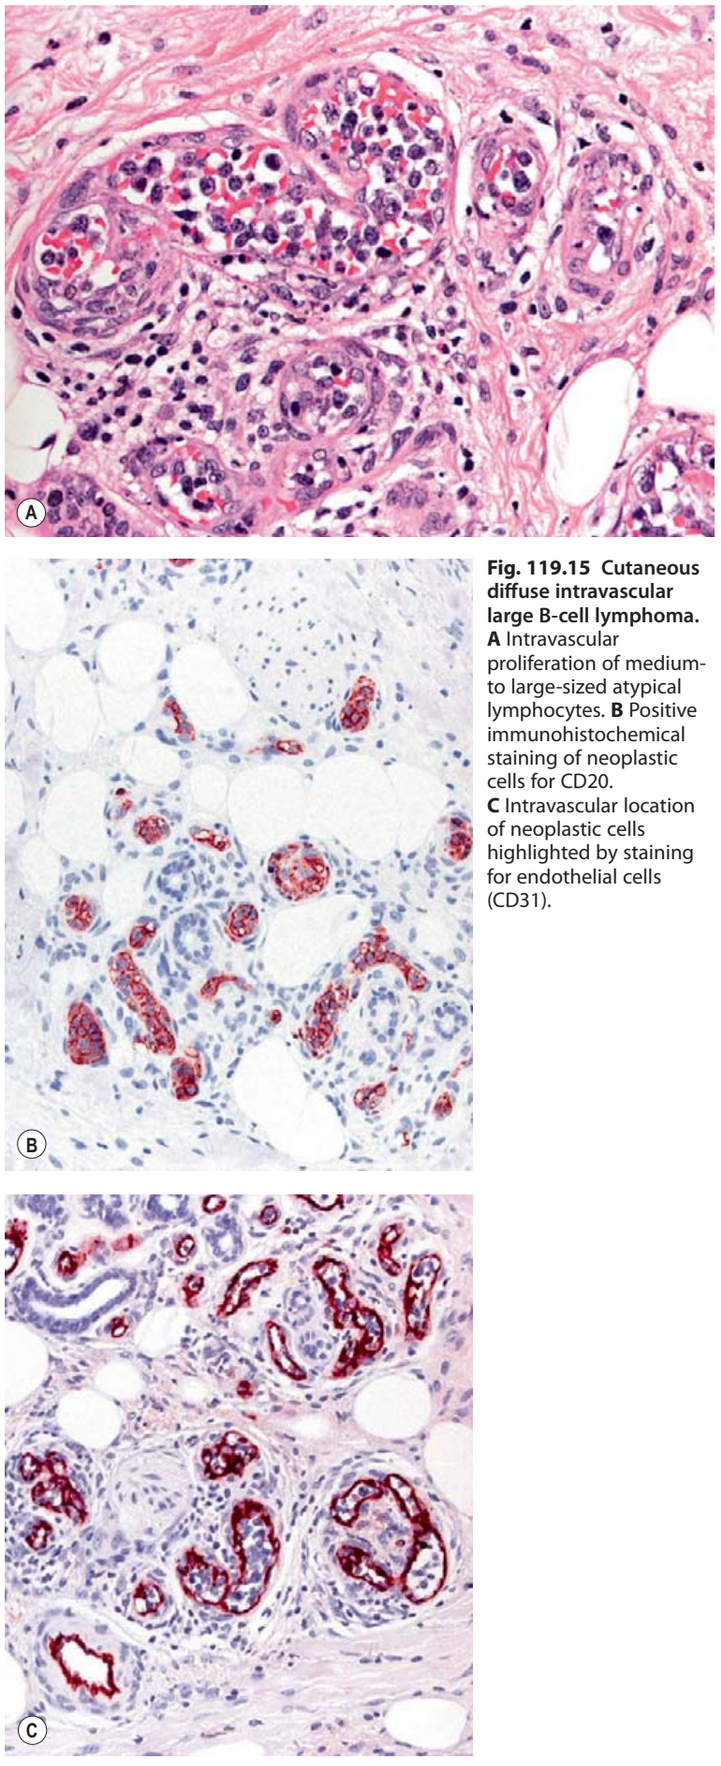

Fig. 119.15 Cutaneous diffuse intravascular large B-cell lymphoma. **A** Intravascular proliferation of medium- to large-sized atypical lymphocytes. **B** Positive immunohistochemical staining of neoplastic cells for CD20. **C** Intravascular location of neoplastic cells highlighted by staining for endothelial cells (CD31).

lineage. Immunohistology demonstrates positive staining for TdT (terminal deoxynucleotidyl transferase; present on precursor T and B cells), CD10 and the cytoplasmic μ-chain of immunoglobulins and, in most cases, CD20 and CD79a. CD20 is negative in the pre-pre-B-cell variant, which is $CD34^+$. Molecular analyses usually show a monoclonal rearrangement of the *IGH* genes and a polyclonal pattern for the T-cell receptor (*TCR*) genes, but a lack of rearrangement of the *IGH* genes or monoclonal rearrangement of both the *TCR* and *IGH* genes may be observed.

Other Cutaneous B-Cell Lymphomas

Plasmablastic lymphoma is characterized by a proliferation of plasmablasts with large eccentric nuclei, abundant cytoplasm and prominent nucleoli. The neoplastic cells are positive for CD38 and CD138, and they express monotypic immunoglobulin light chains.

Cutaneous EBV-associated diffuse large B-cell lymphoma of the elderly is characterized by a predominance of large rounded B cells. In contrast to DLBCLLT, these lesions may show loss of CD20 expression, thus representing a potential diagnostic pitfall. CD79a is usually positive on neoplastic cells, as well as MUM1. Detection of EBV by *in situ* hybridization is a prerequisite for the diagnosis.

DIFFERENTIAL DIAGNOSIS

Differential diagnoses of pCBCLs vary according to the type of lymphoma and include primarily inflammatory processes that may simulate malignant lymphomas either clinically, histopathologically, or both (cutaneous lymphoid hyperplasia or "pseudolymphoma"; see Ch. 121). It must be emphasized that a definitive diagnosis of pCBCL can be reached only after careful examination of the clinical, histopathologic, immunophenotypic and molecular features; in some cases, only

repeated examination of the patient and sequential biopsy specimens will allow the correct classification[3,29]. A schematic diagram with examples of the use of immunohistochemical stains and PCR in the differential diagnosis of pCBCLs is presented in Figure 119.17.

Patients for whom no definitive diagnosis can be established at the time of presentation should provisionally be classified as having "cutaneous atypical lymphoid proliferation of B-cell lineage", and they should be re-examined at regular intervals[3]. A complete staging investigation does not belong in the diagnostic evaluation of these patients; that is, patients without a definitive diagnosis of cutaneous B-cell lymphoma should not be screened for extracutaneous disease until the diagnosis is established with certainty[3]. In contrast, once the diagnosis of cutaneous B-cell lymphoma has been established, complete staging is mandatory, as clinicopathologic features alone do not allow the differentiation of primary from secondary cutaneous B-cell lymphomas. A diagnostic algorithm for evaluation of patients at first presentation is provided in Figure 119.18. In the following section, the major differential diagnoses of each of the main types of pCBCL are outlined separately, as they differ according to the lymphoma type.

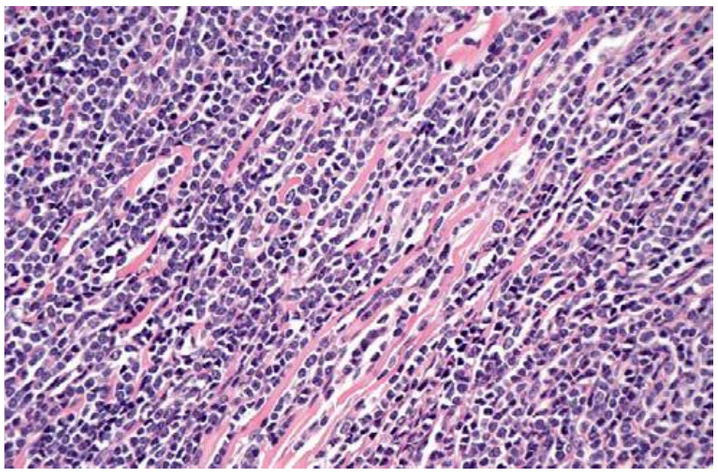

Fig. 119.16 Precursor B lymphoblastic lymphoma/leukemia. Medium-sized blasts with the characteristic "mosaic-stone" linear arrangement.

PCFCL with a follicular pattern of growth should be differentiated from B-cell pseudolymphomas with prominent germinal centers, such as *Borrelia*-induced lymphocytoma cutis (cutaneous lymphoid hyperplasia)[13,36]. Lymphocytoma cutis often occurs in children, and it shows a predilection for particular body sites such as the earlobes, nipples and scrotum[36]. Clinically, lesions are usually solitary and relatively small. Although histologically a follicular pattern is almost always observed, germinal centers in lymphocytoma cutis are reactive, and they are accompanied by inflammatory infiltrates with small lymphocytes, plasma cells and often eosinophils[3,36]. The germinal centers in *Borrelia*-induced lymphocytoma cutis are often devoid of a clearcut mantle, but they are characterized by the presence of: many tingible body macrophages, "clear" and "dark" areas, and a normal (high) proliferation rate[36].

Rare cases of cutaneous PCMZL can have a prominent presence of reactive germinal centers, and they should be differentiated from the follicular type of PCFCL. In these cases, so-called follicular colonization

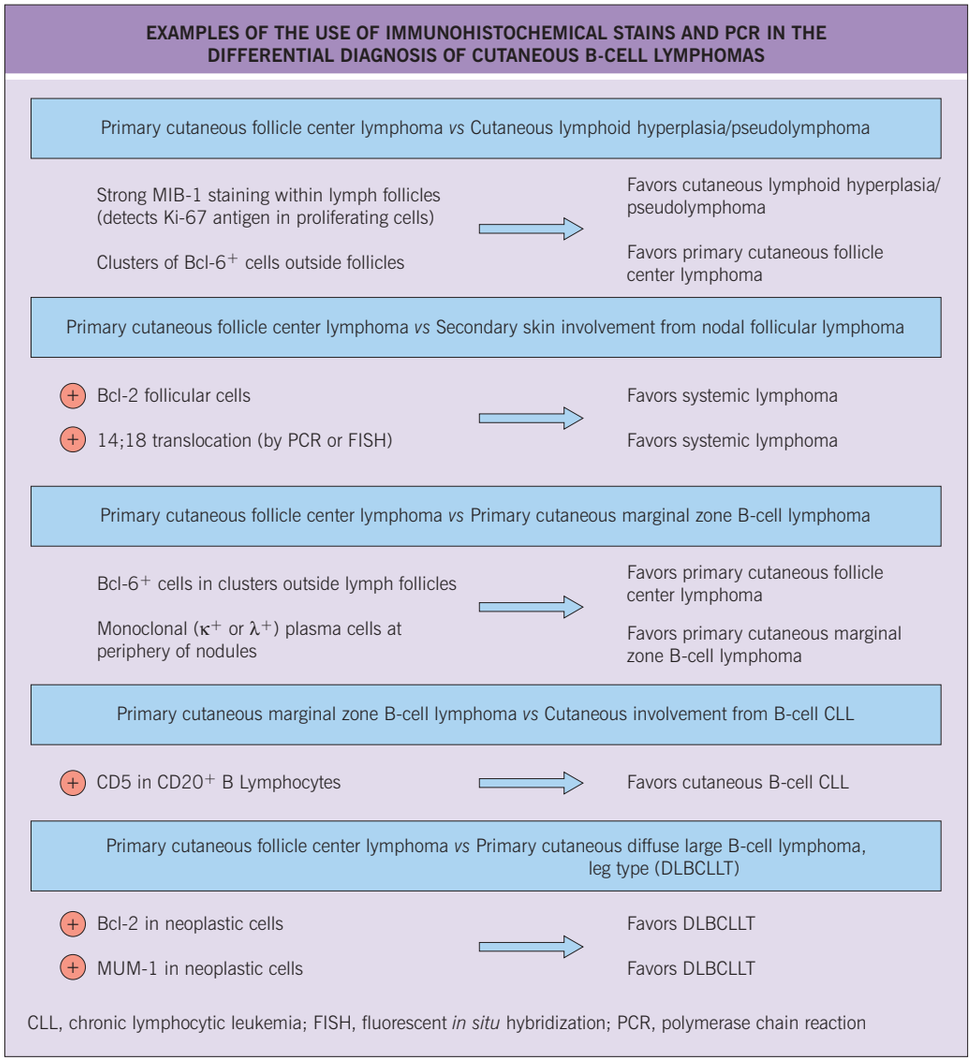

Fig. 119.17 Examples of the use of immunohistochemical stains and PCR in the differential diagnosis of cutaneous B-cell lymphomas. This does represent a simplification and is intended to assist dermatologists in their interpretation of pathology reports. $CD20^+/CD5^+$ infiltrates are also seen in secondary skin involvement from mantle cell lymphoma, but in contrast to CLL, mantle cell lymphoma is also positive for cyclin D.

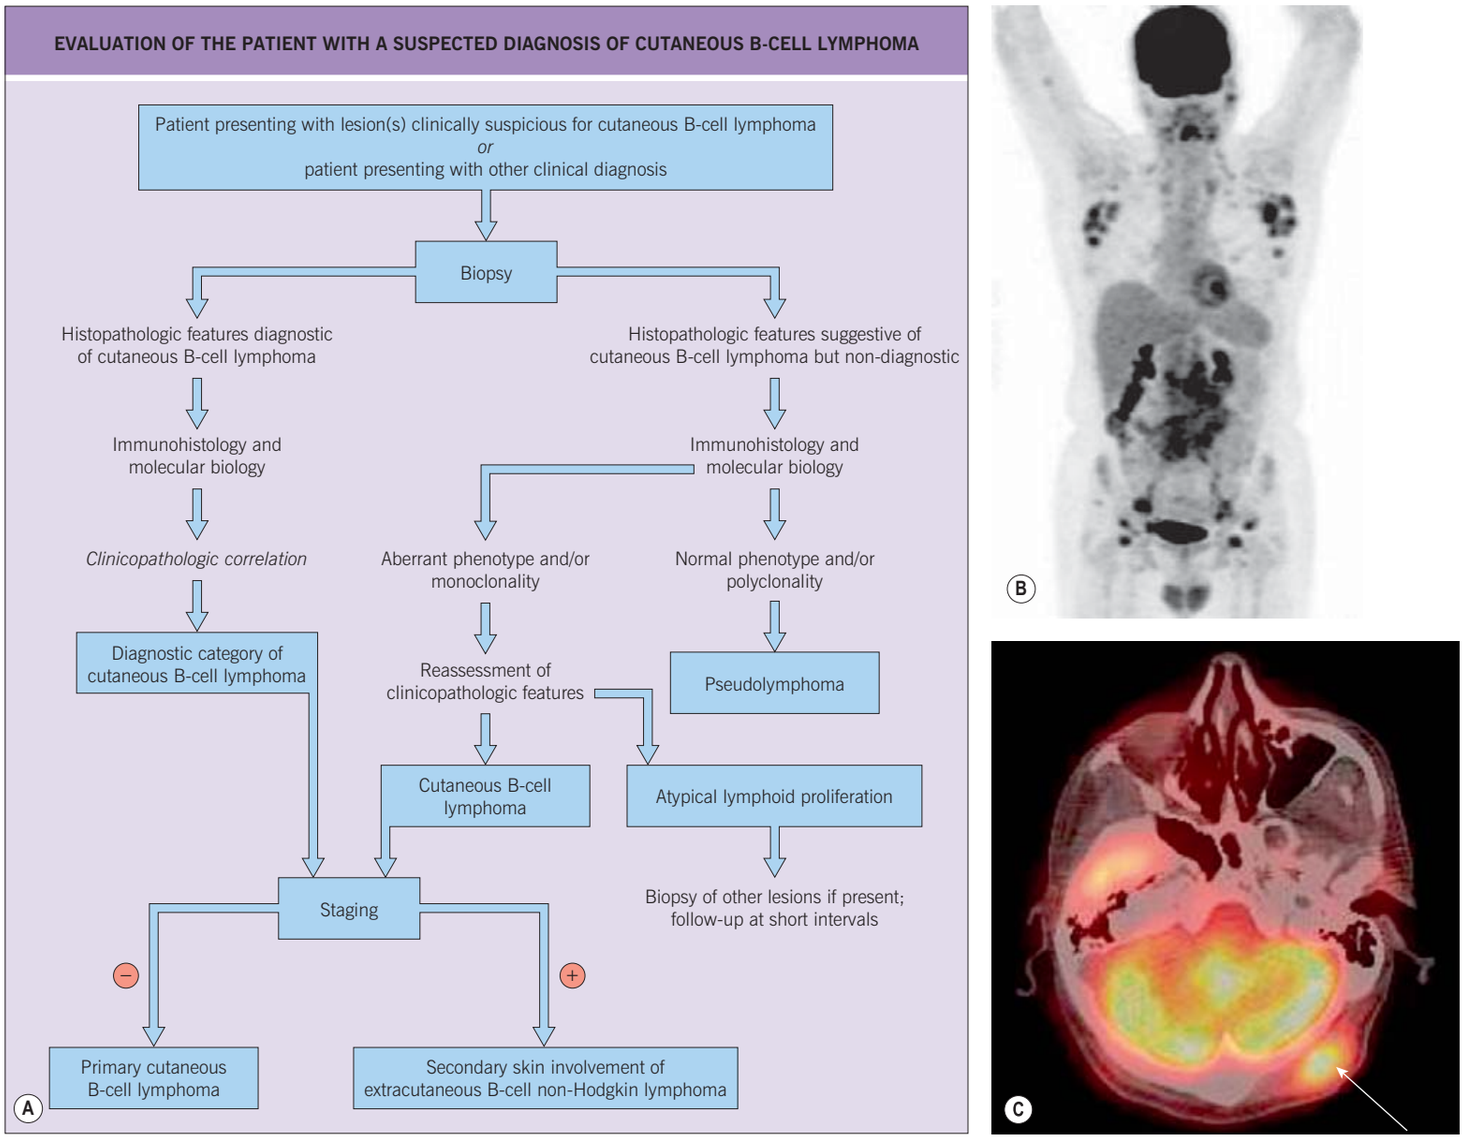

Fig. 119.18 Evaluation of the patient with a suspected diagnosis of cutaneous B-cell lymphoma. A Algorithm outlining approach to the patient. **B, C** Positron emission tomography (PET) scans in a 66-year-old patient with stage IV non-Hodgkin B-cell lymphoma. He had a 1-year history of a cutaneous nodule of the scalp that was originally diagnosed as an epidermoid inclusion cyst. Biopsy of the nodule showed a diffuse large B-cell lymphoma ($CD10^+$, $CD20^+$, variably $Bcl\text{-}2^+$, $MUM1^-$) and a PET/CT scan was performed for staging. There is evidence of widespread disease involving multiple lymph node basins in the dedicated (MIP) image (**B**) as well as a scalp lesion in a PET/CT fusion image (**C**; arrow). *B, C, Courtesy, Dennis Cooper, MD.*

by neoplastic marginal zone cells can indeed cause significant problems in histopathologic differential diagnosis, similar to what happens in B-cell lymphomas of the MALT type. However, the overall architecture of the infiltrate, the presence of a population of monoclonal plasma cells belonging to the neoplastic clone, and the negativity of neoplastic cells for CD10 and Bcl-6 usually allow the diagnosis of cutaneous PCMZL to be established.

As mentioned previously, secondary cutaneous involvement by primary extracutaneous follicular lymphomas has morphologic and phenotypic features similar or identical to those observed in primary cutaneous B-cell lymphoma, except for the usual positivity of neoplastic cells for Bcl-2 in secondary cutaneous lesions. Consequently, the occurrence of a cutaneous follicular lymphoma with clearcut positivity for Bcl-2 within neoplastic follicles should be considered as a strong hint (although exceptions can be encountered) for the diagnosis of secondary skin lesions of nodal lymphoma.

The differential diagnosis of **PCMZL** consists primarily of reactive processes and other types of low-grade pCBCL. Benign, reactive processes do not have monotypic restriction of immunoglobulin light chain expression, in contrast to what is observed in the great majority of cases of PCMZL. PCFCL, diffuse type, can be differentiated from PCMZL by the architectural pattern and cytomorphology, the former being characterized by a diffuse infiltrate of B lymphocytes with a predominance of centrocytes and centroblasts. Moreover, in contrast to PCMZL, neoplastic cells in PCFCL express Bcl-6.

PCMZL should also be distinguished from secondary cutaneous lesions of B-cell chronic lymphocytic leukemia (B-CLL), a condition in which neoplastic B lymphocytes display positivity for CD20 and CD43, and usually for CD5. Helpful diagnostic features are: (1) the absence, in B-CLL, of plasma cells belonging to the neoplastic clone; and (2) the positivity for CD5 observed in most cases of cutaneous B-CLL, but practically never in PCMZL. $CD20^+/CD5^+$ infiltrates are also seen in secondary skin involvement from mantle cell lymphoma, but in contrast to CLL, mantle cell lymphoma is also positive for cyclin D. Finally, it seems likely that cases classified in the past as "cutaneous lymphoid hyperplasia with monotypic plasma cells" represent, in fact, examples of PCMZL with prominent plasma cell differentiation.

PCMZL with prominent plasma cell differentiation must be differentiated from reactive plasma cell proliferations and from inflammatory pseudotumors (plasma cell granulomas). In reactive conditions, plasma cells are not atypical, and they display a polyclonal pattern of immunoglobulin light chain expression. Besides inflammatory pseudotumors, reactive skin diseases with a predominance of plasma cells are very rare, with the exception of lesions arising on mucosal surfaces, spirochetal infections (e.g. syphilis, pinta, yaws), and cutaneous and systemic plasmacytosis. The latter disorder displays a polyclonal

pattern of immunoglobulin light chain expression. A silver stain (e.g. Warthin-Starry) or immunohistochemical staining for *Treponema pallidum* can help to highlight the microorganisms in cases of syphilis (see Fig. 0.32).

DLBCLLT must be differentiated from a number of entities, including cutaneous involvement from systemic lymphomas as well as specific infiltrates of acute myelogenous leukemia and non-lymphoid tumors (e.g. solid organ metastases; see Ch. 122). The clinicopathologic pattern together with phenotypic and molecular features allow correct classification of these lesions in most instances. In order to avoid diagnostic errors, detailed immunophenotyping is mandatory in all cases of cutaneous lymphoma, especially in those showing medium- to large-sized cell morphology.

The differential diagnosis of **IVDLBCL** is not a problem in typical cases. The large number of atypical cells within blood vessels is pathognomonic of this condition. Distinction between T- and B-cell types cannot be achieved on morphologic grounds alone. IVDLBCL should be distinguished from so-called intravascular histiocytosis, a condition in which the vessels in the dermis show intraluminal collections of histiocytes. Morphologic, immunophenotypic and molecular features allow one to distinguish these entities with confidence. Intravascular histiocytosis has been observed in different clinical settings, including chronic erysipelas.

Cases of precursor B lymphoblastic lymphoma/leukemia should be differentiated from other cutaneous lymphomas and from non-lymphoid tumors such as Ewing's sarcoma and small cell lung carcinoma. Positivity for TdT represents the most important immunohistochemical feature for the diagnosis of cutaneous lymphoblastic lymphoma. Histologic features of cutaneous lesions do not allow the differentiation of T-cell from B-cell lymphoblastic lymphomas, thus emphasizing the importance of complete immunophenotypic and genotypic analyses.

TREATMENT

The most appropriate treatment modality for patients with a pCBCL is selected after exact classification of the lymphoma, analysis of results of staging investigations, and consideration of the overall condition of the patient[3]. Those patients with secondary cutaneous lesions of extracutaneous B-cell lymphoma should be treated in a hemato-oncologic, not dermatologic, setting[3,37,38].

Before reviewing the major therapeutic strategies, it must be emphasized that many patients with low-grade pCBCL can be managed conservatively with a so-called watchful-waiting strategy, similar to what is often adopted for indolent B-cell lymphomas and leukemias at extracutaneous sites[3,39]. Follow-up examinations in these patients should be performed at least every 6 months or at the onset of new lesions and/or new symptoms, in order to treat the patient as soon as it is necessary. Many patients managed conservatively with a watchful-waiting strategy experience a prolonged course and long survival, and they do not need aggressive treatment. Especially if only a few lesions are present, some of the patients in the watchful-waiting group may choose to have injections of intralesional corticosteroids into their papulonodules.

Most patients with pCBCLs that are low-grade (PCFCL, PCMZL) and who have a solitary or few lesions can be treated by local radiotherapy, simple surgical excision, or surgical excision followed by radiotherapy of the surgical field[3,37,39,40]. It has been reported that recurrences are less frequently seen in patients treated by radiotherapy with wide margins (about 10–20 cm beyond clinically apparent lesions); this approach seems to be justified for so-called Crosti's lymphoma, a type of PCFCL arising on the back, in which erythematous nodules, papules and patches surrounding the tumor represent specific infiltrates that can extend far beyond the main bulk of the lesion[41]. Radiotherapy with wide margins, however, does not seem to be justified for lesions other than Crosti's lymphoma, as margins of about 3–5 cm usually suffice (depending on the size of the lesion). Surgical excision with narrow margins is a valuable therapeutic modality for patients with solitary well-circumscribed lesions. In these patients, relapse rates do not seem to be higher than in patients treated with more time-intensive modalities such as local radiotherapy.

A few reports have appeared in which low-grade pCBCLs were treated with systemic antibiotics, achieving a complete resolution in at least a percentage of the patients[38,42,43]. This type of treatment is conceptually analogous to that adopted for *Helicobacter pylori*-associated MALT lymphomas of the stomach, which in their early stages can be cured by eradication of *H. pylori* infection. Complete response to antibiotic therapy has been observed in some patients with *Borrelia*-associated pCBCL. Although not yet corroborated by adequate data, antibiotic treatment of patients with pCBCLs should be considered before more aggressive therapeutic options are employed, particularly in European countries endemic for *Borrelia* infections. It is important to treat patients at the onset of the disease, because, in later stages, lesions may no longer be sensitive to systemic antibiotics. PCR analysis of *Borrelia* DNA is a rapid test that should be performed in all patients with pCBCL from endemic areas, in order to identify those who would more likely benefit from early antibiotic treatment.

Another treatment modality for low-grade pCBCL is subcutaneous or intralesional interferon, particularly interferon-α-2a[38]. Although some favorable results have been reported, it seems that treatment with interferon is associated with a complete response in about 50% of patients. Therapy with interferon should be considered for patients presenting with multiple lesions at different body sites, such that local radiotherapy becomes difficult to administer.

Intralesional or systemic injection of anti-CD20 monoclonal antibody (rituximab) has been used to induce tumor reduction in patients with indolent pCBCLs[44,45]. Intralesional administration should be considered in patients presenting with a few, localized lesions. Therapy with intravenous rituximab represents a valid alternative to established treatments, especially in patients who present with disseminated skin lesions or relapse after radiotherapy. Rituximab can also be administered in combination with other treatment modalities for pCBCLs with more aggressive behavior (e.g. DLBCLLT). Anti-CD20 monoclonal antibody has also been conjugated to radioisotopes (e.g. I-131, Y-90), in an attempt to provide selective irradiation of tumor cells.

Patients with disseminated lesions of PCFCL, diffuse type, or with DLBCLLT need more aggressive treatment modalities (e.g. systemic chemotherapy plus rituximab). This treatment, however, is usually necessary in only a small proportion of patients with PCFCL[38,46,47]. The regimen used most frequently is cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP) plus rituximab, and it represents the standard of care for DLBCLLT. In the absence of signs of transformation into high-grade lymphoma, aggressive treatment is not indicated in patients with PCMZL. In the setting of significant co-morbidities, rituximab alone or in combination with local radiotherapy may be administered.

Systemic chemotherapy plus rituximab is the treatment of choice for patients with IVDLBCL, regardless of results of staging investigations. As with DLBCLLT, the addition of rituximab to anthracycline-based chemotherapy significantly improves outcome in "Western" patients with this lymphoma[48]. Finally, patients with precursor B lymphoblastic lymphoma/leukemia should be treated with aggressive modalities (chemotherapy plus rituximab; hematopoietic stem cell transplantation) by a hematologist.

PLASMA CELL DYSCRASIAS, INCLUDING MULTIPLE MYELOMA

A plasma cell dyscrasia represents a clonal proliferation of plasma cells and it can lead to a monoclonal gammopathy composed of intact immunoglobulins, isolated light chains (15% of patients) or, rarely, isolated heavy chains. The term plasma cell dyscrasia encompasses a number of entities, including monoclonal gammopathy of undetermined significance (MGUS), smoldering/asymptomatic myeloma and active/symptomatic myeloma, as well as light and heavy chain deposition disease and amyloidosis (AL). While proliferations of plasma cells within the skin are rare, an understanding of the spectrum and natural history of plasma cell dyscrasias is important for dermatologists given the number of cutaneous disorders associated with monoclonal gammopathies (Table 119.2). Table 119.3 outlines the differences between MGUS and smoldering myeloma in addition to the risk factors for progression to symptomatic myeloma. The diagnosis of symptomatic myeloma requires the presence of CRAB: *c*alcium elevation, *r*enal insufficiency, *a*nemia and/or *b*one lesions (osteolytic > osteosclerotic) due to the myeloma.

CUTANEOUS CONDITIONS ASSOCIATED WITH MONOCLONAL GAMMOPATHY
PROLIFERATION OF LYMPHOPLASMACYTIC CELLS IN THE SKIN
• Extramedullary cutaneous plasmacytoma*
• Cutaneous Waldenström's macroglobulinemia†
DEPOSITION OF THE MONOCLONAL PROTEIN IN THE SKIN, BY DEFINITION
• Primary systemic amyloidosis (light chains)
• Cryoglobulinemic occlusive vasculopathy (type I cryoglobulins‡)
• Hyperkeratotic spicules (follicular > non-follicular)
• Crystal-storing histiocytosis
• IgM storage papules (cutaneous macroglobulinosis)†
• Subepidermal bullous dermatosis associated with IgM gammopathy†
DEPOSITION OF THE MONOCLONAL PROTEIN IN THE SKIN FREQUENTLY OBSERVED
• Plasma cell dyscrasia-associated acquired cutis laxa, acral or generalized (amyloid and/or IgG)
• Plasma cell dyscrasia-associated reactive angioendotheliomatosis (type I cryoglobulins or amyloid)
ALMOST ALWAYS ASSOCIATED WITH MONOCLONAL GAMMOPATHY
• Scleromyxedema
• POEMS syndrome§
• AESOP syndrome – *a*denopathy and *e*xtensive *s*kin patch *o*verlying a *p*lasmacytoma; may coexist with POEMS syndrome†
• Schnitzler's syndrome
• Necrobiotic xanthogranuloma
FREQUENTLY ASSOCIATED WITH MONOCLONAL GAMMOPATHY
• Normolipemic plane xanthoma
• Scleredema (type 2; see Ch. 46)
• Angioedema secondary to acquired C1 esterase inhibitor deficiency
• Clarkson's syndrome (idiopathic systemic capillary leak syndrome)
SIGNIFICANT ASSOCIATION WITH MONOCLONAL GAMMOPATHY (AT LEAST 15% OF CASES)
• Erythema elevatum diutinum
• Subcorneal pustular dermatosis (SPD) and SPD-type IgA pemphigus
• Pyoderma gangrenosum
OCCASIONALLY ASSOCIATED WITH MONOCLONAL GAMMOPATHY
• Sweet's syndrome
• Cutaneous small vessel vasculitis‡,‖
• Xanthoma disseminatum
• Epidermolysis bullosa acquisita
• Paraneoplastic pemphigus
• Atypical scleroderma¶
*In the current WHO-EORTC classification (see Table 119.1), primary cutaneous plasmacytoma is classified as primary cutaneous marginal zone B-cell lymphoma.
†IgM monoclonal gammopathy is present by definition; in Schnitzler's syndrome, IgG gammopathy has occasionally been observed; Waldenström's macroglobulinemia is due to a lymphoplasmocytic lymphoma.
‡Cryoglobulinemic vasculitis can occur secondary to type II cryoglobulins.
§Polyneuropathy (P), organomegaly (O), endocrinopathy (E), M-protein (M), skin changes (S; see Ch. 53 for list of skin changes); diagnosis requires monoclonal plasmaproliferative disorder & neuropathy + one other major criterion (sclerotic bone lesions, Castleman's disease, increased VEGF levels) and one minor criterion (extravascular volume overload, papilledema, O, E, S, thrombocytosis/polycythemia).
‖Henoch–Schönlein purpura in adults is occasionally associated with an IgA monoclonal gammopathy.
¶Possible association; sclerodermoid changes can also occur in the setting of primary systemic amyloidosis.

Table 119.2 Cutaneous conditions associated with monoclonal gammopathy.

RELATIONSHIP OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE TO MYELOMA	
MGUS	• Serum monoclonal protein <3 g/dl • <10% plasma cells in the bone marrow • No end-organ damage (*h*ypercalcemia, *r*enal insufficiency, *a*nemia and/or *b*one lesions [CRAB]) that is associated with symptomatic myeloma • Prevalence: 3% in those ≥50 yrs; 5% in those ≥70 yrs
Risk factors for progression of MGUS to myeloma or lymphoproliferative disorder*	• Increase in serum free light chains • MGUS of non-IgG origin (e.g. IgA, IgM) • Serum monoclonal protein ≥1.5 g/dl • Chance of progression from MGUS to myeloma (at 20 yrs): – 58% if 3 risk factors – 37% if 2 risk factors – 21% if 1 risk factor – 5% if 0 risk factors
Smoldering (asymptomatic) myeloma	• Serum monoclonal protein ≥3 g/dl – *or* – • ≥10% plasma cells in the bone marrow • No end-organ damage (see above) • Cumulative probability of progression to symptomatic myeloma or amyloidosis: – 51% at 5 yrs – 66% at 10 yrs – 73% at 15 yrs
*2–3% of monoclonal gammopathies are due to lymphoproliferative disorders, e.g. CLL, and approximately 3% represent Waldenström's macroglobulinemia (IgM) which is due to a lymphoplasmacytic lymphoma.	

Table 119.3 Relationship of monoclonal gammopathy of undetermined significance (MGUS) to myeloma. CLL, chronic lymphocytic leukemia. Adapted from references 49 & 50.

Of note, the level of circulating monoclonal protein associated with several of the skin disorders listed in Table 119.2 may be so low as to fall below the detection limit of a serum protein electrophoresis. As a result, the more sensitive serum immunofixation electrophoresis (IFE) is required to detect an intact immunoglobulin (e.g. IgG or IgA) paraprotein. In patients with primarily light chain disease (e.g. systemic amyloidosis), the serum free light chain (SFLC) ratio is much more sensitive than even the serum IFE. Because light chains are rapidly excreted into the urine, a urine IFE in addition to SFLC assay is necessary to exclude a light chain-producing plasma cell dyscrasia.

Histopathology

In specific skin lesions (see Table 119.2), diffuse infiltration of the dermis by atypical plasma cells or lymphoplasmacytoid cells is present, usually with prevalent mitoses. Multinucleated plasma cells may be found. The infiltrating cells can be difficult to recognize as plasma cells, and CD45 and CD20 are negative as a rule. Neoplastic plasma cells can be stained with CD38 and CD138, and they express monotypic immunoglobulins. Intracytoplasmic eosinophilic inclusions (Russell bodies) are often present; the cells are called Mott cells when these bodies form grape-like clusters. PAS-positive eosinophilic inclusions in the nucleus (Dutcher bodies) can also be observed. These are thought to be immunoglobulin or glycoprotein accumulations, and can be found in other neoplastic conditions in which plasma cells are prevalent (plasma cell-rich PCMZL; see Fig. 119.11B).

Differential Diagnosis

The differential diagnosis of PCMZL with prominent plasma cell differentiation (formerly called cutaneous plasmacytoma) is discussed above. Waldenström's macroglobulinemia has histologic features similar to PCMZL with prominent lymphoplasmacytic differentiation (formerly called cutaneous immunocytoma), except that direct immunofluorescence demonstrates monoclonal IgM within and around the infiltrating cells. Immunofixation electrophoresis of the serum detects the circulating monoclonal protein as IgM.

Introduction

The term cutaneous T-cell lymphoma (CTCL) describes a heterogeneous group of neoplasms of skin-homing T cells that show considerable variation in clinical presentation, histologic appearance, immunophenotype and prognosis. CTCL represents approximately 75–80% of all primary cutaneous lymphomas, whereas primary cutaneous B-cell lymphomas (CBCL) account for approximately 20–25%[1]. For many years, mycosis fungoides (MF) and Sézary syndrome (SS) were the only known types of CTCL. Over the past two decades, based on a combination of clinical, histologic and immunophenotypical criteria, new types of CTCL and CBCL have been defined and new classifications for the group of primary cutaneous lymphomas have been formulated[1–4]. A major advantage in the management of primary cutaneous lymphomas compared with lymphomas arising at other sites is that the former can be seen and can be biopsied easily, giving the dermatologist the unique opportunity to correlate the clinical appearance and clinical behavior with histologic, immunophenotypical and genetic aspects of these conditions. Hence, the dermatologist can play a key role in the diagnosis, classification and treatment of these diseases.

History

In 1806, a French physician, Jean Louis Alibert, was the first to describe a patient with MF. This case was designated *pian fungoïde* in his atlas, but in 1835 it was renamed *mycosis fungoïde* because of the resemblance of some skin tumors to mushrooms. In 1870, Bazin described the natural progression from a nonspecific premycotic phase to plaque lesions and finally to tumors, which probably represents one of the first descriptions of the "multistep model" in the development of a malignancy. In 1885, Vidal and Brocq used the term "mycosis fungoides d'emblée" for patients presenting with skin tumors not preceded by patches or plaques. It has now become clear that such cases represent another type of CTCL or a CBCL. The erythrodermic form of MF was described in 1892 by Besnier and Hallopeau. These early descriptions of the main clinical forms of MF were followed by descriptions of Sézary syndrome by Sézary and Bouvrain in 1938, pagetoid reticulosis by Woringer and Kolopp in 1939, and lymphomatoid papulosis (LyP) by Macaulay in 1968.

Thus, in the early 1970s, MF and some related conditions were the only types of cutaneous lymphoma that had been rather well described. Reports on cutaneous lymphomas other than MF/SS, commonly designated in the past as malignant reticulosis or reticulum cell sarcoma, were few. Moreover, they were firmly believed to represent skin manifestations of a systemic lymphoma and treated as such.

The CTCL concept

In 1968, Lutzner and Jordan described the ultrastructural features of the circulating atypical cells in SS. Characteristically, the nuclei of these cells had deep and narrow indentations, giving them a cerebriform appearance. In 1971, similar cells were found in the skin and lymph nodes of patients with MF. In 1975, based on the observation that the neoplastic cells in MF, SS and related conditions not only had the same morphology but also a common T-cell phenotype, the term "CTCL" was suggested for this group of diseases[5]. Within a short time, this term gained wide acceptance, particularly in the US. The introduction of the CTCL concept can be considered as a landmark in the history of this group of diseases. However, a major disadvantage has been that in many subsequent studies, distinction was no longer made between MF, SS and other T-cell neoplasms, entities which may vary considerably in clinical presentation and clinical behavior.

The concept of primary cutaneous lymphomas

At about the same time that the CTCL concept was introduced, several European groups started to classify cutaneous lymphomas according to the criteria of the Kiel classification, a system used by hematopathologists for the categorization of nodal lymphomas. It was then determined that many types of CBCL and CTCL (other than classical MF and SS) can present in the skin without any evidence of extracutaneous disease at the time of diagnosis. It appeared that these primary cutaneous lymphomas often have a completely different clinical behavior and prognosis when compared to morphologically similar lymphomas arising in lymph nodes, and therefore require different types of treatment[1]. In addition, differences in the presence of specific chromosomal translocations and in the expression of oncogenes, viral sequences or antigens (e.g. EBV), and adhesion receptors involved in tissue-related lymphocyte homing were found[1].

Such differences underscored that primary cutaneous lymphomas represent a distinct group and may explain, at least in part, their different clinical behavior. For instance, the observation that the neoplastic T cells in most CTCLs express cutaneous lymphocyte antigen (CLA) and the CC-chemokine receptors 4 (CCR4) and 10 (CCR10), indicates that they are the neoplastic counterparts of normal skin-homing T cells, and this explains why these CTCLs present in the skin. Perhaps most important, it appeared that different types of CTCL and CBCL with different clinical behaviors and different therapeutic requirements may have an identical histologic appearance. This implies that histologic features should always be combined with clinical and immunophenotypical data, before a definite diagnosis (classification) can be made.

Over the past two decades, such an approach resulted in the delineation of several new types of CTCL and CBCL, and it formed the basis of the European Organization for Research and Treatment of Cancer (EORTC) classification for primary cutaneous lymphomas[1].

EORTC, WHO and WHO-EORTC classification schemes

The EORTC classification scheme was the first one that was specifically designed for the group of primary cutaneous lymphomas. It contained

a limited number of well-defined types of CTCL and CBCL, which together accounted for more than 95% of all primary cutaneous lymphomas, in addition to some provisional entities, which were not yet fully defined clinically. A distinction was made between cutaneous lymphomas with indolent, intermediate or aggressive clinical behavior. By including well-defined and recognizable disease entities, this classification provided the clinician with detailed information on staging, preferred mode of treatment, clinical behavior and prognosis, serving as a useful guide to optimal management and treatment.

The third edition of the World Health Organization (WHO) classification for malignant lymphomas adopted the most common types of CTCL from the EORTC classification, but there was controversy with regard to the categorization of some rare types of CTCL[2]. In addition, the WHO classification contained some new entities not yet included in the EORTC scheme. In 2004, representatives from both organizations reached an agreement on a new classification scheme for the group of cutaneous lymphomas: the WHO-EORTC classification[3]. Importantly, the fourth edition of the WHO classification for malignant lymphomas, published in 2008, which is used by pathologists and hematologists worldwide, has adopted the terminology and definitions of the WHO-EORTC classification, and therefore, it now includes all the types of CTCL and CBCL included in previous classifications of primary cutaneous lymphomas[4]. The frequency and survival of patients with the different types of CTCL recognized in the WHO-EORTC classification are presented in Table 120.1. Following a description of practical guidelines for diagnosis, classification and staging, relevant features of the different types of CTCL included in this classification are presented.

WHO-EORTC CLASSIFICATION FOR CUTANEOUS T-CELL LYMPHOMAS

WHO-EORTC classification	Frequency (%)*	5-year survival rate (%)*
INDOLENT CLINICAL BEHAVIOR		
Mycosis fungoides (MF)	54	88
Mycosis fungoides variants and subtypes		
• Folliculotropic MF	6	80
• Pagetoid reticulosis	1	100
• Granulomatous slack skin	<1	100
Primary cutaneous CD30-positive lymphoproliferative disorders		
• Primary cutaneous anaplastic large cell lymphoma (C-ALCL)	10	95
• Lymphomatoid papulosis (LyP)	16	100
Subcutaneous panniculitis-like T-cell lymphoma (SPTCL)	1	82
Primary cutaneous CD4-positive small/medium pleomorphic T-cell lymphoma‡	3	75
AGGRESSIVE CLINICAL BEHAVIOR		
Sézary syndrome (SS)	4	24
Adult T-cell leukemia/lymphoma (ATLL)	NDA	NDA
Extranodal NK/T-cell lymphoma, nasal type	1	<5
Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma‡	<1	18
Primary cutaneous gamma/delta T-cell lymphoma (PCGD-TCL)‡	1	<5
Primary cutaneous peripheral T-cell lymphoma (PTCL), unspecified§	3	16

*Data are based on 1476 CTCL patients registered by the Dutch and Austrian Cutaneous Lymphoma Groups[3].
†α/β T-cell phenotype.
§Primary cutaneous T-cell lymphoma, unspecified, excluding the three provisional entities indicated by ‡.

Practical Guidelines for Diagnosis, Classification and Staging of CTCL

Diagnosis

The first step in the evaluation of a patient suspected of having CTCL is to decide if it represents a lymphoma or a benign condition. Skin biopsies – preferably deep punch biopsies 4–6 mm wide or an excisional or incisional biopsy from the most representative skin lesions – should be performed.

Since prior treatment with topical corticosteroids or PUVA may change the original histology profoundly, biopsies from untreated skin lesions are preferred. Even if an adequate biopsy specimen is obtained, a definite diagnosis is not always possible. First, several types of CTCL, such as MF, are often preceded for years by skin lesions that are neither clinically nor histologically diagnostic. The gradual progression from this prediagnostic phase to overt lymphoma explains why it has always been so difficult to reach a consensus on the minimal histologic criteria needed for an unequivocal diagnosis of MF[6]. Because of the indolent clinical behavior of the disease in such patients, a conservative approach is justified. In most cases, repeated biopsies, when appropriate, will ultimately result in the correct diagnosis.

Secondly, atypical T-cell infiltrates are found not only in CTCL but also in reactive conditions, e.g. lymphomatoid drug eruptions (pseudo-T-cell lymphomas)[7]. Therefore, a definite diagnosis should always be based on a combination of clinical, histologic and, in most cases, immunophenotypical criteria, and it may be supplemented with the results of gene rearrangement analysis[8].

Immunophenotyping

Immunohistochemical studies on paraffin or frozen sections using antibodies reactive with cell-surface or cytoplasmic molecules are extremely important in the diagnosis and classification of cutaneous lymphomas. Using a panel of such antibodies (see Ch. 0), distinction can be made between neoplasms of T-cell, B-cell, NK-cell and myeloid or monocytic origin. Within the group of CTCLs, such studies have contributed to the delineation of new subtypes and provided important diagnostic and prognostic criteria.

With respect to the diagnosis of CTCL, demonstration of an aberrant phenotype, i.e. loss of one or more T-cell-associated antigens, such as CD2, CD3, CD4 or CD5, by the neoplastic T cells, can be considered as an important additional criterion in establishing a definite diagnosis of CTCL[8]. However, loss of CD7 expression, which may be caused by chronic T-cell stimulation and is commonly observed in benign dermatoses as well, is not a reliable marker. Recently, new antibodies have become available, which, in combination with antigen retrieval techniques, now also allow demonstration of "marker loss" on paraffin sections.

T-cell receptor gene rearrangement analysis

In the past decade, T-cell receptor gene rearrangement analysis, either by Southern blot analysis or by more sensitive polymerase chain reaction (PCR)-based techniques, has increasingly been used in the diagnosis and staging of malignant lymphomas[9]. However, caution is warranted in interpreting the results of such analyses. Clonal T-cell populations have been detected not only in skin lesions, lymph nodes and peripheral blood of patients with CTCL, and in cases of chronic dermatitis preceding MF ("clonal dermatitis"; see Ch. 9), but also in skin lesions of patients with apparently benign conditions, such as pityriasis lichenoides et varioliformis acuta, lichen planus, lichen sclerosus and some pseudolymphomas[9,10].

Demonstration of clonal T-cell populations can therefore not be used as an absolute criterion of malignancy, but should always be considered in conjunction with clinical and histologic features, which together remain the "gold standard". If the clinical and histologic findings are not consistent, and an aberrant phenotype is not detected, a definite diagnosis of CTCL should not be made.

Classification

Once a diagnosis of CTCL has been made, the type of CTCL should be determined. As noted before, the histologic diagnosis is not the final diagnosis, which means that CTCL cannot be classified on the basis of histologic criteria alone. For instance, in the case of a skin biopsy showing a dermal infiltrate which is composed predominantly of CD30-positive large anaplastic or pleomorphic T cells, the *histologic diagnosis* will be (CD30-positive) anaplastic large cell lymphoma (ALCL). However, depending upon the clinical presentation, the *definite diagnosis* may be a primary cutaneous ALCL; cutaneous involvement of a systemic ALCL; large cell transformation of MF with expression of CD30; or LyP (in cases of recurrent self-healing papules). Obviously, each of these conditions requires a different approach in terms of staging and treatment.

In Table 120.2, the differential diagnosis of four histologic categories has been elaborated. This histologic subdivision into epidermotropic CTCL, CTCL with diffuse pleomorphic infiltrates, CD30-positive CTCL and subcutaneous CTCL is neither complete nor meant as an alternative classification. It is only presented as an illustration of how histology should be combined with clinical and immunophenotypical data to arrive at a definite diagnosis.

Practical guidelines

For those not regularly involved in the diagnosis and classification of CTCL and perhaps overwhelmed by the many new types of CTCL introduced in recent years, a stepwise approach, as presented in Figure 120.1, may serve as a practical guide.

Step one: Based on a combination of clinical, histologic and immunophenotypical criteria, distinction is first made between classic MF, MF variants and SS on the one hand *and* CTCL other than these conditions on the other. The rationale for this first step is that dermatologists are familiar with the former set of conditions, which comprise approximately 65% of CTCLs, and these lymphomas require a different clinical approach in terms of staging and therapy compared to the other forms of CTCL. Cases of unequivocal LyP can be included in this first step.

Step two: The second category to be considered is the group of *primary* cutaneous CD30-positive lymphoproliferative disorders. It implies that evaluation of skin biopsies from patients with (suspected) CTCL should always include CD30 immunostaining. This group includes cases of cutaneous ALCL (C-ALCL) and LyP, which together represent the second most common group of CTCL (see Table 120.1). Patients within this spectrum of disease generally have an excellent prognosis, and most individuals can be managed easily by dermatologists.

Step three: With the first two steps, approximately 90% of CTCL will be classified correctly. The remaining group (10% of patients) contains rare types of CTCL, including subcutaneous panniculitis-like T-cell lymphoma (SPTCL), extranodal NK/T-cell lymphoma, nasal type, and the broad group of primary cutaneous peripheral T-cell lymphoma (PTCL), unspecified. From the latter group, primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma, primary cutaneous gamma/delta T-cell lymphoma (PCGD-TCL) and primary cutaneous CD4-positive small/medium pleomorphic T-cell lymphoma have been separated out as provisional entities (see Table 120.1)[3]. In the WHO-EORTC classification, the term PTCL, unspecified, is maintained for remaining cases that do not fit into any of the provisional entities.

Apart from SPTCL and primary cutaneous CD4-positive small/medium pleomorphic T-cell lymphomas, lymphomas included in this third category have an aggressive clinical course, and should be treated by, or in close collaboration with, a hemato-oncologist. It should be emphasized that distinction between these different types of aggressive CTCL is sometimes very difficult, because of overlapping clinicopathologic features and highly aberrant phenotypes. Distinction between primary and secondary cutaneous involvement is less important than in other types of cutaneous lymphoma. Patients presenting with only skin lesions generally develop extracutaneous disease within a short period of time and have a poor prognosis as well.

Staging

Apart from CTCL, a term preferably used only for *primary* CTCL, systemic T-cell lymphomas frequently present or relapse in the skin. Adequate staging procedures are required to differentiate between CTCL and these systemic lymphomas secondarily involving the skin. The extent of staging procedures is dependent on the type of (suspected) CTCL, and, in the case of classical MF, on the clinical stage of the disease[11]. In cases of early patch/plaque stage MF, unequivocal cases of LyP and probably pagetoid reticulosis as well, staging procedures are generally not worthwhile. In cases of suspected SS, adequate staging with special emphasis on assessment of peripheral blood involvement by cytology, immunophenotyping (flow cytometry) and TCR gene rearrangement analysis is essential. In all other types of CTCL, routine hematological staging, including complete and differential blood cell counts, a blood chemistry panel, computed tomographic (CT) scans of the chest and abdomen, and bone marrow sampling, are required[12].

MYCOSIS FUNGOIDES

Definition

Mycosis fungoides (MF) represents the most common type of CTCL and accounts for approximately 50% of all primary cutaneous lymphomas (see Table 120.1). The term MF should be restricted to the classic "Alibert–Bazin" type characterized by the typical evolution of patches, plaques and tumors, or for clinicopathologic variants showing a similar clinical course.

Epidemiology

MF has an incidence of about 0.4 per 100 000 inhabitants per year in the US[13]. MF typically affects older adults (median age at diagnosis: 55–60 years), but it may occur in children and adolescents as well. Men are affected more often than women, with a male-to-female ratio of 1.6–2.0 : 1.

Pathogenesis

The etiology and the pathogenetic mechanisms involved in the development and stepwise progression of MF are largely unknown. Genetic, environmental and immunologic factors have all been considered.

Genetic factors

Lymphomagenesis is considered to be a multifactorial process, in which a stepwise accumulation of genetic abnormalities may result in clonal proliferation, malignant transformation and, ultimately, progressive and widely disseminated disease. Although the successive clinical steps of tumor progression were described more than a century ago, the molecular events underlying the different steps of tumor progression have not been identified. Many genetic abnormalities have been reported in patients with MF, but a consistent pattern has not emerged[14]. Constitutive activation of *STAT3* and inactivation or loss of *CDKN2A*, *PTEN* and *p53* have been identified in advanced, but not early, stages of MF, suggesting that these are secondary genetic events[15–17]. Gene expression profiling studies have shown activation of the tumor necrosis factor (TNF) antiapoptotic pathway in the tumorigenesis of MF[18].

Environmental factors

Persistent antigenic stimulation has been demonstrated to play a crucial role in the development of various malignant lymphomas, including *m*ucosa-*a*ssociated *l*ymphoid *t*issue (MALT) lymphomas (*Helicobacter pylori* infection), CBCL (*Borrelia burgdorferi* infection) and enteropathy-type T-cell lymphoma (celiac disease). In MF, persistent antigenic stimulation has also been proposed as an initial event, but the nature of the antigen(s) involved is unknown. Large case–control studies do not support a relationship between industrial or environmental exposure and the development of MF[19]. Whereas the etiologic roles of human T-cell leukemia virus 1 (human T-cell lymphotropic virus 1; HTLV-1) in adult T-cell leukemia/lymphoma and Epstein-Barr virus (EBV) in nasal NK/T-cell lymphoma have been firmly established, conclusive evidence for a primary etiologic role of these viruses in MF is lacking[20].

Immunological factors

Recent studies suggest that $CD8^+$ cytotoxic T cells (CTL) play a crucial role in the antitumor response in MF. A relationship between high percentages of $CD8^+$ CTL in the dermal infiltrates and better survival has been described[21]. These $CD8^+$ T cells exert their antitumor effect

DIFFERENTIAL DIAGNOSIS OF COMMON HISTOLOGIC PATTERNS IN CUTANEOUS T-CELL LYMPHOMA		
Histologic category	**Differential diagnosis**	**Diagnostic criteria/clues**
Epidermotropic CTCL (simulating or consistent with plaque stage MF)	Mycosis fungoides (MF)	• Characteristic patches and plaques • Most atypical cells within the epidermis (basal layer)
	Pagetoid reticulosis	• Solitary plaque, commonly on distal extremities • Neoplastic cells confined to an often acanthotic epidermis • Often $CD8^+$ phenotype; CD30 expression common
	Lymphomatoid papulosis (LyP), type B or type D	• Recurrent, self-healing papular eruption • Sometimes extension of infiltrate into lower dermis • In some cases admixture with large atypical cells as in type A LyP (mixed type A and B) • LyP type D is $CD8^+$
	Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma	• Infiltrated plaques, but often eruptive nodules and tumors with ulceration • Intraepidermal accumulation of medium-sized pleomorphic T cells or small blast cells; no typical cerebriform appearance • Phenotype: $CD8^+$, TIA-1^+, granzyme B^+, $CD45RA^+$, $CD7^{-/+}$
	Sézary syndrome	• Often more monotonous infiltrate histologically • Erythroderma • Peripheral blood involvement
	Adult T-cell leukemia/lymphoma	• Sometimes clinically and histologically identical to MF • Check HTLV-1 status in patients from endemic areas
CTCL with diffuse pleomorphic infiltrates ($CD30^-$) (simulation or consistent with tumor stage MF; few $CD30^+$ tumor cells may be present)	Tumor stage MF	• Concurrent patches and plaques • Variable numbers of small, medium-sized and/or large cerebriform T cells and/or blast cells and variable admixture with inflammatory cells
	Primary cutaneous peripheral T-cell lymphoma, unspecified	• Histologically, often indistinguishable from MF with blastic transformation • No prior or concurrent patches and plaques
	Primary cutaneous CD4-positive small/medium pleomorphic T-cell lymphoma	• Less than 30% large neoplastic T cells • Histologically, sometimes indistinguishable from tumor stage MF • No prior or concurrent patches and plaques
	Pseudo-T-cell lymphoma	• Presentation with solitary plaque or tumor (2–3 cm) • Scattered medium-sized to large pleomorphic T cells (no clusters) • Many admixed $CD8^+$ T cells, B cells and histiocytes • No aberrant phenotype ("marker loss") • Clonal T-cell population uncommon
CD30-positive CTCL (see Fig. 120.11)	Lymphomatoid papulosis, type A/C	• Recurrent self-healing papules and nodules • Histologic spectrum (from typical LyP to C-ALCL)
	Primary cutaneous anaplastic large cell lymphoma (C-ALCL)	• Generally, solitary or localized nodules or tumors • No evidence of prior or concurrent MF or another type of CTCL • No extracutaneous disease (staging negative) • Histologic spectrum (from typical C-ALCL to LyP) • Phenotype: CLA^+, EMA^-, ALK^-
	Systemic ALCL with secondary skin involvement	• Prior or concurrent extracutaneous involvement (exception: involvement of one regional lymph node basin) • Often generalized skin lesions • Phenotype: CLA^-, EMA^+, ALK^+ (mainly in pediatric subgroup)
	MF with blastic transformation	• Histologically, an admixture with typical cerebriform cells, but sometimes indistinguishable from C-ALCL • Prior or concurrent patches and plaques
CTCL with subcutaneous involvement	Subcutaneous panniculitis-like T-cell lymphoma	• Infiltrates confined to subcutis • Characteristic rimming of individual fat cells by neoplastic T cells • Deeply seated nodules and plaques, mainly involving the legs and trunk • Characteristic $CD3^+$, $CD4^-$, $CD8^+$, $CD56^-$, $\beta F1^+$ T-cell phenotype
	Other types of CTCL	• Subcutaneous infiltrates represent extension from dermal infiltrates • For specific features: see text

Table 120.2 Differential diagnosis of common histologic patterns in cutaneous T-cell lymphoma (CTCL). ALK, anaplastic lymphoma kinase; CLA, cutaneous lymphocyte antigen; C-ALCL, cutaneous anaplastic large cell lymphoma; EMA, epithelial membrane antigen; TIA, T-cell restricted intracellular antigen; βF1, positivity reflects α/β T-cell origin.

both by a direct cytotoxic effect and by the production of cytokines, particularly interferon (IFN)-γ. They can mediate tumor cell lysis by exocytosis of cytotoxic granules containing perforin, granzymes and T-cell-restricted intracellular antigen (TIA-1), and by expression of Fas ligand (FasL), which interacts with Fas (CD95; APO-1) on the neoplastic T cells[21]. Both pathways ultimately lead to activation of caspase 3 and tumor cell death. Loss of Fas expression or function by the neoplastic T cells is one of the many mechanisms by which tumor cells can escape from an effective antitumor response[22].

More recent studies suggest that the neoplastic T cells in SS and tumor stage MF are derived from $CD4^+$ T cells with a Th2 cytokine profile (production of IL-4, IL-5 and IL-10), whereas the cytotoxic T cells are the main producers of IFN-γ, which plays an important role in augmenting T-cell- and NK-cell-mediated killing. In accordance with this

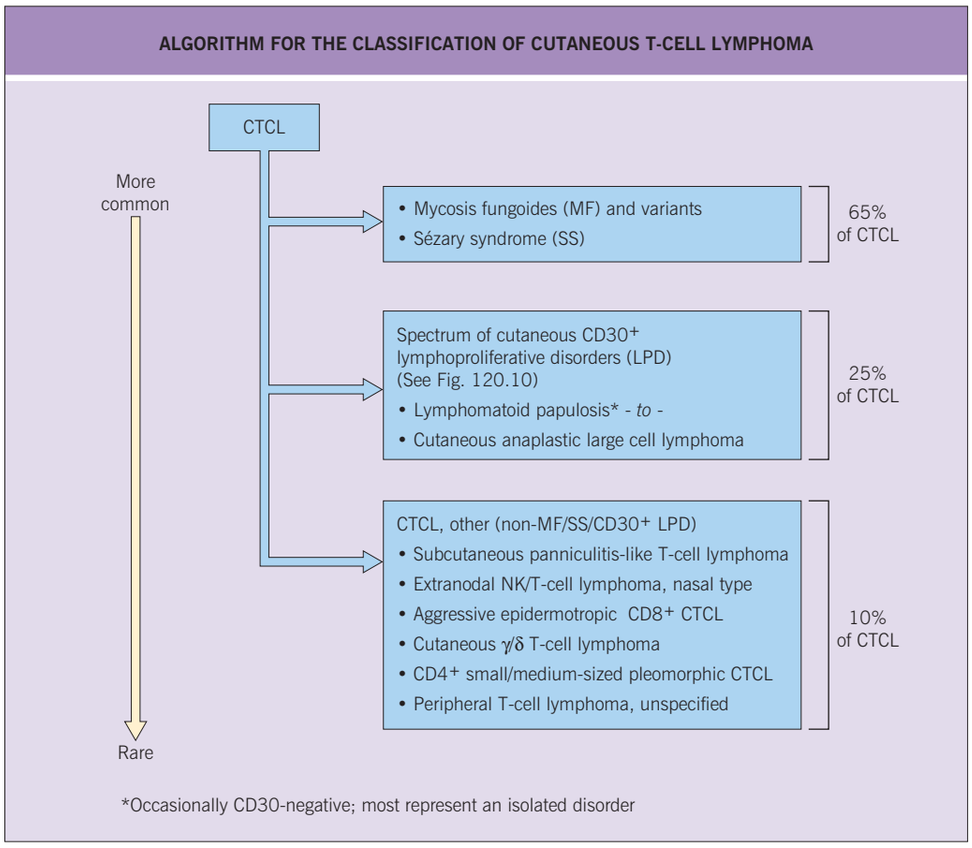

Fig. 120.1 Algorithm for the classification of cutaneous T-cell lymphoma (CTCL). *Adapted from Willemze R, Beljaards RC, Meijer CJLM. Classification of primary cutaneous T-cell lymphoma. Histopathology. 1994;24:405–15.*

concept, a gradual shift from a predominantly type 1 cytokine profile in MF plaques to a predominantly type 2 cytokine profile in MF tumors has been suggested[23]. Increased levels of Th2 cytokines may impair the Th1 cell-mediated antitumor response and contribute to the immunosuppression seen in patients with advanced MF.

Clinical features

Characteristically, patients with classical MF progress from patch stage to plaque stage and finally to tumor stage disease, and they have a protracted clinical course over years or even decades. Before a definite diagnosis is made, patients generally have many years of nonspecific eczematous or psoriasiform skin lesions and non-diagnostic biopsies. The median duration from onset of skin lesions to the diagnosis of MF is 4–6 years, but it may vary from several months to more than five decades[24,25].

Early patch stage MF is characterized by the presence of variably sized erythematous, finely scaling lesions, which may be mildly pruritic (Fig. 120.2A). These early lesions may show variable degrees of atrophy, and a poikilodermatous variant consisting of patches with mottled hyper- and hypopigmentation, atrophy and telangiectasia has been described (formerly called poikiloderma vasculare atrophicans). Generalized hypopigmented lesions may be observed in patients with darkly pigmented skin, and this is also a common presentation of juvenile-onset MF (Fig. 120.3). The initial skin lesions have a predilection for the buttocks and other covered sites of the trunk and limbs. With progression, more infiltrated reddish-brown, scaling plaques develop, which gradually enlarge and may have an annular, polycyclic or typical horseshoe-shaped configuration (Fig. 120.4A). It should be stressed that many patients never progress beyond the plaque stage of the disease. However, a number of patients may develop nodules or tumors. These patients with tumor stage MF characteristically show a combination of patches, plaques and tumors (Fig. 120.5A); the latter often show ulceration.

If only skin tumors are present without preceding or concurrent patches or plaques, a diagnosis of MF is highly unlikely and another type of CTCL should be considered. The risk of developing extracutaneous disease correlates with the extent and type of skin lesions. It is exceedingly rare in patients with limited patch/plaque stage disease, relatively uncommon in patients with generalized plaques, and most likely in patients with skin tumors or erythroderma[24,25]. Extracutaneous dissemination, almost without exception, first involves the regional lymph nodes draining areas of extensive skin involvement. Visceral involvement may develop subsequently and can involve any organ. The bone marrow is rarely involved.

Pathology

Early patch lesions in MF show superficial band-like or lichenoid infiltrates, mainly consisting of lymphocytes. Atypical cells, with small to medium-sized, highly convoluted (cerebriform) and sometimes hyperchromatic nuclei, are few in number and are mostly confined to the epidermis (epidermotropism). These lymphocytes characteristically colonize the basal layer of the epidermis as single cells surrounded by vacuolated halos, often in a linear configuration (see Fig. 120.2B)[8,26]. In plaques, epidermotropism is generally more pronounced (see Fig. 120.4B). The presence of intraepidermal nests of atypical cells (Pautrier's microabscesses) is a highly characteristic feature, but is observed in only a minority of cases. The epidermis may show acanthosis and elongated rete ridges, but spongiosis is generally mild or absent. The dermal infiltrates are also more pronounced, and they may contain a higher number of atypical cells with cerebriform nuclei and occasional blast cells, as well as admixed eosinophils and plasma cells. With progression to tumor stage, the dermal infiltrates can involve the entire dermis and extend into the subcutaneous tissue. Epidermotropism may no longer be present. The tumor cells increase in number and size, showing variable proportions of small, medium-sized or large cells with cerebriform nuclei, blast cells with prominent nuclei and intermediate forms (Fig. 120.5B). Large cell transformation, defined by the presence of CD30-negative or CD30-positive large cells exceeding 25% of the infiltrate or forming microscopic nodules, may occur and is generally associated with a poor prognosis[27].

Immunophenotype

The neoplastic cells in MF have a mature $CD3^{+}$, $CD4^{+}$, $CD45RO^{+}$, $CD8^{-}$ memory T-cell phenotype. In rare cases of otherwise classic MF, a $CD3^{+}$, $CD4^{-}$, $CD8^{+}$ mature T-cell phenotype may be seen. Immunophenotyping may demonstrate an aberrant phenotype in plaque or tumor stage MF, but rarely in early patch lesions, and is therefore of little help in early diagnosis.

Differential diagnosis

Regarding the differential diagnosis of MF, three categories should be considered. The first category contains a diverse group of benign dermatoses, which early MF may resemble clinically, and it includes several types of eczema, psoriasis, superficial fungal infections and drug reactions. These specific diagnoses can generally be excluded by histologic and other standard dermatological examinations. This category may also include patients with *large plaque parapsoriasis* (parapsoriasis en plaque) who show slightly scaly, sometimes atrophic, erythematous patches or plaques, which are commonly located on the trunk and buttocks (see Ch. 9). Whereas large plaque parapsoriasis cannot be distinguished clinically from early patch or plaque stage MF, the histologic features are often not consistent with MF. Long-term follow-up studies have documented progression of large plaque parapsoriasis to overt MF in approximately 10% of cases. One prevailing opinion is that large plaque parapsoriasis should be considered a form of MF, rather than a potential precursor of MF, but the author feels there is no consensus. There is even less consensus about whether small plaque parapsoriasis represents MF.

A second category includes several benign conditions with histologic features highly suggestive of MF. Examples of these are lymphomatoid

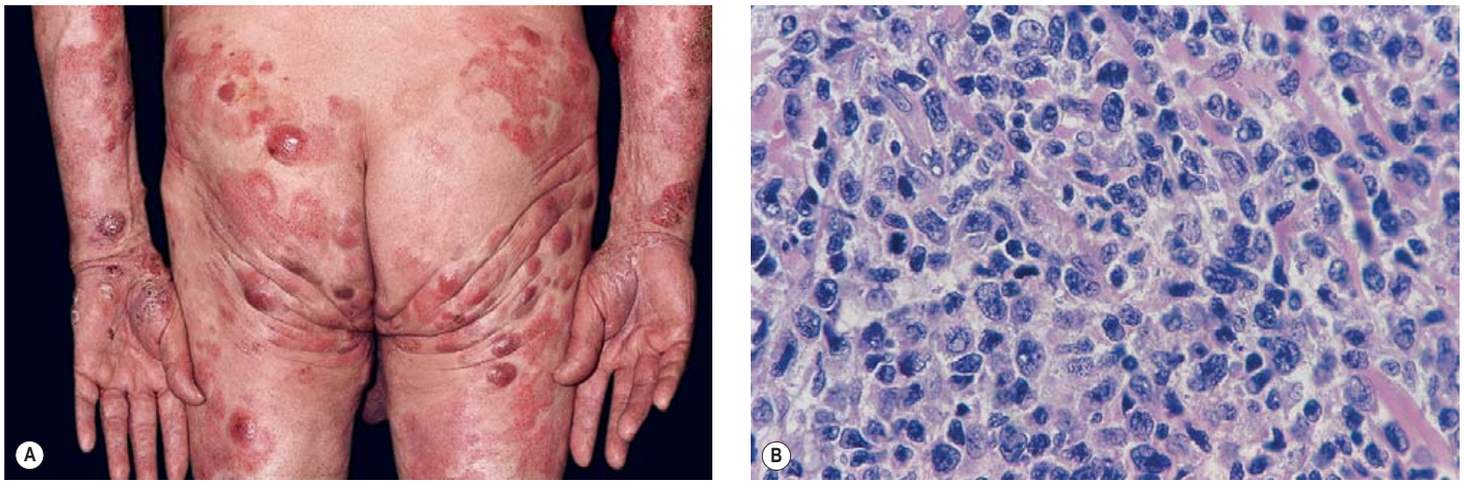

Fig. 120.5 Mycosis fungoides, tumor stage. A Multiple skin tumors in combination with typical patches and plaques. **B** Diffuse dermal infiltrates of medium-sized to large neoplastic T cells.

contact dermatitis, lymphomatoid drug reactions, and actinic reticuloid. Apart from subtle histologic differences (e.g. the predominance of atypical T cells in the dermal infiltrates rather than in the epidermis), careful evaluation of the clinical features, which are generally not consistent with MF, often results in a correct diagnosis[7].

The third category includes other types of (epidermotropic) CTCL, which may resemble MF histologically. Diagnostic features of these entities are presented in Table 120.2.

Staging systems and staging procedures

Staging patients with MF and SS is important, since it determines management and treatment and has prognostic significance. Recently, a revised clinical staging system for MF and SS was proposed, which is based on the TNM (tumor–node–metastasis) classification system and takes into account the type and extent of skin lesions (T1–4) as well as the presence or absence of nodal (N0–3), visceral (M0–1) and peripheral blood involvement (B0–2) (Tables 120.3 & 120.4)[11].

Evaluation of patients suspected of having MF should include a thorough physical examination with special attention to the type and extent of skin lesions and the presence of palpable lymph nodes, as well as skin biopsies, complete blood counts and serum chemistries. Enlarged lymph nodes should be biopsied. Histologically, distinction can be made between lymph nodes showing dermatopathic lymphadenopathy without involvement by MF (N1), dermatopathic lymphadenopathy with early MF involvement (N2), and lymph nodes showing effacement of the normal lymph node architecture by neoplastic T cells (N3). The prognostic significance of such a subdivision has been well established.

No further examinations are recommended for patients with stage IA–B disease. CT scans of the chest and abdomen are recommended in patients in whom extracutaneous disease is suspected, but they are less useful in patients with limited patches and/or plaques without lymphadenopathy. Examination of other organs, including the bone marrow, should only be performed if clinically indicated.

Treatment

The choice of an initial treatment in MF depends on the stage of the disease and the general condition and age of the patient[28,29]. Given the chronic and recurrent nature of MF, treatment should be aimed at improving symptoms while limiting toxicity. Following the traditional "stage-based" approach, skin-directed therapies are preferred in the early stages of MF (stages IA–IIA) and even in patients with limited tumor stage MF (IIB) (Table 120.5). These skin-directed therapies include topical or intralesional corticosteroids, topical cytotoxic agents (e.g. nitrogen mustard [mechlorethamine]), phototherapy and radiotherapy. The efficacy of skin-directed therapies in MF is explained by the preferential localization of the neoplastic skin-homing T cells to the epidermis and superficial dermis. Systemic multi-agent chemotherapy is not useful in these early stages, since it does not improve survival and is associated with considerable morbidity[30]. In patients with refractory or progressive skin disease, skin-directed therapies can be combined with IFN-α or systemic retinoids. Alternatively, novel agents such as denileukin diftitox or *h*istone *deac*etylase *i*nhibitors (HDACi) can be used, before systemic chemotherapy is considered. In general, systemic chemotherapy is only indicated in advanced stages when there is nodal or visceral involvement or in patients with rapidly progressive tumors unresponsive to less aggressive therapies.

Skin-directed therapies

Topical corticosteroids

In many MF patients with only patches and thin plaques, application of topical corticosteroids is effective in controlling disease activity. In patients with limited patch/plaque stage disease (mainly patches), complete remissions in up to 60% of patients have been reported[31]. In the more advanced stages, they continue to be an important adjuvant therapy.

Topical chemotherapy

Topical application of the chemotherapeutic agents mechlorethamine (nitrogen mustard) and carmustine (bis-chloronitrosourea [BCNU]) has proven to be an effective treatment for early stage MF. Nitrogen mustard, either dissolved in water or compounded in an ointment-based preparation, results in complete remissions in approximately 60–80% of patients with stage IA-B[32]. Most patients with early MF remain clear on maintenance therapy. Side effects include skin irritation, allergic contact dermatitis and an increased risk for the development of skin cancer related to long-term use. The complete remission rate with BCNU is similar to that of nitrogen mustard[33]; side effects include telangiectasias and myelosuppression, which requires careful monitoring of the complete blood count.

Radiotherapy

Total skin electron beam irradiation (TSEB) with an energy of 4–6 MeV is a highly effective treatment in patients with skin-limited MF (see Ch. 139)[29–34]. The total dose is generally 36 Gy administered in fractions of 1.5–2 Gy over an 8–10-week period. TSEB is most effective in patients with stage IA–B disease, with complete response rates of more than 80%. However, in most centers, such patients are treated with PUVA or topical chemotherapy. TSEB is particularly useful in patients with tumor stage MF, where complete response rates of approximately 40% have been reported. Side effects are generally mild and include erythema, scaling, and temporary loss of hair, nails and sweat gland function.

Local radiotherapy with X-ray or preferably electron beam may be considered for single tumors in patients with plaque stage disease, either in combination with other modalities (e.g. PUVA) as an alternative for TSEB, or for new tumors following TSEB. A dose of 10–20 Gy suffices. In patients with unilesional MF, local radiotherapy may be curative.

TNMB CLASSIFICATION OF MYCOSIS FUNGOIDES AND SÉZARY SYNDROME	
T (SKIN)	
T_1	Limited patch/plaque (involving <10% of total skin surface)
T_2	Generalized patch/plaque (involving ≥10% of total skin surface)
T_3	Tumor(s)
T_4	Erythroderma
N (LYMPH NODE)	
N_0	No enlarged lymph nodes
N_1	Enlarged lymph nodes, histologically uninvolved
N_2	Enlarged lymph nodes, histologically involved (nodal architecture uneffaced)
N_3	Enlarged lymph nodes, histologically involved (nodal architecture [partially] effaced)
M (VISCERA)	
M_0	No visceral involvement
M_1	Visceral involvement
B (BLOOD)	
B_0	No circulating atypical (Sézary) cells (or <5% of lymphocytes)
B_1	Low blood tumor burden (≥5% of lymphocytes are Sézary cells, but not B_2)
B_2	High blood tumor burden (≥1000/μl Sézary cells + positive clone)

Table 120.3 TNMB classification of mycosis fungoides and Sézary syndrome.

CLINICAL STAGING SYSTEM FOR MYCOSIS FUNGOIDES AND SÉZARY SYNDROME				
CLINICAL STAGE				
IA	T_1	N_0	M_0	$B_{0–1}$
IB	T_2	N_0	M_0	$B_{0–1}$
IIA	$T_{1–2}$	$N_{1–2}$	M_0	$B_{0–1}$
IIB	T_3	$N_{0–1}$	M_0	$B_{0–1}$
III	T_4	$N_{0–2}$	M_0	$B_{0–1}$
IVA_1	$T_{1–4}$	$N_{0–2}$	M_0	B_2
IVA_2	$T_{1–4}$	N_3	M_0	$B_{0–2}$
IVB	$T_{1–4}$	$N_{0–3}$	M_1	$B_{0–2}$

Table 120.4 Clinical staging system for mycosis fungoides and Sézary syndrome.

TREATMENT OF MYCOSIS FUNGOIDES
PREMYCOTIC PHASE
• Topical or intralesional corticosteroids; UVB • If former not effective, PUVA
STAGE IA–IIA (PATCHES/PLAQUES)
• PUVA; HN2; topical BCNU • UVB (if only patches) • Topical corticosteroids or topical bexarotene (if only limited patches/thin plaques as second-line therapy) • RT (if single lesion) • TSEB (if generalized thick plaques)
STAGE IIB (SKIN TUMORS)
• PUVA or HN2 + RT (if only a few tumors) • TSEB (followed by skin-directed therapies) • Relapse: PUVA + IFN-α; PUVA + retinoids (acitretin; oral bexarotene*); second-line therapy: denileukin diftitox*; HDACi* • Add RT (if persistent tumors); consider second course of TSEB (10–20 Gy)
STAGE III (ERYTHRODERMA)
• ECP; if not effective, add IFN-α • Low-dose chlorambucil and prednisone; low-dose methotrexate • Add skin-directed therapies (PUVA; HN2; RT), if necessary • Second-line therapy: oral bexarotene*; denileukin diftitox*; HDACi*
STAGE IV (NODAL, VISCERAL INVOLVEMENT)
• Multi-agent chemotherapy (e.g. CHOP) • Biological response modifiers (denileukin diftitox; IFN-α; oral retinoids) • Add skin-directed therapies (PUVA; HN2), if necessary • Allogeneic hematopoietic stem cell transplantation (in selected cases)
*Efficacy compared to traditional treatments yet to be determined.

Table 120.5 Treatment of mycosis fungoides. BCNU, topical bis-chloronitrosourea (carmustine); CHOP, cyclophosphamide, hydroxydaunomycin (doxorubicin), Oncovin® (vincristine) and prednisone; ECP, extracorporeal photopheresis; HDACi, histone deacetylase inhibitors; HN2, topical nitrogen mustard (mechlorethamine); IFN, interferon; RT, local radiotherapy; TSEB, total skin electron beam.

Phototherapy

Several types of phototherapy can be used in the treatment of MF (Ch. 134). These include UVA irradiation following photosensitization with 8-methoxypsoralen (PUVA therapy), broadband and narrowband UVB therapy, and, more recently, UVA1 therapy. Extracorporeal photopheresis (ECP) may be effective in patients with erythrodermic MF (see the section on Sézary syndrome).

PUVA treatment has become a standard therapy for the early stages of MF[35]. In patients with stages IA–IIA, complete response rates of 80–90% have been reported. In many centers, maintenance PUVA therapy (every 2 to 4 weeks) is given to prolong remission. Although sustained complete remissions have been reported, most patients will relapse after cessation of PUVA therapy or during maintenance treatment. Recurrent or persistent lesions particularly favor UV-shielded areas, such as the inner thighs and the gluteal cleft. In tumor stage MF, PUVA therapy alone is unlikely to result in complete responses, but favorable results may be achieved when combined with IFN-α, systemic retinoids or radiotherapy.

In patients with only patches, broadband UVB therapy (300–320 nm) has been reported as a safe and effective alternative, with complete response rates of up to 75%[36]. Recent studies reported favorable results with narrowband UVB (311 nm) and UVA1 therapy in the early stages of MF, but it remains to be determined how these new therapies compare to the established forms of phototherapy.

Systemic therapies (other than chemotherapy)

Most agents within this category are biological response modifiers aimed at potentiating the host's immune response to the neoplastic T cells. They include cytokines (e.g. IFN-α, IL-12), retinoids, immunotoxins (e.g. denileukin diftitox), and monoclonal antibodies such as zanolimumab (anti-CD4) and alemtuzumab (anti-CD52). Current evidence suggests that biological response modifiers are most effective when combined with (or preceded by) traditional therapies aimed at tumor cell eradication. HDACi represent a new class of drugs being employed for the treatment of MF and SS.

Interferons

The most commonly prescribed biological response modifier is interferon-alpha (IFN-α). In most centers, IFN-α is administered subcutaneously in doses of 3 to 9 million units three times a week. Side effects are generally mild and reversible, and they include flu-like symptoms, hair loss, nausea, depression and bone marrow suppression. The overall response rate of IFN-α, when used as a single agent, is approximately 50%, with 17% representing complete remissions[37]. The combination of PUVA and IFN-α appears to produce higher response rates than PUVA alone, and this combination may also be considered in patients with early tumor stage disease, when PUVA therapy alone is insufficient.

Retinoids

When used as a single agent, the overall and complete response rates of several first- and second-generation oral retinoids (isotretinoin, etretinate, acitretin) and a novel RXR-selective retinoid (bexarotene) are

roughly similar to those of IFN-α[29,38]. A combination of retinoids and PUVA (RePUVA) produces response rates similar to those of PUVA alone, although patients treated with RePUVA require fewer treatments and a significantly lower cumulative UVA dose. In many centers, bexarotene has replaced the earlier-generation retinoids, but comparative studies have never been performed. In patients with patches or thin plaques, topical bexarotene may be considered, but cost is an issue.

Denileukin diftitox

Denileukin diftitox is a fusion protein, in which diphtheria toxin is linked to IL-2. It binds to the high-affinity IL-2 receptor expressed by the neoplastic T cells in MF, and internalization of the toxin results in inhibition of protein synthesis and cell death. Overall and complete clinical response rates are approximately 30% and 10%, respectively[28,29,39]. Denileukin diftitox can have substantial side effects, including capillary leak syndrome, fever, and fluid retention.

Histone deacetylase inhibitors

HDACi, such as vorinostat and depsipeptide, represent a novel class of drugs used in cancer therapy. Inhibition of the enzyme HDAC affects the expression of many genes (and their protein products) that are involved in cellular proliferation, differentiation, migration and apoptosis. Recent studies of both vorinostat and depsipeptide report overall response rates of approximately 35% in patients with MF and SS, but complete responses are rare[29,40]. The most common side effects are fatigue, gastrointestinal symptoms and reversible thrombocytopenia. It remains to be determined which patients are most likely to benefit from this therapy.

Systemic chemotherapy

Systemic multi-agent chemotherapy should only be used in patients with unequivocal lymph node or visceral involvement, or in patients with progressive skin tumors that have failed to respond to other therapies[28,29]. In many centers, the standard treatment in such cases is the administration of six cycles of CHOP (*c*yclophosphamide, *h*ydroxydaunomycin [doxorubicin], *O*ncovin® [vincristine] and *p*rednisone). With this and other combination regimens, high response rates can be achieved for extracutaneous involvement, but the responses are generally short-lived. Moreover, concurrent patches and plaques are often less responsive, and may require additional treatment with PUVA or nitrogen mustard. Recent studies utilizing pentostatin, gemcitabine and liposomal doxorubicin have demonstrated high overall response rates in patients with advanced MF, but controlled studies are still lacking.

In young patients with refractory and/or progressive MF and SS, an allogeneic hematopoietic stem cell transplantation may be considered. Durable responses have been reported, but experience is still limited and the optimal conditioning regimen and optimal timing for the transplant are currently unknown. Results with autologous hematopoietic stem cell transplantation in MF and SS have been disappointing[41], suggesting the need for a graft-versus-tumor response.

Prognosis

The prognosis of patients with MF is dependent on the stage, and in particular the type and extent of skin lesions and the presence of extracutaneous disease[24,25]. Patients with limited patch/plaque stage MF have a similar long-term life expectancy as an age-, sex-, and race-matched control population. In a study of 309 Dutch MF patients, the disease-related 10-year survival for those with limited patch/plaque disease, generalized patch/plaque disease, and tumor stage disease (without concurrent lymph node involvement) was 97%, 83% and 42%, respectively, but it was only 20% for patients with histologically documented lymph node involvement[25]. An aggressive clinical course is seen in patients with effaced lymph nodes, visceral involvement, and large cell transformation. Patients usually die of systemic involvement or infections.

VARIANTS OF MYCOSIS FUNGOIDES

Apart from the classical Alibert–Bazin type of MF, many clinical and/or histologic variants have been reported. Clinical variants, such as bullous and hyper- or hypopigmented MF, have clinical behavior similar to that of classic MF, and they are therefore not considered separately. In contrast, folliculotropic MF, pagetoid reticulosis, and granulomatous slack skin have distinctive clinicopathologic features, and therefore they have been included as distinct variants or subtypes of MF in the WHO-EORTC classification scheme.

Folliculotropic MF

Synonyms: ■ MF-associated follicular mucinosis ■ Folliculocentric or pilotropic MF

Definition

Folliculotropic MF is a distinct variant of MF characterized by the presence of folliculotropic infiltrates, often with sparing of the epidermis and preferential involvement of the head and neck region. Most cases show mucinous degeneration of the hair follicles (follicular mucinosis; Ch. 46) and are traditionally designated as MF-associated follicular mucinosis. Similar cases, but without follicular mucinosis, have been reported as folliculocentric or pilotropic MF. From a biologic point of view, the most relevant feature (irrespective of the presence or absence of follicular mucinosis) is the deep, follicular and perifollicular localization of the neoplastic infiltrates, which makes them less accessible to skin-directed therapies. For both groups, the term folliculotropic MF is therefore preferred[3].

Epidemiology

This variant is found in approximately 10% of MF patients[25]. It occurs mostly in adults, but may occasionally affect children and adolescents. Men are affected more often than women.

Clinical features

Patients may present with (grouped) follicular papules, acneiform lesions, indurated plaques and sometimes tumors, which preferentially involve and are most pronounced in the head and neck area. The skin lesions are often associated with alopecia, and sometimes with mucinorrhea. Infiltrated plaques in the eyebrow region with concurrent alopecia are a common and highly characteristic finding (Fig. 120.6A). Pruritus is often more severe than in classic MF and may represent a reliable parameter of disease activity. Secondary bacterial infections are frequently observed.

It should be stressed that the clinical staging systems for MF are not very helpful in patients with folliculotropic MF. Because of the perifollicular localization of the neoplastic infiltrates, patients presenting with one or a few plaques on the face do not have stage IA disease, but should always be considered as having tumor stage disease. Consistently, the survival of patients with folliculotropic MF is similar to that of classic tumor stage MF[42,43].

Pathology

Characteristic findings include primarily perivascular and periadnexal localization of the dermal infiltrates, with variable infiltration of the follicular epithelium by small, medium-sized or sometimes large T cells with hyperchromatic and cerebriform nuclei, and sparing of the epidermis (folliculotropism instead of epidermotropism) (Fig. 120.6B). Most cases show mucinous degeneration of the follicular epithelium (follicular mucinosis), as assessed with Alcian blue or colloidal iron staining. There is often a considerable admixture with eosinophils and sometimes plasma cells. In the perifollicular infiltrates, the neoplastic T cells may be blast cells rather than cerebriform cells, and therefore may be easily mistaken for histiocytes. In most cases, the neoplastic T cells have a $CD3^+$, $CD4^+$, $CD8^-$ phenotype as in classic MF. Admixture with CD30-positive blast cells is common.

Differential diagnosis

The distinctive clinical and histologic features should facilitate an early and correct diagnosis. However, because of the preferential involvement of the head and neck area, the absence of patches and plaques on the trunk and buttocks, and particularly because of the absence of epidermotropic atypical T cells, the diagnosis of MF or CTCL is often not considered and is misinterpreted as seborrheic dermatitis or atopic dermatitis. Clinicopathologic correlation is also required to

Fig. 120.6 Folliculotropic mycosis fungoides. **A** Infiltrated plaques on the forehead and eyebrow with concurrent hair loss. **B** Characteristic perifollicular infiltrates with extensive follicular mucinosis (asterisks). Note absence of epidermotropism.

differentiate folliculotropic MF from other types of CTCL[42]. The relationship between folliculotropic MF and the so-called benign or idiopathic form of follicular mucinosis (alopecia mucinosa) resembles the relationship between classic MF and "parapsoriasis". In the case of persistent lesions of the idiopathic form, patients should be monitored regularly, since progression into overt folliculotropic MF has been frequently reported.

Treatment

Because of the perifollicular localization of the dermal infiltrates, folliculotropic MF is often less responsive to skin-directed therapies, such as PUVA and topical nitrogen mustard, than is classic plaque stage MF. In the case of unresponsive disease, a combination of PUVA with either IFN-α or retinoids, local radiotherapy or TSEB can be used, although sustained complete remissions are rarely achieved[42,43].

Pagetoid Reticulosis

Synonyms: ■ Woringer–Kolopp disease ■ Unilesional MF

Definition

This is a rare variant of MF, characterized by the presence of localized patches or plaques with an intraepidermal proliferation of neoplastic T cells. The term pagetoid reticulosis should only be used for the localized type (Woringer–Kolopp type) and not for the disseminated type (Ketron–Goodman type). Nowadays, patients with generalized disease would most likely be classified as primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma, primary cutaneous gamma/delta T-cell lymphoma, or tumor stage MF[3].

Epidemiology

Pagetoid reticulosis is extremely rare, and it accounts for fewer than 1% of CTCL cases. It mostly affects adults.

Clinical features

Patients present with a solitary psoriasiform or hyperkeratotic patch or plaque, which is usually localized on an extremity and slowly progressive (Fig. 120.7A). In contrast to classic MF, extracutaneous dissemination or disease-related deaths have never been reported.

Pathology

The typical histologic picture consists of a hyperplastic epidermis with marked infiltration by large atypical pagetoid cells, arranged singly or in nests or clusters (Fig. 120.7B). The atypical cells have medium-sized or large, sometimes hyperchromatic and cerebriform nuclei and abundant, vacuolated cytoplasm. The superficial dermis may have an infiltrate of mostly small lymphocytes, but rarely contains neoplastic T cells.

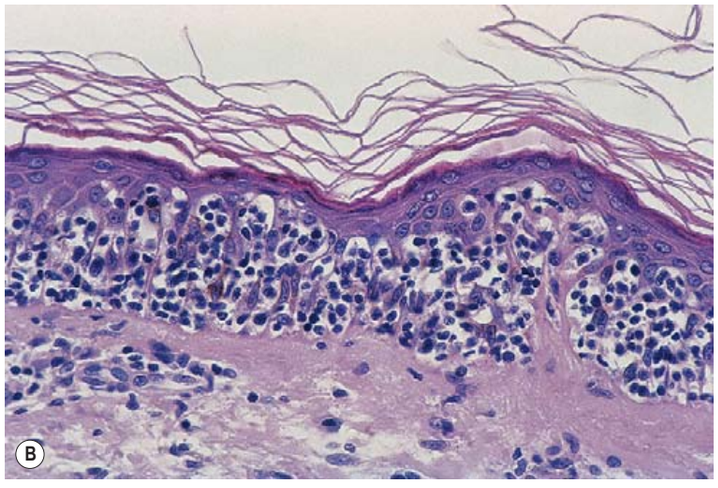

Fig. 120.7 Pagetoid reticulosis. **A** Solitary plaque on the left upper leg. **B** Purely intraepidermal proliferation of atypical T cells.

Immunophenotype

The neoplastic T cells may show either a $CD3^+$, $CD4^+$, $CD8^-$ or a $CD3^+$, $CD4^-$, $CD8^+$ phenotype. CD30 is often expressed[44].

Differential diagnosis

Pagetoid reticulosis should be differentiated from other types of epidermotropic CTCL, such as MF, LyP type B, and primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma (see Table 120.2). Useful criteria for pagetoid reticulosis include the characteristic clinical presentation and the often strictly epidermal localization of the neoplastic T cells.

Treatment

The preferred mode of treatment is radiotherapy or surgical excision.

Granulomatous Slack Skin

Definition

This is an extraordinarily rare type of CTCL, characterized by the slow development of folds of lax skin and a granulomatous infiltrate with clonal T cells[45].

Epidemiology

This is an extremely rare type of CTCL, with approximately 60 cases reported. It typically affects adolescents and adults, and mostly occurs in men.

Clinical features

This condition is characterized by circumscribed areas of pendulous lax skin with a predilection for the axillae and groin (Fig. 120.8A). In approximately one-third of the reported patients, an association with Hodgkin lymphoma was observed. Most patients have an indolent clinical course.

Pathology

Fully developed lesions show dense granulomatous dermal infiltrates containing atypical T cells with cerebriform nuclei, macrophages and often many multinucleated giant cells, as well as destruction of elastic tissue and elastophagocytosis by the multinucleated cells (Fig. 120.8B). The epidermis may be infiltrated by small atypical T cells with cerebriform nuclei, as in classic MF. The atypical T cells have a $CD3^+$, $CD4^+$, $CD8^-$ phenotype. A recent study noted overlapping histologic features between granulomatous slack skin and granulomatous MF[46].

Treatment

Radiotherapy may be effective, but experience is still limited. Rapid recurrences after surgical excision have been reported.

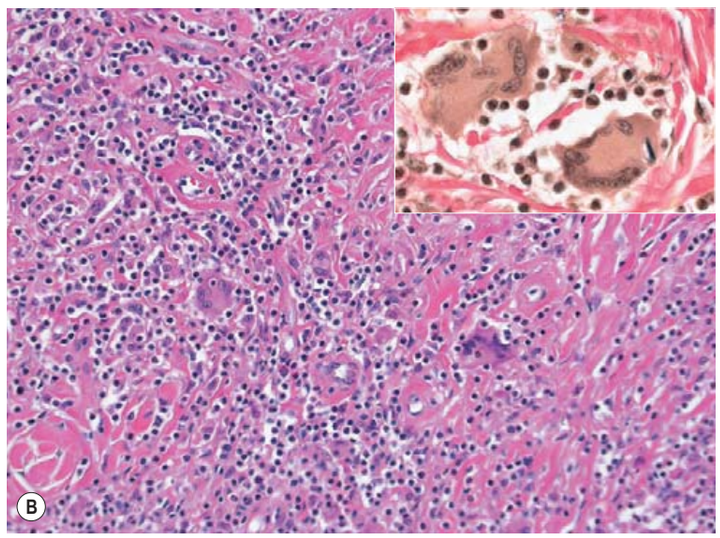

Fig. 120.8 Granulomatous slack skin. A Pendulous fold of atrophic lax skin in the right inguinal area. **B** Multinucleated giant cells with intracellular leukocytes (emperipolesis), surrounded by a dense leukocytic infiltrate. Inset: Elastic tissue stain showing a multinucleated giant cell containing an elastic fiber (elastophagocytosis).

SÉZARY SYNDROME

Definition

Sézary syndrome (SS) is defined historically by the triad of erythroderma, generalized lymphadenopathy, and the presence of neoplastic T cells (Sézary cells) in the skin, lymph nodes and peripheral blood (Fig. 120.9). Criteria recommended for the diagnosis of SS include demonstration of a T-cell clone in the peripheral blood by molecular or cytogenetic methods, demonstration of immunophenotypical abnormalities (an expanded $CD4^+$ T-cell population resulting in a CD4/CD8 ratio greater than 10 and/or aberrant expression of pan-T-cell antigens), and an absolute Sézary cell count of least 1000 cells per µl[47]. In the WHO-EORTC classification, demonstration of a T-cell clone (preferably the same T-cell clone in skin and peripheral blood) in combination with one of the aforementioned cytomorphologic or immunophenotypical criteria are suggested as minimal criteria for the diagnosis of SS, so as to exclude patients with a benign inflammatory condition simulating SS.

Epidemiology

SS is a rare disease accounting for less than 5% of all CTCL (see Table 120.1). It occurs exclusively in adults.

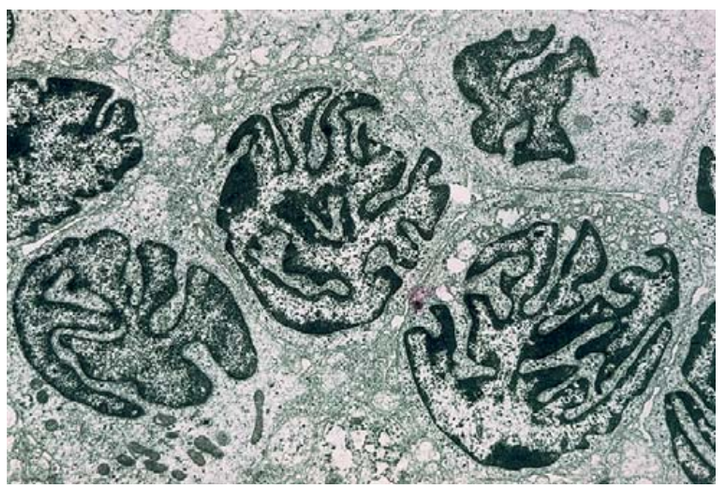

Fig. 120.9 Sézary syndrome. Electron photomicrograph of a skin biopsy showing characteristic Sézary cells.

Fig. 120.10 Sézary syndrome. Erythroderma with diffuse scaling.

Clinical features

SS is characterized by erythroderma, which may be associated with marked exfoliation, edema and lichenification; it is intensely pruritic (Fig. 120.10). Lymphadenopathy, alopecia, onychodystrophy and palmoplantar hyperkeratosis are common findings. The overt clinical picture may be preceded by a non-diagnostic dermatitis. The prognosis is generally poor, with an overall 5-year survival of approximately 25%. Most patients die of opportunistic infections due to immunosuppression.

Pathology

The histologic features in SS may be similar to those in MF. However, the cellular infiltrates in SS are more often monotonous, and epidermotropism may sometimes be absent. In up to one-third of skin biopsies from patients with otherwise classic SS, the histologic findings may be nonspecific[48]. Involved lymph nodes characteristically show a dense, monotonous infiltrate of Sézary cells with effacement of the normal lymph node architecture. The bone marrow may be involved, but the infiltrates are often sparse and mainly interstitial. The neoplastic T cells have a $CD3^+$, $CD4^+$, $CD8^-$ phenotype and characteristically lack CD7 and CD26 expression[48].

Pathogenesis

The pathogenesis of SS is unknown. Conclusive evidence of an etiological role for HTLV-1 is lacking. Recurrent chromosomal translocations have not been detected in SS, but complex karyotypes are common. Several studies have identified a consistent pattern of identical chromosomal abnormalities in SS, with deletions involving chromosomes 10q and 17p and gains involving chromosomes 8q, 10p and 17q being the most common findings[49–51]. While SS is often designated as a leukemic phase or variant of MF, recent studies have revealed major genomic and phenotypical differences between these two conditions, suggesting that SS and MF should be considered as separate lymphomas arising from distinct functional T-cell subsets[51a,51b].

Differential diagnosis

Differentiation between SS and non-neoplastic forms of erythroderma may be extremely difficult. The differential diagnosis includes erythroderma secondary to psoriasis, atopic dermatitis or other forms of dermatitis, pityriasis rubra pilaris and drug reactions as well as idiopathic erythroderma (see Ch. 10). Demonstration of clonal T cells in the peripheral blood is considered an important diagnostic criterion favoring SS. Demonstration of a predominant $CD3^+$, $CD4^-$, $CD8^+$ T-cell population in the skin and peripheral blood is highly suggestive of actinic reticuloid (see Ch. 87)[52].

Treatment

Being a systemic disease (leukemia) by definition, systemic treatment is required. Skin-directed therapies like PUVA or potent topical corticosteroids may be used as adjuvant therapy. Extracorporeal photopheresis (ECP), either alone or in combination with other treatment modalities, has been suggested as the treatment of choice in SS and erythrodermic MF, with overall response rates of 30–80%, and complete response rates of 14–25%[53,54]. This great variation in response rates may reflect differences in patient selection and/or concurrent therapies. The suggested superiority of ECP over traditional low-dose chemotherapy regimens has not yet been substantiated by randomized controlled trials[54]. Beneficial effects have also been reported with IFN-α (either alone or in combination with PUVA therapy), prolonged treatment with low-dose chlorambucil plus prednisone, or methotrexate, but complete responses are uncommon. CHOP or CHOP-like regimens may produce higher response rates, but these responses are generally short-lived. Recent studies have observed possible benefits with bexarotene, denileukin diftitox, HDACi and alemtuzumab (anti-CD52), but the long-term effects of these therapies remain to be established[28,29].

ADULT T-CELL LEUKEMIA/LYMPHOMA

Definition

Adult T-cell leukemia/lymphoma (ATLL) is a type of T-cell neoplasm etiologically associated with HTLV-1. Skin lesions are generally a manifestation of widely disseminated disease. However, a slowly progressive form that sometimes has only skin lesions has been described (smoldering variant)[55].

Epidemiology

ATLL is endemic in areas with a high prevalence of HTLV-1 in the population, such as southwestern Japan, the Caribbean Islands and parts of Central Africa. In addition, a high prevalence is seen in Jewish individuals whose ancestors were from Mashad, Iran. However, only a minor proportion of seropositive patients eventually develops ATLL. The disease occurs in adults, and men are affected more frequently than women. Vertical transmission is more common than horizontal transmission.

Clinical features

Most patients present with acute ATLL characterized by the presence of leukemia, lymphadenopathy, organomegaly, hypercalcemia and frequently skin lesions; it has a poor prognosis. Chronic and smoldering variants often present with patches, plaques and papular skin lesions, which may closely resemble MF, and circulating neoplastic T cells are few or absent. Such cases have a more protracted clinical course, but progression to a high-grade malignant disseminated form of the disease may occur.

Pathology

Skin lesions demonstrate a superficial or more diffuse infiltration of small, medium-sized or large pleomorphic T cells, which often display marked epidermotropism. The histologic picture may be indistinguishable from MF. Skin lesions in the smoldering type may have sparse dermal infiltrates with only slightly atypical cells. The neoplastic T cells express a $CD3^+$, $CD4^+$, $CD8^-$, $CD25^+$ phenotype.

Differential diagnosis

Differentiation between chronic or smoldering variants of ATLL and MF may be extremely difficult, particularly in endemic areas. In such cases, a definite diagnosis of ATLL requires demonstration of clonally integrated HTLV-1.

Treatment

ATLL may be treated with a combination of zidovudine and IFN-α, but in most cases, systemic chemotherapy is required[56]. In chronic and smoldering cases mainly affecting the skin, skin-directed therapies as in MF are preferred.

PRIMARY CUTANEOUS CD30-POSITIVE LYMPHOPROLIFERATIVE DISORDERS

Primary cutaneous CD30-positive lymphoproliferative disorders represent the second most common group of CTCL, accounting for approximately 25% of CTCL (see Table 120.1). This group includes primary cutaneous anaplastic large cell lymphoma (C-ALCL), lymphomatoid papulosis (LyP), and borderline cases. C-ALCL and LyP have overlapping clinical, histologic and immunophenotypical features and form a spectrum of disease. Thus, histologic criteria alone are often insufficient to distinguish between the two ends of the spectrum. In the end, the clinical appearance and course are used as decisive criteria for the definite diagnosis and choice of treatment. The term "borderline case" refers to patients in whom, despite careful clinicopathologic correlation, a definite distinction between C-ALCL and LyP cannot be made. Longitudinal clinical evaluation will generally disclose whether the patient has C-ALCL or LyP[57]. Cases previously designated as *regressing atypical histiocytosis*, as well as rare cases of primary cutaneous Hodgkin lymphoma with an indolent clinical course, also belong to this spectrum[57].

Primary cutaneous CD30-positive lymphoproliferative disorders should be differentiated from: (1) skin involvement by systemic ALCL; (2) CD30-positive transformed MF; (3) other well-defined types of CTCL, which may sometimes express the CD30 antigen; and (4) reactive skin conditions with infiltrates containing CD30-positive blast cells, including various viral infections, arthropod bite reactions, scabies and atopic dermatitis[58] (see Table 120.2). Guidelines for the diagnosis and treatment of primary cutaneous CD30-positive lymphoproliferations are provided in Figure 120.11.

Primary Cutaneous Anaplastic Large Cell Lymphoma

Definition

Primary cutaneous anaplastic large cell lymphoma (C-ALCL) is composed of large cells with an anaplastic, pleomorphic or immunoblastic cytomorphology and expression of the CD30 antigen by the majority (greater than 75%) of tumor cells. Patients should not have clinical evidence or a history of MF. In such individuals, a diagnosis of tumor stage MF with blastic transformation is more likely.

Epidemiology

These lymphomas account for approximately 12% of all CTCLs (see Table 120.1). They predominantly affect adults and are rare in children or adolescents. The male-to-female ratio is approximately 2:1.

Clinical features

Most patients present with solitary or localized nodules or tumors (sometimes papules) that often develop ulceration (Fig. 120.12A). Multifocal lesions are seen in about 20% of the patients. The skin lesions may show partial or complete spontaneous regression, as in LyP. These lymphomas frequently relapse in the skin. Extracutaneous dissemination occurs in approximately 10% of the patients, and it mainly

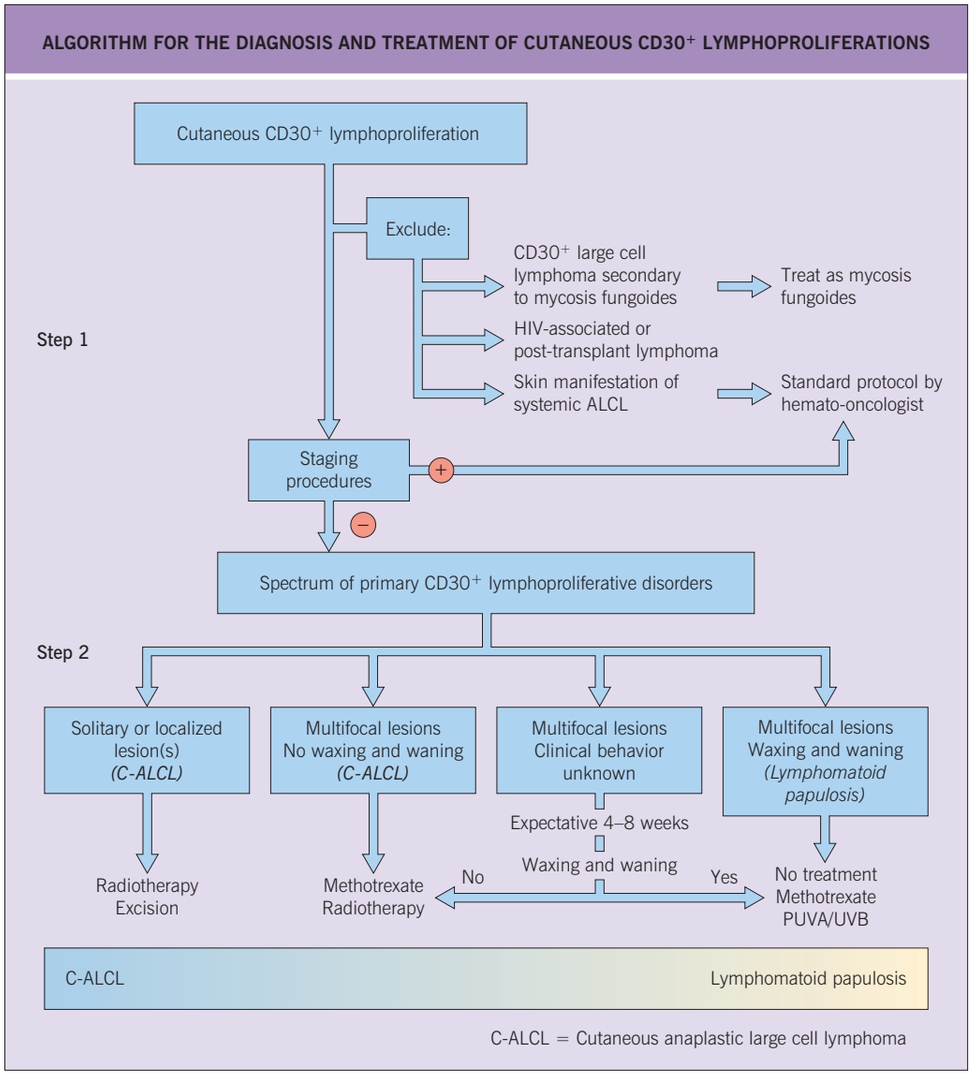

Fig. 120.11 Algorithm for the diagnosis and treatment of primary cutaneous CD30-positive lymphoproliferations. Cases previously designated as regressing atypical histiocytosis, as well as rare cases of primary cutaneous Hodgkin lymphoma with an indolent clinical course, also belong to this spectrum. From ref. 57.

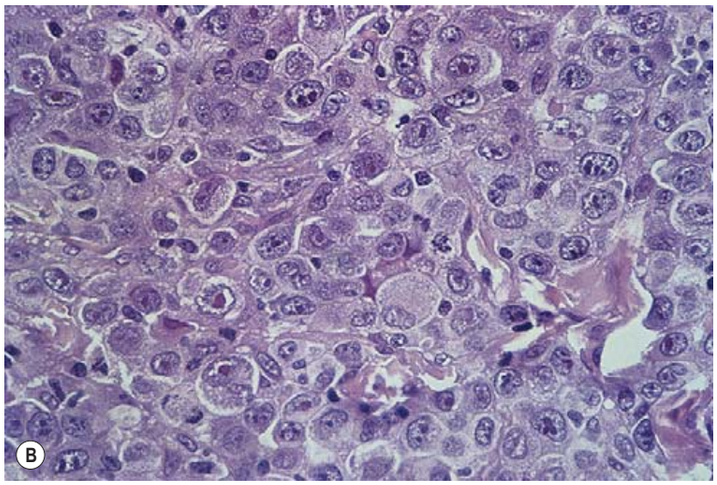

Fig. 120.12 Primary cutaneous anaplastic large cell lymphoma. **A** Characteristic clinical presentation with a solitary ulcerating tumor. **B** Detail of dermal infiltrate showing cohesive clusters of large (CD30-positive) anaplastic cells with pronounced eosinophilic nucleoli and abundant cytoplasm.

involves the regional lymph nodes. The prognosis is usually favorable, with a 10-year disease-related survival exceeding 85%[57,59].

Pathology

Histologically, these lymphomas show diffuse non-epidermotropic infiltrates with cohesive sheets of large CD30-positive tumor cells (Fig. 120.12B). In most cases, the tumor cells have the characteristic morphology of anaplastic cells, with round, oval or irregularly shaped nuclei, prominent (eosinophilic) nucleoli and abundant cytoplasm. Less commonly (20–25%), tumor cells have a pleomorphic, immunoblastic or Reed–Sternberg cell-like appearance. The mitotic index is generally high. Reactive lymphocytes are often present at the periphery of the tumor. Ulcerating lesions may show an LyP-like histology with an abundant inflammatory infiltrate of reactive T cells, histiocytes, eosinophils, neutrophils, and relatively few CD30-positive cells. In such cases, epidermal hyperplasia may be prominent.

Immunophenotype

The neoplastic cells often express a $CD4^+$ T-cell phenotype with variable loss of CD2, CD5 and/or CD3. Some cases (<5%) have a $CD8^+$ T-cell phenotype. CD30 must be expressed by the majority of neoplastic cells. Expression of cytotoxic proteins (granzyme B, TIA-1, perforin) is noted in approximately 70% of cases, while MUM1/IRF4 (multiple myeloma oncogene 1/interferon regulatory factor 4) is expressed in almost all cases[60]. Unlike systemic ALCL, most C-ALCLs express CLA (cutaneous lymphocyte antigen), but do not express EMA (epithelial membrane antigen) and ALK (anaplastic lymphoma kinase); the latter is indicative of the t(2;5) chromosomal translocation[61]. Coexpression of CD56 is observed in rare cases, but does not appear to be associated with an unfavorable prognosis[62].

Genetic features

The t(2;5) translocation, which is found predominantly in systemic ALCL in children, is rarely, if ever, found in C-ALCL[60]. Recent studies demonstrated a recurrent translocation of *IRF4* in a subset of C-ALCL[63,64].

Treatment

Radiotherapy is the initial choice of treatment in patients presenting with a solitary or a few localized nodules or tumors. However, if a solitary lesion has been excised completely or disappeared spontaneously, no further therapy is required. Patients presenting with multifocal skin lesions can best be treated with radiotherapy (if there are only a few lesions) or with low-dose methotrexate as in LyP[57,65]. Patients who present with or develop extracutaneous disease or those rare patients with rapidly progressive skin disease should be treated with doxorubicin-based multi-agent chemotherapy. Early systemic chemotherapy may also be considered in patients presenting with extensive skin lesions on one or both legs, since they often have an aggressive clinical course and the prognosis is unfavorable[66,67].

Lymphomatoid Papulosis

Definition

Lymphomatoid papulosis (LyP) is defined as a chronic, recurrent, self-healing papulonecrotic or papulonodular skin disease with histologic features suggestive of a (CD30-positive) malignant lymphoma. Since the introduction of the term LyP in 1968 by Macaulay[68], there has been continued discussion as to whether LyP is a malignant, premalignant or benign condition. Because of the overlapping clinical and histologic features between LyP and C-ALCL, including the presence of an aberrant T-cell phenotype, the presence of clonally rearranged TCR genes in 60–70% of the patients, and the presence of identical T-cell clones in LyP lesions and associated lymphoma lesions, LyP is best regarded as a low-grade variant of CTCL.

Pathogenesis

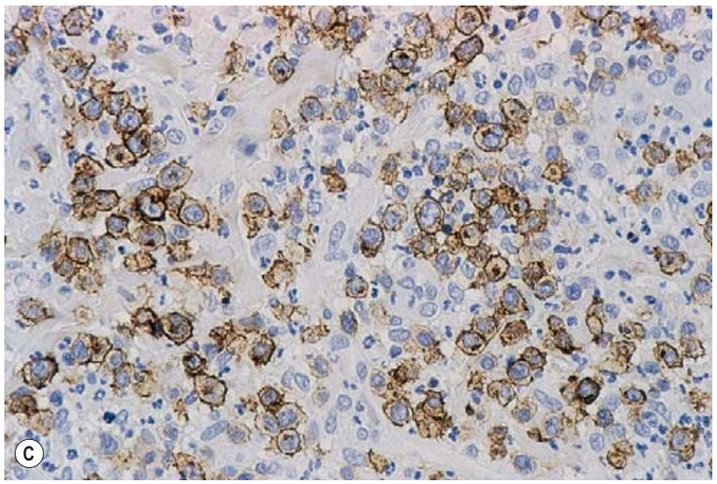
The initiating event in LyP is unknown. Several authors have suggested a viral etiology. However, studies searching for an etiologic role for HTLV-1, EBV and other herpes viruses, including herpes simplex virus types 1 and type 2 and human herpesvirus-6, have been consistently negative. The mechanisms involved in the spontaneous disappearance of skin lesions, or in the tumor progression observed in some patients with LyP, have not yet been identified. It has been suggested that interactions between CD30 and its ligand (CD30L) may contribute to apoptosis of the neoplastic T cells and the subsequent regression of the skin lesions, but the exact mechanism is as yet unknown[69]. Unresponsiveness to the growth inhibitory effect of transforming growth factor-β (TGF-β) due to a mutation in the gene that encodes the TGF-β type I receptor on the CD30-positive tumor cells has been suggested as one of the possible mechanisms in tumor progression[70].

Epidemiology

LyP accounts for approximately 15% of all CTCL (see Table 120.1). It may occur at any age. The youngest patient reported to date was 8 months old, and the oldest was 84 years of age. In large series, the average age of onset varies between 35 and 45 years. The male-to-female ratio is approximately 1.5:1.

Clinical features

The typical skin lesions in LyP are red–brown papules and nodules that may develop central hemorrhage, necrosis and crusting; they subsequently disappear spontaneously within 3 to 8 weeks. Characteristically, skin lesions in different stages of evolution coexist (Fig. 120.13A). The papulonodules may leave transient hypopigmented or hyperpigmented macules and, occasionally, superficial atrophic (varioliform) scars, or they may disappear without ulceration or sequelae. The



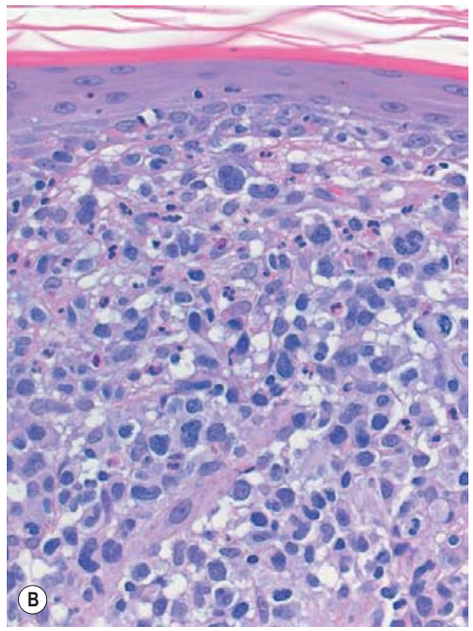


Fig. 120.13 Lymphomatoid papulosis (LyP). A Clinical presentation with papulonecrotic skin lesions at different stages of evolution. **B** Diffuse infiltrate with many large atypical lymphocytes. Scattered neutrophils are seen both in the epidermis and dermis. **C** Detail of dermal infiltrate showing a mixed inflammatory infiltrate with scattered (CD30-positive by immunohistochemistry) large anaplastic T cells (LyP, type A).

number of lesions varies from several to more than one hundred. Lesions may be localized, sometimes clustered within rather well-defined areas, or generalized. The predominant sites of involvement are the trunk and limbs. The eruption is generally asymptomatic.

The duration of the disease ranges from several months to more than 40 years. In up to 20% of patients, LyP may be preceded by, associated with, or followed by another type of cutaneous or systemic lymphoma, generally MF, C-ALCL or Hodgkin lymphoma[71]. However, the prognosis is usually excellent. In a recent study of 118 patients with LyP, only five patients (4%) developed a systemic lymphoma, and only two patients (2%) died of systemic disease over a median follow-up period of 77 months[57]. Risk factors for the development of a systemic lymphoma are unknown.

Pathology

The histologic picture of LyP is extremely variable, but in part it correlates with the age of the sampled skin lesion. In addition, four histologic types of LyP have been described: types A, B, C and D.

LyP type A lesions show a wedge-shaped, initially non-epidermotropic, infiltrate with scattered or small clusters of large atypical, sometimes multinucleated or Reed–Sternberg-like, CD30-positive T cells, interspersed in an extensive inflammatory infiltrate composed of small lymphocytes, neutrophils and/or eosinophils (Fig. 120.13B,C). The large atypical cells, which have the morphologic and immunophenotypical characteristics of the neoplastic cells in C-ALCL, are relatively few in early lesions and more numerous in fully developed lesions, but they may be completely absent in resolving lesions. The presence of scattered neutrophils within a moderately acanthotic and parakeratotic, but otherwise unaffected, epidermis is a characteristic finding.

LyP type B lesions are relatively uncommon (<10%) and are characterized by superficial perivascular to band-like lymphocytic infiltrates, which show early infiltration of the basal and parabasal layers of the epidermis. Occasionally, these perivascular infiltrates can also be found in the lower dermis. The infiltrates are composed predominantly of small to medium-sized atypical cells with cerebriform nuclei and the phenotype of $CD3^+$, $CD4^+$, $CD30^-$ or $CD30^+$ T cells, similar to those observed in MF.

LyP type A and type B may occur in different but concurrent lesions, and occasionally a single LyP lesion shows histologic features characteristic of both type A and type B[57].

LyP type C lesions demonstrate a monotonous population or large clusters of large CD30-positive T cells with relatively few admixed inflammatory cells, a histologic appearance typically found in C-ALCL.

Recently, a type of LyP that simulates $CD8^+$ aggressive epidermotropic T-cell lymphoma has been described and termed *LyP type D*. The intraepidermal cells express CD8 and CD30 with the usual loss of some pan-T-cell antigens[71a].

Recognition of these four histologic types has contributed to our understanding of the relationship between LyP and other types of CTCL and to the definition of the spectrum of primary cutaneous $CD30^+$ lymphoproliferations. However, from a practical point of view, histologic subtyping is not necessary, since the four histologic subtypes do not differ clinically.

Differential diagnosis

LyP is often diagnosed clinically as more common entities. Small recurrent LyP lesions on the trunk are frequently misinterpreted as folliculitis or arthropod bites for years. On the other hand, because of the presence of multifocal skin lesions with the histologic features of CD30-positive CTCL, LyP patients are regularly treated unnecessarily with multi-agent chemotherapy by physicians not familiar with this condition. Obviously, when the clinical features are taken into account, differentiation between LyP and the malignant lymphomas it may resemble histologically is not difficult.

Because of the clinical similarities between LyP and pityriasis lichenoides, a relationship between the two conditions was initially suggested. In addition, more recent studies have demonstrated clonal T-cell populations in skin biopsies of both conditions. However, differentiation is generally not difficult. Pityriasis lichenoides occurs more often in younger patients, is often relatively short-lived, does not develop nodular lesions, and rarely, if ever, progresses to a lymphoma. Histologically, the diseases are usually easily distinguished, and CD30-positive blast cells are generally not seen in pityriasis lichenoides[72].

Treatment

The treatment of patients with LyP is unsatisfactory. Topical or systemic corticosteroids or antibiotics are not effective. Aggressive treatment modalities such as systemic chemotherapy or TSEB irradiation may produce complete remissions, but after discontinuation of therapy, the LyP lesions generally reappear within weeks or months, and the disease follows its natural course. Since a curative therapy is not available and none of the available treatment modalities affects the natural course of the disease, the short-term benefits of active treatment should be balanced carefully against potential side effects[57]. In patients with relatively few non-scarring lesions, active treatment is not necessary. In the case of cosmetically disturbing lesions (e.g. scarring or many papulonodules), low-dose oral methotrexate (5–20 mg/week) is the most effective therapy for reducing the number of skin lesions[65]. Beneficial effects have been reported from PUVA, topical mechlorethamine or carmustine, and low-dose etoposide. When larger skin tumors develop in the course of LyP, they can be observed for a period of 4 to 12 weeks for the possibility of spontaneous remission. If spontaneous resolution does not occur, such lesions can be excised or treated with radiotherapy. Because of the potential risk for developing a systemic lymphoma, long-term follow-up is required in all patients with LyP.

SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA

Definition

In the WHO-EORTC classification (2004) and the most recent WHO classification (2008), subcutaneous panniculitis-like T-cell lymphoma (SPTCL) is defined as a cytotoxic T-cell lymphoma characterized by the presence of primarily subcutaneous infiltrates of small, medium-sized or large pleomorphic T cells with an α/β^+ T-cell phenotype, in association with many macrophages[3,4]. In past classification schemes, the SPTCL category included cases with an α/β T-cell phenotype (75%) *and* cases with a γ/δ T-cell phenotype (25%)[1,2]. However, recent studies have shown clinical, histologic and immunophenotypical differences between cases of SPTCL with an α/β T-cell phenotype and those with a γ/δ T-cell phenotype, suggesting that they may represent different entities. Whereas SPTCLs with an α/β T-cell phenotype are homogeneous with a rather indolent clinical behavior in many patients, SPTCL with a γ/δ T-cell phenotype overlaps with other types of γ/δ-positive T-cell lymphoma and invariably runs a very aggressive clinical course[73,74]. Therefore, in both the WHO-EORTC classification and the most recent WHO classification, the term SPTCL is only used for cases with an α/β^+ T-cell phenotype, whereas cases with a γ/δ^+ T-cell phenotype are included in the category of primary cutaneous gamma/delta T-cell lymphoma (Table 120.6).

Epidemiology

SPTCL is a rare condition, accounting for less than 1% of all CTCL. It may occur in adults as well as in young children, and both sexes are equally affected.

Clinical features

Patients generally present with a solitary or multiple nodules or deeply seated plaques with a diameter varying from 1 to 20 cm. The skin lesions involve primarily the extremities and the trunk and less commonly the face; when the nodules and plaques resolve, they may be replaced by areas of lipoatrophy (Fig. 120.14A). Ulceration is uncommon. Systemic symptoms such as fever, fatigue and weight loss may be present in over half of the patients. Laboratory abnormalities including cytopenias and elevated liver function tests are common, but

COMPARISON OF SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA AND PRIMARY CUTANEOUS GAMMA/DELTA T-CELL LYMPHOMA WITH SUBCUTANEOUS INVOLVEMENT

	SPTCL	PCGD-TCL with subcutaneous involvement
Phenotype	α/β T-cell phenotype	γ/δ T-cell phenotype
T-cell receptor	$\beta F1^+$, $TCR\delta1^-$	$\beta F1^-$, $TCR\delta1^+$

a frank hemophagocytic syndrome is observed in only ~15% of patients[74]. Dissemination to extracutaneous sites is rare and while hepatosplenomegaly may be seen, it is generally not due to lymphomatous involvement.

SPTCL may be preceded for years or decades by a seemingly benign panniculitis. Up to 20% of patients have an associated autoimmune disease, most commonly systemic lupus erythematosus. Recent studies have suggested overlapping features between SPTCL and lupus profundus[75]. SPTCL has a favorable prognosis with a 5-year overall survival of approximately 80%[74]. However, the presence of hemophagocytic syndrome is associated with a more unfavorable prognosis. In a recent study, patients with or without an associated hemophagocytic syndrome had a 5-year overall survival of 46% and 91%, respectively[74].

Pathology

Subcutaneous infiltrates simulating a lobular panniculitis are seen in SPTCL. Small, medium-sized or sometimes large pleomorphic T cells with hyperchromatic nuclei are present and are often admixed with many macrophages. The overlying epidermis and dermis are typically uninvolved. Rimming of individual fat cells by neoplastic T cells is a helpful, although not entirely specific, diagnostic feature (Fig. 120.14B). Necrosis, karyorrhexis and cytophagocytosis are common findings. In the early stages, the neoplastic infiltrates may lack significant atypia and a heavy inflammatory infiltrate may predominate.

Immunophenotype

These lymphomas have a TCR-α/β$^+$, CD3$^+$, CD4$^-$, CD8$^+$ T-cell phenotype, with expression of cytotoxic proteins. The neoplastic T cells express βF1 and are negative for CD56, facilitating differentiation from primary cutaneous gamma/delta T-cell lymphoma with subcutaneous involvement and panniculitis-like lesions (see Table 120.6). CD30 is rarely, if ever, expressed.

Treatment

While doxorubicin-based chemotherapy has traditionally been used, recent studies suggest that more conservative immunosuppressive regimens (e.g. prednisone, cyclosporine) may be effective and should initially be considered in patients with SPTCL without an associated hemophagocytic syndrome. In patients presenting with a solitary lesion, local radiotherapy may be effective[74].

EXTRANODAL NK/T-CELL LYMPHOMA, NASAL TYPE

Definition

Extranodal NK/T-cell lymphoma, nasal type is nearly always an EBV-positive lymphoma with an NK-cell, or more rarely a cytotoxic T-cell, phenotype. The skin is the most common site of involvement after the nasal cavity/nasopharynx, and skin involvement may be a primary or secondary manifestation of the disease.

Epidemiology

Extranodal NK/T-cell lymphoma is a rare disease, particularly in Europe and the US. It is more common in Asia, Central America and South America. Patients are adults, with a predominance of males.

Clinical features

Patients generally present with multiple plaques or tumors on the trunk and extremities or, in the case of nasal NK/T-cell lymphoma, with a midfacial destructive tumor (previously referred to as lethal midline granuloma)[76,77] (Fig. 120.15). Ulceration is common. Although patients presenting with only skin lesions have a somewhat better prognosis than patients presenting with both cutaneous and extracutaneous disease, the disease in both groups has a very aggressive clinical behavior and requires the same type of treatment.

Pathology

These lymphomas are characterized by dense infiltrates involving the dermis and often the subcutis. Prominent angiocentricity and angiodestruction are often accompanied by extensive necrosis[76,77]. NK/T-cell lymphoma has a broad cytologic spectrum ranging from small to large cells, with most cases consisting of medium-sized cells with irregular or oval nuclei, moderately dense chromatin and pale cytoplasm. In some cases, a heavy inflammatory infiltrate of small lymphocytes, histiocytes, plasma cells and eosinophils can be seen. The T-cell receptor usually has a germline configuration, but can be clonally rearranged in the rare tumors with a cytotoxic T-cell phenotype.

Fig. 120.15 Nasal NK/T-cell lymphoma. An extensive ulceronecrotic nasal mass, previously referred to as lethal midline granuloma.

Immunophenotype

The neoplastic cells express CD2, CD56, cytoplasmic CD3ε and cytotoxic proteins (TIA-1, granzyme B, perforin), but they lack surface CD3. In rare CD56-negative cases, detection of EBV by *in situ* hybridization and expression of cytotoxic proteins is required for diagnosis.

Treatment

In patients with localized disease, radiotherapy is the preferred treatment. For individuals with advanced disease, systemic chemotherapy is recommended, but the results are disappointing.

PRIMARY CUTANEOUS CD8-POSITIVE AGGRESSIVE EPIDERMOTROPIC CYTOTOXIC T-CELL LYMPHOMA

These tumors are characterized by a proliferation of epidermotropic CD8-positive cytotoxic T cells and an aggressive clinical behavior[78,79]. Differentiation from other types of CTCL expressing a CD8-positive cytotoxic T-cell phenotype – more than 50% of patients with pagetoid reticulosis and rare cases of MF, LyP and C-ALCL – is based on the clinical presentation and clinical behavior. In the latter conditions, no differences in clinical presentation or prognosis are observed between CD4$^+$ and CD8$^+$ cases.

Clinically, these lymphomas are characterized by the presence of localized or disseminated eruptive papules, nodules and tumors with central ulceration and necrosis *or* by superficial, hyperkeratotic patches and plaques (Fig. 120.16). They may disseminate to other visceral sites (lung, testis, central nervous system, oral mucosa), but lymph nodes are often spared[78].

Histologically, these lymphomas show strongly epidermotropic, band-like to diffuse infiltrates of small, medium-sized or large pleomorphic T cells with a CD3$^+$, CD4$^-$, CD8$^+$, CD7$^{-/+}$, CD45RA$^+$, granzyme B$^+$, perforin$^+$, TIA-1$^+$ phenotype[78]. The epidermis may be acanthotic or atrophic, and there may be necrotic keratinocytes, ulceration and variable spongiosis, sometimes with blister formation. Invasion and destruction of cutaneous adnexal structures are commonly seen. Angiocentricity and angioinvasion may be present.

These lymphomas run an aggressive clinical course and should be treated with systemic chemotherapy.

Fig. 120.16 Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma. Generalized skin tumors with central ulceration. Previously, such cases were designated as disseminated pagetoid reticulosis (Ketron–Goodman type).

Fig. 120.17 Primary cutaneous peripheral T-cell lymphoma, unspecified. Rapidly growing nodules and tumors. Note: the skin lesions in the left upper corner do not represent patches, but rather deep plaques present for 2 weeks.

PRIMARY CUTANEOUS GAMMA/DELTA T-CELL LYMPHOMA

Primary cutaneous gamma/delta T-cell lymphoma (PCGD-TCL) is a lymphoma composed of a clonal proliferation of mature, activated gamma/delta T cells with a cytotoxic phenotype. This group includes cases previously known as SPTCL with a gamma/delta T-cell phenotype.

PCGD-TCL generally presents with disseminated plaques and/or ulceronecrotic nodules or tumors, particularly on the extremities[74,80]. Involvement of mucosal and other extranodal sites is frequently observed, but involvement of lymph nodes, spleen or bone marrow is uncommon. In patients with panniculitis-like tumors, a hemophagocytic syndrome may occur.

Histologically, three major patterns of involvement can be seen: epidermotropic, dermal and subcutaneous. Often more then one histologic pattern is present within a single biopsy specimen or in different biopsy specimens from the same patient. The epidermal pattern can vary from mild epidermotropism to a marked pagetoid reticulosis-like infiltrate. Rimming of fat cells may be observed when there is subcutaneous involvement, similar to SPTCL. Angiocentricity and angiodestruction are commonly seen. The neoplastic cells are generally medium to large in size with coarsely clumped chromatin, and they have a $\beta F1^-$, $CD3^+$, $CD2^+$, $CD4^-$, $CD5^-$, $CD7^{+/-}$, $CD8^-$, $CD56^+$ phenotype with strong expression of cytotoxic proteins. In frozen sections, the cells are strongly positive for TCR-delta.

Most patients have aggressive, often rapidly fatal disease, which is resistant to multi-agent chemotherapy. Patients with subcutaneous fat involvement may have a worse prognosis in comparison to patients with epidermal or dermal disease only[80].

PRIMARY CUTANEOUS CD4-POSITIVE SMALL/MEDIUM PLEOMORPHIC T-CELL LYMPHOMA

These lymphomas are defined as CTCL with a predominance of small to medium-sized CD4-positive pleomorphic T cells without (a history of) patches and plaques typical of MF and, in most cases, a favorable clinical course. In contrast to the EORTC classification, the WHO-EORTC classification restricts the term primary cutaneous small/medium pleomorphic T-cell lymphoma to cases with a $CD4^+$ T-cell phenotype. Cases with a $CD3^+$, $CD4^-$, $CD8^+$ phenotype usually have a more aggressive clinical course similar to that of primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma[81].

Characteristically, these lymphomas present with a solitary plaque or tumor, generally on the face, the neck or the upper trunk. Less commonly, they present with generalized skin lesions[82–84]. Histologically, these lymphomas have dense, diffuse or nodular infiltrates within the dermis with a tendency to infiltrate the subcutis. Epidermotropism may be present focally. There is a predominance of small/medium-sized $CD3^+$, $CD4^+$, $CD8^-$, $CD30^-$ pleomorphic T cells. A small proportion (<30%) of large pleomorphic cells may be present. The proliferative rate is generally low. In most cases, a considerable admixture with reactive CD8-positive T cells, B cells, plasma cells and histiocytes is observed. Demonstration of an aberrant T-cell phenotype and clonality has been considered as helpful in differentiating small/medium pleomorphic T-cell lymphomas from pseudo-T-cell lymphomas, but the reported clinicopathologic features of these two entities do have considerable overlap[7,84]. For example, clonal T cells have been found in pseudo-T-cell lymphomas, and the large atypical cells in both conditions express programmed death-1 (PD-1), Bcl-6 and CXCL13, suggesting a common follicular helper T-cell phenotype[84a,84b].

Patients presenting with a solitary lesion have an excellent prognosis. In contrast, those with rapidly evolving tumors, a high proliferation index and few admixed $CD8^+$ T cells have been reported to be at risk for a more aggressive clinical course[82]. Surgical excision or radiotherapy is the preferred mode of treatment for a solitary skin lesion. Cyclophosphamide (as a single agent) and IFN-α have been reported to be effective in patients with more generalized skin disease[85]. However, the optimal treatment for this group has yet to be defined.

PRIMARY CUTANEOUS PERIPHERAL T-CELL LYMPHOMA, UNSPECIFIED

The designation "primary cutaneous peripheral T-cell lymphoma (PTCL), unspecified" is maintained for CTCLs that do not fit into any of the better-defined subtypes outlined in Table 120.1. It is therefore a diagnosis of exclusion. Clinically, these patients present with solitary or localized, but more frequently generalized, nodules or tumors[81] (Fig. 120.17).

Histologically, there are nodular or diffuse infiltrates with variable numbers of medium-sized to large pleomorphic or immunoblast-like T cells. Epidermotropism is generally mild or absent. Most cases have an aberrant $CD4^+$ T-cell phenotype with variable loss of pan-T-cell antigens. CD30 staining is negative or restricted to a few scattered tumor cells. Rare cases may show coexpression of CD56.

Patients should be treated with systemic chemotherapy, but the prognosis is generally poor, with a 5-year survival of less than 20%[81].

Malignant hematopoietic infiltrates *2041*

BENIGN LYMPHOCYTIC INFILTRATES

LYMPHOCYTIC INFILTRATE OF JESSNER

Synonyms: ■ Benign lymphocytic infiltration of the skin ■ Jessner's lymphocytic infiltration of the skin ■ Jessner's lymphocytic infiltrate of the skin ■ Jessner–Kanof lymphocytic infiltration of the skin

Key features

- Erythematous papules, plaques and, less commonly, nodules
- Most common on the head, neck and back
- Dermal infiltrate of lymphocytes without epidermal involvement

History

Lymphocytic infiltrate of Jessner (LIJ) was initially described in 1953 by Jessner and Kanof[1] as circinate papules on the face, surrounding a central area of clearing.

Epidemiology

Lymphocytic infiltrate of Jessner occurs primarily in middle-aged adults. There is no gender predilection.

Pathogenesis

Lymphocytic infiltrate of Jessner remains a controversial entity. Some authors believe it is a variant of either lupus erythematosus (LE), cutaneous lymphoid hyperplasia or polymorphic light eruption[2], while in Europe, it has been associated with *Borrelia burgdorferi* infection[3]. There are cases of co-occurrence with LE and with polymorphic light eruption, further raising the possibility that these entities are related. Lastly, rare cases of drug-induced LIJ (e.g. angiotensin-converting enzyme [ACE] inhibitors, glatiramer acetate) have been described[4,5].

Clinical features

Lymphocytic infiltrate of Jessner occurs primarily on the head, neck and upper back as one or several asymptomatic erythematous papules, plaques and, less commonly, nodules, with an absence of secondary changes such as scale (Fig. 121.1). Annular plaques with central clearing are commonly observed and individual lesions last several weeks to months. There are no associated systemic manifestations. Emotional stress has been associated with exacerbation of the eruption in a minority of patients. The eruption resolves spontaneously and without sequelae in most patients.

Pathology

The epidermis is unremarkable, with little evidence of lymphocytic exocytosis or interface dermatitis. There is a superficial and deep, primarily perivascular, lymphocytic infiltrate that may surround hair follicles (Fig. 121.2). By immunohistochemistry, a mixed T-cell infiltrate with a predominance of $CD8^+$ lymphocytes is seen[6], admixed with small clusters of $CD123^+$ plasmacytoid dendritic cells. An increase in reticular dermal mucin may be seen.

Fig. 121.1 Lymphocytic infiltrate of Jessner. Annular erythematous plaque on the face.

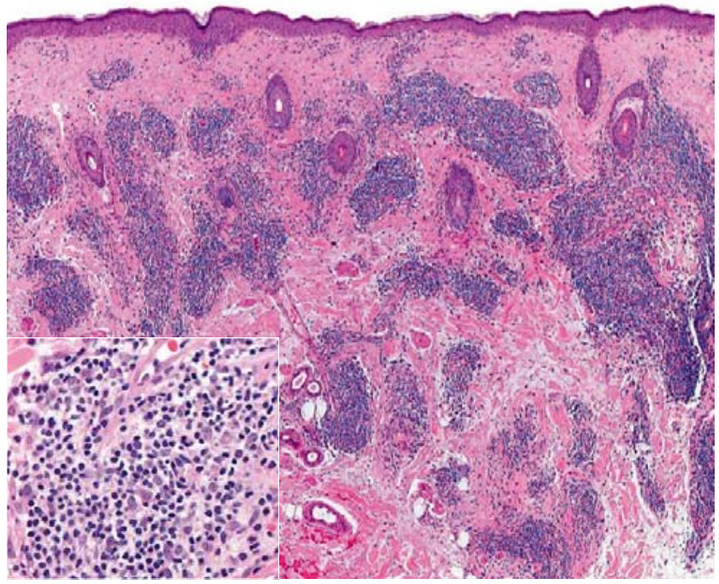

Fig. 121.2 Lymphocytic infiltrate of Jessner. A superficial and deep perivascular infiltrate without an interface component is characteristic. The infiltrate is composed of lymphocytes (insert).

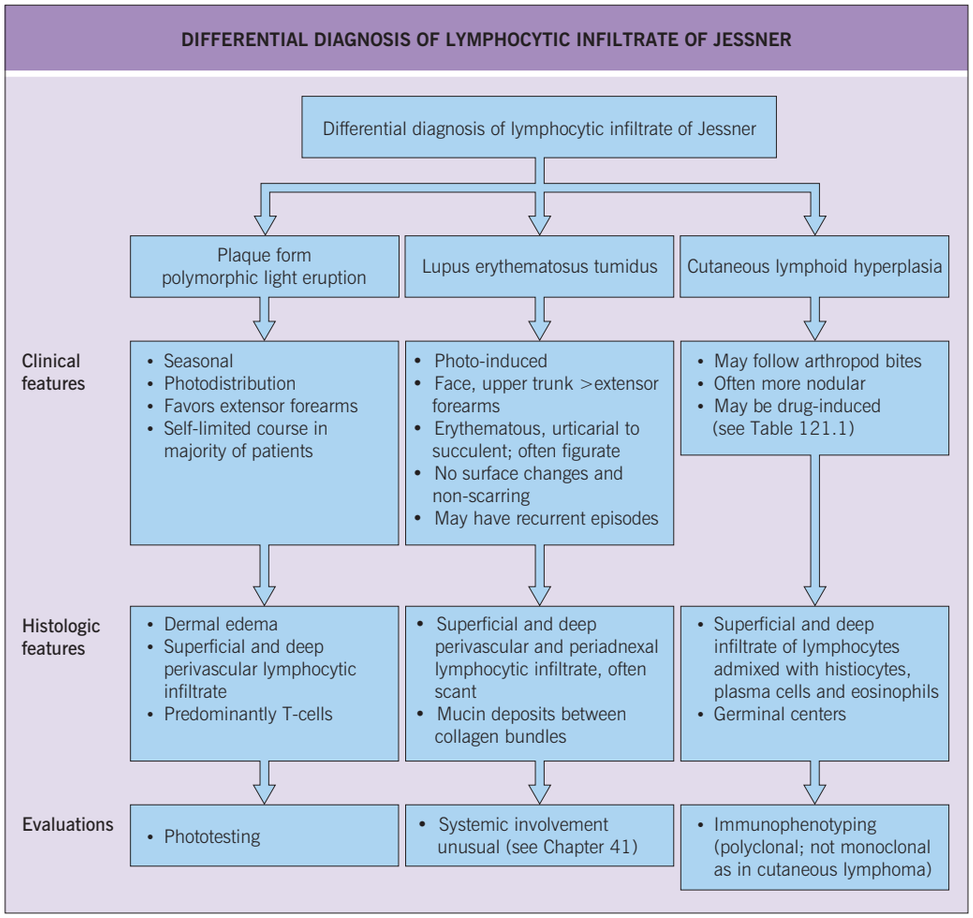

Fig. 121.3 Differential diagnosis of lymphocytic infiltrate of Jessner. Reticular erythematous mucinosis can also be considered in the differential diagnosis; histologically, abundant dermal mucin is observed. Some authors consider lymphocytic infiltrate of Jessner, lupus erythematosus tumidus and reticular erythematous mucinosis to be similar entities along a clinical spectrum.

Differential diagnosis

The differential diagnosis includes the plaque form of polymorphic light eruption, LE tumidus, cutaneous lymphoid hyperplasia (see below), reticular erythematous mucinosis, and cutaneous lymphoma (Fig. 121.3). In contrast to LIJ, subacute and chronic cutaneous LE have secondary changes, including scale, follicular plugging and central hypopigmentation, along with interface changes histologically. However, in LE tumidus, interface changes are sparse, if present at all, and distinction is more difficult. Reticular erythematous mucinosis, which is considered by some as synonymous with LE tumidus, also has abundant dermal mucin.

Polymorphic light eruption is associated with sun exposure and usually has a self-limited clinical course. Histologically, papillary dermal edema is often seen, a feature not present in LIJ. For some patients, it may be difficult to distinguish between these entities and phototesting may prove helpful (see Fig. 121.3).

Cutaneous lymphomas can have significant clinical and histopathologic overlap with LIJ. If the dermal lymphocytic infiltrate is extensive, immunophenotypic analyses may help to distinguish between the two entities (see Chs 119 & 120).

Treatment

The cutaneous manifestations of LIJ resolve spontaneously within months to years, without scarring. Oral antibiotics and topical or intralesional corticosteroids have been used with limited success. Up to 50% of patients may improve with hydroxychloroquine. In general, LIJ is resistant to radiation therapy. A crossover study of oral thalidomide (100 mg/day) versus placebo in 25 patients resulted in a clinical response of 76% for thalidomide and 16% for placebo. In isolated case reports, improvement following pulsed dye (595 nm) laser treatment or chemotherapy (for an unrelated malignancy) has been described[7,8].

CUTANEOUS LYMPHOID HYPERPLASIA (LYMPHOCYTOMA CUTIS)

Synonyms: ■ Lymphocytoma cutis ■ Pseudolymphoma ■ Lymphadenosis benigna cutis (LABC) ■ Spiegler–Fendt sarcoid ■ Miliary lymphocytoma

Key features

- Erythematous to violaceous nodule or plaque
- Most common on the face and upper trunk
- Mixed dermal infiltrate of lymphocytes, plasma cells and eosinophils
- Follicular/germinal centers with tingible-body macrophages are common
- Polyclonal inflammatory infiltrate

History

Cutaneous lymphoid hyperplasia (CLH) was first reported by Spiegler in 1894. He described patients who presented with clinical features of a sarcoma but experienced a benign clinical course. Subsequent investigators recognized the reactive lymphocytic nature of the process.

Epidemiology

CLH is seen most often in adults and may be slightly more common in women. The disorder has been reported in children.

MEDICATIONS ASSOCIATED WITH CUTANEOUS LYMPHOID HYPERPLASIA	
Anticonvulsants	*Carbamazepine*, *phenobarbital*, *phenytoin*, *ethosuximide*, *lamitrogine*, *valproic acid*, ethotoin
Antiarrhythmics	*Mexiletine*, procainamide
Antibiotics	*Trimethoprim-sulfamethoxazole*, *cefixime*, cefuroxime, *nitrofurantoin*, clarithromycin
Antidepressants	*Amytriptyline*, desipramine, fluoxetine, clomipramine, lithium
Antihistamines	Cimetidine, ranitidine, nizatidine, doxepin
Antihypertensives (including diuretics)	*Atenolol*, *captopril*, lisinopril, *diltiazem*, amlodipine, furosemide, amiloride, losartan, valsartan, clonidine patch
Antipsychotics	Chlorpromazine, perphenazine, thioridazine
Chemotherapeutic agents	*Imatinib*, fluorouracil, gemcitabine, oxaliplatin, tamoxifen, leucovorin
Lipid-lowering agents	Gemfibrozil, lovastatin
Nonsteroidal anti-inflammatory drugs (NSAIDs)	*Aspirin*, *ibuprofen*, *naproxen*, diclofenac, indomethacin, ketoprofen, sulindac, diflunisal, oxaprozin, nabumetone
Rheumatologic agents	*Allopurinol*, *dapsone*, *sulfasalazine,* etanercept, methotrexate, gold, D-penicillamine
Sedatives	Benzodiazepines
Steroid hormones	Estrogen, progesterone
Stimulants	Methylphenidate
Vaccines	Hepatitis A, hepatitis B
Miscellaneous	Cyclosporine, interferon-alpha, adesleukin (interleukin-2), glatiramer acetate, bromocriptine, black cohosh

Table 121.1 Medications associated with cutaneous lymphoid hyperplasia (CLH)[9–12]. The lesions are similar clinically and histologically to idiopathic CLH (T-cell, B-cell, and mixed). For patients with the drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) who have atypical lymphocytes in the blood and skin, the term pseudolymphoma is sometimes applied; however, this is a separate entity (see Ch. 21). The drugs in italics have also been reported to cause DRESS/DIHS. Adapted from references 10-12.

ENTITIES IN WHICH CUTANEOUS LYMPHOID HYPERPLASIA CAN OCCUR		
Common entities	**Less common entities**	**Rare entities**
Arthropod bites or stings, scabies	Post herpes zoster infection (dermatomal)	APACHE syndrome
Borrelia infection (Europe)	Folliculitis (pseudolymphomatous)	Kikuchi–Fujimoto disease
Tattoo reactions	Vaccinations	Sjögren's syndrome (cutaneous)
Drugs (see Table 121.1)		
Infections, e.g. herpes simplex		

Table 121.2 Entities in which cutaneous lymphoid hyperplasia can occur. APACHE, acral pseudolymphomatous angiokeratoma of children.

Pathogenesis

CLH does not represent a single disease state, but rather reflects an exaggerated local immunologic reaction to a stimulus, often unrecognized. The possibility of a hapten-driven immunologic response to cells damaged by a direct toxic effect of stimuli has been suggested[9]. Inciting agents include arthropod bites, metal implants, tattoos, vaccinations and medications (Table 121.1)[9–12]. In addition, several infections and reactive disorders have been associated with CLH (Table 121.2).

Clinical features

Classically, CLH presents as firm, erythematous to violaceous papules, plaques or nodules located on the head, neck or upper extremities. The lesions are often solitary, but may be multiple and grouped (Fig. 121.4). Although the vast majority of papulonodules lack surface changes, occasionally there is scale or follicular accentuation, including in the variant termed "pseudolymphomatous folliculitis". The latter presents as a solitary facial lesion and has rather unique histologic features (see below)[13].

Fig. 121.4 Cutaneous lymphoid hyperplasia (lymphocytoma cutis). A Violet papulonodules on the helix and lobe of the ear (unknown etiology). **B** Multiple red–brown to violet papules at the sites of *Hirudo medicinalis* (medicinal leech) application. *B, Courtesy, Josef Smolle, MD.*

Pathology

The histologic features are variable and the pattern may resemble mycosis fungoides, a B-cell lymphoma or a $CD30^+$ anaplastic large cell lymphoma. Pseudolymphomas with a *mycosis fungoides-like* pattern are most often encountered in drug-induced pseudolymphomas. Histologically, epidermotropism, spongiosis, vacuolar degeneration of the basal layer, papillary dermal edema, and red cell extravasation may be seen. Prominent papillary dermal fibrosis, commonly seen in mycosis fungoides, is absent, but T-cell clonality may be present (see below).

In CLH with *B-cell predominance*, there is typically a single lesion with a superficial and deep nodular or diffuse infiltrate of lymphocytes, admixed with histiocytes and occasional plasma cells and eosinophils. The dermal infiltrate is dense and recapitulates nodal architecture (Fig. 121.5). In florid cases, germinal centers have prominent tingible-body macrophages. A mantle zone surrounds the lymphoid follicles. Differentiation from cutaneous lymphoma may be difficult; however, in most cases, the distinction can be made on routine histologic sections or with the addition of immunohistochemical stains (Table 121.3). Clonality, based upon IgH gene rearrangements, is not seen in CLH[9].

B-cell-predominant infiltrates express a mixture of both kappa and lambda light chains (see Fig. 119.9). In T-cell-predominant infiltrates,

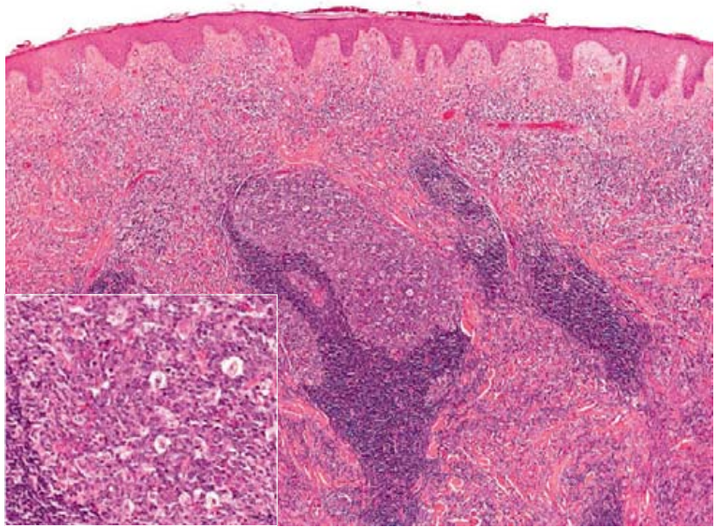

Fig. 121.5 Cutaneous lymphoid hyperplasia (lymphocytoma cutis). Lymphoid cells throughout the dermis in a nodular and diffuse pattern. There is germinal center formation and tingible-body macrophages are present within the germinal centers (insert). *Courtesy, Lorenzo Cerroni, MD.*

MICROSCOPIC DIFFERENCES BETWEEN CUTANEOUS LYMPHOID HYPERPLASIA AND CUTANEOUS FOLLICLE CENTER B-CELL LYMPHOMA	
Cutaneous lymphoid hyperplasia	**Cutaneous follicle center B-cell lymphoma**
HISTOLOGIC FEATURES	
Mixed cellular infiltrate, including eosinophils and plasma cells	Predominantly lymphocytic infiltrate
Reactive germinal centers Mantle zone present Tingible-body macrophages present Polarization of follicles with light and dark areas	Neoplastic germinal centers No or reduced mantle zone No tingible-body macrophages Monomorphous appearance of follicles without polarization
IMMUNOPHENOTYPIC FEATURES	
T and B lymphocytes	Predominance of B lymphocytes ($CD20^+$)
$Bcl\text{-}6^+$ cells restricted to lymph follicles	Clusters of $Bcl\text{-}6^+$ cells outside of lymph follicles
Bcl-2 only on T lymphocytes	Bcl-2 on neoplastic B cells (small minority of cases)
High proliferation of germinal centers	Reduced proliferation of germinal centers
Mixed κ and λ expression	Restricted κ or λ expression (some cases, frozen sections)
*Exception is T-cell-rich B-cell lymphoma.	

Table 121.3 Microscopic differences between cutaneous lymphoid hyperplasia and cutaneous follicle center B-cell lymphoma.

$CD4^+$ T helper lymphocytes are commonly observed within the dermis, beneath a minority population of $CD8^+$ cytotoxic/suppressor T cells in the epidermis. A small proportion of cases have clonal T-cell receptor (TCR) gene rearrangements, and CLH rarely may eventuate into overt cutaneous lymphoma. Whether the presence of clonal populations is a marker for progression to lymphoma, or constitutes a lymphoma at the outset, remains uncertain[14].

In the variant pseudolymphomatous folliculitis, the infiltrate is predominantly perifollicular and periadnexal and is typically mixed, with a predominance of T or B cells. Lymphocyte atypia may be seen. Irregular hyperplasia and distortion of the follicular epithelium, with blurring of the dermal–epidermal junction, are seen. Characteristically, infiltrates of $CD1a^+/S100^+$ mononuclear cells surround and infiltrate the distorted follicles. Granulomas may be variably present[13,15,16].

Differential diagnosis

The clinical differential diagnosis usually includes lymphoma cutis, non-lymphoid metastatic disease, and lymphocytic infiltrate of Jessner. Histologically, the differential diagnosis includes primarily cutaneous lymphoma, lymphocytic infiltrate of Jessner, polymorphic light eruption, and LE tumidus (see Fig. 121.3).

Cutaneous lymphoid hyperplasia may be difficult to differentiate from cutaneous lymphomas (see Pathology section). Features that differentiate CLH from cutaneous follicle center B-cell lymphoma are outlined in Table 121.3. Although the presence of clonality may aid in distinguishing reactive from neoplastic processes, it should not be used to establish malignancy.

Acral pseudolymphomatous angiokeratoma of children (APACHE), originally thought to represent a vascular nevus, is now categorized as a pseudolymphoma. In contrast to CLH, it favors the extremities of children between the ages of 2 and 16 years, usually presenting as a unilateral grouping of small, red to violet, "angiomatous" papules. Histologically, there is a dermal infiltrate of lymphocytes, histiocytes and plasma cells accompanied by prominently thickened capillaries.

Kikuchi–Fujimoto disease, also known as histiocytic necrotizing lymphadenitis, is an idiopathic systemic inflammatory disease most commonly seen in young adult women. It is associated with a variety of viral and bacterial infections (e.g. Epstein-Barr virus, cytomegalovirus) as well as autoimmune diseases (e.g. systemic lupus erythematosus). In addition to fevers, malaise, weight loss and gastrointestinal symptoms, patients develop cervical lymphadenopathy. Histologically, there is necrosis and histiocytic infiltration of the paracortical areas of involved lymph nodes, without an identifiable pathogen. Cutaneous findings, present in 40% of patients, include acneiform eruptions, urticaria, ulcers and indurated erythematous plaques. Histologically, dense superficial and deep perivascular lymphohistiocytic infiltrates with nuclear debris (in the absence of neutrophils) are seen; interface changes are commonly present[17,18].

Treatment

Cutaneous lymphoid hyperplasia is a benign, reactive condition and it should be treated conservatively. Spontaneous resolution may occur without scarring. For persistent lesions, topical and/or intralesional corticosteroids may lead to improvement. Simple excision, cryosurgery, laser ablation and radiation therapy are other options. Thalidomide has been utilized with success in recalcitrant cases[19]. Performance of a biopsy, even if partial, can be followed by spontaneous regression.

EXTRAMEDULLARY HEMATOPOIESIS

Key features

- Evidence of bone marrow dysfunction
- Most common associations are TORCH (*to*xoplasmosis, *r*ubella, *c*ytomegalovirus and *h*erpes virus) infections in neonates and myelofibrosis in adults
- Widely disseminated erythematous to violaceous papules and nodules, with neonatal form referred to as "blueberry muffin baby"
- Diffuse dermal infiltrate of immature erythrocytes, leukocytes and megakaryocytes

Epidemiology

Extramedullary hematopoiesis (EMH) is most commonly seen in neonates secondary to underlying bone marrow dysfunction. It may occur in adults with myeloproliferative disorders such as myelofibrosis or after splenectomy.

Pathogenesis

Cutaneous EMH occurs normally during early embryogenesis and abates prior to birth. Thereafter, it occurs only as a secondary phenomenon in response to altered bone marrow function. Rarely, primary cutaneous neoplasms such as pilomatricomas, nevus sebaceus, hemangiomas, and pyogenic granulomas may be associated with localized extramedullary hematopoiesis[20].

Clinical features

The clinical presentation consists of erythematous to violaceous papules and nodules which may ulcerate. When widely disseminated in neonates, it leads to the classic "blueberry muffin baby" (Fig. 121.6). This can be seen in association with congenital viral infections and prenatal anemias (Table 121.4). Dermal hematopoiesis is most often seen with rubella and cytomegalovirus, and serologic titers for TORCH infections can aid in diagnosis.

Pathology

Extramedullary hematopoiesis is characterized by a dermal infiltrate of immature red and white blood cell precursors and megakaryocytes, centered around vessels of the superficial vascular plexus. It may also extend into the deeper reticular dermis and exhibit a diffuse pattern. All three hematopoietic cell lines are present in varying ratios, depending upon the underlying disease process.

Fig. 121.6 Extramedullary hematopoiesis. "Blueberry muffin baby" secondary to congenital rubella. *Courtesy, James Graham, MD.*

DIFFERENTIAL DIAGNOSIS OF "BLUEBERRY MUFFIN BABY"

- Disseminated extramedullary hematopoiesis
  - Prenatal infections
    - TORCH
      - Congenital rubella
      - Cytomegalovirus
      - Toxoplasmosis
    - Coxsackievirus
    - Parvovirus
  - Severe and chronic prenatal anemias
    - Severe hemolytic anemias
      - Congenital spherocytosis
      - Rhesus hemolytic disease
      - ABO incompatibility
    - Twin–twin transfusion
    - Chronic fetomaternal hemorrhage
    - Severe internal bleeding (e.g. intracranial)
    - Myelodysplasia, congenital leukemia
- Congenital leukemia cutis
- Neonatal neuroblastoma
- Congenital Langerhans cell histiocytosis
- Congenital alveolar cell rhabdomyosarcoma
- Hemangiomatosis, other vascular lesions (e.g. multifocal lymphangioendotheliomatosis, glomuvenous malformations)

Table 121.4 Differential diagnosis of "blueberry muffin baby".

Differential diagnosis

Histologically, the differential diagnosis is limited. Distinguishing EMH from disseminated congenital leukemia cutis and neonatal neuroblastoma is important. Whereas all three hematopoietic cell lines (erythrocytes, leukocytes and megakaryocytes) are represented in EMH, there is an atypical infiltrate of immature leukocytes in leukemia cutis. Patients with overwhelming marrow involvement by leukemia may have both EMH and leukemic involvement of the skin, further complicating the diagnosis.

Treatment

Treatment of the underlying bone marrow dysfunction results in reversal of the cutaneous process. Spontaneous resolution can occur with some viral infections.

MALIGNANT HEMATOPOIETIC INFILTRATES

LEUKEMIA CUTIS

Key features

- Red to purple papules and nodules; hemorrhagic ulcers
- Diffuse dermal infiltrate of neoplastic leukocytes
- Immature precursor cells in some types

Epidemiology

Multiple types of leukemia exist, each with its own epidemiologic characteristics. Acute lymphoblastic leukemia (ALL) tends to be a neoplasm of childhood. Acute myelogenous leukemia (AML) and chronic myelogenous leukemia (CML) occur primarily in adults, and chronic lymphocytic leukemia (CLL) and hairy cell leukemia are most common in elderly patients.

Pathogenesis

Specific chromosomal abnormalities are associated with particular subtypes of leukemia. The Philadelphia chromosome, the primary diagnostic feature of CML, represents a translocation between chromosomes 9 and 22 [t(9;22)]. This translocation results in fusion of the two genes *BCR* and *ABL*, with constitutive activation of the tyrosine kinase activity of the fusion oncoprotein. It is this kinase activity that is selectively inhibited by imatinib mesylate (Gleevec®). Additionally, 95% of patients with promyelocytic leukemia have a t(15;17) translocation, which leads to abnormal expression of a fusion retinoic acid receptor that is the target of all-*trans* retinoic acid therapy. A variety of non-random chromosomal abnormalities exists in ALL and AML. Table 121.5 outlines the relationship between specific abnormalities and prognosis in CLL.

Clinical features

Leukemia can lead to nonspecific reactive skin lesions (Table 121.6) or specific infiltrates. The latter most commonly present as firm papules

RELATIONSHIP BETWEEN SPECIFIC CHROMOSOMAL ABNORMALITIES AND PROGNOSIS IN CHRONIC LYMPHOCYTIC LEUKEMIA

Chromosomal abnormalities	Prognosis
13q deletion	Good
Trisomy 12	Intermediate
6q deletion	Poor
11q deletion	Poor
17p deletion	Poor

Table 121.5 Relationship between specific chromosomal abnormalities and prognosis in chronic lymphocytic leukemia.

"INFLAMMATORY" DISORDERS ASSOCIATED WITH ACUTE AND CHRONIC LEUKEMIAS	
Disorder	**Associated leukemias**
NEUTROPHILIC DERMATOSES	
Sweet's syndrome	AML > CML, hairy cell leukemia, CNL > ALL, CLL
Pyoderma gangrenosum*	AML, CML, hairy cell leukemia > ALL, CLL
Neutrophilic eccrine hidradenitis	AML >> ALL, CML, CLL
REACTIVE ERYTHEMAS	
Exaggerated arthropod reactions	CLL
Erythroderma	CLL†
VASCULITIS	
Polyarteritis nodosa	Hairy cell leukemia >> CMML
Vasculitis (small vessel/ leukocytoclastic)	Hairy cell leukemia, CLL > AMML, ALL
Erythema elevatum diutinum	Hairy cell leukemia, CLL
PANNICULITIS	
Erythema nodosum‡	AML, CML, CMML
Other panniculitides§	Hairy cell leukemia, AML, CMML
OTHER	
Erythema multiforme#	CLL
Urticaria	CLL, hairy cell leukemia
Paraneoplastic pemphigus	CLL
Recalcitrant adult-onset eczema	CLL (T cell)
Acral ischemia with lividity	CML¶

*Especially bullous.
†Many probably represented Sézary syndrome.
‡Isolated case reports; may occur concomitantly with Sweet's syndrome.
§Sweet's syndrome may have a subcutaneous component.
#May have represented paraneoplastic pemphigus.
¶Leukostasis/hyperleukocytosis syndrome.

Table 121.6 "Inflammatory" disorders associated with acute and chronic leukemias[21–25]. ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; AMML, acute myelomonocytic leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; CNL, chronic neutrophilic leukemia.

and nodules (Fig. 121.7) that are frequently hemorrhagic; thrombocytopenia often plays a role in this associated hemorrhage. Ulcerative and rarely bullous lesions occur. Leukemia cutis can develop in any location, but the head, neck and trunk are most commonly involved. Leukemic infiltrates may arise at sites of trauma or scars.

Rarely, myelogenous leukemias may present with dermal nodules known as chloromas, granulocytic sarcomas or extramedullary myeloid tumors. Granulocytic sarcomas may precede the development of systemic leukemia by months. Gingival hyperplasia, secondary to leukemic infiltrates, favors acute monocytic or acute myelomonocytic leukemia.

In one series, cutaneous eruptions of leukemia accounted for 30% of all skin biopsy specimens in patients with leukemia[21]. Other diagnoses included GVHD, drug eruptions, infectious processes, purpura and small vessel vasculitis. In most patients with acute leukemia, cutaneous lesions are present at the time of diagnosis or recurrence, but, occasionally, skin involvement precedes the appearance of leukemia in the peripheral smear ("aleukemic" leukemia cutis). Rarely, leukemia cutis predates apparent bone marrow involvement by months or even years. Of note, asymptomatic dermal leukemic infiltrates of CLL may be evident in biopsy specimens of primary cutaneous neoplasms (e.g. squamous cell carcinoma) and inflammatory disorders[22].

The characteristics of the different forms of leukemia cutis are summarized in Table 121.7.

Fig. 121.7 Leukemia cutis. Multiple red–brown papules and plaques in a patient with hairy cell leukemia.

Pathology

Histologic features of leukemia cutis vary with the type of leukemia. The neoplastic infiltrate may be perivascular, nodular and diffuse, or densely surrounding the eccrine glands[23,24].

AML represents a neoplastic proliferation of immature myeloid cells and encompasses multiple subtypes[26]. In general, the neoplastic cells recapitulate myeloid precursor cells in their immature stages of development. In many cases, cytoplasmic granules can be found. A chloroacetate esterase stain is helpful in detecting myeloid differentiation, but in very immature precursor cells, granules may not be present. The most common forms of AML that involve the skin and present *de novo* (without previous evidence of systemic disease) are the more mature subtypes – acute myelomonocytic and acute monocytic leukemia. Immunohistochemically, the infiltrates of AML are positive for myeloid markers such as myeloperoxidase, CD13, CD33 and CD68.

ALL represents a clonal expansion of immature lymphocytes, most commonly of B-cell lineage and less commonly T-cell lineage. Rarely, cytoplasmic granularity may be present, and this corresponds with a precursor B-cell immunophenotype. Cells of ALL may be difficult to identify in skin biopsy specimens and immunostaining for terminal deoxytransferase may prove helpful.

CML demonstrates a range of myeloid precursors, including promyelocytes, metamyelocytes, bands and mature neutrophils. Although cutaneous lesions of CML are rare, they are typically seen in patients with chronic myelomonocytic leukemia and are associated with blast transformation and a poor prognosis.

Cutaneous CLL is characterized by a dense infiltrate of uniform-appearing, small, round lymphocytes of B-cell lineage (Fig. 121.8). The infiltrating cells appear mature, but the monomorphous nature and paucity of other cell types within the infiltrate suggest a leukemic infiltrate. The lymphocytes often surround adnexal and vascular structures with the infiltrates having prominent crush artifact. Immunohistochemically, CLL shows positivity for CD5, CD20, and CD43[25].

Differential diagnosis

The clinical differential diagnosis includes lymphoma cutis, infectious emboli, vasculitis and drug eruptions. The histologic differential diagnosis of leukemia cutis depends upon the type of leukemia present. Distinguishing some cases of leukemia cutis from lymphomas involving the skin can be difficult. For myeloid leukemias, the differential diagnosis includes extramedullary hematopoiesis (see above), Sweet's syndrome, cutaneous small vessel vasculitis and other neutrophilic dermatoses. Recognizing immature and atypical granulocytic precursors within leukemic infiltrates allows the distinction from reactive neutrophilic infiltrates.

CHARACTERISTICS OF DIFFERENT TYPES OF LEUKEMIA CUTIS				
SUBTYPE OF LEUKEMIA	**ALL**	**CLL**	**AML**	**CML**
Characteristic age	Predominantly <6 years of age	6th decade or older	Variable, most commonly 5th decade	Variable, most commonly 5th–6th decade
Presenting anatomic site	Variable	Predominantly head and neck, but can occur at any site	Variable	Variable
Clinical course	Aggressive	Indolent	Aggressive	Intermediate*
Subtype of leukemia/ immunophenotype	• Predominantly B-cell ALL (TdT^+/ $CD5^+$/$CD19^+$/$CD20^+$/$CD10^+$) • Rarely T-cell ALL (TdT^+/$CD1a^+$/ $CD2^+$/$CD3c^+$/$CD5^+$/$CD7^+$)	• B-cell type ($CD5^+$/ $CD20^+$/ $CD43^+$)	• Most commonly, AMML (M4) & AMoL (M5) • $CD13^+$/$CD33^+$/$CD68^+$/ myeloperoxidase-positive	• Most commonly, CMML • Cutaneous involvement associated with blast transformation
Incidence of cutaneous involvement	Rare	Rare†	• More common than other types • May be presenting sign	Rare
Time of presentation	Late	Late‡	Early	Late
Clinical appearance	• Large, nonulcerated tumors • Nonspecific papulonodules	• Nonspecific papulonodules • Rarely, erythroderma	Nonspecific papulonodules	• Nonspecific pruritic papules, plaques and nodules • Rarely, vitiligo-like presentation unless patient is receiving imatinib

*When acceleration or blast transformation occurs, becomes aggressive.
†Often an incidental finding in biopsy specimens of primary cutaneous neoplasms (e.g. squamous cell carcinoma) and inflammatory disorders.
‡Unless incidental finding.

Table 121.7 Characteristics of different types of leukemia cutis. Most patients with CML who develop vitiligo-like changes are receiving imatinib. ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; AMML, acute myelomonocytic leukemia; AMoL, acute monocytic leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia.

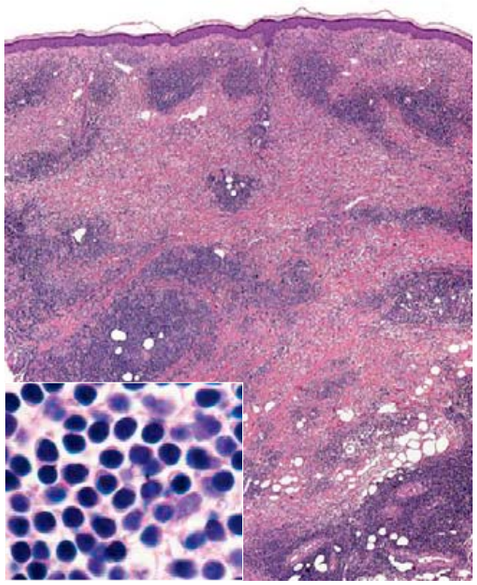

Fig. 121.8 Chronic lymphocytic leukemia (CLL). Nodular-diffuse CLL infiltrates within the entire dermis and superficial subcutis. The cells in CLL are small, monomorphous, hyperchromatic lymphocytes that lack significant cytologic atypia (insert). *Courtesy, Lorenzo Cerroni, MD.*

Treatment

No specific treatment for leukemia cutis currently exists. The cutaneous eruptions typically resolve following successful treatment of the leukemia.

NON-B-CELL, NON-T-CELL LYMPHOMAS

Hodgkin Disease

Synonym: ■ Hodgkin lymphoma

Key features

- Advanced stage in most patients with skin involvement
- Dermal nodules and plaques, sometimes ulcerated
- Dense dermal infiltrate with lymphocytes and eosinophils
- Atypical cells (lacunar cells, Reed–Sternberg cells)

History

In 1832, Thomas Hodgkin described a series of patients with lymphadenopathy, splenomegaly and weight loss, all of whom died of their disease. Wilks reported a subsequent series of patients in 1885, and designated the illness Hodgkin's disease.

Epidemiology

Isolated cutaneous involvement by Hodgkin disease (HD), termed "specific cutaneous Hodgkin's" by Grosz in 1906, is unusual[27]. In one large study, only 0.5% of patients with HD had cutaneous involvement and the development of specific skin lesions prior to apparent nodal disease is rare[28]. Individuals with isolated (primary) cutaneous HD may follow a more indolent course than their systemic counterparts, even with the subsequent development of nodal involvement. In the majority of patients, however, cutaneous involvement occurs in the setting of advanced systemic disease and is a marker of poor prognosis.

The incidence of HD peaks in young adults, with a second, smaller peak in individuals in their fifties. Of note, compared to the general population, mycosis fungoides is seen at higher rates in patients with HD. This reflects the increased incidence of non-Hodgkin lymphomas in general in HD patients. The underlying reason for this phenomenon is not known[29].

Pathogenesis

The pathogenesis of HD is unknown, although Epstein–Barr virus (EBV) has been detected in a minority of cases[30]. Evidence suggests that in the majority of patients with classic HD, the Reed–Sternberg cell represents a malignant B lymphocyte; however, in isolated cutaneous cases, evidence suggests that the malignant cells are of a T-cell lineage[31].

Clinical features

Isolated cutaneous HD presents as one or several papules, plaques or ulcerated nodules with no site predilection. Signs of systemic involvement (e.g. hepatosplenomegaly, lymphadenopathy) and constitutional symptoms (e.g. fevers, chills, night sweats) may not develop. There are scattered reports of spontaneous regression of primary lesions.

The most common presentation is that of multiple, disseminated papulonodules and plaques appearing rapidly in a patient with known, advanced disease. Cutaneous lesions often occur at sites distal to

affected lymph nodes. The trunk is the most common site of involvement (Fig. 121.9).

In 20–50% of patients with HD, paraneoplastic cutaneous disorders can develop. These include primary pruritus, acquired ichthyosis, persistent dermatitis, hyperpigmentation and, occasionally, erythema nodosum.

Pathology

The histologic features of cutaneous HD (primary or secondary) are similar to affected lymph nodes. A dermal infiltrate consisting of lymphocytes with occasional eosinophils and plasma cells is present; epidermotropism is not seen. Depending upon the histologic subtype, Reed–Sternberg cells (or mononuclear variants) (Fig. 121.10) and lacunar cells may be present. The latter, most common in the nodular sclerosing subtype of HD, are large cells with abundant eosinophilic cytoplasm. The retraction of this cytoplasm from adjacent cells during fixation gives rise to a giant cell residing within a clear space. Areas of dermal sclerosis may be seen and extension into the subcutaneous fat is common.

Reed–Sternberg cells express CD30 (Ki-1), fascin and CD15, but not CD45RB (leukocyte common antigen) or CD20. The background infiltrate of lymphocytes is composed predominantly of T cells[31]. In lymphocyte-predominant HD, the malignant cells may stain positively for CD20.

Fig. 121.9 Cutaneous Hodgkin disease. A large pink plaque with central clearing is noted on the lower abdomen. The small ulceration represents the site of a previous skin biopsy.

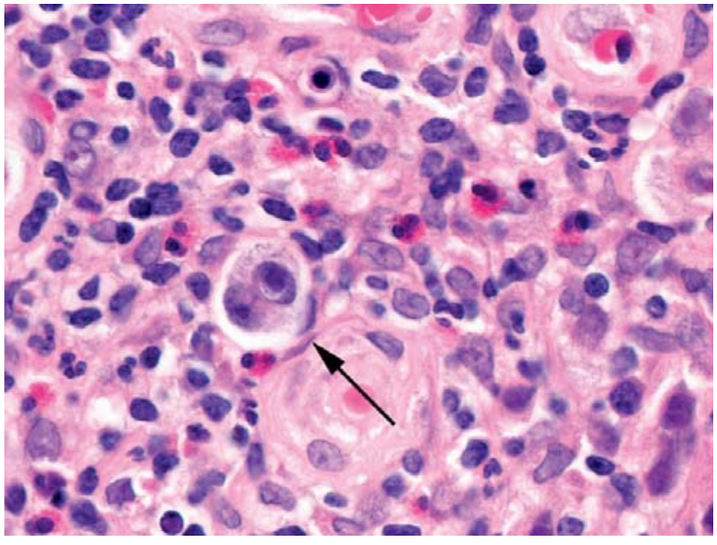

Fig 121.10 Cutaneous Hodgkin disease. Polymorphic infiltrate with lymphocytes, eosinophils, histiocytes, and a Reed–Sternberg cell (arrow). *Courtesy, Lorenzo Cerroni, MD.*

Differential diagnosis

The histologic differential diagnosis of HD includes primary cutaneous anaplastic large cell lymphoma (C-ALCL) and lymphomatoid papulosis (LyP) (see Ch. 120). Clinicopathologic correlation is important in differentiating between these entities. Both LyP and C-ALCL can present with variably ulcerated papules and nodules, but patients with LyP do not have evidence of systemic involvement (unless there is a concomitant lymphoma) and crops of their lesions appear and then spontaneously resolve. Patients with C-ALCL rarely have nodal involvement. In contrast, primary cutaneous HD is not just very rare, but nearly all patients with cutaneous involvement have advanced systemic disease.

All three entities demonstrate a mixed infiltrate with varying numbers of large $CD30^+$ atypical cells, but, in HD, unlike the other two, the cells also express CD15. In C-ALCL, the majority of the infiltrate is composed of malignant cells (with a relatively small number of reactive inflammatory cells) and the infiltrate tends to be deeper than in LyP. The majority of the neoplastic cells of C-ALCL are $CD4^+$; ALK expression is variable. In LyP, the infiltrate is more heterogeneous, with fewer large atypical cells. Like in C-ALCL, the atypical cells in LyP are $CD4^+$, $CD45^+$ and $CD30^+$, but $CD15^-$.

Treatment

Although the number of cases reported is small, the prognosis for patients with primary cutaneous HD appears to be similar to (or perhaps better than) that of patients with classic early-stage HD. Many patients do not develop systemic disease. Patients with stage IV HD, who may have secondary cutaneous disease, have a cure rate of approximately 60–70% following combination chemotherapy[32].

Blastic Plasmacytoid Dendritic Cell Neoplasm

Synonyms: ■ Blastic plasmacytoid dendritic cell lymphoma ■ $CD4^+$/$CD56^+$ hematodermic neoplasm ■ Blastic NK-cell lymphoma

Key features

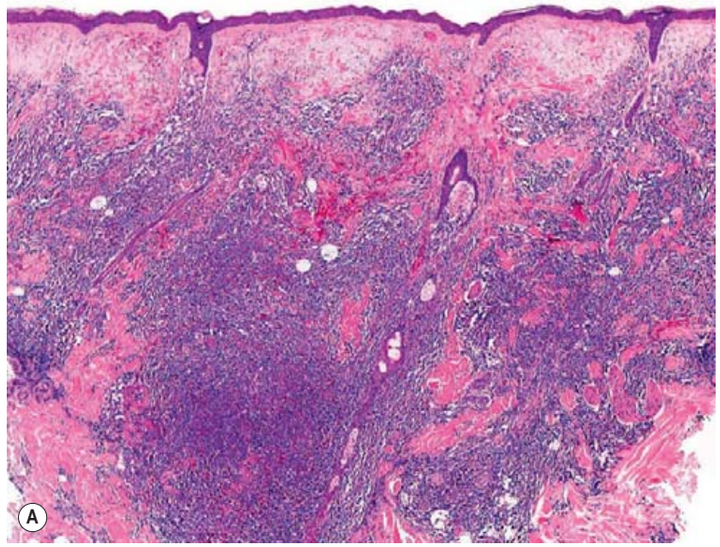
- Single to multiple, non-tender papules, nodules and plaques
- At initial presentation, skin is the most common site of involvement
- Dense perivascular infiltrate of uniformly atypical medium-sized mononuclear cells
- Immunohistochemical profile: $CD123^+$, $CD4^+$, $CD56^+$
- T-cell receptor (TCR) and IgH gene rearrangements are not present
- Predictable good initial response to chemotherapy, with relapses common and poor survival

History and epidemiology

In 1994, blastic plasmacytoid dendritic cell neoplasm (BPDCN) was described by Adachi et al.[33] as a $CD4^+$/$CD56^+$ lymphoma presenting predominantly in the skin. Initially classified as blastic NK-cell lymphoma due to its CD56 expression, this rare tumor was subsequently reclassified, first as a hematodermic neoplasm and then as a neoplasm of plasmacytoid dendritic cells.

BPDCN is a disease of adults, usually those over the age of 50 years. The male-to-female ratio is 3:1 and rare pediatric cases have been reported.

Fig. 121.11 Blastic plasmacytoid dendritic cell neoplasm. Two firm violaceous nodules on the cheek. *Courtesy, Lorenzo Cerroni, MD.*



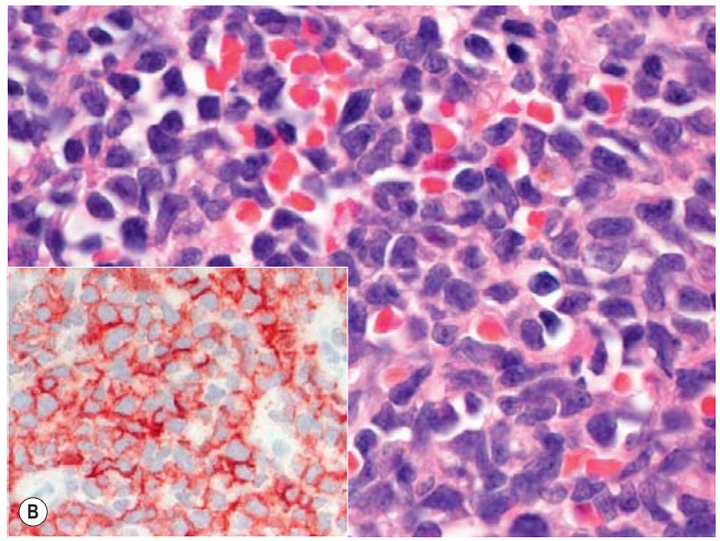


Fig. 121.12 Blastic plasmacytoid dendritic cell neoplasm. A Dense diffuse infiltrates of monomorphous blastoid cells within the entire dermis, without involvement of the epidermis. **B** Diffuse infiltrate of medium-sized blastoid mononuclear cells admixed with extravasated erythrocytes; positive immunohistochemical staining for CD56 (insert). *Courtesy, Lorenzo Cerroni, MD.*

Pathogenesis

A BPDCN arises within the interfollicular zones of peripheral lymphoid tissue, an area that plays a crucial role in the first-line response to various pathogens. Plasmacytoid dendritic cells produce large amounts of type I interferons (IFN), specifically IFN-α, and they express several Toll-like receptors (e.g. TLR7, TLR9), making them critical in the defense against viruses and other pathogens[34].

Clinical features

Clinically, BPDCN presents as solitary or multiple, non-tender, variably pruritic, erythematous to violaceous papules, plaques or nodules (Fig. 121.11). In 50% of patients, the skin is the presenting site of involvement. However, further evaluation usually reveals subclinical regional lymph node, peripheral blood and bone marrow involvement in a majority of patients[35]. Symptoms of fevers, chills, night sweats or weight loss are uncommon at presentation but may develop with disease progression.

Pathology

A diffuse dermal infiltrate of monotonous, atypical, medium-sized mononuclear cells is seen (Fig. 121.12). These cells have fine blastic chromatin, indistinct nucleoli and scant agranular eosinophilic cytoplasm. There are numerous mitoses, but neither necrosis nor angioinvasion. In early lesions, the dense infiltrate may be perivascular and periadnexal. A grenz zone is often present and the infiltrate commonly extends into the subcutis.

Immunohistochemical studies are necessary to establish the diagnosis. The cells are $CD4^+$, $CD56^+$, $CD123^+$, $TCL1^+$, $BDCA2^+$, and myeloperoxidase-negative; TdT is variably positive. TCL1, an Akt kinase regulator expressed in non-neoplastic B cells and plasmacytoid dendritic cells, is positive in 90% of BPDCNs. These tumors have nonspecific chromosomal aberrations[36] and are negative for EBV. There are descriptions of aberrant $CD4^-$ or $CD56^-$ cases[36].

Differential diagnosis

The differential diagnosis includes AML and other cutaneous lymphomas. BPDCN, however, lacks IgH and TCR gene rearrangements and has a characteristic immunohistochemical profile (see above). In addition, there are subtypes of AML that may express CD4 and CD56 and can present in the skin (without evidence of systemic disease), but expression of CD123, TCL1, BDCA2 and CD2-associated protein (CD2AP) points to the diagnosis of BPDCN[37]. Of note, there are isolated reports of patients with BPDCN developing associated AML.

Treatment

Initial treatment of BPDCN usually consists of multidrug chemotherapeutic regimens. Although response rates are high (up to 80%), relapse followed by progression is common, with the overall survival rate ranging from 12 to 17 months. For that reason, eligible patients are offered autologous or allogeneic hematopoietic stem cell transplantation. Favorable prognostic factors include a $CD7^-/TdT^+$ phenotype, a young age, and disease limited to the skin[38].

ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA

Synonyms: ■ Angioimmunoblastic lymphadenopathy ■ Angioimmunoblastic lymphadenopathy with dysproteinemia ■ Immunoblastic lymphadenopathy ■ Lymphogranulomatosis X

Key features

- Constitutional symptoms (fever, sweats, weight loss)
- Variable cutaneous manifestations, including morbilliform erythema, urticaria and, rarely, erythroderma
- Polyclonal gammopathy, autoantibodies, hemolytic anemia, thrombocytopenia, eosinophilia and pleural effusions
- Generalized lymphadenopathy and hepatosplenomegaly
- Most commonly, a superficial perivascular infiltrate with eosinophils, but not atypia of the lymphocytes

History

This disease was initially described in 1974 as angioimmunoblastic lymphadenopathy with dysproteinemia, and its features included generalized lymphadenopathy, hepatosplenomegaly, polyclonal hypergammaglobulinemia, and a hemolytic anemia[39].

Epidemiology

Angioimmunoblastic T-cell lymphoma (AITCL) is a rare disease of the middle-aged and elderly, with a nearly equal incidence in men and women[26].

Pathogenesis

Formerly, AITCL was considered to be an atypical reactive process or an abnormal immunologic reaction, until non-random chromosomal abnormalities, clonal rearrangements of the TCR, and progression to an aggressive lymphoma were frequently noted. Currently, it is classified as a subtype of peripheral T-cell lymphoma in the World Health Organization (WHO) Classification of Haematopoietic Tumours[26].

Clinical features

Patients with AITCL usually present at an advanced stage with fever, weight loss, night sweats, generalized lymphadenopathy, and hepatosplenomegaly[26,40]. Approximately one-half of the patients have cutaneous manifestations. The most common presentation is a widespread morbilliform erythema that resembles a viral exanthem[41]. Other cutaneous findings include petechiae (often associated with thrombocytopenia), urticaria, purpura and, rarely, erythroderma. Generalized pruritus may be a presenting symptom. AITCL has an aggressive behavior, with a median survival of <3 years[26].

Pathology

The histopathologic features vary[41], with five patterns described to date. These include: (1) a superficial perivascular infiltrate composed of eosinophils and lymphocytes that lack atypia (most common pattern); (2) a sparse perivascular infiltrate with atypical lymphocytes; (3) a dense superficial and deep infiltrate of pleomorphic lymphocytes; (4) a vasculitis, with or without atypical lymphocytes; and (5) necrotizing granulomas[42]. Similar to involved lymph nodes, the skin may have increased vascularity with hyperplastic endothelial cells. The immunohistochemical profile supports a nonspecific T-cell phenotype ($CD2^+/CD3^+/CD5^+$ with $CD4^+$ lymphocyte predominance). Although EBV-positive B cells are frequently seen within involved lymph nodes, EBV is rarely detected in the skin[40,42].

Differential diagnosis

The morbilliform nature of the eruption belies its malignant nature. Consequently, confusion with a drug eruption or viral exanthem is common. As cutaneous histologic changes are subtle, a specific diagnosis often cannot be rendered.

Treatment

Few prognostic factors exist and the majority of patients present with stage III–IV disease[40,43]. In a recent prospective, randomized clinical trial, in which most of the 157 patients received various intensive anthracycline-based chemotherapeutic regimens, there were no observable differences amongst the varying regimens, even with the addition of hematopoietic stem cell transplantation[43]. Despite achieving a complete response in 46% of patients following induction therapy, the 5- and 7-year survival rates were 33% and 29%, respectively.

LYMPHOMATOID GRANULOMATOSIS

Key features

- EBV-driven angiocentric/destructive lymphoproliferative disorder
- Presents with cough, dyspnea, chest pain and constitutional symptoms
- Cavitary pulmonary nodules on chest radiograph
- Nodular or ulcerative cutaneous lesions in 25–50% of patients

History

Lymphomatoid granulomatosis was first described in 1972 as a pulmonary angiitis/granulomatosis mimicking Wegener's granulomatosis. Initially thought to represent a reactive process, subsequent studies demonstrated a malignant clonal B-cell population admixed with an abundant, polyclonal, reactive T-cell population[44].

Epidemiology

Lymphomatoid granulomatosis is a rare disease of adults, usually presenting in the fifth to sixth decade of life. The male-to-female ratio is approximately 2 : 1. The disease can affect children, most commonly in the setting of immunodeficiency syndromes.

Pathogenesis

The pathogenesis of lymphomatoid granulomatosis is often related to EBV infection, occasionally in combination with immunosuppression. Based upon case reports, immunosuppressive factors associated with lymphomatoid granulomatosis include renal transplantation, Wiskott–Aldrich syndrome, HIV infection and X-linked lymphoproliferative syndrome[44].

Clinical features

Patients with lymphomatoid granulomatosis present with symptoms related to pulmonary involvement, such as cough, dyspnea and chest pain. Constitutional symptoms include fever, weight loss, malaise, arthralgias and myalgias. Cutaneous lesions develop in 25–50% of patients and usually present as nodules or ulcerated plaques (Fig. 121.13). Rarely, lymphomatoid granulomatosis may present as an exanthem of macules and papules. The kidney, brain and gastrointestinal tract may be affected. In contrast to angioimmunoblastic T-cell lymphoma, the lymph nodes and spleen are rarely involved.

Pathology

Lesions of lymphomatoid granulomatosis show nodular lymphoid infiltrates composed of lymphocytes, plasma cells and large atypical mononuclear cells with convoluted nuclei and prominent nucleoli. These infiltrates surround and invade arteries and veins. Granulomatosis, as defined by necrosis within lymphoid aggregates in the absence of granuloma formation, is a distinct and prominent feature. The atypical cells stain with the B-cell markers CD20 and CD79a, and EBV DNA can be detected via *in situ* hybridization.

Differential diagnosis

The clinical differential diagnosis includes various forms of cutaneous lymphoma, as well as infectious and inflammatory disorders (e.g.

Fig. 121.13 Lymphomatoid granulomatosis. Ulcerated violaceous plaque in the popliteal fossa. *Courtesy, Jean L Bolognia, MD.*

medium vessel vasculitis, pyoderma gangrenosum). The histologic differential diagnosis is broad and encompasses most of the lymphoproliferative disorders mentioned above, including B-cell and T-cell lymphomas. Other disorders with histologic evidence of granulomatosis (as defined above) include Wegener's granulomatosis, sarcoidosis and infectious processes. Diagnosis is based upon histopathologic findings plus immunohistochemical and molecular analyses.

Treatment

Lymphomatoid granulomatosis follows an aggressive course, with 5-year mortality ranging from 60% to 90%. Treatment commonly involves multidrug chemotherapy and/or rituximab (anti-CD20 monoclonal antibody), and, for milder cases, IFN-α. Reversal of exogenous immunosuppression may also lead to clinical improvement[44].

Cutaneous Metastases 122

Matthew B Zook, Hong Wu and Stuart R Lessin

Key features

- Cutaneous metastases are uncommon and rarely they may be the presenting sign of an internal malignancy
- In general, cutaneous metastases are associated with a poor prognosis
- In women, breast carcinoma and melanoma are the most common malignancies that metastasize to the skin
- In men, melanoma and head and neck, lung and colon carcinomas are the most common malignancies that metastasize to the skin
- Among common malignancies, breast carcinoma is the most likely and prostate carcinoma is the least likely to metastasize to the skin
- The most common clinical presentation for a cutaneous metastasis is a firm, painless, erythematous nodule
- Cutaneous metastases may arise in the anatomic vicinity of the primary cancer
- Cutaneous metastases typically have histologic features similar to, but not identical to, those of the primary malignancy
- Treatments include excision, chemotherapy, immunotherapy and radiotherapy; the latter is often administered for palliation

INTRODUCTION

Given their prognostic implications, cutaneous metastases represent an important dermatologic entity. The skin is not a particularly common site for metastatic spread, and because the clinical appearance of cutaneous metastases can mimic more common disorders, e.g. epidermoid inclusion cysts (inflamed and non-inflamed), lipomas, cellulitis, there may be a delay in diagnosis. An understanding of the clinical spectrum as well as advances in histological assessment of skin metastases is vital to establishing the correct diagnosis.

EPIDEMIOLOGY

Depending upon the series, cutaneous metastases occur in 1% to 10% of patients with metastatic disease (to any organ)[1,2]. While unusual, their recognition is important because they can be the first sign of extranodal metastatic disease and, as a result, have profound prognostic implications. The proportion of patients with metastatic disease who have cutaneous metastases depends upon the particular malignancy, e.g. the highest incidence is in individuals with metastatic melanoma, where up to 45% of patients can develop skin metastases (Table 122.1)[2]. Gender-specific cancer rates also influence the frequency of the various types of cutaneous metastases. In women, skin metastases from breast carcinoma (70%) and melanoma (12%) are the most common, followed by carcinomas originating from the ovary, head and neck (SCC), and lung[2]. In men with skin metastases, melanoma (32%) and head and neck (16.5%), lung (12%), and colon (11%) carcinoma are the most common primary malignancies. In addition, the overall prevalence of a cancer is an important determinant. For instance, although skin metastases develop in only 2.5% of patients with metastatic lung cancer, they account for 12% of all cutaneous metastases in men due to the high prevalence of lung cancer[2]. Similarly, the age of the patient plays a role, with rhabdomyosarcoma, leukemia and neuroblastoma responsible for the majority of cutaneous "metastases" seen in children[3].

Cutaneous metastases develop an average of 36 months[4] (range, 1 to 177 months)[5] after the initial diagnosis of the primary malignancy. Unfortunately, the vast majority (~95%) of patients with cutaneous metastases have advanced, stage III or IV disease. Rarely, cutaneous metastases can be the presenting sign of an internal malignancy (<1% of all new cancer diagnoses).

PATHOGENESIS

In 1889, Dr Stephen Paget espoused the "seed and soil" hypothesis as the paradigm of metastatic disease – a malignancy must develop the capability to dissociate from its native environment, survive during transit, and then propagate in a new milieu (detachment, intravasation, circulation, stasis, extravasation, and finally proliferation; Table 122.2)[6,7]. It is estimated that that ≤0.01% of tumor cells shed into the vasculature form metastatic foci at distant sites[3,8].

The ability of a malignancy to acquire metastatic potential is thought to occur via one of two mechanisms[9]. In the clonal expansion or linear progression model, selective growth advantages are acquired during the course of tumor development. Over time, subpopulations of cells acquire genetic characteristics that enable them to dissociate and then propagate in distant tissues. In this model, metastatic foci have similar phenotypes and genotypes to the original tumor. Alternatively, in the

CUTANEOUS METASTASES IN PATIENTS WITH METASTATIC CANCER

Primary malignancy	Percentage of all patients with metastatic disease who developed cutaneous metastases*	Percentage of all patients with cutaneous metastases*
Melanoma	45	18
Breast	30	50
SCC (head and neck)†	13	7
Endocrine glands	12.5	1
Esophagus	8.5	1
Urinary bladder	8	1.5
Unknown	7.5	4.5
Gallbladder/bile ducts	5.5	<1
Liver	5	<1
Kidney	4.5	<1

Stomach	2	<1
Pancreas	2	<1
Uterine cervix	1	<1
Prostate	<1	<1
Testes	<1	<1

*The percentages are for men and women combined.
†Larynx, oropharynx, nasal sinuses.

Table 122.1 Cutaneous metastases in patients with metastatic cancer. Rates of metastatic spread do vary depending upon the series. Adapted from ref. 2.

DIFFERENT STAGES OF METASTASIS – UNDERLYING FACTORS	
Stage of metastasis	**Factors**
Detachment	E-cadherin, integrins
Intravasation	Matrix metalloproteinases, other proteases, N-cadherin
Circulation	Vascular endothelial growth factor (VEGF)
Stasis	Mechanical forces
Extravasation	Pseudopod formation
Proliferation	Chemokines, growth factors, genetic & epigenetic changes

Table 122.2 Different stages of metastasis – underlying factors.

rare variant or parallel progression model, rare, highly aggressive stem cell-like clones with high metastatic potential exist within the tumor and can cause dissemination at any point during tumorigenesis.

It is generally accepted that certain cancers tend to metastasize to distinct tissues. The mechanism by which they choose their final destination is related to hemostatic forces and surface protein expression patterns. When tumor emboli lodge in the first vascular bed they encounter, adhesion molecule interactions (e.g. integrins) facilitate extravasation and account for the commonly noted involvement of regional nodal basins. Yet, certain cancers have an affinity for specific tissues that are not anatomically convenient, such as prostate cancer spreading to bone or ocular melanoma to the liver[1]. Adhesion molecule expression seems likely to influence this tissue-specific homing of metastases. However, these mechanisms may be attenuated in highly aggressive, undifferentiated tumors that display a random distribution of metastases.

ANATOMIC LOCATION OF CUTANEOUS METASTASES			
Anatomic site	**Primary malignancy (men)**	**Primary malignancy (women)**	**Comments**
Scalp	Lung, renal	Breast	Can lead to alopecia
Face & neck	SCC of the head & neck*, lung	Breast	Eyelid metastases from breast carcinoma have been reported; breast & lung metastases can lead to a "clown nose"
Upper extremities	Lung, kidney, colon	Breast	Uncommon site in men and usually occurs late during disease
Lower extremities	Melanoma > lung, kidney	Melanoma > lung, kidney	Uncommon site: 36% of BSA but site of only 4% of metastases
Chest	Lung	Breast	
Abdomen	Colon, lung, stomach	Colon, ovary, breast	Sister Mary Joseph nodule: most commonly gastric, colon, ovarian or pancreatic cancers
Back	Lung	Breast	20% of BSA, but site of 8% of metastases
Pelvis	Colon	Colon, ovary	Site of 8% of cutaneous metastases

*e.g. larynx, oropharynx, nasal sinuses.

Table 122.3 Anatomic location of cutaneous metastases. The trunk is the most common site (~55% of metastases) and the scalp is the site of ~15% of metastases[1]. BSA, body surface area; SCC, squamous cell carcinoma. Adapted from refs 9 & 10.

CLINICAL FEATURES

When a patient with a known history of cancer presents with an extremely firm and rapidly growing erythematous nodule or an eruption of multiple nodules, the diagnosis of cutaneous metastasis is relatively straightforward. However, the clinical lesions may be more slowly progressive or they may mimic more common entities, from lipomas or dermatitis to erysipelas and ulcers. Occasionally, cutaneous metastases may even be the presenting sign of an unknown primary tumor. Therefore, for a number of reasons, there may be a delay in diagnosis. Hopefully, an appreciation of the spectrum of clinical presentations will lead to an improvement in diagnostic accuracy.

Location can be a clue to the diagnosis of cutaneous metastases. For example, in patients with cutaneous melanoma, satellitosis and in-transit metastases have a clear relationship to the primary site and its lymphatic drainage (see Ch. 113). Papules vary in color from pink to blue to black and initially may require palpation for detection. In addition to hematogenous and lymphatic spread of metastases, there can also be direct extension of a malignancy, especially SCC of the head and neck and breast carcinoma; in this situation, the site of involvement aids in the differential diagnosis (Table 122.3). Occasionally, implantation of tumor occurs at the time of a surgical procedure, e.g. chest tube placement for a malignant pleural effusion due to lung cancer, and the location plus the relationship to a scar point to the correct diagnosis. Lastly, certain malignancies favor particular anatomic sites, e.g. the periumbilical region (Sister Mary Joseph nodule; Fig. 122.1) for gastrointestinal malignancies.

As discussed in the section on epidemiology, the propensity of a particular malignancy to metastasize to the skin (see Table 122.1), prevalence of the specific carcinoma in the population, gender and age all play a significant role in determining which malignancies are most likely to metastasize to the skin. In addition, certain metastases can have a more unique clinical appearance, e.g. both Paget's disease and extramammary Paget's disease may resemble dermatitis, and renal carcinoma metastases may have the appearance of bright red vascular tumors and/or bleed easily (Table 122.4). However, "classic" presentations are not necessarily the most common presentation and a more generic clinical appearance is always possible (e.g. pink papulonodules). Occasionally, cutaneous metastases, including those of renal origin, may have a zosteriform distribution pattern (Fig. 122.2).

Fig. 122.1 Cutaneous metastasis of colon carcinoma. A Sister Mary Joseph nodule presenting as a pink plaque with scale-crust.

Of all the carcinomas metastatic to the skin, breast cancer may be the one with the widest range of clinical presentations (see Table 122.4). Due to its high prevalence in the population and its propensity to metastasize to the skin (lymphatic, hematogenous and direct extension), breast cancer accounts for 70% of cutaneous metastases in women[2]. The presentations vary from papulonodules to patches of erythema mimicking erysipelas (inflammatory carcinoma) to marked induration with a *peau d'orange* appearance (given the name "*en*

CLINICAL PRESENTATIONS OF CUTANEOUS METASTASES AND HISTOLOGIC CORRELATES			
Type	**Clinical description**	**Histology**	**Associated primary malignancy**
Dermal or subcutaneous nodules	Small miliary lesions to large tumors; single or multiple	Tumor cells infiltrating among collagen bundles or replacing dermis; Grenz zone often present	Most common presentation; any type
Inflammatory carcinoma (carcinoma erysipeloides)	Erythematous patch with spreading border; resembles erysipelas	Tumor cells within dilated lymphatic vessels	Breast >> lung, ovary, prostate, GI, others
En cuirasse	Morpheaform or sclerodermoid, depending upon extent; indurated with *peau d'orange* appearance	Fibrosis with infiltrating tumor cells	Breast >> lung, GI, kidney, others
Carcinoma telangiectodes	Red–violet papules	Tumor cells within superficial lymphatics and RBC sludging	Breast
Paget's disease*	Patches extending from the nipple and areola that resemble dermatitis	Large, atypical epithelial cells with abundant pale cytoplasm arranged in solitary units and small nests within all layers of the epidermis	Breast
Alopecia neoplastica	Nodules or plaques on the scalp in association with alopecia	Cords of tumor cells between collagen bundles	Breast > lung, renal, others
Pyogenic granuloma-like	Rapidly growing nodule resembling a vascular tumor (particularly a pyogenic granuloma)	Neoplastic cells in cords and lobules admixed with prominent hemorrhage and "pseudovascular" spaces	Renal clear cell carcinoma, hepatocellular carcinoma > others

*Lesions of extramammary Paget's disease share similar histopathologic features with those of Paget's disease of the breast, but usually represent (>75% of patients) primary cutaneous adenocarcinomas (see Ch. 73); an underlying visceral malignancy is most likely when there is perianal involvement.

Table 122.4 Clinical presentations of cutaneous metastases and histologic correlates. An individual patient can have an admixture of the various types. Occasionally, cutaneous metastases have a zosteriform distribution pattern and clinically they can resemble dermatoses, including eczema, vasculitis and erythema annulare centrifugum. Obviously, they can also mimic cutaneous tumors, including non-melanoma skin cancers, epidermoid or pilar cysts, lipomas, granular cell tumors or angiosarcoma[5]. GI, gastrointestinal; RBC, red blood cell.

Fig 122.2 Cutaneous metastases of renal cell carcinoma. Pink plaques in a zosteriform pattern on the flank.

HISTOLOGIC CLUES TO THE DIAGNOSIS OF CUTANEOUS METASTASES
Well-circumscribed dermal or subcutaneous nodules of atypical cells with numerous mitoses and without connection to the epidermis
Presence of atypical cells within lymphatic vessels (differential diagnosis: intravascular lymphoma, intravascular histiocytosis)
Atypical cells arranged in lines within the dermis ("Indian files") (differential diagnosis: myelogenous leukemia)
Presence of necrosis *en masse* at the center of a nodule of atypical cells (differential diagnosis: some lymphomas, some primary cutaneous adnexal carcinomas)

Table 122.5 Histologic clues to the diagnosis of cutaneous metastases. *Courtesy, Lorenzo Cerroni, MD.*

cuirasse" due to its resemblance to the armor of a cavalry soldier [*cuirassier*][1]) (Fig. 122.3). In addition, intralymphatic metastases can lead to vascular-appearing papules that may be confused clinically with the vascular proliferations (including angiosarcoma) that can follow breast irradiation (see Ch. 114).

In addition to metastases from solid organs, patients can also have involvement of the skin by systemic lymphomas and leukemias (see Chs 119–121). The lesions are often pink–violet to red–brown papulonodules and therefore can have an appearance similar to the most common clinical presentation of cutaneous metastases. Distinction of metastases of SCC to the skin and primary cutaneous SCCs can sometimes prove challenging, especially in patients with SCC of the oropharynx or larynx[11].

PATHOLOGY

The initial step in establishing the histologic diagnosis of a cutaneous metastasis is to exclude other entities that may share some common features, e.g. primary cutaneous adnexal carcinomas, cutaneous involvement with myelogenous leukemia[12], and intravascular histiocytosis (benign angioendotheliomatosis) or intravascular lymphoma. Histologic clues to the diagnosis of cutaneous metastases are outlined in Table 122.5. Once the diagnosis of a cutaneous metastasis is suspected, the next step is to try to determine the underlying primary malignancy. The two most common histologic patterns for a cutaneous metastasis are: (1) nodules of tumor cells within the dermis, and possibly the panniculus; and (2) cords of tumors cells admixed with a fibrotic stroma[5]. When these findings are not accompanied by any unique or distinguishing features (Table 122.6), precise identification via routine histology may prove difficult. The clinical analogy would be a patient with a cutaneous metastasis presenting as an erythematous nodule on the trunk. The reason for the difficulty is the number of primary malignancies that can give rise to this histologic picture. If available, a comparison should be made with tissue from previously diagnosed primary tumors. While separation of carcinomas into broad categories, e.g. adenocarcinoma versus SCC, can often be accomplished via routine histology, complete evaluation usually requires the application of a panel of histochemical stains (see Table 122.6).

When evaluating cutaneous metastases histologically, the presence of tumor cells within lymphatics or blood vessels should be noted (Fig. 122.4)[5]. While this pattern is commonly the pathologic correlate of

Fig. 122.3 Various presentations of cutaneous metastases of breast carcinoma. A Eroded erythematous nodules in the axilla. **B** Inflammatory form (carcinoma erysipeloides) with patches of erythema that may initially be misdiagnosed as infectious cellulitis. **C** Primarily *en cuirasse* form with obvious induration and *peau d'orange* appearance in addition to papulonodules. **D** Mixed pattern – reticulated erythema of carcinoma erysipeloides as well as *peau d'orange* appearance near the areola.

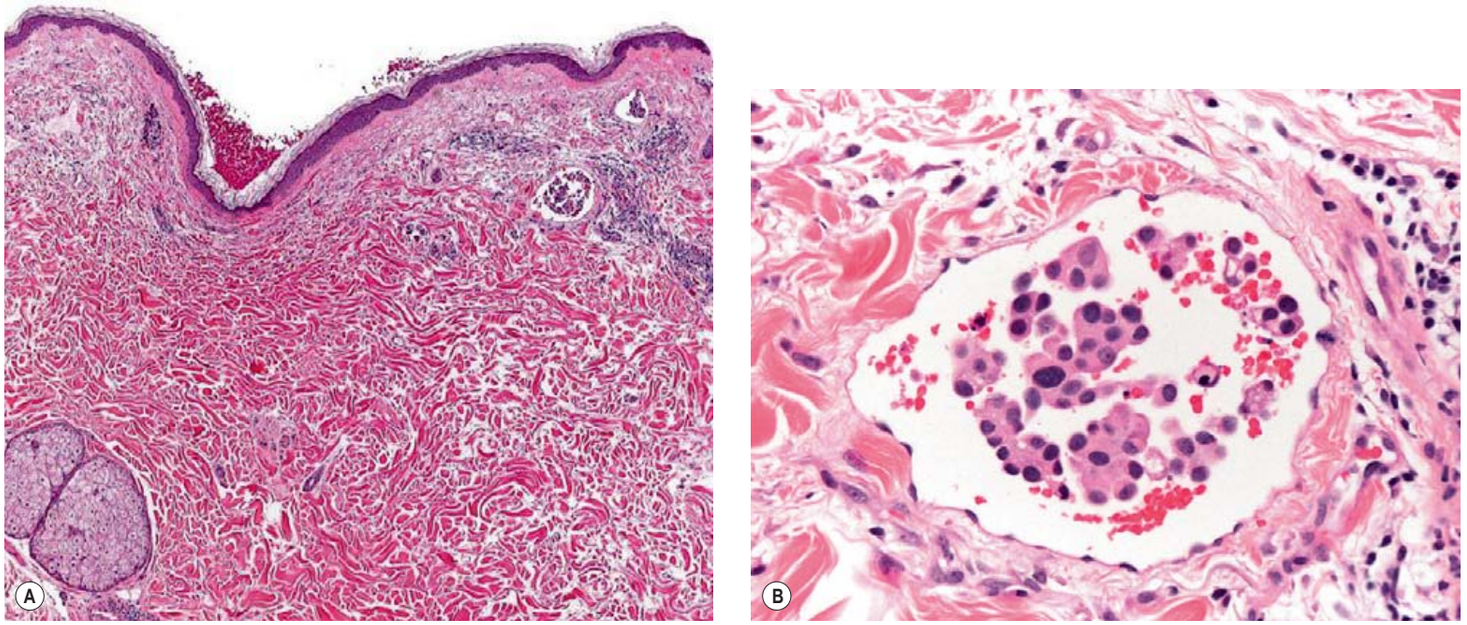

Fig. 122.4 Histopathologic features of cutaneous metastasis of urothelial micropapillary bladder carcinoma. A Complexes of neoplastic cells within dilated lymphatic spaces in the dermis. **B** Detail of a lymphatic space with intravascular tumor complexes admixed with erythrocytes. Neoplastic urothelial (transitional) cells exhibit round–ovoid nuclei and abundant eosinophilic cytoplasm, and they form small rosette-like aggregates. These histopathologic features may simulate a benign condition, namely, intravascular histiocytosis. *Courtesy, Lorenzo Cerroni, MD.*

PATHOLOGIC FINDINGS IN CUTANEOUS METASTASES			
Malignancy	**Histological features**	**Immunohistochemical markers**	**Comments**
Breast	Single filing or cords of cells (lobular CA); tumor cells form glandular structures (ductal CA)	CK7, ER/PR, mammoglobulin, gross cystic disease fluid protein-15 (GCDFP-15)	Breast CA can be ER/PR-negative; GCDFP-15 positivity also seen in cutaneous adnexal and salivary gland tumors; occasionally, ER/PR positivity in non-breast CA
Colon	Columnar cells with basally oriented nuclei and intracytoplasmic mucin production; gland formation; "dirty" necrosis	CK20, CK7, CDX2, villin	Mucinous CA can develop from other tissues (lung, ovary, uterine cervix)
Small cell (including lung)	Nuclear molding, scant cytoplasm, indistinct nucleoli	Keratins, TTF-1, CD56, neuron-specific enolase, chromogranin, synaptophysin	Some small cell CAs, including lung, may not express neuroendocrine markers
Non-small cell lung (adenocarcinoma)	Gland formation	CK7, TTF-1	Non-small cell lung CA can be TTF-1-negative; TTF-1 positivity not limited to lung or thyroid CA
Prostate	Glandular structures formed by cells with prominent nucleoli	PSA, PSAP	High-grade CA may lose glandular differentiation as well as PSA & PSAP expression
Thyroid	Thyroid follicle formation (follicular CA); papillary structure, psammoma bodies (papillary CA)	TTF-1, thyroglobulin	High-grade tumors (insular CA, anaplastic CA) may lose characteristic thyroid gland morphology
Neuroendocrine	Nests of cells with neuroendocrine morphology	Neuroendocrine markers (CD56, chromogranin); medullary thyroid CA: calcitonin & TTF-1	Poorly preserved tissue may resemble lymphoma, carcinoma or small cell CA
Renal (clear cell)	Clear cytoplasm, highly vascular	Coexpression of EMA and vimentin, CD10, RCC-Ma	Other types of renal cell CA do not have prominent clear cells (e.g. sarcomatoid CA)
Ovarian	Psammoma bodies can be seen in papillary serous CA	CA125, CK7, ER/PR, WT-1 (serous CA)	Mucinous ovarian CA may closely resemble other types of mucinous CA
Melanoma	Epithelioid cells with prominent nucleoli	Vimentin, S100, tyrosinase, Melan-A (MART-1), HMB45, MITF	Great morphological mimicker of other tumors; rare undifferentiated melanoma may lose all melanocytic markers
Pancreatobiliary	Well-differentiated glands formed by cells with abundant cytoplasm	CK7, CK20, CA19.9, CA125	CA19.9 is not specific for pancreatobiliary tumors
Stomach	Signet ring cells (signet ring type)	CK7, CK20, CDX2	Non-signet ring cell type gastric CA may not have distinct morphology; signet ring cell CA is not limited to the stomach (e.g. can be seen in breast CA)
Bladder / urothelial	Medium-sized tumor cells arranged in nests or sheets	p63, CK5/6, CK7, CK20	May resemble high-grade cutaneous adnexal CA
SCC	Large cells with intercelllar bridges; keratin pearls	CK5/6, p63, CK903	Small cell SCC variant resembles small cell CA

Table 122.6 Pathologic findings in cutaneous metastases. p63 negativity strongly favors metastases (with the exception of mucinous eccrine carcinoma); for p63-positive tumors, a combined pattern of D2-40 (podoplanin)$^+$, B72.3$^+$, CK5/6$^+$, and calretinin$^-$ immunostains favors metastases[5]. CA, carcinoma; CDX2, homeobox protein CDX2; CK, cytokeratin; EMA, epithelial membrane antigen; ER, estrogen receptor; MITF, microphthalmia transcription factor; PR, progesterone receptor; PSA, prostate-specific antigen; PSAP, prostatic-specific acid phosphatase; RCC-Ma, renal cell carcinoma marker – detects a renal tubule antigen (highly specific); SCC, squamous cell carcinoma; TTF-1, thyroid transcription factor 1; WT-1, product of Wilms tumor gene.

"inflammatory carcinoma" (carcinoma erysipeloides), it can also be seen in other forms of cutaneous metastases, in particular carcinoma "*en cuirasse*". In addition, a search for the presence of distinguishing features such as signet ring cells (most commonly, gastric adenocarcinoma or breast carcinoma; Fig. 122.5)[13], clear cell differentiation (renal clear cell carcinoma; Fig. 122.6), or psammoma bodies (ovarian carcinoma), is always performed. Occasionally, the metastasis may show epidermotropism and the neoplastic cells are contained within the epidermis. In addition to melanoma, this may be seen with metastases from carcinomas of the prostate, breast, colon, larynx, penis and vagina[13]. In rare instances, epidermotropic metastases (particularly from breast carcinoma) may contain pigment and even an intratumoral increase in melanocytes, leading to the misdiagnosis of a melanocytic tumor.

As noted previously, the use of a panel of immunohistochemical stains can assist in determining the underlying primary malignancy and while it is not a substitute for diagnostic imaging and procedures, the resulting information provides direction and can be invaluable in those patients with an unknown primary (so-called cancer of unknown primary [CUP] syndrome). A panel also aids in differentiating a primary cutaneous carcinoma from a metastasis. In the latter situation, a helpful initial panel includes p63, CK5/6, D2-40 (podoplanin), B72.3 (an antibody that stains adenocarcinomas originating from several different organs) and calretinin immunostains in conjunction with appropriate organ-restricted markers (e.g. TTF-1, CDX2; Figs 122.6C & 122.7). In general, p63 negativity strongly favors a metastasis (with the exception of mucinous eccrine carcinoma). For p63-positive tumors, a combined pattern of D2-40$^+$, B72.3$^+$, calretinin$^-$ and CK5/6$^+$ would favor a metastasis[5]. However, panels of immunostains are no substitute for the clinician informing the dermatopathologist of known primary malignancies in a particular patient and diagnostic imaging[14].

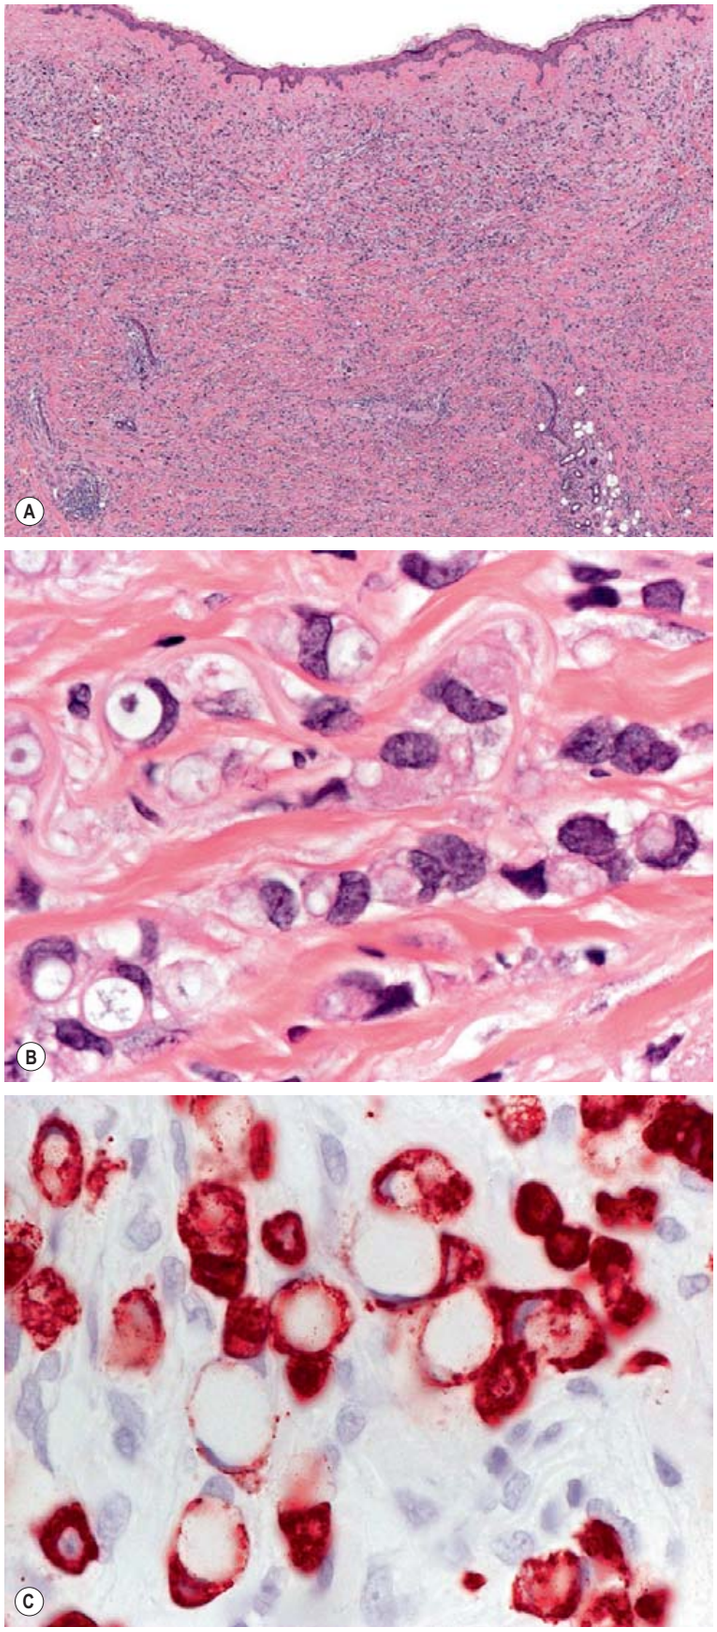

Fig. 122.5 Histopathologic features of cutaneous metastases of signet ring adenocarcinoma of the breast (A,B) and stomach (C). A Diffuse infiltration of neoplastic cells throughout the entire dermis. **B** Detail of neoplastic cells with signet ring cell morphology due to intracellular mucin accumulation. **C** Signet ring cells are not unique to breast carcinoma and may be observed in a variety of adenocarcinomas, particularly those from the gastrointestinal tract; a cytokeratin stain in this metastatic signet ring cell carcinoma of the stomach highlights the peculiar morphology of the cells, with intracellular mucin pressing the nuclei and distorting them, thus conferring the characteristic shape similar to that of a signet ring. *Courtesy, Lorenzo Cerroni, MD.*

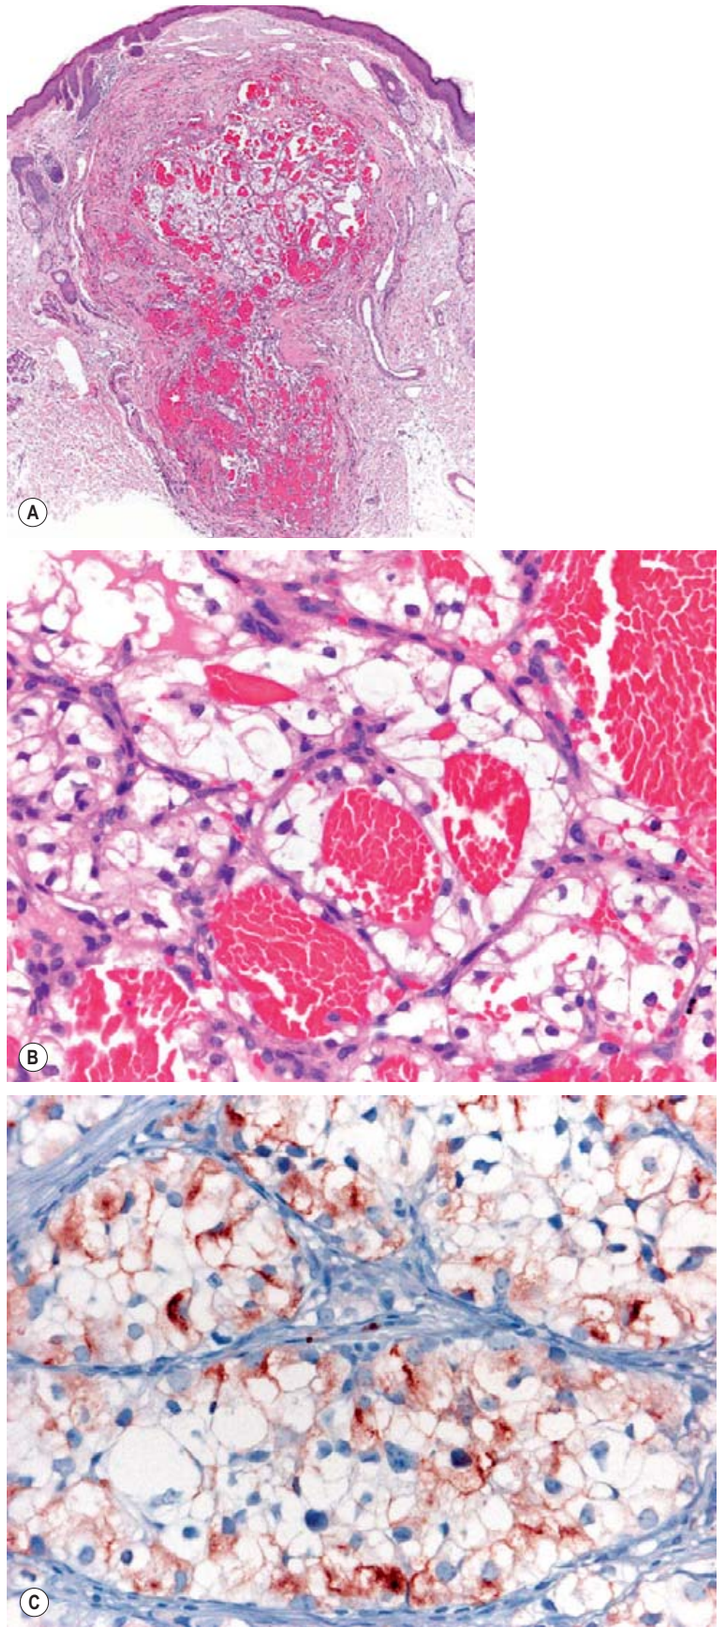

Fig. 122.6 Histopathologic features of cutaneous metastasis from renal clear cell carcinoma. A Vertically oriented hemorrhagic tumor within the dermis resembling an angiomatous tumor. **B** Tumor cells with clear cytoplasm arranged as fine trabecular structures and lobules surrounding hemorrhagic areas. The lack of prominent atypia can be misleading and lead to the erroneous diagnosis of hemangioma. **C** Positive immunohistochemical staining with RCC-Ma (renal cell carcinoma marker), a monoclonal antibody directed against a proximal tubule antigen and highly specific for clear cell renal carcinoma. *Courtesy, Lorenzo Cerroni, MD.*

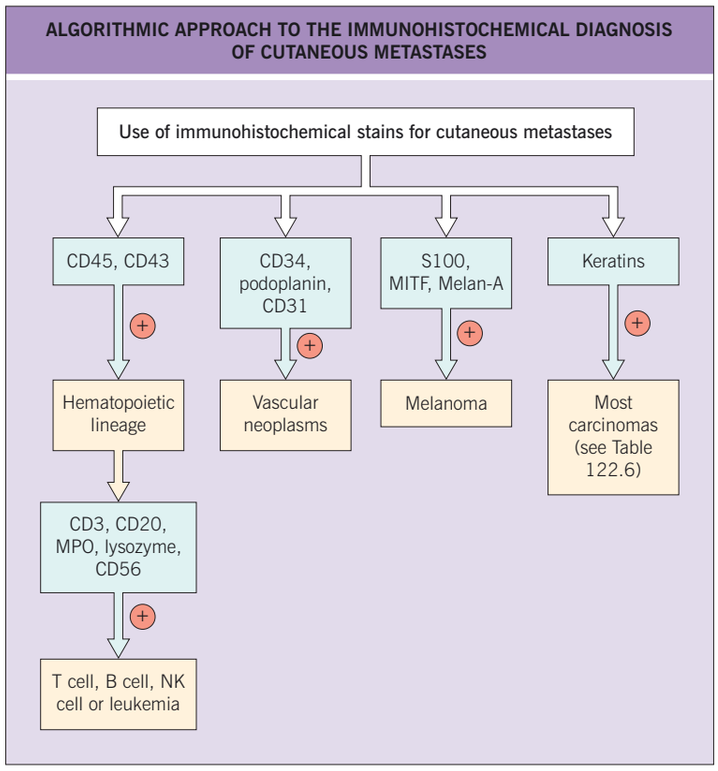

Fig. 122.7 Algorithmic approach to the immunohistochemical diagnosis of cutaneous metastases. See Chapter 0 for explanation of CD markers; MPO, myeloperoxidase. A combination of hematopoietic, vascular, melanocytic and keratinocytic markers allows one to identify the lineage of neoplastic cells in most cases. A more precise classification, particularly of hematopoietic neoplasms and of carcinomas, relies on detailed phenotypic analyses.

TREATMENT AND PROGNOSIS

Typically, cutaneous metastases are a harbinger of late-stage or progressive disease and as such portend a poor prognosis. The average survival time following the initial diagnosis of cutaneous metastasis is 7.5 months[15] and half of the patients expire within the first 6 months[16]. Whether the patient has a known or unknown primary malignancy, the development of cutaneous metastases calls for a multidisciplinary approach, including medical and surgical oncologists, radiation oncologists, and mental health care providers when appropriate. Localized treatment of cutaneous metastases can be undertaken for functional, palliative or cosmetic indications. When feasible, surgical excision is performed; however, radiation and focal chemotherapeutics or immunotherapies can be considered on a case-by-case basis. Systemic therapies are indicated for immuno- or chemotherapy-responsive tumors. When malodorous, topical metronidazole solution (supplied for intravenous use) can be applied via cotton gauze or pump spray once to twice daily.

Public Health and Dermatology 123

Sarah Nakib and Abrar A Qureshi

INTRODUCTION

As a dermatologist walks into the examination room of the patient in Figure 123.1, several differential diagnoses likely come to mind. The patient's history, additional examination findings, and other clues help narrow the differential. In this case, knowing the patient's history of atopic dermatitis lends context to the appearance of punched-out erosions and allows one to arrive at the diagnosis of eczema herpeticum. Therefore, awareness of the epidemiology of a disease, how it is distributed in populations and the factors that influence its distribution can assist with making a diagnosis[1–2a].

Considering the high prevalence of skin conditions, dermatologists have the potential to play an important role in public health research and policy. This chapter seeks to highlight the relevance of dermatologic conditions to public health, the impact epidemiology can have on a dermatology practice, major types of public health studies and terminology used in epidemiology.

THE PUBLIC HEALTH IMPORTANCE OF DERMATOLOGY

Office visits to a dermatologist account for 4% of all outpatient visits, representing the third most common subspecialty ambulatory visit (after ophthalmology and orthopedics). In addition, dermatologic conditions account for approximately 5% to 8% of primary care visits[3–5] and 4% of primary diagnoses made in the emergency room[6]. Additional data on skin conditions addressed in various medical settings are presented in Table 1.

Not only are dermatologic conditions common, but some are becoming more common, with rapidly rising incidence rates. The rate of melanoma increased by approximately 2.6% per year in the US from 1985 to 2007[8]. In addition, some countries have experienced an increase in non-melanoma skin cancers, such as basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs)[9–11].

ROLE OF EPIDEMIOLOGY IN DERMATOLOGY

Epidemiologic studies have yielded information on the etiology, risk factors, natural history, prognosis, incidence, prevalence, and effective treatments of dermatologic diseases. The impact that epidemiologic data can have on patient care and systems-based practice in dermatology is outlined in Table 123.2.

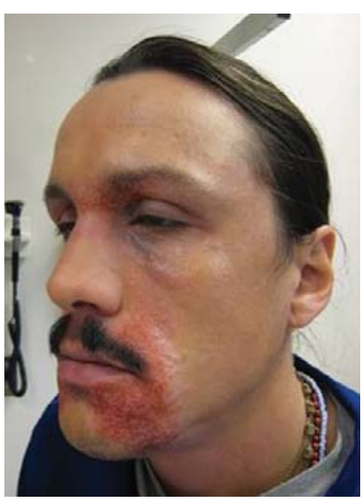

Fig. 123.1 Eczema herpeticum: diagnosis facilitated by knowledge of epidemiology. Grouped vesicles and punched-out erosions are evident. Based on this information alone, eczema herpeticum is in the differential diagnosis. However, awareness of the patient's history of atopic dermatitis, in combination with knowledge regarding the epidemiology of eczema herpeticum, allows for greater certainty in establishing the diagnosis.

OBSERVATIONAL STUDIES

Participants in observational studies are observed and certain outcomes are measured, without external manipulation or an attempt to affect the outcome. Characteristics of different types of observational studies, including the "level of evidence" provided[12,13], are summarized in Table 123.3.

Descriptive Studies

Many of the studies currently being done in dermatology are descriptive. These include case reports and case series. A *case report* is a detailed description of an individual patient's clinical presentation, characteristics (e.g. demographic information), diagnosis, treatment, and disease course. A *case series* reports on some aspect(s) of a disease, diagnostic procedure or treatment in a group of patients with common characteristics[12]. Case reports and series are useful for determining the manifestations of rare conditions, reporting the preliminary outcomes of experimental therapies, and generating hypotheses for larger studies. A major limitation of case series is the lack of a control group, although previous data (e.g. on the prevalence of risk factors in the general population) can sometimes be utilized for comparison.

PUBLIC HEALTH IMPORTANCE OF DERMATOLOGY
• Dermatologist visits account for 4% of all outpatient visits are dermatologist visits (third most common subspecialty visit) • 4.7% to 8.4% of primary care visits are related to dermatologic conditions – Most common conditions addressed (in decreasing frequency) are eczema, infections, benign neoplasms, acne, psoriasis and skin cancer. • 4.2% of primary diagnoses in the ER are diseases of the skin and subcutaneous tissue • In pediatric patients (age < 15 years), "skin rash" accounts for 3.4% of visits to the ER – Common conditions include viral exanthems, urticaria, atopic dermatitis, varicella, diaper dermatitis, herpetic gingivostomatitis

Table 123.1 Public health importance of dermatology. ER, emergency room.

USES FOR EPIDEMIOLOGY IN DERMATOLOGY
EPIDEMIOLOGY APPLIED AT THE PATIENT CARE LEVEL
• Provide context to assist with diagnosis • Give guidance to patients on avoiding triggers and modifiable risk factors for their disease • Provide evidence for management strategies • Prevent associated comorbidities for patients and their families through early screening
EPIDEMIOLOGY APPLIED AT THE SYSTEMS LEVEL
• Raise awareness of the burden and distribution of skin disease in the community • Allow for appropriate allocation of resources for common and emerging conditions • Help in anticipating and addressing future needs • Affect public policy

Table 123.2 Uses for epidemiology in dermatology.

STUDY TYPES AND THEIR CHARACTERISTICS						
Type of study	**Study group**	**Control group**	**Association measure frequently used**	**Advantages**	**Limitations**	**Level of evidence for whether a therapy is efficacious***
Case series	Persons with disease	None	Varies (e.g. percentile)	• Describes rare conditions and therapies	• No control group, no information on background level of exposure for comparison	4
Case–control	Persons with disease	Persons without disease	OR (approximates the RR in rare diseases)	• Can study rare diseases • Short duration, inexpensive, small size	• Potential for bias and confounding because sampling two different populations • Does not establish causal relationship • Limited to one disease	3
Cohort	Persons exposed	Persons not exposed	RR or absolute risk†	• *Causal inference* • Can evaluate a number of diseases • Yields *incidence* of disease • Can study rare exposures	• Often requires a large sample size • Less feasible for rare diseases	2**
Cross-sectional	Persons with disease or exposed	Either of the above	OR or relative prevalence	• Can study several exposures and diseases • Relatively short duration • Yields *disease and exposure prevalence*	• Does not establish causality • Less feasible for rare diseases	2**
Randomized controlled trials (RCTs)	Persons randomized to treatment	Persons randomized to control	Varies (e.g. RR or percentiles)	• Ability to demonstrate causality • Randomization and blinding help to decrease bias or confounding	• Expensive • Can expose participants to potential harm • Answers a narrow clinical question	1

*The level of evidence for a therapeutic efficacy has a scale of 1–5, 1 being the best. Expert opinions represent level 5. The level of evidence for therapeutic efficacy for a systematic review depends on the types of studies it reviews. A systematic review of RCTs with good homogeneity ranks above an individual RCT.

**In general, a cohort study (2b) is ranked as better than a cross-sectional study (2c).

†***Absolute risk reduction*** is the incidence rate of disease in the exposed group subtracted by that of the unexposed group. This is affected by the rate of disease in the population; the greater the prevalence of disease, the higher the absolute risk reduction. The reciprocal of absolute risk reduction is the ***number needed to treat*** to avoid one person getting the disease.

Table 123.3 Study types and their characteristics[2,13,14]. OR odds ratio; RR, relative risk.

An example of a valuable case series is the description of scalp involvement in patients with dermatomyositis by Kasteler and Callen[15]. Fourteen of the 17 patients with dermatomyositis who were seen in the authors' practice over a 5-year period had scalp involvement, manifesting as atrophic, erythematous, scaly plaques. Five of the 14 affected individuals had previously been diagnosed with scalp psoriasis or seborrheic dermatitis. This study helped raise awareness of scalp involvement as a manifestaton of dermatomyositis.

Using Epidemiology to Identify the Cause of Disease

Case–control, cohort, and cross-sectional studies are often performed to help elucidate the etiology and risk factors of a disease. These methods involve studying a disease of interest (e.g. SCC) and an exposure that is suspected of being a risk factor for the disease (e.g. ultraviolet [UV] radiation), so that the study participants can be categorized as having the disease or not and as being exposed to the potential risk factor or not (Table 123.4).

CATEGORIZATION OF STUDY PARTICIPANTS, BASED ON THEIR DISEASE AND EXPOSURE		
	Disease (e.g. SCC)	**No disease (e.g. no SCC)**
Exposed (e.g. high-dose UV)	a	b
Non-exposed (e.g. no high-dose UV)	c	d

Table 123.4 Categorization of study participants, based on their disease and exposure. SCC, squamous cell carcinoma; UV, ultraviolet radiation.

Case–control study

A case–control study identifies a group of individuals with a disease, as well as a comparison group without the disease from the same population. The study design retrospectively evaluates the level of exposure in the disease group (cases), as compared to that in the group without disease (controls). To ensure that those with disease and without are comparable, both types of participants should be sampled from a single population and data collected in the same way for each group[14]. In addition, cases and controls should be matched on possible confounding factors; for example, if there is a 60-year-old female case, then a 60-year-old female control from the same general population would be selected.

A *confounder* is an extraneous variable that is associated with both the exposure and disease being studied; it could therefore account for a part or all of the relationship between the exposure and disease. Although the confounder may be a contributing factor to the disease, it is not caused by the exposure and thus is not along the "causal pathway" between the exposure and disease[1,2] (Figure 123.2). Age and gender are examples of possible confounders. These and other baseline characteristics that may be associated with both the exposure and disease should also be recorded and placed in the statistical model. If an association remains after accounting for confounders, it is more likely to be a true one.

In a case–control study, one can calculate the odds of having had the exposure among those with disease (a/c), as compared to the odds of having had the exposure among those without disease (b/d) (see Table 123.4). The association measure used for case–control studies is an *odds ratio* (OR), which equals (a/c)/(b/d) or ad/bc. An OR = 1 denotes a null association. If it is statistically significantly greater or less than 1, then there is a positive or negative association, respectively. An OR is different from a *relative risk* (RR), the rate of disease among those exposed divided by that among those unexposed, (a/a+b)/(c/c+d), see Cohort study section below. While the RR cannot be directly calculated

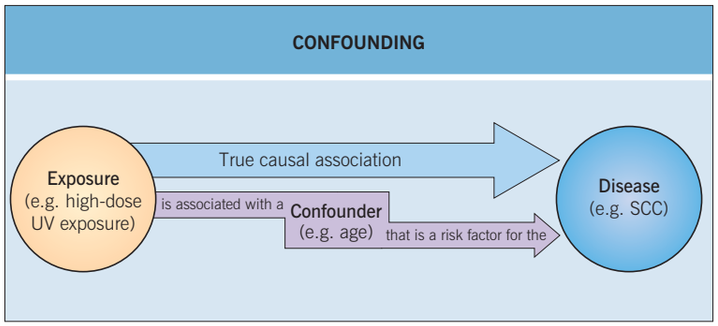

Fig. 123.2 Confounding. The blue arrow represents a true association, in this case a causal one. The purple arrow does not represent a true association, but one found because of confounding. SCC, squamous cell carcinoma; UV, ultraviolet radiation.

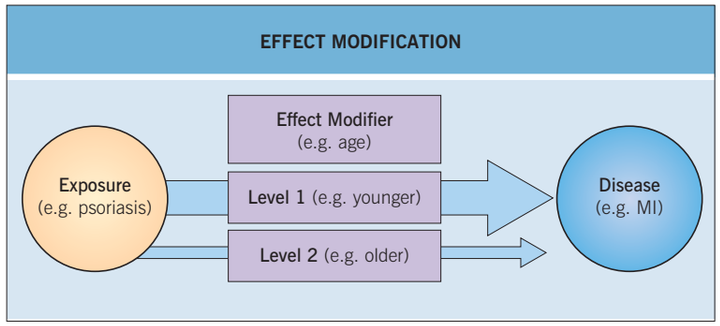

Fig. 123.3 Effect modification. The blue arrow represents a true association, in this case a causal one; the thicker it is, the stronger the association. If a variable causes effect modification, the strength of the association between exposure and disease varies across levels of the effect modifier. In some cases, there may not be an association for a given level of the effect modifier. Age is an effect modifier for many conditions. Interaction represents a similar concept that occurs when the exposure and another variable are interdependent in their effect on disease. MI, myocardial infarction.

from a case–control study, the OR approximates the RR when the disease is rare.

One of the major advantages of a case–control study is that it can yield information on a disease with many possible predictors, using only a limited number of participants. Therefore, it works well for rare conditions. Also, these studies are relatively inexpensive and time-efficient. One of the disadvantages of a case–control study is that it is not clear if the exposure preceded the disease, so causality cannot be established. In addition, this type of study has several potential biases. *Sampling bias* can occur when cases and controls are collected separately and may not be comparable. Because of the retrospective ascertainment of exposure, *recall bias* can occur; for example, those with disease may recall the exposure with greater detail because they have been contemplating the potential causes of their condition. Of note, a case–control study does not yield information on the incidence or prevalence of a disease.

An example of a recent case–control study is that by Lazovich et al.[16], which compared the amount of indoor tanning exposure in patients with cutaneous melanoma (aged 25–59, selected from a statewide cancer registry) to that in age- and gender-matched controls (randomly selected from state driver's license lists). The investigators found that 62.9% of cases and 51.1% of controls had tanned indoors, with an adjusted OR of 1.74 (95% confidence interval [CI] of 1.42–2.14). In other words, after adjusting for potential confounders (e.g. sun exposure and other melanoma risk factors), those with melanoma had a 1.74 times or 74% greater odds of having tanned indoors, when compared to those without melanoma. The 95% CI shows that the OR is statistically significant because it does not include 1.

Cohort study

A cohort study recruits its participants from the general population, and those recruited must be without the disease of interest. Using the example given in Table 123.4, all participants would need to be SCC-free at the onset of the study. They are categorized as having or not having high-dose UV exposure and are then followed over time. At the end of the study, one can calculate the rate of SCC among those with high-dose UV exposure (a/a+b) and compare it to the rate of SCC among those without high-dose UV exposure (c/c+d). Therefore, a cohort study compares the incidence of disease between those exposed and not exposed to particular risk factor(s). This is usually expressed in terms of a RR (see definition above). Similar to an OR, a RR of 1 represents a null association, whereas an RR statistically significantly greater or less than 1 indicates a positive or negative association, respectively. A cohort study can be done prospectively, allowing for more control over measuring outcomes (preferred particularly for fatal diseases), or retrospectively, which is less expensive and requires less time.

One of the advantages of a cohort study is that it can determine the *incidence* of a disease, which is the number of new cases divided by the total number of people at risk in a particular population (e.g. participants in the study) over a specified time period (e.g. length of study)[1]. It also gives information on the natural history of a disease, since it captures data from the time of disease onset. Another advantage is that a cohort study establishes temporality, as the exposure precedes the outcome, and therefore allows for causal inference between the exposure and disease. The disadvantages are that a cohort study often requires a large sample size and is less feasible for rare outcomes.

An example of a recent cohort study is one by Gelfand et al.[17], which looked at the association between psoriasis and risk of myocardial infarction (MI). Here, psoriasis was the "exposure" and MI was the "disease". Their study population comprised persons aged 20 to 90 years of age who saw a general practitioner in the UK. Their results revealed that the incidence of MI per 1000 person-years was 3.58 (95% CI, 3.52–3.65) for the control group, 4.04 (95% CI, 3.88–4.21) for the group with mild psoriasis, and 5.13 (95% CI, 4.22–6.17) for the group with severe psoriasis. After adjusting for potential confounders (e.g. age, gender, smoking, hypertension, diabetes), they found that psoriasis was significantly associated with MI. They also found that age was an effect modifier (see below) in the association between psoriasis and MI. Therefore, they reported the association across strata of age. The adjusted RRs of an MI for 30-year-old patients with mild or severe psoriasis were 1.29 (95% CI, 1.14–1.46) and 3.10 (95% CI, 1.98–4.86), respectively, as compared to controls. In contrast, the adjusted RRs of an MI for 60-year-old patients with mild or severe psoriasis were 1.08 (95% CI, 1.03–1.13) and 1.36 (95% CI, 1.13–1.64), respectively, as compared to controls. This means that a 30-year-old patient with mild psoriasis has a risk of MI that is 1.29 times or 29% greater than that of a 30-year-old person without psoriasis, after controlling for confounding factors.

Effect modification or *interaction* occurs when the association between the exposure and disease varies across levels of a variable (e.g. age; Fig. 123.3). Therefore, the exposure and effect modifier have an interdependent role in their effect on the disease. When this happens, the association between exposure and disease should be displayed at various levels or strata of the effect modifier[1,2].

Cross-sectional study

A cross-sectional study is similar to a cohort study, except that the initial population does not need to be free of the disease of interest and both the exposure and disease are measured in a single time point, without a follow-up period. It yields information on the *prevalence* of disease, which is the number of affected individuals divided by the number of people in the population at risk (e.g. total number of study participants), at a given time. It allows one to study the association between exposure and disease, but it does not provide information about which preceded the other. Its results are often expressed in terms of ORs or *relative prevalence*, which compares the prevalence rate of a disease among those exposed to that among the unexposed. While mathematically it is represented by (a/a+b)/(c/c+d) (see Table 123.4), here a/a+b and c/c+d are prevalence rates, rather than incidence rates as in a cohort study.

The advantages of a cross-sectional study are that it is relatively fast, without requiring follow-up time, and inexpensive. It is the only epidemiologic study that gives the prevalence of a disease, exposure, or other risk factor. One of its weaknesses is that it does not demonstrate temporality, and so it does not establish a causal relationship between the exposure and disease. Also, it is not practical for rare diseases or rare exposures, which would require a very large study population.

An example of a cross-sectional study is one by Love et al.[18], which used a national database representative of the non-institutionalized civilian US population, the National Health and Nutrition Examination Survey. It found that the prevalence of metabolic syndrome was 40% among psoriasis cases, compared to 23% among controls. After adjusting for age, sex, race/ethnicity, smoking status, and C-reactive protein levels, the OR for the association between psoriasis and metabolic syndrome was 1.96 (95% CI 1.01–3.77). Therefore, those with psoriasis had a 1.96 times or 96% greater odds of having metabolic syndrome, as compared to those without psoriasis.

ASSESSING THE EFFICACY OF A PREVENTIVE OR THERAPEUTIC INTERVENTION

Clinical Trials

Unlike most observational studies, clinical trials involve an intervention. In a randomized controlled trial (RCT), participants are randomized to receive the intervention or placebo. Participants can be blinded to their group, as can the observers (double-blinded). The participants are followed for a given period of time, during which disease outcomes and safety are measured. Table 123.5 presents the four phases for testing of new drug therapies. *Intention-to-treat analysis* is then performed, which classifies participants into the intervention group that they were assigned through randomization, rather than the actual intervention that they received (which may vary if participants crossed over into the other intervention group because of non-compliance, side effects, or other reasons). This preserves the randomization of the study design. However, an analysis taking into account the actual intervention received is done as well, for comparison. The outcome measures for a RCT vary according to the outcome of interest (e.g. relative risk, percentile improvement comparison across groups, prognosis measures; Table 123.6). The concept of statistical significance is applied to assess whether the outcomes differed in the treatment and control groups.

The major advantage of a controlled trial is its ability to demonstrate causality (see Table 123.7). Randomization can eliminate confounding effects and blinding can eliminate bias. The disadvantages of this kind of study are that they are relatively expensive and can expose participants to potential harm. In addition, they answer a narrow clinical question. Therefore, RCTs are often reserved for well-developed research questions that are based on previous evidence from smaller or observational studies. Generally, participants in clinical trials should be easy to recruit and have be likely to benefit and unlikely to be harmed from the intervention; participants with a high level of adherence to the treatment and follow-up plan are also desirable. The design of the intervention should balance efficacy and safety, with interim monitoring during the trial to ensure that participants are not exposed to a harmful intervention, denied a beneficial intervention, or continued in a trial that cannot answer the question it was intended to answer. Whenever possible, trials should include comparison with placebo. When comparing active treatments in an equivalence or superiority trial, comparison with the gold-standard treatment for the patient population being studied can maximize the relevance to clinical practice. A well-designed blinded RCT is thought of as the gold standard for study design[13] (see Table 123.3).

An example of a recent RCT was that by Paller et al.[19] to assess the efficacy and safety of etanercept in children and adolescents with moderate to severe plaque psoriasis. It involved randomizing 211 pediatric patients (4 to 17 years of age) with psoriasis to a double-blinded trial of once-weekly subcutaneous injections of etanercept or placebo, for 12 weeks. The primary endpoint was ≥75% improvement from baseline in the psoriasis area and severity index (PASI 75). The patients randomized to receive etanercept were significantly more likely to achieve a PASI 75 (57%) than those receiving placebo (11%) ($P < 0.001$). The authors were able to conclude that etanercept significantly reduced disease severity in children and adolescents with moderate to severe plaque psoriasis.

Systematic Reviews

A systematic review identifies completed studies that address a specific research question and then aggregates and statistically analyzes the

FIVE WAYS OF EXPRESSING PROGNOSIS AND SURVIVAL DATA	
Case-fatality rate	The number who died from the disease of interest divided by the number of those with the disease, used more for short-term acute conditions
Five-year survival	The percentage of patients who are alive 5 years after diagnosis or after treatment begins, often used in evaluating cancer research
Observed survival rate	Expressed in probability of survival each year of the study (e.g. a life table) or based on the time interval from baseline to when a study participant dies (e.g. a Kaplan-Meier plot)
Median survival rate	The length of time at which half of the study population survives, which can be useful for diseases with extremes in survival
Relative survival rate	The observed survival in those with the disease divided by expected survival if the disease were absent

Table 123.6 Five ways of expressing prognosis and survival data. Considering that there are some dermatologic conditions that are fatal, being aware of survival measures is useful[2].

THE FOUR PHASES OF TESTING A NEW DRUG	
Phase I	An unblinded, uncontrolled study, involving a few volunteers, that focuses on a drug's safety and pharmacologic profile
Phase II	A small randomized trial that tests for efficacy, as well as relative safety
Phase III	A larger randomized trial that tests for effectiveness and safety
If the drug passes phase III, it can be approved by the FDA	
Phase IV	A trial or observational study used for post-marketing surveillance to assess the rate of serious side effects and evaluate for additional therapeutic uses

Table 123.5 The four phases of testing a new drug[2,14].

FACTORS THAT STRENGTHEN CAUSAL INFERENCE
Evidence of temporality – i.e. the exposure preceded the disease or outcome
Consistent across other studies and reproducible
A strong association (e.g. the further the RR or OR is from 1), given that it is statistically significant in a well-powered study
A dose–response relationship – i.e. the greater the exposure, the greater the risk of disease
Cessation of the exposure is associated with *decreased risk of disease*
Biological plausibility and *consistency with other scientific knowledge* – i.e. there is a mechanism linking the exposure to the disease that makes sense

Table 123.7 Factors that strengthen causal inference. A well-designed randomized controlled trial provides the best evidence for establishing causality. Cohort studies can infer causality, as the exposure precedes the disease in these studies[2,14]. OR, odds ratio, RR, relative risk.

results across studies, to arrive at a conclusion about a body of research[1]. Although traditionally applied to RCTs, systematic reviews can also be used for observational studies. A systematic review should have a written protocol addressing the research question it seeks to answer, comprehensive and unbiased methods for identifying studies, and a display of the statistical aspects of the review, i.e. meta-analysis. It should also include a summary estimate of effect and confidence interval based on the findings of all eligible studies (Fig. 123.4). In addition, it should have an assessment of heterogeneity across the studies used, to indicate the degree of variability in the findings in different studies. It should address publication bias, to ensure that it has taken into account unpublished studies, as positive studies are more likely to get published. It also usually includes subgroup analyses based on additional measures done by some or all of the studies that are supplemental to the main research question. Analyses to assess how sensitive the findings of the meta-analysis are to decisions taken in designing the study or inclusion of certain studies should be done if any of the design decisions were questionable or arbitrary. Here, the less sensitive the study the better. The characteristics and the findings of individual studies should be displayed clearly in tables and figures to allow the reader to visualize the data and not rely solely on the conclusions of the meta-analysis[2,14].

The advantage of a systematic review is that it enables the integration of the results of multiple studies, allowing for greater power. While it is often time-consuming, it does not require significant financial or other resources. Because it involves intimate knowledge of the literature related to the research question, it can establish the investigator as an expert in the area. In addition, the results are sometimes used to develop practice guidelines. It must be noted that a systematic review is only as valuable as the quality of the studies it is based on. Caution must be exercised in interpreting systematic reviews, with recognition that they may not take into account unpublished studies, the quality of all of the studies may not be equal, studies may not be comparable (e.g. different outcome measures), and adjusting for biases can be a formidable task. In addition, having a single estimate of risk based on that of several studies may give a false sense of certainty regarding the magnitude of the risk[2,14]. A systematic review of RCTs that have homogeneous results gets the highest ranking of all study types[13] (see Table 123.3) however, the level of evidence is considerably lower for systematic reviews limited by the factors discussed above.

The Cochrane Skin Group, which stems from the larger Cochrane Collaboration Group that reviews a variety of healthcare studies, is dedicated to the production of systematic reviews on dermatologic topics[20]. Another example of a systematic review is that done by Warycha et al.[21], which sought to estimate the risk, potential predictors, and outcomes of a positive sentinel lymph node (SLN) biopsy among patients with thin (≤1 mm) melanomas. The rate of SLN positivity was the primary outcome. To conduct this study, the authors searched large databases (MEDLINE, EMBASE and Cochrane databases) for studies on SLN positivity in patients with thin melanoma. They assessed the methodologic quality of studies, heterogeneity, and publication bias through established criteria. They found that there were 34 studies, with 3651 patients, that met inclusion criteria. These studies were mostly descriptive. The pooled SLN positivity rate was 5.6%. There was significant heterogeneity among studies (P=0.005), but no statistical evidence of publication bias (P=0.21). They did a subgroup analysis on 18 studies, and reported the clinical and histopathologic features of thin melanomas in 113 SLN-positive patients. They concluded that relatively few patients with thin melanoma have a positive SLN and that there are no clinical or histopathologic criteria that can reliably predict which patients with thin melanomas will have a positive SLN.

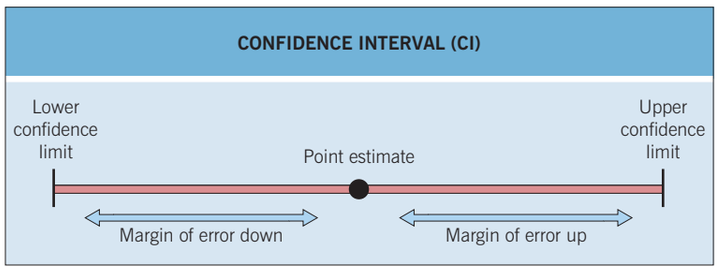

Fig. 123.4 Confidence interval (CI). A confidence interval derived from a valid analysis will, over unlimited repetitions of the study, contain the true parameter 95% of the time.

GENETIC EPIDEMIOLOGY

When considering the etiology of a disease, it is important to account for not only environmental factors but also genetic susceptibility. Because of recent advances in molecular and genetic techniques, epidemiologic studies have expanded to include use of biologic samples. With the completion of the Human Genome Project in 2003 and the International HapMap Project in 2005, researchers in genetic epidemiology are using a technique known as the genome-wide association study (GWAS; see Ch. 54). This technique examines the association between single nucleotide polymorphisms (SNPs), markers for groups of DNA variation inherited together in blocks (haplotypes), and a variety of diseases. Findings from these studies can be used to investigate the molecular pathways of disease. One can look for associations in a hypothesis-driven or non-hypothesis-driven manner.

A study by Petukhova et al.[22] illustrates the use of GWAS techniques to elucidate the pathogenesis of alopecia areata (AA). Using genetic samples from 1054 cases and 3278 controls, they identified 139 SNPs significantly associated with AA ($P \leq 5\times10^{-7}$). They found an association between these SNPs and the genomic regions containing several genes that control the activation of T cells and the production of cytokines. The results of the study implicated both innate and acquired immunity in the pathogenesis of AA and suggested potential autoimmune mechanisms for this condition.

HEALTH SERVICES RESEARCH

The field of health services research applies techniques of epidemiologic investigation to assess the association between health services provided in the community and disease outcomes. Outcomes for this kind of research include traditional endpoints such as mortality and morbidity, as well as others such as usage and access, patient satisfaction, quality of life, and disability measures. It involves the concepts of efficacy, effectiveness and efficiency. *Efficacy* is where an association is demonstrated in an ideal, controlled situation; for example, showing that skin cancer screening in a dermatology office is associated with early detection of skin cancer. *Effectiveness* is finding an association in a "real life", uncontrolled environment, e.g. skin cancer screening in a community setting, such as a booth at the state fair. There may be factors in this environment (but not an ideal setting) that decrease compliance. Finally, once efficacy and then effectiveness are demonstrated, *efficiency*, i.e. cost–benefit ratios, can be evaluated[2].

Quality-of-Life Measures

Quality of life (QOL) has been defined by the World Health Organization (WHO) as "the individuals' perception of their position in life, in the context of the cultural and value systems in which they live and in relation to their goals, expectations, standards and concerns". QOL is an important outcome measure for dermatologic conditions because, while many conditions are not fatal, they can cause significant morbidity in the form of decreased QOL. Patients may place different weights on various QOL measures depending on their personal values, background and education. Therefore, development of a QOL measure that is valid can be challenging. The most commonly used QOL instrument in dermatology is the Dermatology Life Quality Index (DLQI), which has been employed for numerous conditions. It is a self-administered, 10-item questionnaire about the patients' perception of the impact of skin diseases on different aspects of their QOL over the last week[23]. The DLQI has been validated for dermatology patients aged 16 years and above. Its internal consistency has been rated as good to excellent, its test–retest reliability has a high Spearman's correlation coefficient, and the results correlate with those of other QOL instruments (although less so for mental and emotional aspects[24]). Another commonly used QOL instrument in dermatology is the Skindex-29, a 30-item questionnaire that is more comprehensive than

the DLQI. The Skindex-29 is often used in cross-sectional studies for a variety of conditions, especially psoriasis[24].

IMPORTANT CONCEPTS WHEN DESIGNING AND REVIEWING A STUDY

Research Question and Design

There are important concepts to consider when thinking about one's own research and in reviewing that published by others in the literature. These concepts apply to both observational studies and clinical trials (Table 123.8). First, it is important to be aware of the study design needed to best answer the research question of interest. Alternatively, given a certain study design, one must recognize the questions that it can and cannot answer (e.g. a case–control study cannot answer a question about causality).

Methods

When designing or reviewing the methods, it is important to have a control group whenever possible. Also, it is important to consider the types of errors that can affect the study. There are two types of errors, random (due to chance) and systematic. *Systematic errors* are due to bias, "sources of variation that distort the study findings in one direction"[14]. The opposite of systematic errors is validity. Several types of bias that can occur in epidemiologic studies are described in Table 123.9. Some studies are particularly prone to certain types of bias. For example, retrospective studies are especially susceptible to recall bias, a type of information bias (see section on Case–control study). An effort should be made in the study design to decrease systematic errors.

The baseline patient characteristics, exposures, other risk factors, and disease characteristics should be measured reliably and accurately (Fig. 123.5). Information on validity (accuracy) is often expressed using sensitivity and specificity or predictive values. *Sensitivity* represents the likelihood of testing positive for someone who has the disease (a/a+c) (Table 123.10). *Specificity* is the likelihood of testing negative for someone who does not have the disease (d/b+d). These measures yield information on how well we are able to identify those who have or do not have the disease, when we test the general population. A different perspective on the validity of a test is gained through measuring predictive value. This allows us to inform individual patients about what their test results mean. The *positive predictive value* is the likelihood of having the disease when testing positive (a/a+b). The *negative predictive value* is the likelihood of not having the disease when testing negative (d/c+d). Predictive values depend on the prevalence of a disease

IMPORTANT CONSIDERATIONS WHEN REVIEWING A STUDY

Research question and study design	Given the study design, what are the questions it can and cannot answer? See Table 123.3
Methods	• ***Is there a control group?*** • Was an effort made to decrease systematic errors? • Were exposure and disease measured reliably and accurately? • ***Were potential confounders included in the statistical model for the association between exposure and disease?*** • Were tests done looking for effect modification or interaction between the exposure and other study variables (see Fig. 123.3)?
Results	• Are baseline characteristics significantly different across exposure groups, as well as across outcome groups? If so, were these variables adjusted for in the statistical model? • ***Was the correct outcome measure for a given study design used?*** • Is the association statistically significant? (e.g. P value >0.05 or a 95% CI that does not include 1, in the case of a ratio) • Did the study have enough power, usually referring to number of participants, to detect statistical significance?
Conclusions	• ***How strong is the evidence for a causal association?*** (see Table 123.7) • Could a type I error have occurred (false positive) • Could a type II error have occurred (false negative)? • ***What conclusions can be drawn given the type of the study design, its strengths and limitations, including biases*** (see Table 123.3)? • How generalizable are the findings? • Was the study industry-sponsored? • Are the findings compelling enough to affect current clinical practice and the direction of future research?

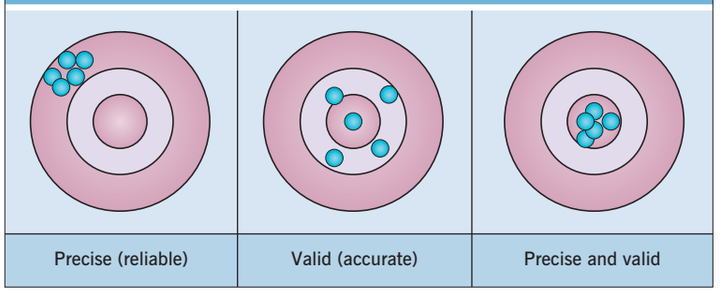
Table 123.8 Important considerations when reviewing a study. Common pitfalls are in bold italics.CI, confidence interval; OR, odds ratio[2,14].

TYPES OF ERRORS AND BIAS

- **Random errors**
- **Systematic errors**
  - *Ascertainment bias* is when not all of those who are supposed to be represented in a population are represented
  - *Selection bias* occurs when participants are selected differently across exposure or disease categories.
  - *Misclassification bias* occurs when participants are wrongfully thought to belong to one category of exposure or disease, when they actually belong to another
  - *Information bias* relates to inaccuracies in the collection of data on the exposure or disease (e.g. *recall bias*).

Table 123.9 Types of errors and bias. There are two types of errors: random (due to chance) and systematic.

PRECISION AND VALIDITY



Precise (reliable) | Valid (accurate) | Precise and valid

Fig. 123.5 Precision and validity. Precision (reliability) is the relative lack of random error, and validity (accuracy) is the relative lack of systematic error[1].
From Porta, Miquel. Dictionary of Epidemiology (5th Edition). Cary, NC, USA: Oxford University Press, 2008. p 2. Copyright © 2008. Oxford University Press. All rights reserved.

CONCEPTS OF SENSITIVITY, SPECIFICITY, POSITIVE PREDICTIVE VALUE, AND NEGATIVE PREDICTIVE VALUE

	True condition (as determined by gold standard)		
Result of screening test	**Disease**	**No disease**	
Positive	a (true positives)	b (false positives)	Positive predictive value = a/a+b (increases with increased disease prevalence)
Negative	c (false negatives)	d (true negatives)	Negative predictive value = d/c+d (decreases with increased disease prevalence)
	Sensitivity = a/a+c	Specificity = b/b+d	

Table 123.10 Concepts of sensitivity, specificity, positive predictive value, and negative predictive value.

– the higher the prevalence, the higher the positive predictive value and the lower the negative predictive value.

Statistical methods should include adjustment for potential confounders in the statistical model for the association between exposure and disease (see Fig. 123.2). If not adjusted for, confounders may be the reason the exposure and disease are associated. It is also important to test for effect modification between the exposure and other study variables suspected of playing an interdependent role with the exposure in affecting the disease outcome (see Fig. 123.3). If there is a significant effect modification variable for an association, then the association measure should be presented for different levels of the effect modification variable.

Results

In thinking about the display of results, it is important to assess whether baseline characteristics significantly differ across exposure groups, as well as across outcome groups. If they differ significantly across both exposure and outcome categories, then they could be confounders and need to be placed in the statistical model for the association between the exposure and disease so that they may be adjusted for. Next, it is important to use the correct outcome measure for a given study design (e.g. the outcome measure for a case–control study is an OR). Associated with each outcome measure is an indication of whether it is statistically significant. This is indicated by a P value or a 95% CI. *Statistical significance* is shown by a P value less than or equal to 0.05 (in most cases) and or by a 95% CI that does not include 1 within the interval for measures that represent a ratio (zero for measures that represent a difference). A *95% CI* that shows significance indicates that there is 95% confidence that the association is not due to chance alone (see Fig. 123.4). It is also important to note whether the study was powered enough to detect a statistically significant difference. *Power* is affected by the number of participants. One can do a power calculation when planning a study to attempt to include enough participants to detect a statistically significant difference between study groups. The variables included in the calculation vary according to study design, but they always include the expected magnitude of the association being measured, desired level of significance, and sample size.

Conclusions

In drawing conclusions about the results, it is important to consider those factors that support causality and how many are satisfied for the association in question (see Table 123.7). If statistical significance is found, one needs to determine whether the association makes biological and clinical sense. If it does not make sense, a *type I error* may have occurred, where a statistically significant association is found when one does not truly exist (false positive). It is important to note that the more statistical tests done for a study, the more likely a statistically significant association will be found based on chance alone. Alternatively, if an association is not found when one would be expected, a *type II error* may have occurred, where no statistical significance is found when one truly exists (false negative). This can be caused by a study not having enough power.

It is again important to consider what conclusions can be drawn given the type of study design, taking into account its strengths and limitations, including potential biases. In extrapolating the results, the *generalizability* of the study must also be considered. This pertains to how applicable the results are to the greater population and groups that did not participate in the study. It should also be noted if a trial was industry-sponsored. Lastly, it is important to consider the implications of the study on current clinical practices and the direction of future research.

Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) and the Consolidated Standards for Reporting Trials (CONSORT)

There is currently a need to improve reporting of findings in dermatologic studies. A study by Langan et al.[25] found that dermatologic papers infrequently reported sample size calculations, missing data, losses to follow-up, and statistical methods. Another paper by Ubriani et al.[26] found that only 20–49% of articles in three prominent dermatology journals reported the design of their study in the title or abstract of the paper.

In order to improve the quality of reporting of observational studies in medical research, criteria for reporting have been suggested in the form of the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) checklist. The items marked as critical for inclusion include the design of the study in the title or abstract and an informative summary of what was done in the abstract. Also, the methods section should have a description of: eligibility criteria for participants, sources of participants, methods of participant selection, methods of follow-up, matching criteria (if this was done), numbers of exposed and unexposed individuals, all outcomes measured, all exposures measured, all predictors, potential confounders, effect modifiers, diagnostic criteria, all statistical methods (including those dealing with confounding), whether subgroups and interactions were examined, how missing data was addressed, how losses to follow-up were addressed, and any sensitivity analysis[27]. A similar initiative for improving the quality of reporting of RCTs exists, with the Consolidated Standards for Reporting Trials (CONSORT) statement. This is a 25-item checklist that emphasizes reporting on how the trial was designed, analyzed, and interpreted. It also includes a flow diagram that displays the progress of all participants through the trial[28].

OPPORTUNITIES FOR RESEARCH IN DERMATO-EPIDEMIOLOGY

While each of the above study types provides valuable information, there appears to be a paucity of studies that include a control group or a large study population in dermatologic research. Considering the high prevalence of skin conditions and the rising incidence of diseases such as melanoma, the field of dermatology is likely to play a bigger role in public health research in the future. Therefore, it will be important for dermatologists to gain a greater understanding of epidemiologic and clinical research techniques. Also, it will be important to advocate for the inclusion of dermatology-related questions in local, state, and national surveys, allowing for larger epidemiologic studies to be conducted with limited resources.

There are currently some sources of data that can be analyzed for information on skin conditions, including national databases and disease registries (e.g. the National Alopecia Areata Foundation patient registry). Other options for getting involved in epidemiologic research include conducting a systematic review or enrolling one's clinic in a drug trial. There are also new molecular technologies on the horizon that warrant further research. Dermatologists interested in gaining greater experience in epidemiologic research may consider enrolling in a public health class, connecting with a mentor in the field, or getting involved with a community of researchers in this area. There are several funding sources currently available for dermato-epidemiology research, including those from dermatologic societies or foundations and national grants. As dermatologists become more active in these arenas, patients will be more likely to reap the benefits of research in dermato-epidemiology.

Chapter Contents

Structure and origin of the skin barrier *2065*
Parameters affecting skin permeability *2068*
Strategies to enhance transdermal drug delivery *2070*

The skin provides the largest interface between the human body and the external environment. Therefore, one of its most important functions is to regulate what enters the body via the skin, as well as what exits. In general, the skin is designed to let very little enter, since other tissues, such as the permeable epithelia of the gastrointestinal tract and lung, provide the primary means of regulated entry into the body. Likewise, the skin must prevent excessive loss of water and other bodily constituents.

The skin's remarkable barrier properties are due in large part to the stratum corneum, which represents the thin outer layer of the epidermis[1]. In contrast to other tissues in the body, the stratum corneum consists of corneocytes (composed primarily of aggregated keratin filaments encased in a cornified envelope) that are surrounded by an extracellular milieu of lipids organized as multiple lamellar bilayers. These structured lipids prevent excessive loss of water from the body and likewise block entry of most topically applied drugs, other than those that are lipid-soluble and of low molecular weight. This poses a significant challenge to administering medications via the skin either for local cutaneous effects or as systemic therapy following their entry into superficial dermal capillaries.

STRUCTURE AND ORIGIN OF THE SKIN BARRIER

Stratum Corneum Structure and Organization

The stratum corneum is a composite material made of proteins and lipids structurally organized as "bricks and mortar" (Fig. 124.1; Table 124.1)[2]. Instead of being uniformly dispersed, the highly hydrophobic lipids in normal stratum corneum are sequestered within the extracellular spaces, where this lipid-enriched matrix is organized into lamellar membranes that surround the corneocytes[3]. Hence, rather than stratum corneum thickness, variations in number of lamellar membranes (= lipid weight %), membrane structure, and/or lipid composition provide the structural and biochemical basis for site-related variations

FEATURES OF THE STRATUM CORNEUM
• Primary barrier to drug absorption into skin
• Two-compartment organization: "bricks and mortar"
• Microheterogeneity within extracellular spaces: "There's more to the mortar than lipid"
• Persistent metabolic activity: dynamic changes in cytosol, cornified envelope, and interstices from inner to outer stratum corneum
• Homeostatic links to the nucleated cell layers: barrier function regulates epidermal DNA and lipid synthesis
• Pathophysiologic links to deeper skin layers: barrier abrogation and/or epidermal injury initiates epidermal hyperplasia and inflammation
• Stratum corneum as a biosensor: changes in external humidity alone regulate proteolysis of filaggrin, epidermal DNA/lipid synthesis, and initiation of inflammation

Table 124.1 Features of the stratum corneum.

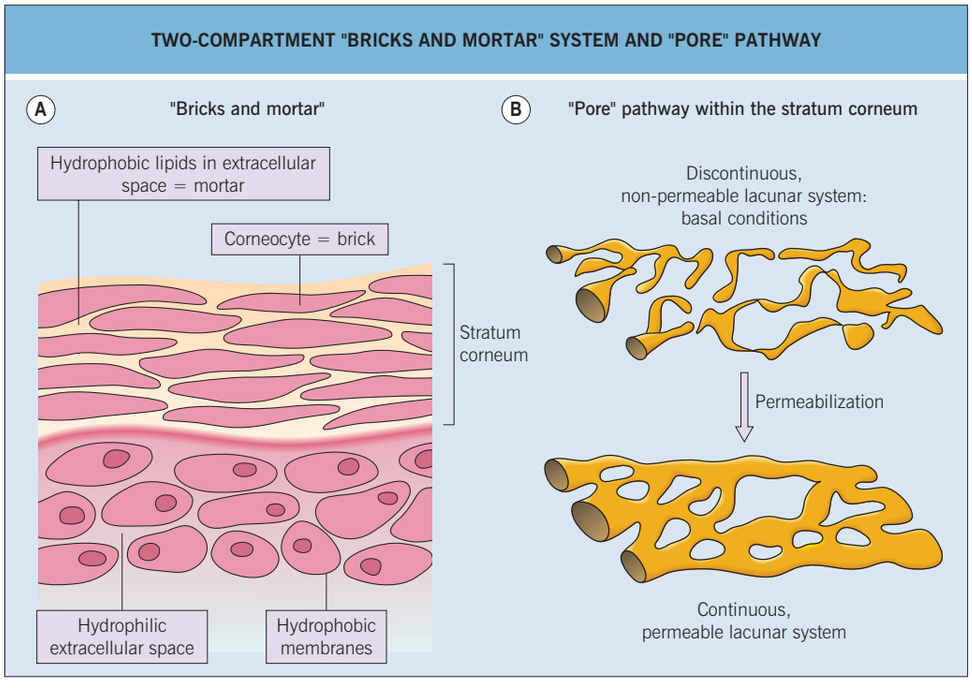

Fig. 124.1 Two-compartment "bricks and mortar" system and "pore" pathway. A The stratum corneum is a unique two-compartment system, analogous to a brick wall. Whereas lipids are sequestered extracellularly within the stratum corneum, the corneocyte is lipid-depleted but protein-enriched. **B** The degradation of corneodesmosomes results in discontinuous lacunar domains, which represent the likely aqueous "pore" pathway. These lacunae can enlarge and extend, forming a continuous but collapsible network under certain conditions, e.g. occlusion, prolonged hydration, sonophoresis.

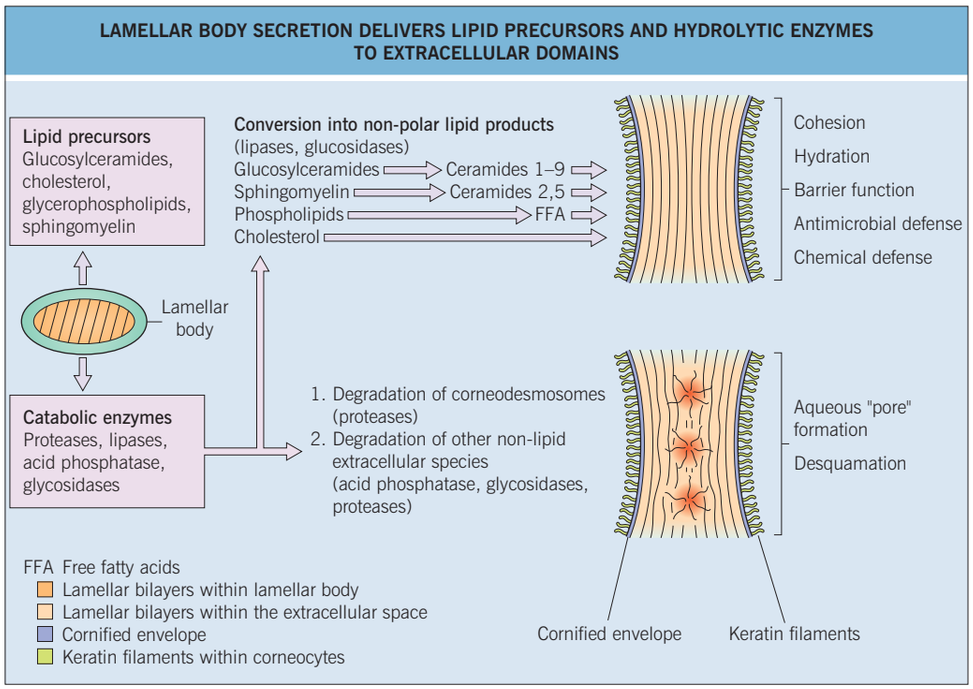

Fig. 124.2 Lamellar body secretion delivers not only lipid precursors, but also several hydrolytic enzymes to extracellular domains. These organelles also release antimicrobial peptides, including human β-defensin 2 and LL-37 (the carboxy-terminal fragment of human cathelicidin). As a result, the antimicrobial barrier is intimately linked to the permeability barrier. In atopic dermatitis, for example, there is both an impaired permeability barrier and reduced expression of antimicrobial peptides, explaining in part the predisposition to colonization with *Staphylococcus aureus*.

FACTORS AFFECTING HOW STRATUM CORNEUM LIPIDS MEDIATE BARRIER FUNCTION
• Extracellular localization: only intercellular lipids play a role
• Amount of lipid (lipid weight %)
• Elongated, tortuous pathway: increases diffusion length
• Organization into lamellar membrane structures
• Hydrophobic composition: absence of polar lipids and presence of very-long-chain saturated fatty acids
• Correct molar ratio: approximately 1:1:1 of three key lipids: ceramides, cholesterol and free fatty acids
• Unique molecular structures (e.g. acylceramides)

Table 124.2 Factors affecting how stratum corneum lipids mediate barrier function.

in permeability[4]. It follows, then, that the extracellular, lipid-enriched matrix of the stratum corneum comprises not only the structure that limits transdermal delivery of hydrophilic drugs, but also the so-called stratum corneum "reservoir"[5], within which lipid-soluble drugs, such as topical corticosteroids, can accumulate and be slowly released.

Human stratum corneum is typically comprised of about 20 corneocyte cell layers, which differ in their thickness, packing of keratin filaments, filaggrin content, and number of corneodesmosomes, depending on body site. Corneocytes are surrounded by a highly cross-linked, resilient sheath, the cornified envelope, while the cell interior is packed with keratin filaments embedded in a matrix composed mainly of filaggrin and its breakdown products (the latter are also referred to as "natural moisturizing factors"). As noted above, individual corneocytes, in turn, are surrounded by a lipid-enriched extracellular matrix, organized largely into lamellar membranes, which derive from secreted lamellar body precursor lipids (Fig. 124.2). Following secretion, lamellar body contents fuse end-to-end, forming progressively elongated membrane sheets[3], a sequence requiring the action of a battery of lipolytic "processing" enzymes (see below). Although corneocytes play a role both as spacers and as a scaffold for the extracellular matrix, transdermal drug delivery strategies have focused primarily on manipulations of the extracellular lipid milieu[6,7]. Lastly, the existence of aqueous pores within the extracellular matrix[8] not only adds further complexity to the extracellular pathway (see Fig. 124.1), but also provides additional opportunities for novel delivery strategies.

The exceptionally low permeability of normal stratum corneum to water-soluble drugs is the consequence of several characteristics of the lipid-enriched, extracellular matrix (Table 124.2), including its organization into a highly convoluted and tortuous extracellular pathway imposed by geometrically arrayed corneocyte "spacers"[9]. Moreover, not only the paired-bilayer arrangement of extracellular lipids, but also their extreme hydrophobicity and the composition and distribution of the three key species (ceramides, cholesterol and free fatty acids) in a critical (1:1:1) molar ratio are further characteristics that provide for barrier function.

Ceramides account for approximately 50% of the total stratum corneum lipid mass[10,11], and are crucial for the lamellar organization of the stratum corneum barrier[12]. Of the nine ceramide classes, acylceramides or ceramides 1, 4 and 7 (which contain ω-hydroxy-linked, essential fatty acids in an ester linkage) are epidermis-unique compounds, known to be important for the barrier[13]. *Cholesterol*, the second most abundant lipid by weight in the stratum corneum, promotes the intermixing of different lipid species and regulates its "phase" behavior[14]. *Free fatty acids*, which account for 10–15% of stratum corneum lipids, consist predominantly of very-long-chain, saturated species with ≥18 carbon atoms[10]. A decrease in the concentrations of any of these critical lipid species compromises barrier integrity, by altering the molar ratio of the membranes that mediate normal barrier function.

The "domain-mosaic model" advocates a meandering, polar (pore) pathway for water transport through lamellar boundaries within the lipid mosaic[15], adding potential complexity to the already tortuous, extracellular pathway. An alternative model is based upon the presence of lacunar domains embedded within the lipid bilayers[8] (see Fig. 124.1). These lacunae correspond to sites of subjacent corneodesmosome degradation (see Fig. 124.2), and presumably they contain the hydrophobic degradation products of corneodesmosomes[16]. Whereas these lacunae are scattered and discontinuous under basal conditions, following certain types of permeabilization (e.g. occlusion, prolonged hydration, sonophoresis, iontophoresis), they are thought to expand until they interconnect, forming a continuous "pore pathway" (see Fig. 124.1). The pore pathway can revert back to its original, discontinuous state once the permeabilizing stimulus disappears.

Epidermal Lipid Metabolism and the Skin Barrier

Biosynthetic activities

Epidermal differentiation is a vectorial process that is accompanied by dramatic changes in lipid composition, including loss of phospholipids with the emergence of ceramides, cholesterol and free fatty acids in the stratum corneum[11,13] (see Fig. 124.2). Although epidermal lipid synthesis is both highly active and largely autonomous from

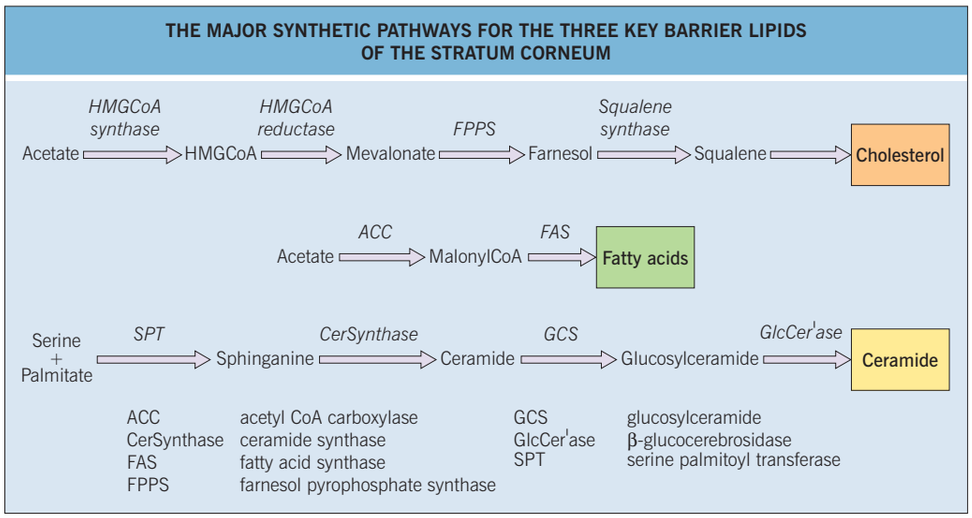

Fig. 124.3 The major synthetic pathways that lead to the generation of the three key barrier lipids of the stratum corneum. The rate-limiting enzymes in each pathway are shown. Applications of specific, conduritol-type inhibitors of β-glucocerebrosidase to intact skin lead to a progressive abnormality in barrier function. In both a transgenic murine model of Gaucher disease (GD) (produced by targeted disruption of the β-glucocerebrosidase gene) and in the severe, type 2 neuronopathic form of GD, infants present with a barrier abnormality. This was attributable to accumulation of glucosylceramides, depletion of ceramides, and persistence of immature lamellar bodies within the interstices of the stratum corneum.

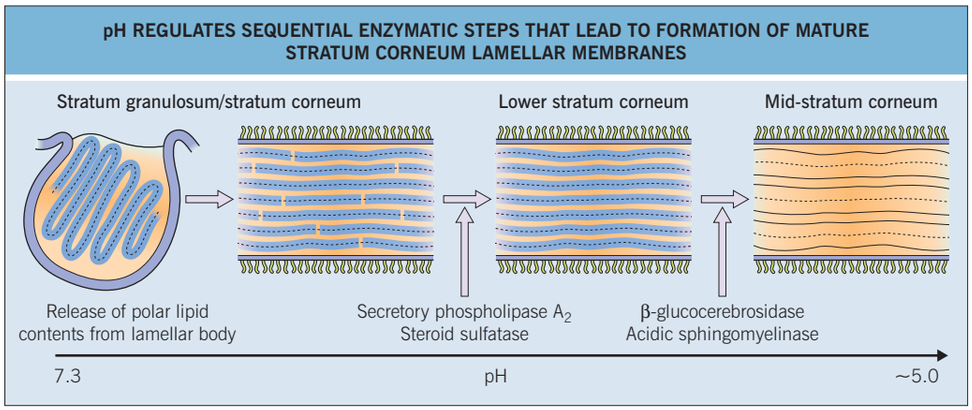

Fig. 124.4 pH regulates sequential enzymatic steps that lead to formation of mature stratum corneum lamellar membranes. The process begins at the stratum granulosum–stratum corneum interface. Of note, in atopic dermatitis, a higher pH is observed.

systemic influences, it can be regulated by external influences, i.e. changes in the status of the permeability barrier[17]. Acute perturbations of the permeability barrier stimulate a characteristic recovery sequence that leads to restoration of normal function over about 72 hours in young skin (the cutaneous stress test). This sequence includes an increase in cholesterol, free fatty acid and ceramide synthesis that is restricted to the underlying epidermis, and attributable to a prior increase in mRNA and enzyme activity/mass for each of the key synthetic enzymes (Fig. 124.3). Furthermore, synthesis of each of the three key lipids is required for normal barrier homeostasis, i.e. topically applied inhibitors of the key enzymes in each pathway produce abnormalities in permeability barrier homeostasis[17].

Lamellar body secretion

The unique two-compartment organization of the stratum corneum is attributable to the secretion of lamellar body-derived lipids and co-localized hydrolases at the stratum granulosum–stratum corneum interface[3]. Under basal conditions, lamellar body secretion is slow, but sufficient to provide for barrier integrity. Following acute barrier disruption, calcium is lost from the outer epidermis, and much of the preformed pool of lamellar bodies in the outermost cells of the stratum granulosum is quickly secreted[18–20]. Calcium is an important regulator of lamellar body secretion, with the high levels of Ca^{2+} in the stratum granulosum restricting lamellar body secretion to low, maintenance levels[21].

Extracellular processing

Extrusion of the polar lipid contents of lamellar bodies at the stratum granulosum–stratum corneum interface is followed by the processing of those lipids into more hydrophobic species that form mature, lamellar membranes[8] (Fig. 124.4). The extracellular processing of glucosylceramides, phospholipids and cholesterol sulfate with accumulation of ceramides, free fatty acids and cholesterol in the stratum corneum is attributable to the co-secretion of a set of hydrolytic enzymes[3] (see Fig 124.2).

Extracellular processing of *glucosylceramides* plays a key role in barrier homeostasis (see legend to Fig. 124.3). In addition, phospholipid hydrolysis, catalyzed by one or more secretory phospholipases (e.g. $sPLA_2$), generates a family of non-essential free fatty acids, which are required for barrier homeostasis[22–24]. Since applications of either bromphenacylbromide or MJ33 (chemically unrelated $sPLA_2$ inhibitors) modulate barrier function in intact skin, $sPLA_2$ appears to play a critical role in barrier homeostasis[22–24]. Moreover, applications of either inhibitor to perturbed skin sites delay barrier recovery.

Sphingomyelin hydrolysis by acidic sphingomyelinase generates two of the nine ceramides required for normal barrier homeostasis (see Fig 124.2). Moreover, patients with mutations in the gene encoding acidic sphingomyelinase (Niemann–Pick, Type A) that lead to low enzyme activity display an ichthyosiform dermatosis, and transgenic mice with an absence of acidic sphingomyelinase also demonstrate a barrier abnormality. Finally, applications of nonspecific inhibitors of acidic sphingomyelinase to perturbed skin sites lead to a delay in barrier recovery[25].

Just as with glucosylceramides and sphingomyelin, *cholesterol sulfate* content increases during epidermal differentiation, and then decreases progressively as the latter is desulfated during passage from the inner to the outer stratum corneum[26]. Both cholesterol sulfate and its processing enzyme, steroid sulfatase, are concentrated in membrane domains of the stratum corneum. Of note, the content of cholesterol sulfate in these sites increases by approximately 10-fold[26] in recessive X-linked ichthyosis (see Ch. 57). Not only is recessive X-linked ichthyosis characterized by a barrier defect[27], but also repeated applications of cholesterol sulfate to intact skin produce a barrier abnormality[28]. In both cases, the barrier abnormality is attributable to cholesterol sulfate-induced phase separation in lamellar membrane domains[27]. But the barrier defect may also be, in part, attributed to a reduction in

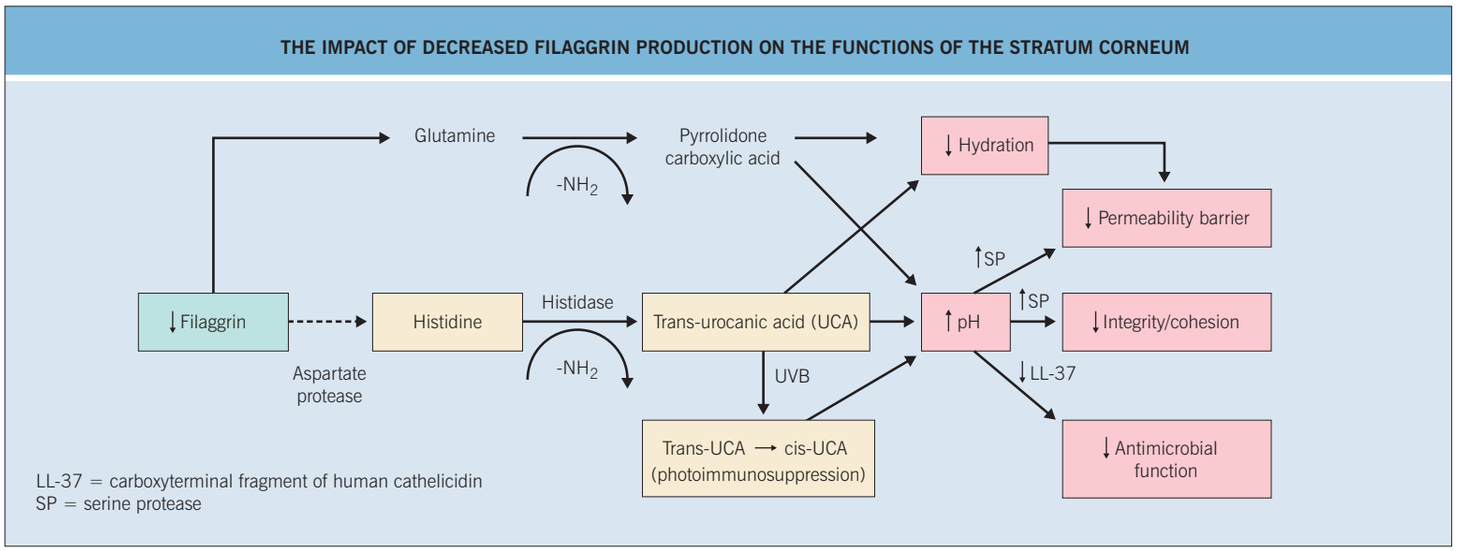

Fig. 124.5 The impact of decreased filaggrin production on the functions of the stratum corneum. UVB, ultraviolet B.

cholesterol content, since cholesterol sulfate is a potent inhibitor of HMG-CoA reductase (see Fig. 124.3).

In addition to lipid precursors and hydrolytic enzymes (e.g. steroid sulfatase, acidic sphingomyelinase), lamellar bodies contain proteases and antiproteases that orchestrate the orderly digestion of corneodesmosomes, allowing corneocyte shedding. These organelles also release antimicrobial peptides, including human β-defensin 2 and LL-37 (the carboxy-terminal fragment of human cathelicidin). As a result, the antimicrobial barrier is intimately linked to the permeability barrier. In atopic dermatitis, for example, there is both an impaired permeability barrier and reduced expression of antimicrobial peptides, explaining in part the predisposition to colonization with *Staphylococcus aureus* (see Table. 12.3). Inherited abnormalities in serine protease/antiprotease expression and filaggrin production are also observed in patients with atopic dermatitis and the impact of reduced filaggrin production on various functions of the stratum corneum is depicted in Figure 124.5.

Acidification

The fact that the stratum corneum displays an acidic external pH ("acid mantle") is well documented, but its origin is not fully understood. Extraepidermal mechanisms (including surface deposits of eccrine- and sebaceous gland-derived products as well as metabolites of microbial metabolism), endogenous catabolic processes (e.g. phospholipid-to-free fatty acid hydrolysis, deamination of histidine to urocanic acid; see Fig. 124.5), and local generation of protons within the lower stratum corneum (by sodium-proton antiporters [NHE_1] inserted into the plasma membrane[29,30]) could actively acidify the extracellular space. These mechanisms would explain not only the pH gradient across the interstices of the stratum corneum (see Fig. 124.4), but also selective acidification of membrane microdomains within the lower stratum corneum.

The concept that acidification is required for permeability barrier homeostasis is supported by the observation that barrier recovery is delayed when acutely perturbed skin sites are immersed in neutral pH buffers[31], or when either the sodium–proton exchanger/antiporter or $sPLA_2$-mediated phospholipid catabolism to free fatty acids is blocked[29]. Acidification appears to impact barrier homeostasis through regulation of enzymes involved in extracellular processing, such as β-glucocerebrosidase and acidic sphingomyelinase, which exhibit acidic pH optima (see Fig. 124.4).

PARAMETERS AFFECTING SKIN PERMEABILITY

As discussed in greater detail in the following sections, the skin is an attractive site for drug delivery[6,7]. However, normal skin provides a significant barrier to drug absorption. Understanding the parameters that affect the permeability of this barrier is essential for achieving successful drug therapy via the skin. While local cutaneous effects are generally achieved by dissolving or suspending the drug in a vehicle that is applied topically as a semi-solid formulation (e.g. cream or ointment)[32], administration of systemic therapy via the skin is typically accomplished through the use of a patch. In either situation, drug is supplied at the surface of the skin for diffusion across the stratum corneum, with the goal of reaching therapeutic targets within the skin and/or systemic uptake via superficial dermal capillaries.

Parameters Controlling Absorption

Conventional transdermal drug delivery is a passive process governed by Fick's law, that is, the rate of absorption or flux (J) of any substance across a barrier is proportional to its concentration difference across that barrier[33,34]. For topically applied drugs, the concentration difference can be simplified as the concentration of drug in the vehicle, C_v, and the proportionality constant relating flux to concentration is the permeability coefficient, K_p (equation 1). K_p is composed of factors that relate to both drug and barrier, as well as their interaction. These factors are: K_m, the partition coefficient; D, the diffusion coefficient; and L, the length of the diffusion pathway (equation 2). Thus, four factors control the kinetics of percutaneous drug absorption (equation 2); however, it is of great practical importance that two of the four (C_v, K_m) are highly dependent on one additional factor, the vehicle.

$$J = K_p C_v \quad (1)$$

$$J = \left(\frac{DK_m}{L}\right) C_v \quad (2)$$

Role of the Vehicle

The vehicle is an important link between drug potency and therapeutic effectiveness, since extensive pharmaceutical research has shown that the composition of the vehicle can profoundly influence the rate and extent of absorption (bioavailability). As illustrated by the potency ranking scale for glucocorticoids[35], the same drug appears in different potency classes when formulated in different vehicles (Table 124.3). It was once axiomatic that ointments were more potent than creams. Though true for the early glucocorticoid products, it is no longer generally applicable. Greater understanding of the science underlying topical formulations has allowed creams, gels, solutions and foams to be specifically formulated equipotent to ointments (see Table 124.3).

In the rational design of dermatologic vehicles that maximize bioavailability, two factors are of critical importance: (1) solubilizing the drug in the vehicle (C_v); and (2) maximizing movement (partitioning) of drug from vehicle to stratum corneum (K_m). The partition

EFFECT OF VEHICLE ON POTENCY	
Corticosteroid*	**Potency class**

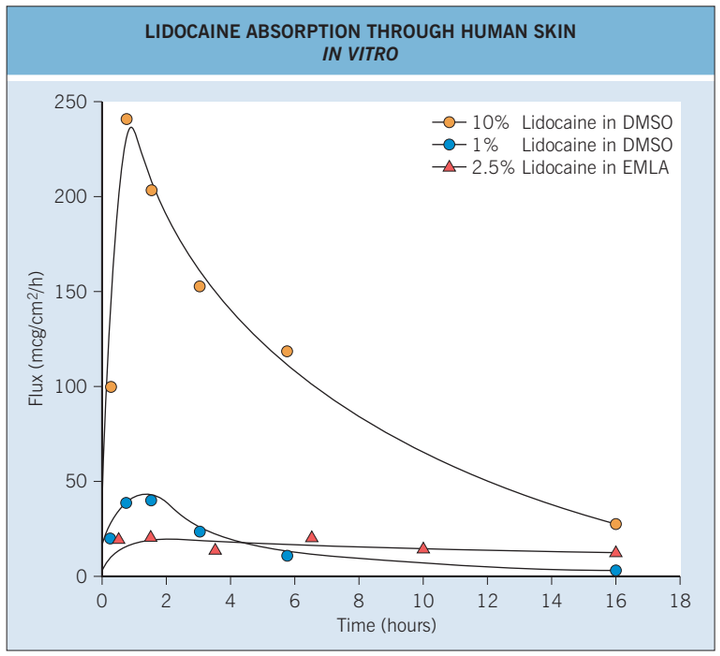

Fig. 124.6 Lidocaine absorption through human skin *in vitro*. Incorporation of DMSO as a co-solvent with ethanol results in both increased drug solubility (C_v) and partitioning (K_m). At 10% drug concentration, the maximum flux is 10-fold greater than that achieved in an emulsion formulation (eutectic mixture of lidocaine 2.5% and prilocaine 2.5% [EMLA]). At 1% drug concentration in DMSO the maximum flux is twofold greater than 2.5% drug in EMLA. *Reproduced from Mallory SB, et al. Topical lidocaine for anesthesia in patients undergoing pulsed dye laser treatment for vascular malformations. Pediatr Dermatol. 1993;10:370–5.*

coefficient describes the ability of a drug to escape from the vehicle and move into the outermost layer of the stratum corneum. It is defined as the equilibrium solubility of drug in the stratum corneum (sc) relative to its solubility in the vehicle ($K_m = C_{sc}/C_v$).

Drug Concentration

The driving force for percutaneous absorption is the concentration of *soluble* drug in the vehicle. Many older topical drug products were marketed with the expectation that higher concentrations were more potent. Although true for some products, e.g. tretinoin gels and creams (0.01–0.1%) in which the drug is completely solubilized at all concentrations, for others it is not. Hydrocortisone 1% and 2.5% in a cream formulation have been shown to be of equal potency, as have triamcinolone acetonide 0.025%, 0.1% and 0.5% creams[35]. One of the major advances in formulating glucocorticoids, as first shown with fluocinonide, came when it was discovered that the addition of propylene glycol to the vehicle could completely solubilize the drug. This led to corticosteroid products with greater potency, as demonstrated in the vasoconstrictor assay. Newer products are now tested during the development process to ensure that increased drug concentration results in increased bioavailability. However, excess non-dissolved drug can sometimes be advantageous, especially in transdermal patches worn for prolonged periods of time (e.g. up to a week). In this situation, as dissolved drug is absorbed into the body, non-dissolved drug can then become dissolved in order to maintain an equilibrium, thereby maintaining a constant dissolved drug concentration over time and providing a constant rate of delivery[36].

Partition Coefficient

In general, topically applied drugs are poorly absorbed because only a small fraction partitions into the stratum corneum. Most of the drug remains on the skin surface, subject to loss from a multitude of factors (exfoliation, sweating, wash-off, rub-off, adsorption onto clothing, and chemical or photochemical degradation). Even 10–12 hours following dosing, a drug that has not been lost by exfoliation or rub-off remains largely on the skin surface, and it is easily removed by a simple soap and water wash[37]. In the case of patches worn for several days, as much as half of the original amount of drug may still be present in the patch when it is removed, and this can pose a safety hazard upon disposal, especially with potentially dangerous drugs such as fentanyl[38].

A number of physical and chemical factors can improve partitioning. Hydration of the skin due to occlusion, either from a topical formulation or a patch, expands the reservoir volume available to drugs within the stratum corneum; this can increase absorption as much as five- to tenfold[39]. Common excipients such as ethanol and propylene glycol can also alter barrier structure so as to increase partitioning[40]. In addition, many excipients have good solvent properties and, as a result, positively affect C_v as well as K_m. The use of high concentrations of propylene glycol to maximize bioavailability has become pervasive among the super- and high-potency corticosteroids, but at a price. Adverse events such as burning and stinging are common when such preparations are applied to fissured or eroded skin, and contact dermatitis may occur.

A number of other compounds have been identified as enhancers. Dimethylsulfoxide (DMSO), the archetypical enhancer, exemplifies the effects that can be achieved (Fig. 124.6). As with ethanol and propylene glycol, both C_v and K_m are affected. Because DMSO is a superb solvent, higher drug concentrations can be achieved than with other solvents, but it also expands the stratum corneum barrier, permitting increased drug uptake and possibly an increased rate of diffusion (D) through the barrier. However, the use of powerful enhancers such as DMSO is constrained by excessive skin irritation or toxicity[41].

Regional Variation

All body sites are not equally permeable[42]. Variations in stratum corneum thickness, the number of sebaceous glands, and hydration status can all affect absorption. Current data and clinical experience suggest that one can crudely rank regional permeability as follows: nail < < palm/sole < trunk/extremities < face/scalp < < scrotum.

STRATEGIES TO ENHANCE TRANSDERMAL DRUG DELIVERY

Despite the significant permeability barrier of the stratum corneum, drug delivery via the skin is a very attractive option and is widely employed for both local and systemic therapy (Table 124.4; Fig. 124.7)[6,7]. Topical treatment of cutaneous disorders obviously targets the site of disease, thereby minimizing adverse side effects elsewhere within the body. Delivery of systemic therapies via the skin avoids degradation of the medication within the gastrointestinal tract and first-pass metabolism by the liver, both of which are associated with oral administration of drugs, in addition to evading the pain and safety issues associated with injections. Transdermal delivery of drugs, especially via long-acting patches, enables infrequent dosing and maintenance of steady-state drug levels.

Many dermatologic medications can be applied topically to the skin because the required dosage is often exceedingly small and therefore they can be effective even in the setting of highly inefficient absorption. In addition, a number of skin disorders are associated with compromised barrier function, which leads to enhanced drug uptake in sites of involvement[43].

In contrast, systemic drug delivery via the skin typically requires administration of larger doses through normal skin. As a result, at the time of writing, only ~20 drugs have been FDA-approved for transdermal administration. The drugs contained within these patches share several characteristics – they are low molecular weight (<400 Da), lipophilic (octanol–water partition coefficient up to 10 000), and relatively low dose (typically <10 mg per day)[44] (Table 124.5).

Significant efforts have been expended on the development of new approaches to enhance transdermal drug delivery and thereby increase the number of drugs administered via this route (Fig. 124.8). These strategies can be broadly subdivided into chemical, biochemical and physical approaches (Table 124.6).

TRANSDERMAL DRUG DELIVERY: THEORETICAL ADVANTAGES
• Improved patient compliance
• Improved efficacy, i.e. continuous release
• Reduced toxicity: (a) no "peaks" and (b) lower total absorbed dose
• Bypass hepatic first-pass metabolism
• Avoid local GI side effects/metabolism
• Decreased dosing frequency
• Avoid painful injections
• Decreased costs to patient due to decreased: (a) total dose and (b) dosing frequency (increased efficiency)

GI, gastrointestinal.

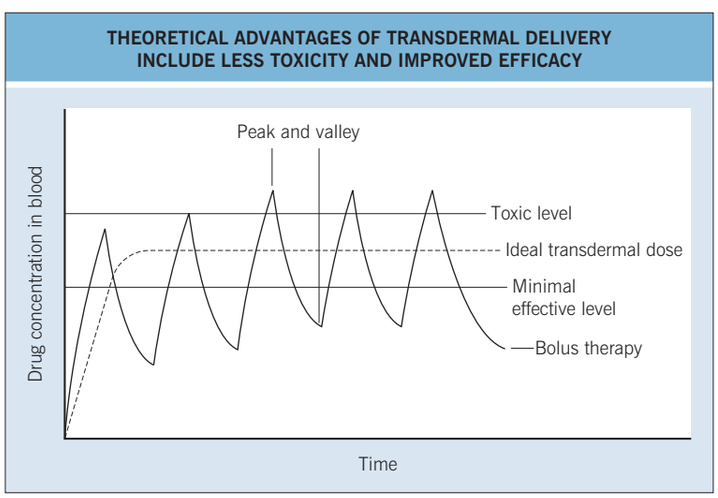

Fig. 124.7 Theoretical advantages of transdermal delivery include less toxicity and improved efficacy. This is due to a reduction in the "peaks" and "valleys" associated with bolus therapy.

Chemical Enhancement

Chemical enhancers include compounds that interact with the lipid matrix of the stratum corneum to alter its nanostructure and thereby increase permeability[7,40]. The major advantages of chemical enhancers are that they are typically low cost, can be incorporated into a conventional patch or topical formulation, and do not require the complexity of a battery-powered device. The primary disadvantage of chemical enhancers is that they are often associated with skin irritation or toxicity when present at high concentrations and with long exposure times[41]. Thus, chemical enhancers have been employed principally to increase permeability to compounds that already cross the skin reasonably well, but they have generally been unable to significantly impact delivery of new classes of molecules (e.g. highly water-soluble drugs) or macromolecules such as proteins, gene-based medicines and vaccines.

The most common chemical enhancer is water, which leads to hydration of the stratum corneum when it accumulates during prolonged occlusion; the occlusion can result from a topical formulation or a patch[39,45]. Following 24–48 hours of occlusion, corneocytes swell, the intercellular spaces become distended, and the lacunar network becomes dilated. Distention of lacunae is thought to eventually lead to connections within an otherwise discontinuous system, creating "pores" in the stratum corneum interstices through which polar and non-polar substances can penetrate more readily (see Fig. 124.1).

Solvents, such as ethanol, methanol, chloroform and acetone, as well as detergents can extract barrier lipids and/or disrupt their bilayer structures, which then permeabilizes the stratum corneum[7,40,41]. Morphologic changes in human stratum corneum following exposure

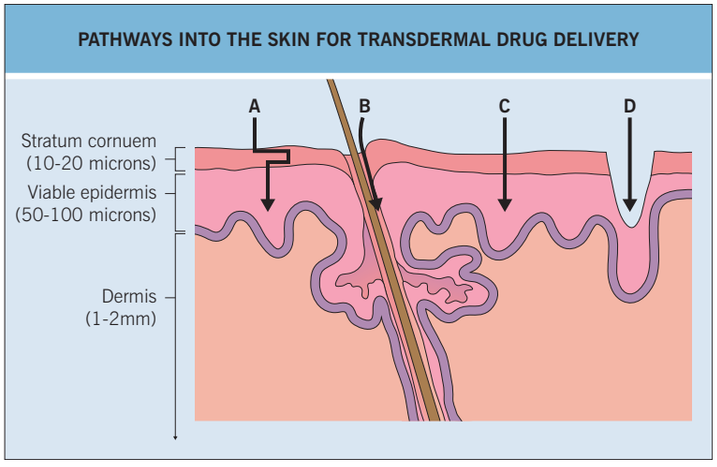

Fig. 124.8 Pathways into the skin for transdermal drug delivery.
A Transdermal transport via a tortuous pathway largely within extracellular lipids. This pathway is utilized during drug absorption in association with chemical, biochemical and some physical enhancers. **B** Transport through hair follicles and sweat ducts can be enhanced by iontophoresis and certain particulate formulations. **C** Transport directly across the stratum corneum is enabled by electroporation. **D** Stripping, ablation, abrasion and microneedles remove stratum corneum to make micron-scale (or larger) pathways into the skin. *Reproduced with permission from Prausnitz MR, et al. Current status and future potential of transdermal drug delivery. Nat Rev Drug Discov. 2004;3:115–24.*

to solvents[46] include phase separation and disruption of lamellar bilayers in addition to the creation of defects in corneocyte membranes (with detergents). Moreover, surfactants, such as sodium dodecyl (lauryl) sulfate, and vehicles (e.g. propylene glycol) extract lipids and create extensive expansion of pre-existing lacunar domains. Furthermore, solvent-based penetration enhancers, such as azone, sulfoxides, urea and free fatty acids, not only extract extracellular lipids, but they also alter stratum corneum lipid organization (phase behavior), thereby increasing transdermal delivery and expanding intercellular domains (Fig. 124.9; see Fig. 124.6). Recent work suggests that combinations of particular chemical enhancers that adhere to specific, narrow-range compositions can be especially effective[47].

Finally, *liposomes* represent yet another "chemical" method frequently employed to enhance delivery into the skin, especially in the case of cosmetics and moisturizers[48]. While intact liposomes probably do not penetrate the stratum corneum[49], they can be used to increase effective drug solubility in a vehicle (C_v) and facilitate partitioning into the skin (K_m).

Biochemical Enhancement

Biochemical methods have been developed to *directly* increase permeability of the stratum corneum lipid matrix as well as to *indirectly* affect skin permeability via alteration of lipid metabolism. Much of the work in this area has focused on peptides that are believed to disrupt or penetrate stratum corneum lipids. For example, polyarginine has been shown to ferry molecules attached to it across the stratum corneum and into the viable epidermis and dermis[50] (Fig. 124.10). Other peptides, identified by phage-display screening, appeared to target transfollicular pathways and did not require the drug to be attached[51]. Magainin, a naturally occurring pore-forming peptide, has been shown to increase skin permeability by direct interaction with and disruption of stratum corneum lipids[52].

In a related strategy, metabolically based approaches aim to enhance the efficacy of standard enhancers by biochemically inhibiting the repair (metabolic) response *in vivo* and thereby delaying barrier recovery[53]. This can be accomplished by altering the critical molar ratio of the three key stratum corneum lipids or by inducing discontinuities in the lamellar bilayer system. Both lipid synthesis inhibitors and agents that interfere with the assembly, secretion or extracellular processing of lamellar bodies have been examined, including brefeldin A, monensin, chloroquine, high Ca^{2+}/K^{+} levels and neutral pH buffers. Overall, biochemical enhancement methods are relatively new and to date they have not been used much in clinical drug delivery.

Physical Enhancement

There are a number of physical methods to increase drug delivery via the skin, many of which require the use of devices and some of which hold the promise to significantly expand the spectrum of drugs that can be administered transdermally to include water-soluble molecules and macromolecules[54,55].

Stripping is a simple technique used in research protocols to remove stratum corneum by sequential application of adhesive tape or cyanoacrylate glue[53,56]. Tape stripping removes both corneocytes and extracellular lipids, thereby reducing the elongated path length that drugs otherwise need to traverse, and it mechanically disrupts lamellar bilayers, even in the retained lower stratum corneum layers. Barrier disruption of human skin requires multiple strippings, which can lead to inflammation. More strippings are required to disrupt the barrier in skin phototypes V and VI (darkly pigmented) than in phototypes I and II (lightly pigmented) subjects[57].

Iontophoresis and electroporation represent electrically assisted, physical approaches to enhance delivery of drugs/macromolecules across the stratum corneum[58]. *Iontophoresis* uses low currents applied

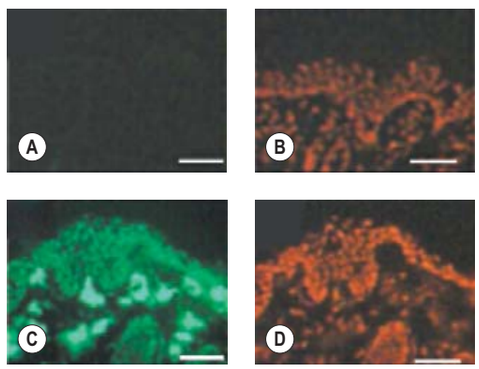

Fig. 124.10 Biochemical enhancement of drug delivery to the skin in mice. **A** Fluorescein does not penetrate intact skin. **C** Fluorescein conjugated to a heptamer of D-arginine penetrates extensively across the stratum corneum and localizes within viable epidermis and dermis. **B,D** Propidium iodide counter-staining shows tissue architecture in the same tissue sections as **A** and **C**. Nat Med. 2000;6:1253–7.*

for minutes to hours from an externally placed electrode (with the same charge as the drug) in order to drive these molecules across the stratum corneum, primarily by electrophoresis[59]. As the rate of drug delivery is generally proportional to the applied current, iontophoresis offers an opportunity for programmable drug delivery, especially with the recent development of miniaturized microprocessor systems. Clinically, iontophoresis has been employed to deliver: fentanyl and lidocaine for pain relief[60], pilocarpine to induce sweating (as a diagnostic test)[61], and tap water to treat hyperhidrosis[62]. Reverse iontophoresis has been used to extract glucose from the skin as a means of monitoring glucose levels in diabetic patients[63].

Electroporation (electropermeabilization) utilizes very short (microsecond to millisecond) and relatively high voltage (~100 V) electrical pulses to induce structural rearrangement of stratum corneum lipids, leading to pore formation[64,65]. Properly designed systems can minimize sensations from the pulses and facilitate delivery, especially of hydrophilic and charged molecules into the skin. Although only at the research stage with regard to transdermal delivery, electroporation is currently being used to drive chemotherapeutic agents into superficial skin tumors by applying surface or penetrating electrodes[66].

While *ultrasound* is widely and safely employed in both medical diagnostics and physical therapy, this technology can also be used to enhance transdermal delivery. When ultrasound is utilized in a manner that resembles medical imaging, it is not very effective at increasing skin permeability. However, ultrasound administered in the context of heating deep tissues, for example during physical therapy, has been shown to increase drug penetration into the skin, and this technique is actually used to increase local delivery of anti-inflammatory agents at the time of physical therapy[67]. With still different settings (in particular low frequencies such as <1 MHz), ultrasound can be used to generate bubble activity, referred to as "*cavitation*". Cavitation bubbles oscillating and imploding in the medium between the ultrasound transducer and the skin surface generate shockwaves that mechanically impact the skin, creating submicroscopic defects in stratum corneum structure. These defects increase skin permeability to water-soluble molecules and some macromolecules[68]. In a related approach, pulsed laser beams have also been used to generate photomechanical shockwaves at the skin surface, which also increase skin permeability[69]. Cavitational ultrasound of the skin has been approved as a pretreatment prior to the application of lidocaine as a means of accelerating local anesthesia.

In addition to the methods described above that disrupt stratum corneum structure on a nanometer scale, there are methods for producing micron-scale holes within the stratum corneum. This enables delivery of much larger molecules with much greater fluxes into the skin. With *thermal ablation*, microsecond- to millisecond-long pulses of heat are applied utilizing electrical filaments, radiofrequency electrodes or lasers which lead to micron-sized holes in the stratum corneum[70,71]. Because the pulses are so short, there is not enough time for heat to propagate deeply into the tissue, thereby localizing the ablation to the epidermis and minimizing pain; these latter effects have been demonstrated in clinical trials. An at least partial removal of the stratum corneum and an increase in skin permeability can also be accomplished via sandpaper abrasion and microdermabrasion[72,73].

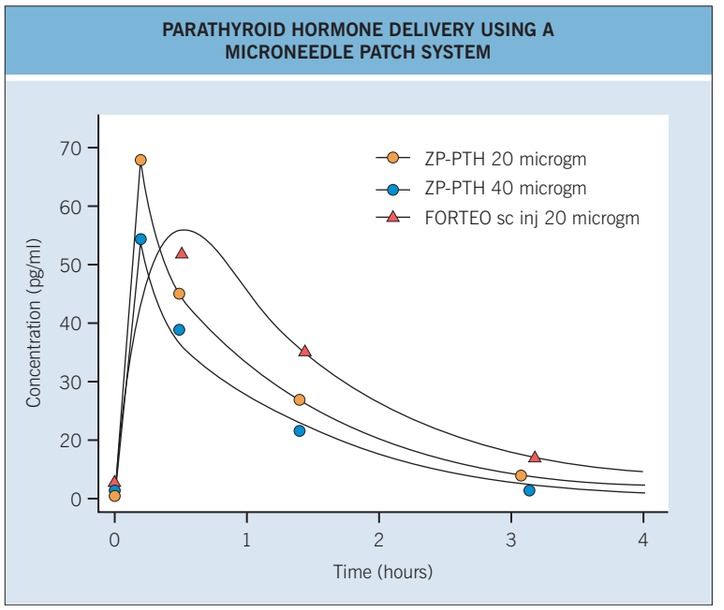

Fig. 124.11 Parathyroid hormone delivery to human subjects using a microneedle patch system. Subcutaneous (sc) injection of synthetic human parathyroid hormone 1-34 (FORTEO) achieved a peak drug concentration (T_{max}) at 23 min, whereas application of a microneedle patch coated with the same drug achieved a T_{max} of 8 min (ZP-PTH). *Reproduced with permission from Daddona PE, et al. Parathyroid hormone (1-34)-coated microneedle patch system: clinical pharmacokinetics and pharmacodynamics for treatment of osteoporosis. Pharm Res. 2011;28:159–65.*

Finally, *microneedles* represent another micron-scale approach to drug delivery via the skin[74]. Microneedles typically measure 0.1–1 mm in length; they can be solid or hollow and are manufactured by microfabrication tools similar to those used in the microelectronics industry. When solid, microneedles can be incorporated into patches that are applied to the skin and possibly worn for some time. In clinical trials, microneedles have been used to punch microscopic holes into the skin prior to the application of drug-loaded patches such as those containing naltrexone[75]. Drug-coated solid microneedles, designed to undergo dissolution upon insertion into the skin, have also been tested, and the efficacy of parathyroid hormone delivered in this manner for the treatment of osteoporosis has been demonstrated[76] (Fig. 124.11).

In contrast to the Mantoux technique, which requires clinical training to ensure an intradermal location for the needle injection[77], hollow microneedles enable simple and reliable intradermal injections. Clinical trials in patients with diabetes have shown accelerated pharmacokinetics of insulin after microneedle injections into the skin, when compared to conventional subcutaneous infusions[78]. Influenza vaccine that is approved for injection into the skin using a microneedle demonstrated increased immunogenicity in the elderly and a lower dose was effective in non-elderly adults[79]. This increased effectiveness of the vaccine is due to the highly immunoresponsive environment in the skin compared to muscle, the conventional site of vaccination.

Glucocorticosteroids 125

Scott M Jackson and Lee T Nesbitt Jr

Key features

- Glucocorticosteroids continue to be among the most commonly prescribed anti-inflammatory agents in dermatology and all of medicine, with a large number of disorders responding to these drugs
- Proper systemic use of glucocorticosteroids requires a working knowledge of the hypothalamic–pituitary–adrenal (HPA) axis
- Proper local (topical and intralesional) use of glucocorticosteroids requires awareness of their various formulations and potencies
- Glucocorticosteroids have a broad range of potential adverse effects that can be minimized by a variety of strategies
- Clinical usage guidelines facilitate proper dosing and administration of glucocorticosteroids for both short-term and long-term therapy

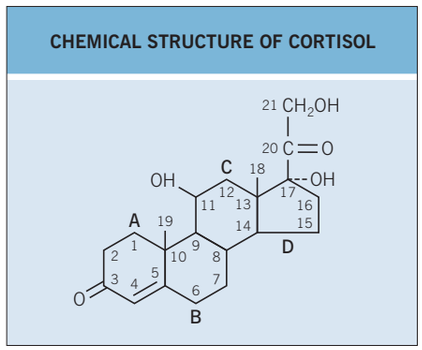

Fig. 125.1 Chemical structure of cortisol (hydrocortisone). Note the hydroxyl group at the 11 position.

INTRODUCTION

The Nobel Prize in Medicine was awarded in 1950 to Hench and associates[1] for their initial work on the beneficial effects and toxicities of glucocorticosteroids (glucocorticoids), which focused on rheumatic disorders. In 1951, Sulzberger and colleagues[2] first reported the use of systemic cortisone and adrenocorticotropic hormone (ACTH) as therapies for inflammatory skin diseases. One year later, Sulzberger and Witten successfully treated eczematous eruptions with topical hydrocortisone. In 1961, Reichling and Kligman[3] employed alternate-day oral glucocorticosteroid therapy for skin conditions. A novel method of high-dose glucocorticosteroid therapy was introduced to dermatology in 1982 by Johnson and Lazarus[4], who used pulse intravenous therapy for pyoderma gangrenosum. During the past 40 years, a variety of other anti-inflammatory/immunomodulatory drugs have been developed, allowing for a "corticosteroid-sparing" effect and minimization of risks from long-term therapy with systemic glucocorticosteroids.

PHARMACOLOGY AND MECHANISM OF ACTION

Structure and Metabolism

All steroids, including glucocorticosteroids, have the basic four-ring structure of cholesterol, with three hexane rings and one pentane ring. Figure 125.1 shows the chemical structure of hydrocortisone (cortisol). Modifications in the basic four-ring structure of glucocorticosteroids result in systemic agents that have different potencies, mineralocorticoid effects, durations of action (biologic half-life), and metabolism. Table 125.1 lists the key pharmacologic properties of the major systemic agents used today. Similar changes in the basic structure of the glucocorticosteroid molecule have resulted in various topical agents with differing solubilities, lipophilic properties, degrees of percutaneous absorption, and glucocorticoid receptor-binding activities.

When examining the chemical structure of glucocorticosteroids, it is important to recognize that active agents such as hydrocortisone (see Fig. 125.1) have a hydroxyl group at the 11 position. The corresponding inactive drug, cortisone, has a ketone group at the 11 position and must undergo hepatic conversion to hydrocortisone for biologic activity. The same is true for prednisone, which must undergo the identical 11-hydroxylation by the liver to produce an active agent, prednisolone. Since conversion of the inactive drug to its active analogue is impaired in patients who have severe hepatic disease, it is best to treat such individuals with a medication such as prednisolone that does not require metabolic alteration to be of therapeutic benefit[5].

In addition to indicating equivalent glucocorticosteroid doses in milligrams, Table 125.1 shows that these agents differ in their relative mineralocorticoid as well as glucocorticosteroid potencies. Cortisone and hydrocortisone have fairly significant mineralocorticoid potency, whereas prednisone and prednisolone have slight mineralocorticoid effects. A drug that has no mineralocorticoid activity, such as methylprednisolone, would be an excellent choice in situations in which mineralocorticoid effects must be avoided[5].

Plasma half-lives of the various systemic glucocorticosteroids vary from about 1 to 5 hours, as seen in Table 125.1. However, the plasma half-life is a poor indicator of the duration of action (biologic activity) of each drug. Duration of biologic effect is best assessed by the period of suppression of ACTH secretion by the pituitary gland after the administration of a single dose of a particular glucocorticosteroid. As seen in Table 125.1, short-acting glucocorticosteroids have an effect for 8–12 hours, intermediate-acting agents for 24–36 hours, and long-acting agents for more than 48 hours. Duration of biologic activity is a critical factor in choosing a glucocorticosteroid for alternate-day therapy. Intermediate-acting agents should be used for this purpose, with long-acting agents avoided because there would be no period for recovery of the hypothalamic–pituitary–adrenal (HPA) axis (see below)[5].

Absorption and Distribution

Oral glucocorticosteroids are absorbed in the jejunum, with peak plasma levels occurring 30–90 minutes after intake. Administration of these drugs with food may delay absorption but does not decrease the amount absorbed.

Once glucocorticosteroids reach the plasma, the primary carrier protein is corticosteroid-binding globulin (CBG), also known as transcortin. Most endogenous cortisol is bound to CBG, and low doses of exogenous glucocorticosteroids are initially primarily bound by this high-affinity, but low-capacity, carrier system. With larger glucocorticosteroid doses, some binding also occurs to albumin in a low-affinity fashion, but with a greater capacity because of the larger amount of albumin in the plasma. The avidity with which exogenous glucocorticosteroids bind to these two carrier proteins is less than that of endogenous cortisol. As exogenous glucocorticosteroids fill CBG binding

PHARMACOLOGY OF SYSTEMIC GLUCOCORTICOSTEROIDS					
	Equivalent GCS *dose* (mg)	GCS *potency* (relative)	Mineralocorticoid potency (relative)	Duration of action (hours)*	Plasma half-life (minutes)
SHORT-ACTING					
Cortisone	25	0.8	1.0	8–12	60
Hydrocortisone	20	1	0.8	8–12	90
INTERMEDIATE-ACTING					
Prednisone	5	4	0.25	24–36	60
Prednisolone	5	4	0.25	24–36	200
Methylprednisolone	4	5	0	24–36	180
Triamcinolone	4	5	0	24–36	300
LONG-ACTING					
Dexamethasone	0.75	25–30	0	36–54	200
Betamethasone	0.6	30–35	0	36–54	200

*Differs for intramuscular administration (see text).

Table 125.1 Pharmacology of systemic glucocorticosteroids (GCSs).

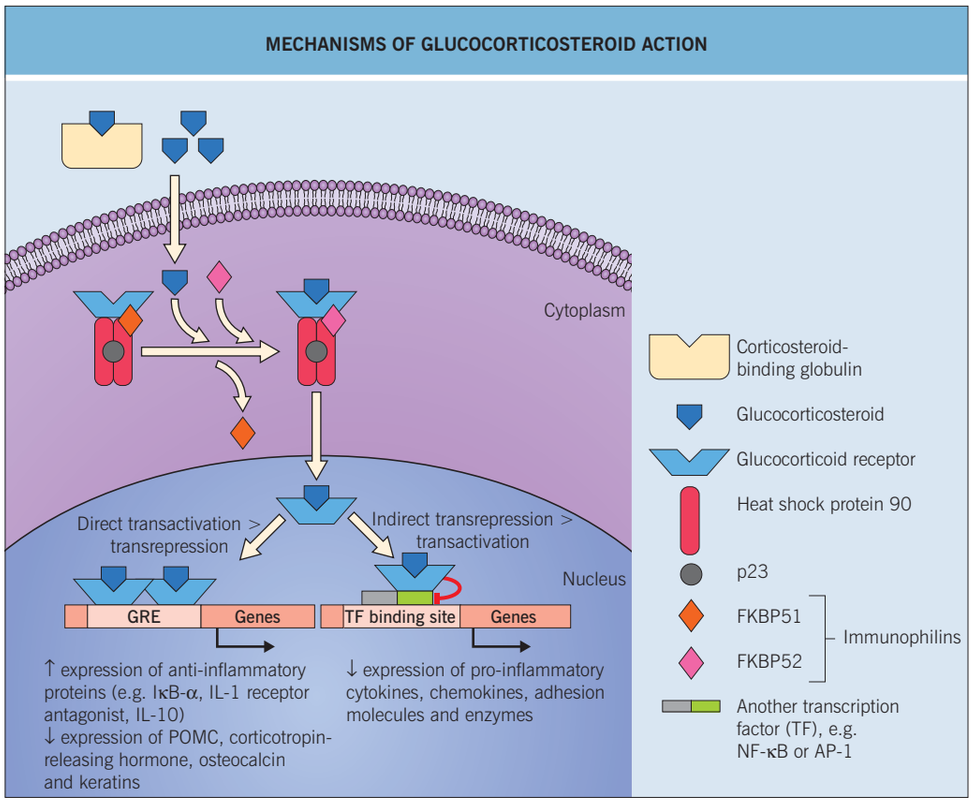

Fig. 125.2 Mechanisms of glucocorticosteroid action. "Free" glucocorticosteroid enters the cell and binds to the glucocorticoid receptor (which forms a complex that includes the 90 kDa heat shock protein and an immunophilin, FK506-binding protein 51 [FKBP51]) in the cytoplasm. After glucocorticosteroid binding, FKBP52 replaces FKBP51 and facilitates nuclear translocation. In the nucleus, ligand-bound glucocorticoid receptor homodimers directly bind to glucocorticoid response elements (GREs) in the promoter regions of target genes, which leads to activation or (less often) repression of transcription. Glucocorticoid receptor monomers can also indirectly affect gene expression by interacting with and inhibiting other transcription factors such as nuclear factor-κB (NF-κB) or activator protein 1 (AP-1), resulting in decreased transcription of proinflammatory genes. IL, interleukin; IκB-α, inhibitor κB-α; POMC, proopiomelanocortin.

sites, increased low-affinity binding to albumin leads to a greater fraction of free (unbound) glucocorticosteroid. The free fraction is biologically active, entering cells and mediating glucocorticosteroid effects[5]. Disorders that result in decreased binding proteins in the plasma, such as hepatic or renal disease, increase the free fraction of exogenous glucocorticosteroids and thereby augment the therapeutic effects and toxicities of these drugs.

The Hypothalamic–Pituitary–Adrenal (HPA) Axis

A working knowledge of the normal function of the HPA axis is required to understand glucocorticosteroid physiology. The hypothalamus produces corticotropin-releasing hormone, which is released in small pulses into the pituitary circulation. The anterior pituitary responds to corticotropin-releasing hormone with synthesis of ACTH and its subsequent pulsatile secretion into the peripheral circulation. ACTH is the hormone that stimulates the middle layer of the adrenal cortex to generate and release cortisol. In an individual with a normal sleep cycle, the greatest amount of cortisol is released during the early morning hours prior to waking. Under basal conditions, the adrenals produce approximately 20–30 mg of cortisol (equivalent to 5–7.5 mg of prednisone) per day in an adult, but this may increase up to 10-fold under times of maximal stress. ACTH also has some role in stimulating adrenal androgen production, but it is not significantly involved in the production of the major mineralocorticoid, aldosterone. The major mineralocorticoid control mechanisms are the renin–angiotensin system and serum potassium levels.

There are three main control mechanisms for endogenous cortisol secretion[6]. The first is a negative feedback effect by plasma cortisol, which inhibits the secretion of corticotropin-releasing hormone and ACTH by the hypothalamus and pituitary, respectively. The second method of regulation is the pulsatile secretion of ACTH, which is based on a circadian cycle, with increasing pulses beginning several hours

ANTI-INFLAMMATORY EFFECTS OF GLUCOCORTICOSTEROIDS
DECREASED PRODUCTION OF CYTOKINES AND OTHER PRO-INFLAMMATORY MOLECULES
• Tumor necrosis factor-α • Granulocyte–macrophage colony-stimulating factor • Interleukin (IL)-1, IL-2, IL-6 and IL-8 • Intercellular adhesion molecule (ICAM)-1, E-selectin • Leukotrienes and prostaglandins (due to decreased phospholipase A_2 and cyclooxygenase activity)
EFFECTS ON INFLAMMATORY CELLS
• **Neutrophils** – Increased release from the bone marrow, resulting in neutrophilia (due to larger circulating pool) – Decreased infiltration into sites of inflammation (due to reduced expression of endothelial adhesion molecules and chemoattractants) – Decreased apoptosis – Phagocytosis and bactericidal function less affected • **Lymphocytes** – Redistribution of T cells to lymphoid depots, resulting in transient lymphopenia – Decreased activation and proliferation of effector (helper > cytotoxic) T cells (related to decreased IL-2 signaling and antigen presentation) – Decreased B-cell function and antibody production (at high doses) – Increased apoptosis – Increased regulatory T-cell function • **Eosinophils** – Decreased release from bone marrow and recruitment to sites of inflammation – Increased apoptosis • **Monocytes/macrophages** – Decreased production, differentiation and antigen presentation • **Mast cells** – Decreased maturation, cytokine production, high-affinity IgE receptor (FcεRI) expression and mediator release • **Erythrocytes** – Decreased destruction (due to reduced autohemolysis and erythrophagocytosis)

Table 125.2 Anti-inflammatory effects of glucocorticosteroids.

MAJOR USES OF SYSTEMIC GLUCOCORTICOSTEROIDS IN DERMATOLOGY
SEVERE DERMATITIS
• Contact dermatitis (various forms) • Atopic dermatitis • Photodermatitis • Exfoliative erythrodermas
BULLOUS DERMATOSES
• Pemphigus (all forms) • Bullous pemphigoid • Mucous membrane (cicatricial) pemphigoid • Linear IgA bullous dermatosis • Epidermolysis bullosa acquisita • Gestational pemphigoid • Erythema multiforme (major)
VASCULITIS
• Cutaneous (various types) • Systemic (various types)
AUTOIMMUNE CONNECTIVE TISSUE DISEASES
• Lupus erythematosus • Dermatomyositis • Systemic sclerosis • Morphea (severe generalized and linear variants) • Eosinophilic fasciitis • Mixed connective tissue disease • Relapsing polychondritis
NEUTROPHILIC DERMATOSES
• Pyoderma gangrenosum • Sweet's syndrome (acute febrile neutrophilic dermatosis) • Behçet's disease
OTHER DISORDERS
• Sarcoidosis • Lichen planus • Panniculitis (some types) • Urticaria/angioedema (acutely) • Drug reaction with eosinophilia and systemic symptoms (DRESS) • Arthropod bites/stings • Infantile hemangiomas

Table 125.3 Major uses of systemic glucocorticosteroids in dermatology.

after the onset of sleep and reaching a maximum shortly before waking. From these ACTH pulses, the peak release of cortisol in a typical sleep cycle is at about 6–8 a.m. With other sleep cycles, the circadian pattern will adjust so that peak cortisol levels occur just prior to waking. The third form of control of endogenous cortisol production comes from neural effects on the HPA axis in response to various emotional or physical stresses. These neural stimuli include catecholamine production from the brainstem, corticotropin-releasing hormone from sites other than the hypothalamus, and vasopressin.

Molecular Mechanisms

As depicted in Figure 125.2, the glucocorticosteroid free (unbound) fraction enters cells and exerts its effects by binding to the glucocorticoid receptor, which is located in the cytoplasm of almost all cells of the body in a protein complex that includes the 90 kDa heat shock protein[7]. Binding of glucocorticosteroids to this receptor leads to their translocation into the nucleus and eventual release from the protein complex. In the nucleus, the glucocorticoid receptor forms a dimer that binds to glucocorticoid response elements in the promoter region of certain genes (see Fig. 125.2). Approximately 10–100 genes in each cell are regulated directly by glucocorticosteroids[8]. This binding affects the rate of transcription, inducing or (less often) repressing messenger RNA production and protein synthesis.

The glucocorticoid receptor also interacts with other transcription factors (see Fig. 125.2) that have a central role in the inflammatory response as well as their coactivator molecules, such as cAMP response element binding protein (CREB)-binding protein. Nuclear factor-κB (NF-κB) is an important transcription factor that induces the expression of many genes that play a significant role in chronic inflammation, encoding various cytokines, adhesion molecules, inflammatory enzymes, and growth factors. By indirectly and directly inhibiting NF-κB, the glucocorticoid receptor can dramatically reduce the inflammatory process[8]. The glucocorticoid receptor also has an inhibitory effect on activator protein 1 (AP-1; a collective term for the heterodimeric transcription factor composed of proteins such as c-jun, c-fos and activating transcription factor), which likewise controls expression of growth factor and cytokine genes. The key cytokines and other proinflammatory molecules that are inhibited by glucocorticosteroids and the effects of these drugs on inflammatory cells are summarized in Table 125.2[9,10].

CLINICAL INDICATIONS, DOSAGES AND CONTRAINDICATIONS

Table 125.3 lists major categories of dermatologic disease in which systemic glucocorticosteroids are used. There are many more skin conditions for which topical and intralesional glucocorticosteroids can be helpful, such as papulosquamous disorders and other localized inflammatory processes.

Oral Therapy

Dermatologists use glucocorticosteroids for short periods to treat acute conditions such as extensive allergic contact dermatitis and other acute eczematous disorders. Therapy is considered as short-term if it is administered for approximately 3 weeks or less. An oral agent with an intermediate duration of action, such as prednisone, is usually given in a single early-morning dose to achieve the least HPA axis suppression[11]. In some severe acute dermatoses, the dose can be divided and administered twice (or occasionally up to four times) daily for better initial

control, but conversion to a single early-morning dose should occur as soon as possible. Split-dose therapy results in parallel increases in efficacy and toxicity. Despite the same total number of milligrams, the split dose may simply be considered to represent the equivalent of a slightly higher single morning dose. The daily dose of prednisone can vary depending on the severity of the dermatosis, but for most moderate, self-limited conditions in average-weight adults, a common initial dose is 40–60 mg/day (corresponding to approximately 1 mg/kg/day in children).

Long-term therapy is usually defined as that lasting 4 weeks or more, but it often refers to treatment lasting for months to years[5]. In these situations, corticosteroid-sparing agents are usually added in an attempt to reduce the glucocorticosteroid dose required to control the disease process, or to eliminate the glucocorticosteroid altogether.

Prednisone is often the intermediate-acting glucocorticosteroid of choice for both short-term and long-term therapy. It is inexpensive and available in many dosage forms[6].

Methylprednisolone can be used if there is a need to eliminate all mineralocorticoid effects. Intermediate-acting drugs such as prednisone and methylprednisolone are also utilized for alternate-morning therapy (a common component of tapering regimens; see below), which allows the HPA axis to recover in the last 12 hours of the off-day of therapy. Other advantages of alternate-morning glucocorticosteroid therapy are listed in Table 125.4. Two important side effects of long-term glucocorticosteroid therapy that are not minimized by alternate-morning dosing are osteoporosis and cataracts (see below).

Although it may help to prevent a disease rebound, tapering of the glucocorticosteroid dose is not usually necessary from an adrenal recovery standpoint in short-term therapy. However, tapering to allow adrenal recovery is an important consideration when treatment is for longer than a few weeks. Manifestations of the glucocorticosteroid withdrawal syndrome include arthralgias, myalgias, mood changes, fatigue, headache, and gastrointestinal symptoms (e.g. nausea, vomiting, anorexia)[12]. When this syndrome occurs, a return to the previous dose of glucocorticosteroid, followed by more gradual tapering, is recommended. In general, the rate of prednisone tapering depends on both features of the dermatosis (e.g. type, activity, severity) and adrenal recovery issues. The prednisone dose can usually be tapered in 20 mg increments at doses greater than 60 mg/day, 10 mg increments between 30 and 60 mg/day, and 5 mg increments between 30 mg and the physiologic dose range. Once the physiologic dose range of 5–7.5 mg/day of prednisone is reached, a more gradual reduction (e.g. in 1–2.5 mg increments) may be necessary to allow adrenal recovery.

Another method of glucocorticosteroid dosage tapering is to convert from daily to alternate-day therapy once the prednisone dose is about 20–30 mg/day[5]. The simplest way to convert is to multiply the previous daily dose by 2–2.5 times for the on-day dose, and taper therapy rapidly on the off-day. An alternative method is to increase the on-day dose by 5 mg increments and decrease the off-day dose by a similar amount, until therapy is eventually doubled on the on-day and stopped on the off-day. Finally, simultaneous tapering and alternate-morning conversion can be accomplished by decreasing the dose by 5 mg on the alternate morning, with the patient eventually taking the same dose every other morning as they were taking daily.

ALTERNATE-MORNING GLUCOCORTICOSTEROID THERAPY
• "Off" days allow recovery of hypothalamic–pituitary–adrenal (HPA) axis
• Decreases risks of:
– Growth suppression
– Myopathy
– Hypertension
– Opportunistic infections
– Neuropsychiatric effects*
– Electrolyte imbalances (e.g. hypokalemia, hypocalcemia)
• Does *not* substantially alter risks of osteoporosis or cataracts
• Fluctuations in glucose levels can make diabetes mellitus more difficult to manage
*Except occasional worsening of bipolar behavior.

Table 125.4 Alternate-morning glucocorticosteroid therapy.

Intramuscular Therapy

Dermatologists occasionally use intramuscular administration of glucocorticosteroids for control of acute dermatoses[13]. Although some acute dermatoses respond very well to intramuscular glucocorticosteroid therapy, serious conditions such as pemphigus vulgaris or severe drug reactions are best treated by other routes of systemic administration because of the initial need for higher daily doses and the requirement for more control over dosage changes. Advantages of intramuscular glucocorticosteroid therapy include guaranteed compliance due to physician administration and an assured steady release of glucocorticosteroids achieved by depot preparations. Opponents of intramuscular therapy stress that oral morning doses are more physiologic, are absorbed more predictably, allow more precise tapering, and can be administered on alternate-morning schedules to further decrease HPA axis suppression. There also is the possibility of lipoatrophy or a sterile abscess at an injection site, especially with triamcinolone if the injection is not given deeply enough into the muscle. Intramuscular agents such as betamethasone and dexamethasone, which have a duration of action of less than 1 week, may be preferred in self-limited dermatoses. Longer-acting intramuscular agents that produce effects for about 3 weeks, such as triamcinolone acetonide and methylprednisolone acetate, should not be given more than about four to six times per year. The physician might be lulled into thinking that therapy is intermittent and relatively safe, while in fact it is continuous for ≥3 weeks per injection, necessitating time for HPA axis recovery.

Intravenous and Pulse Therapy

Intravenous doses of glucocorticosteroids may be necessary in life-threatening dermatologic conditions. A total daily dose of 2 mg/kg or more of methylprednisolone is given initially in divided doses every 6–8 hours in these acute and critical situations. Another method of dosing glucocorticosteroids in severe dermatologic disease is intravenous pulse therapy[14]. With this method, methylprednisolone is given intravenously in doses of 0.5–1 g over 2 hours daily for 1–5 days. This therapy was formerly given in an inpatient setting with cardiac monitoring because arrhythmias and rare cases of sudden death are possible if this treatment is given too quickly. Acute electrolyte shifts are a possible cause for these cardiac effects, so infusion of potassium during the methylprednisolone administration may prevent this problem. In addition, slow infusion of the methylprednisolone over 2 hours usually prevents cardiac effects and has allowed use of this therapy in an outpatient setting. Most commonly, oral doses are continued on a maintenance basis after pulse therapy is given. Pulse therapy allows for a dramatic acute effect in severe dermatoses, but hopes that it would greatly reduce the need or dose of maintenance therapy have not been realized.

Topical Therapy

For topical glucocorticosteroid therapy, there are many different medications available in a wide range of potencies and a variety of vehicles[15]. Topical glucocorticosteroids can be categorized into seven classes based on potency, ranging from the superpotent agents in class 1 to the very low potency agents in class 7. These classes have been developed based on vasoconstrictor assays and double-blind clinical studies[16]. A partial list of topical preparations in each class is shown in Table 125.5. The vehicle can greatly influence the percutaneous absorption and therapeutic efficacy of a particular glucocorticosteroid. In some instances, brand-name and generic formulations may have different potencies. As a result, in the era of generic substitutions and limited formularies, the clinician needs to consider these points, as well as non-compliance, as potential explanations for an unresponsive dermatosis.

In general, a glucocorticosteroid molecule in an ointment vehicle is more potent than the same molecule in a cream or lotion base, because occlusive vehicles enhance percutaneous absorption through increased hydration of the stratum corneum. Gel preparations also tend to be readily absorbed. In selecting a topical glucocorticosteroid preparation for clinical use, one must first choose the desired potency based on the type, location, thickness and extent of lesions. Next, one must select the proper vehicle based on the need for hydration or a drying effect,

POTENCY RANKING OF SOME COMMONLY USED TOPICAL GLUCOCORTICOSTEROIDS
CLASS 1 (SUPERPOTENT)
• Clobetasol propionate gel, ointment, cream, lotion, foam, spray and shampoo 0.05% • Betamethasone dipropionate gel* and ointment* 0.05% • Diflorasone diacetate ointment* 0.05% • Fluocinonide cream 0.1% • Flurandrenolide tape 4 mcg/cm^2 • Halobetasol propionate ointment and cream 0.05%
CLASS 2 (HIGH POTENCY)
• Amcinonide ointment 0.1% • Betamethasone dipropionate cream*, lotion*, gel and ointment 0.05% • Clobetasol propionate solution ("scalp application") 0.05% • Desoximetasone ointment and cream 0.25% and gel 0.05% • Diflorasone diacetate ointment and cream* 0.05% • Fluocinonide gel, ointment, cream and solution 0.05% • Halcinonide ointment, cream and solution 0.1% • Mometasone furoate ointment 0.1% • Triamcinolone acetonide ointment 0.5%
CLASS 3 (HIGH POTENCY)
• Amcinonide cream and lotion 0.1% • Betamethasone dipropionate cream and lotion 0.05% • Betamethasone valerate ointment 0.1% • Diflorasone diacetate cream 0.05% • Fluticasone propionate ointment 0.005% • Triamcinolone acetonide ointment 0.1% and cream 0.5%
CLASS 4 (MEDIUM POTENCY)
• Betamethasone valerate foam 0.12% • Desoximetasone cream 0.05% • Fluocinolone acetonide ointment 0.025% • Flurandrenolide ointment 0.05% • Hydrocortisone valerate ointment 0.2% • Mometasone furoate cream and lotion 0.1% • Triamcinolone acetonide ointment (Kenalog®) and cream 0.1% or spray 0.2%
CLASS 5 (MEDIUM POTENCY)
• Betamethasone dipropionate lotion 0.05% • Betamethasone valerate cream and lotion 0.1% • Clocortolone pivalate cream 0.1% • Fluocinolone acetonide cream 0.025% or oil and shampoo 0.01% • Fluticasone propionate cream and lotion 0.05% • Flurandrenolide cream and lotion 0.05% • Hydrocortisone butyrate ointment, cream and lotion 0.1% • Hydrocortisone probutate cream 0.1% • Hydrocortisone valerate cream 0.2% • Prednicarbate ointment and cream 0.1% • Triamcinolone acetonide ointment 0.025% and lotion 0.1%
CLASS 6 (LOW POTENCY)
• Alclometasone dipropionate ointment and cream 0.05% • Triamcinolone acetonide cream 0.1% (Aristocort®) • Betamethasone valerate lotion 0.1% • Desonide gel, ointment, cream, lotion and foam 0.05% • Fluocinolone acetonide cream and solution 0.01% • Triamcinolone acetonide cream and lotion 0.025%
CLASS 7 (LOW POTENCY)
• Topicals with hydrocortisone, dexamethasone and prednisolone

OPHTHALMIC GLUCOCORTICOSTEROIDS
MAXIMUM STRENGTH
• Loteprednol suspension 0.5% • Prednisolone suspension and solution 1% • Rimexolone suspension 1%
MODERATE STRENGTH
• Fluorometholone ointment 0.1% and suspension 0.1% or 0.25% • Loteprednol suspension 0.2% • Prednisolone suspension and solution 0.125%
LOWER STRENGTH
• Betamethasone solution 0.1%* • Dexamethasone ointment 0.05%, suspension and solution 0.1% • Difluprednate emulsion 0.05% • Medrysone suspension 1%
*Not available in the US.

Table 125.6 Ophthalmic glucocorticosteroids.

location on the body, and potential for irritation or sensitization by components of the vehicle. Lotions are elegant for the face, creams rub in well, ointments are beneficial for dry lesions, and gels or foams are more useful in hairy areas or for a drying effect. For the face and body folds, high potency and superpotent glucocorticosteroid preparations should be avoided if possible due to the risks of epidermal atrophy in both locations and steroid rosacea/perioral dermatitis on the face. There is some evidence that pulse dosing (i.e. twice daily on the weekends only) may reduce the risk of epidermal atrophy with more potent corticosteroids. Other than decreasing the potency or the frequency of application, it is not certain that any modification reduces the risk of cutaneous atrophy or perioral dermatitis/steroid rosacea.

Innovative topical glucocorticosteroids such as mometasone furoate and fluticasone propionate have low percutaneous absorption and are rapidly metabolized in the liver, minimizing their systemic bioavailability[17]. The latter agent is highly lipophilic and has high affinity for the glucocorticoid receptor without significant binding to androgen, progesterone, estrogen or mineralocorticoid receptors.

Commonly prescribed ophthalmologic glucocorticosteroid preparations are listed in Table 125.6.

Intralesional Therapy

For many localized disorders, especially when topical therapy is not beneficial and systemic therapy is best avoided, intralesional glucocorticosteroid therapy can be very effective. With this method, triamcinolone acetonide is diluted to the desired concentration (which depends on the condition to be treated) and injected in small amounts into the lesion(s), usually with a 30-gauge needle. With thick dermal lesions such as keloids, concentrations as high as 20–40 mg/ml of triamcinolone may be injected, as the desired result is to decrease the excessive connective tissue. However, with other disorders, atrophy of the dermis or fat can occur as a side effect, and a more dilute concentration (as low as 2 mg/ml of triamcinolone acetonide) should be used. The ideal concentration varies depending on the type of lesion to be treated and its location. This method of administration allows the clinician to bypass the barrier of a thickened stratum corneum and/or to treat a dermal inflammatory process (e.g. sarcoidosis, granuloma annulare) directly with higher concentrations of corticosteroid at the site of the pathology, reducing the possibility of epidermal atrophy.

Contraindications

Finally, one must always consider contraindications to glucocorticosteroid therapy, whether it be systemic or local[6]. Herpes simplex keratitis is considered a contraindication to local glucocorticosteroid therapy of the eye. Also, active tuberculosis and systemic fungal infections are usually considered as contraindications to systemic glucocorticosteroid therapy. Previous history of hypersensitivity to an intravenous preparation, which is rare, should preclude further use of that particular intravenous drug. Many other situations, such as active peptic ulcer disease, severe depression or psychosis, and extensive chronic dermatoses (e.g. psoriasis) likely to flare with a rebound after rapid corticosteroid taper, should be relative contraindications to systemic glucocorticosteroid therapy, with these agents used only when necessary.

MAJOR SIDE EFFECTS

Short-term glucocorticosteroid therapy is usually extremely safe for self-limited and acute dermatoses. When side effects do occur with short courses of therapy, those listed in Table 125.7 are most common. With long-term glucocorticosteroid therapy at supraphysiologic doses, there is an increased incidence of more serious effects. Table 125.8 lists the major categories of complications and major adverse effects in each category. Most of these side effects are dose-related. As shown in Table 125.9, some patients have a higher risk of side effects from glucocorticosteroids[6]. The following discussion highlights selected toxicities of glucocorticosteroid therapy.

Osteoporosis

Osteoporosis is one of the most prevalent side effects in patients receiving long-term systemic glucocorticosteroid therapy. Without preventative measures, osteoporosis develops in 30–50% of all patients treated chronically with glucocorticosteroids[18]. The most significant demineralization occurs during the first 6–12 months of therapy, with slowing after this time. Postmenopausal women are most at risk for complications such as fractures, because they have the lowest bone mass before beginning therapy. The greatest amount of bone loss is usually observed in young men, because they have the highest pretreatment bone mass. The development of osteopenia and osteoporosis is not avoided by alternate-morning treatment schedules.

Trabecular bone, which is present in the axial skeleton (vertebrae, ribs), has a metabolic turnover rate eight times that of cortical bone (long bones), making trabecular bone much more prone to demineralization[19]. Although many patients with osteoporosis have no symptoms, more advanced disease can produce bone pain, fractures and vertebral collapse. The mechanism of glucocorticosteroid-induced bone loss includes both reduced intestinal absorption of calcium and decreased renal tubular resorption of calcium. A diet high in sodium may increase calcium loss even further. Decreased serum calcium results in parathyroid hormone release and produces a form of secondary hyperparathyroidism, stimulating osteoclast activity and resulting in bone resorption. Inhibition of osteoblasts in bone and collagen matrix synthesis also occurs through several mechanisms.

Although routine radiographs can detect vertebral compression fractures, these plain X-ray studies are not sensitive enough to detect osteoporosis until 20–60% of bone mass is lost (Fig. 125.3). Currently, the best measurement of osteoporosis is quantification of bone mineral density with dual-energy X-ray absorptiometry (DEXA), which is preferred because of its sensitivity, reproducibility and low radiation exposure. Ideally, patients on long-term glucocorticosteroids should have a baseline DEXA examination of the hip and lumbar spine, with a repeat study performed at least annually at the same sites (due to variability in density among different sites). In densitometry reports, T scores are used to connote a standard deviation from the mean of a healthy control population. Osteopenia is defined as a T score between –1 and –2.5 standard deviations below the mean, with a T score less than –2.5 defining osteoporosis[18]. For patients beginning long-term glucocorticosteroid therapy, risk factors for decreased bone density should be assessed and guidelines for the prevention and treatment of osteoporosis followed (Fig. 125.4)[20,21]. Endocrinologic consultation should be obtained in patients who develop significant osteopenia or osteoporosis. Further information on recommended regimens for osteoporosis prevention and treatment in patients receiving long-term glucocorticosteroid therapy is provided in Figure 125.4.

In general, experts agree that postmenopausal women, men over 50–65 years of age, and patients with a history of low-impact fractures should begin concomitant bisphosphonate therapy when started on long-term glucocorticosteroid treatment. Since the largest reduction in bone mass occurs during the first 6 months of glucocorticosteroid therapy, it is important to initiate this and other preventative measures promptly[20]. Alendronate or risedronate are first-line oral agents. They should be taken on an empty stomach, only with water, upon arising in the morning; patients should not lie flat for 1 hour after administration. Although generally well tolerated, gastrointestinal side effects can occur and, if severe, may necessitate changing to a different agent. Intravenous bisphosphonates such as pamidronate 30 mg IV every 3 months or zoledronate 4–5 mg IV once yearly are alternatives. Osteonecrosis of the jaw represents an occasional complication of bisphosphonate therapy, occurring most often with intravenous administration (especially in patients with an underlying malignancy such as multiple myeloma). Several case reports and small series have described atypical fractures of the subtrochanteric or diaphyseal femur in patients receiving long-term bisphosphonate therapy, but the larger studies performed to date have failed to confirm this association. All

SIDE EFFECTS OF SHORT-TERM SYSTEMIC GLUCOCORTICOSTEROID THERAPY
• Mood changes, anxiety insomnia
• Gastrointestinal intolerance (e.g. nausea, vomiting)
• Hyperglycemia
• Fluid/sodium retention
• Increased appetite, weight gain
• Acneiform eruptions
• Increased infections
• Amenorrhea
• Muscular weakness, muscle effects
• Wound healing effects

Table 125.7 Side effects of short-term systemic glucocorticosteroid therapy.

MAJOR SIDE EFFECTS OF LONG-TERM SYSTEMIC GLUCOCORTICOSTEROID THERAPY	
MUSCULOSKELETAL	**GYNECOLOGIC, OBSTETRIC**
Osteoporosis	Amenorrhea
Osteonecrosis (e.g. hip)	Fetal effects
Growth retardation	**HEMATOLOGIC, CELLULAR**
Muscle atrophy	Leukocytosis
Myopathy	Lymphopenia
OPHTHALMOLOGIC	Eosinopenia
Cataracts	Immunosuppression
Glaucoma	Impaired fibroplasia
Infection	Decreased mitotic rate
Hemorrhage	Infections
Exophthalmos	**NERVOUS SYSTEM**
GASTROINTESTINAL	Mood, personality changes
Nausea, vomiting	Psychiatric problems, psychosis
Gastroesophageal reflux	Seizures
Peptic ulcer disease	Pseudotumor cerebri
Intestinal perforation	Peripheral neuropathy
Pancreatitis	Epidural lipomatosis
Esophagitis (reflux or candidal)	**CUTANEOUS**
METABOLIC	Atrophy, striae, telangiectasias
Hyperglycemia	Vascular fragility, purpura
Hyperlipidemia	Acne, acneiform eruptions
Obesity	Hirsutism
Hypocalcemia	Infections
Hypokalemic alkalosis	**HYPOTHALAMIC–PITUITARY–ADRENAL (HPA) AXIS**
CARDIOVASCULAR	Suppression
Hypertension	Withdrawal syndrome
Peripheral edema	Adrenal crisis
Atherosclerosis	

Table 125.8 Major side effects of long-term systemic glucocorticosteroid therapy.

PATIENTS AT HIGHER RISK FOR TOXICITY FROM GLUCOCORTICOSTEROID THERAPY	
Patient group	**Concerns**
Female patients	• Slower metabolism/clearance of GCSs due to estrogen • Lower baseline bone density • Often given a higher dose per kg when not adjusted based on weight
Postmenopausal women, elderly patients	• Increased risk of osteoporosis, especially if limited physical activity
Pediatric patients	• Temporary retardation of growth • Increased likelihood of striae distensae in adolescents
Patients with SLE, (dermato)myositis or rheumatoid arthritis	• Long-term use associated with a higher risk of aseptic necrosis of bone, muscle atrophy and osteoporosis, respectively
Patients with hepatic disease (e.g. secondary to alcoholism)	• Decreased metabolism of GCSs and lipids, leading to high serum triglyceride levels
Patients with hypoalbuminemia	• Increased free fraction of GCSs results in greater side effects
Patients who smoke and/or have high alcohol intake	• Increased risk of osteoporosis and peptic ulcer disease

Table 125.9 Patients at higher risk for toxicity from glucocorticosteroid (GCS) therapy. SLE, systemic lupus erythematosus.

Fig. 125.3 Radiograph of the spine showing severe demineralization. This is indicative of advanced osteoporosis.

bisphosphonates, especially those with long half-lives (e.g. ibandronate), should be avoided in premenopausal women who might become pregnant, as these agents cross the placenta and produce teratogenicity, including fetal skeletal abnormalities. Although not as effective as bisphosphonates, intranasal calcitonin (200 IU daily) is a second-line agent when bisphosphonates are not tolerated or are contraindicated.

Hormonal therapy in women was once considered a treatment of choice for management of postmenopausal osteoporosis, and it is effective, as demonstrated by the Women's Health Initiative (WHI) study[22]. Unfortunately, the WHI also revealed increased breast cancer, stroke, thromboembolism and myocardial infarction in women on estrogen–progesterone hormonal therapy, with these risks outweighing the benefits of osteoporosis prevention. It is as yet unclear if low-dose estrogen without progesterone has the same risk profile. Raloxifene, a selective estrogen receptor modulator (SERM), is not as effective as estrogen in preventing osteoporosis but has beneficial effects in breast cancer prevention and treatment, making it a consideration for preventing bone loss in some women on long-term glucocorticosteroids. In men with low testosterone levels who are on long-term glucocorticosteroid therapy, testosterone replacement (250 mg intramuscularly once monthly) can be considered if there are no contraindications (e.g. a history of prostate or breast cancer, severe prostatic hyperplasia).

In patients who have a T score less than –2.5, a history of osteoporotic fractures, or previously failed bisphosphonates and other osteoporosis management, treatment with teriparatide, a fragmented portion of human parathyroid hormone (PTH), can be considered. The cost of teriparatide is a limiting factor, and it should not be used in combination with bisphosphonates, which may inhibit the effectiveness of teriparatide. Recently, denosumab, a monoclonal antibody directed against RANKL (receptor activator of NF-κB ligand), was approved for the treatment of osteoporosis in postmenopausal women who are at high risk for osteoporotic fractures or have failed other therapies. Activation of osteoclast maturation via the binding of this ligand (RANKL) to the RANK receptor on osteoclasts is interrupted by denosumab. Potential side effects include hypocalcemia, dermatitis, osteonecrosis of the jaw and an increased risk of infections.

Osteonecrosis

Osteonecrosis (also known as aseptic necrosis or avascular necrosis) has numerous causes, and it occasionally occurs as a complication of glucocorticosteroid treatment[23]. Co-risk factors include physical trauma, alcohol abuse, cigarette smoking and elevated serum triglycerides. The incidence of glucocorticosteroid-related osteonecrosis is higher in renal transplant recipients and patients with systemic lupus erythematosus (SLE), altered lipid metabolism, fatty degeneration of the liver or alcoholism.

Localized bone pain during activity is the usual initial symptom of osteonecrosis, with the pain eventually occurring at rest and requiring analgesics for relief. The proximal femur is the most common site, although the distal femur or humeral head may be affected. Most patients who develop osteonecrosis while on glucocorticosteroids have been treated for at least 6–12 months, paralleling the time needed to induce changes in bone marrow fat deposition.

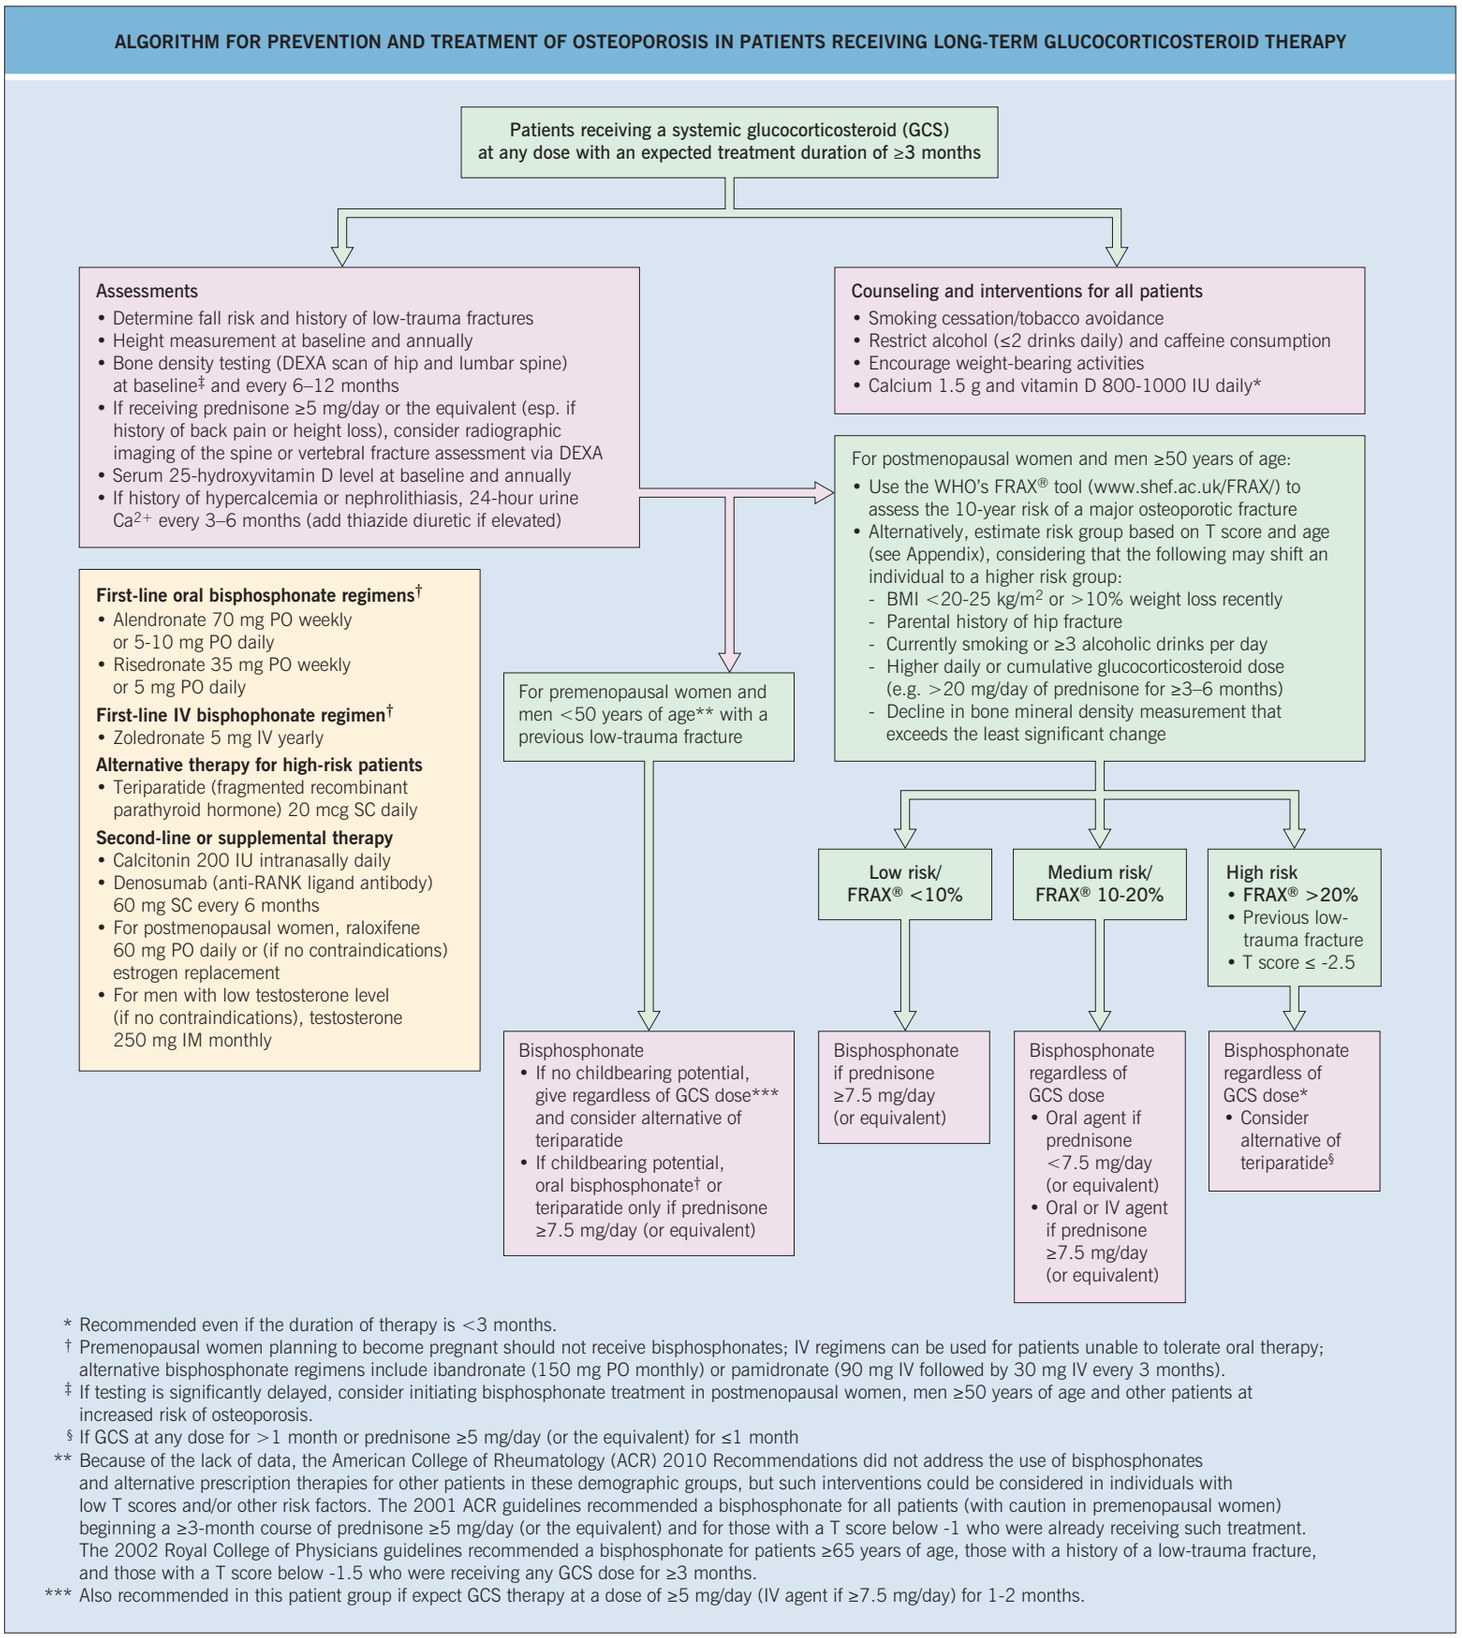
The mechanism of this condition is not completely understood, although intraosseous hypertension secondary to fat cell enlargement may compromise terminal arterioles at certain sites. Some investigators believe that fat emboli can originate from fatty deposits in the liver or from serum triglycerides, whereas others believe that only bone-derived fat emboli produce arterial occlusion with subsequent infarction.

Signs of osteonecrosis may not be evident on standard X-rays for as long as 6 months after bone pain begins (Fig. 125.5). Therefore, early MRI, the most specific and sensitive radiologic examination, is recommended for confirmation of diagnosis (Fig. 125.6). Initial medical treatment is conservative and consists of trauma prevention, rest, and modified weight bearing with the use of crutches[23]. More advanced cases in young patients may require hip salvaging procedures such as core decompression to reduce intraosseous pressure, vascularized fibular grafting, or electric stimulation. Eventual total joint arthroplasty is often unavoidable.

Growth Retardation

The doses of systemic glucocorticosteroids required to produce growth suppression are not much larger than physiologic doses. Alternate-morning therapy can minimize this effect but does not eliminate it completely[24]. Glucocorticosteroid therapy via inhalants or extensive, chronic use of topical agents may also rarely produce growth suppression. Once the glucocorticosteroid therapy is discontinued, there is often a compensatory growth spurt with normal development of height, except if chronic glucocorticosteroid therapy is given during the two major spurts of childhood – prior to age 2 years and at puberty. If glucocorticosteroids are given just before puberty, the usual compensatory growth may be negated by epiphyseal closure.

Glucocorticosteroids produce growth retardation by many mechanisms, including interference with nitrogen and mineral retention, inhibition of collagen and protein matrix synthesis, and a decreased effect of growth hormone[24]. Growth monitoring should be done every 3–6 months, and growth hormone therapy might be considered in certain situations to restore linear growth and reverse other catabolic effects.



* Recommended even if the duration of therapy is <3 months.
† Premenopausal women planning to become pregnant should not receive bisphosphonates; IV regimens can be used for patients unable to tolerate oral therapy; alternative bisphosphonate regimens include ibandronate (150 mg PO monthly) or pamidronate (90 mg IV followed by 30 mg IV every 3 months).
‡ If testing is significantly delayed, consider initiating bisphosphonate treatment in postmenopausal women, men ≥50 years of age and other patients at increased risk of osteoporosis.
§ If GCS at any dose for >1 month or prednisone ≥5 mg/day (or the equivalent) for ≤1 month
** Because of the lack of data, the American College of Rheumatology (ACR) 2010 Recommendations did not address the use of bisphosphonates and alternative prescription therapies for other patients in these demographic groups, but such interventions could be considered in individuals with low T scores and/or other risk factors. The 2001 ACR guidelines recommended a bisphosphonate for all patients (with caution in premenopausal women) beginning a ≥3-month course of prednisone ≥5 mg/day (or the equivalent) and for those with a T score below -1 who were already receiving such treatment. The 2002 Royal College of Physicians guidelines recommended a bisphosphonate for patients ≥65 years of age, those with a history of a low-trauma fracture, and those with a T score below -1.5 who were receiving any GCS dose for ≥3 months.
*** Also recommended in this patient group if expect GCS therapy at a dose of ≥5 mg/day (IV agent if ≥7.5 mg/day) for 1-2 months.

Fig. 125.4 Algorithm for prevention and treatment of osteoporosis in patients receiving long-term glucocorticosteroid therapy. Based on the American College of Rheumatology 2010 recommendations[20]. Androgen-deprivation therapy in men and medical conditions such as hyperthyroidism, hyperparathyroidism and (especially in women) rheumatoid arthritis represent additional risk factors for osteoporosis. BMI, body mass index; DEXA, dual-energy X-ray absorptiometry.

Myopathy

Myopathy is an uncommon complication of glucocorticosteroid therapy. The classic (chronic) form presents as painless, symmetrical proximal muscle weakness, most often of the lower extremities. It typically begins many weeks to months after systemic therapy is initiated, usually in patients treated with doses equivalent to >40 mg/day of prednisone. Although possibly more common with fluorinated glucocorticosteroids (e.g. dexamethasone, betamethasone, triamcinolone), the condition can occur with any agent[25]. Alternate-morning therapy might decrease its incidence. Diagnosis of myopathy may be difficult, as serum muscle enzyme levels and electromyographic studies tend to be normal. Muscle biopsy findings are relatively nonspecific, with

Fig. 125.5 Radiograph of the head of the femur, which fails to demonstrate early stages of osteonecrosis.

Fig. 125.6 MRI study of the head of the femur demonstrating osteonecrosis (arrows). (Same patient as in Fig. 125.5.)

FEATURES THAT DISTINGUISH GLUCOCORTICOSTEROID-RELATED MYOPATHY FROM MYOSITIS

Feature	Glucocorticosteroid-related myopathy	Myositis
Clinical setting	• More likely with a high GCS dose • Improves when the GCS dose is decreased	• Less likely with a high GCS dose • Worsens when the GCS dose is decreased
Clinical presentation	• Weakness, usually without myalgias	• Weakness, often associated with myalgias
Laboratory findings	• Normal serum creatine kinase • Elevated urine creatine, which decreases as the GCS dose is decreased	• Elevated serum creatine kinase • Elevated urine creatine, which increases as the GCS dose is decreased
EMG findings	• Normal	• Abnormal
MRI findings	• Signs of muscle atrophy	• Signs of muscle inflammation/edema
Muscle biopsy findings	• Atrophy	• Inflammation and necrosis

Table 125.10 Features that distinguish glucocorticosteroid (GCS)-related myopathy from myositis. EMG, electromyography; MRI, magnetic resonance imaging.

Fig. 125.7 A 12–year-old girl treated intermittently with systemic glucocorticosteroids for severe atopic dermatitis. Note lens opacity of the left eye, due to development of a cataract.

variable muscle fiber diameters and atrophy of type II fibers but no substantial inflammation or necrosis. Increased urinary creatine excretion can be a clue to the diagnosis. Gradual reduction of the glucocorticosteroid dose along with physical therapy is useful in managing this complication, although muscle function may not return to normal for many months.

When treating inflammatory muscle diseases such as dermatomyositis, glucocorticosteroids are vital for controlling the disorder but may actually increase the tendency for muscle atrophy. Corticosteroid-sparing agents are often utilized after initial control with glucocorticosteroids, especially if glucocorticosteroid tapering is not occurring at an acceptable rate[5] (see Ch. 42). Findings that help to distinguish glucocorticosteroid-related myopathy from myositis are presented in Table 125.10.

Cataracts

The cumulative dosage and duration of therapy are the most important factors in the development of posterior subcapsular cataracts in patients receiving systemic glucocorticosteroid therapy. This adverse effect has been noted in patients receiving as little as 10 mg/day of prednisone for 1 year. Cataract development is not reduced by alternate-morning schedules, although patients on continuous therapy are at higher risk than those receiving intermittent treatment. While there may be some individual susceptibility factors, children are at greatest risk, developing cataracts with lower doses and shorter treatment durations compared to adults. Cataracts that occur as a manifestation of the disease process in atopic dermatitis are usually anterior plaques in the papillary zone, but cataracts may occur in a posterior location and be indistinguishable from those associated with glucocorticosteroids (Fig. 125.7).

Ophthalmologic examinations are recommended every 6–12 months for patients on long-term systemic glucocorticosteroid therapy. Progression of cataracts can still occur despite decreasing or discontinuing glucocorticosteroid therapy, but discontinuing the glucocorticosteroids may occasionally deter further cataract formation or reverse lens opacification[26].

Metabolic Effects

Glucocorticosteroids produce hyperglycemia by affecting glucose metabolism through enhanced hepatic gluconeogenesis and decreased peripheral insulin-mediated glucose uptake. Relative insulin resistance is produced by decreasing the affinity of cellular receptors for insulin.

Although worsening of pre-existing or subclinical glucose intolerance is common, new-onset diabetes mellitus usually occurs only with high-dose therapy, and ketoacidosis is rare. Most patients will revert to their prior glucose status within a few months of discontinuing glucocorticosteroid therapy. Blood glucose levels should be assessed periodically during high-dose or long-term glucocorticosteroid therapy. Diabetic patients require closer monitoring, and they may need to be switched from oral antidiabetic agents to insulin or (because glucocorticosteroids induce relative insulin resistance) given higher insulin doses. Alternate-morning glucocorticosteroid schedules are usually not possible in diabetic patients because of the resulting fluctuations in insulin requirements.

Hyperlipidemia is a common side effect of glucocorticosteroid therapy, especially in patients with prior lipid abnormalities. Elevation of triglycerides is most frequently observed, but elevations of high- or low-density lipoproteins occur in some patients. The mechanism of hypertriglyceridemia is likely related to relative insulin insufficiency. A diet low in saturated fat and calories should be instituted in patients on long-term glucocorticosteroids.

Other metabolic effects from glucocorticosteroids include weight gain with central redistribution of fat (including the classic "buffalo hump" and "moon facies"), hypokalemic alkalosis (associated with high-dose therapy, especially with agents that have a substantial mineralocorticoid effect), and the uncommon development of hypocalcemia (a rare cause of tetany in children on high-dose therapy). Potassium supplementation may be necessary, and adequate calcium intake is mandatory.

Cardiovascular Effects

Although the majority of patients with endogenous glucocorticosteroid excess (Cushing's syndrome) have hypertension, administration of exogenous glucocorticosteroids produces hypertension in only about 20% of patients, because of the lower mineralocorticoid effect of these agents. Glucocorticosteroid therapy-associated hypertension is more common in patients with pre-existing hypertension or decreased renal function, in the elderly, and when glucocorticosteroids with greater mineralocorticoid activity are used[27]. Because glucocorticosteroids rarely affect blood pressure during the first 2 weeks of therapy, short courses of glucocorticosteroids in hypertensive patients almost never produce problems. When such patients receive long-term therapy, sodium restriction is important along with the possible institution of a thiazide diuretic. Alternate-morning therapy may reduce blood pressure elevation. The pathogenesis of glucocorticosteroid-induced hypertension is not totally understood, but it is likely related to vasoconstriction (from potentiation of catecholamines and inhibition of vasodilators), sodium retention (related to mineralocorticoid activity), and intravascular volume expansion.

Certain patients, including those with SLE, rheumatoid arthritis and renal transplants, have a tendency to develop accelerated atherosclerosis with long-term systemic glucocorticosteroid therapy. This adverse effect has also been observed in children treated with glucocorticosteroids, and it has long been noted in patients with Cushing's syndrome from chronic endogenous glucocorticosteroid excess. Instances of thromboembolic complications and atrioventricular conduction problems have also been reported with glucocorticosteroid therapy.

Gastrointestinal Effects

The relationship between glucocorticosteroid therapy and peptic ulcer disease (PUD) is controversial, with varying results in different published case series. There does seem to be an increased incidence of PUD in patients (such as those with rheumatoid arthritis) treated concomitantly with glucocorticosteroids and nonsteroidal anti-inflammatory drugs or aspirin[28]. Other additive risk factors include smoking, alcohol use, and a history of PUD. When PUD occurs in patients receiving glucocorticosteroids, it is more likely to be gastric than duodenal, with milder pain symptoms and a greater chance of a major complication such as hemorrhage or perforation. This is related to the tendency of glucocorticosteroids to mask signs and symptoms of inflammation and to inhibit wound healing. A possible mechanism of ulceration in these situations is decreased mucus production and mucosal cell renewal. The administration of oral glucocorticosteroids with food, as well as the use of H_2 receptor antagonists or proton pump inhibitors in higher-risk settings, decreases the likelihood of PUD in patients on glucocorticosteroids.

Other gastrointestinal side effects of glucocorticosteroids include nausea, vomiting and symptoms of gastroesophageal reflux (also minimized by administering with food and/or taking acid-suppressing medications); candidal esophagitis (especially in patients with an erosive oral mucosal disease such as pemphigus vulgaris), which requires treatment with oral antifungals (e.g. fluconazole); pancreatitis in patients with hypertriglyceridemia; fatty liver changes; and (rarely) intestinal perforation.

Infection

Patients receiving glucocorticosteroids have an increased susceptibility to many bacterial, viral, fungal and parasitic infections. Cutaneous staphylococcal and superficial fungal infections are extremely common. Fever and signs of inflammation may be masked in patients taking glucocorticosteroids, making early recognition of infection difficult. Alternate-morning therapy and doses equivalent to less than 10 mg/day of prednisone reduce the chance of opportunistic infection.

Reactivation of tuberculosis has long been a concern in patients on chronic glucocorticosteroid therapy, but this risk may be less than previously believed. A tuberculosis history should be taken and, if negative or uncertain, a tuberculin skin test or interferon-γ release assay performed prior to beginning therapy. A baseline chest radiograph should be obtained for patients with a positive tuberculin reaction (defined as ≥5 mm of induration in individuals receiving the equivalent of ≥15 mg/day of prednisone for a month or more) or interferon-γ release assay, a history of tuberculosis, or other risk factors (e.g. pre-existing immunosuppression). A 9-month course of isoniazid is recommended for those with an untreated latent tuberculosis infection.

An increased risk of *Pneumocystis jiroveci (carinii)* pneumonia has been observed in certain patient groups receiving systemic glucocorticosteroid therapy for longer than 2 months[29]. Susceptible individuals include those with systemic inflammatory disorders such as Wegener's granulomatosis or SLE, especially if they are receiving additional immunosuppressive agents and/or have comorbid medical conditions (e.g. pre-existing pulmonary disease, lymphopenia)[30]. Trimethoprim–sulfamethoxazole (TMP-SMX; typically one double-strength tablet three times weekly) can be used for prophylaxis in high-risk patients[31]. While HIV-positive patients with $CD4^+$ counts <200/ml routinely receive daily TMP-SMX prophylaxis, it should also be considered in HIV-positive individuals with $CD4^+$ counts >200/ml who are receiving systemic glucocorticosteroid therapy.

Patients receiving chronic glucocorticosteroid therapy at supraphysiologic doses may have inadequate antibody responses to immunizations. Live-virus vaccines (see Table 128.9) should not be given to children or adults during or (if treated for ≥2 weeks) within a month after discontinuing glucocorticosteroid therapy at a dose equivalent to ≥20 mg/day of prednisone (≥2 mg/kg/day in children weighing <10 kg)[32]. An increase in complications associated with naturally acquired varicella has also been reported in patients taking systemic glucocorticosteroids.

Obstetric and Gynecologic Effects

An increased incidence of cleft palate has been noted in rodents exposed to very large doses of glucocorticosteroids early in gestation; therefore, the safety of glucocorticosteroids during the first trimester of pregnancy has been debated. However, clinical experience and several clinical trials have shown minimal effects in the offspring of women treated with glucocorticosteroids during pregnancy[33]. Only small amounts of prednisone reach the fetus of a pregnant patient in an active form, because a placental enzyme, 11-hydroxysteroid dehydrogenase type 2, inactivates most prednisolone crossing into the fetal circulation. This enzyme has a limited ability to metabolize fluorinated glucocorticosteroids (e.g. betamethasone and dexamethasone), so greater amounts of these agents reach the fetus. Pregnant patients on glucocorticosteroids do have a slightly increased risk of both hypertension, which might account indirectly for smaller fetal gestational size, and gestational glucose intolerance, which is relatively common on moderate to high glucocorticosteroid doses. When large glucocorticosteroid doses are used near the time of delivery, fetal HPA axis suppression may occasionally occur, producing a pseudo-addisonian neonate. Even though glucocorticosteroids are excreted into breast milk, the American Academy of

Pediatrics has determined that prednisone therapy is compatible with breastfeeding; if possible, nursing should be delayed for approximately 4 hours after prednisone administration.

In non-pregnant women, amenorrhea may occur from systemic therapy with glucocorticosteroids, most frequently with intramuscular injections. To prevent unnecessary concern, premenopausal women receiving systemic glucocorticosteroids should be alerted to this possibility. Decreased sperm counts have also been reported in men receiving systemic glucocorticosteroids.

Nervous System Effects

Mood changes, anxiety and insomnia are common dose-related side effects of glucocorticosteroids. Patients with a prior history of personality disorders are at a greater risk for glucocorticosteroid-related neuropsychiatric symptoms. Depression and fatigue are not uncommon during the tapering phase of glucocorticosteroid therapy.

Psychosis is an uncommon side effect that is dose-related and occurs more commonly in patients with a previous history of major psychiatric disease. When psychosis develops in patients with SLE on glucocorticosteroids, it may be difficult to determine if the psychosis is due to the underlying disease or the glucocorticosteroid. If glucocorticosteroid doses are reduced, steroid psychosis should improve, whereas lupus encephalopathy would be expected to worsen or remain the same.

Pseudotumor cerebri is a possible complication of high-dose or long-term glucocorticosteroid therapy and presents with headache, nausea, vomiting, visual changes and papilledema. It typically develops after rapid tapering or discontinuation of the glucocorticosteroid, so returning to a higher dose followed by more gradual tapering is recommended. Although the condition is reversible, there is potential for visual loss.

Seizures occur uncommonly, primarily affecting seizure-prone patients on high glucocorticosteroid doses. Other infrequent neurologic complications include electroencephalographic changes, enhancement of tremor, peripheral neuropathy and epidural lipomatosis. In treating neuropsychiatric complications, consultation with a psychiatrist or neurologist may be necessary and pharmacologic therapy with neuroleptics is sometimes needed. Tricyclic antidepressants may worsen symptoms and are best used under the recommendation of a specialist. Alternate-morning glucocorticosteroid therapy may be beneficial, but bipolar behavior has occasionally been noted to worsen with this schedule.

Cutaneous Effects

A host of cutaneous effects can occur in patients on systemic and topical glucocorticosteroids, many of which are similar to those associated with endogenous Cushing's syndrome. These include purpura, telangiectasias, atrophy, striae (Fig. 125.8), pseudoscars, acneiform or rosacea-like eruptions, and facial plethora. Localized development of telangiectasias, atrophy (Figs 125.9 & 125.10) and hypopigmentation (see Ch. 66) can result from topical (typically with chronic daily application of potent agents or use under occlusion) and intralesional glucocorticosteroid therapy; with intralesional administration, these findings occasionally occur in a linear pattern along pathways of lymphatic drainage.

Systemic glucocorticosteroid-induced acne or folliculitis characteristically presents with monomorphic papulopustules on the chest (Fig. 125.11) and back. Acne vulgaris itself is also frequently worsened by continuous glucocorticosteroid therapy, although inflammatory and cystic acne lesions may be temporarily improved by very short intermittent courses of systemic glucocorticosteroids, or by intralesional injections of cysts (see Ch. 36). An acneiform or rosacea-like perioral or periorbital eruption can also occur secondary to use of inhaled glucocorticosteroids or application of topical glucocorticosteroids (especially more potent agents) to the face (Fig. 125.12). Topical tacrolimus or pimecrolimus may be helpful in treating perioral dermatitis/steroid rosacea (see Ch. 37), although these agents have also been reported to exacerbate rosacea.

Other cutaneous effects from systemic glucocorticosteroids include acanthosis nigricans and telogen effluvium of scalp hair. Hirsutism and increased vellus hair growth can develop on other areas of the body.

Topical and systemic glucocorticosteroid therapy may impair wound healing by inhibiting fibroblast function and collagen production. Angiogenesis, production of the extrafibrillar matrix ("ground substance"), and re-epithelialization of wounds are also inhibited[5]. Some authors have advocated using vitamin C to improve wound healing in glucocorticosteroid-treated patients.

GLUCOCORTICOSTEROID THERAPY: DOSING AND SIDE-EFFECT CONSIDERATIONS RELATED TO DRUG INTERACTONS AND MEDICAL CONDITIONS	
Increased dose of GCS required	Induction of cytochrome P450 metabolism* (particularly CYP3A4; see Table 131.8) • Phenytoin • Phenobarbital • Rifampin Decreased GI absorption, increased hepatic clearance, and lower prednisolone : prednisone ratio • Hyperthyroidism
Decreased dose of GCS required	Inhibition of cytochrome P450 metabolism (particularly CYP3A4; see Table 131.8) • Ketoconazole > other azole antifungals • Erythromycin > clarithromycin Altered protein binding and decreased hepatic metabolism (e.g. via competitive inhibition) • Estrogens/oral contraceptives Increased free (unbound) fraction of GCS • Hypoalbuminemia Renal function impaired Liver function impaired†
Specific side effect potentiated	Risk of GI side effects/peptic ulcer disease • NSAIDs Risk of infections • Other immunosuppressive agents Risk of hypokalemia • Potassium-depleting diuretics • Amphotericin B
Decreased levels/increased dose requirements of other drugs	• Insulin, oral hypoglycemic agents (due to GCS-related insulin resistance) • Isoniazid • Salicylates • Warfarin (variable; GCS can also increase vascular fragility)
Increased levels/decreased dose requirements of other drugs	• β-carotene • Cyclosporine

*Of note, dexamethasone itself may act as a CYP3A4 inducer.
†In patients with severe hepatic disease, conversion of prednisone to its active form (prednisolone) may be decreased.

Table 125.11 Glucocorticosteroid (GCS) therapy: dosing and side-effect considerations related to drug interactions and medical conditions. GI, gastrointestinal, NSAIDs, nonsteroidal anti-inflammatory drugs.

HPA Axis Suppression

Exogenous glucocorticosteroids can produce a secondary type of adrenal insufficiency that is related to both the dose and duration of treatment. Adrenal suppression occurs after 4 weeks of treatment with doses just above physiologic levels and earlier with higher doses. This effect is lessened by administering the glucocorticosteroid in a single morning dose and decreased even more by using an intermediate-acting agent on alternate mornings.

The entire HPA axis is affected by exogenous glucocorticosteroids. The hypothalamus is the first to be suppressed and the quickest to recover, whereas the adrenals are the last of the three glands to be suppressed and the slowest to recover. After high-dose therapy for months to years, ACTH levels may not return to normal for several months. Full recovery of the adrenal glands with normal serum cortisol levels may take even longer, sometimes up to 1 year[6]. There can be altered stress responsiveness in situations such as infection or surgery. Symptoms of weakness, fatigue, anorexia, nausea and fever may occur, and patients may even rarely develop hypotension or shock. Small doses of intravenous glucocorticosteroids may be needed prior to physically stressful situations such as major surgical procedures. Minor surgical procedures under local anesthesia do not require replacement therapy. Endocrinologic consultation should always be obtained if the rare addisonian crisis occurs.

A more common problem than adrenal crisis is the corticosteroid withdrawal syndrome. In this situation, the patient develops

arthralgias, headache, mood swings, lethargy and nausea upon rapid tapering of long-term glucocorticosteroid therapy. Low intracellular corticosteroid levels are thought to be the cause. A return to previous doses with slower tapering alleviates this syndrome.

With regard to HPA axis suppression, the primary screening test for basal function of the entire axis is the morning serum cortisol level. The morning glucocorticosteroid dose should be omitted on the day the cortisol level is checked. Impaired basal HPA axis function is suggested by serum cortisol levels below 10 mcg/dl. Adrenal function alone can be tested by using the more specific ACTH stimulation test, in which serum cortisol levels are measured at baseline and then 30 and/or 60 minutes after parenteral administration of 250 mcg (standard-dose test; can be adjusted for weight in young children) or 1 mcg (low-dose test, which may be more sensitive) of ACTH[34]. If it is necessary to test stress responsiveness of the HPA axis or the adrenal glands in greater detail, endocrinologic consultation should be obtained for the ACTH stimulation test or for other evaluations including the corticotropin-releasing factor test, the insulin hypoglycemia test, or the metyrapone test.

INTERACTIONS AND DOSE ALTERATIONS

Considerations regarding interactions between glucocorticosteroids and other medications as well as medical conditions that may require alteration of the glucocorticosteroid regimen are presented in Table 125.11.

Retinoids 126

Anne-Marie Thielen and *Jean-Hilaire Saurat*

Key features

- Retinoids are structural and functional analogues of vitamin A that exert multiple effects on cellular differentiation and proliferation, the immune system, and embryonic development
- Retinoic acid receptors (RARs) and retinoid X receptors (RXRs) are ligand-dependent transcription factors belonging to the steroid–thyroid hormone nuclear receptor superfamily
- Topical retinoids are used to treat acne, photoaging, psoriasis and a number of other conditions; the limiting factor is dose-related skin irritation, and teratogenicity risk is very low to non-existent
- Oral retinoids are the most effective drugs available for severe acne (isotretinoin) and many disorders of cornification (acitretin and isotretinoin). They are also helpful in the management of psoriasis, especially pustular and erythrodermic forms (acitretin > isotretinoin), pityriasis rubra pilaris (acitretin and isotretinoin), cutaneous T-cell lymphoma (bexarotene) and chronic hand eczema (alitretinoin)
- Systemic retinoid therapy requires careful patient selection and monitoring due to toxicities that can potentially result in laboratory abnormalities (e.g. hypertriglyceridemia, elevated transaminases); ocular, musculoskeletal, and (primarily for bexarotene) endocrinologic or hematologic adverse effects; and teratogenicity

INTRODUCTION

Vitamin A (retinol) and related compounds with either structural (retinol derivative) or functional (vitamin A activity) similarities are known as retinoids (Fig. 126.1). The importance of retinoids in cutaneous biology was first appreciated early in the twentieth century by Wolbach[1], who observed that vitamin A-deficient animals manifested altered keratinization, such as epidermal hyperkeratosis and squamous metaplasia of mucous membranes as well as certain precancerous conditions. The anti-keratinizing properties of vitamin A led von Stuettgen and Bollag to administer topical and systemic retinoids to treat disorders of keratinization. In initial clinical trials with oral vitamin A, it was either ineffective at tolerable doses or too toxic at higher dosage levels. Because of this narrow therapeutic window, a program was launched to engineer synthetic retinoids that would have higher therapeutic activity and lower toxicity. Although retinoids are produced naturally during vitamin A metabolism, most prescribed retinoids are synthetic. Parallel to efforts with systemic agents, a growing interest in topical retinoids emerged.

All-*trans*-retinoic acid (*at*-RA; tretinoin), a naturally occurring metabolite of retinol (see Fig. 126.1), was the first retinoid to be synthesized. Orally, it did not have significant advantages over vitamin A, and, as a result, the primary focus became its topical use, especially for acne vulgaris and photoaging. The ability of tretinoin to promote cellular differentiation has been exploited for the systemic treatment of patients with acute promyelocytic leukemia, but resistance eventually occurs in those who receive tretinoin monotherapy.

First synthesized in 1955, 13-*cis*-retinoic acid (13-*cis*-RA; isotretinoin) was tested years later in clinical trials. Its initial use was hampered by concerns regarding its teratogenicity, which were amplified because of the thalidomide tragedy. Initially, Orfanos and co-workers obtained equivocal results when they used isotretinoin to treat psoriasis, and etretinate was subsequently found to be more effective for psoriasis. This led to the temporary abandonment of studies of isotretinoin. Interest in isotretinoin was rekindled by the discovery of its effectiveness in the treatment of lamellar ichthyosis and other disorders of keratinization as well as its ability to produce complete responses with prolonged remissions in patients with previously treatment-resistant nodulocystic acne[2]. Topical isotretinoin has also been formulated and has efficacy similar to that of topical tretinoin for acne. In 1999, the US Food and Drug Administration (FDA) approved 9-*cis*-retinoic acid (9-*cis*-RA; alitretinoin) 0.1% gel for the topical treatment of cutaneous Kaposi sarcoma. Recently, systemic alitretinoin has been used to treat severe chronic hand eczema that is refractory to potent topical corticosteroids.

In 1972, Bollag developed two aromatic retinoids: etretinate and its free acid metabolite, acitretin. Both had a therapeutic index ten times more favorable than that of tretinoin in the chemically induced rodent papilloma test model. Etretinate and acitretin represent second-generation retinoids, and their development constituted a breakthrough in the systemic treatment of psoriasis and disorders of keratinization.

A major advance in understanding the molecular pharmacologic features and mechanisms of action of retinoids came with the discovery of nuclear receptors known as retinoic acid receptors (RARs) and retinoid X receptors (RXRs). This allowed the development of new retinoids that target specific retinoid receptors. Third-generation retinoids include topical adapalene (acne), topical tazarotene (psoriasis and acne) and oral as well as topical bexarotene (cutaneous T-cell lymphoma [CTCL]). Lastly, topical retinol and retinaldehyde, the precursors of retinoic acid, are included in cosmeceutical products.

MECHANISM OF ACTION

Retinoids are involved in the regulation of diverse biologic functions (Table 126.1). They affect cellular growth, differentiation and morphogenesis; inhibit tumor promotion and malignant cell growth; exert immunomodulatory actions; and alter cellular cohesiveness.

Vitamin A Metabolism

Vitamin A (retinol) must be acquired through the diet and is ingested as retinyl esters and provitamin A carotenoids; of the latter, beta-carotene is particularly efficient in its ability to be converted to vitamin A. Within the intestinal lumen, retinyl esters are hydrolyzed to retinol, which is then absorbed and stored in the liver in the ester form (especially retinyl palmitate; Fig. 126.2). Retinol and its esters represent the main dietary source, as well as transport and storage form, of vitamin A. Once inside the bloodstream, after release of the retinyl ester (storage form) from the liver, retinol is transported bound to a complex of retinol-binding protein (RBP) and transthyretin.

The cellular pathway leading to conversion of retinol to *at*-RA, the biologically active ligand that binds to nuclear receptors, consists of a two-step process (see Figs 126.1 & 126.2). Retinol (vitamin A alcohol) is first reversibly oxidized to retinaldehyde (vitamin A aldehyde), which is then irreversibly converted to retinoic acid (vitamin A acid). Cytosolic RBP (CRBP-I), facilitates these enzymatic reactions by delivering retinol to appropriate enzymes.

Two additional intracellular carriers, cytosolic retinoic acid-binding proteins (CRABP-I and CRABP-II), are thought to function in transporting retinoic acid to the nucleus as well as buffering the level of free *at*-RA in the cell. The latter is accomplished by sequestering *at*-RA and by promoting metabolism of *at*-RA by cytochrome P450 enzymes belonging to the CYP26 family (e.g. CYP26A1). CRABP-I regulates the metabolic fate of its ligands by directly affecting the activities of

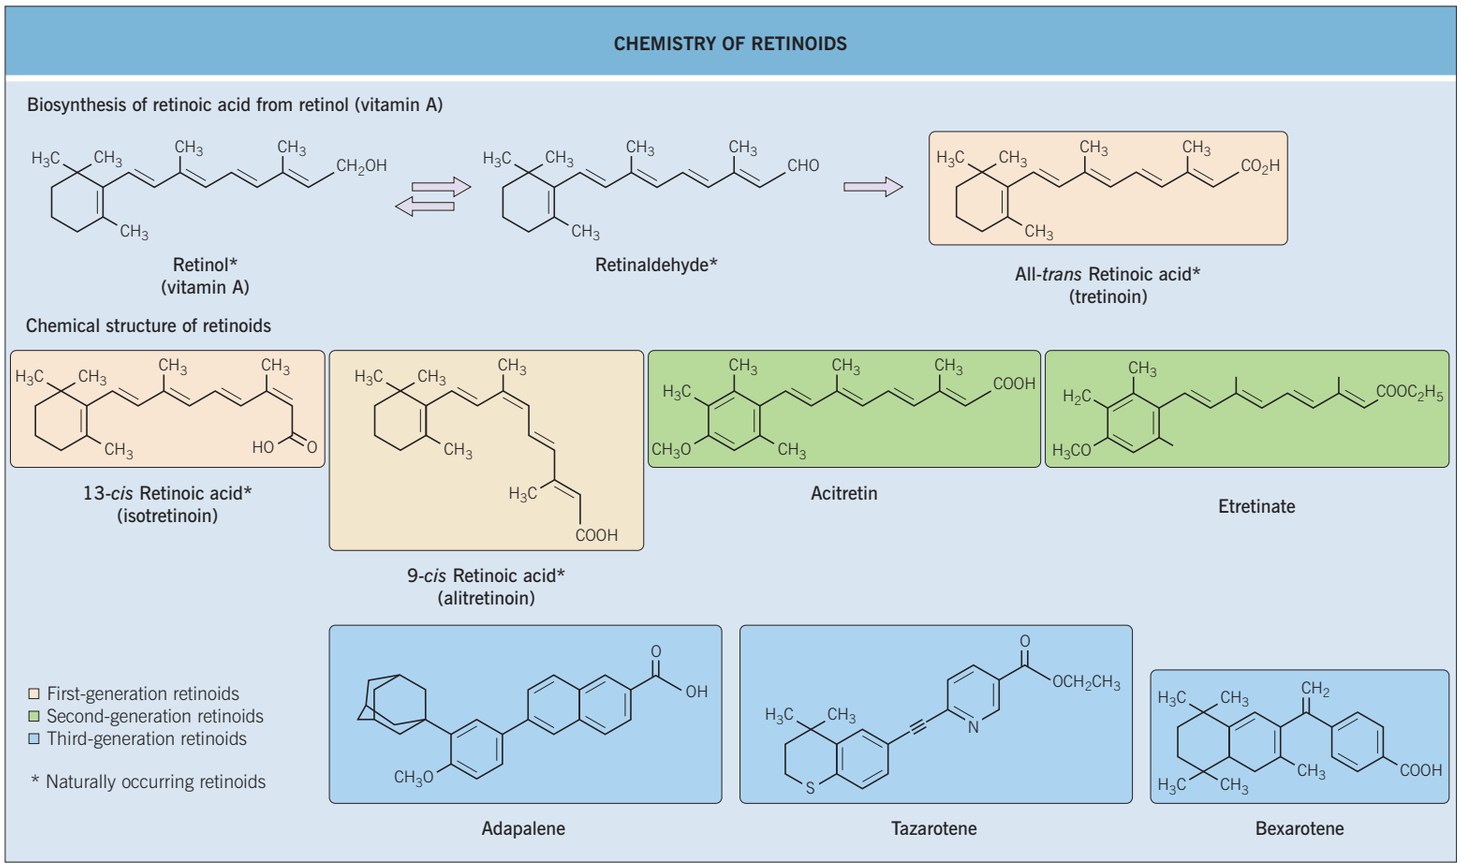

Figure 126.1 Chemistry of retinoids.

BIOLOGIC FUNCTIONS OF RETINOIDS
FUNCTIONS OF VITAMIN A (RETINOL)*
• Embryonic growth • Morphogenesis • Differentiation and maintenance of epithelial tissues • Reproduction (retinol) • Visual function (retinaldehyde)
BIOLOGIC EFFECTS OF RETINOIDS
• Modulation of proliferation and differentiation • Anti-keratinization • Alteration of cellular cohesiveness • Anti-acne and antiseborrheic effects • Immunologic and anti-inflammatory effects • Tumor prevention and therapy • Induction of apoptosis • Effects on extracellular matrix components
*Retinoic acid can substitute for retinol with regard to growth, morphogenesis and epithelial differentiation; it cannot substitute completely for retinol in reproductive function, nor can it replace retinaldehyde in the visual cycle.

Table 126.1 Biologic functions of retinoids.

RA-metabolizing cytochrome P450 enzymes, while CRABP-II markedly stimulates the RA-induced transcriptional activity of RAR through protein–protein interactions.

Intracellularly, retinoic acid is found in both all-*trans* and 9-*cis* configurations (see Fig. 126.2). Physiologically, at-RA is the predominant retinoic acid form, and only a very small fraction is isomerized into 13-*cis*-RA. at-RA is the primary active ligand that binds to the three known nuclear RARs, which mediate, at least in part, the molecular and cellular effects of retinoic acid.

Retinoid Receptors

Retinoids exert their physiologic effects on DNA transcription by binding to two distinct families of nuclear receptors, RARs and RXRs. These receptor families belong to a superfamily of nuclear receptors that act as ligand-activated transcription factors and include the steroid, vitamin D_3 and thyroid hormone receptors as well as peroxisome proliferator-activated receptors (PPAR). The RAR and RXR receptor families each contain three receptor isotypes (α, β and γ) encoded by different genes. at-RA (tretinoin) binds only to RARs, whereas 9-*cis*-RA (alitretinoin) binds both to RARs and RXRs (Table 126.2).

RARs function as heterodimers with RXRs, whereas RXRs may also act as homodimers or participate in the formation of heterodimers with a variety of other nuclear receptors, including vitamin D_3, thyroid hormone and peroxisome proliferator-activated receptors. Such heterodimers provide a mechanism for cross-talk between nuclear hormone signaling pathways. Dimers of retinoid receptors (RAR/RXR or RXR/RXR) are localized to the nucleus and bind, even in the unliganded state, to specific DNA regulatory sequences (called retinoid hormone response elements [RAREs]) in the promoter regions of retinoid-responsive genes (see Fig. 126.2). The unliganded receptors bind to co-repressor molecules and repress transcription. However, when the receptor binds its ligand, it undergoes a conformational change resulting in the release of co-repressors and recruitment of co-activators. These molecules include histone acetylases that change the conformation of chromatin and allow access to DNA by transcriptional machinery. The retinoid–receptor complex thereby modulates the transcription of specific sets of genes, and it is likely that many of the differentiation-inducing actions of retinoids are mediated by this mechanism.

In addition to *direct* upregulation of gene transcription via binding of retinoid–receptor complexes to RAREs, retinoids can have *indirect* effects on gene transcription that result from the downregulation of genes that do not contain RAREs in their promoter region. The retinoid–receptor complex is thought to antagonize transcription factors such as activator protein-1 (AP1) and nuclear factor-interleukin-6 (NF-IL6) by competing for the same set of required co-activator proteins, thereby

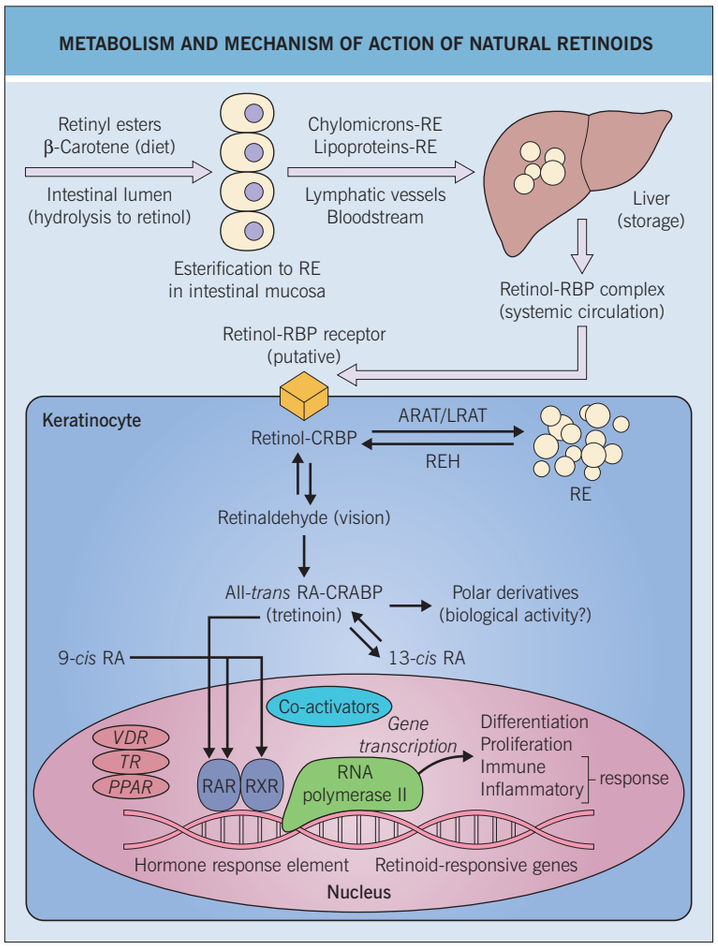

Figure 126.2 Metabolism and mechanism of action of natural retinoids. leading to decreased expression of AP1 and NF-IL6-responsive genes. The antiproliferative and anti-inflammatory actions of retinoids are believed to be mediated by this type of indirect negative gene regulation. AP1 and NF-IL6 are key transcription factors in proliferative and inflammatory responses, and "dissociating retinoids" have been synthesized that possess indirect anti-AP1 function but are not capable of direct gene transactivation. Retinoic acid was recently found to have important roles in inhibiting interleukin-6-driven induction of proinflammatory Th17 cells and in promoting differentiation of anti-inflammatory regulatory T cells[3]. The anti-inflammatory effects of *at*-RA (tretinoin) have also been associated with its ability to regulate the expression and activation of Toll-like receptors (TLRs; especially TLR2)[4]. The biologic relevance of non-genomic effects of retinoids (e.g. phosphorylation, membrane effects) is still a matter of investigation.

The existence of several types and varied distributions of receptors, dimers, hormone response elements, mechanisms of action, and regulatory proteins shows that retinoid action is mediated via multiple pathways and results in the complex activation or inhibition of a large set of coordinately regulated genes. However, the exact mechanism of retinoid action in many dermatologic conditions is still unknown, and, so far, the nuclear receptor concept does not fully explain the biologic diversity of retinoid effects.

Synthetic Retinoids

Three generations of synthetic retinoids have been developed (see Fig. 126.1). The first-generation monoaromatic retinoids (tretinoin, isotretinoin, alitretinoin) are produced by chemically modifying the polar end group and the polyene side chain of vitamin A. Second-generation monoaromatic retinoids (etretinate, acitretin) are formed by replacing the cyclic end group of vitamin A with different substituted and unsubstituted ring systems. The third-generation polyaromatic retinoids (adapalene, bexarotene, tazarotene), called arotinoids, are produced by cyclization of the polyene side chain.

Commercially available retinoids differ not only in their spectrum of clinical efficacy but also in their observed toxicity and pharmacokinetics. Each retinoid should be investigated as a unique drug, and the lack of disease response to one retinoid does not necessarily signify unresponsiveness to other retinoids.

The oral bioavailability of all retinoids is considerably enhanced when administrated with food, especially with a fatty meal, due to their lipophilic properties. Retinoid metabolism is predominantly hepatic. It involves oxidation and chain shortening to biologically inactive and polar metabolites, facilitating biliary and/or renal elimination. The oxidative metabolism is induced by the retinoids themselves and possibly also by other agents known to stimulate hepatic cytochrome P450 isoforms. Table 126.2 summarizes the key pharmacologic features and nuclear binding profile of retinoids used in dermatology.

Adapalene

Adapalene is a light-stable, rigid, and highly lipophilic synthetic retinoid with higher affinity for RAR-β/γ than for RAR-α. Since RAR-β is not expressed in keratinocytes, RAR-γ is the primary target receptor for adapalene in the epidermis. Adapalene does not bind to CRABPs but induces expression of CRABP-II. Due to its lipophilic properties, there is selective uptake into the pilosebaceous unit, which may contribute to topical adapalene's low systemic absorption (due to dissolution within the sebum) and anti-acne activity. Systemically absorbed adapalene is excreted through the hepatobiliary route and, given its negligible transdermal absorption, teratogenic risks appear to be minimal. Adapalene affects cellular differentiation, keratinization and inflammatory processes that are abnormal in acne. However, it has no sebostatic effect.

Tazarotene

Tazarotene is a prodrug that is rapidly converted by skin esterases to its free carboxylic acid (tazarotenic acid), which is the active metabolite. It has a higher affinity for RAR-β/γ than for RAR-α and no affinity for RXR. Because of its rapid metabolism, systemic exposure is low. Tazarotene appears to modulate the pathogenesis of psoriasis by regulating expression of retinoid responsive genes, including those involved in: (1) cell proliferation, which leads to downregulation of proliferation-associated proteins, including ornithine decarboxylase, hyperproliferative keratins (i.e. K6, K16) and epidermal growth factor receptor; (2) cell differentiation; and (3) inflammation, including downregulation of proinflammatory cytokine interleukin-6 and migration inhibition factor-related protein 8. Tazarotene's antiproliferative effects may occur via upregulation of *t*azarotene-*i*nducible genes (TIG-1,2,3)[5]. An oral form of tazarotene had beneficial effects for psoriasis patients in phase III clinical trials, but it is not approved by the FDA.

Acitretin

Acitretin is the major metabolite and the pharmacologically active form of etretinate. Although acitretin and etretinate are equally effective, acitretin has much more rapid elimination. Etretinate is approximately 50 times more lipophilic than acitretin and binds strongly to plasma proteins, particularly lipoproteins and albumin. Etretinate is stored in adipose tissue (including subcutaneous fat), from which it is released slowly, with a long terminal half-life of up to 120 days. Under identical conditions, acitretin carries a negatively charged group that makes it much less lipophilic than etretinate. As a result, acitretin does not accumulate in adipose tissue and is eliminated from the body more rapidly, with a half-life of 2 days.

The major serious adverse effect of oral retinoids is teratogenicity, and, therefore, the length of time that these drugs are present in the body is of great importance. Re-esterification of acitretin to etretinate may occur when acitretin is taken simultaneously with alcohol. This finding prompted the manufacturer to extend the time of contraception in patients taking acitretin to 2 years after discontinuation, as it is for

KEY PHARMACOLOGIC FEATURES AND NUCLEAR BINDING PROFILE OF RETINOIDS						
Retinoid	**Type**	**Systemic absorption* or bioavailability† (% dose)**	**Elimination half-life**	**Metabolism**	**Excretion**	**Nuclear receptor and binding protein profile**
TOPICAL RETINOIDS						
Tretinoin	Natural (1st generation)	<2% in normal skin	Normally present in the skin	Isomerization to 13-*cis*-RA (epidermis)	Desquamation, biliary	RAR; CRABP; not RXR
Alitretinoin (9-*cis*-retinoic acid)	Natural (1st generation)	Minimal	Normally present in the skin	Main metabolite: 4-oxo-9-*cis*-RA	Desquamation, biliary	RXR and RAR
Adapalene	3rd generation	Minimal	Unknown	Minimal biotransformation due to chemical rigidity	Desquamation, biliary	RAR-β, -γ > -α; not RXR
Tazarotene	3rd generation	<1–6% in normal skin	16 hours (tazarotenic acid)	Rapid (within 20 minutes) ester hydrolysis within the skin to form its active metabolite, tazarotenic acid; excreted metabolites: sulfoxides, sulfones	Desquamation, renal (within 3 days), biliary (within 7 days)	RAR-β, -γ > -α; not RXR
SYSTEMIC RETINOIDS						
Tretinoin	Natural (1st generation)	50%	1 hour	Hepatic; main metabolites: *cis*- and *trans*-4-oxo derivatives	Biliary, renal	RAR; CRABP; not RXR
Isotretinoin (13-*cis*-RA)	Natural (1st generation)	25%	20 hours	Hepatic, endogenous concentration reached within 2 weeks; main metabolite: 4-oxo-isotretinoin	Biliary, renal	–‡
Alitretinoin	Natural (1st generation)	Unknown	2–10 hours	Hepatic; main metabolite: 4-oxo-alitretinoin	Renal, biliary	RXR and RAR
Etretinate	2nd generation	40%	120 days	Hepatic, hydrolysis to acitretin	Biliary, renal (accumulation in fat)	–‡
Acitretin	2nd generation	60%	2 days	Hepatic, re-esterification to etretinate indirectly increased by alcohol consumption; main metabolite: *cis*-acitretin	Biliary, renal	–‡
Bexarotene	3rd generation	Unknown	7–9 hours	Hepatic	Biliary	RXR

*Limited propensity for distribution to systemic tissues.
†Increased with food intake, highly variable.
‡No clearly identified affinity for any retinoid receptor; acitretin and etretinate activate the RARs despite binding poorly to them.

Table 126.2 The key pharmacologic features and nuclear binding profile of retinoids. CRABP, cellular retinoic acid-binding protein; RA, retinoic acid; RAR, retinoic acid receptor; RXR, retinoid X receptor.

etretinate. The FDA advises a contraceptive period of at least 3 years for acitretin, based on the pharmacokinetics of acitretin and etretinate observed in clinical trials and on previous safety experience with etretinate. However, acitretin retains its shorter half-life in women who strictly avoid alcohol during treatment and for 2 months thereafter[6]. Because of its improved risk–benefit ratio, acitretin was approved by the FDA in 1996 as a substitute for etretinate, which is no longer commercially available[6].

Acitretin's mechanism of action is still not clearly understood. Paradoxically, it activates all three RAR subtypes despite binding poorly to them. Evidence supports a normalization of differentiation and proliferation as well as a modification of inflammatory responses and neutrophil function.

Isotretinoin (13-cis-retinoic acid)

Isotretinoin is a naturally occurring compound resulting from the metabolism of vitamin A (see Fig. 126.2). 13-*cis*-RA and a*t*-RA are two physiologically interconvertible isomers that differ in their elimination half-lives: approximately 20 hours and 1 hour, respectively. Isotretinoin undergoes first-pass metabolism in the liver and subsequent enterohepatic recycling. In plasma, more than 99% of isotretinoin is protein-bound, mainly to albumin. There is neither liver nor adipose tissue storage, in contrast to vitamin A. The major metabolite of isotretinoin (4-oxo-isotretinoin) is produced by oxidation. Isotretinoin and its metabolites are excreted in the urine and feces. After discontinuation of isotretinoin, natural concentrations of the drug and its major metabolites are reached within 2 weeks, ranging from 2 days for a*t*-RA to 10 days for 4-oxo-isotretinoin. Therefore, 1 month of post-therapy contraception provides an adequate safety margin to avoid teratogenicity.

Among natural and synthetic retinoids, only oral isotretinoin significantly suppresses sebum production, which explains its dramatic effects on acne. Since no clear affinity for isotretinoin has been identified for any known retinoid receptor[7], isotretinoin may target the sebaceous gland via other pathways or with its metabolites or isomers. Isotretinoin induces cell cycle arrest and apoptosis of sebocytes through what appears to be an RAR-independent mechanism; tretinoin and alitretinoin do not have these effects on sebocytes. Neutrophil gelatinase-associated lipocalin (NGAL), which functions in innate immune defense and induces apoptosis of murine B lymphocytes, was recently shown to mediate isotretinoin-induced sebocyte apoptosis[8]. Isotretinoin was found to upregulate NGAL expression in acne patients' sebaceous glands as well as in cultured human sebocytes, and recombinant NGAL led to apoptosis of cultured sebocytes. This suggests that strategies to selectively induce NGAL expression in sebaceous glands might be of benefit in the treatment of acne[8].

Bexarotene

Bexarotene, an RXR-selective retinoid (rexinoid), is FDA-approved in oral (1999) and topical (2000) forms for treatment of CTCL. This compound is about 100-fold more potent at binding to RXRs than to

RARs. In plasma, bexarotene is highly bound (>99%) to various proteins that have yet to be characterized. Both the ability of bexarotene to displace other drugs bound to plasma proteins and the ability of other drugs to displace bexarotene are unknown. Bexarotene has a clearance profile similar to that of isotretinoin, with a terminal half-life of between 7 and 9 hours[9]. Bexarotene is metabolized by CYP3A4 and generates its own oxidative metabolites via hepatic CYP3A4 induction. Neither bexarotene nor its metabolites are excreted in the urine; their elimination is thought to occur primarily via the hepatobiliary system[9]. The exact mechanism of action of bexarotene in CTCL is still unknown, but it probably acts through regulation of cellular differentiation and proliferation, and induction of apoptosis.

Alitretinoin (9-cis-retinoic acid)

Alitretinoin is a naturally occurring pan-agonist retinoid that binds to both RARs and RXRs[10], representing the endogenous ligand for the latter. Topical alitretinoin 0.1% gel is indicated for the treatment of cutaneous Kaposi sarcoma, whereas oral alitretinoin is a recently introduced therapy for refractory chronic hand eczema. The absorption of oral alitretinoin from the gastrointestinal tract is variable and dose-proportional over the therapeutic range of 10–30 mg daily; the absolute bioavailability of alitretinoin has not been determined. Alitretinoin is metabolized via oxidation by CYP3A4 enzymes of the liver into 4-oxo-alitretinoin, and both the parent drug and its metabolite also undergo isomerization into *at*-RA and 4-oxo-*at*-RA, respectively. Elimination is primarily renal, with the half-life of unchanged alitretinoin ranging between 2 and 10 hours. Alitretinoin concentrations return to normal within 1 to 3 days after treatment cessation.

The mechanism of action of alitretinoin in chronic hand eczema is unknown. Alitretinoin has immunomodulatory and anti-inflammatory effects that are relevant to cutaneous inflammation, including suppressing the expansion of cytokine-activated leukocyte subsets and antigen-presenting cells.

Retinoic acid metabolism blocking agents

*R*etinoic *a*cid *m*etabolism *b*locking *a*gents (RAMBAs) inhibit catabolism of *at*-RA by P450 enzymes in the CYP26 family, thereby raising the intracellular levels of endogenous *at*-RA in the skin and other targeted tissues[11]. This limits systemic exposure and the potential for toxicity, and *at*-RA levels return to the physiologic range within 24 hours of discontinuing these medications. Liarozole, an imidazole derivative without antifungal properties, is a RAMBA with low isoenzyme specificity that also inhibits P450-mediated pathways of steroid biosynthesis. Talarozole (R115866), a triazole derivative, is a more selective and highly active CYP26 enzyme inhibitor.

Both topical and oral forms of liarozole and talarozole have been developed, but they are not currently available in the US. However, liarozole has been granted orphan drug status for congenital ichthyosis by the European Commission and the FDA, and a randomized controlled trial showed that oral liarozole had equal efficacy to acitretin but greater tolerability in patients with moderate to severe forms of ichthyosis. Preliminary studies of talarozole have shown potential benefit for plaque-type psoriasis and acne.

INDICATIONS (Table 126.3)

Topical Retinoids

The most important element in topical therapy with retinoids is patient education. Local skin irritation can be expected, and noticeable beneficial effects may take weeks or months to appear. Administration of topical retinoids should be titrated depending on cutaneous irritation, which may mean decreasing the concentration or the frequency of application. It is generally wise to begin with the lowest-strength formulation and then increase the concentration as tolerance builds. Another tactic is to start by applying a given concentration every other day. Daytime moisturizers with sunscreen are important components of any topical retinoid regimen.

Acne

Topical retinoids, of which tretinoin is the prototype, are mainstays in the treatment of comedonal and inflammatory acne vulgaris. The primary mode of action in acne is normalization of differentiation and proliferation of the follicular epithelium (see Ch. 36), which leads to the loosening and unseating of microcomedones, thereby preventing obstruction of the pilosebaceous unit. In addition, topical retinoids may have anti-inflammatory activity and they decrease expression of potentially destructive matrix metalloproteinases (MMPs). The mechanism of action of topical isotretinoin (not available in the US) is similar to that of topical tretinoin because of intraepithelial isomerization of isotretinoin to tretinoin. Topical isotretinoin (in contrast to oral isotretinoin) fails to significantly suppress sebum production, and it is less irritating but probably somewhat less effective than tretinoin.

The newer topical synthetic retinoids, adapalene and tazarotene, are intended to have comparable or improved tolerability while maintaining efficacy similar to that of topical tretinoin. In company-sponsored studies of patients with acne, adapalene 0.1% gel was as effective as tretinoin 0.025% gel against open and closed comedones and more effective against inflammatory lesions, with less irritation[12]. Tazarotene 0.05% and 0.1% gels significantly decreased acne lesions in treated individuals compared with control patients, with clinical tolerability comparable to tretinoin.

Topical retinoids should be applied to the entire face or all acne-prone areas once a day (if tolerated), preferably in the evening to prevent inactivation by UV light. The medication should be applied to dry skin to minimize dermal absorption, which correlates with skin irritation. Patients should be advised that beneficial effects do not become evident for weeks to months. An apparent exacerbation may occur during the first month of therapy, representing the externalization of deeper-seated acne lesions as the follicular epithelium is loosening. With the exception of mild, primarily comedonal acne, topical retinoids should be used concomitantly with antibiotics (oral or topical) and/or benzoyl peroxide products, which have different modes of action that target inflammatory lesions.

Psoriasis

Topical application of tretinoin or isotretinoin has limited efficacy in psoriasis. However, topical tazarotene was shown to be effective in treating mild to moderate plaque-type psoriasis not exceeding 20% of the body surface area. When compared with twice-daily fluocinonide cream, tazarotene 0.05% and 0.1% gels applied once daily were found to produce similar reductions in plaque elevation, and tazarotene 0.1% gel carried a significantly lower risk of relapse than fluocinonide cream after 12 weeks off therapy[13]. A combination of tazarotene and a mid-potency topical corticosteroid improved efficacy and reduced the incidence of local adverse effects; this combination may also reduce the risk of corticosteroid-induced atrophy.

Photoaging

Photodamaged skin is characterized by fine and coarse wrinkling, a rough texture, a sallow color, and irregular pigmentation. Several controlled studies have clearly demonstrated that topical retinoids, including tretinoin and (more recently) tazarotene cream, can improve fine wrinkling and lighten uneven pigmentation. It generally takes 3–6 months of daily applications to see significant clinical improvement. Cutaneous irritation is usually the limiting factor. Retinaldehyde was found to be as effective as tretinoin in treating photodamage in less extensive trials[14], and it had a better tolerance profile that may reflect more controlled delivery of retinoic acid to target cells.

Photoaging is the consequence of UV radiation-induced damage to the skin, which is characterized by decreased expression of RXR-α and RAR-γ (the major retinoid receptors in keratinocytes) in the acute setting and by upregulation of AP1-driven MMPs. Topical retinoids promote cellular differentiation and extracellular matrix synthesis, including an increase in hyaluronic acid via a CD44-mediated mechanism and decreased MMP production[15]. Histologic findings after repeated topical application of tretinoin include compaction of the stratum corneum, epidermal hyperplasia (acanthosis), correction of atypia (e.g. actinic keratoses), dispersion of melanin granules, increased dermal collagen synthesis, and angiogenesis. These findings explain the reported smoother skin, rosy glow, decrease in blotchy pigmentation, and diminished fine lines and wrinkles.

CLINICAL INDICATIONS FOR RETINOIDS			
Topical retinoids	FDA-approved indications	Acne vulgaris (tretinoin, adapalene, tazarotene) Photoaging (wrinkling, mottled pigmentation, facial roughness) (tretinoin, tazarotene) Psoriasis (<20% of body surface area) (tazarotene) Cutaneous T-cell lymphoma (bexarotene) Kaposi sarcoma (alitretinoin)	
	Selected non-FDA-approved indications	Limited disorders of keratinization (Darier disease, ichthyoses) Pityriasis rubra pilaris Rosacea Pigmentary disorders (melasma, postinflammatory hyperpigmentation) Lentigines Actinic keratoses Striae Wound healing Lichen planus (oral and cutaneous) Verrucae planae (flat warts) Corticosteroid-induced atrophy Therapy and prevention of skin cancer (basal cell carcinoma; xeroderma pigmentosum)	
Systemic retinoids	FDA-approved indications	Psoriasis (acitretin)	Pustular psoriasis (localized and von Zumbusch) Erythrodermic psoriasis Severe and recalcitrant psoriasis
		Acne (isotretinoin)	Nodulocystic acne Recalcitrant acne with tendency for scarring
		Cutaneous T-cell lymphoma (bexarotene)	Resistant to at least one systemic therapy
	Selected non-FDA-approved indications	Rosacea and acne-related disorders	Hidradenitis suppurativa Eosinophilic pustular folliculitis (Ofuji's disease) AIDS-associated eosinophilic folliculitis Pyoderma faciale (rosacea fulminans) Acne with solid facial edema Dissecting cellulitis of the scalp
		Disorders of keratinization and related disorders	Ichthyosis, various forms (see Ch. 57) Darier disease Keratoderma Papillon-Lefèvre syndrome
		Inflammatory disorders	Chronic hand eczema Pityriasis rubra pilaris Lupus erythematosus Lichen planus
		Chemoprophylaxis of neoplastic processes	Xeroderma pigmentosum Nevoid basal cell carcinoma syndrome Skin cancer in solid organ transplant patients
		Treatment of neoplastic processes	Epithelial precancerous conditions Basal cell carcinoma Advanced squamous cell carcinoma Keratoacanthoma Kaposi sarcoma Sebaceous hyperplasia Muir–Torre syndrome Leukoplakia Langerhans cell histiocytosis
		Miscellaneous conditions	Atrophoderma vermiculatum Ulerythema ophryogenes Confluent and reticulated papillomatosis of Gougerot and Carteaud Bazex paraneoplastic acrokeratosis Follicular mucinosis Sarcoidosis Granuloma annulare Lichen sclerosus (genital or extragenital) Subcorneal pustular dermatosis Graft-versus-host disease (chronic sclerodermoid) Verruca vulgaris, condyloma

Table 126.3 Clinical indications for retinoids.

Other indications

Other FDA-approved indications for topical retinoids include alitretinoin 0.1% gel for cutaneous Kaposi sarcoma and bexarotene 1% gel for CTCL. In one study, 67 patients with early-stage (IA–IIA) CTCL achieved an overall response rate of 63% and a clinical complete response rate of 21% after using topical bexarotene for a median of 20 weeks[16]. There are also numerous "off-label" uses for topical retinoids (see Table 126.3).

Systemic Retinoids

Psoriasis

Several randomized, controlled multicenter trials have been performed to ascertain the efficacy of acitretin in plaque-type[17] and pustular psoriasis. Acitretin appears to be as effective as etretinate and can be used in the same combination regimens. Adverse effects appear to be similar in quality and incidence. The best results have been obtained in acral or generalized (von Zumbusch) pustular psoriasis, in which

acitretin is considered to be a first-line therapy. The lesions of both localized and generalized pustular psoriasis, as well as those of erythrodermic psoriasis, cleared more rapidly with etretinate or acitretin monotherapy than with most other therapies[18]. Rebound does not usually occur after stopping treatment, and reintroduction produces a beneficial response.

Plaque-type psoriasis responds variably to both drugs. Although complete clearance of plaques is achieved in only about 30% of treated patients, a significant improvement is obtained in an additional 50%[19]. The mean decrease in the Psoriasis Area and Severity Index (PASI) score is approximately 60–70%, depending on the dosage and duration of treatment. Many of the plaques may remain, but they are thinner with less scale and erythema. Approximately 20% of patients may be considered treatment failures[19].

One of the main reasons for treatment interruption is an initial worsening of the disease with an increase in erythema and/or the extent of involvement. This may occur within a few days of starting therapy at a dosage of 0.5–1 mg/kg/day (i.e. 30–70 mg/day in adults). Utilization of a low dose (10 mg/day) of acitretin initially, followed by progressively increasing the dose, helps to avoid this complication. In order to define the efficacy of acitretin as monotherapy for psoriasis, different doses (10–75 mg/day) were compared with placebo in a double-blind fashion. At the end of an 8-week treatment period in two studies, acitretin at doses of 25 to 75 mg/day was superior to placebo, whereas the efficacy of 10 mg/day was not significantly different from that of placebo[20,21].

Total clearance of psoriatic lesions usually requires a combination of retinoids with other treatments such as topical corticosteroids, topical vitamin D derivatives, anthralin (dithranol) or photo(chemo)therapy (narrowband UVB or psoralen plus UVA [PUVA]). The main advantages of the "Re-PUVA" combination, in which retinoids are given for 14 days before starting PUVA, are an accelerated response rate and resolution of lesions that would not clear with a retinoid or PUVA alone (Fig. 126.3). The cumulative radiation exposure required to produce a remission is also significantly lower with Re-PUVA, reducing the risk of PUVA-induced carcinogenesis which is UVA dose-dependent. Oral retinoids can also be combined with bath PUVA. Lastly, the combination of etretinate or acitretin with UVB phototherapy has been shown to be more effective than retinoid or UVB phototherapy alone in patients with psoriasis[22,23].

Isotretinoin is less effective than acitretin or etretinate for psoriasis, although some efficacy has been shown in combination with PUVA[24]. Isotretinoin is still occasionally used in women of childbearing age with psoriasis who need a systemic retinoid to avoid the long post-acitretin contraception period.

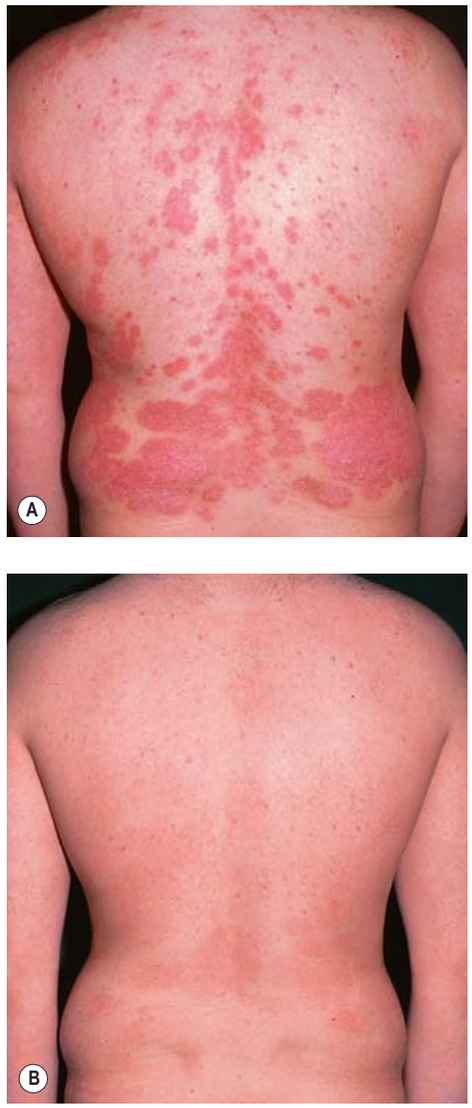

Figure 126.3 Chronic plaque-type psoriasis. Before (**A**) and after (**B**) treatment with a combination of acitretin and PUVA.

Acne

The introduction of isotretinoin was a key advance in dermatologic therapy. Isotretinoin is still the only treatment that has been shown to induce long-term remissions and even "cure" acne, because it is the only medication that affects, albeit not to the same degree or permanently, all the etiologic factors implicated in acne: sebum production, comedogenesis, and colonization with *Propionibacterium acnes* (Fig. 126.4). Among natural and synthetic retinoids studied in humans, only isotretinoin has been found to suppress sebum production (see above).

In the early 1980s, oral isotretinoin use was restricted to patients suffering from severe nodulocystic acne. With increasing experience, however, its use has been extended to patients with less severe disease who have responded unsatisfactorily to conventional therapies such as topical retinoids plus oral antibiotics. Patients with moderate acne that shows signs of scarring also represent candidates for oral isotretinoin therapy.

Acne morbidity extends beyond the aesthetics of physical appearance. Psychosocial consequences of acne range from depression and anxiety to interpersonal and work-related difficulties. Studies with quality-of-life instruments have shown that isotretinoin treatment significantly improves sociability and self-esteem.

It was initially considered that optimal benefit would be achieved with an isotretinoin dose of approximately 1 mg/kg/day[25]. However, this can induce undesirable dose-dependent effects, and similar short-term therapeutic results have been obtained with doses below 0.5 mg/kg/day. In order to avoid the higher incidence of relapses associated with lower-dose isotretinoin, treatment can be continued for a longer period of time in order to reach a critical cumulative dose threshold. The cumulative dose was first recognized to be important in isotretinoin therapy for acne by Harms et al. in 1989[26]; it refers to the total amount of oral isotretinoin taken by the patient over the entire course, divided by the body weight (mg/kg body weight). For example, a patient weighing 50 kg and receiving 25 mg/day of isotretinoin for 100 days would have received a cumulative dose of 50 mg/kg (25 mg × 100 = 2500 mg, divided by 50 kg = 50 mg/kg). Data from several studies have indicated that post-therapy relapse is minimized by a treatment course amounting to a total of at least 120 mg/kg[27], with no further therapeutic gain beyond about 150 mg/kg[28]. However, a 6-month course of low-dose isotretinoin (20 mg/day; mean cumulative dose = 70 mg/kg) was also found to be effective in the treatment of moderate acne, with a low incidence of severe side effects and a reduced cost compared to higher doses[29].

A lag period of 1–3 months may occur before the onset of the therapeutic effect, and continued healing after the discontinuation of therapy is frequently observed. Consequently, it is not necessary to maintain treatment until total clearance is achieved. Approximately one-third of patients with acne require a second course of isotretinoin therapy, either for persistent disease or for relapse. A major predictive factor of resistance to isotretinoin treatment is closed comedonal and microcystic acne[30]. Women with a history of acne that is refractory to isotretinoin or with repeated relapses should be examined for hirsutism, questioned regarding abnormal menstruation, and referred

Figure 126.4 Severe acne vulgaris. Before (**A**) and after (**B**) treatment with oral isotretinoin.

for an endocrinologic evaluation to exclude ovarian or adrenal dysfunction.

A flare of disease during the first few weeks of treatment, and subsequent evolution of acne cysts into lesions resembling pyogenic granulomas, is occasionally observed with isotretinoin treatment. The incidence of this side effect may be reduced by using lower doses of isotretinoin during the first 3–4 weeks of therapy.

Women of childbearing potential must have at least one (in the US, two) negative pregnancy test(s) and practice effective contraception for 1 month prior to therapy, during therapy, and for 1 month after completing therapy. To afford a sufficient safety margin, a 1-month post-therapy contraceptive period is mandatory because plasma concentrations of isotretinoin take approximately 10 days to return to physiologic levels after completing therapy.

Isotretinoin has a more limited effect on hidradenitis suppurativa and dissecting cellulitis of the scalp, disorders that may occur together with acne conglobata as part of the follicular occlusion tetrad. Some investigators recommend oral isotretinoin during the weeks or months preceding surgery for hidradenitis suppurativa, and sometimes also during the postoperative period.

Cutaneous T-cell lymphoma

Isotretinoin and etretinate are somewhat effective and are considered to be of equal potency in the treatment of mycosis fungoides (MF). Retinoids can be used in combination with PUVA, interferon or systemic chemotherapy. Despite initial improvement of the various stages of MF, it is often impossible to maintain remissions with these retinoids as monotherapy.

Both oral and topical bexarotene can produce responses in CTCL. Two multicenter clinical trials of oral bexarotene were conducted in patients with stage I–IIA (early) disease (n = 58)[31] or stage IIB–IVB (advanced) disease (n = 94)[32]. Patients in the early-stage study who were randomly assigned to a low-dose arm of 6.5 mg/m^2/day had a 20% response rate, in contrast to 54% and 67% for patients receiving starting doses of 300 mg/m^2/day and 650 mg/m^2/day (then decreased to 500 mg/m^2/day), respectively[31]. However, dose-dependent toxicity was a significant problem. Responses rates were approximately 50% for the patients with advanced CTCL, who all received doses of 300–650 mg/m^2/day[32,33].

The FDA approved bexarotene in December 1999 as oral therapy for CTCL that has been refractory to at least one systemic agent, and in June 2000 as a topical gel formulation for refractory early-stage CTCL. Given the high incidence of side effects, in particular hyperlipidemia (see below), a commonly recommended starting dose for oral bexarotene is 150 mg/m^2/day (Table 126.4). Combination therapies utilizing bexarotene together with PUVA, narrowband UVB, interferon-α, denileukin diftitox or methotrexate have also been evaluated in clinical trials and case series.

Chronic hand eczema

In a randomized, double-blind, placebo-controlled, multicenter study, 1032 adults with severe chronic hand eczema were treated with 30 or 10 mg of oral alitretinoin or placebo once daily for 12–24 weeks. Responses, defined as clear or almost clear hands, were achieved in 48%, 28% and 17% of the patients in the three groups, respectively. Treatment was well tolerated, with dose-dependent adverse events including headache, mucocutaneous side effects, hyperlipidemia and hypothyroidism. The median time to relapse, defined as recurrence of 75% of initial signs and symptoms, was 6 months in the absence of any further therapy[34].

Oral alitretinoin (which is not currently available in the US) therefore represents a therapeutic option for adults with severe, recalcitrant chronic hand eczema. Improvement is more rapid at higher doses (e.g. 30 mg daily) and typically develops after approximately 4 weeks of treatment. Because alitretinoin tends to induce remissions in hand eczema patients, intermittent 12- to 24-week courses may be suitable for long-term management of this condition.

Other "off-label" clinical uses

The pleomorphic effects of retinoids explain the potential benefits that they provide to patients with a broad spectrum of cutaneous disease. Although many skin disorders respond to retinoids (see Table 126.3), benefit has been established in controlled studies for relatively few conditions[35].

Ichthyosis

The best results can be obtained by using acitretin for non-bullous congenital ichthyosiform erythroderma and lamellar ichthyosis (Fig. 126.5). Good results have also been observed in patients with X-linked recessive ichthyosis and ichthyosis vulgaris; however, these diseases tend to be less severe and do not usually require systemic retinoid therapy. Given the lifelong duration of heritable ichthyoses, intermittent retinoid courses are sometimes prescribed.

Darier disease

Severe forms of Darier disease are often treated with systemic retinoids, but therapy should be initiated with a very low dose (e.g. acitretin 10 mg/day) in order to prevent an initial exacerbation of the disease; 20 mg/day of acitretin is usually sufficient for significant improvement.

APPROACH TO INITIATING ORAL BEXAROTENE THERAPY FOR CUTANEOUS T-CELL LYMPHOMA			
	Bexarotene administration	**Monitoring**	**Management of side effects**
Prior to treatment		Baseline CBC, basic metabolic panel, hepatic panel, TSH, free T4, fasting lipid panel, CK Determine if patient takes medications that inhibit or induce CYP3A4 (see Ch. 131)	Dietary and lifestyle modifications to minimize risk of hyperlipidemia If pre-existing laboratory abnormalities, administer: • Levothyroxine to achieve normal free T4 levels • A fibrate (e.g. fenofibrate)* to achieve triglyceride level <200 mg/dl and HDL level >50 mg/dl • A statin† to achieve LDL level <160 mg/dl
Day −7			Start fibrate (e.g. fenofibrate 145–200 mg daily)*
Day 0	Start bexarotene 150 mg/m^2 daily		Start levothyroxine 0.05 mg daily
Days 7 to 28		Free T4‡ & fasting lipid panel every 1–2 weeks	Adjust levothyroxine and fibrate doses and/or add statin† as required to keep laboratory values in target ranges above
Day 28§	Increase to bexarotene 300 mg/m^2 daily		
Day 29 onward	Adjust bexarotene dose as needed depending on disease response	Free T4‡ & fasting lipid panel every 1–2 weeks until in target range and after subsequent dose changes, otherwise every 1–2 months CBC every 1–2 months	As above; a triglyceride level <400 mg/dl may be a more realistic target for some patients

*Reduce dose for patients with decreased creatinine clearance; because gemfibrozil raises bexarotene levels, these medications should ***not*** be administered concomitantly.
†Niacin represents another option for patients with combined hyperlipidemia; patients receiving a fibrate and statin concomitantly may be at increased risk of rhabdomyolysis.
‡Monitor free T4 as indicator of hypothyroidism; bexarotene lowers TSH levels (central hypothyroidism)
§May increase dose as early as day 14 or, if more time is required to normalize lipid and free T4 levels, after day 28.

Table 126.4 Approach to initiating oral bexarotene therapy for cutaneous T-cell lymphoma. CBC, complete blood count; CK, creatine kinase; HDL, high-density lipoprotein; LDL, low-density lipoprotein; T4, thyroxine; TSH, thyroid-stimulating hormone.

Figure 126.5 Lamellar ichthyosis. Before (**A**) and after (**B**) treatment with acitretin.

Pityriasis rubra pilaris

Treatment with an oral retinoid can lead to clearance of pityriasis rubra pilaris (PRP) (Fig. 126.6). In extensive cases, concomitant use of methotrexate may be advantageous. Etretinate and acitretin are considered to be superior to isotretinoin for the treatment of adult-onset PRP[36].

Rosacea

In severe or treatment-resistant rosacea, isotretinoin typically has a greater effect on inflammatory lesions than on vascular manifestations[37]. A low daily dose (10 mg) is often sufficient, although higher-dose acne vulgaris regimens are sometimes used for severe disease.

Premalignant and malignant skin lesions

Etretinate and acitretin were both shown to be effective in the treatment of premalignant skin lesions, including human papillomavirus-induced neoplasia and actinic keratoses. In patients with nevoid basal cell carcinoma syndrome and xeroderma pigmentosum, these drugs may reduce the development of skin cancers. A double-blind study demonstrated that acitretin (30 mg/day for 6 months) prevented the development of premalignant and malignant cutaneous neoplasms in renal transplant recipients[38].

Lupus erythematosus

Both isotretinoin and acitretin have been used successfully in patients with various forms of lupus erythematosus (LE). Recurrence of the

Figure 126.6 Pityriasis rubra pilaris. Before (**A**) and after (**B**) treatment with acitretin.

lesions after completion of the treatment is a limiting factor. Comparable therapeutic efficacy has been observed for acitretin and hydroxychloroquine in chronic and subacute cutaneous LE[39].

DOSAGE

The different formulations, strengths and standard dosage ranges of topical and systemic retinoids currently available for use in dermatology are outlined in Table 126.5.

CONTRAINDICATIONS

Topical Retinoids

Topical retinoids should be avoided during pregnancy and nursing, due primarily to medicolegal issues raised by the teratogenicity of oral isotretinoin. Concomitant use of irritating topical products (e.g. abrasive cleansers, astringents) should be avoided.

Systemic Retinoids

The absolute contraindications are pregnancy or women contemplating becoming pregnant, non-compliance with contraception, breastfeeding, and hypersensitivity to preservatives present in acitretin's capsule (parabens). Relative contraindications are leukopenia, moderate to severe hypercholesterolemia or hypertriglyceridemia, significant hepatic (especially for bexarotene) or renal dysfunction, hypothyroidism (especially for bexarotene), suicidal ideation and pseudotumor cerebri. Patients should be advised not to take vitamin A supplements in excess.

MAJOR SIDE EFFECTS

Topical Retinoids

By far the most common side effect of topical retinoids is skin irritation characterized by erythema and peeling (Table 126.6). This "retinoid dermatitis" typically occurs during the first month of treatment and tends to recede thereafter. It usually responds to a temporary reduction

VARIOUS FORMULATIONS OF TOPICAL AND SYSTEMIC RETINOIDS				
Retinoid	**Route (Pregnancy category)**	**Formulations**	**Standard dosage range**	**Major indications**
Retinol	Topical	Various (0.15%, 0.3%)		Cosmeceutical products
Retinaldehyde	Topical	Various (0.05–0.1%)		
Tretinoin	Topical (C)	Gel, cream, solution (0.1%, 0.05%, 0.04%, 0.025%, 0.02%, 0.01%)		Acne vulgaris Photoaging
	Oral (X)	10 mg capsules	45 mg/m^2/day	Acute promyelocytic leukemia
Tazarotene	Topical (X)	Gel, cream (0.05%, 0.1%)		Acne vulgaris Plaque-type psoriasis Photoaging
Adapalene	Topical (C)	Gel, cream, lotion (0.1%, 0.3%)		Acne vulgaris
Isotretinoin	Topical (C)	Gel (0.05%)		Acne vulgaris*
	Oral (X)	10, 20, 30, 40 mg capsules	0.5–2 mg/kg/day	Severe, recalcitrant acne; related dermatoses*
Acitretin	Oral (X)	10, 17.5, 22.5, 25 mg capsules	25–50 mg/day	Psoriasis Disorders of keratinization*
Bexarotene	Topical (C)	Gel (1%)		Cutaneous T-cell lymphoma
	Oral (X)	75 mg capsules	300 mg/m^2/day	
Alitretinoin	Topical (D)	Gel (0.1%)		Kaposi sarcoma
	Oral	10, 30 mg capsules	10–30 mg/day	Chronic hand eczema*
Motretinide (etretinate derivative)	Topical (C)	Cream, solution (0.1%)		Acne vulgaris*

*Not an FDA-approved indication.

ADVERSE EFFECTS OF TOPICAL RETINOIDS	
Skin irritation (retinoid dermatitis)	Erythema Peeling, scaling Dryness Burning Pruritus Photosensitivity
Uncommon	Hypo- or hyperpigmentation Ectropion Allergic contact dermatitis Sticky skin

Table 126.6 Adverse effects of topical retinoids.

in the frequency, amount or duration (e.g. "short contact" therapy) of retinoid application and to the use of moisturizers. Desquamation and peeling correspond to the hyperproliferative response of the epidermis to tretinoin mediated by RARs, but the erythema does not seem to be receptor-mediated[40]. The perioral area of the face is most sensitive to peeling, and retinoid use in this region can be limited or avoided.

Although no photoallergic or phototoxic reactions have been proven for topical retinoids, many patients note a decreased tolerance to UV radiation. This reaction tends to develop shortly after sun exposure and is often accompanied by a sensation of heat, raising the question of involvement of infrared irradiation. The potential for teratogenicity from use of topical retinoids is very low. Systemic absorption of topically applied retinoids has been inconsequential in both animal and human studies[41], and there is no evidence that topical application of tretinoin during pregnancy causes congenital disorders. Temporary worsening of acne may occur within the first weeks of therapy. Uncommon side effects include transient hypo- or hyperpigmentation, koebnerization of psoriasis (especially with tazarotene), allergic contact dermatitis, and ectropion.

RETINOID EMBRYOPATHY
CRANIOFACIAL
• Atresia of the ear canal, microtia, anotia • Microphthalmia • Asymmetry of the face • Cleft palate • Micrognathia
CARDIOVASCULAR (ESPECIALLY CONOTRUNCAL AND AORTIC ARCH DEFECTS)
• Transposition of the great vessels • Tetralogy of Fallot • Truncus arteriosus • Supracristal ventricular septal defect • Interrupted aortic arch • Retroesophageal right subclavian artery • Hypoplastic aorta
CENTRAL NERVOUS SYSTEM
• Hydrocephalus • Microcephaly • Cortical agenesis • Cerebellar hypoplasia • Mental retardation • Difficulty with visual motor integration
THIRD AND FOURTH PHARYNGEAL POUCHES
• Thymic hypoplasia • Parathyroid hypoplasia
OTHER
• Limb anomalies • Anal and vaginal atresia

Table 126.7 Retinoid embryopathy.

Systemic Retinoids

Teratogenicity is the most concerning adverse effect of oral retinoids (Table 126.7). The side-effect profile of systemic retinoids (Table 126.8) resembles the toxic effects of vitamin A or hypervitaminosis A syndrome. Acute retinoid toxicity can include mucocutaneous (most common) and laboratory abnormalities, while chronic retinoid toxicity may occasionally produce bony changes.

Teratogenicity

Systemic retinoids are potent teratogens, and fetal deformities are the major concern in treating fertile women with oral retinoids. So far, with regard to teratogenicity, no safe minimal dose during pregnancy has been established. The defects seen in retinoid embryopathy can include craniofacial (microtia/anotia, micrognathia), cardiovascular, thymic and central nervous system (CNS; hydrocephalus, microcephaly) abnormalities (see Table 126.7)[42]. These malformations may lead to spontaneous abortion, premature birth, or fetal death. The putative mechanism involves toxic effects on neural crest cells, particularly with exposure during the fourth week of gestation. No typical retinoid embryopathy malformations have been reported in pregnancies where only the male partner was taking acitretin or isotretinoin at the time of conception. However, it is usually recommended that men who are actively trying to father children avoid systemic retinoid therapy.

In the US, physicians and patients (female or, to prevent sharing of medication, male) must register with a pregnancy risk management program (iPLEDGE) in order for isotretinoin to be prescribed. The program requires monthly office visits for all patients and monthly pregnancy testing for female patients with childbearing potential.

Skin and mucous membrane adverse effects

Dose-dependent mucocutaneous toxicity is the most commonly observed side effect of oral retinoids, and it reflects decreased production of sebum, reduced stratum corneum thickness, and altered skin barrier function (Fig. 126.7). Dry lips or cheilitis is the earliest and the most frequent finding (Fig. 126.8). Dryness of the mouth (accompanied by thirst), nasal mucosa (associated with fragility and epistaxis) and eyes (see below) are other potential manifestations.

Xerosis of the skin and associated pruritus, peeling (especially of the palms and soles) and fissuring (particularly of the fingertips) are frequent side effects. Exacerbations of atopic dermatitis may occur. Photosensitivity is occasionally observed, in particular with isotretinoin, and probably reflects a reduction in the thickness of the stratum corneum. *Staphylococcus aureus* colonization correlates with isotretinoin-induced reduction in sebum production and may lead to overt cutaneous infections. Diffuse hair loss (telogen effluvium) is a relatively common complaint, although objective alopecia tends to occur only at high dosage levels. Effects on the nail apparatus can include thinning, fragility and shedding of the nail plate as well as paronychia-like changes with periungual granulation tissue.

Mucocutaneous side-effect profiles vary among the systemic retinoids. Isotretinoin causes more mucosal dryness, and acitretin has been associated with higher incidences of alopecia and palmoplantar peeling, whereas bexarotene induces milder mucocutaneous and ocular side effects than other oral retinoids.

Systemic toxic effects

Bone toxicity

Bone pain can occur in retinoid-treated patients without objective evidence of any abnormalities and without sequelae. Several reports have also implicated therapy with oral retinoids, including etretinate and isotretinoin, in the formation of diffuse hyperostoses of the spine (diffuse idiopathic skeletal hyperostosis [DISH] syndrome-like changes) as well as calcification of tendons and ligaments, particularly in the ankles[43]. Specific findings include anterior spinal ligament calcification, osteophyte ("spur") formation, extraspinal calcifications, and bony bridges, but not narrowing of the disk space (Fig. 126.9). More rarely, ossification of the spinal posterior longitudinal ligament has been reported; this change, which can be progressive, may lead to spinal cord compression with signs of partial spastic paraplegia[44].

Based on data from retrospective studies, it was concluded that although many of the bone changes observed were common in the general population (especially adults) and could *not* be attributed with certainty to etretinate or acitretin therapy, spurs and interosseous membrane and tendon calcifications were probably treatment-related[45]. Of

ADVERSE EFFECTS OF SYSTEMIC RETINOIDS		
Acute effects	Mucocutaneous	Xerosis with pruritus* Cheilitis* Dry mucosa*: mouth, nose (epistaxis), eyes (see below) Skin fragility* Retinoid dermatitis (see Table 126.6)* Palmoplantar peeling* Photosensitivity Sticky sensation (palms, soles) Granulation tissue and pyogenic granuloma-like lesions Nail fragility with softening, onycholysis, paronychia Facial swelling *Staphylococcus aureus* infection Telogen effluvium, hair thinning
	Ocular	Xerophthalmia* Blepharoconjunctivitis, corneal ulceration Reduced night vision Blurred vision, photophobia, keratitis
	Systemic	Myalgias Arthralgias Anorexia, nausea, diarrhea, abdominal pain Headache, pseudotumor cerebri (rare) Fatigue, lethargy, irritability Depression, suicidal ideation (rare and controversial) Toxic hepatitis (rare) Clinical signs of hypothyroidism (with bexarotene*) Pancreatitis secondary to hypertriglyceridemia (rare) Hyperuricemia with gout (rare)
	Laboratory	Elevated liver function tests (usually transient, minor): AST, ALT, alkaline phosphatase, LDH, bilirubin Hyperlipidemia: hypertriglyceridemia*; increased cholesterol, VLDL and LDL; decreased HDL Decreased free thyroxine (T4) (with bexarotene*) Elevated creatine kinase Leukopenia (with bexarotene) Agranulocytosis (with bexarotene) Thrombocytosis, thrombocytopenia Hypercalcemia (rare)
Chronic effects	Mucocutaneous	Alopecia (rare) Dry eyes (rare)
	Systemic	DISH syndrome-like bone changes: Osteophyte and bony bridge formation, especially of vertebrae (rarely clinically significant at dosages for acne) Anterior > posterior spinal ligament calcification Extraspinal tendon and ligament calcification Osteoporotic changes in long bones (rare, with possible exception of long-term etretinate) Premature epiphyseal closure (rare) Periosteal thickening Myopathy (rare)

Figure 126.7 Retinoid dermatitis: Xerosis, peeling and erythema of the face in a patient treated with oral isotretinoin.

Figure 126.8 Cheilitis in an isotretinoin-treated patient.

Figure 126.9 Osteophytes and bony ridges without narrowing of the disk spaces in an acne patient treated with a prolonged (several-year) course of isotretinoin.

note, prospective studies have shown that the effect of retinoids on bone, if present at all, is likely to involve worsening of pre-existing skeletal overgrowth rather than induction of *de novo* changes. Even long-term use of isotretinoin in acne patients rarely causes clinically significant radiologic abnormalities, as most hyperostoses are asymptomatic and clinically insignificant[46].

Osteoporosis has been observed with hypervitaminosis A and after long-term therapy with etretinate but not with isotretinoin[47]. A mean bone density loss of 4.4% in Ward's triangle of the femur was observed in 18 young men (without measurable alterations of calcium metabolism) after 6 months of isotretinoin use (1 mg/kg); bone changes differed compared with controls at this site ($p = 0.04$) but not in the humoral neck or lumbar spine[48]. Subsequent investigations in patients receiving similar isotretinoin regimens, including an open-label trial in 217 adolescents and two controlled studies in adolescents and young adults (21 and 36 patients), showed no significant change in bone mineral density[49,50]. In children, only a few cases of skeletal abnormalities, including osteoporosis, periosteal thickening, slender long bones and premature epiphyseal closure[51,52], have been reported. No baseline X-rays are required, although monitoring high-risk patients who require prolonged high-dose retinoid therapy may be useful.

Muscle effects

Although muscular pain and cramps can occur in patients taking etretinate or acitretin, these symptoms are more common with isotretinoin therapy, especially in individuals involved in vigorous physical activity. Occasionally, elevated creatine kinase levels may be observed. Increased muscle tone as well as axial muscle rigidity and myopathy have been reported in patients receiving etretinate and acitretin therapy, respectively[53].

Central nervous system and psychiatric effects

CNS side effects are rare. Although individual signs of increased intracranial pressure, such as headache, nausea and vomiting, are occasionally observed, the complete pseudotumor cerebri syndrome with papilledema and blurred vision is very rare[54]. Concomitant use of other drugs associated with intracranial hypertension (e.g. tetracyclines) is considered a risk factor for developing pseudotumor cerebri and should therefore be avoided[55]. Examination for papilledema should be performed immediately when a patient receiving retinoid therapy complains of a persistent headache, especially if it is accompanied by visual changes, nausea or vomiting, or when pseudotumor cerebri is otherwise suspected.

Although anecdotal reports have suggested a link between isotretinoin therapy in acne patients and depression, psychosis and suicide attempts, a causal association has not been established[56]. Multiple prospective studies have failed to find a significant increase in depressive symptoms or depression diagnoses following initiation of isotretinoin therapy for acne, and several studies actually noted a significant decrease in depressive symptoms compared to baseline or a control group receiving other acne therapies[57]. Among population-based studies, large case–control and prescription sequence symmetry analyses did not provide evidence of an association between isotretinoin exposure and depression or suicidal behavior, but a small case-crossover study showed a significant 2.8-fold higher likelihood of exposure to isotretinoin in the 5 months prior to (compared with the 7–12 months prior to) an initial diagnosis of depression in patients with acne[56]. Patients with depressive symptoms or suicidal ideation should be advised about the possible association with psychiatric effects prior to initiating treatment and carefully monitored[56].

Ophthalmologic side effects

The most common ocular retinoid effects are dryness and irritation. Xerophthalmia due to decreased meibomian gland secretions may prohibit the use of contact lenses and can lead to blepharoconjunctivitis or corneal ulceration. If artificial tears and topical ophthalmologic antibiotic ointment fail to alleviate the conjunctivitis, ophthalmologic consultation should be sought. Alterations in visual function, mainly nyctalopia (reduced night vision), excessive glare sensitivity, and changes in color perception, have also been reported[58]. Competitive inhibition of ocular retinol dehydrogenase by retinoids, resulting in decreased rhodopsin formation, may be the cause of nyctalopia.

Other systemic effects

Hypothyroidism

Clinical and biochemical central hypothyroidism occurred in 40% of patients in the CTCL trials with bexarotene and was rapidly and completely reversible with cessation of therapy, without any clinical sequelae[31,59]. This effect is probably mediated through suppression of thyroid-stimulating hormone β-subunit (TSH-β) secretion by the thyrotrope cells of the anterior pituitary, which express RXR-γ. Free T4 levels should be monitored before and during bexarotene therapy and normalized with thyroid hormone replacement as necessary (see Table 126.4)[33].

Gastrointestinal side effects

Uncommon nonspecific gastrointestinal complaints have been reported in association with retinoid therapy. Retinoids have been temporally linked with other gastrointestinal conditions, such as case reports of isotretinoin administration preceding the onset of inflammatory bowel disease. However, a cause-and-effect relationship has not been established to date. One recent large population-based study found that patients with inflammatory bowel disease were no more likely to have used isotretinoin prior to diagnosis than matched controls[60], but another large case-control study found that ulcerative colitis (but not Crohn's disease) was associated with previous isotretinoin use[60a].

Renal effects

Renal toxicity is not characteristic of retinoid therapy. Isotretinoin has been safely administered to patients with end-stage kidney disease who were undergoing hemodialysis. However, reversible renal dysfunction (with elevated creatinine levels) during etretinate therapy has been described. Renal function should be monitored in patients with a history of kidney disease[61].

Laboratory abnormalities

Dyslipidemia

Hypertriglyceridemia is the most frequently observed systemic effect of retinoid therapy. Isotretinoin and etretinate/acitretin elevate triglycerides in 50% and cholesterol in 30% of treated patients[62], whereas bexarotene induces elevated triglycerides and cholesterol in approximately 79% and 48% of patients, respectively[31]. In addition, a concomitant increase in total and low-density lipoprotein (LDL)

cholesterol is frequently observed. In cases of severe retinoid-induced hypertriglyceridemia, eruptive xanthomas and acute hemorrhagic pancreatitis may occur. A higher incidence of acute hemorrhagic pancreatitis has been encountered in patients taking bexarotene, as compared to first- or second-generation retinoids.

Baseline fasting serum lipid levels should be obtained before initiating bexarotene therapy and every 1 to 2 weeks during therapy until levels become stable (generally in 4 to 8 weeks) (see Table 126.4). For other oral retinoids, monitoring levels monthly for the first 2 months and then at 2- to 3-month intervals is adequate if baseline lipid levels are normal, there are no increases in dosage, and risk factors (obesity, high alcohol intake, diabetes) are absent. Discontinuation of therapy is suggested if fasting triglycerides reach 800 mg/dl (8 g/l). Less severe increases may be treated by dose reduction, withdrawing therapy until normalization of serum lipids occurs, and changes in diet or lifestyle. In some instances, lipid-lowering agents may be indicated[63]. Coadministration of bexarotene with a statin (e.g. atorvastatin) for hypercholesterolemia and/or fenofibrate for hypertriglyceridemia is recommended to treat retinoid-induced hyperlipidemia and to lower the risk of pancreatitis[6,64]. Some authors recommend starting all patients on fenofibrate 7 days before initiating bexarotene treatment (see Table 126.4)[33].

The effects of retinoid-induced hyperlipidemia during long-term therapy on the development of atherosclerotic cardiovascular disease is unknown. Retinoids probably cause hyperlipidemia by interfering with lipid clearance. Bexarotene increases the expression of apolipoprotein C-III, which prevents the uptake of lipids from very-low-density lipoproteins (VLDL) into cells[65]. Of note, individuals who develop hypertriglyceridemia during isotretinoin therapy for acne may be at increased risk for future metabolic syndrome.

Liver toxicity

Transitory elevations in serum transaminases occur in approximately 20% of patients treated with either etretinate or acitretin and much less frequently in those receiving isotretinoin or bexarotene therapy. Circulating levels of alkaline phosphatase, lactic dehydrogenase and bilirubin may also become elevated during retinoid therapy. Liver function test abnormalities are typically mild, usually developing between 2 and 8 weeks after starting therapy and then returning to normal within another 2–4 weeks despite continued therapy. Severe or persistent hepatotoxic reactions occur in fewer than 1% of patients. Acitretin therapy elicited no biopsy-proven hepatotoxicity in a 2-year prospective study, thus suggesting that periodic liver biopsy is not necessary[66]. No studies have specifically evaluated the use of retinoids in patients with hepatic insufficiency. However, since retinoids are metabolized by hepatic cytochrome P450 isoenzymes (e.g. CYP3A4) and undergo partial biliary elimination, significant hepatic insufficiency is likely to interfere with drug elimination. Transaminase elevations to greater than three times the upper limit of normal should prompt discontinuation of retinoid therapy. With two- to three-fold transaminase elevations, therapy should be withdrawn until normalization occurs[6]. Other causes of hepatic dysfunction should be excluded.

Hematologic toxicities

A high incidence (28%) of dose-related leukopenia was reported in studies of bexarotene for CTCL, occurring as early as 2–4 weeks, and characterized by a decrease in neutrophils rather than lymphocytes[31]. Hematologic abnormalities are much less common with other retinoids, but careful hematologic monitoring in HIV-infected patients is warranted.

Summary

Most adverse effects associated with retinoids are preventable or manageable through proper patient selection, diligent monitoring and dose adjustments (or occasionally discontinuation of treatment) as indicated.

INTERACTIONS

Concurrent use of retinoids with alcohol or other medications having similar side effects may increase the incidence of adverse events. The following should be avoided or used with caution:

- tetracycline, doxycycline, minocycline (may increase intracranial pressure)
- alcohol (increased conversion of acitretin to etretinate and hepatotoxicity)
- methotrexate (synergistic liver toxicity with retinoids; however, combination may be used with caution in patients with PRP or severe psoriasis)
- vitamin A supplements (risk of hypervitaminosis A).

Retinoid drug levels and resultant potential for toxicity may increase with CYP3A4 inhibitors such as azoles and macrolides. In contrast, antituberculosis drugs (rifampin) and anticonvulsants (phenytoin and carbamazepine) may decrease the drug levels of retinoids via CYP3A4 induction. Retinoids may also increase the drug levels of cyclosporine via competition for CYP3A4 metabolism[6]. Concomitant administration of bexarotene and gemfibrozil results in a substantial increase in plasma concentrations of bexarotene, at least partially because of cytochrome P450 CYP3A4 inhibition that is induced by gemfibrozil. Concomitant fenofibrate (for hypertriglyceridemia) or atorvastatin (for hypercholesterolemia) administration does not affect bexarotene plasma levels and, therefore, can be utilized together with bexarotene (see Table 126.4).

In rare instances, patients with diabetes mellitus may have more difficult glucose control while taking a retinoid; however, the causal relationship remains uncertain. Acitretin has been shown to possibly reduce the efficacy of progestin-only contraceptives. Also, unprotected UV radiation exposure or photosensitizing medications should be avoided because of increased photosensitivity caused by retinoid therapy. Since retinoids act through nuclear receptor dimers, cross-talk with other nuclear receptors may provide synergistic effects: for example, interactions between RXR and VDR positively influence the action of vitamin D_3; however, cross-talk with PPAR and its ligands is still under investigation.

USE IN PREGNANCY AND LACTATION

All systemic retinoids are teratogenic and are absolutely contraindicated during pregnancy and lactation (FDA category X), which should be excluded by pregnancy test(s) before considering retinoid therapy and then at regular intervals (e.g. monthly in the case of isotretinoin) during its administration. In the US, two pregnancy tests are required before instituting isotretinoin therapy. Pregnancy not only is an absolute contraindication to starting therapy; it must also be avoided throughout therapy and for an appropriate interval after completion of therapy. Adequate contraception for at least 1 month before therapy is required for all systemic retinoid therapy. Acitretin requires contraception for 3 years (US) or 2 years (Europe) after cessation of therapy, whereas isotretinoin, bexarotene and alitretinoin require contraception for just 1 month after cessation of therapy.

Although no evidence exists for teratogenicity of topical retinoids in humans, they are nevertheless not recommended for use during pregnancy. Since no dermatologic condition that is known to be responsive to topical retinoids is life-threatening to the mother or fetus, it is wiser to postpone treatment until after delivery (primarily due to medicolegal rather than scientific data in the opinion of the authors). The same recommendations are also valid for lactating women, as it is not known whether topical retinoids pass into the breast milk. Consequently, topical retinoid use is not recommended during breastfeeding.

Antimicrobial Drugs 127

Jack L Lesher Jr and R Carol McConnell

Key features

- Bacterial, fungal and viral infections of the skin and soft tissue are very common
- Selection of the appropriate treatment depends on the infecting microbe, the site and extent of the infection, and patient characteristics (e.g. age, pregnancy/lactation, comorbid medical conditions)
- Physicians must be aware of the drug interactions and potential adverse effects of antimicrobial medications

ANTIBACTERIAL AGENTS

Introduction

The hundreds of antibiotics now available provide physicians with a formidable armamentarium against bacterial diseases. While physicians have gained abundant therapeutic options, some find the vast number of antibacterial medications confusing and overwhelming. Selection of the most appropriate antibiotic depends upon identification of the infecting organism and its sensitivity to antimicrobial agents. Often a patient will present with a clinical picture strongly suggestive of a particular organism. When possible and practical, a culture should be obtained prior to starting therapy.

In acutely ill patients, empiric therapy with broad-spectrum antibiotics may be necessary initially. Knowledge of local bacterial resistance patterns should guide antibiotic selection. Once the microbe is identified, preferably along with antibiotic sensitivities, the medication can be adjusted accordingly. Indiscriminate use of broad-spectrum antibiotics leads to the development of resistant bacteria[1,2]. The site and extent of the infection; the side effect profiles and costs of possible medication choices; and patient characteristics, including age and medical comorbidities (e.g. impaired renal or hepatic function) as well as pregnancy and lactation status, also influence drug selection.

Antibacterial drugs are characterized as being either bacteriostatic or bactericidal. Bacteriostatic drugs stop growth and replication of bacteria and limit spread of infection, allowing the immune system to eliminate the pathogen. Bactericidal agents kill bacteria directly. Table 127.1 outlines into which category commonly used antibiotics are classified.

BACTERIOSTATIC VERSUS BACTERICIDAL DRUGS

Bacteriostatic	Bactericidal
Chloramphenicol	Aminoglycosides
Clindamycin	Bacitracin
Erythromycin	Carbapenems
Sulfonamides	Monobactams
Tetracyclines	Penicillins
Trimethoprim	Polymyxin B
	Quinolones
	Vancomycin

Table 127.1 Bacteriostatic versus bactericidal drugs. Clindamycin may be either bacteriostatic or bactericidal depending on the susceptibility of the infecting organism and the concentration achieved at the site of infection. Factors such as the infecting organism and growth conditions can also affect whether other drugs are bacteriostatic or bactericidal.

Topical Antibacterial Agents

Introduction

Topical antibacterials are used to treat acne vulgaris, rosacea and superficial bacterial infections and to prevent infection after surgery or injuries. Topical antibacterials can easily be applied directly to the affected skin and thus deliver a high concentration of the medication locally with relatively little chance of adverse systemic effects. However, their utility is limited to localized superficial conditions.

Topical antibacterial agents used to treat acne vulgaris and rosacea

Table 127.2 lists topical antibiotics commonly used to treat acne vulgaris and rosacea. Topical antibiotics are used in these conditions for their anti-inflammatory properties as well as for their antibacterial effects. They have limited benefit for non-inflammatory, comedonal acne.

Mechanisms of action

Table 127.3 lists the mechanisms of action of topical antibacterials used to treat acne vulgaris and rosacea.

Azelaic acid (see Ch. 129) is a dicarboxylic acid derivative found in whole grain cereals and animal products, and it is normally present in human plasma. *In vitro*, azelaic acid has activity against *Propionibacterium acnes* and *Staphylococcus epidermidis*. It is usually bacteriostatic but may be bactericidal in high concentrations. Its activity may be due to inhibition of microbial cellular protein synthesis. Azelaic acid has anticomedonal effects by normalizing keratinization. It thins the stratum corneum, decreases the number and size of keratohyalin granules, and reduces the amount and distribution of filaggrin in the epidermis. Azelaic acid has antiproliferative effects against hyperactive and abnormal melanocytes, but it rarely causes hypo- or depigmentation of normally pigmented skin (see Table 127.4).

Benzoyl peroxide is bacteriostatic against *P. acnes*. Once absorbed by the skin, it is converted to benzoic acid. Its effects are believed to be due to oxidation of bacterial proteins by reactive oxygen species, which are released when the drug is decomposed by cysteine in the skin. Daily use of 10% benzoyl peroxide for 2 weeks decreases free fatty acids by 50% and *P. acnes* by 98%, which is comparable to results obtained after use of topical antibiotics for 4 weeks[3]. Benzoyl peroxide is also keratolytic and desquamative.

Clindamycin is a semisynthetic lincosamide antibiotic that is active against Gram-positive cocci and anaerobes including staphylococci, streptococci, *P. acnes, Corynebacterium* spp., *Clostridium* spp. and *Gardnerella vaginalis*. Clindamycin may be either bacteriostatic or bactericidal depending on the susceptibility of the infecting organism and the concentration achieved at the site of infection.

Erythromycin is a macrolide antibiotic that is active against Gram-positive cocci including group A β-hemolytic streptococci and *Staphylococcus aureus,* as well as some Gram-negative bacilli. Erythromycin also has anti-inflammatory properties.

Studies have shown that the combination of erythromycin and benzoyl peroxide is more effective for the treatment of acne than erythromycin alone both *in vivo* and *in vitro*[4–8]. Randomized, double-blind, controlled trials have also demonstrated that acne patients treated with the combination of clindamycin and benzoyl peroxide had a greater reduction in the number of inflammatory papules and pustules than did those treated with benzoyl peroxide alone, clindamycin alone or vehicle alone[9,10]. These synergistic combinations may also slow the development of antibiotic resistance. Several products containing erythromycin or clindamycin together with benzoyl peroxide are available.

TOPICAL ANTIBACTERIALS USED FOR ACNE VULGARIS AND ROSACEA				
Generic name	**Trade name(s)®**	**Formulations**	**Dosing frequency**	**FDA pregnancy category**
Azelaic acid	Azalea, Azelex, Cutacelan, Finacea, Finevin, Skinoderm, Skinoren	20% cream, 15% gel	bid	B
Benzoyl peroxide	Acetoxyl, Acne-Aid, Acnomel, Ambi, Benoxyl, Benzac, Benzagel, BenzaShave, BenzEFoam, Benziq, Brevoxyl, Clearasil, Clearplex, Clinac, Del-Aqua, Dermoxyl, Desquam-E, Desquam-X, Fostex, Inova, Lavoclen, Loroxide, Oxy, Oxyderm, NeoBenz, PanOxyl, Pacnex, Persa-Gel, Solugel, Triaz, Zapzyt	2.5–10% lotion, cream, gel, foam, solution, stick, cleansing bar, cleansing lotion, cloths, pads, mask, shaving cream	qd–tid; mask qwk	C
Clindamycin	Basocin, Cleocin T, Clinac, Clinda-Derm, Clindagel, Clindets, Cutaclin, Dalacin, Dalagis, Euroclin, Evoclin	1% gel, lotion, solution, foam, pledgets; 2% vaginal cream	bid	B
Erythromycin	Akne-Mycin, A/T/S, Emgel, Erycette, Eryderm, Erygel, Erymax, Ery-Sol, Erythra-Derm, ETS, Ilotycin, Sans-Acne, Staticin, Theramycin Z, T-Stat	1.5% or 2% solution; 2% pledgets, gel, ointment	bid	B
Sodium sulfacetamide	Klaron, Mexar, Ovace, Seb-Prev, Sebizon *With 5% sulfur:* Avar Cleanser, Clarifoam, Clenia, Novacet, Plexion, Prascion, Rosac, Rosaderm, Rosanil, Rosula, Sulfacet-R, Sulfatol, SulZee, Sumaxin, Suphera, Topisulf, Zetacet	10% lotion, cream, suspension, foam, wash/cleanser, cleansing cloths	bid	C
Metronidazole	MetroGel, MetroCream, MetroLotion, Noritate	0.75% or 1% gel, cream, lotion	qd–bid	B
Dapsone	Aczone	5% gel	bid	C
Benzoyl peroxide/erythromycin	Benzamycin	5%/3% gel	bid	C
Benzoyl peroxide/clindamycin	Acanya, Benzaclin, Duac, Z-Clinz	2.5–10%/1% gel	bid	C
Benzoyl peroxide/adapalene	Epiduo	2.5/0.1% gel	qd	C
Clindamycin phosphate/tretinoin	Veltin, Ziana	1.2/0.025% gel	qd	C

Table 127.2 Topical antibacterials used for acne vulgaris and rosacea. bid, twice daily; qd, daily; qwk, weekly; tid, three times daily.

Erythromycin (4%) has been combined with 1.2% zinc acetate, as has benzoyl peroxide (3–10%) with zinc lactate. The former product is not available in the US. Zinc has antiandrogen activity *in vitro* and suppresses sebum secretion[11]. Studies have shown erythromycin combined with zinc to be superior to placebo *in vivo*[12–15] and effective *in vitro* against erythromycin-resistant *P. acnes*[16]. However, it may be inferior to benzoyl peroxide combined with erythromycin[17].

Sodium sulfacetamide is bacteriostatic. It is active against some Gram-positive and Gram-negative organisms. Some topical preparations combine sodium sulfacetamide with sulfur, which acts as a keratolytic as well as antimicrobial agent (see Ch. 129).

Metronidazole is a nitroimidazole. Topical metronidazole has antioxidant and anti-inflammatory as well as antimicrobial effects.

Dapsone is a sulfone drug that, in addition to its antimicrobial properties, has anti-inflammatory effects that target neutrophils (e.g. inhibiting neutrophil chemotaxis, decreasing myeloperoxidase activity).

Indications

Azelaic acid, benzoyl peroxide, clindamycin, erythromycin, sodium sulfacetamide and dapsone can be used for mild to moderate inflammatory acne vulgaris. Azelaic acid may also be useful for melasma and other forms of hyperpigmentation. Benzoyl peroxide has been used for decubitus and stasis ulcers. Topical clindamycin and erythromycin can treat superficial bacterial infections of the skin, whereas topical clindamycin and metronidazole are both indicated for bacterial vaginosis. Sodium sulfacetamide and topical metronidazole are indicated for the treatment of rosacea.

Dosages

Topical antibacterial agents are usually used once or twice a day (see Table 127.2). A small amount of medication is applied in a thin layer onto clean, dry skin. Benzoyl peroxide cleansing bars and washes are used one to three times a day. Benzoyl peroxide shave cream is used like any other shaving cream, and the mask is applied in a thin layer once a week, left on for 15 to 25 minutes, and then rinsed off.

MECHANISMS OF ACTION OF TOPICAL ANTIBACTERIAL AGENTS USED TO TREAT ACNE VULGARIS AND ROSACEA		
Generic name	**Class**	**Mechanism of action**
Azelaic acid	Dicarboxylic acid derivative	Possibly inhibition of bacterial protein synthesis
Benzoyl peroxide	Oxidizing agent	Oxidation of bacterial proteins by reactive oxygen species
Clindamycin	Lincosamide	Inhibits protein synthesis by binding to the bacterial 50S ribosomal subunit
Erythromycin	Macrolide	Inhibits protein synthesis by binding to the bacterial 50S ribosomal subunit
Sodium sulfacetamide	Sulfonamide	Inhibits nucleic acid and protein synthesis and cell growth by impeding bacterial synthesis of dihydrofolic acid. Competitive inhibition of dihydropteroate synthetase prevents condensation of pteridine precursors with PABA (see Fig. 127.4)
Metronidazole	Nitroimidazole	May cause DNA strand breaking. Also has antioxidant and anti-inflammatory effects
Dapsone	Sulfone	Inhibits dihydropteroate synthase and prevents bacterial folic acid synthesis. Also decreases neutrophil chemotaxis and myeloperoxidase activity

Table 127.3 Mechanisms of action of topical antibacterial agents used to treat acne vulgaris and rosacea. PABA, para-aminobenzoic acid.

Contraindications

The chief contraindication for these medications is a history of hypersensitivity to any component of the formulation. Azelaic acid preparations contain propylene glycol, which may be a sensitizer. Topical clindamycin should be avoided in patients with a history of

SIDE EFFECTS OF TOPICAL ANTIBACTERIAL AGENTS USED FOR ACNE VULGARIS AND ROSACEA	
Generic name	**Side effects**
Azelaic acid	Pruritus, burning, stinging, tingling, erythema, xerosis, peeling, irritant contact dermatitis, allergic contact dermatitis Rarely reported: hypopigmentation, depigmentation, hypertrichosis, keratosis pilaris, exacerbation of recurrent herpes labialis
Benzoyl peroxide	Irritation; occasionally blistering, crusting, severe erythema, edema Bleaches hair and colored fabrics
Clindamycin	Gram-negative folliculitis Rare cases of pseudomembranous colitis (the suggested risk of pseudomembranous colitis from topical use appears not to be clinically significant[18])
Erythromycin	Eye irritation, skin tenderness, Gram-negative folliculitis, rarely generalized urticarial reactions Bacterial resistance
Sodium sulfacetamide	Xerosis, pruritus; may cross-react in patients allergic to related oral medications
Metronidazole	Watery eyes, metallic taste in the mouth, nausea, numbness and paresthesias have been reported with topical use[19]; may cross-react in patients allergic to the oral form
Dapsone	Dryness, peeling, erythema; in patients with G6PD deficiency, occasionally associated with a drop in the hemoglobin level

Table 127.4 Side effects of topical antibacterial agents used for acne vulgaris and rosacea. G6PD, glucose-6-phosphate dehydrogenase.

inflammatory bowel disease or antibiotic-associated colitis. These conditions may increase the chance of gastrointestinal side effects.

Major side effects

Adverse reactions to the topical antibacterial agents used to treat acne vulgaris and rosacea are usually mild and transient. Stinging is especially common with alcohol-containing solutions and pledgets. Table 127.4 lists side effects of individual drugs.

Interactions

Application of more than one topical medication simultaneously may increase or decrease the effect of one or both of the medications. Benzoyl peroxide may have additive irritant effects when used with other topical acne medications, and it can oxidize and thereby decrease the activity of tretinoin when these products are applied at the same time. Topically applied clindamycin may interact with other drugs as a result of systemic absorption. Clindamycin has neuromuscular blocking properties that may enhance the effects of similar agents. It should be used with caution in patients receiving neuromuscular blocking agents. Clindamycin, erythromycin and chloramphenicol may antagonize each other due to their similar mechanisms of action. Oral metronidazole may potentiate the anticoagulant effect of warfarin, resulting in a prolonged prothrombin time. It is not known whether topical preparations have the same effect. A temporary yellow–orange staining of the skin and hair occasionally occurs with concomitant use of topical dapsone and benzoyl peroxide, and systemic levels of dapsone increase if it is administered together with co-trimoxazole.

Pregnancy and lactation

Table 127.2 lists the FDA pregnancy categories of the topical antibacterial agents used to treat acne vulgaris and rosacea.

Azelaic acid has not been adequately studied in pregnant women. There is a small amount of systemic absorption of azelaic acid through topical application. Passage of azelaic acid into maternal milk may occur. There have been no reported problems due to azelaic acid in nursing infants.

Studies on the effects of benzoyl peroxide in pregnancy have not been done in either humans or animals. There may be systemic absorption of topically applied benzoyl peroxide. It is not known whether benzoyl peroxide is excreted in breast milk, but has not been reported to cause problems in nursing infants.

There are no adequate studies of topical clindamycin in pregnant or lactating women. It is not known whether topically applied clindamycin passes into breast milk. No serious adverse effects have been reported in nursing infants. Clindamycin vaginal cream is not recommended during pregnancy, except for women who are at high risk for a bad outcome due to bacterial vaginosis or in women who are at low risk of adverse pregnancy outcomes who also have symptomatic bacterial vaginosis.

Studies on the effects of topical erythromycin in pregnancy have not been done in humans or animals. Animal reproduction studies have not been done. Systemically administered erythromycin is excreted in breast milk, but it is not known whether topical erythromycin is excreted in breast milk. Erythromycin topical preparations have not been reported to cause problems in nursing infants.

Sulfonamides may increase the chance of kernicterus in newborns and should not be used late in pregnancy. Systemic sulfonamides are excreted in breast milk and may cause kernicterus, anemia and other adverse effects in nursing infants, especially those with glucose-6-phosphate dehydrogenase deficiency.

Topical metronidazole has not been studied in pregnant women. Systemic metronidazole crosses the placental barrier and enters the fetal circulation, and whether or not it has the potential to cause birth defects or other problems in animal studies has been the subject of controversy; it is generally recommended that systemic administration be avoided during the first trimester. Topical metronidazole results in blood levels much lower than those achieved with systemically administered metronidazole. The small amounts of this medication that are absorbed are unlikely to cause problems in nursing infants.

Topical antibacterial agents used to treat superficial infections

Table 127.5 lists antibacterial agents commonly used to prevent and treat superficial skin infections.

Mechanisms of action

The mechanisms of action of the topical antibacterial agents used to treat superficial infections are listed in Table 127.6.

Mupirocin (pseudomonic acid A) is derived from *Pseudomonas fluorescens*. It is clinically active against staphylococci, groups A, B, C and G streptococci, and some Gram-negative aerobic bacteria. It is usually bacteriostatic, but may be bactericidal at high concentrations.

Retapamulin is the first drug in the new pleuromutilin class, derived from fermentation of a mushroom, *Clitopilus passeckerianus*[20].

Neomycin and *gentamicin* are aminoglycoside antibiotics isolated from cultures of *Streptomyces fradiae* and *Micromonospora purpurea*, respectively. Neomycin is bactericidal against Gram-positive and Gram-negative bacteria including *S. aureus, Escherichia coli, Haemophilus influenzae, Proteus* spp. and *Serratia* spp. It is generally not effective against *Pseudomonas aeruginosa*. Gentamicin is effective against sensitive strains of group A β-hemolytic and α-hemolytic streptococci, *S. aureus* (coagulase-positive, coagulase-negative and some penicillinase-producing strains) and Gram-negative bacteria including *P. aeruginosa, Aerobacter aerogenes, E. coli, Proteus vulgaris* and *Klebsiella pneumoniae*.

Bacitracin is a cyclic polypeptide antibiotic produced by the Tracey I strain of *Bacillus subtilis*. It has a thiazolidine ring and peptide side chains. Bacitracin is active against Gram-positive organisms such as staphylococci, streptococci, corynebacteria and clostridia.

Polymyxin B is a cyclic lipopeptide antibiotic isolated from the aerobic Gram-positive rod *Bacillus polymyxa*, a soil organism. It is rapidly bactericidal for various Gram-negative organisms, including *P. aeruginosa, E. coli, K. pneumoniae, Enterobacter aerogenes, H. influenzae, Proteus mirabilis* and *Serratia marcescens*. It is not active against Gram-positive organisms.

Indications

Mupirocin, neomycin, gentamicin, bacitracin and combination products containing polymyxin B are all indicated for the treatment and prevention of superficial bacterial skin infections. The intranasal

TOPICAL ANTIBACTERIAL AGENTS USED FOR SUPERFICIAL INFECTIONS				
Generic name	**Trade name(s)®**	**Formulations**	**Dosing frequency**	**FDA pregnancy category**
Mupirocin	Bactoderm, Bactroban, Centany, Eismycin	2% ointment or cream	tid	B
Retapamulin	Altabax	1% ointment	bid	B
Neomycin	Myciguent	0.5% ointment or cream	qd–tid	C
Gentamicin	Garamycin, Gentamar, G-Myticin	0.1% ointment or cream	tid–qid	C
Bacitracin	Baciguent	400–500 units per gram ointment	tid	C
Polymyxin B	Polysporin ointment = bacitracin + polymyxin B Neosporin ointment = bacitracin, polymyxin B + neomycin Neosporin cream = polymyxin B + neomycin only	5000–10 000 units per gram ointment	qd–tid	C

Table 127.5 Topical antibacterial agents used for superficial infections. bid, twice daily; qd, daily; tid, three times daily.

MECHANISMS OF ACTION OF TOPICAL ANTIBACTERIAL AGENTS USED FOR SUPERFICIAL INFECTIONS		
Generic name	**Class**	**Mechanism of action**
Mupirocin	Unique	Inhibits protein synthesis by reversibly binding to bacterial isoleucyl transfer RNA synthetase
Retapamulin	Pleuromutilin	Selectively inhibits bacterial protein synthesis by interacting with the ribosomal protein L3 on the 50S ribosomal subunit
Neomycin	Aminoglycoside	Binds to the 30S subunit of the bacterial ribosome and causes misreading of the mRNA and inhibition of bacterial protein synthesis. May also inhibit bacterial DNA polymerase
Gentamicin	Aminoglycoside	Binds to the 30S subunit of the bacterial ribosome and causes misreading of the mRNA and inhibition of bacterial protein synthesis
Bacitracin	Cyclic polypeptide	Forms a complex with C55-phenol pyrophosphate, a component of the bacterial cell wall, impeding bacterial cell wall synthesis
Polymyxin B	Cyclic lipopeptide	Interacts with the phospholipids of bacterial cell membranes, increasing their cellular permeability

Table 127.6 Mechanisms of action of topical antibacterial agents used for superficial infections.

preparation made with the calcium salt of mupirocin is indicated for the eradication of nasopharyngeal carriage of *S. aureus*. Studies implicating nasal staphylococci as a potential source for wound infections and bacteremia suggest mupirocin intranasally may have an effect in decreasing the incidence of these bacterial infections in susceptible individuals (e.g. those with recurrent staphylococcal infections)[21]. Mupirocin has been shown to be as effective as systemic antibiotics for limited impetigo[22,23]. Retapamulin is indicated for the topical treatment of impetigo due to *Streptococcus pyogenes* and methicillin-susceptible *S. aureus* in patients as young as 9 months of age.

Dosages
Table 127.5 outlines the formulations and dosing for the antibacterial agents used for the treatment of superficial skin infections. Intranasal mupirocin is applied into the nares two to four times a day for 5 to 14 days.

Contraindications
As with all topical medications, the main contraindication is a history of hypersensitivity to any component of the formulations.

Major side effects
Potential side effects of mupirocin include burning, stinging, tenderness, pain and pruritus, as well as erythema, edema, increased exudate, allergic contact dermatitis, headache and nausea. Use of nasal mupirocin is occasionally associated with headaches, rhinitis, respiratory tract congestion, pharyngitis, taste perversion, burning, stinging and cough. Use of mupirocin on extensive areas of skin with decreased barrier function has been reported to cause systemic absorption of polyethylene glycol leading to renal toxicity. Retapamulin can cause application site irritation and pruritus.

Side effects of neomycin include allergic contact dermatitis in 5% to 15% of patients[19], in particular when neomycin is applied to cutaneous ulcerations and/or areas of chronic stasis dermatitis. The most common symptoms are pruritus, erythema and edema. The risk of side effects increases if the patient has impaired renal function; for example, patients with decreased renal function may develop irreversible ototoxicity manifested by hearing loss. Caution should be exercised if the medication is used over extensive areas. Nephrotoxicity, neuromuscular blockade and death have been reported after application of neomycin[19]. It may also cause mast cell degranulation and histamine release[3].

Possible side effects of gentamicin are erythema, pruritus, edema and photosensitization. There is a risk of producing gentamicin-resistant strains of *Pseudomonas* when this topical agent is applied to heavily colonized skin (e.g. leg ulcers).

Adverse effects of bacitracin include irritant and allergic contact dermatitis. Chronic stasis dermatitis predisposes to the latter. Anaphylaxis has been reported in patients with a history of multiple previous exposures when bacitracin was applied to open wounds.

There are very few side effects from polymyxin B. Contact sensitization has been reported. Of note, some cross-reactivity exists between bacitracin and polymyxin B because they are both derived from *Bacillus* species.

Interactions
In studies utilizing *E. coli*, chloramphenicol interferes with the effect of mupirocin on bacterial RNA synthesis. Otherwise, there are no known significant drug interactions with the topical antibiotics used for superficial skin infections.

Pregnancy and lactation
Table 127.5 lists the FDA pregnancy categories of the topical antibacterials used to treat superficial infections.

Neither topical nor nasal mupirocin has been adequately studied in pregnant women. It has not been shown to cause birth defects or other problems in animal studies using rats and rabbits. It is not known whether topical or nasal mupirocin is excreted in breast milk. There is very little systemic absorption of topically applied mupirocin. Topical neomycin has not been shown to cause birth defects in humans and has not been reported to cause problems in nursing infants. Animal studies have not been conducted with polymyxin B, and it is not known whether polymyxin B is excreted in breast milk.

Other topical antibacterial agents
Fusidic acid is a fusidane antibiotic isolated from the fungus *Fusidum coccineum*[24]. It is not approved in the US but is used in Europe and Canada for mild to moderately severe cutaneous infections, external eye infections and eradication of nasopharyngeal carriage of *S. aureus*. It is available as a 2% cream, ointment and impregnated gauze that is

applied three times a day. It may also be given orally or intravenously. It has a steroid-like structure but does not have any steroid effects[24,25]. Fusidic acid inhibits bacterial protein synthesis by interfering with elongation factor G. It is active against Gram-positive bacteria, especially *S. aureus*. This medication has a bacteriologic efficacy comparable to that of mupirocin for impetigo and may be more cost-effective[26–28]. When combined with topical corticosteroids, it is useful in treating atopic dermatitis with superimposed staphylococcal infection[25]; it is also effective in erythrasma[29,30]. Fusidic acid has few adverse effects, although allergic contact dermatitis has been reported.

Iodoquinol (1%) combined with 1% hydrocortisone has been commercially available for many years. Iodoquinol is a halogenated oxyquinoline with antibacterial and antifungal activity. Its mechanism of action is unknown. The combination product is applied three to four times a day for superficial bacterial and fungal skin infections. It is in FDA pregnancy category C and its safety during pregnancy is unknown. Topical iodoquinol (1%) preparations have a high iodine content. There is a systemic form of iodoquinol used for amebiasis, which is contraindicated in patients with iodine intolerance, may interfere with thyroid function tests, and may cause iododerma[31]. A related medication, topical *clioquinol* (iodochlorhydroxyquin), is used primarily for the treatment of superficial fungal infections (see below).

Mafenide acetate cream is a sulfonamide used for thermal burns and is applied once or twice daily. It has antibacterial and antifungal activity. The most common side effect is burning, and, less often, urticaria or facial edema can occur. Rarely, mafenide acetate may cause bone marrow suppression or lead to hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. It should be used with caution in patients with renal or pulmonary disease owing to its potential to cause metabolic acidosis. Furthermore, mafenide acetate may cause intense pain upon application and can be associated with *Candida* superinfection.

Nitrofurazone is used for thermal burns and skin grafting. It is available as a 0.2% cream, ointment and solution. Nitrofurazone is used once a day. It works by inhibiting bacterial metabolic enzymes and is effective against staphylococci, streptococci, *E. coli*, *Clostridium perfringens*, *Aerobacter enterogenes* and *Proteus* spp.

Silver sulfadiazine is a 1% cream applied once to twice a day for thermal burns. In addition to its sulfonamide properties, the silver interacts with bacterial cell walls and membranes. When used in conjunction with cimetidine, there is an increased risk of leukopenia. Silver sulfadiazine may interfere with collagenase (Santyl®), papain (Panafil®) and sutilains (Travase®). It is contraindicated in patients with a history of hypersensitivity to sulfonamides and should be used with caution in patients with G6PD deficiency, renal or hepatic disease, and porphyria. Sulfonamides can generate oxidants and induce an acute hemolytic anemia in patients with G6PD deficiency. They may precipitate an attack of pseudoporphyria or unmask a case of true porphyria. The mechanism for this is unclear, but may be direct hepatocellular damage, increased cytochrome P450 activity, or inhibition of liver enzymes leading to increased production of porphyrins. Localized argyria due to deposits of silver in the dermis can also occur.

Topical tetracyclines

Tetracycline hydrochloride is available as a 3% solution and as an ointment. It is applied twice a day for acne vulgaris and is also indicated for superficial skin infections. Meclocycline sulfosalicylate solution and cream are indicated for acne but are not available in the US. Chlortetracycline ointment is indicated for superficial skin infections. Topical tetracyclines may be less effective than topical clindamycin or erythromycin. They work by inhibition of protein synthesis and are bacteriostatic against a wide range of Gram-negative and Gram-positive bacteria. The products currently available have been formulated to reduce the yellow color associated with topical tetracyclines. Side effects include stinging, burning and an unpleasant odor. It is not known whether topically applied tetracyclines are excreted in breast milk. However, because tetracyclines can cause permanent yellow, gray or brown discoloration of the teeth, they should not be used in pregnant women, nursing mothers, or children under 8 years of age. Topical tetracycline contains sodium bisulfite, which may cause anaphylaxis in susceptible individuals.

Systemic Antibacterial Agents

Systemic antibacterial agents have the potential to cause a wide range of adverse effects and to have significant interactions with other systemic medications. For example, rifampin may reduce the efficacy of oral contraceptives. Bacteriostatic antibacterial agents can decrease the efficacy of bactericidal antibacterial agents, because the latter target actively dividing cells. In addition, use of systemic antibacterial agents is associated with a risk for the development of bacterial resistance. The mechanisms of action of the major classes of antibacterial drugs are listed in Table 127.7 and illustrated in Figure 127.1. Systemic antibiotics may be used perioperatively by dermatologic surgeons to prevent surgical site infections in high-risk situations such as procedures involving the lower extremity or groin, wedge excisions on the lip or ear, skin flaps on the nose, and skin grafts. Antibiotic prophylaxis is also recommended in patients at high risk for infective endocarditis or

SITES OF ACTION OF DIFFERENT CLASSES OF SYSTEMIC ANTIBACTERIAL DRUGS

Site of action	Drug class(es)
Cell wall	Penicillins Cephalosporins Carbapenems Monobactams Vancomycin β-lactamase inhibitors
Inhibit nucleic acid synthesis	Sulfonamides Trimethoprim
DNA gyrase	Quinolones
DNA strand breakage	Metronidazole
Ribosomal subunit	Aminoglycosides – 30S Tetracyclines – 30S Chloramphenicol – 50S Clindamycin – 50S Macrolides – 50S

Table 127.7 Sites of action of different classes of systemic antibacterial drugs.

SITES OF ACTION OF ANTIBACTERIAL DRUGS

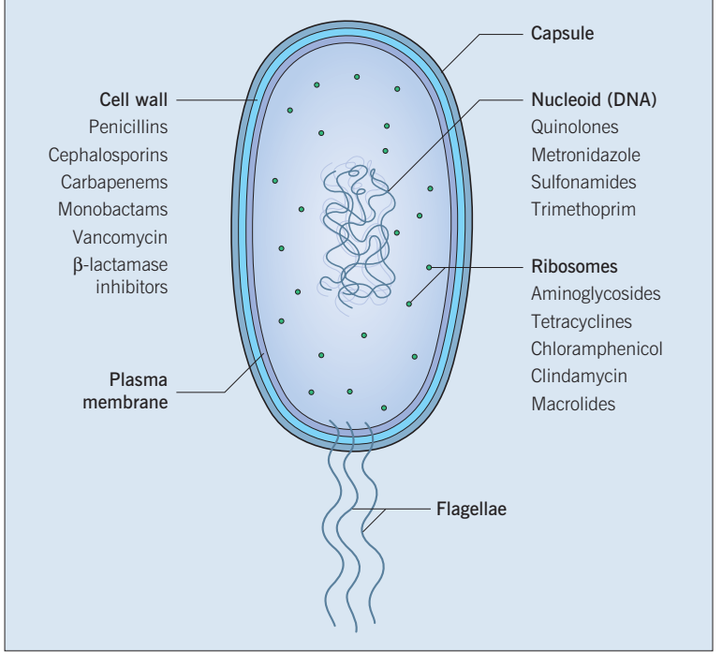

Fig. 127.1 Sites of action of antibacterial drugs. This figure illustrates a prototypical bacterial cell. Each class of antibacterial drug exerts its effect on a particular component of the cell.

hematogenous total joint infection who have surgery involving the oral mucosa or infected skin (see Ch. 151)[32].

Penicillins

Mechanism of action

Penicillins are β-lactam antibiotics that exert a bactericidal effect by binding to and inactivating penicillin-binding proteins in the bacterial cell wall. They are thought to inhibit bacterial cell wall synthesis by blocking the transpeptidase cross-linking of peptidoglycan chains (Fig. 127.2).

The natural penicillins (penicillin G and penicillin V) are active against Gram-positive and Gram-negative cocci, most Gram-positive bacilli, and spirochetes. Penicillinase-resistant penicillins or anti-staphylococcal penicillins (methicillin, nafcillin and dicloxacillin) have greater efficacy against *S. aureus*. Aminopenicillins (ampicillin, amoxicillin) have an extended spectrum to include *H. influenzae*, *E. coli*, *Salmonella* and *Shigella* spp. and some other Gram-negative bacteria, but not *Pseudomonas* spp. Antipseudomonal penicillins (carbenicillin, ticarcillin and piperacillin) cover *P. aeruginosa* and *B. fragilis*. Carbenicillin and ticarcillin have no activity against *Klebsiella* spp., whereas mezlocillin, azlocillin and piperacillin do. Addition of the β-lactamase inhibitors clavulanic acid, sulbactam and tazobactam extends the spectrum of penicillins to include staphylococci and other β-lactamase-producing bacteria (Fig. 127.3).

Indications

Penicillins are used for syphilis and streptococcal skin infections such as erysipelas and perianal disease as well as other cutaneous infections such as erysipeloid[33]. Amoxicillin with clavulanic acid is the drug of choice for cat, dog and human bites. It is useful also for acute paronychia. The penicillinase-resistant penicillins, e.g. dicloxacillin, are used for staphylococcal skin infections, including impetigo, folliculitis and furunculosis, although the incidence of methicillin-resistant *Staphylococcus aureus* (MRSA) is rising and sensitivity testing should be obtained when MRSA is a clinical concern. Amoxicillin may be used for Lyme disease when tetracyclines are contraindicated. Penicillins are also used to treat non-cutaneous infections caused by susceptible bacteria, including pneumonia, gonorrhea, urinary tract infections, otitis media and sinusitis.

Dosages

The pediatric and adult dosages of commonly used penicillins are listed in Table 127.8. Amoxicillin and amoxicillin with clavulanic acid should be taken with food. Other penicillins should be taken on an empty stomach.

Contraindications

Penicillins are contraindicated in patients with known immediate-type (IgE-mediated) hypersensitivity to any penicillin (i.e. a history of urticaria, angioedema or anaphylaxis). However, it has been shown that only 10% to 20% of patients who report a history of allergy to penicillins have a true allergy proven by skin testing[34]. Cross-reaction with penicillins occurs in approximately 2–10% of patients allergic to cephalosporins. Benzylpenicilloyl polylysine, benzylpenicillin G, benzylpenicilloate and penicilloyl propylamine, as well as negative (saline) and positive (histamine) controls, are used to test for penicillin allergy. Antihistamines should be avoided prior to testing. Patients who have had a life-threatening reaction to penicillin should be tested with 100-fold dilutions of the allergens before being tested with full-strength allergens in a monitored setting where treatment for anaphylaxis is available. Epicutaneous (prick) testing may be performed by placing drops of antigen solutions on the volar forearm and using a 26-gauge needle to pierce the epidermis without drawing blood. An epicutaneous test is positive if, within 15 minutes, the average wheal diameter is 4 mm larger than the wheal of negative controls. For intradermal testing, antigen solutions and controls are injected in the volar forearm. An intradermal test is positive if, 15 minutes after injection, the average wheal diameter is at least 2 mm greater than the initial wheal size and is also at least 2 mm greater than the negative controls. Patients who report a history of penicillin allergy but are skin-test-negative to the entire battery of major (benzylpenicilloyl polylysine) and minor (benzylpenicillin G, benzylpenicilloate and penicilloyl propylamine) allergenic determinants can use penicillin in a monitored setting. Skin-test-positive patients may be desensitized orally or intravenously in a hospital setting in about 4 hours. Rarely, serious IgE-mediated allergic reactions can occur. Blood tests can also be used to detect specific IgE directed against penicillin, but this method is less sensitive and gives less information than skin tests.

Major side effects

Drugs in the penicillin group cause hypersensitivity reactions characterized by urticaria, flushing and pruritus in 7% to 15% of patients. In severe cases, they may give rise to anaphylaxis, shock and death. Penicillins may also cause delayed hypersensitivity reactions associated with fever, eosinophilia and (occasionally) serum sickness-like

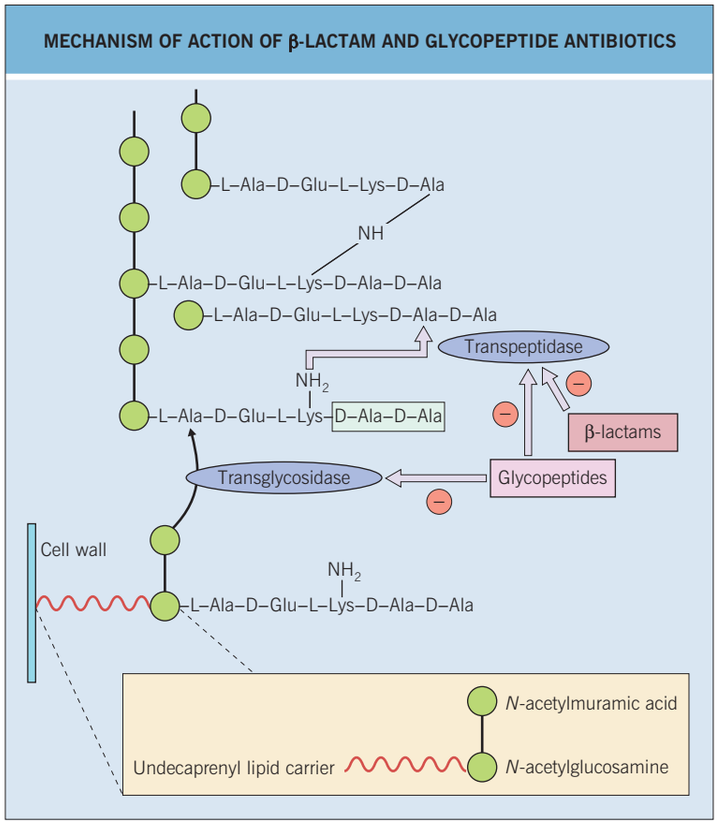

Fig. 127.2 Mechanism of action of β-lactam and glycopeptide antibiotics. Simplified schematic of mechanisms of action of β-lactam antibiotics (penicillins, cephalosporins) and glycopeptides (e.g. vancomycin, dalbavancin) in interfering with enzymatic steps in bacterial cell wall (peptidoglycan) synthesis.

DOSAGES OF COMMONLY USED PENICILLINS

Generic name	Pediatric oral dosage	Adult oral dosage
Penicillin V potassium	25–50 mg/kg/day divided q6–8 h	250–500 mg qid
Dicloxacillin	12.5–50 mg/kg/day divided q6 h	125–500 mg qid
Ampicillin	50–100 mg/kg/day divided q6 h	250–500 mg qid
Amoxicillin	25–50 mg/kg/day divided q8 h or q12 h	250–500 mg bid
Amoxicillin/clavulanate	20–40 mg/kg/day (of amoxicillin) divided q8 h or q12 h*	500–875 mg bid

*Do not double the dose of clavulanate if you double the amoxicillin dose, as this causes excessive clavulanate dosage and increased risk of gastrointestinal side effects like diarrhea.

Table 127.8 Dosages of commonly used penicillins. bid, twice daily; h, hours; q, every; qid, four times daily.

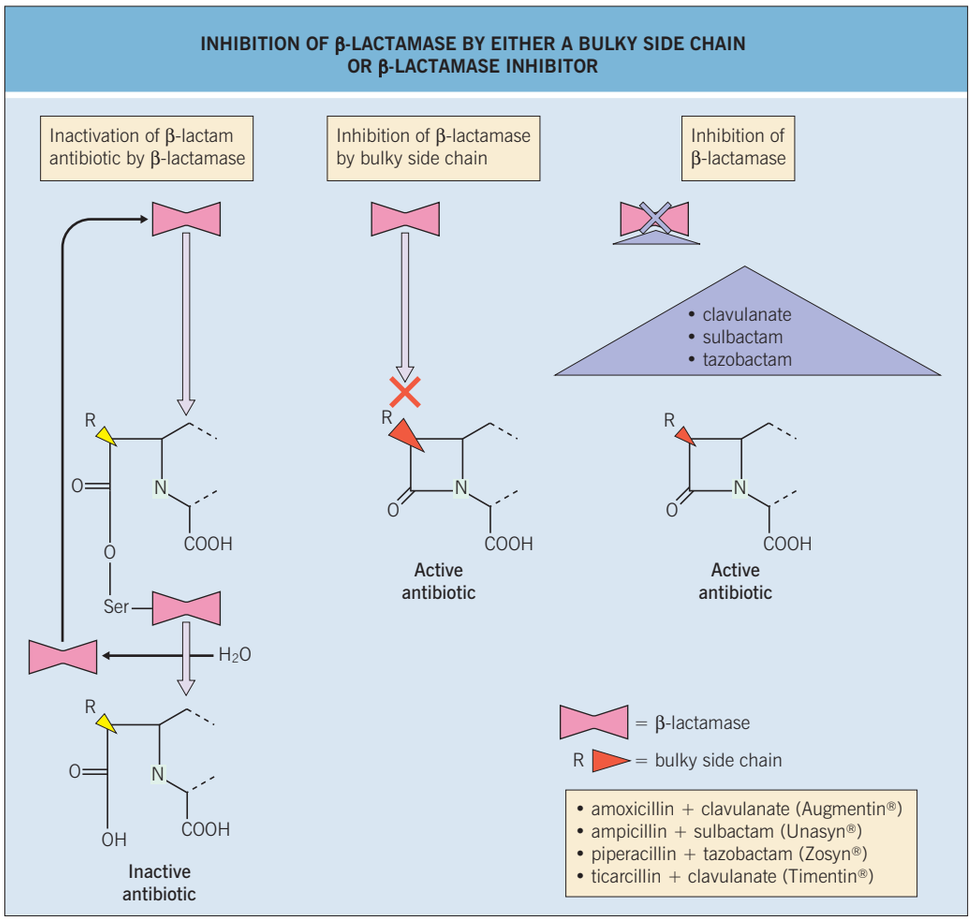

Fig. 127.3 Inhibition of β-lactamase by either a bulky side chain or β-lactamase inhibitor. Placement of a bulky side chain on the penicillin molecule (e.g. methicillin, nafcillin, dicloxacillin) can inhibit bacterial β-lactamase, as can the combination of a penicillin with a β-lactamase inhibitor (e.g. clavulanic acid, sulbactam, tazobactam). The latter group of drugs has no inherent antibacterial activity. Inhibition of β-lactamase allows the antibiotic to remain active and inhibit bacterial transpeptidase.

reactions. Stevens–Johnson syndrome, toxic epidermal necrolysis, and pustular eruptions such as acute generalized exanthematous pustulosis are also potential side effects. These drugs sometimes lead to autoimmune phenomena, including hemolytic anemia or vasculitis. Ampicillin and amoxicillin almost invariably cause a generalized morbilliform eruption when used in patients with infectious mononucleosis; this type of reaction is also more likely in patients with lymphocytic leukemia and those who are taking concomitant allopurinol. When administered in high doses to patients with renal insufficiency, penicillins may lead to neurotoxicity with hyperirritability, confusion, seizures and coma. Rapid infusion, high blood levels or intrathecal injection may also cause seizures.

Penicillins can induce an acute interstitial nephritis characterized by proteinuria, hematuria, renal casts, eosinophilia, eosinophiluria, fever, arthralgias and declining renal function. Prolonged use of penicillins may lead to reversible neutropenia, anemia, agranulocytosis and platelet dysfunction. Penicillins can cause diarrhea, pseudomembranous colitis and hepatic dysfunction. For example, oxacillin and carbenicillin are associated with "oxacillin hepatitis", an anicteric liver dysfunction with eosinophilia that may occur in as many as 15% of patients. Treatment with penicillins is associated with oral or vaginal overgrowth of *Candida* spp. in over 10% of patients.

Interactions
Because probenecid blocks the secretion of penicillins in the distal renal tubules, concomitant administration of these two drugs increases the serum levels and duration of action of the penicillins. When amoxicillin or ampicillin is used with allopurinol, there is an increased risk of morbilliform drug eruption, and when tetracyclines are used with penicillins, the bactericidal effect of penicillins is decreased.

Pregnancy and lactation
Penicillins are grouped in pregnancy category B and are considered to be safe for use in nursing mothers.

Cephalosporins

Mechanism of action
Like the penicillins, the cephalosporins (Table 127.9) are bactericidal β-lactam antibiotics that bind to penicillin-binding proteins and interfere with bacterial cell wall synthesis. First-generation cephalosporins are very effective against Gram-positive organisms (staphylococci and streptococci) and less effective against Gram-negative organisms; however, they are active against *E. coli, Klebsiella* and *Proteus* spp. Second-generation cephalosporins are equally effective against Gram-positive and Gram-negative bacteria. Their spectrum includes all of the organisms covered by first-generation cephalosporins plus *Enterobacter* spp., *Neisseria gonorrhea* and *H. influenzae*. Third-generation cephalosporins are more effective against Gram-negative bacteria than Gram-positive bacteria. Fourth-generation cephalosporins have an extended spectrum for Gram-negative and Gram-positive organisms, but have minimal resistance to β-lactamase. They are active against *Enterobacter* and *Klebsiella* spp. Cephamycins are resistant to β-lactamase and have a broad spectrum, including *E. coli, Klebsiella*, *Proteus*, *Serratia* and *Bacteroides* spp.

Indications
Cephalosporins are useful in staphylococcal and streptococcal skin and soft tissue infections. A first-generation agent such as cephalexin or cefadroxil is the cephalosporin of choice in uncomplicated skin infections[33]. These drugs are very useful for uncomplicated impetigo, cellulitis, furunculosis, erysipelas and ecthyma; however, strains of MRSA are resistant to cephalosporins as well.

Dosages
See Table 127.10 for dosages of the more commonly used cephalosporins.

Contraindications
Cephalosporins are contraindicated in patients with a history of an immediate-type (IgE-mediated) hypersensitivity to this class of drugs.

DIFFERENT CLASSES OF CEPHALOSPORINS AND ROUTES OF ADMINISTRATION		
Generic name	**Trade name(s)®**	**Route(s) of administration**
FIRST GENERATION		
Cefadroxil	Duracef, Ultracef	po
Cefazolin	Ancef, Kefzol, Zolicef	im, iv
Cephalexin	Keflex, Keftab, Biocef	po
Cephalothin*	Keflin, Seffin	im, iv

DOSAGES OF COMMONLY PRESCRIBED CEPHALOSPORINS		
Generic name	**Pediatric dosage**	**Adult dosage**
Cephalexin	25–100 mg/kg/day divided q6 h or q12 h	250–500 mg qid
Cefadroxil	30 mg/kg/day divided q12 h	1–2 g qd
Cefaclor	40 mg/kg/day divided q8 h or q12 h	250–500 mg tid
Cefprozil	30 mg/kg/day divided q12 h	250–500 mg qd
Cefuroxime axetil	20–30 mg/kg/day divided q12 h	250–500 mg bid
Cefpodoxime proxetil	10 mg/kg/day divided q12 h	100–400 mg bid
Ceftibuten	9 mg/kg/day divided q24 h	400 mg qd
Cefixime	8 mg/kg/day divided q12 h or q24 h	200 mg bid or 400 mg qd
Ceftriaxone	50 mg/kg im x 1 (max. 1 g)	1–4 g im qd; 250 mg im × 1 for uncomplicated gonorrhea
Cefdinir	14 mg/kg/day divided q12 h or q24 h	300 mg bid or 600 mg qd

Table 127.10 Dosages of commonly prescribed cephalosporins. Administration is oral unless otherwise noted. bid, twice daily; h, hours; im, intramuscularly; q, every; qd, daily; qid, four times daily; tid, three times daily.

Approximately 15% of patients allergic to penicillins have cross-reactivity to cephalosporins (2% in pediatric patients)[35].

Major side effects

Cephalosporins can cause morbilliform eruptions, urticaria, anaphylaxis, drug fever, eosinophilia, and acute generalized exanthematous pustulosis. Cutaneous reactions are similar to those seen with the penicillins. Approximately 2% of patients allergic to cephalosporins exhibit cross-reactivity with penicillins. Cefaclor has been reported to have a significantly higher rate of drug eruptions (especially serum sickness-like reactions) in children compared to other cephalosporins and other antibiotic classes[36]. Cephalosporins may also lead to neutropenia, thrombocytopenia, hemolytic anemia and a positive direct Coombs test, especially in the setting of renal insufficiency. They can cause diarrhea, nausea and pseudomembranous colitis. Certain cephalosporins with a methylthiotetrazole side group (e.g. cefotetan, cefoperazone, cefamandole) can cause a disulfiram-like effect when alcohol is ingested concomitantly and have anti-vitamin K effects leading to an enhanced risk of bleeding.

Interactions

Administration of oral cephalosporins together with aminoglycosides can increase the likelihood of nephrotoxicity. Probenecid may decrease renal clearance of cephalosporins. Antacids, didanosine and proton pump inhibitors may decrease absorption of some oral cephalosporins (e.g. cefuroxime).

Pregnancy and lactation

Cephalosporins are in FDA pregnancy category B. They have not shown any adverse effects during pregnancy or lactation. However, their safety has not been definitively established. Cephalosporins are excreted in breast milk.

Sulfonamides and co-trimoxazole

Mechanism of action

Sulfamethoxazole, *sulfasalazine* and *sulfisoxazole* are sulfonamides that compete with para-aminobenzoic acid (PABA) to be the substrate for the enzyme dihydropteroate synthetase (Fig. 127.4). Dihydropteroate synthetase catalyzes the reaction that combines pteridine precursors with PABA to make folic acid. Thus, sulfonamides prevent the synthesis of bacterial folic acid, an essential cofactor for bacterial nucleic acid synthesis. They have a bacteriostatic effect against Gram-positive bacteria (including *S. aureus* and *Str. pyogenes*), Gram-negative bacteria, *Chlamydia* and *Nocardia* spp.

Co-trimoxazole is a synergistic combination of sulfamethoxazole and trimethoprim. It blocks two consecutive steps in the biosynthesis of bacterial nucleic acids (see Fig. 127.4). The sulfonamide inhibits dihydropteroate synthetase and trimethoprim blocks the action of dihydrofolate reductase, which normally converts dihydrofolate to tetrahydrofolate (the active form of folic acid). This combination may be bactericidal or bacteriostatic depending on the concentration of the drug and the susceptibility of the infecting organism. It is active against most Gram-positive organisms and Gram-negative organisms.

Indications

Systemic sulfonamides are indicated for uncomplicated urinary tract infections. They are also used for *Chlamydia* conjunctivitis and

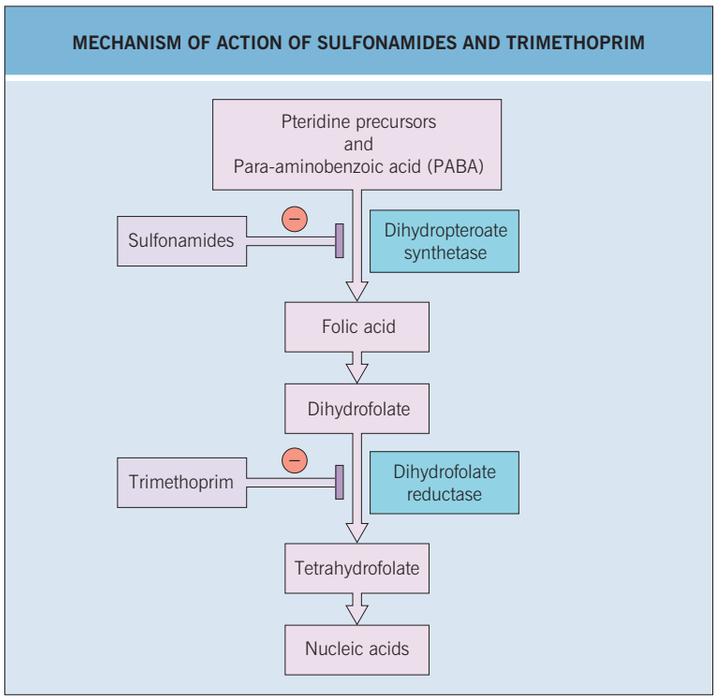

Fig. 127.4 Mechanism of action of sulfonamides and trimethoprim. Sulfonamides inhibit the conversion of pteridine precursors and PABA to folic acid by dihydropteroate synthetase. Trimethoprim inhibits the conversion of dihydrofolate to tetrahydrofolate by dihydrofolate reductase. The end result of both actions is inhibition of bacterial nucleic acid synthesis.

Nocardia infections. Sulfasalazine is commonly prescribed for ulcerative colitis. Co-trimoxazole is used to treat respiratory tract, prostate, urinary tract and gastrointestinal infections, as well as to treat, and as prophylaxis against, *Pneumocystis jiroveci* pneumonia. The latter indication is for patients who are immunosuppressed, e.g. as a result of HIV infection or systemic medications. Co-trimoxazole is also used for skin infections (e.g. furuncles or purulent cellulitis suspected to be due to MRSA), inflammatory acne vulgaris recalcitrant to other antibacterial agents, and granuloma inguinale.

Dosages
In pediatric patients, sulfadiazine and sulfisoxazole are given as 120–150 mg/kg/day divided every 4 to 6 hours. One double-strength capsule of co-trimoxazole contains 160 mg of trimethoprim and 800 mg of sulfamethoxazole, and in adults is given twice a day. In children, the dose is 6–12 mg/kg of trimethoprim and 30–60 mg/kg of sulfamethoxazole every 12 hours.

Contraindications
The sulfonamides and co-trimoxazole are contraindicated in patients with a history of hypersensitivity to this class of medications. Sulfonamides are contraindicated in the third trimester of pregnancy and in lactating patients (see below). They are also contraindicated in patients with porphyria. Sulfonamides can precipitate an acute attack of pseudoporphyria or true porphyria, possibly by increasing levels of porphyrins via hepatocellular damage, stimulating cytochrome P450 activity or inhibiting other liver enzymes. Co-trimoxazole is contraindicated in patients with megaloblastic anemia, folate deficiency or G6PD deficiency. It should be used cautiously in patients with impaired hepatic or renal function and in individuals with bone marrow suppression.

Major side effects
The sulfonamides and co-trimoxazole may cause fixed drug or morbilliform eruptions, urticaria, angioedema, photosensitivity, Stevens–Johnson syndrome, toxic epidermal necrolysis, exfoliative erythroderma and vasculitis. Additional cutaneous side effects include acute generalized exanthematous pustulosis, Sweet's syndrome, linear IgA bullous dermatosis, erythema nodosum and radiation recall. In HIV-infected patients, these drugs are common causes of cutaneous eruptions. Non-cutaneous side effects include hemolytic anemia in the setting of G6PD deficiency, agranulocytosis, thrombocytopenia, eosinophilia, methemoglobinemia, nephrotoxicity, hepatotoxicity, neurotoxicity and kernicterus in newborns. Co-trimoxazole may also cause nausea, vomiting, glossitis and stomatitis, as well as dizziness and headaches. Trimethoprim (alone or in combination with sulfamethoxazole) can induce a folate deficiency with megaloblastic anemia, leukopenia and granulocytopenia. It can also cause thrombocytopenia. Giving folinic acid, which does not impair antibacterial activity because it does not enter bacteria, can reverse all of the sequelae of folate deficiency.

Interactions
The sulfonamides and co-trimoxazole can potentiate the effects of oral hypoglycemics and the anticoagulant effect of warfarin. They should not be used in patients on methenamine for urinary tract infections. Sulfonamides decrease protein binding and renal clearance of methotrexate, leading to potentially life-threatening methotrexate myelosuppression toxicity. Monoamine oxidase (MAO) inhibitors and probenecid may increase sulfonamide adverse effects through altered hepatic metabolism and renal clearance, respectively.

Pregnancy and lactation
Co-trimoxazole must be avoided during pregnancy and lactation and for the first 2 months of life. The sulfonamides and co-trimoxazole are in pregnancy category C during the first two trimesters owing to their inhibition of folic acid, but they are in category D during the third trimester owing to the increased risk of kernicterus. Systemic sulfonamides are excreted in breast milk, and they may cause hepatic toxicity, anemia and other adverse effects in nursing infants.

Macrolides
Mechanism of action
Macrolides are bacteriostatic and inhibit bacterial protein synthesis by binding to the 50S ribosomal subunit. Erythromycin is effective against Gram-positive and Gram-negative cocci, most Gram-positive bacilli, and spirochetes. Clarithromycin has an expanded spectrum that includes *H. influenzae* and *Moraxella catarrhalis*. Azithromycin also covers *H. influenzae*. Clarithromycin and azithromycin are both effective against atypical mycobacteria, *Treponema pallidum* and *Borrelia burgdorferi*; however, they are not first-line agents for infections with the latter two organisms.

Macrolides also have anti-inflammatory effects, including inhibiting production of proinflammatory cytokines (e.g. interleukin [IL]-8, tumor necrosis factor-α [TNF-α]), reducing expression of matrix metalloproteinases, and decreasing leukocyte migration and adhesion.

Indications
Macrolides are commonly used for staphylococcal and streptococcal skin infections as they often represent a suitable treatment alternative for patients allergic to penicillin. However, there are regions where a significant percentage of *S. aureus* isolates are erythromycin-resistant. Erythromycin and azithromycin may be used for inflammatory acne, erythrasma, pitted keratolysis, bacillary angiomatosis and cat scratch disease. These agents also represent therapeutic options for several sexually transmitted diseases, e.g. chancroid, lymphogranuloma venereum, chlamydia and granuloma inguinale.

Erythromycin and azithromycin have been used for both the acute and chronic forms of pityriasis lichenoides, employing their anti-inflammatory properties. Macrolides are also indicated for pharyngitis, bacterial respiratory infections (including *Mycoplasma* pneumonia and Legionnaire's disease), diphtheria, pertussis and disseminated *Mycobacterium avium-intracellulare* complex treatment and prophylaxis.

Dosages
Table 127.11 outlines the dosages for commonly prescribed macrolides. Erythromycin base should be taken on an empty stomach; other formulations should be taken with food.

Contraindications
Macrolides are contraindicated in patients with hepatic dysfunction, renal dysfunction (clarithromycin) and hypersensitivity to the drug. Macrolides are also contraindicated in patients taking terfenadine, astemizole or cisapride (three drugs which have been removed from the

DOSAGES OF COMMONLY USED MACROLIDES		
Generic name	**Oral pediatric dosage**	**Oral adult dosage**
Azithromycin	Bacterial infections: 10 mg/kg (max 500 mg) on day 1, then 5 mg/kg (max 250 mg) qd on days 2–5	Bacterial infections: 500 mg on day 1, then 250 mg qd on days 2–5 Chancroid: 1 g once
Clarithromycin	15 mg/kg qd divided q12 h Maximum 1 g/day Adjust for decreased renal function	250–500 mg bid Adjust for decreased renal function
Erythromycin base	30–50 mg/kg qd divided q6–8 h Maximum 2 g/day	250–500 mg qid or 333 mg tid or 500 mg bid
Erythromycin estolate	20–50 mg/kg qd divided q6–12 h Maximum 2 g/day	250–500 mg bid–qid
Erythromycin ethyl succinate	20–50 mg/kg qd divided q8–12 h Maximum 2 g/day	400 mg qid
Erythromycin stearate	20–50 mg/kg qd divided q6 h	250–500 mg bid–qid

Table 127.11 Dosages of commonly used macrolides. bid, twice daily; h, hours; q, every; qd, daily; qid, four times daily.

US market and are banned or severely restricted in many other countries).

Major side effects

The use of erythromycin may be limited by gastrointestinal intolerance (e.g. nausea, vomiting, abdominal cramping). Erythromycin estolate can cause intrahepatic cholestasis in adults, and this risk increases during pregnancy. Less common side effects include stomatitis, jaundice, transient deafness and cardiac arrhythmias. Although hypersensitivity reactions to macrolides are uncommon, pustular eruptions (generalized exanthematous pustulosis) may occur; Stevens–Johnson syndrome, toxic epidermal necrolysis, urticaria and vasculitis are unusual complications.

Interactions

Macrolides have numerous significant drug interactions. Due to CYP3A4 inhibition (see Ch. 131), macrolides increase the risk of *torsades de pointes* when used with grepafloxacin, sparfloxacin, terfenadine, astemizole or cisapride. By the same mechanism, macrolides increase serum levels and potential toxicity of anticonvulsants, benzodiazepines, buspirone, corticosteroids, warfarin, HMG-CoA reductase inhibitors, oral contraceptives, cyclosporine, tacrolimus, disopyramide, felodipine and ergot alkaloids. Macrolides can increase serum levels of theophylline by inhibiting CYP1A2, leading to cardiac arrhythmias. Macrolides may also increase digoxin levels by altering gut flora, which metabolize digoxin.

Clarithromycin administered in conjunction with calcium channel blockers increases the risk of bradycardia and hypotension. Erythromycin used concomitantly with lovastatin has been reported to cause rhabdomyolysis. Macrolides may interfere with the effectiveness of chloramphenicol or clindamycin (see below), and antacids can decrease the absorption of azithromycin. Clarithromycin levels may be increased when this drug is administered with fluconazole, hexobarbital, alfentanil, disopyramide or bromocriptine. Of note, azithromycin has improved gastrointestinal tolerance and little potential for significant metabolism-based drug interactions[37].

Pregnancy and lactation

Erythromycin and azithromycin are in FDA pregnancy category B; clarithromycin is category C. The macrolides are generally considered safe during pregnancy, except for erythromycin estolate. This drug is contraindicated in pregnancy owing to the risk of maternal cholestatic hepatitis. The latter may represent a hypersensitivity reaction to the estolate component, and it can be accompanied by fever, leukocytosis and eosinophilia in addition to findings related to liver disease (nausea, vomiting, abdominal pain, jaundice, liver enzyme abnormalities); occasionally, a cutaneous eruption is seen.

DOSAGES AND ROUTES OF ADMINISTRATION OF THE TETRACYCLINES			
Generic name	**Trade name(s)®**	**Routes of administration**	**Adult dosage**
Demeclocycline	Declomycin, Declostatin, Ledermycin	po	300 mg q12 h
Doxycycline hyclate	Vibramycin, Vibra-Tabs, Periostat, Doxy-Caps, Microdox, Novo-Doxylin	po	50–100 mg qd– q12 h; 20 mg q12 h (sub-antimicrobial)
Doxycycline hyclate delayed release	Doryx	po	75–150 mg qd
Doxycycline monohydrate	Monodox, Adoxa, Doxyhexal	po	50–100 mg qd–q12 h
Doxycycline monohydrate immediate and delayed release	Oracea	po	40 mg qd
Minocycline	Minocin, Dynacin, Vectrin	po	50–100 mg qd–q12 h
Minocycline extended release	Solodyn	po	45–135 mg qd
Oxytetracycline	Terramycin	po, im	250–500 mg q6 h
Tetracycline	Sumycin, Achromycin, Robitet, Panmycin	po, iv	250–1500 mg/day divided into 2-4 doses

Table 127.12 Dosages and routes of administration of the tetracyclines. h, hours; im, intramuscularly; iv, intravenously; po, orally; q, every; qd, daily.

Tetracyclines

Mechanism of action

Tetracyclines (Table 127.12) inhibit bacterial protein synthesis by binding to the 30S ribosomal subunit. They are mainly bacteriostatic, but may be bactericidal at high concentrations. Tetracyclines are active against most bacteria, *Rickettsia*, *Chlamydia* and *Mycoplasma* spp. However, they are not active against *Proteus* spp. or *P. aeruginosa*. Tetracyclines also have anti-inflammatory effects, including decreasing matrix metalloproteinase activity, inhibiting leukocyte chemotaxis and reducing production of proinflammatory cytokines (e.g. TNF-α, IL-1β).

Indications

Tetracyclines are indicated for acne vulgaris, rosacea and perioral dermatitis, taking advantage of their anti-inflammatory as well as antimicrobial properties. They are first-line treatments for rickettsial infections (Rocky Mountain spotted fever, rickettsialpox, typhus, Q fever and trench fever), Lyme disease and ehrlichiosis. They are used in syphilis (in penicillin-allergic patients), granuloma inguinale, chlamydial infections (including lymphogranuloma venereum and psittacosis), actinomycosis, brucellosis, pulmonary infections (e.g. *Mycoplasma* pneumonia) and cholera. Tetracyclines are also useful for treating skin infections due to MRSA (e.g. furuncles or purulent cellulitis), *Vibrio vulnificus* or *Mycobacterium marinum*. Tetracyclines are used in conjunction with nicotinamide for bullous pemphigoid.

Dosages

Tetracycline should be taken 1 hour before or 2 hours after meals. Doxycycline and minocycline may be taken with or without food. To decrease the likelihood of esophagitis, the pills should not be "dry swallowed" and should be taken at least half an hour prior to bedtime. Table 127.12 lists the dosages of commonly prescribed tetracyclines.

Fig. 127.5 Minocycline pigmentation. Blue–gray macules and patches on the lower leg.

Contraindications
Tetracyclines should not be used in patients under 8 years of age (to avoid tooth discoloration) or in pregnant women. All tetracyclines except doxycycline should be avoided in patients with renal impairment, because they can accumulate; doxycycline has a compensatory gastrointestinal secretion.

Major side effects
Common side effects of tetracyclines include gastrointestinal upset, vaginal candidiasis and phototoxicity (especially doxycycline). Minocycline does not typically lead to overt phototoxicity but may cause diffuse "muddy brown" hyperpigmentation that is accentuated in sun-exposed areas as well as bluish discoloration of scars (including those due to acne) and normal skin (in particular on the shins)[33] (Fig. 127.5; see Table 67.3). Gray to blue–gray discoloration of the oral mucosa, sclerae, nails and teeth (including occasional tooth discoloration in adults) can also occur, as can black pigmentation of the thyroid gland. Deposition of tetracyclines in the teeth and bones occurs in children, causing discoloration and hypoplasia of the teeth (deciduous and permanent) and occasionally temporarily stunting growth. Dizziness is another potential side effect of minocycline.

Tetracyclines (especially minocycline) can cause allergic reactions, including urticaria and a minocycline "hypersensitivity syndrome" (drug reaction with eosinophilia and systemic symptoms [DRESS]; see Ch. 21) that often includes pneumonitis as well as hepatitis[38]; these reactions may occur more frequently in black patients[39]. Tetracyclines have also been associated with serum sickness-like reactions, esophageal ulcerations, infectious enterocolitis, blood dyscrasias, a pseudotumor cerebri-like syndrome (risk of which may be increased when given together with a systemic retinoid), nephrotoxicity, nephrogenic diabetes insipidus and even fatal fulminant hepatitis. Minocycline use has been linked to a variety of autoimmune conditions, including drug-induced lupus, polyarteritis nodosa, polyarthritis and autoimmune hepatitis[40,41]. These reactions often develop after a year or more of therapy, and affected individuals frequently have antineutrophil cytoplasmic antibodies (ANCA; usually with perinuclear staining and myeloperoxidase specificity) as well as antinuclear antibodies (ANA)[42].

Interactions
Food decreases the absorption of tetracycline by about 50%. Therefore, tetracycline should be taken 1 hour before or 2 hours after a meal. Minocycline and doxycycline may be taken with food to diminish the gastrointestinal upset caused by these medications. Absorption of tetracyclines is impaired by polyvalent cations such as calcium, aluminum, magnesium, iron, zinc and bismuth. Thus, antacids, some laxatives, medications containing magnesium (e.g. quinapril), dietary supplements and dairy products can inhibit absorption of tetracyclines (tetracycline > doxycycline > minocycline). Antacids, H_2 blockers and proton pump inhibitors increase stomach pH and thereby decrease tetracycline absorption. Tetracyclines increase the serum levels and potential toxicity of digoxin, lithium and warfarin, and they can reduce insulin requirements. Barbiturates, phenytoin and carbamazepine decrease the half-life of doxycycline. As noted above, bacteriostatic tetracyclines may interfere with the effectiveness of bactericidal penicillins.

Pregnancy and lactation
Systemic tetracyclines should not be used during pregnancy or lactation because they cross the placenta and are excreted in breast milk. They cause staining of the deciduous teeth and enamel hypoplasia and may impair skeletal growth in developing fetuses and in nursing infants[43]. They are designated pregnancy category D.

Clindamycin

Mechanism of action
Clindamycin is a lincosamide that suppresses bacterial protein synthesis by binding to the bacterial 50S ribosomal subunit. It is active against Gram-positive cocci including *S. aureus*, *Streptococcus pneumoniae*, *Str. pyogenes*, *Str. viridans* and anaerobic streptococci. It is not active against enterococci. Clindamycin is also active against anaerobes including peptostreptococci, peptococci, *Bacteroides* spp. and fusobacteria.

Indications
Clindamycin may be used in infections caused by susceptible bacteria, including anaerobic abscesses, chlamydial infections and bacterial vaginosis. Clindamycin can be effective in skin infections caused by MRSA as well as methicillin-sensitive *S. aureus* or *Str. pyogenes*, including impetigo, cellulitis, folliculitis, furunculosis and ecthyma. It may also be useful in necrotizing fasciitis and (considering its inhibition of protein production) toxin-mediated conditions such as toxic shock syndromes. Of note, staphylococci and β-hemolytic streptococci that are sensitive to clindamycin but resistant to erythromycin on initial susceptibility testing should be evaluated with the D (double-disk diffusion)-test for inducible clindamycin resistance. This occurs in bacteria that carry the *erm* gene encoding the erythromycin ribosomal methylase; when expression of this protein is induced (e.g. by erythromycin) or becomes constitutive (which commonly occurs and is selected for during clindamycin therapy), it modifies the bacterial ribosome and results in resistance to both macrolides and lincosamides (see Ch. 74).

Dosages
Clindamycin is formulated for oral, intravenous and intramuscular administration. It is typically dosed from 150 to 450 mg four times a day.

Contraindications
Clindamycin is contraindicated in patients with hypersensitivity to the drug and in patients with colitis.

Major side effects
Clindamycin carries a relatively high risk of pseudomembranous colitis. Studies have reported rates from 0.1% to 10%[44–46]. It occasionally increases serum levels of liver enzymes. Clindamycin may also cause hypersensitivity reactions, especially in HIV-positive patients. It may cause transient neutropenia or thrombocytopenia, eosinophilia and (possibly) neuromuscular blockade. Stevens–Johnson syndrome rarely occurs.

Interactions
Clindamycin binds at or near the sites of binding of erythromycin and chloramphenicol. These drugs should not be used concomitantly. It may potentiate the neuromuscular effect of botulinum toxin or neuromuscular blockers.

Pregnancy and lactation
Clindamycin is in pregnancy category B. There are no known adverse effects of systemic clindamycin on the developing fetus. In rat and mouse studies, oral and subcutaneous clindamycin have not been shown to cause birth defects. Clindamycin may modify the bowel flora of nursing infants and may interfere with the interpretation of bacterial culture results obtained during a fever evaluation of a nursing infant.

QUINOLONES		
Generic name	**Trade name(s)®**	**Routes of administration**
Alatrofloxacin*	Trovan IV	iv, im

Norfloxacin	Chibroxin, Noroxin	po
Ofloxacin	Floxin	po, iv
Sparfloxacin*	Zagam	po
Trovafloxacin*	Trovan	po, iv
*Withdrawn from US market.		

Table 127.13 Quinolones. im, intramuscularly; iv, intravenously; po, orally.

Quinolones

Mechanism of action

Quinolones are rapidly bactericidal by inhibiting DNA gyrase (topoisomerase II). They are active against Gram-negative aerobes, staphylococci and streptococci, but not against anaerobes.

Table 127.13 lists the drugs in this class.

Indications

Quinolones are indicated for sinusitis, acute exacerbations of chronic bronchitis, community acquired pneumonia, urinary tract infections, gastrointestinal infections, chlamydia, osteomyelitis, and some skin and soft tissue infections. Second-generation quinolones (ciprofloxacin, ofloxacin, enoxacin, lomefloxacin and norfloxacin) have good coverage of Gram-negative rods and some Gram-positive coverage. They are the most potent antipseudomonal quinolones. Third-generation quinolones (levofloxacin, gatifloxacin and sparfloxacin) are broad spectrum, with coverage of Gram-negative rods and greater Gram-positive cocci coverage, especially of *Pneumococcus* spp. Fourth-generation quinolones (alatrofloxacin, moxifloxacin and trovafloxacin) are very broad spectrum, with coverage of Gram-negative rods, Gram-positive cocci, anaerobes and atypical bacteria. They have minimal antipseudomonal activity but cover streptococcus and *S. aureus*; however, quinolone resistance to the latter organism can develop rapidly.

Dosages

Ciprofloxacin and levofloxacin are dosed at 250 to 750 mg twice a day. Quinolones must be adjusted for renal impairment. The safety of quinolones in children has not been established, and their use in pediatric patients is generally avoided unless there is no safe and effective alternative[46a] (see below). However, ciprofloxacin has been given to children at levels of 20–30 mg/kg per day in divided doses.

Contraindications

Quinolones are contraindicated in pregnancy and in patients with QT prolongation or hypokalemia. Historically, quinolones have been avoided in patients under 18 years of age because of a potential risk of arthropathy or tendinopathy based on studies in animals. However, quinolones have been used to treat children with cystic fibrosis, and a recent systematic literature review found that joint changes (most often arthralgias or stiffness) were reversible and affected 1.4% (232/16 184) of pediatric patients treated with ciprofloxacin[46a,47].

Major side effects

In studies involving juvenile animals, quinolones have been shown to damage cartilage in weight-bearing joints[48]. Quinolones may cause gastrointestinal upset, changes in taste, abnormal liver function tests, phototoxicity, nephrotoxicity, headache, dizziness, lightheadedness, drowsiness and, rarely, increased intracranial pressure and seizures. Rupture of tendons, in particular the Achilles tendon, has been rarely observed. Exacerbation of myasthenia gravis has also been described.

Interactions

Cations (e.g. calcium, aluminum, magnesium, iron and zinc salts), antacids and sucralfate prevent absorption of quinolones. Quinolones increase serum levels and potential toxicities of caffeine, theophylline and aminophylline due to CYP1A2 inhibition. They may also increase serum levels of warfarin. Use of quinolones in combination with cyclosporine may increase serum creatinine levels in renal transplant patients. Quinolones can also increase circulating levels of procainamide by decreasing its renal clearance.

Quinolones should be used with caution in patients who are taking antiarrhythmics, erythromycin, antipsychotics, tricyclic antidepressants or other drugs that can cause QT prolongation or lower the seizure threshold. Quinolones may also increase seizure risk if administered with nonsteroidal anti-inflammatory drugs. Gatifloxacin can cause hypoglycemia when used with sulfonylureas.

Pregnancy and lactation

Quinolones are designated pregnancy category C. They should not be used during pregnancy or nursing because of the arthropathy found in animal studies.

Metronidazole

Mechanism of action

Metronidazole is an imidazole. Its mechanism of action is thought to be due to DNA strand breaking.

Indications

In addition to its antiprotozoal actions, metronidazole has activity against anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* spp.), anaerobic Gram-negative bacilli (including *Bacteroides* and *Fusobacterium* spp.) and anaerobic Gram-positive bacilli (including *Clostridium* spp.). It is indicated for trichomoniasis, amebiasis and anaerobic bacterial infections. Metronidazole has been used for skin and soft tissue infections, oral and dental infections, intra-abdominal, pelvic and brain abscesses, anaerobic pulmonary infections and osteomyelitis. It can be used in combination with a broad-spectrum β-lactamase inhibitor–penicillin combination to treat Fournier's gangrene. Metronidazole is also used to treat giardiasis, New World mucocutaneous leishmaniasis and bacterial vaginosis.

Dosages

Metronidazole is available for oral and intravenous administration. For bacterial infections, it is given as 500 mg orally every 6 to 8 hours for 7 to 14 days. For bacterial vaginosis or trichomoniasis, a single 2 g dose is given or 500 mg may be taken twice a day for 7 days. The pediatric dose is 30 mg/kg/day in divided doses every 6 hours.

Contraindications

Metronidazole is contraindicated in patients with prior hypersensitivity to the drug and during the first trimester of pregnancy. It should be used with caution in patients with impaired liver function.

Major side effects

Metronidazole can cause a morbilliform eruption, pruritus, fever, gastrointestinal disturbances, a metallic taste and xerostomia, in addition to thrombophlebitis, transient leukopenia, dark urine and neurologic symptoms (e.g. headache, confusion, syncope, seizures, sensory neuropathy).

Interactions

Metronidazole increases circulating levels of cyclosporine, tacrolimus and phenytoin; it may increase the anticoagulant effect of warfarin. Metronidazole can cause a disulfiram-like reaction when combined with ethanol or with protease inhibitors, and administration of metronidazole with disulfiram may precipitate psychosis. Metronidazole may increase the risk of neuropathy due to reverse transcriptase inhibitors.

Pregnancy and lactation

Metronidazole is pregnancy category B. It has been shown to be teratogenic in rodents, but it has no known adverse effects on the developing human fetus. It is contraindicated during the first trimester of

NEWER ANTIBACTERIAL AGENTS					
Generic name	**Trade name(s)®**	**Formulations**	**Indications and dosing**	**FDA pregnancy category**	**Major side effects**
Daptomycin	Cubicin	iv	Complicated Gram-positive skin infections: 4 mg/kg iv q24 h × 7–14 days Adjust dose for renal or hepatic impairment	B	Constipation, diarrhea, nausea/vomiting, headache, insomnia, morbilliform eruptions, infusion site reactions, elevated transaminase and creatine kinase levels, myopathy (at higher doses), nephrotoxicity, eosinophilic pneumonia (rare)
Linezolid	Zyvox	600 mg tablet 100 mg/5 ml oral suspension iv	Skin infections (e.g. with MRSA): 10 mg/kg up to 400–600 mg po or (if complicated) iv q12 h* × 7–14 days Adjust dose for renal impairment	C	Headache, insomnia, diarrhea (occasionally due to *Clostridium difficile*), nausea/vomiting, bone marrow suppression (thrombocytopenia > anemia or leukopenia; especially if treated >14 days), neuropathy (peripheral or optic; primarily if treated >28 days), pancreatitis, elevated transaminase levels, lactic acidosis (rare), serotonin syndrome (when taken concurrently with other MAOIs, SSRIs or tricyclics), hypertension (when taken with α-agonist drugs)
Quinupristin/dalfopristin	Synercid	iv	Serious skin infections due to *S. aureus* or *S. pyogenes*: 7.5 mg/kg iv q12 h	B	Hyperbilirubinemia, infusion site reactions, arthralgias/myalgias, headache, nausea/vomiting, diarrhea (occasionally due to *C. difficile*)
Telavancin	Vibativ	iv	Complicated skin infections due to MRSA or other Gram-positive bacteria: 10 mg/kg iv q 24 h × 7–14 days Adjust dose for renal impairment	C	Nephrotoxicity, infusion site reactions, "red-man" syndrome, QT prolongation, headache, insomnia, foamy urine, dysgeusia, nausea/vomiting, diarrhea (occasionally due to *C. difficile*)
Tigecycline	Tygacil	iv	Complicated skin infections: 50 mg iv q12 h × 5–14 days Adjust dose for hepatic impairment	D	Nausea/vomiting, diarrhea (occasionally due to *C. difficile*), abdominal pain, headache, infusion site reactions, tooth discoloration (if age <8 years), anaphylaxis/hypersensitivity†, photosensitivity, pancreatitis, hepatic dysfunction, pseudotumor cerebri

*Every 8 hours for children with complicated infections or who are <5 years of age.
†Cross-reacts with tetracyclines.

Table 127.14 Newer antibacterial agents. MAOI, monoamine oxidase inhibitor; MRSA, methicillin-resistant *Staphylococcus aureus*; SSRI, selective serotonin reuptake inhibitor. h, hours; iv, intravenous(ly); po, orally; q, every.

pregnancy based on scattered reports of fetal malformation in women exposed to metronidazole, despite the fact that there has never been a reported increase in the overall risk of birth defects. Metronidazole should be used with caution in nursing women.

New Antibacterial Agents

Linezolid and quinupristin/dalfopristin are useful in serious staphylococcal and streptococcal skin infections, including infections with MRSA. Both inhibit bacterial protein synthesis. Daptomycin is a cyclic lipopeptide used for complicated skin infections. It kills bacteria by binding to and depolarizing bacterial cell membranes, inhibiting protein and nucleic acid synthesis. Tigecycline interferes with protein synthesis by binding to the 30S ribosomal subunit and is also used in complicated skin infections. Table 127.14 outlines the indications, dosages and side effects of these newer antibacterial agents.

Dapsone

The oral form of dapsone, a sulfone drug that is a component of combination therapy for leprosy but also has anti-inflammatory effects that are useful in the treatment of neutrophlic dermatoses, is discussed in Chapters 31 and 130.

ANTIFUNGAL AGENTS

Superficial dermatophytoses usually respond to topical antifungal agents (Table 127.15), which rarely have serious side effects. Several of these products are available without a prescription. Fungal infections of the hair and nails as well as systemic mycoses generally necessitate treatment with systemic antifungal medications. Furthermore, fungal infections in patients who are immunocompromised or who have extensive skin involvement often require systemic treatment. In addition, systemic antifungal therapy is occasionally necessary for superficial infections resistant to topical treatments in immunocompetent individuals[49].

Mechanisms of action

The mechanisms of action of antifungal agents are outlined in Table 127.16 and illustrated in Figures 127.6 and 127.7. Most azoles are fungistatic, although some are fungicidal at high concentrations. Allylamines, benzylamines and ciclopirox olamine have both fungistatic and fungicidal effects. The polyene antifungal agents – nystatin and amphotericin B – are fungistatic at low concentrations and fungicidal at high concentrations. Amphotericin B is available in three lipid formulations (liposomal, a lipid complex and a cholesteryl complex [colloidal dispersion]) that are less nephrotoxic but more expensive than the conventional form of this agent.

The aforementioned classes of antifungal agents all have anti-inflammatory effects. For example, naftifine inhibits chemotaxis and the production of reactive oxygen intermediates by neutrophils[50]. Azoles inhibit neutrophil chemotaxis, calmodulin activity, synthesis of leukotrienes and prostaglandins, and histamine release from mast cells[51–53]. Ketoconazole has anti-inflammatory activity comparable to that of hydrocortisone[54]. Ciclopirox olamine is also anti-inflammatory due to its inhibition of prostaglandin and leukotriene synthesis[52,55].

Griseofulvin is fungistatic against *Trichophyton*, *Microsporum* and *Epidermophyton* spp. It is not active against yeast (including *Malassezia* spp.), dimorphic fungi, *Cryptococcus* spp. or the fungi that cause chromomycosis.

Indications

Topical azoles are indicated for tinea corporis, tinea pedis, tinea cruris, pityriasis versicolor and mucocutaneous candidiasis. Within this group, oxiconazole and sulconazole have relatively weak activity against *Candida* spp. Butoconazole, clotrimazole, econazole, miconazole, terconazole and tioconazole are available in vaginal preparations to treat *Candida* vaginitis. Ketoconazole is additionally indicated for seborrheic dermatitis.

Topical allylamines and benzylamines are indicated for tinea pedis, tinea cruris and tinea corporis. Butenafine has been shown, *in vitro*,

Amphotericin B*	Fungizone	3% cream, ointment, lotion	B	Rx
OTHERS				
Ciclopirox olamine	Batrafen, Batrafen Nail Lacquer, Brumixol, Ciclochem, Fungowas, Loprox, Miclast, Micoxolamina, Mycoster, Nail Batrafen, Penlac, Primax	0.77% and 1% cream, gel, lotion, solution, 8% nail lacquer	B	Rx
Tolnaftate	Aftate, Equate, Genaspore, NP-27, Pitrex, Tinactin, Ting	1% cream, gel, powder, solution, aerosol liquid, aerosol powder	–	OTC
Undecylenic acid	Caldesene, Cruex, Decylenes, Gordochom	20% cream, 25% ointment, solution, 15% powder, aerosol foam, aerosol powder	–	OTC
Clioquinol*	Vioform HC, Lococorten-Vioform	3% clioquinol with 1% hydrocortisone or 0.02% flumethasone in a cream or ointment	C	–
Iodoquinol (iodochlorhydroxyquin)†	Alcortin, Vytone	1% iodoquinol with 2% hydrocortisone gel	C	Rx

*Not currently available in the US.
†A synthetic hydroxyquinoline with both antifungal and antibacterial effects.

Table 127.15 Topical antifungal agents. Other topical agents with antifungal activity not listed in this table include Whitfield's ointment (benzoic acid and salicylic acid), selenium sulfide, sodium thiosulfate, salicylic acid plus sulfur, zinc pyrithione, haloprogin, mafenide, amorolfine, propylene glycol and benzoyl peroxide. OTC, over the counter.

to be 10 to 100 times more effective than azole antifungals against common dermatophytes[56]. Terbinafine is 2 to 30 times more potent than azole antifungal agents against common dermatophytes *in vitro*[57]. Clinical trials have shown that terbinafine, butenafine and naftifine are superior to azole antifungals for tinea pedis[58,59]. The mycologic cure rates are significantly higher a month after treatment has stopped[60]. Post-treatment relapse rates are also lower for allylamines and benzylamines than for azole antifungal drugs[58,61,62]. For example, butenafine 1% cream applied once a day for 2 weeks for tinea cruris resulted in an 81% mycologic cure rate 4 weeks after the end of treatment[63]. In addition, topical terbinafine and butenafine are indicated for *Candida* infections, though they have relatively weak anti-*Candida* action compared to the topical azoles.

Of the two topical polyenes, only nystatin is commonly used. It is indicated for mucocutaneous *Candida* infections. Polyenes are not effective against dermatophytes[64,65]. Nystatin is not well absorbed when taken orally. However, this fact may be used to an advantage in treating anogenital candidiasis and candidal diaper dermatitis[65,66].

Ciclopirox olamine is active against dermatophytes, *Malassezia* spp., *Candida*, actinomycetes, molds, and Gram-positive and Gram-negative

MECHANISM OF ACTION OF ANTIFUNGAL DRUGS	
Drug class(es)	**Mechanism of action**
Polyenes	Bind irreversibly to cell membrane sterols (e.g. ergosterol) and increase membrane permeability
Echinocandins	Interfere with cell wall synthesis/permeability via inhibition of β-(1,3)-D-glucan synthesis
Imidazoles Triazoles	Interfere with cell membrane synthesis via inhibition of the fungal cytochrome P450-dependent 14-α-demethylase, which normally converts lanosterol to 14-demethyl lanosterol; this leads to accumulation of toxic 14-α-methyl sterols and prevents synthesis of ergosterol, which is required for structural integrity of the fungal cell membrane; these drugs may also impair fungal triglyceride/phospholipid synthesis and inhibit fungal oxidative/peroxidase enzymes (resulting in accumulation of toxic levels of hydrogen peroxide)
Allylamines Benzylamines Tolnaftate (a thiocarbamate)	Interferes with cell membrane synthesis via inhibition of squalene epoxidase, which is required for lanosterol formation; the resultant accumulation of intracellular squalene is fungicidal
Flucytosine	Cytosine analogue that interferes with DNA synthesis
Griseofulvin	Disrupts mitotic spindle by interacting with microtubules, thereby inhibiting mitosis in dermatophytes
Ciclopirox olamine (a hydroxypyridone)	Chelates polyvalent cations (e.g. Fe^{3+}) that have important functions in fungal cytochromes, catalases and peroxidases; it thereby inhibits respiration, blocks transport of amino acids and alters cell membrane permeability
Selenium sulfide	Antimitotic properties; reduces cellular adhesion in the stratum corneum, facilitating shedding of fungi

Table 127.16 Mechanism of action of antifungal drugs. In addition to antifungal effects, these agents have anti-inflammatory properties (see text).

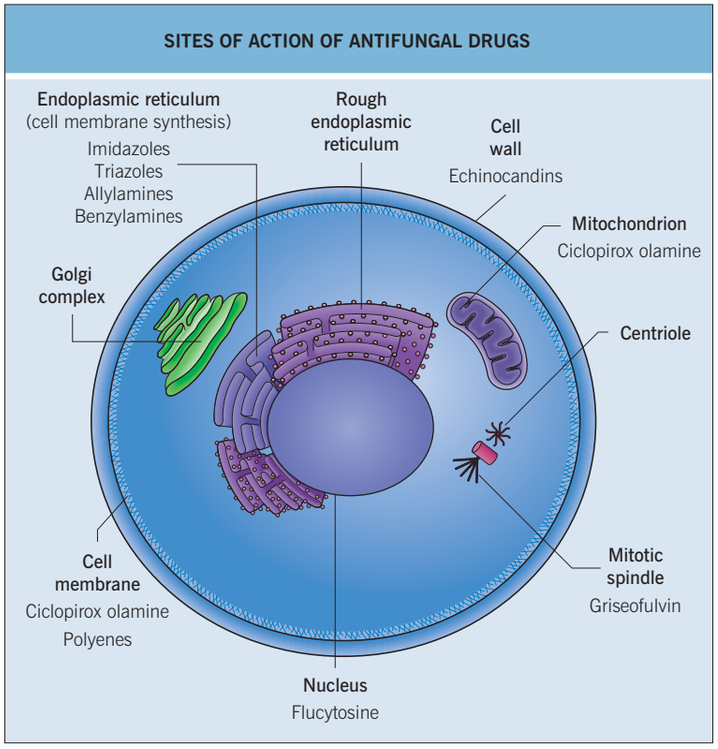

Fig. 127.6 Sites of action of antifungal drugs. Of note, ciclopirox olamine has more than one site of action.

bacteria. It is indicated for tinea corporis, tinea pedis, tinea cruris, pityriasis versicolor, mucocutaneous candidiasis and seborrheic dermatitis. *In vitro*, it is less potent against dermatophytes than the allylamine and benzylamine antifungals, but more potent than the azole antifungals. However, it is more effective than the azoles, allylamines or benzylamines against *Candida*.

Tolnaftate, undecylenic acid and clioquinol are indicated for dermatophyte infections, but they are less efficacious than the aforementioned topical agents; tolnaftate is also effective for *Malassezia* infections.

Indications for systemic antifungal agents are outlined in Table 127.17. Griseofulvin is classically the drug of choice for treating dermatophyte infections resistant to topical therapy in children. Mycologic cure rates are usually 80% to 95%. Terbinafine, itraconazole and fluconazole have also been successful in treating superficial dermatophyte infections of the skin, hair and nails in adults and children[49,67]. Terbinafine at standard doses results in a mycologic cure rate of approximately 70% for onychomycosis of the toenails and 80% for fingernails. Itraconazole, used continuously or in a pulse regimen, produces similar mycologic cure rates. Terbinafine has been shown to have a higher combined clinical and mycologic cure rate than itraconazole (38% versus 23%, $p = 0.004$) after 12 weeks of continuous oral therapy for toenail onychomycosis[68]. Fluconazole is generally the drug of choice for systemic candidiasis. However, cases of fungemia due to azole-resistant *Candida* have been reported[69]; amphotericin B is then the next best alternative. Fluconazole is relatively hydrophilic compared to other systemic azole antifungal drugs and thus is distributed to the cerebrospinal fluid and can be used to treat fungal meningitis. Flucytosine is generally used concomitantly with amphotericin B for a synergistic effect and to decrease the likelihood of resistance.

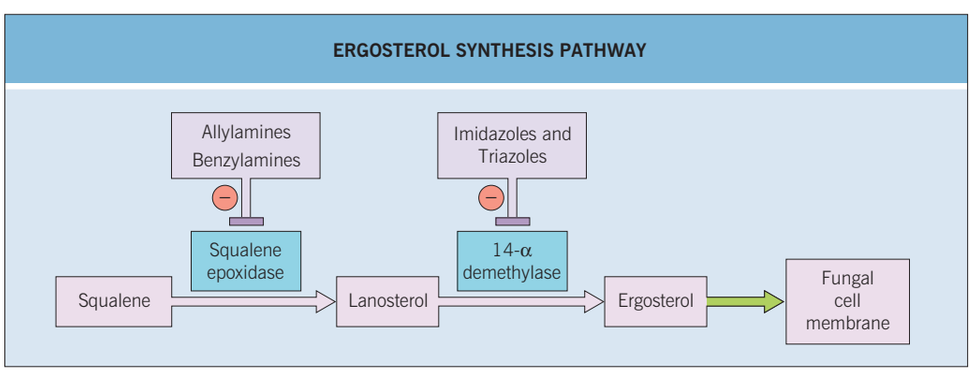

Fig. 127.7 Ergosterol synthesis pathway. Squalene is converted to lanosterol by squalene epoxidase. This enzyme is inhibited by the allylamine and benzylamine antifungals. 14-α demethylase converts lanosterol to ergosterol. Imidazole and triazole antifungals inhibit this conversion.

INDICATIONS FOR SYSTEMIC ANTIFUNGAL AGENTS			
Generic name	**Antifungal spectra**	**Indications**	**FDA pregnancy category**
Terbinafine	*Epidermophyton floccosum*, *Trichophyton mentagrophytes*, *T. rubrum*, *T. tonsurans*	Onychomycosis Superficial fungal infections: widespread, severe or resistant to topical antifungals*	B
Ketoconazole	Most dermatophytes, *Candida* spp.	Systemic fungal infections: histoplasmosis, non-meningeal cryptococcosis, blastomycosis, mucocutaneous candidiasis, oropharyngeal and esophageal candidiasis, vaginal candidiasis and nail candidiasis Superficial fungal infections: widespread, severe or resistant to topical antifungals*	C
Itraconazole	Dermatophytes, yeasts (*Candida*, *Pityrosporum* spp.), some molds	Blastomycosis, histoplasmosis and aspergillosis (oral and intravenous), onychomycosis (oral), oropharyngeal and esophageal candidiasis (solution) Superficial fungal infections: widespread, severe or resistant to topical antifungals*	C
Fluconazole	*Candida* spp., *T. tonsurans*, *T. rubrum*, *Microsporum canis*	Oropharyngeal, esophageal, vaginal and systemic candidiasis Cryptococcal meningitis Superficial fungal infections resistant to topical antifungals*	C
Voriconazole	*Aspergillus*, *Candida*, *Fusarium*, *Scedosporium* spp.	Invasive aspergillosis (superior to amphotericin B), esophageal candidiasis, serious infections caused by *Fusarium* and *Scedosporium apiospermum*	D
Posaconazole	*Candida*, *Aspergillus*, *Cryptococcus*, *Fusarium*, *Zygomycetes* spp.	Prevention of invasive aspergillosis and *Candida* infections in immunosuppressed hosts	C
Pramiconazole†	*Dermatophytes, Pityrosporum* spp.	Tinea capitis, tinea corporis, tinea cruris, tinea pedis, onychomycosis, tinea versicolor	NA
Griseofulvin	*Trichophyton*, *Microsporum*, *Epidermophyton* spp. (no activity against *Candida* or *Malassezia* spp.)	Tinea capitis and onychomycosis Superficial fungal infections: widespread, severe or resistant to topical antifungals	C
Amphotericin B	*Candida* spp., *Cryptococcus neoformans*, dimorphic fungi (*Histoplasma capsulatum*, *Coccidioides immitis* and *Blastomyces dermatitidis*), *Aspergillus* spp.	Severe fungal infections including disseminated systemic candidiasis, cryptococcal meningitis, blastomycosis, disseminated histoplasmosis, extracutaneous sporotrichosis, coccidioidomycosis, paracoccidioidomycosis, mucormycosis and aspergillosis	B
Flucytosine	*Candida*, *Cryptococcus*, *Aspergillus* spp., agents of chromomycosis	Second-line therapy for severe fungal infections including candidiasis, cryptococcosis, aspergillosis and chromomycosis	C
Caspofungin acetate**	*Aspergillus fumigatus*, *A. flavus*, *A. terrus*, *Candida* spp.	Invasive aspergillosis in patients refractory to or intolerant of other antifungals, candidemia, esophageal candidiasis	C
Micafungin**	*Candida*, *Aspergillus* spp.	Prophylaxis for *Candida* infections in hematopoietic stem cell transplant patients, esophageal candidiasis	C
Anidulafungin**	*Candida*, *Aspergillus* spp.	Candidemia, esophageal candidiasis, intra-abdominal *Candida* infections and peritonitis	C

*Resistant superficial fungal infections treated by systemic terbinafine and azole antifungals include tinea corporis, tinea cruris and tinea pedis. The azoles are also used for pityriasis versicolor.
†This drug is under development.
**Members of the echinocandin class of antifungal drugs.

Table 127.17 Indications for systemic antifungal agents. The use of flucytosine is declining, but it is still given in certain situations. NA, not applicable.

Dosages

Topical antifungal agents are generally applied twice a day until clinical signs and symptoms are improved, usually for 1 to 4 weeks. Occlusion should not be used. Shampoos are used every 3 to 4 days and are left in place for 5 minutes before rinsing. Nystatin oral suspension is held in the mouth for as long as possible before swallowing or expectorating, which is repeated four times a day. There is essentially no systemic absorption. The pastilles are allowed to dissolve slowly in the mouth four to five times a day for up to 14 days. Ciclopirox olamine nail lacquer is applied daily for 1 week and then removed with alcohol; this cycle is then repeated.

A typical treatment course of systemic terbinafine is 12 weeks for toenail onychomycosis or 6 weeks for fingernail onychomycosis, and 2 weeks for superficial tinea infections resistant to topical antifungal agents. Dosages are based on age and weight and are shown in Table 127.18[49]. For tinea capitis in children, terbinafine is given continuously for 3 to 4 weeks.

Ketoconazole is available in 200 mg tablets. Adults take one or two tablets daily. Children over 2 years of age take 6.6 mg/kg orally once daily (typically for 5 days) for pityriasis versicolor. For other tinea infections and cutaneous candidiasis, children over 2 years of age take 3.3 to 6.6 mg/kg/day orally for 2 to 4 weeks. For mucocutaneous candidiasis in children, the dose is 5 to 10 mg/kg/day divided into two doses; the maximum dose is 400 mg a day. Absorption is improved with an acidic stomach pH. The manufacturer suggests ketoconazole should be taken with food. However, some clinicians suggest plasma levels are higher when the drug is taken on an empty stomach.

Itraconazole is available as 100 mg capsules and a 10 mg/ml cherry-caramel-flavored solution. The solution should be taken on an empty stomach, and the capsules should be taken with a full meal to enhance absorption. Pediatric dosing is 3 to 5 mg/kg daily[67,70]. Doses over 200 mg should be divided into two doses per day. For tinea capitis in children, itraconazole may be given continuously for 2 to 4 weeks or as 1- to 3-week-long pulses (with 3 weeks without drug in between each pulse). Adult oral dosages for various indications are outlined in Table 127.19. Itraconazole is also available for intravenous infusion, given 200 mg intravenously twice a day for four doses and then 200 mg every day. The maximum length of intravenous treatment is usually 14 days. Treatment of oropharyngeal and esophageal candidiasis is for at least 3 weeks and should be continued for at least 2 weeks after symptoms resolve. Itraconazole solution is swished in the mouth, 10 mg at a time, for several seconds and then swallowed.

Fluconazole is available as 50 mg, 100 mg and 200 mg tablets and as an orange-flavored suspension in 10 mg/ml and 40 mg/ml strengths. Table 127.20 outlines the dosing of fluconazole. Unlike ketoconazole and itraconazole, fluconazole is not dependent on a low gastric pH for absorption.

Voriconazole is used for invasive aspergillosis at 4 mg/kg intravenously every 12 hours or 100 to 200 mg orally every 12 hours. A loading dose of 6 mg/kg intravenously, given twice, 12 hours apart, is administered prior to the intravenous or oral regimen. Dose adjustments must be made in patients with renal or hepatic dysfunction.

Posaconazole is a 40 mg/ml suspension, given with food. It is indicated for prophylaxis of invasive fungal infections in immunocompromised patients. The dosage is 200 mg orally three times daily in patients over 13 years of age. For oropharyngeal candidiasis, it may be given as 100 mg orally twice daily (on the first day) and then 100 mg daily for 12 days. In cases refractory to fluconazole or itraconazole, the dose is increased to 400 mg orally twice daily. Duration of treatment varies according to patient response[71].

Dosages for griseofulvin are shown in Table 127.21. In the US, increasing doses have been required for the treatment of tinea capitis

DOSING OF TERBINAFINE	
ORAL TABLETS	
Adults	250 mg qd
Children over 2 years old and under 20 kg	62.5 mg qd
Children over 2 years old and 20–40 kg	125 mg qd
Children over 2 years old and over 40 kg	250 mg qd
ORAL GRANULES FOR TINEA CAPITIS	
Children over 4 years old and under 25 kg	125 mg qd
Children over 4 years old and 25–35 kg	187.5 mg qd
Children over 4 years old and over 35 kg	250 mg qd

Table 127.18 Dosing of terbinafine. Terbinafine comes in 250 mg tablets and 125 mg or 187.5 mg packets of granules; the latter are taken after sprinkling on a non-acidic, non-fruity, soft food. qd, daily.

ADULT DOSING OF ORAL ITRACONAZOLE	
Indication	**Adult dosage**
Pityriasis versicolor	200 mg po qd for 5–7 days
Tinea corporis, tinea cruris	100 mg po qd for 2 weeks *or* 200 mg po qd for 1 week
Tinea pedis	100 mg po qd for 2 weeks *or* 200 mg po qd for 1 week
Blastomycosis, histoplasmosis	200 mg po qd May increase by 100 mg increments to a maximum of 400 mg po qd for at least 3 months
Cutaneous sporotrichosis	200 mg po qd for 3–6 months or until 2–4 weeks after all lesions have resolved
Aspergillosis	200–400 mg po qd for at least 3 months May give loading dose of 200 mg tid for first 3 days in life-threatening conditions
Onychomycosis of toenails	200 mg po qd for 12 weeks *or* 200 mg po bid for 1 week, then 3 weeks without treatment, repeated twice more for a total of three pulses of therapy
Onychomycosis of fingernails	200 mg po qd for 6 weeks *or* 200 mg po bid for 1 week, then 3 weeks without treatment, then 200 mg po bid for 1 week
Oropharyngeal candidiasis	Swish and swallow 200 mg qd for 1–2 weeks
Oropharyngeal candidiasis refractory to fluconazole	Swish and swallow 100 mg bid
Esophageal candidiasis	Swish and swallow 100–200 mg qd

Table 127.19 Adult dosing of oral itraconazole. Itraconazole is available in 100 mg capsules and a 10 mg/ml solution. The safety of itraconazole in children has not been established. Children 3 to 16 years old have been treated for systemic fungal infections with itraconazole capsules or solution, typically at a dose of 5 mg/kg/day, without any problems. Animal studies have shown teratogenicity at high doses, causing skeletal defects in rats. Of note, itraconazole oral solution contains the excipient hydroxypropyl-β-cyclodextrin, which produced pancreatic adenocarcinomas in rats (but not mice) when given for extended periods. bid, twice daily; po, orally; qd, daily; tid, three times daily.

DOSING OF ORAL FLUCONAZOLE		
Indication	**Pediatric dosage**	**Adult dosage**
Pityriasis versicolor		400 mg po once *or* 300 mg po once, with possible second dose in 1 week, depending on clinical response
Tinea corporis, tinea cruris		50–100 mg po qd *or* 150 mg po qwk for 2–4 weeks
Tinea pedis		Pulse doses of 150 mg po qwk for 2–6 weeks
Tinea capitis		6 mg/kg/day for 2–3 weeks
Oropharyngeal candidiasis	6 mg/kg on day 1 then 3 mg/kg q24–72 h for 14 days*	200 mg on day 1 then 100 mg qd for at least 2 weeks
Vaginal candidiasis		150 mg po once
Esophageal candidiasis	6 mg/kg on day 1 then 3–12 mg/kg q24–72 h for 21 days*	200 mg on day 1 then 100 mg qd for at least 3 weeks Treat for at least 2 weeks after symptoms resolve
Systemic candidiasis	6–12 mg/kg q24–72 h for 28 days*	Up to 400 mg qd
Prophylaxis of candidiasis in bone marrow transplantation	10–12 mg/kg q24 h (maximum 600 mg/day)	400 mg qd
Cryptococcal meningitis	12 mg/kg iv on day 1 then 6–12 mg/kg q24–72 h* (maximum 600 mg/kg iv qd; continue until 10–12 weeks after culture is negative)	400 mg on day 1 then 200–400 mg qd Continue until 10–12 weeks after spinal fluid is negative
Prevention of relapse of cryptococcal meningitis in HIV patients		200 mg po qd

*If the patient is less than 14 days old, dosing is every 24–72 h. If the patient is over 14 days old, dosing is every 24 h.

Table 127.20 Dosing of oral fluconazole. h, hours; iv, intravenously; po, orally; q, every; qd, daily; qwk, weekly.

ORAL DOSING OF GRISEOFULVIN			
Generic name	**Adult**		**Pediatric (over 2 years of age)**
	Tinea corporis, cruris	**Tinea pedis, manuum, unguium, capitis**	
Griseofulvin microsize* (125 mg/5 ml suspension; 250 and 500 mg tablets)	500–1000 mg daily	750–1500 mg daily	15–20 mg/kg daily (usual maximum 1 g); use higher range (20-25 mg/kg daily) for tinea capitis
Griseofulvin ultramicrosize* (125 and 250 mg tablets)	375–500 mg daily	500–750 mg daily	10–15 mg/kg/day (maximum usually 750 mg/day)
DURATION OF TREATMENT			
2–4 weeks for tinea corporis 6–12 weeks for tinea capitis 4–8 weeks for tinea pedis 4 months for fingernail onychomycosis† 6 months for toenail onychomycosis†			

*To increase absorption, griseofulvin should be taken with a fatty meal.
†No longer commonly used for this indication; may require a longer duration of treatment.

Table 127.21 Oral dosing of griseofulvin.

due to *Trichophyton tonsurans*. The long duration of therapy required with griseofulvin is a significant disadvantage and contributes to noncompliance. Absorption of griseofulvin is improved when it is administered with fatty foods. Drug particle size reduction through micronization and ultra-micronization has also significantly enhanced oral absorption.

Dosing of intravenous amphotericin B varies depending upon the formulation of the medication (e.g. 0.75–1 mg/kg/day of conventional amphotericin B versus 3–5 mg/kg/day of lipid formulations). In adults, flucytosine is given at a dose of 150 mg/kg orally daily, divided into four doses. Taking the medicine over 15 minutes decreases associated nausea. Doses of both drugs should be adjusted in patients with renal insufficiency.

Caspofungin acetate is given as a slow intravenous infusion over 1 hour. For treatment of *Aspergillus* infections, the loading dose on the first day is 70 mg. The dose is 50 mg intravenously per day thereafter. Patients who do not respond to this dose may respond to 70 mg intravenously per day. Caspofungin must not be mixed with solutions containing dextrose, and patients with moderate hepatic insufficiency should receive 35 mg per day after the 70 mg loading dose. This drug has not been adequately studied in children.

Micafungin is only available in an intravenous form. For esophageal candidiasis, it is administered as 150 mg intravenously daily. In hematopoietic stem cell transplant patients, as prophylaxis for *Candida* infections, it may be given at a dose of 50 mg intravenously daily. Anidulafungin is also available in an intravenous form for *Candida* infections[72]. In candidemia, the dose is 100 mg intravenously daily after a loading dose of 200 mg; treatment should continue until 2 weeks after the most recent positive blood culture. For esophageal candidiasis, the dose is 50 mg daily.

Contraindications

Topical and systemic antifungals are contraindicated in patients with hypersensitivity to any of the formulation components. Systemic antifungals are contraindicated in patients who are taking other drugs that may cause potentially serious interactions (see below). Itraconazole is contraindicated in patients with left-sided heart disease and should be avoided in pregnant or lactating patients. Ketoconazole and itraconazole may not be absorbed in patients with achlorhydria. Fluconazole absorption, however, is not dependent on a low gastric pH[73]. Griseofulvin is contraindicated in patients with acute intermittent porphyria, variegate porphyria, porphyria cutanea tarda or liver failure. All systemic antifungal agents should be used with caution in patients with liver or kidney disease. Flucytosine should be used with caution in patients with bone marrow suppression.

Major side effects

The most common side effect of topical antifungal drugs is local skin irritation, which may be more severe with occlusion. Clinical manifestations include burning, stinging, pruritus, erythema, edema, peeling, blistering and allergic contact dermatitis. Clioquinol can cause discoloration of clothes, skin, hair and nails.

Oral terbinafine may cause a morbilliform eruption and, less commonly, urticaria, pruritus, alopecia or dermatitis. Severe cutaneous reactions that have been caused by systemic terbinafine include Stevens–Johnson syndrome and toxic epidermal necrolysis, as well as acute generalized exanthematous pustulosis, pustular psoriasis, flares of psoriasis and subacute cutaneous lupus erythematosus[74–78]. Non-cutaneous side effects of terbinafine include gastrointestinal disturbances, elevated liver enzymes, headaches, taste and visual disturbances, transient decreases in absolute lymphocyte count, and, rarely, neutropenia in immunosuppressed patients. This drug should be used with caution in patients with liver or kidney disease. It is recommended that liver enzyme tests be performed before and (for courses lasting >6 weeks or in patients at risk for hepatic disease) during treatment. The side effects of the systemic azole antifungals are listed in Table 127.22.

Griseofulvin has been used for over 40 years with infrequent adverse effects and is considered a very safe medication. Its most common side effects are headache and gastrointestinal disturbances. It also may cause a fixed drug eruption, photosensitivity, petechiae, pruritus, exfoliative dermatitis or urticaria, and it can precipitate or exacerbate lupus erythematosus or porphyria. Griseofulvin has occasionally been associated with enuresis, proteinuria, increased urinary frequency, arthralgias, fever, hypersensitivity reactions (including angioedema and serum sickness-like reactions), neurologic side effects (e.g. confusion, blurred vision, vertigo, depression, nightmares, insomnia, ataxia, paresthesias), syncope, epistaxis, estrogen-like effects, sore throat, hepatotoxicity and leukopenia.

Amphotericin B commonly causes fever, chills, nausea and vomiting. These side effects may be minimized by pretreatment with aspirin or acetaminophen, diphenhydramine and/or intravenous hydrocortisone. Less commonly, it may also cause anorexia, diarrhea, orthostatic hypotension or hypertension, tachycardia, dyspnea, headache and skin eruptions, including exanthems, exfoliative dermatitis, fixed drug eruption, flushing, urticaria, and infusion site reactions. Amphotericin B can produce hypokalemia, thrombocytopenia and renal toxicity characterized by increased BUN and creatinine. Damage to the kidney may be mediated directly or through vasoconstriction and can be severe and irreversible after high doses. Less commonly, amphotericin B can cause seizures, arrhythmias, agranulocytosis, liver failure or anaphylaxis.

Flucytosine can cause a number of neurologic side effects, including headaches, fatigue, vertigo, ataxia, paresthesias, confusion and hallucinations. In addition to gastrointestinal disturbances (e.g. nausea, vomiting, abdominal pain and diarrhea), hypokalemia and hypoglycemia may occur with use of this drug. Flucytosine can also cause more serious side effects, including cardiac and respiratory arrest, renal failure, aplastic anemia, agranulocytosis, thrombocytopenia, gastrointestinal bleeding and colitis.

Caspofungin acetate may cause headaches, fever, infusion site reactions, phlebitis, flushing, erythema, induration, facial swelling and pruritus as well as nausea and vomiting. Anaphylaxis has been reported. Laboratory abnormalities that have been encountered include increased alkaline phosphatase, hypokalemia, eosinophilia, proteinuria and hematuria. Micafungin may uncommonly cause anaphylaxis, liver or kidney dysfunction, thrombophlebitis or hemolytic anemia. It can also result in headaches, nausea, rigors and leukopenia. Skin reactions include "rash" and injection site reactions. Anidulafungin may cause liver toxicity, diarrhea, hypokalemia and infusion reactions.

SIDE EFFECTS OF SYSTEMIC AZOLE ANTIFUNGAL AGENTS

Generic name	Side effects
Ketoconazole	• Nausea, vomiting, abdominal pain, idiosyncratic hepatotoxicity • Anaphylaxis, urticaria, pruritus • At higher doses, suppresses testosterone and cortisol synthesis
Itraconazole	• Morbilliform eruption, pruritus, urticaria, alopecia, Stevens–Johnson syndrome (rarely); parenteral administration may result in infusion site reactions • Anorexia, nausea, vomiting, abdominal pain, hepatic dysfunction • Fatigue, headaches, dizziness • Fever, edema, hypokalemia, neutropenia (rarely) • Rarely causes congestive heart failure, pulmonary edema, anaphylaxis, peripheral neuropathy
Fluconazole	• Morbilliform eruption, exfoliative dermatitis (rarely) • Nausea, vomiting, abdominal pain, diarrhea, hepatotoxicity • Headache
Voriconazole	• Phototoxicity; this can lead to pseudoporphyria and (with chronic use) accelerated photoaging (Fig. 127.8), aggressive or multifocal cutaneous squamous cell carcinomas (especially in the setting of immunosuppression), and melanoma[79,80] • Visual disturbances (e.g. blurred vision, altered color perception, photophobia), headache, hallucinations • Nausea, vomiting, diarrhea, abdominal pain, hepatotoxicity • Fever, peripheral edema • QT prolongation

Table 127.22 Side effects of systemic azole antifungal agents.

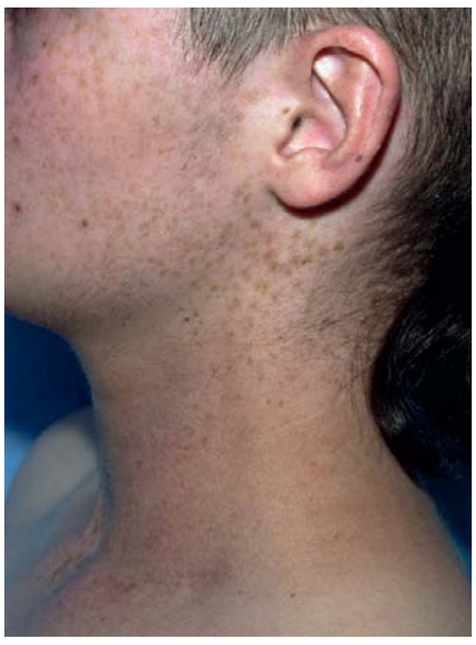

Fig. 127.8 Accelerated photoaging due to chronic voriconazole therapy. Note the solar lentigines in this young man with chronic granulomatous disease. *Courtesy, Edward Cowen, MD.*

Interactions

Systemic terbinafine inhibits the cytochrome P450 isoform CYP2D6. As such, it may increase serum levels and toxic effects of other drugs metabolized by this pathway, including β-blockers, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), MAO inhibitors, and type B and class IC antiarrhythmics. Terbinafine increases cyclosporine clearance by 15% and decreases caffeine clearance by 19%. It also decreases the efficacy of codeine. Terbinafine used with thioridazine may cause prolonged QT intervals and arrhythmias. Whereas cimetidine increases terbinafine levels, rifampin decreases terbinafine levels by doubling its rate of clearance.

Azole antifungal drugs exert their therapeutic effect by inhibiting cytochrome P450 enzymes (see above). Cytochrome P450 enzymes play a major role in transforming lipophilic drugs to more easily excreted metabolites[73]. Inhibition of this enzyme family is the cause of many of the azole antifungals' drug–drug interactions. These interactions have resulted in black box warnings in the package insert by the FDA in the US. The interactions are listed in Table 127.23.

Griseofulvin may decrease the levels and efficacy of warfarin and salicylates. Barbiturates may decrease griseofulvin efficacy by decreasing its absorption. Griseofulvin potentiates the effect of alcohol or may induce a disulfiram-like reaction[73]. It also increases estrogen-metabolizing liver enzymes, which may make oral contraceptives less effective or cause menstrual irregularities.

Systemic corticosteroids, loop diuretics and thiazide diuretics increase the risk of developing hypokalemia due to amphotericin B. Antipsychotics used concomitantly with amphotericin B may cause QT prolongation and cardiac arrhythmias. Nephrotoxic drugs such as cisplatin, flucytosine, gentamicin and vancomycin may compound the nephrotoxicity of amphotericin B. Amphotericin may increase digoxin levels. Cisplatin used in conjunction with flucytosine increases the risk for nephrotoxicity and bone marrow suppression.

Caspofungin acetate does not affect the cytochrome P450 system. It does decrease tacrolimus levels, and cyclosporine increases caspofungin levels. Phenytoin, rifampin, dexamethasone, carbamazepine and several antiretroviral drugs (efavirenz, nelfinavir, nevirapine) can decrease caspofungin levels.

Pregnancy and lactation

Topical imidazoles have not been shown to cause any problems during pregnancy; their pregnancy categories are listed in Table 127.15. Clotrimazole used intravaginally during the second and third trimesters has not been shown to cause birth defects or other problems in humans. Topical imidazoles have not been shown to cause any problems during breastfeeding. Topical oxiconazole is excreted in breast milk, but it is not known whether the other topical imidazoles are excreted in breast milk. Topical nystatin has not been shown to cause birth defects or other problems in humans; it is not known whether topically applied nystatin is excreted in breast milk. There are not adequate studies of ciclopirox olamine in pregnant women. Although a small amount of this drug is absorbed through the skin, animal studies involving mice, rats, rabbits and monkeys showed no impairment of fertility or harm to the fetus at doses 10 times higher than the topical human dose. It is not known whether ciclopirox olamine is secreted in breast milk. Tolnaftate and undecylenic acid have not been reported to cause problems during pregnancy or with breastfeeding.

The FDA pregnancy categories of the systemic antifungal drugs are listed in Table 127.17. These drugs should not be used to treat onychomycosis if the patient is pregnant or contemplating pregnancy. During pregnancy, they should be reserved for systemic fungal infections only if the benefit outweighs the risk. Although animal studies of oral terbinafine have shown no adverse effects during pregnancy, there are no adequate studies in pregnant women. Orally administered terbinafine is secreted in breast milk and is not recommended for use in nursing mothers.

There are no adequate human studies of the effects of azole antifungals during pregnancy or nursing. Itraconazole is contraindicated in lactating patients because it is excreted in human milk. Fluconazole is excreted in breast milk. Griseofulvin has been associated with fetal abnormalities in rats and dogs. Rare cases of conjoined twins have been reported in women taking griseofulvin in the first trimester of pregnancy. Patients should avoid pregnancy for at least 1 month after discontinuing griseofulvin[81]. There are no adequate studies of

DRUG INTERACTIONS OF SYSTEMIC AZOLE ANTIFUNGAL AGENTS		
Interacting drug	**Result**	**Azoles involved**
Astemizole, terfenadine, cisapride (banned or restricted)	Arrhythmia, torsade de pointes	K, I, F, V
Warfarin	Increased warfarin levels	K, I, F, V
Cyclosporine, tacrolimus	Increased cyclosporine or tacrolimus levels, nephrotoxicity, neurotoxicity, hypertension	K, I, F, V
Rifampin, rifamycin	Decreased plasma levels of azole antifungals (ketoconazole also decreases absorption of rifamycin)	K, I, F, V
Phenytoin	Phenytoin causes decreased levels of itraconazole, ketoconazole Fluconazole causes increased levels of phenytoin	K, I, F, V
Sildenafil (Viagra®)	Increased sildenafil levels	K, I, F, V
Oral hypoglycemics	Hypoglycemia	K, I, F, V
Oral contraceptives	Increased levels of estrogens & progestins; effects on contraception debated	K, I, F, V
Antacids, H_2 antihistamines, proton pump inhibitors, anticholinergics, didanosine	Decreased gastrointestinal absorption of azole antifungals Administration of omeprazole with voriconazole causes increased levels of both drugs	K, I, V
Benzodiazepines	Excessive sedation	K, I, F, V
Indinavir	Increased indinavir levels	K
Corticosteroids	Increased corticosteroid levels	K
Digoxin	Increased digoxin levels	I, F, V
HMG-CoA reductase inhibitors (e.g. atorvastatin, simvastatin)	Rhabdomyolysis, myopathy	I, V
Dihydropyridine calcium channel blockers	Edema	I, V
Phenobarbital, carbamazepine, isoniazid, revirapine	Decreased levels of itraconazole	I, V
Pimozide, buspirone, quinidine, vincristine	Increased levels of interacting drug	I, V
Thiazide diuretics (e.g. HCTZ)	Increased levels of fluconazole	F
Theophylline, nucleoside analogues	Increased levels of interacting drug	F, V
Ritonavir	Increased levels of interacting drug	I, K

Table 127.23 Drug interactions of systemic azole antifungal agents. K, ketoconazole; I, itraconazole; F, fluconazole; V, voriconazole.

amphotericin B or flucytosine in pregnant or lactating women. Flucytosine has been teratogenic in rat and mouse studies. Caspofungin acetate is toxic to rat and rabbit embryos and is excreted in breast milk in rats.

ANTIVIRAL AGENTS

This section reviews antiviral agents used for herpes simplex virus (HSV) and varicella–zoster virus (VZV) infections. Table 127.24 lists the topical antiherpetic antiviral medications. Antiretroviral medications (see Ch. 78) and immunomodulating medications (see Ch. 128) are addressed elsewhere in the text.

Mechanisms of action

Figure 127.9 illustrates the mechanism of action of the major antiherpetic drugs.

Valacyclovir is the prodrug of acyclovir. It is almost completely converted to acyclovir by valacyclovir hydrolase while passing through the gastrointestinal tract and liver. It has an oral bioavailability approximately three times greater than that of acyclovir (55% versus 15–30%) and is also more conveniently dosed than acyclovir.

Penciclovir is an acyclic guanosine analogue with a mechanism of action similar to acyclovir. It reaches higher intracellular concentrations and has a longer intracellular half-life than acyclovir (2.3–3 hours versus 1.3–1.5 hours). However, it is less potent because it does not cause chain termination of viral DNA, and it has a poor oral bioavailability. For these reasons, this medication is only available in topical form[82]. Famciclovir is the prodrug of penciclovir. The bioavailability of famciclovir is about 77%. Like valacyclovir, it is converted to its active form in the gastrointestinal tract and liver[83]. *In vitro* studies show that penciclovir is at least as effective as acyclovir against HSV-1 and HSV-2[84].

Docosanol, also known as behenyl alcohol, is a saturated 22-carbon aliphatic alcohol that exhibits antiviral activity against several lipid-enveloped viruses, including HSV. After the virus has attached to the host cell, n-docosanol prevents the fusion of the HSV envelope with the plasma membrane of uninfected cells[85].

Indications

Topical acyclovir is indicated for the initial episode of genital herpes. It decreases the duration of viral shedding from 7 days to 4 days[86]. In some studies it has also been shown to be effective in recurrent genital

TOPICAL ANTIHERPETIC ANTIVIRAL AGENTS				
Generic name	**Trade name(s)®**	**Formulations**	**FDA pregnancy category**	**OTC/Rx**
Acyclovir	Acic, Acicloftal, Aciclor, Aciclosina, Acivir, Acivir Eye, Aclovir, Acyclo-V, Acyvir, Avirax, Avorax, Azovir, Cicloferon, Cicloviral, Clinovir, Clovicin, Clovix, Cusiviral, Cyclivex, Cyclovir, Deherp, Eduvir, Entir, Herpefug, Herpex, Herpoviric Rp, Hexidol, Inmerax, Lisovyr, Lovir, Lovire, Maynor, Norum, Oppvir, Poviral, Quavir, Supra-Vir, Supraviran, Vacrovir, Vicorax, Virogon, Virex, Virless, Virobis, Zevin, Zoter, Zovir, Zovirax, Zyclir With 1% hydrocortisone: Xerese	5% ointment, cream	B	Rx
Penciclovir	Denavir, Vectavir	1% cream	B	Rx
Docosanol	Abreva	10% cream	B	OTC

Table 127.24 Topical antiherpetic antiviral agents. OTC, over the counter.

herpes[87]. Topical acyclovir is indicated for non-life-threatening mucocutaneous herpes simplex infections in immunocompromised patients, but these patients often require systemic therapy. In immunocompetent individuals, acyclovir ointment is less effective for orolabial herpes infections than for genital herpes; however, a topical combination of acyclovir and hydrocortisone can shorten healing time and is indicated for orolabial herpes in this group of patients.

Penciclovir is active against HSV-1, HSV-2, VZV and EBV. Penciclovir cream is indicated for treatment of recurrent orolabial herpes simplex infections. It has not been studied in immunocompromised patients. Compared to placebo, penciclovir shortens healing time and decreases pain and viral shedding in herpes labialis[82]. Docosanol is available in the US as a non-prescription drug and is also indicated for the topical treatment of recurrent orolabial herpes.

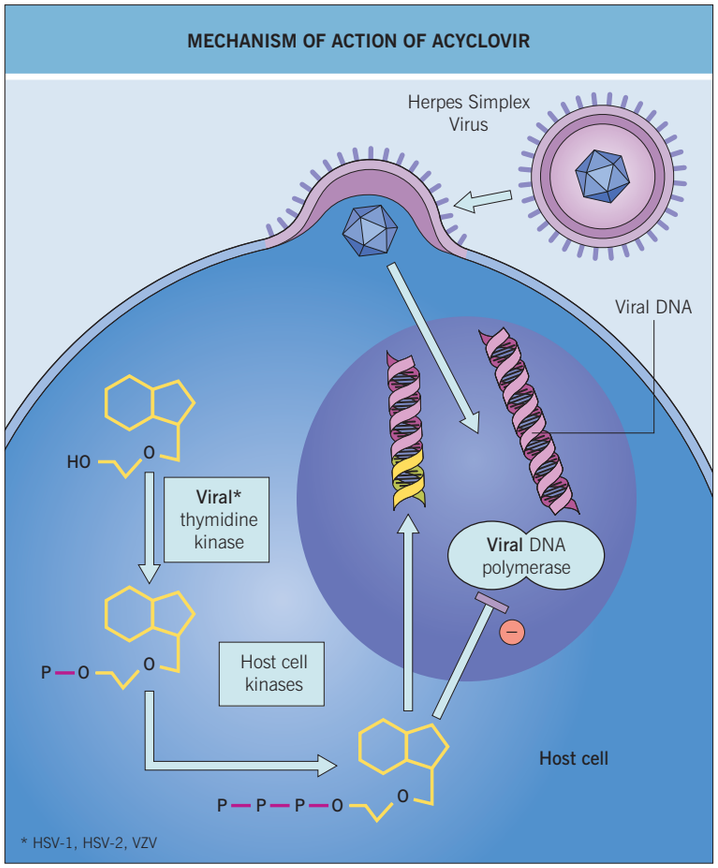

Fig. 127.9 Mechanism of action of acyclovir. Acyclovir is a synthetic purine nucleoside analogue (similar in chemical structure to deoxyguanosine) that has a high affinity for HSV-1, HSV-2 and VZV thymidine kinase, which phosphorylates and activates the drug. Human cellular guanylate kinase then phosphorylates acyclovir twice, to transform it into acyclovir triphosphate, which blocks viral DNA synthesis by competitively inhibiting and inactivating viral DNA polymerase and by becoming irreversibly incorporated into the viral DNA chain, causing DNA chain termination. Valacyclovir, penciclovir and famciclovir have similar mechanisms of action.

Systemic acyclovir and valacyclovir are indicated for primary and recurrent episodes of genital herpes simplex infection, herpes simplex suppression, varicella (acyclovir for both children and adults, valacyclovir for children) and herpes zoster. Acyclovir is also indicated for varicella. Intravenous acyclovir is used in immunocompromised patients with disseminated HSV or VZV and in patients with severe herpes zoster[88]. Other off-label uses of acyclovir are prevention of recurrent herpes-associated erythema multiforme and treatment of eczema herpeticum, primary herpes gingivostomatitis, herpetic whitlow and neonatal herpes. Famciclovir is indicated for herpes zoster, primary or recurrent genital herpes, herpes suppression in immunocompetent patients and recurrent herpes simplex in HIV-infected patients. Oral valganciclovir and valacyclovir are used for CMV prophylaxis in solid organ transplant patients.

Acyclovir, valacyclovir and famciclovir are considered equivalent in safety and efficacy (time to healing, duration of pain, and viral shedding) for initial episodes of genital herpes[89]. Famciclovir and valacyclovir have the advantage of greater oral bioavailability and more convenient dosing. Valacyclovir is at least as effective as acyclovir in decreasing the duration of pain in herpes zoster[90,91]. Table 127.25 lists the relative susceptibilities of herpes viruses to the antiviral drugs.

Dosages

Antivirals (topical or systemic) should be started as soon as possible after the onset of signs and symptoms. A glove or applicator should be used to apply topical antivirals to prevent autoinoculation of the finger. Table 127.26 details the dosing regimens of the topical antiviral drugs. Table 127.27 lists the available formulations of systemic antiviral medications. Table 127.28 outlines the dosages of the systemic antiherpetic medications for their various indications. Intravenous, rather than oral, treatment may be required in severely immunosuppressed patients, patients who cannot take medications orally, and those who cannot be relied upon to take the medication correctly[92].

The majority of people who are seropositive for HSV-2 are asymptomatic[93,94], and it is thought that asymptomatic viral shedding leads to most transmission of genital herpes. The physician must decide whether to treat on an episodic basis or in a continuous suppressive fashion. Factors that influence this decision include the number of outbreaks per year, the severity of outbreaks, a lack of prodromal symptoms, and an HSV-seronegative sexual partner[92]. Suppression with acyclovir 400 mg twice daily can decrease recurrences by 80–90% and asymptomatic shedding by 95%[95]. A year-long, double-blind, placebo-controlled study demonstrated that 1 g of valacyclovir taken daily reduced recurrence rates by 78%[96]. In addition, a multicenter, randomized, placebo-controlled study showed that daily valacyclovir significantly lowered the risk of transmission of genital herpes in heterosexual, immunocompetent, monogamous, HSV-2 discordant couples[97].

Acyclovir, valacyclovir and famciclovir are all effective against herpes labialis when used intermittently or suppressively, and they are all effective in treating herpes zoster. Treatment of varicella in children is controversial, but it does not alter antibody production at 28 days or at 1 year[98]. Oral therapy is recommended for healthy adolescents and adults as well as children with chronic skin or lung disease or on long-term salicylates; intravenous administration is indicated for

COMPARATIVE SUSCEPTIBILITY OF HERPESVIRUSES TO ANTIVIRAL DRUGS

Antiviral drug	Viral susceptibility				Main target organisms
	HSV-1	HSV-2	VZV	CMV	
Acyclovir, valacyclovir	+++	+++	++	–	HSV-1, HSV-2, VZV
Cidofovir	+	+	++	+++	CMV, resistant HSV
Famciclovir	+++	+++	++	–	HSV-1, HSV-2, VZV
Foscarnet	++	++	+	++	CMV, resistant HSV, VZV
Ganciclovir, valganciclovir	+	+	+	+++	CMV

Table 127.25 Comparative susceptibility of herpesviruses to antiviral drugs. CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella–zoster virus.

DOSING OF TOPICAL ANTIVIRAL DRUGS		
Antiviral drug	**Dosage**	**Side effects**
Acyclovir	q3 h, 6 times/day for 7 days In Canada: 4–6 times/day for up to 10 days Combined with hydrocortisone: 5 times/day for 5 days	Burning, stinging and discomfort at the application site; less commonly, pruritus, erythema, edema or mucosal irritation (when applied to genital lesions)
Penciclovir 1% cream	q2 h while awake (at least 6 times/day) for 4 days	Burning, stinging and discomfort at the application site; less commonly, erythema and decreased cutaneous sensation (particularly to touch); occasionally, headache and dysgeusia
Docosanol	5 times/day until episode is resolved	Burning, pruritus, xerosis, erythema, edema and acne

Table 127.26 Dosing of topical antiviral drugs. q, every; h, hours.

FORMULATIONS OF SYSTEMIC ANTIVIRAL DRUGS	
Antiviral drug	**Available formulations**
Acyclovir	200 mg capsules; 400 mg and 800 mg tablets; iv solution; 200 mg/5 ml banana-flavored suspension
Valacyclovir	500 mg and 1000 mg tablets*
Famciclovir	125 mg, 250 mg and 500 mg tablets
Ganciclovir	250 mg and 500 mg capsules; iv solution
Valganciclovir	450 mg tablets; 50 mg/ml oral solution
*Pharmacies can compound valacyclovir tablets into an oral suspension (25 or 50 mg/ml).	

Table 127.27 Formulations of systemic antiviral drugs. iv, intravenous.

immunocompromised individuals, including those receiving chronic systemic corticosteroid therapy[99].

Contraindications

As with other medications, antiviral agents are contraindicated in patients with hypersensitivity to any components of the formulation. Systemic antivirals need to be dose-adjusted for patients with impaired renal function (Table 127.29); renal function should be monitored in patients taking nephrotoxic medications. Thrombotic thrombocytopenic purpura and hemolytic uremic syndrome have been reported in immunocompromised patients receiving valacyclovir[100].

Major side effects

Table 127.26 lists the side effects of topical antiviral agents, which have limited systemic absorption, and Table 127.30 lists the side effects of systemic antiherpetic medications.

Interactions

No clinically important drug interactions with topical antivirals have been identified. Table 127.31 lists the interactions of the systemic antiviral agents with other medications.

Pregnancy and lactation

There are no adequate studies of topical antiviral agents in pregnant or lactating women. Small amounts of topical acyclovir are absorbed through the skin and mucous membranes, and it is not known if topically applied antivirals are excreted in breast milk. Topical docosanol has not been shown to cause birth defects or other problems in animal studies using rats or rabbits. It is unknown whether docosanol passes into breast milk. To date, no problems in nursing infants due to topical antiviral agents have been reported.

Systemic antiviral drugs should not be used during pregnancy unless the benefit justifies the potential risk to the fetus. Systemic acyclovir is FDA pregnancy category C. Acyclovir crosses the placenta and is mutagenic at high doses *in vitro*[101]. However, it has not been shown to be teratogenic in animal studies, and a prospective registry of 756 pregnant patients who took acyclovir showed an incidence of birth defects similar to that in the general population[102]. Acyclovir is the drug of choice for primary genital herpes in pregnant women because it has been used safely more often than other antivirals. Recurrent herpes simplex during pregnancy is generally not an indication for acyclovir. Varicella in pregnant women should be treated with acyclovir due to the high risk of maternal mortality from varicella pneumonia as well as fetal death or premature delivery[103]. It is not known, however, whether acyclovir prevents congenital varicella syndrome. Acyclovir is excreted in breast milk, but no data are available regarding the risk to nursing infants. There are no adequate human studies of valacyclovir (pregnancy category B) in pregnancy or lactation.

Systemic famciclovir (pregnancy category B) and penciclovir have not been shown to be teratogenic in animal studies. Very high doses of penciclovir are mutagenic, and prolonged exposure to high-dose famciclovir is associated with benign mammary tumors in rats[101]. There is an ongoing registry maintained by the manufacturer to monitor pregnant patients exposed to famciclovir[19]. Penciclovir does pass into the milk in animals when given orally. The safety of famciclovir and penciclovir use during lactation has not been established.

INDICATIONS AND DOSAGES OF SYSTEMIC ANTIHERPETIC DRUGS	
Indication	**Dosage**
Primary genital herpes	Acyclovir 200 mg po 5 times a day for 10 days *or* 400 mg po tid for 10 days Valacyclovir 1 g po bid for 10 days Famciclovir 250 mg po tid for 10 days
Recurrent genital herpes	Acyclovir 400 mg po tid for 5 days *or* 800 mg po bid for 5 days *or* 800 mg po tid for 2 days Valacyclovir 500 mg po bid for 3 days *or* 1 g po qd for 5 days Famciclovir 125 mg po bid for 5 days *or* 1 g po bid × 1 day *or* 500 mg po × 1 dose then 250 mg bid for 2 days
Chronic suppression of herpes	Acyclovir 400 mg po bid Valacyclovir 500 mg (if <10 outbreaks/year) or 1 g (if ≥10 outbreaks/year) po qd Valacyclovir 1 g po qd for patients with over 10 recurrences per year Famciclovir 250 mg po bid
Herpes zoster	Acyclovir 800 mg po 5 times a day for 7–10 days Valacyclovir 1 g po tid for 7 days Famciclovir 500 mg po tid for 7 days
Varicella	Patients over 2 years of age, over 40 kg: Acyclovir 800 mg po qid for 5 days Patients over 2 years of age, under 40 kg: Acyclovir 20 mg/kg (800 mg max) po qid for 5 days Valacyclovir 20 mg/kg (1 g max) po tid for 5 days*
Mucocutaneous herpes simplex in immunocompromised patients, including HIV-infected	Acyclovir 5 mg/kg (if age ≥10 years) or 10 mg/kg (if age <10 years) iv q8 h for 7 days† Acyclovir 400 mg po 3–5 times a day for 14–21 days† Valacyclovir 1 g po bid–tid for 7 days† Famciclovir 500 mg po bid for 5–10 days†
HSV encephalitis	Acyclovir 10 mg/kg iv q8 h for 10 days
Disseminated herpes zoster	Acyclovir 5–10 mg/kg iv q8 h for 7–10 days
Recurrent orolabial herpes	Famciclovir 1500 mg po once Valacyclovir 2 g po bid × 1 day
*FDA-approved for ages 2–17 years. †Continue until lesions have all healed.	

Table 127.28 Indications and dosages of systemic antiherpetic drugs. Dosage frequency and amount must be adjusted for renal failure and dialysis (see Table 127.29). bid, twice daily; h, hours; iv, intravenously; po, orally; q, every; qd, daily; qid, four times daily; tid, three times daily.

Other antiviral agents

Herpes infection resistant to commonly used drugs is a problem in immunocompromised patients. Foscarnet and cidofovir are two alternative treatments in this situation (see Table 127.25).

DOSE REDUCTIONS FOR ACYCLOVIR, VALACYCLOVIR AND FAMCICLOVIR IN PATIENTS WITH RENAL DISEASE						
Indication	**Acyclovir**		**Valacyclovir**		**Famciclovir**	
	Creatinine clearance (ml/min)	**Adjusted dose**	**Creatinine clearance (ml/min)**	**Adjusted dose**	**Creatinine clearance (ml/min)**	**Adjusted dose**
Primary genital herpes	<10	200 mg po bid	10–29 <10	1 g qd 500 mg qd	20–39 <20	125 mg bid 125 mg qd
Recurrent genital herpes			<30	500 mg qd	40–59 20-39 <20	500 mg bid × 1 day 500 mg once 250 mg once
Chronic suppression of herpes			<30	500 mg q48 h or qd	20–39 <20	125 mg bid 125 mg qd
Herpes zoster	10–25 <10	800 mg po tid 800 mg po bid	30–49 10–29 <10	1 g bid 1 g qd 500 mg qd	40–59 20–39 <20	500 mg bid 500 mg qd 250 mg qd
Recurrent orolabial herpes (2 g bid × 1 day)			30–49 10–29 <10	1 g bid × 1 day 500 mg bid × 1 day 500 mg once	40–59 20–39 <20	750 mg once 500 mg once 250 mg once
Immunocompromised patients with mucocutaneous herpes; for acyclovir, also herpes encephalitis and disseminated zoster	25–50 10–24 <10	5–10 mg/kg iv q12 h 5–10 mg/kg iv q24 h 2.5–5 mg/kg iv q24 h			20–39 <20	500 mg qd 250 mg qd

Table 127.29 Dose reductions for acyclovir, valacyclovir and famciclovir in patients with renal disease. In hemodialysis patients, the medication should be administered after dialysis. bid, twice daily; h, hours; iv, intravenously; po, orally; q, every; qd, daily; tid, three times daily.

SIDE EFFECTS OF SYSTEMIC ANTIVIRAL AGENTS	
Acyclovir and valacyclovir	• Cutaneous: morbilliform eruption, Stevens–Johnson syndrome, injection site reaction, urticaria, angioedema • Gastrointestinal: nausea, vomiting, diarrhea, abdominal pain • Hematologic: aplastic anemia, leukopenia, thrombocytopenia • Neurologic: headaches, vertigo, lethargy, confusion, hallucinations, depression, seizures, encephalopathy, coma (CNS disturbances more likely in elderly patients) • Cardiovascular: hypertension, tachycardia, anaphylaxis • Other: malaise, arthralgia, myalgia, dyspnea, dysmenorrhea • Reversible crystalluria-induced nephropathy with intravenous acyclovir (typically in patients with pre-existing renal dysfunction or dehydration) • Thrombotic thrombocytopenic purpura or hemolytic uremic syndrome in immunocompromised patients with valacyclovir
Famciclovir	• Pruritus, paresthesias, headache, fatigue, nausea, vomiting, diarrhea, and flatulence

Table 127.30 Side effects of systemic antiviral agents.

DRUG INTERACTIONS OF SYSTEMIC ANTIVIRAL AGENTS	
Interacting drug	**Result**
Amphotericin	Increases serum acyclovir level
Cimetidine	Decreases rate of conversion of valacyclovir to acyclovir Increases serum levels of acyclovir and valacyclovir
Digoxin	Famciclovir increases digoxin levels
Glyburide with metformin (Glucovance®)	Acyclovir or valacyclovir may cause lactic acidosis in patients with decreased renal function
Interferon	May worsen potential neurotoxicity of acyclovir
Intrathecal methotrexate	May worsen potential neurotoxicity of acyclovir
Nephrotoxic drugs (i.e. cisplatin)	Acyclovir increases risk of nephrotoxicity
Probenecid	Decreases rate of conversion of valacyclovir to acyclovir Increases serum levels of acyclovir and valacyclovir
Theophylline	Acyclovir causes decreased metabolism and increased serum levels of theophylline Theophylline increases serum levels of acyclovir and valacyclovir
Zidovudine	Increases serum levels of acyclovir and valacyclovir

Table 127.31 Drug interactions of systemic antiviral agents.

Foscarnet is an intravenous antiviral used for CMV retinitis or CMV skin infection in HIV-infected patients and for acyclovir-resistant herpes simplex infections. Foscarnet is an inorganic pyrophosphate analogue that selectively inhibits viral DNA polymerase by blocking its pyrophosphate binding sites. This prevents the cleavage of pyrophosphate from deoxyadenosine triphosphate. Foscarnet does not require phosphorylation to be activated, and thus it circumvents the commonest mode of viral resistance involving viral thymidine kinase. Foscarnet is active against all herpesviruses. Side effects of the intravenous form include nephrotoxicity, anemia, erosive penile lesions, thrombophlebitis, seizures, gastrointestinal disturbances, and changes in serum calcium, magnesium and phosphate levels[104,105]. Topical formulations of the drug are being studied.

Cidofovir is an acyclic nucleoside phosphate analogue of deoxycytosine monophosphate. It inhibits viral DNA polymerase and causes DNA chain termination. It differs from acyclovir and penciclovir in that it does not require viral thymidine kinase to become activated[105]. It is also used for CMV retinitis in HIV-infected patients. Cidofovir is currently available in intravenous form only, and side effects include nephrotoxicity, iritis, neutropenia, metabolic acidosis and gastrointestinal disturbances. However, a compounded topical form has been used with some success for herpes simplex resistant to acyclovir, molluscum contagiosum, condyloma acuminata and verruca vulgaris[106,107]. *In vitro*, cidofovir is active against DNA viruses including monkeypox, variola and vaccinia.

Compounds that target the HSV helicase-primase complex (composed of three proteins that unravel DNA) have been shown to be effective *in vitro* as well as in animal models[108–110]. Resiquimod, a topical immune-response modifier, has been shown to reduce the number of recurrences of genital herpes.

INTERFERONS

Key features

- Human cells produce three antigenically distinct forms of interferon (IFN), originally described as leukocyte (α), fibroblast (β) and immune (γ)
- Recombinant DNA technology can produce large quantities of highly purified human IFN
- IFNs have antiviral, antiproliferative and immunoregulatory properties
- Dermatologic FDA-approved indications for IFNs include condyloma acuminata (IFN-α-2b), melanoma (IFN-α-2b) and AIDS-associated Kaposi sarcoma (IFN-α-2a and IFN-α-2b)
- Side effects include flu-like symptoms, leukopenia, nausea, vomiting and hepatitis

INTRODUCTION

Interferons (IFNs) are a family of secretory glycoproteins produced by most eukaryotic cells in response to a variety of viral and non-viral inducers. All IFNs display antiviral activity, and they also modulate other cellular functions. IFN does not inactivate viruses directly but rather renders cells resistant to viruses.

There are three antigenically distinct IFNs, originally described as leukocyte (α), fibroblast (β) and immune (γ)[1] (Table 128.1). Utilization of recombinant DNA technology has led to the production of large quantities of highly purified human IFN by *Escherichia coli*. This chapter will focus primarily on IFN-α-2a and IFN-α-2b, which are the most frequently used IFNs for patients with dermatologic diseases.

PHARMACOLOGY AND MECHANISM OF ACTION

There are over 30 subtypes of IFN-α, each composed of 165–172 amino acids with very similar sequences. For example, IFN-α-2a and IFN-α-2b differ in just a single amino acid. IFN-β has 29% structural homology to IFN-α, but IFN-γ has no significant structural homology to either IFN-α or IFN-β[2].

IFNs must be injected intralesionally or be given parenterally. Systemic absorption via the intramuscular or subcutaneous route is >80% for IFN-α, with a peak effect 3–12 hours after injection and becoming undetectable after 24 hours[1]. Pegylated forms of IFN-α have attachment of polyethylene glycol (PEG) side chains, which prolongs the therapeutic effect; as a result, the drug can be administered less frequently (see Table 128.1). IFNs undergo renal catabolism.

IFN activity is dependent upon its ability to bind to specific receptors on the surface of target cells. IFN-α and IFN-β (referred to as type I IFNs) share the same IFN-α/β receptor, whereas IFN-γ (a type II IFN) binds to a separate receptor; both receptors signal via Janus kinase (JAK)-STAT-mediated pathways. Underlying mechanisms of antiviral, antiproliferative and immunoregulatory activity of are listed in Table 128.2.

INDICATIONS AND DOSAGES (Table 128.3)

Genital and Perianal Warts (Condylomata Acuminata)

Intralesional IFN-α-2b has been found to be safe and effective in the treatment of condylomata acuminata on the external surfaces of genital and perianal areas[3]. The regimen that is typically used is 1 million IU per wart three times weekly for 3 weeks, with a maximal dose of 5 million IU per session. In a recent meta-analysis of randomized controlled trials of IFN for the treatment of condylomata, the overall complete response rate for local/intralesional administration was 44% (compared to 16% for placebo), whereas systemic administration was no better than placebo[4]. In general, IFN treatment is reserved for highly motivated patients who have failed simpler and less costly modes of therapy for condylomata.

Common Warts (Verruca Vulgaris)

In the early 1980s, Nimura[5] reported a "good response" in 81% of common warts treated with intralesional IFN-β, compared to a rate of 17% in controls. Berman et al.[6] then reported a mean reduction of 86% in the lesional area of common warts treated with 0.1 million IU IFN-α-2b, compared to 38% in the placebo-injected group.

Cutaneous T-Cell Lymphoma

The use of IFN for cutaneous T-cell lymphoma dates back to the early 1980s. IFN-α-2a is the most frequently utilized type. Although IFN may be used as a monotherapy, its administration in combination with other agents (e.g. psoralen plus ultraviolet A [PUVA], total skin electron beam, oral retinoids) results in higher response rates (e.g. as high as 70–80% for IFN-α-2a plus PUVA)[7] (see Ch. 120).

Infantile Hemangiomas

IFN-α-2a has been used to treat severe, life- or function-threatening, corticosteroid-unresponsive infantile hemangiomas[8] (see Ch. 103). However, this therapy has been associated with spastic diplegia and other neurologic dysfunction; consequently, its administration for hemangiomas has become extremely uncommon[9].

AIDS-Associated Kaposi Sarcoma

Both IFN-α-2a and IFN-α-2b are used to treat Kaposi sarcoma associated with AIDS (see Ch. 78). The overall response rates with IFN-α-2a

INTERFERONS					
Generic name	**Trade name®**	**Manufacturer**	**Route**	**Half-life**	**Peak effect**

DERMATOLOGIC DISEASES TREATED WITH INTERFERONS
FDA-APPROVED INDICATIONS
Condyloma acuminata (α)
AIDS-associated Kaposi sarcoma (α)
Melanoma (adjuvant) (α)
Chronic granulomatous disease (γ)
SOME OFF-LABEL DERMATOLOGIC USES
Neoplasms
Basal cell carcinoma (α)
Actinic keratoses (α)
Squamous cell carcinoma (α)
Giant condyloma of Buschke-Lowenstein (α)
Cutaneous T-cell lymphoma (α, β, γ)
Granulomatous slack skin (α, γ)
Infantile hemangioma (α)
Tufted angioma (α)
Infections
Verruca vulgaris (α, β, γ)
Epidermodysplasia verruciformis (α)
Herpes zoster (α)
Herpes simplex (α)
Necrolytic acral erythema (with hepatitis C) (α)
Leishmaniasis (γ)
Leprosy (γ)
Mycobacterium avium complex infections (γ)
Inflammatory/other
Atopic dermatitis (γ)
Keloids (α, γ)
Behçet's disease (α)
Progressive systemic sclerosis (γ)
Scleromyxedema (α)

Table 128.3 Dermatologic diseases treated with interferons. *Adapted from Wolverton SE, Comprehensive Dermatologic Drug Therapy, 2nd edition. Philadelphia: WB Saunders, 2007.*

and IFN-α-2b have equaled or surpassed those achieved with conventional cytotoxic chemotherapy. The recommended dosages of IFN-α-2a and IFN-α-2b are 36 and 30 million IU, respectively, administered subcutaneously daily. Monotherapy with high-dose IFN-α-2a has been reported to achieve response rates of 7%, 27% and 45% for patients with <200, 200–400 and >400 $CD4^+$ cells/mm^3, respectively[10]. In many patients who respond, the tumors recur within 6 months, and the response to the second course of treatment is not reliable. This has led to a recommendation for maintenance therapy for as long as adverse effects are tolerated[10]. Unlike antiretroviral therapy (see Ch. 78), IFN does not reverse the underlying immunodeficiency. In addition to its immune-enhancing and antiproliferative effects, the response of Kaposi sarcoma to IFN could be explained by an antiviral effect on human herpesvirus-8 (see Ch. 80).

Basal Cell Carcinoma

Intralesional injection of IFN-α-2b into a nodular or superficial basal cell carcinoma (BCC) is occasionally used as an alternative treatment in highly selected patients (e.g. if surgery is not an option)[11]. The highest cure rates are approximately 85%, which is far below what would be expected for traditional surgical approaches.

Squamous Cell Carcinoma and Keratoacanthoma

As with BCC, IFN-α-2b therapy can be considered for patients with actinically induced or human papillomavirus (HPV)-associated squamous cell carcinoma (SCC) or keratoacanthoma who are not candidates for surgical excision[12,13].

Melanoma

The results of several trials of adjuvant interferon therapy for cutaneous melanoma are outlined in Table 113.14.

Keloids

In 1989, Berman and Duncan[14] reported a 41% reduction in the area of a keloid following intralesional injections of 1.5 million IU of IFN-α-2b twice over 4 days (the effect was seen by day 9 after the injection, when a biopsy specimen of the keloid was obtained). Lee et al.[15] compared the efficacy of intralesional therapy for keloids with IFN-α-2b plus triamcinolone acetonide to that of triamcinolone alone and found that the combination was superior.

Granstein et al.[16] performed a placebo-controlled, double-blind trial of intralesional IFN-γ for the treatment of keloids in 10 patients. Eight of the patients completed the course of treatment with injections of either diluent or IFN-γ (0.1 or 0.01 mg) three times per week for 3 weeks. The average percentage reduction in keloidal height 22 days after the initial injection was 30% for the IFN-γ-treated keloids and

only 1% for the diluent-treated keloids ($P<0.002$). No statistically significant difference was found between the effects of the lower versus the higher dose of IFN-γ. In another study of 10 scars, interferon-γ at doses of 0.5 mg (intralesionally) once weekly for 10 weeks decreased the linear dimensions by at least 50% in 5 of 10 scars, with minimal adverse effects[17].

In the postoperative setting, Berman and Flores[18] demonstrated that intralesional IFN-α-2b was superior to triamcinolone acetonide injections in preventing recurrences of excised keloids. However, Davison et al.[19] found that triamcinolone was significantly more effective than IFN-α-2b, with recurrence rates of 15% and 54%, respectively. Based on the data currently available, IFN is not considered as a first-line modality for the prevention of keloid recurrences.

Atopic Dermatitis

Evidence of reduced production of IFN-γ *in vitro* by mononuclear cells of patients with atopic dermatitis and the suppression of interleukin (IL)-4-mediated IgE stimulation by IFN-γ prompted evaluation of IFN treatment for atopic dermatitis. A randomized, placebo-controlled, double-blind, multicenter trial studied the effects of daily subcutaneous injection (50 microg/m^2) of IFN-γ versus placebo for 12 weeks in 78 patients. Altogether, 45% of the IFN-γ-treated group and 21% of the placebo-treated patients achieved a significant response (>50% improvement) by physicians' evaluations[20]. The results of additional studies using other doses and regimens have ranged from 57% clinical improvement (open trial of 14 patients)[20] to no differences compared with controls[21].

Therapy with IFN-α has also been investigated in patients with atopic dermatitis, again with varied and contradictory results. Torrelo et al.[22] reported a satisfactory response (investigator and patient global assessment) in 5 of 13 patients treated with IFN-α-2a (3 million IU subcutaneously three times weekly for 4 weeks). However, Mackie[23] reported no benefit from the same regimen administered for a total duration of 12–14 weeks. Further clinical trials are necessary in order to determine the clinical effectiveness of this expensive treatment.

Behçet's Disease

Fourteen patients with Behçet's disease who had oral ulcers, genital ulcers, pustular vasculitis, erythema nodosum and/or thrombophlebitis were treated with IFN-α-2a (3 million IU subcutaneously three times per week, escalating to 12 million IU, for a 2-month period). All patients were symptom-free at 2 months and had fewer recurrences in the post-treatment period compared with the pretreatment period[24]. Similar response rates with IFN-γ injected subcutaneously have been reported[25]. Maintenance doses once or twice weekly, however, were required to prevent early relapses.

Systemic Sclerosis

The *in vitro* ability of IFN-α, -β and -γ to inhibit collagen production and other functions of activated dermal fibroblasts derived from the involved skin of patients with scleroderma, morphea or keloids (see above) has been demonstrated[26]. IFN-γ has also been shown to temporarily inhibit the proliferation of scleroderma fibroblasts[26]. Kahan et al.[27] reported benefit of IFN-γ therapy in a small group of patients with systemic sclerosis.

CONTRAINDICATIONS

Absolute contraindications are hypersensitivity to components of the formulations. The relative contraindications are cardiac arrhythmias, depression or other psychiatric disorders, leukopenia, coagulopathies and previous organ transplantation.

MAJOR SIDE EFFECTS

The adverse effects of IFN are dose-dependent and generally improve or remit during continued therapy or following dose reduction. In addition, the adverse effects are usually rapidly reversible upon cessation of treatment.

Cutaneous Reactions

Approximately 5% of patients treated with IFN-β-1b for multiple sclerosis develop skin necrosis at the site of injection secondary to a localized vasculopathy[28] (Fig. 128.1). Plaques of psoriasis can also develop at the sites of injection of IFN, as can flares of psoriasis in patients receiving IFN (Fig. 128.2). Other occasional cutaneous side effects include alopecia, xerosis and vitiligo.

Flu-like Symptoms

The most common adverse effects are flu-like symptoms of fever, chills, fatigue, myalgias, headache and arthralgias. Generally, in healthy individuals, subcutaneous administration of IFN-α in doses of ≤3 million IU every other day induces nominal and tolerable flu-like symptoms, or no adverse effects at all. Prophylactic (1–2 hours prior to injection) administration of acetaminophen (650 mg), aspirin (650 mg) or nonsteroidal anti-inflammatory drugs (e.g. ibuprofen 400 mg) helps to prevent these effects.

Fig. 128.1 Postinflammatory hyperpigmentation and ulceration at sites of interferon-β-1b injection in a woman with multiple sclerosis. *Courtesy, Jean L Bolognia, MD.*

Fig. 128.2 Interferon-induced flare of psoriasis.

Neurologic and Psychiatric Effects

Spastic diplegia was reported in 5 of 26 patients with hemangiomas treated with 1.0–3.6 million IU/day of IFN-α-2a[9]; postulated explanations included the immaturity of the infant's central nervous system and preservatives (e.g. benzyl and phenol alcohol) in the preparations used. Depression and suicidal ideation/behavior have been reported in association with IFN-α therapy[29].

Cardiovascular Effects

Significant hypotension, arrhythmias or tachycardia (heart rate ≥150 beats/minute) can occur in association with IFN therapy[30]. Although these side effects are usually managed by modifying the dosages of IFN or discontinuing treatment, they may require specific additional therapy. Patients with a history of a myocardial infarction or arrhythmias require close monitoring.

Rhabdomyolysis

Rhabdomyolysis is occasionally seen and has proved fatal in at least one patient treated with high-dose IFN-α-2b (20 million IU intravenously twice daily for 5 days)[31]. Elevated serum creatine kinase levels should lead to a reduction in dose or cessation of therapy, depending on the severity of the elevation.

Gastrointestinal Effects and Bone Marrow Suppression

Gastrointestinal disturbances such as nausea, vomiting and diarrhea can occur, as can anorexia and hepatitis. Fatal cases of hepatitis have been reported in patients receiving high-dose IFN. Bone marrow suppression is another side effect of IFN, and it is a particular problem in patients receiving high-dose therapy or who have other reasons for bone marrow suppression (e.g. concomitant medications). Serial evaluation of liver function tests and complete blood counts is recommended.

Other Adverse Effects

Neutralizing antibodies can develop in patients receiving IFN-α-2a or IFN-α-2b, and they appear to be specific to recombinant (rather than natural) IFN[32,33]. Thyroiditis and/or hypothyroidism occurs in up to 40% of hepatitis C patients treated with IFN-α[34].

INTERACTIONS

IFN-α-2a may reduce the clearance of aminophylline, probably due to inhibition of the cytochrome P450 enzyme system[35]. Caution must be used when IFN is administered in conjunction with other potentially myelosuppressive (including zidovudine) or neurotoxic (e.g. vinca alkaloids) drugs. The concomitant use of IFN and IL-2 may increase the risk of renal failure.

USE IN PREGNANCY

IFNs are rated as pregnancy category C, although they do not appear to cross the placenta. While it is unknown whether IFN is excreted into human milk, it is excreted into mouse milk.

IMIQUIMOD

Key features

- Commercially available as a 3.75% and 5% cream
- Initially used for anogenital warts, it is now also FDA-approved for actinic keratoses on the face/scalp and superficial BCCs
- Off-label uses include common warts, molluscum contagiosum, keloids, lentigo maligna, SCC *in situ* and extramammary Paget's disease
- Stimulates an innate immune response via induction of IFN-α and TNF-α; also stimulates cell-mediated immunity

INTRODUCTION

Imiquimod (1-[2 methylpropyl]-1 H-imidazo [4, 5c] quinolin-4 amine) is an immune response modifier that stimulates innate and adaptive immune pathways, resulting in antiviral, antitumor and immunoregulatory properties.

MECHANISM OF ACTION

Imiquimod's stimulation of the innate immune response results in increased production of cytokines such as IFN-α, IL-6 and tumor necrosis factor-α (TNF-α)[36]; enhanced natural killer (NK) cell activity; and secretion of nitric oxide from macrophages[37]. Its effects on the cell-mediated arm of the adaptive immune system include augmented production of the Th1 cytokine IFN-γ (Fig. 128.3). Imiquimod also activates and enhances the migration of Langerhans cells to the regional lymph nodes, resulting in antigen presentation to T cells[38].

One important mechanism for imiquimod's effects is activation of Toll-like receptor 7 (TLR7) (see Fig. 4.1). Following binding of imiquimod to TLR7 on antigen-presenting cells (APCs), nuclear factor-κB activation stimulates production of IFN-α, IL-12 and IL-18 (see Fig. 128.3), which induce $CD4^+$ T cells to produce the IL-12 β_2 receptor (via IFN-α) and IFN-γ. This leads to enhancement of cell-mediated immunity.

After topical application of imiquimod to hairless mice, increased levels of IFN-α and TNF-α were found in treated (but not untreated) mouse skin[36]. Imiquimod's antiviral and antitumor activity in animal models is explained at least in part by the actions of IFN-α (see Table 128.2). In addition, IFN-γ stimulates cytotoxic T lymphocytes, which kill virally infected cells as well as tumors and provide the immune memory needed for future protection. In a murine tumor model, mice became free of tumor after 30 days of imiquimod treatment and remained resistant to challenge with the same tumor cells 8 months later. This demonstrated imiquimod's effects on the adaptive as well as innate arm of the immune system.

Metabolism

Percutaneous absorption of imiquimod 5% cream is minimal, with less than 0.9% of a radiolabeled 5 mg dose being recovered in the urine and feces. The site of potential metabolism is unknown, as is the degree of protein binding, if any.

INDICATIONS

Human Papillomavirus Infection

The importance of treating HPV infection is highlighted by the association of the oncogenic anogenital subtypes with SCC as well as the discomfort and psychological effects of anogenital and cutaneous warts.

External genital and perianal warts[39]

In randomized vehicle-controlled clinical trials, the topical application of imiquimod 5% cream three times a week for up to 16 weeks completely cleared lesions in approximately 50% of patients and was well tolerated. Women tend to have higher clearance rates than men, which is thought to be due to the lower degree of keratinization of the vulva compared with the shaft of the penis, the most common locations of warts. Topical imiquimod is considered to be among the first-line topical therapies for anogenital warts.

Common warts

The efficacy of topical imiquimod in the treatment of common warts, periungual warts and plantar warts is substantially lower than its efficacy for anogenital warts. However, combination therapy with sequential application of salicylic acid preparations and imiquimod can enhance its penetration and effectiveness. Several case studies have reported the successful treatment of common warts in immunocompromised patients[40]. There are also reports of the resolution of recalcitrant facial flat warts after treatment with imiquimod 5% cream.

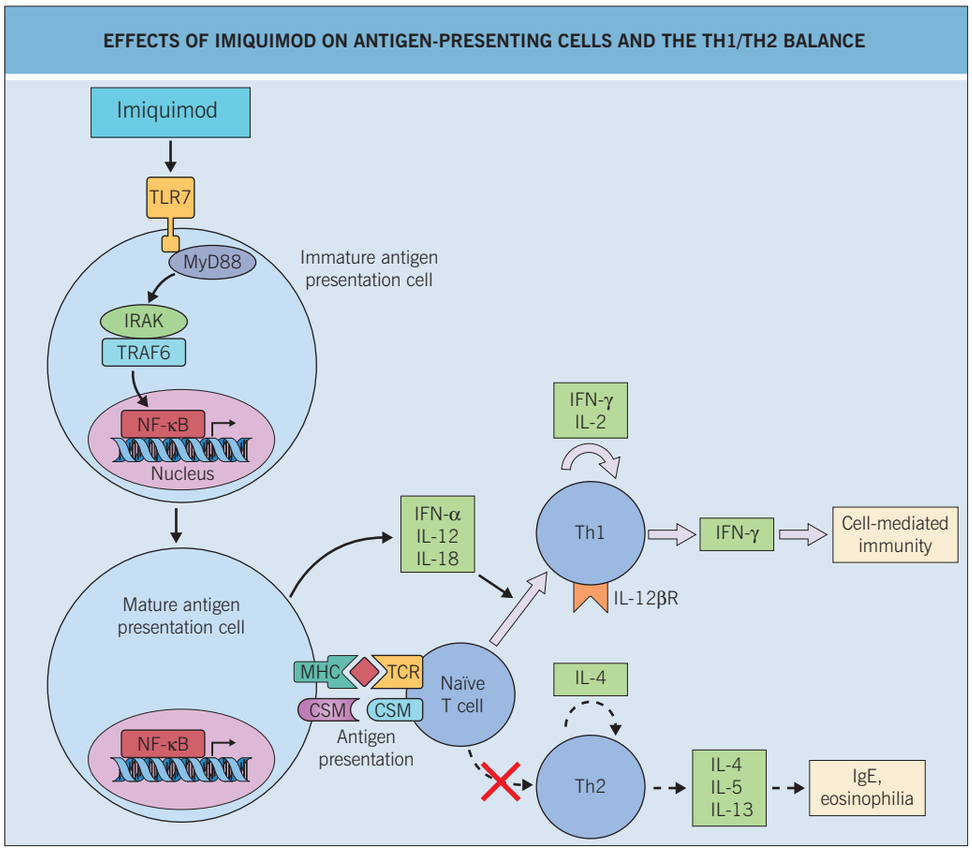

Fig. 128.3 Effects of imiquimod on antigen-presenting cells and the Th1/Th2 balance. Binding of imiquimod to Toll-like receptor 7 (TLR7) on antigen-presenting cells (e.g. Langerhans cells, other dendritic cells, macrophages) leads to interaction of the cytoplasmic portion of the receptor with MyD88. This facilitates association of MyD88 with IL-1 receptor-associated kinase (IRAK), which in turn activates TNF receptor-activated 6 (TRAF6) and ultimately results in stimulation of nuclear factor-κB-mediated signaling. Imiquimod thereby promotes antigen-presenting cell maturation and secretion of IL-12 and other cytokines, which induce IFN-γ production by naive T cells and result in a Th1-type immune response. CSM, costimulatory molecule; MHC, major histocompatibility complex; TCR, T-cell receptor.

Molluscum Contagiosum

Molluscum contagiosum, a cutaneous infection by a virus in the Poxviridae family, has been successfully treated with imiquimod 5% cream. Molluscum contagiosum tends to occur in young children, sexually active adults, and HIV-infected patients (up to 20% of the latter group). Open-label trials and some case reports have suggested that imiquimod might be effective in the treatment of molluscum contagiosum. One double-blind, placebo-controlled trial involving 23 children found a significant decrease in the number of molluscum lesions within 12 weeks of treatment with imiquimod applied three times per week compared to placebo[41]. In a randomized, observer-blinded study, treatment of molluscum contagiosum in children with imiquimod 5% cream five days per week had similar efficacy but less pain and a better cosmetic outcome than cryotherapy weekly. As with warts, sequential application of a keratolytic and imiquimod may lead to additional benefit.

Keloids

A pilot study was undertaken to evaluate the recurrence rate of keloids following surgical excision and subsequent topical application of imiquimod 5% cream[42]. Thirteen keloids (12 earlobe, 1 mid-back) in 12 patients were surgically excised and closed primarily. Nightly application of imiquimod 5% cream directly to the suture line and to the surrounding area was initiated on the day of surgery and continued for a total of 8 weeks. None of the 11 keloids recurred in the 10 patients who completed both the treatment period and at least 6 months of postoperative follow-up[42]. However, subsequent studies have had mixed results, with most failing to demonstrate benefit of imiquimod in preventing recurrence following surgical excision of keloids[43,44].

Basal Cell Carcinoma[45]

Imiquimod is FDA-approved for the treatment of superficial BCCs. Studies of both superficial and nodular BCCs have been performed using imiquimod 5% cream. Application 5–7 days per week for 6–12 weeks results in clearance rates (clinical and histologic) of roughly 70–75%. Although highly statistically significant compared to placebo, these rates are substantially lower than those for destructive and surgical methods. There are also anecdotal reports of successful use of imiquimod to treat BCCs in the setting of nevoid BCC syndrome[46].

Actinic Keratoses

Imiquimod is also FDA-approved for treatment of actinic keratoses (AKs) on the face and scalp. The results of a meta-analysis showed that application of imiquimod 5% cream three times per week for 12–16 weeks resulted in complete clearance of AKs in 50% of patients, compared to 5% for placebo[47]. In a more recent study, treatment with imiquimod 3.75% cream daily for two 2-week cycles (separated by a 2-week interval without treatment) led to complete clearance of AKs on the face and scalp in 35% of patients, compared to 6% for placebo[48]. An inflammatory reaction is often seen during therapy, especially in skin with substantial photodamage (Fig. 128.4). Various other treatment schedules have been suggested, but their efficacy has not been demonstrated with the same rigor as the "labeled" regimens. Treatment of AKs on the dorsal aspect of the hands and forearms with imiquimod appears to be less effective and to result in more inflammation[49].

Bowen's Disease (Cutaneous SCC *in situ*)

Imiquimod has been studied in a double-blind, placebo-controlled trial in patients with Bowen's disease[50]. This relatively small study demonstrated a highly significant level of efficacy compared to placebo (73% vs 0%). Follow-up periods averaging 9 months failed to demonstrate any recurrence among the complete responders. Successful use of imiquimod to treat Bowen's disease in solid organ transplant recipients and SCC *in situ* in the anogenital area (including lesions in HIV-infected patients) has also been described in case reports[51,52].

Other Dermatologic Diseases[53,54]

Imiquimod 5% cream has been reported in non-controlled case reports and series to be effective in the treatment of cutaneous T-cell lymphoma[55], extramammary Paget's disease[56], lentigo maligna[57], cutaneous melanoma metastases[58] and cutaneous leishmaniasis[59]. However, caution should be exercised when utilizing imiquimod for these

Fig. 128.4 Reaction to topical imiquimod. A Inflammation and erosions developed after application of imiquimod to an actinic keratosis and actinically damaged skin. **B** Following discontinuation of imiquimod, the inflammation subsided and the actinic keratosis had cleared. Note the residual hypopigmentation.

disorders, because in many instances failures have also been reported, including non-response of lentigo maligna melanoma[60,60a].

DOSAGES

Imiquimod 5% cream is approved in the US for the treatment of external genital and perianal warts, actinic keratoses on the face and scalp, and superficial BCCs. The recommended regimen is application three times weekly for up to 16 weeks for wart therapy, twice weekly for up to 16 weeks for actinic keratoses, and up to five times per week for up to 6 weeks for BCCs. Imiquimod 3.75% cream is approved for daily use for external genital/perianal warts (for up to 8 weeks) and actinic keratoses on the face or scalp (in two 2-week treatment cycles as described above). The frequency of application for "off-label" indications varies, and the optimal frequency and duration of therapy are still being determined in most instances.

CONTRAINDICATIONS

None are known.

MAJOR SIDE EFFECTS

The most common adverse reactions to imiquimod cream are restricted to the site of application and include erythema (Fig. 128.5; see also Fig. 128.4A), edema, scaling and ulceration. These reactions tend to be more intense and frequent in patients with actinic keratoses and BCC, and reactions with histologic findings mimicking those of lupus erythematosus have been described[60b]. Development of erosive pustular dermatosis of the scalp has been associated with the use of imiquimod for actinic keratoses of the scalp[61]. Possible systemic adverse effects include flu-like symptoms (e.g. fatigue, fever, headache, diarrhea and myalgias), which occur in approximately 1–2% of patients. Thus far, there are no reports of systemic immune alteration, an important consideration when treating patients with solid organ transplants who are on immunosuppressive therapies.

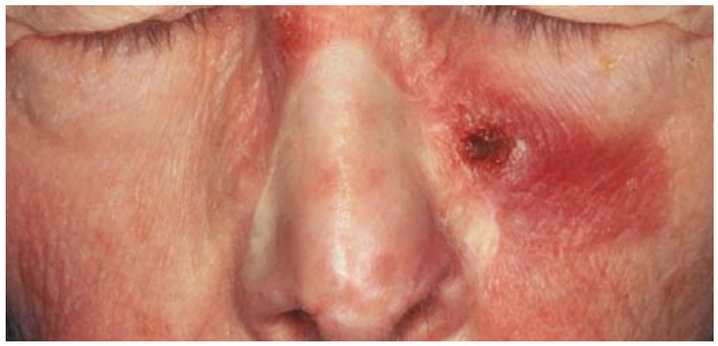

Fig. 128.5 Inflammation at the site of application of imiquimod to an amelanotic lentigo maligna. The patient had residual disease despite multiple surgical procedures including skin graft placement. The inflammation did not occur until the tenth month of application. Three years later, the lesion recurred, but only within the graft. *Courtesy, Jean L Bolognia, MD.*

INTERACTIONS

There are no known drug interactions with imiquimod cream.

USE IN PREGNANCY

Imiquimod cream is classified as pregnancy category C. It is not known whether topically applied imiquimod cream is excreted in breast milk.

GRANULOCYTE–MACROPHAGE AND GRANULOCYTE COLONY-STIMULATING FACTORS (GM-CSF AND G-CSF)

The indications and side effects of granulocyte–macrophage and granulocyte colony-stimulating factors (GM-CSF and G-CSF) are outlined in Table 128.4.

TOPICAL CALCINEURIN INHIBITORS

Key features

- Topical calcineurin inhibitors are anti-inflammatory agents that allow treatment of inflammatory dermatoses without the side effects of topical corticosteroids
- Topical tacrolimus and pimecrolimus are approved for the treatment of "moderate to severe" and "mild to moderate" atopic dermatitis, respectively; they are also effective in treating a number of other corticosteroid-responsive dermatoses

INTRODUCTION

Topical corticosteroids have been the mainstay of therapy for eczematous dermatoses and other inflammatory disorders since their introduction 60 years ago. Unfortunately, these agents may result in local side effects such as cutaneous atrophy, telangiectasias, striae, perioral

GRANULOCYTE–MACROPHAGE AND GRANULOCYTE COLONY-STIMULATING FACTORS (GM-CSF & G-CSF)
PROPERTIES
These glycoproteins regulate the survival, proliferation, differentiation and functional activation of hematopoietic cells
INDICATIONS
• Treatment of neutropenia in settings of myelosuppressive chemotherapy and hematopoietic stem cell transplantation • Other forms of neutropenia (e.g. AIDS-related, associated with dyskeratosis congenita) • Mobilization of peripheral blood progenitor cells • In dermatology, both have been studied as promoters of wound healing, and GM-CSF has been investigated as a component of melanoma therapy
SIDE EFFECTS
GM-CSF • ***Systemic:*** fever, myalgias, bone pain; occasionally flares of autoimmune disease • *Cutaneous:* morbilliform eruption (within 24–48 hours of administration; mixed infiltrate with granulocytes/macrophages); pustular or urticarial injection site reactions (Fig. 128.6); Sweet's syndrome, small vessel vasculitis, urticarial plaques with tense bullae, epidermolysis bullosa acquisita
G-CSF • ***Systemic:*** bone pain (transient, mild "dull ache"; 20% of recipients); occasionally, elevated serum uric acid, LDH or alkaline phosphatase • *Cutaneous:* Sweet's syndrome (within 1–2 weeks of administration); injection site reactions, pyoderma gangrenosum, small vessel vasculitis, folliculitis; histologically, the infiltrate is composed of neutrophils, eosinophils and large histiocytes with cytologic atypia and many mitotic figures
INTERACTIONS
Additive effects with other drugs that cause neutrophilia, e.g. corticosteroids and lithium
PREGNANCY AND LACTATION
Category C; unknown if excreted in breast milk

Table 128.4 Granulocyte–macrophage and granulocyte colony stimulating factors (GM-CSF & G-CSF). LDH, lactate dehydrogenase.

Fig. 128.6 Urticarial plaque at the site of GM-CSF injection.

dermatitis (when used on the face), and cataracts or glaucoma (when used around the eyes). Systemic absorption can also occur.

Tacrolimus ointment (0.1% and 0.03%) and pimecrolimus cream (1%) are approved for the treatment of atopic dermatitis, and they have been used for other eczematous and "steroid-responsive" dermatoses.

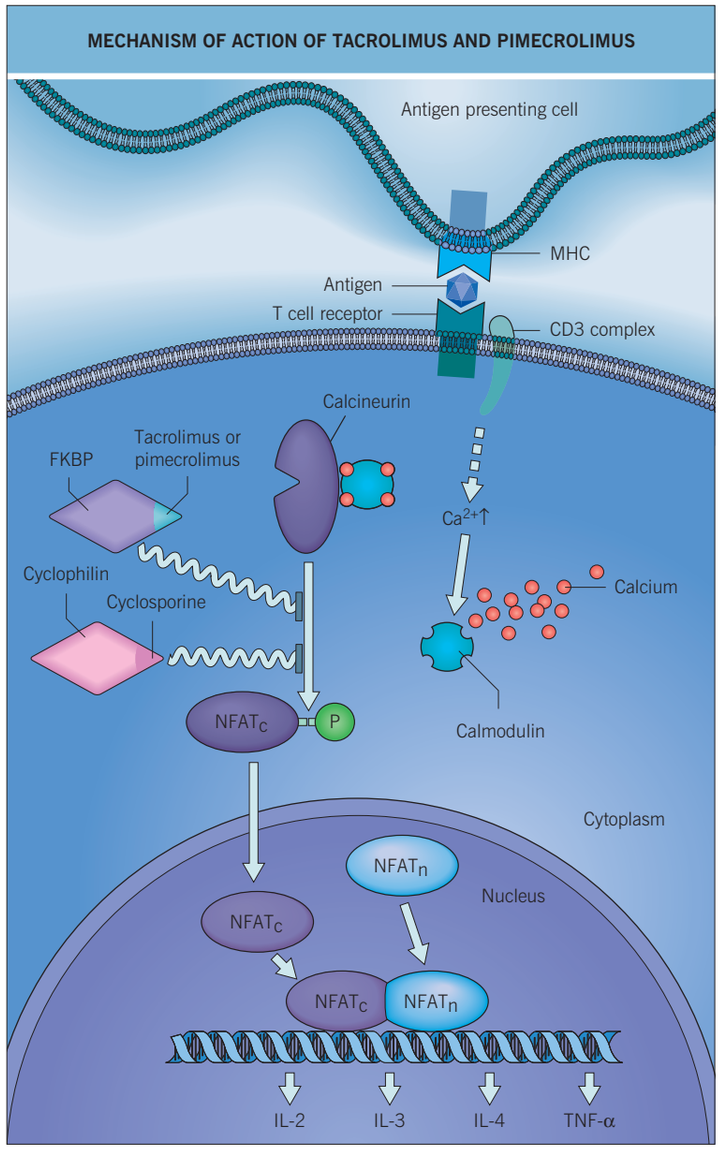

Fig. 128.7 Mechanism of action of tacrolimus and pimecrolimus. FKBP, FK506-binding protein. NFAT, nuclear factor of activated T cells.
From Nghiem P, Pearson G, Langley RG. Tacrolimus and pimecrolimus: from clever prokaryotes to inhibiting calcineurin and treating atopic dermatitis. J Am Acad Dermatol. 2002;46:228–41.

MECHANISM OF ACTION

Tacrolimus and pimecrolimus are inhibitors of the phosphatase calcineurin[62]. T-lymphocyte activation begins when costimulatory ligands on APCs interact with T-cell receptors. This increases the levels of free calcium within the cell; the calcium binds to calmodulin, which in turn activates calcineurin (Fig. 128.7). Calcineurin dephosphorylates the cytoplasmic subunit of the nuclear factor of activated T cells (NFAT). The dephosphorylated subunit is then able to translocate to the nucleus, where it forms a complex that assists in transcription of numerous cytokines. Tacrolimus and pimecrolimus bind to the FK506-binding protein, forming complexes that inhibit calcineurin, thus preventing the dephosphorylation activity of this important phosphatase and blocking cytokine-driven inflammation.

INDICATIONS

Tacrolimus ointment 0.1% and 0.03% are indicated for the treatment of "moderate to severe" atopic dermatitis in adults and in persons ≥2 years of age, respectively. Pimecrolimus cream is indicated for the treatment of "mild to moderate" atopic dermatitis in individuals ≥2 years

of age. There are numerous anecdotal reports and case series describing the use of these agents to treat other inflammatory dermatoses, including eczematous dermatitis of the eyelids, intertriginous sites and hands as well as lichen planus (oral and genital), psoriasis (facial and intertriginous), seborrheic dermatitis, vitiligo (especially facial), pyoderma gangrenosum, perioral dermatitis, granulomatous rosacea, cutaneous Crohn's disease, cutaneous lesions of dermatomyositis, cutaneous lupus erythematosus, lichen sclerosus and chronic graft-versus-host disease (GVHD)[63].

DOSAGES

Topical tacrolimus is commercially available in 0.1% and 0.03% concentrations. The 0.1% formulation is somewhat more effective than the 0.03% formulation, but only the 0.03% formulation is FDA-approved for use in children. Pimecrolimus cream is available in a 1% concentration.

CONTRAINDICATIONS

The package inserts recommend that the benefits and risks of tacrolimus ointment and pimecrolimus cream be evaluated when prescribing them in the presence of varicella or active herpes simplex virus infection (including eczema herpeticum). In addition, both labels were revised in 2006 to include warnings stating that the long-term safety has not been established regarding the theoretical potential for future malignancy. However, systematic reviews have failed to find indications of an increased level of risk from the use of these agents in humans[64], and there has been no short-term or intermediate-term (>10 years) evidence of systemic immunosuppression or an increased risk for malignancy in clinical studies or post-marketing surveillance of either medication.

Because tacrolimus and pimecrolimus shorten the time to skin tumor formation in animal photocarcinogenicity studies, the package inserts recommend that patients minimize or avoid natural or artificial sunlight exposure. Due to increased absorption of tacrolimus ointment in patients with Netherton syndrome, its use in this condition is not recommended[65]; pimecrolimus should also be used with caution in Netherton syndrome patients, but there is evidence that absorption of this agent is not as substantially elevated[66]. Systemic absorption (generally at low levels) has also been identified following application of tacrolimus to eroded mucosal surfaces or ulcers[67,68].

MAJOR SIDE EFFECTS

Application site reactions (e.g. burning, stinging, a sensation of warmth) are the most common side effects of tacrolimus ointment and pimecrolimus cream. There are scattered reports of allergic contact dermatitis and a rosacea-like granulomatous reaction on the face due to tacrolimus. Regarding skin infections, *Staphylococcus aureus* colonization is actually reduced in the skin of atopic dermatitis patients treated with tacrolimus ointment.

INTERACTIONS

Formal clinical studies have not been conducted using tacrolimus ointment together with other topical or systemic medications, but anecdotal use of tacrolimus in conjunction with topical corticosteroids suggests that the combination reduces burning and enhances efficacy. Compatibility studies of tacrolimus ointment applied in combination with desoximetasone ointment or clobetasol ointment indicate that both agents remain stable in the setting of concomitant use.

USE IN PREGNANCY

Because there are no adequate studies of topically administered tacrolimus or pimecrolimus in pregnant women, both are rated as category C. Animal studies with systemically administered tacrolimus indicate harmful fetal effects only at doses that are toxic to the mother.

TARGETED IMMUNE MODULATORS

Key features

- Agents that interfere with T-cell activation (e.g. alefacept) can be effective in the treatment of psoriasis
- Agents that block TNF-α (e.g. etanercept, infliximab, adalimumab) can also be effective as treatments for psoriasis, as well as for other dermatoses in which TNF-α signaling has a pathogenic role
- Ustekinumab, an agent that blocks IL-12 and IL-23 signaling (important for the Th17 immune response) by binding to the p40 receptor subunit shared by these cytokines, is approved for the treatment of psoriasis
- IL-1 antagonists (e.g. anakinra), which are used to treat rheumatoid arthritis, also have benefits for a few rare cutaneous diseases
- Rituximab, an agent that blocks CD20 on B cells, is approved for the treatment of B-cell lymphoma and rheumatoid arthritis but is also useful in B-cell-mediated skin diseases
- Multiple other targeted immune modulators are being developed and may have therapeutic applications for dermatologic diseases and/or cutaneous adverse reactions

INTRODUCTION

Advances in molecular technology have allowed the creation of bioengineered molecules that target specific proteins involved in the pathogenesis of immune-mediated disorders, including psoriasis (and psoriatic arthritis), pemphigus and B-cell lymphomas as well as extracutaneous conditions such as Crohn's disease, asthma, juvenile idiopathic arthritis (JIA), rheumatoid arthritis and ankylosing spondylitis. These drugs (referred to as "biologic" agents) work by mechanisms that include altering T-cell activation and differentiation (e.g. affecting the development of Th1 or Th17 cells), blocking cytokines and eliminating pathogenic B cells.

ALEFACEPT

Introduction

Alefacept (Amevive®) is a fusion protein in which the extracellular domain of lymphocyte function-associated antigen (LFA)-3 is connected to the Fc portion of human IgG1[69].

Mechanism of Action

Two signals must be delivered between APCs and T cells for activation to occur (see Fig. 4.9). The first signal occurs when the major histocompatibility complex on an APC (bound to a specific peptide antigen) interacts with the T-cell receptor. The second costimulatory signal can be one of a number of interactions between APCs and T cells, as shown in Figure 128.8A. Alefacept binds to CD2 on T cells, preventing its interaction with LFA-3 on APCs and the resultant T-cell activation (Fig. 128.8B). CD2 is maximally expressed in activated $CD45RO^+$ T cells. In addition to the interaction between the LFA-3 portion of alefacept and CD2 on $CD45RO^+$ T cells, the Fc portion of alefacept binds to receptors on the surface of natural killer cells, which leads to a reduction in the number of $CD45RO^+$ cells in the circulation.

Indications

In 2003, alefacept became the first targeted immune modulator approved by the FDA for the treatment of moderate to severe plaque-type psoriasis. Studies demonstrated that alefacept was significantly more effective than placebo in achieving a 75% reduction in the Psoriasis Area and Severity Index (PASI) score (see Ch. 8). However, only a minority of patients (~10–20%) achieve this level of improvement[70]. Some reports demonstrate greater efficacy with a 16-week rather than 12-week course[71] or additional improvement with successive courses[72].

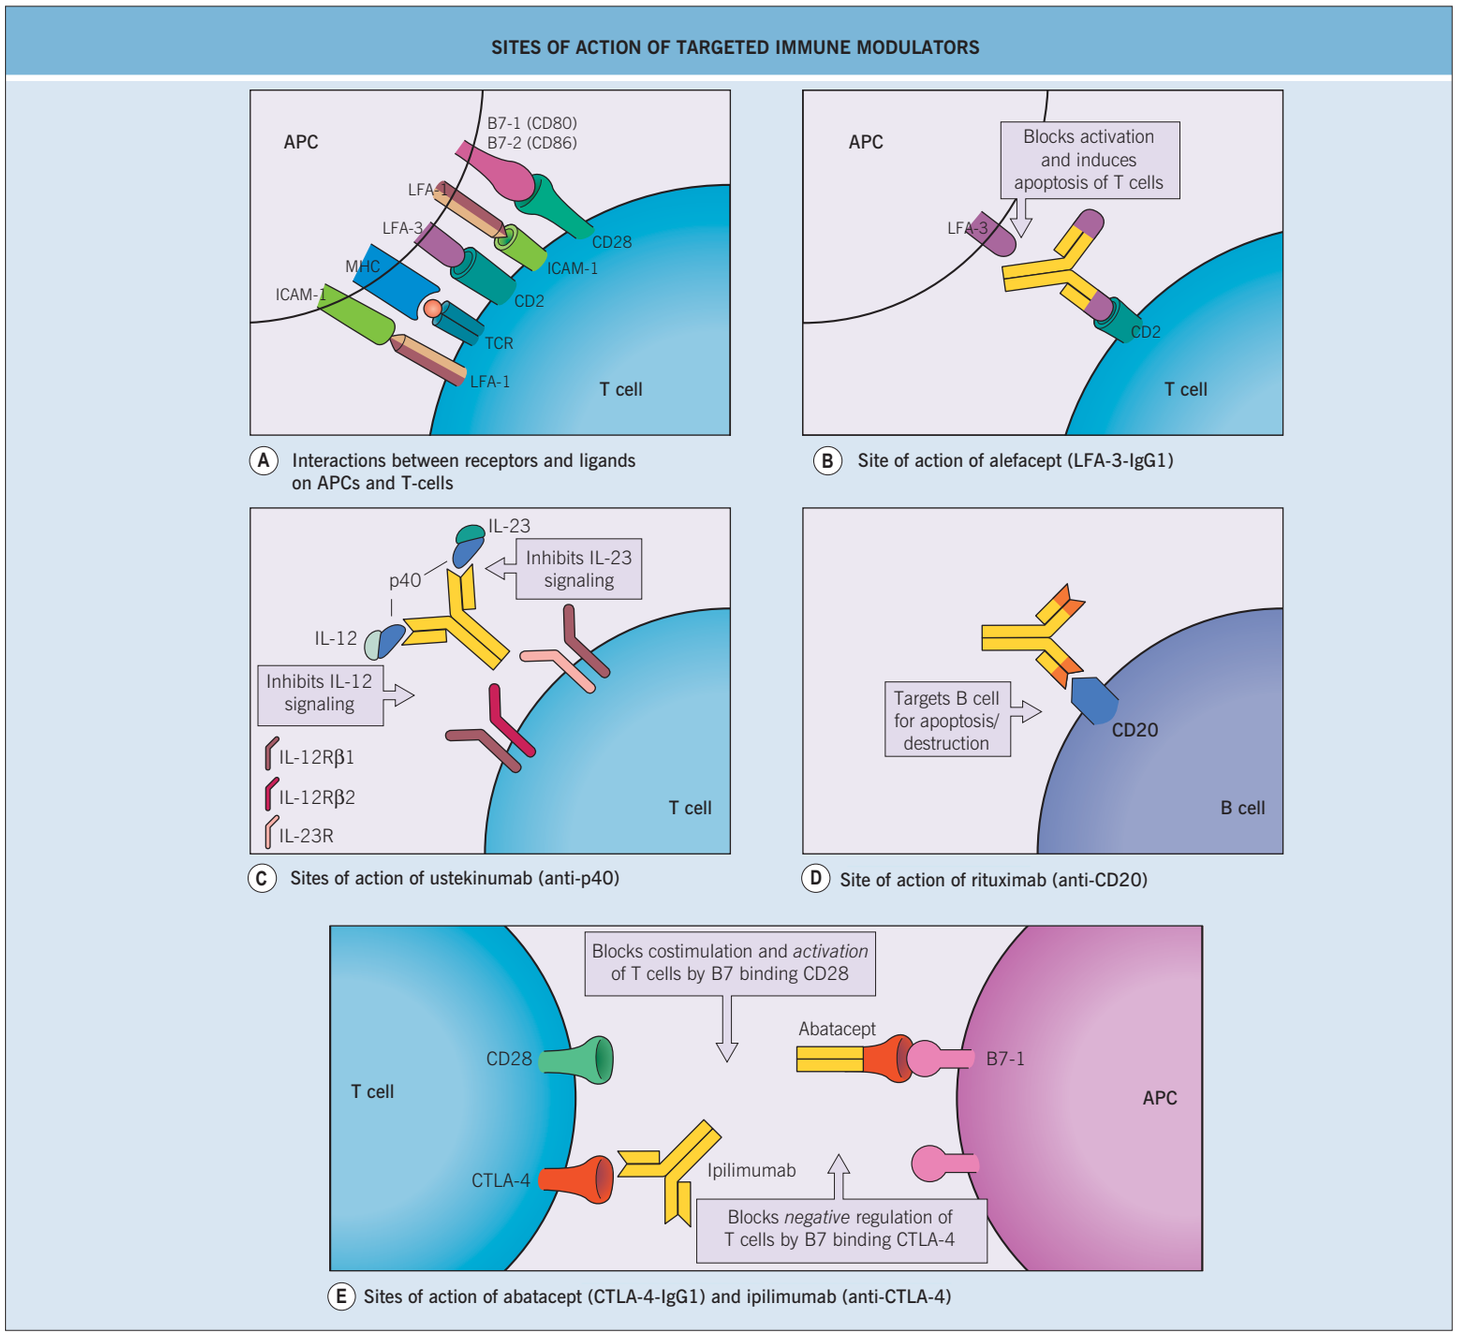

Fig. 128.8 Sites of action of targeted immune modulators. A Activation of T cells requires two signals. The first occurs when the major histocompatibility complex antigen interacts with the T-cell receptor. A second costimulatory signal is required for T-cell activation to occur. **B** Site of action of alefacept. **C** Sites of action of ustekinumab. **D** Site of action of rituximab. **E** Sites of action of abatacept and ipilimumab. APC, antigen-presenting cell; CTLA-4, cytotoxic T lymphocyte-associated antigen 4; IL-12, interleukin-12; IL-12Rβ1, interleukin-12 receptor β1; LFA, lymphocyte function antigen.

Alefacept may also have a role in the treatment of other T-cell-dependent diseases such as lichen planus[73], cutaneous lupus erythematosus[74] and chronic GVHD[75]. Although previous reports suggested that alefacept might have utility in the treatment of alopecia areata[76], a recent randomized placebo-controlled trial failed to demonstrate a significant benefit[77]. In a pilot study, alefacept showed some efficacy in the treatment of pyoderma gangrenosum[78].

Dosages

Although both intravenous and intramuscular forms of alefacept were studied, the intravenous preparation was withdrawn from the market shortly after its approval. The dosing for intramuscular administration is 15 mg weekly. The approved regimens are a 12-week course or two 12-week courses separated by a 12-week period without treatment. Additional courses given to responsive patients can result in similar (or perhaps better) responses with the potential for more prolonged remissions.

Contraindications

Alefacept should not be administered to patients with a CD4 count <250 cells/mcl, HIV infection, other active infections or malignancies.

Major Side Effects

The most frequent side effect is a local injection site reaction. Although the label suggests that malignancy risk is increased (Table 128.5), there have not been excessive numbers of malignancies noted during or following therapy with alefacept. Primary and secondary immune responses are unaffected by treatment with alefacept, as demonstrated by normal responses to new antigens (e.g. bacteriophage phi xl74) and

FDA WARNINGS AND PRECAUTIONS FOR TARGETED IMMUNE MODULATORS WITH DERMATOLOGIC INDICATIONS
ALEFACEPT
• Induces dose-dependent decreases in $CD4^+$ (and $CD8^+$) T-cell counts • Should not be given to HIV-infected patients • Has the potential to increase the risk of infections or reactivation of latent infections • Could potentially increase the risk of malignancies • Hypersensitivity reactions (e.g. urticaria, angioedema) may occur • Hepatotoxicity has been observed (rare)
TUMOR NECROSIS FACTOR-α (TNF-α) INHIBITORS (E.G. ADALIMUMAB, CERTOLIZUMAB, ETANERCEPT, GOLIMUMAB, INFLIXIMAB)
• Increased risk of serious infections, including tuberculosis, bacterial sepsis, systemic fungal infections (e.g. histoplasmosis) and infections due to opportunistic pathogens • Risk of hepatitis B virus reactivation • Malignancies (especially lymphomas) have been reported in patients receiving these agents, including children and adolescents – For *infliximab*, lymphomas are seen more often than in the general population and fatal hepatosplenic T-cell lymphomas have developed in patients with inflammatory bowel disease who were also receiving azathioprine or 6-mercaptopurine – An increased risk of non-melanoma skin cancer and melanoma has been observed in patients with rheumatoid arthritis treated with TNF-α inhibitors • Congestive heart failure (exacerbation or new onset) has been observed • Demyelinating disease (exacerbation or new onset) has been observed • Anaphylaxis or severe allergic reactions may occur (including serum sickness-like reactions to *infliximab*) • Other potential adverse events include autoimmune hepatitis, cytopenias and a lupus-like syndrome
USTEKINUMAB
• Serious infections have been observed; has the potential to increase the risk of infection and reactivation of latent infections – Patients genetically deficient in IL-12/IL-23 have an increased risk of severe infections with mycobacteria and *Salmonella* • Possibly associated with an increased risk of major adverse cardiovascular events • Could potentially increase the risk of malignancies • Hypersensitivity reactions (e.g. angioedema, anaphylaxis) may occur • Reversible posterior leukoencephalopathy syndrome has been reported (one patient to date)
RITUXIMAB
• Severe infusion reactions can occur – 80% of fatal reactions occur with the first infusion • Tumor lysis syndrome can develop in lymphoma patients, especially those with a high tumor burden, and lead to acute renal failure • Progressive multifocal leukoencephalopathy has been reported • Serious infections (bacterial, fungal or viral; up to 1 year after completing therapy) or reactivation of viral infections may occur, especially hepatitis B virus reactivation with fulminant hepatitis • Cardiac arrhythmias and angina can occur and may be life-threatening. • Bowel obstruction and perforation have been described • Stevens–Johnson syndrome/toxic epidermal necrolysis and onset of paraneoplastic pemphigus have been described

Table 128.5 US Food and Drug Administration (FDA) warnings and precautions for targeted immune modulators with dermatologic indications.

recall antigens (e.g. tetanus and diphtheria toxoids). Although a significant decrease in circulating T-cell counts can occur, there does not appear to be an increase in the risk of infections in patients treated with this agent[79]. Recommended laboratory tests are outlined in Table 128.6.

Interactions

Alefacept has been tested in combination with other psoriasis treatments in a limited number of patients. It appears to be safe to administer alefacept together with UV light therapies, retinoids and perhaps methotrexate[80,81]. Adverse interactions with topical treatments are not likely. The combination of alefacept with other targeted immune modulators (either sequentially or simultaneously), which could potentially result in potentiation of immunosuppressive effects, has not been studied.

RECOMMENDED LABORATORY EVALUATION FOR PATIENTS RECEIVING TARGETED IMMUNE MODULATORS FOR PSORIASIS AND OTHER DERMATOLOGIC DISORDERS		
Drug	**Prior to treatment**	**During treatment**
TNF-α inhibitors (adalimumab, etanercept, golimumab, infliximab)	PPD*/interferon-γ release assay† and/or (e.g. if immunosuppression or history of tuberculosis) chest X-ray CBC, CMP Hepatitis B and C virus serologic profiles Consider HIV testing	Annual PPD*/interferon-γ release assay† and/or chest X-ray CBC & CMP every 3–12 months (or as clinically indicated)
Alefacept	$CD4^+$ T-cell count‡ CBC, CMP Hepatitis B and C virus serologic profiles HIV testing Consider PPD*/interferon-γ release assay† and/or (e.g. if immunosuppression or history of tuberculosis) chest X-ray	$CD4^+$ T-cell count every other week: • If <250 cells/mcl, withhold medication and monitor weekly • Discontinue medication if remains <250 cells/mcl for 1 month CBC & CMP every 3–12 months (or as clinically indicated) Consider annual PPD*/interferon-γ release assay† and/or chest X-ray
Ustekinumab	PPD*/interferon-γ release assay† and/or (e.g. if immunosuppression or history of tuberculosis) chest X-ray CBC, CMP Hepatitis B and C virus serologic profiles Consider HIV testing	Annual PPD*/interferon-γ release assay† and/or chest X-ray CBC & CMP every 3–12 months (or as clinically indicated)

*≥5 mm of induration should be considered as positive.
†e.g. QuantiFERON® TB Gold or T-SPOT®.TB.
‡Initial or subsequent courses of treatment should only be started if the $CD4^+$ T-cell count is within the normal range (i.e. >500 cells/mcl).

Table 128.6 Recommended laboratory evaluation for patients receiving targeted immune modulators for psoriasis and other dermatologic disorders. A complete medical history and physical examination should also be performed, with particular attention to history/risk/symptoms/signs of tuberculosis, other chronic infections, malignancy, neurologic disorders, and cardiovascular disease (especially congestive heart failure in patients receiving TNF-α inhibitors and atherosclerosis in patients receiving ustekinumab). CBC, complete blood count with differential, CMP, comprehensive metabolic panel (includes liver function tests); PPD, purified protein derivative skin test; TNF-α, tumor necrosis factor-α.

Use in Pregnancy

Alefacept is classified as pregnancy category B. Its use in pregnancy or during lactation has not been studied.

EFALIZUMAB

Efalizumab (Raptiva®) is a humanized monoclonal antibody that binds to CD11a on T cells[82–85] (Table 128.7). Although it was approved by the FDA in 2003 for the treatment of moderate to severe plaque-type psoriasis, efalizumab was voluntarily withdrawn from the market by its manufacturer in 2009 because of an increasing number of reports of progressive multifocal leukoencephalopathy in patients receiving long-term therapy[86]. We have included a brief discussion of this agent for historical purposes.

CD11a is a component of LFA-1 on the surface of T cells. LFA-1 interacts with intercellular adhesion molecule-1 (ICAM-1) that is located on: (1) *APCs*, delivering a costimulatory signal for T-cell activation (see Fig. 128.8A); and (2) *endothelial cells*, allowing T-cell migration into the skin. As a result, efalizumab can block both the activation and migration of T cells.

Approximately 25–40% of psoriasis patients treated with efalizumab achieved a 75% improvement in their PASI score. In some patients,

NOMENCLATURE FOR MONOCLONAL ANTIBODIES AND FUSION PROTEINS						
Prefix	**Sub-stem A: *target* system [previous nomenclature system]**		**Sub-stem B: *source* system**		**Suffix**

*If conjugated to (rather than directed at) a toxin, the suffix –tox can be used in a second word.
†Contains contiguous foreign-derived amino acids comprising the entire variable region (both heavy and light chains), linked to a constant region of human origin.
‡Has segments of foreign-derived amino acids interspersed with human-derived amino acids in the variable region, linked to a constant region of human origin.

Table 128.7 Nomenclature for monoclonal antibodies and fusion proteins. For example, ada-lim-u-mab, inf-li-xi-mab and certo-li-zu-mab pegol are immunomodulating immunoglobulins that are human, chimeric and humanized, respectively.

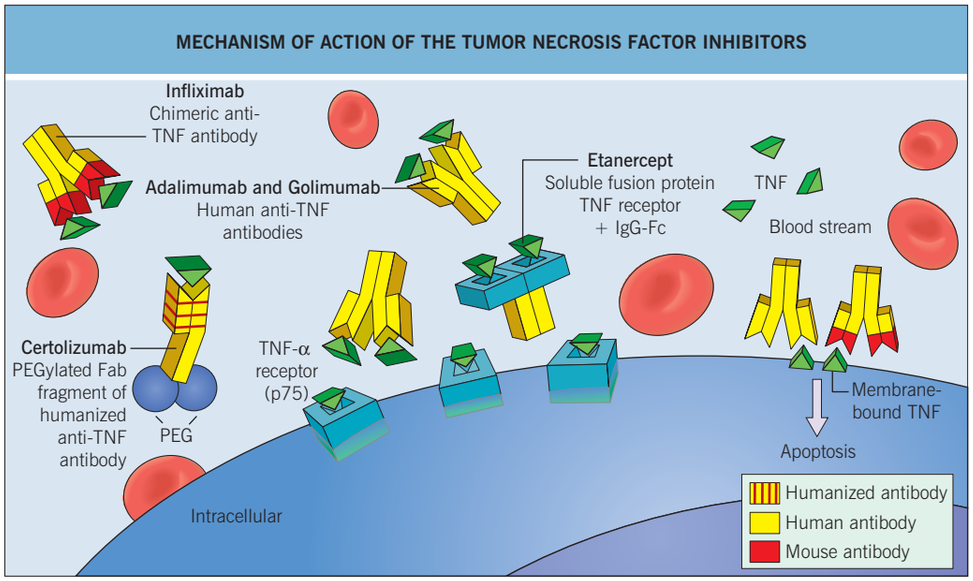

Fig. 128.9 Mechanism of action of the tumor necrosis factor (TNF) inhibitors.

tapering or cessation of therapy was associated with an acute "rebound" flare of psoriasis, which was pustular or intertriginous in a subset of these individuals. Psoriatic arthritis occasionally appeared or worsened during treatment, and other adverse effects included flu-like symptoms, thrombocytopenia and hemolytic anemia. In addition to psoriasis, there were reports of successful efalizumab therapy of several other skin conditions, including generalized granuloma annulare, cutaneous lupus erythematosus, cutaneous dermatomyositis, atopic dermatitis and alopecia areata[85,87].

TNF-α INHIBITORS – GENERAL INFORMATION

To date, five TNF-α inhibitors have been approved by the FDA: etanercept (Enbrel®), infliximab (Remicade®), adalimumab (Humira®), golimumab (Simponi®) and certolizumab pegol (Cimzia®). The mechanism of action and major side effects of these agents as well as contraindications to their use are discussed in this section, and information specific to the individual drugs (e.g. indications, dosages, interactions and pregnancy categories) is presented below.

Mechanism of Action

Four TNF-α inhibitors are monoclonal antibodies (infliximab, adalimumab, golimumab, certolizumab pegol), and one (etanercept) is a dimeric fusion protein composed of the extracellular portions of two p75 TNF-α receptors linked to the Fc portion of IgG1 (Fig. 128.9). Although all four monoclonal antibodies target human TNF-α, infliximab is chimeric (human–mouse) IgG1, adalimumab and golimumab are "fully" human recombinant IgG1, and certolizumab pegol is a humanized pegylated Fab fragment (see Table 128.7).

All of the TNF-α inhibitors can bind to soluble TNF-α and block its ability to activate TNF-α receptors (see Fig. 128.9). By interacting with membrane-bound TNF-α, the IgG1 monoclonal antibodies can also activate complement-dependent cytotoxicity and induce cellular apoptosis[88]. This capacity to destroy TNF-α-producing cells may explain the greater efficacy of these monoclonal antibodies (compared to etanercept) in the treatment of granulomatous conditions as well as the higher risk of infections associated with their use. In addition to the anti-inflammatory effects of TNF-α inhibitors, blocking TNF signaling may have an impact on the neuroendocrine system[89].

Contraindications

Each TNF-α inhibitor is contraindicated in patients with known hypersensitivity to that particular medication, and infliximab is contraindicated in those with an allergy to murine proteins. These agents should be avoided in patients with a significant active infection, malignancy, congestive heart failure (especially if unstable) or multiple sclerosis[90,91].

Major Side Effects (see Table 128.5)

Infections

Disseminated and/or opportunistic infections such as histoplasmosis, coccidioidomycosis, listeriosis and *Pneumocystis jiroveci* (*carinii*) pneumonia may occur in patients treated with TNF-α inhibitors[92]. An

Fig. 128.10 Atypical mycobacterial infection complicating adalimumab therapy. This patient was being treated for Crohn's disease.

increased risk of developing symptomatic mycobacterial infections (Fig. 128.10), including reactivation of latent tuberculosis, has also been observed in patients treated with these agents. However, most of the studies evaluating the risk of infection associated with use of TNF-α inhibitors have been in patients with rheumatoid arthritis or inflammatory bowel disease, who were often concomitantly receiving additional immunosuppressive agents. A recent meta-analysis of 20 randomized controlled trials (total n=6810) of TNF-α inhibitor therapy for psoriasis or psoriatic arthritis (over periods of 12–30 weeks) found no association between the use of these agents and the risk of infection (overall or serious) when adjusted for different follow-up times in treatment and control groups[93].

Recommended monitoring for dermatologic patients receiving TNF-α inhibitors is outlined in Table 128.6. A purified protein derivative (PPD) skin test, IFN-γ release assay (e.g. QuantiFERON® TB Gold, T-SPOT®.TB) and/or (e.g. if immunosuppression or history of tuberculosis) chest X-ray is required at baseline and (typically) repeated annually during therapy. Patients with untreated latent tuberculosis should receive antituberculous therapy (for at least 1–2 months; preferably a full 9-month course) prior to beginning treatment with a TNF-α inhibitor. Reactivation of hepatitis B virus has also been observed in patients who are chronic hepatitis B carriers (i.e. hepatitis B surface antigen positive) while receiving a TNF-α inhibitor, so patients should be evaluated for hepatitis B virus infection prior to therapy. TNF-α inhibitors do not appear to have an adverse effect on viral load or hepatitis activity in psoriasis patients with chronic hepatitis C virus infection[94].

Risk of malignancy

The potential of TNF-α inhibitors to increase the risk of malignancy is a controversial issue and may be dependent upon the disease that is being treated. TNF-α inhibitor therapy in patients with rheumatoid arthritis has been associated with an approximately threefold increase in the risk of lymphoma and malignancy in general[95,96], but this patient group is known to have a heightened susceptibility to lymphoma and often receives additional immunosuppressive agents. Most studies have not demonstrated an increase in the risk of other internal malignancies in patients treated with TNF-α inhibitors[97]. However, in one study there appeared to be an increased risk of solid malignancies associated with etanercept therapy for Wegener's granulomatosis[98]. In addition, non-melanoma skin cancers and melanoma may be more frequent in patients with rheumatoid arthritis who are treated with TNF-α inhibitors than those who do not receive these agents[98a]. A recent meta-analysis of 20 randomized controlled trials (total n=6810) of TNF-α inhibitor therapy for psoriasis or psoriatic arthritis (over periods of 12–30 weeks) found no significant association between the use of these agents and the development of malignancy in this patient population[93].

Fig. 128.11 Excellent clinical response to etanercept. Subacute cutaneous lupus erythematosus, before (**A**) and after (**B**) administration of etanercept.

Adolescents and young adults with inflammatory bowel disease who receive infliximab and concomitant azathioprine or 6-mercaptopurine appear to have an increased risk of a rare, aggressive hepatosplenic T-cell lymphoma[99]. In a recent analysis of 48 malignancies in children and adolescents treated with TNF-α inhibitors that were reported to the FDA[100], it was noted that half were lymphomas, almost two-thirds were in patients taking infliximab, and 88% of the patients were concomitantly receiving another immunosuppressive agent. Although the incidence of malignancy was higher than the background rate in the general pediatric population, the potential role of other medications as well as the underlying disorders (primarily inflammatory bowel disease and JIA) precluded establishing a causal relationship with TNF-α inhibitor therapy.

Autoimmunity

Treatment with TNF-α inhibitors is associated with an increased likelihood of developing antinuclear and anti-dsDNA antibodies. Signs and symptoms of systemic lupus erythematosus (SLE) occasionally arise in patients receiving TNF-α inhibitors, but in general this lupus-like condition resolves upon cessation of treatment[101–103]. Conversely, there are several small case series in which the use of etanercept was associated with marked improvement in subacute cutaneous lupus erythematosus[104,105] (Fig. 128.11). It is not necessary to evaluate patients for autoantibodies before or during therapy with TNF-α inhibitors. However, the development of antinuclear antibodies may be linked to loss of TNF-α inhibitor efficacy[106].

CUTANEOUS SIDE EFFECTS OF TARGETED IMMUNE MODULATORS
INJECTABLE AGENTS
• Injection site reactions (e.g. erythema/edema, occasionally small vessel vasculitis; "recall" reactions at previous sites)
TUMOR NECROSIS FACTOR-α INHIBITORS
• New-onset psoriasis, especially palmoplantar pustulosis • Interstitial granulomatous dermatitis and other granulomatous eruptions • Cutaneous small vessel vasculitis • Eczematous eruptions • Lichenoid dermatitis
EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITORS
• Papulopustular (acneiform) eruption (see Ch. 36) • Paronychia, ingrown nails, acral desquamation • Xerosis, fissures • Telangiectasias, hyperpigmentation • Increased severity of radiation dermatitis • Trichomegaly, facial hair growth, frontal alopecia, curly brittle hair
OTHER KINASE INHIBITORS AND BLOCKING ANTIBODIES – SEE TABLE 21.14
• "Hand–foot reaction" (often eventuating in hyperkeratosis) > intertriginous erythema/erosions (variant of toxic erythema of chemotherapy) • Facial swelling (especially periorbital) and erythema • Exanthematous eruptions (truncal or generalized) • "Erythema marginatum hemorrhagicum", erythema multiforme-like eruptions, small vessel vasculitis (may have an annular configuration) • Xerosis, spiny follicular keratoses • Rapid development of verrucous papules, actinic keratoses, keratoacanthomas or squamous cell carcinomas; eruptive melanocytic nevi • Ultraviolet recall dermatitis, inflammation of actinic keratoses • Leukoderma, yellowish discoloration of the skin • Subungual splinter hemorrhages • Hair de-/repigmentation, alopecia, curly brittle hair, scalp dysesthesia

Table 128.8 Cutaneous side effects of targeted immune modulators. Allergic reactions manifesting with urticaria and angioedema can also occur with most agents.

Fig. 128.12 Psoriasiform reactions to tumor necrosis factor-α inhibitors. **A** Palmoplantar pustulosis that developed as a complication of infliximab. **B** Eruption of plaque-type psoriasis in a patient receiving infliximab therapy. The patient had received infliximab for GVHD of the gastrointestinal tract.

Demyelinating diseases

Although etanercept was originally used as a therapy for multiple sclerosis, several patients treated with etanercept and other TNF-α inhibitors have developed multiple sclerosis[90]. Others with multiple sclerosis have had exacerbations of their disease when treated with these agents. In some patients, the symptoms of multiple sclerosis have abated despite continued therapy. It seems reasonable to avoid using TNF-α inhibitors in patients with a history of multiple sclerosis or other demyelinating diseases.

Congestive heart failure

There have been reports of congestive heart failure worsening or developing in patients receiving TNF-α inhibitors. As a result, it is recommended that therapy with TNF-α inhibitors be avoided in patients with unstable cardiac disease.

Cutaneous reactions

A variety of skin findings have been described as adverse reactions to TNF-α inhibitors (Table 128.8). There are reports of new-onset psoriasis in patients with no previous history of psoriasis, often manifesting as palmoplantar pustulosis (Fig. 128.12)[107]. The exact mechanism for this reaction is not known, and the possibility exists that a subset of such patients with presumed rheumatoid arthritis actually had psoriatic arthritis. Cutaneous small vessel vasculitis can complicate therapy with TNF-α inhibitors[108], but a large portion of these patients have rheumatoid arthritis, a disease known to be associated with vasculitis. In addition, interstitial granulomatous dermatitis (IGD) has been reported in patients receiving TNF-α inhibitors (sometimes in individuals with rheumatoid arthritis, which can itself be associated with IGD)[109]. Other cutaneous reactions that have been described in patients taking TNF-α inhibitors include eczematous eruptions, lichenoid dermatitis, and other granulomatous conditions[110].

VACCINES THAT CONTAIN LIVE ATTENUATED VIRUSES OR BACTERIA
Bacillus Calmette-Guérin (BCG)
Herpes zoster
Influenza (including H1N1), *intranasal form*
Measles, mumps, and rubella
Rotavirus
Polio, *oral form*
Typhoid, *oral form*
Vaccinia (smallpox vaccine)
Varicella
Yellow fever

Table 128.9 Vaccines that contain live attenuated viruses or bacteria.

Vaccination

Live vaccines are contraindicated in patients receiving TNF-α inhibitors (Table 128.9). The effectiveness of vaccines in patients receiving these agents is unknown, but an immune response to influenza and pneumococcal vaccines has been documented[111]. It is recommended that patients (especially children) be brought up-to-date with all immunizations prior to initiating treatment with TNF-α inhibitors.

ETANERCEPT

Introduction

Etanercept (Enbrel®) is a fusion protein consisting of the extracellular domain of the TNF-α receptor fused with the Fc portion of human IgG1[112].

Indications

Etanercept has been approved for the treatment of moderate to severe plaque-type psoriasis in adults since 2004. Depending on the regimen (see below), approximately 30–60% of patients achieve a 75% improvement in their PASI score; significant decreases in fatigue and depression have also been described[70,113]. The efficacy and safety of etanercept for pediatric psoriasis has been demonstrated in a randomized controlled trial including more than 200 children (4–17 years of age)[114]; however, it has not been FDA-approved for treatment of psoriasis in this age group. Other FDA-approved indications for etanercept include rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis and JIA (the latter in children 2 to 17 years of age).

In addition, etanercept has been used to treat a variety of mucocutaneous disorders, including dermatomyositis, neutrophilic dermatoses, cutaneous lupus erythematosus, autoimmune bullous diseases, lichen planus, pyoderma gangrenosum, hidradenitis suppurativa, multicentric reticulohistiocytosis, relapsing polychondritis and GVHD[104,115,116]. Although successful treatment of sarcoidosis has been described in case reports and small series, etanercept therapy failed to improve several systemic manifestations of sarcoidosis in randomized controlled trials[117]. Presumably, all of the disorders for which etanercept might be effective are characterized by elevated levels of TNF-α (in the circulation, tissue or both).

Dosages

For most of its indications, etanercept was initially approved to be administered subcutaneously at a dose of 25 mg twice weekly in adults. Shortly after its approval for psoriatic arthritis, it was demonstrated that 50 mg weekly gave equivalent results to 25 mg twice weekly. The approved dose for moderate to severe plaque psoriasis is 50 mg twice weekly for the first 3 months, followed by 50 mg weekly. Some physicians choose to initiate therapy at a dose of 50 mg weekly and only escalate the dose if the patient fails to respond after 6 to 12 months. Etanercept is available in 25 and 50 mg prefilled syringes, 50 mg autoinjectors, and 25 mg multiple-use vials. The recommended dose for pediatric psoriasis is 0.8 mg/kg (maximum 50 mg) weekly.

Specific Side Effects

Side effects shared with other TNF-α inhibitors (including the potential increased risk of malignancy associated with these agents) are discussed above and summarized in Tables 128.5 and 128.8. Injection site reactions are the most common side effect of etanercept (Fig. 128.13), but in general they are mild to moderate and diminish in frequency after the first month of treatment. Erythema, pruritus, pain and swelling have been described, and "recall" reactions at sites of previous injections have been reported.

Fig. 128.13 Etanercept injection site reaction. Similar reactions occur with nearly all subcutaneously injected biologic therapies.

Interactions

The concomitant use of etanercept and methotrexate is approved for the treatment of rheumatoid arthritis and psoriatic arthritis. Due to the potential for increased immunosuppression, combination of etanercept with other targeted immune modulators should be avoided until well-designed studies demonstrate efficacy and safety. For example, a study of anakinra plus etanercept for patients with rheumatoid arthritis found no increase in efficacy but a substantial increase in the frequency of infection[118]. The use of etanercept together with narrowband UVB without an increase in adverse events (and with added therapeutic benefit) has been documented[119,120].

Use in Pregnancy

Etanercept is pregnancy category B, with no evidence of harm to the fetus in animal studies. Studies in pregnant women have not been conducted. It has been suggested that etanercept and other TNF-α inhibitors be avoided after the first trimester[121]. It is not known whether etanercept is secreted in breast milk; however, in general, this drug is not absorbed via an oral route.

INFLIXIMAB

Introduction

Infliximab (Remicade®) is a chimeric (human–mouse) monoclonal IgG_1 antibody, and its target is human TNF-α[122].

Indications

Infliximab is approved for the treatment of adults with chronic severe plaque-type psoriasis. Compared with the other TNF-α antagonists, its onset of action tends to be faster and a higher proportion of patients (~75–85%) achieve a 75% reduction in the PASI score[70]. Infliximab is also FDA-approved for the treatment of adults with psoriatic arthritis, Crohn's disease (including associated fistulas), ulcerative colitis, rheumatoid arthritis and ankylosing spondylitis, as well as for the treatment of Crohn's disease in children ≥6 years of age. Infliximab appears to be useful for pyoderma gangrenosum, whether or not it is associated with inflammatory bowel disease[123]. It has been effective as a treatment for sarcoidosis, granulomatous cheilitis, Behçet's disease, various vasculitides, pityriasis rubra pilaris, reactive arthritis (formerly Reiter's disease), subcorneal pustular dermatosis, GVHD, Sjögren's syndrome, multicentric reticulohistiocytosis, and hidradenitis suppurativa[124].

Dosages

In patients with plaque psoriasis, the typical infliximab regimen is 5 mg/kg administered by slow intravenous infusion at 0, 2 and 6 weeks, then every 8 weeks. However, doses ranging from 3 to 10 mg/kg have been used, and the frequency of administration as well as the dose can be adjusted when the response is less than adequate. For Crohn's disease, rheumatoid arthritis and psoriatic arthritis, it is approved for concomitant administration with methotrexate, azathioprine or low-dose prednisone. Loss of efficacy over time may be related to the development of neutralizing anti-chimeric antibodies[125,126] and has been associated with the presence of antinuclear antibodies[106]; the concurrent administration of low-dose weekly methotrexate may help to prevent the formation of anti-chimeric antibodies that lessen the effectiveness of the agent.

Specific Side Effects

Side effects shared with other TNF-α inhibitors are discussed above and summarized in Tables 128.5 and 128.8. Infusion-related reactions are the most commonly reported side effect of infliximab, occurring in 16% of patients. The incidence of severe reactions, including anaphylaxis, is approximately 1%. Symptoms consist of fever, chills, pruritus, urticaria, chest pain, hypotension, hypertension and shortness of breath. Infusion reaction risk has also been linked to the presence of human anti-chimeric antibodies. This risk may be lessened by concomitant use of methotrexate, azathioprine or corticosteroids[125].

Interactions

The concomitant use of infliximab and methotrexate is approved for the treatment of rheumatoid arthritis and psoriatic arthritis. Infliximab should not be administered together with other targeted immune modulators due to the potential for additive immunosuppression; concomitant use with anakinra or abatacept has been associated with the development of severe infections.

Use in Pregnancy

Infliximab is rated pregnancy category B. Its use in pregnancy should probably be avoided until long-term studies demonstrate a lack of adverse effect. It is not known whether infliximab is secreted in breast milk, and its administration to nursing mothers is not recommended.

ADALIMUMAB

Introduction

Adalimumab (Humira®) is a "fully" human recombinant IgG1 monoclonal antibody with specificity for human TNF-α[127].

Indications

Adalimumab is approved for the treatment of moderate to severe plaque-type psoriasis in adults, and approximately 50–80% of patients achieve a 75% improvement in their PASI score[70]. It is also approved for the treatment of psoriatic arthritis, rheumatoid arthritis, ankylosing spondylitis and Crohn's disease in adults, and JIA in children ≥4 years of age. There have been reports of successful adalimumab therapy for hidradenitis suppurativa[128], pustular psoriasis[129], sarcoidosis, pyoderma gangrenosum, Behçet's disease, other neutrophilic dermatoses and dermatomyositis.

Dosages

Adalimumab is supplied in a 40 mg prefilled syringe or autoinjector and administered subcutaneously. An initial loading dose of 80 mg is typically given, followed by 40 mg on day 8 and then 40 mg every other week. Weekly doses are occasionally utilized (e.g. for hidradenitis suppurativa). The pediatric dose approved for JIA is 20 mg every other week for children who weigh <30 kg and 40 mg every other week if ≥30 kg. Loss of efficacy of adalimumab over time related to the production of anti-adalimumab antibodies can occur and may be prevented by the concurrent administration of low-dose weekly methotrexate; loss of efficacy has also been associated with the development of antinuclear antibodies[106].

Side Effects

Side effects shared with other TNF-α inhibitors, including risk of infection with mycobacteria (see Fig. 128.10) and fungi, are discussed above and summarized in Tables 128.5 and 128.8.

Interactions

The concomitant use of adalimumab and methotrexate is approved for the treatment of rheumatoid arthritis and JIA. The concomitant administration of other targeted immune modulators with adalimumab may increase the risk of infection and should be avoided.

Use in Pregnancy

Adalimumab is classified as pregnancy category B. Its safety during lactation is unknown.

GOLIMUMAB

Golimumab (Simponi®) is a "fully" human recombinant IgG1 monoclonal antibody with specificity for human TNF-α[127]. It is approved for the treatment of psoriatic arthritis, rheumatoid arthritis and ankylosing spondylitis, and it can be administered along with methotrexate. Golimumab may also be useful in the treatment of other conditions that respond to TNF-α inhibitors. It is supplied in a 50 mg prefilled syringe or autoinjector that is administered subcutaneously monthly.

CERTOLIZUMAB

Certolizumab pegol (Cimzia®) is a pegylated Fab fragment of a humanized monoclonal antibody with specificity for human TNF-α. It is approved for the treatment of rheumatoid arthritis and Crohn's disease. Certolizumab may also be useful in the treatment of other conditions that respond to TNF-α inhibitors. It is supplied in a 200 mg prefilled syringe and administered subcutaneously; 400 mg is given at weeks 0, 2 and 4, followed by 200 mg every 2 weeks or 400 mg monthly for maintenance.

USTEKINUMAB

Introduction

Ustekinumab (Stelera®) is a monoclonal antibody that targets IL-12 and IL-23.

Mechanism of Action

Ustekinumab is a "fully" human IgG1 monoclonal antibody that binds with high affinity and specificity to the p40 subunit that is shared by the heterodimeric IL-12 and IL-23 cytokines (see Fig. 128.8C). IL-12 has a critical role in the development of Th1 cells and NK cell activation, whereas IL-23 is necessary for the generation of Th17 cells (see Fig. 4.10).

Indications

Ustekinumab is approved for the treatment of adults with moderate to severe plaque-type psoriasis, and approximately 65–80% of patients achieve a 75% improvement in their PASI score[130,131].

Dosages

Ustekinumab is administered as a 45 mg (if weight is ≤100 kg) or 90 mg (if weight is >100 kg) subcutaneous injection at weeks 0 and 4, then every 12 weeks.

Contraindications

Ustekinumab is contraindicated in patients with known sensitivity to the drug. It should be avoided in patients with serious active infections or malignancies.

Major Side Effects

There is a theoretical risk of severe and disseminated infections with mycobacteria and *Salmonella* based on the predisposition to these infections that is seen in patients with genetic deficiencies in IL-12/IL-23. A PPD skin test, IFN-γ release assay (e.g. QuantiFERON® TB Gold) and/or (e.g. if immunosuppression or history of tuberculosis) chest X-ray is required at baseline and (typically) repeated annually during therapy (see Table 128.6). Patients with untreated latent tuberculosis should receive antituberculous therapy for at least 1 month prior to beginning treatment.

A possible excess of major adverse cardiovascular events (MACEs; e.g. myocardial infarction, stroke) has been noted in patients who received anti-IL-12/23 therapy in clinical trials, but a recent meta-analysis did not find a significant increase in the risk of MACEs associated with the use of these agents[131a]. The effects of IL-12/23 inhibitors on vascular inflammation and thrombosis (especially early in the course of therapy) remain to be determined, and cardiovascular risk factors should be assessed prior to initiating treatment. Additional potentially severe side effects of ustekinumab are listed in Table 128.5. Injection site reactions can also occur, and retiform purpura progressing to cutaneous necrosis on the lower leg has been reported[131b].

Interactions

Live vaccines should be avoided (see Table 128.9). The response to vaccines may be muted. Other targeted immune modulators should not be administered together with ustekinumab. The concomitant administration of other immunosuppressive agents might increase the risk of infection.

Use in Pregnancy

Ustekinumab is pregnancy category B. Its safety during lactation is unknown.

ANAKINRA

Introduction

Anakinra (Kineret®) is an IL-1 antagonist[132].

Mechanism of Action

Anakinra is a recombinant, non-glycosylated form of the human IL-1 receptor antagonist. The drug binds to IL-1 type 1 receptors and thereby acts as a competitive inhibitor of IL-1, downregulating its inflammatory effects.

Indications

Anakinra is approved for the treatment of rheumatoid arthritis[132]. It is also an effective therapy for the cryopyrin-associated periodic syndrome, which includes neonatal-onset multisystem inflammatory disease (NOMID; also known as chronic infantile neurologic cutaneous articular [CINCA] syndrome), Muckle–Wells syndrome and the familial cold autoinflammatory syndrome[133] (see Table 45.2). This spectrum of autosomal dominant disorders is caused by gain-of-function mutations in the gene that encodes cryopyrin, a protein that functions in an "inflammasome" complex that produces IL-1β (see Ch. 45); additional treatments include rilonacept (a dimeric fusion protein composed of the extracellular portion of the IL-1 receptor and the Fc portion of IgG1) and canakinumab (a human monoclonal antibody against IL-1β). In addition, anakinra has been demonstrated to aid in the control of urticarial lesions associated with Schnitzler's syndrome[134] and the pustular eruptions and bone lesions (e.g. osteomyelitis) of the autosomal recessive *d*eficiency of the *I*L-1 *r*eceptor *a*ntagonist (DIRA).

Dosages

Anakinra is administered at a dose of 100 mg (2 mg/kg in children) daily via a subcutaneous injection.

Contraindications

Anakinra should not be given to patients with active infections, severe renal impairment or hypersensitivity to the drug.

Major Side Effects

Infection, neutropenia and thrombocytopenia are potentially serious reactions that can develop. Monitoring patients with complete blood counts is indicated. Injection site reactions are usually mild and tend to abate with continued therapy. Flu-like symptoms may also occur.

Interactions

Other immunosuppressive agents, particularly TNF-α inhibitors, should be avoided in patients taking anakinra[118]. Live vaccines should also be avoided, and it is unknown whether vaccines have a full effect.

Use in Pregnancy

Anakinra is pregnancy category B. Its safety during lactation is unknown.

RITUXIMAB

Introduction

Rituximab (Rituxan®) is a chimeric monoclonal antibody directed against the CD20 antigen present on the surface of mature B cells[135].

Mechanism of Action

Rituximab binds to CD20 on the surface of mature B cells and causes apoptosis of these cells (see Fig. 128.8D). It targets and selectively depletes $CD20^+$ B cells without affecting stem cells or existing plasma cells. Possible mechanisms of cell lysis include complement-dependent cytotoxicity and antibody-dependent cell-mediated cytotoxicity. In patients with pemphigus vulgaris, downregulation of desmoglein-3-specific $CD4^+$ T cells (as well as depletion of B cells and decreased anti-desmoglein-3 antibody levels) has been observed[136]. Radioactive anti-CD20 antibodies (e.g. ibritumomab tiuxetan conjugated to yttrium-90 or indium-111; tositumomab conjugated to iodine-131) have also been approved for the treatment of non-Hodgkin B-cell lymphomas.

Indications

Rituximab is approved for the treatment of non-Hodgkin B-cell lymphoma, chronic lymphocytic leukemia, rheumatoid arthritis, Wegener's granulomatosis and microscopic polyangiitis[137]. It has been successfully used to treat cutaneous B-cell lymphoma[138]. In addition to its approved indications, rituximab has efficacy in the treatment of autoimmune bullous dermatoses (including pemphigus vulgaris[139], bullous pemphigoid and para-neoplastic pemphigus), SLE, cutaneous lupus erythematosus[140], chronic GVHD[141] small vessel vasculitis[142] and dermatomyositis[143]. Its use in pemphigus vulgaris has been associated with prolonged responses in some patients.

Dosages

For lymphomas, rituximab 375 mg/m^2 is given intravenously weekly for 4–8 weeks. For rheumatoid arthritis, rituximab is administered in "courses" consisting of a 1000 mg infusion on each of two consecutive weeks, which can be repeated at 16–24-week intervals. Methylprednisolone 100 mg intravenously is typically given 30 minutes prior to each infusion. It is approved for concomitant use with methotrexate in patients with rheumatoid arthritis, and with chemotherapy in patients with B-cell lymphoma. The optimal dosing and frequency for patients with pemphigus vulgaris are not known, but 375 mg/m^2 weekly for 3–4 weeks (sometimes followed by monthly doses) has been utilized[144]. The efficacy of rituximab might be reduced in patients who develop anti-rituximab antibodies[145].

Contraindications

Rituximab is contraindicated in patients allergic to the drug or its components, hepatitis B carriers, and patients with cardiac arrhythmias, angina pectoris, a high tumor burden or active infections.

Major Side Effects

Deaths within 24 hours of rituximab infusion have been reported. These fatalities followed infusion reactions that included hypoxia, pulmonary infiltrates, acute respiratory distress syndrome, myocardial infarction, ventricular fibrillation and cardiogenic shock. Approximately 80% of the deaths occurred in association with the first infusion. Acute renal failure requiring dialysis (with instances of fatal outcome) has also been reported in the setting of tumor lysis syndrome following treatment with rituximab. Severe mucocutaneous reactions, including Stevens–Johnson syndrome/toxic epidermal necrolysis, have occasionally been noted in patients given rituximab. Rarely patients have had the onset of paraneoplastic pemphigus during treatment, but it is not clear whether this phenomenon is drug-related or disease-related. Progressive multifocal leukoencephalopathy and hepatitis B virus activation (potentially leading to fulminant hepatitis) have been associated with the use of rituximab.

The safety profile of rituximab has been established primarily in patients with lymphoproliferative diseases and includes >730 000 patient exposures over a period of 8 years. In general, the adverse events observed in patients with rheumatoid arthritis were similar to those seen in patients with non-Hodgkin lymphoma. The most common adverse events observed in clinical trials were infusion reactions and infections. No significant change in average immunoglobulin levels was observed in treated patients within clinical trials.

Interactions

Live vaccines are contraindicated and the response to vaccines may be muted. Combination with other targeted immune modulators, particularly natalizumab, may increase the risk of infection. Combination with cisplatin increases the risk of nephrotoxicity.

SOME TARGETED IMMUNE MODULATORS THAT ARE UNDER DEVELOPMENT FOR PSORIASIS				
Name	**Company**	**Delivery mechanism**	**Mechanism of action**	**Phase**
Briakinumab (ABT874)*	Abbott	Injectable	IL-12/IL-23 inhibitor	III
Secukinumab (AIN-457), AMG827, LY2439821	Novartis, Amgen, Lilly	Injectable	IL-17 blockers	II
SCH-900222	Merck	Injectable	IL-23 blocker	II
BT-061	Biotest	Injectable	Regulatory T cell activator	II
Apremilast (CC-10004)	Celgene	Oral	Phosphodiesterase-4 inhibitor	III
Tofacitinib (CP-690,550), ASP015K	Pfizer, Genzyme	Oral	JAK3 inhibitors	III, II
AEB071	Novartis	Oral	Protein kinase C blocker	II
BMS-582949	Bristol-Myers Squibb	Oral	p38 MAP kinase inhibitor	II
*No longer being developed by Abbott.				

Table 128.10 Some targeted immune modulators that are under development for psoriasis. In addition, topical psoriasis therapies that are under development include Janus kinase 1 & 2 (JAK1/2) inhibitors and a pan-selectin inhibitor (bimosiamose). IL, interleukin; JAK, Janus kinase; LFA, lymphocyte function-associated antigen. *Adapted from the National Psoriasis Foundation website (www.psoriasis.org), updated August 2011.*

Use in Pregnancy

Rituximab is pregnancy category C, and it may be unsafe during lactation.

OMALIZUMAB

Introduction

Omalizimab (Xolair®) is a recombinant humanized monoclonal antibody that targets IgE.

Mechanism of Action

Omalizumab is a humanized monoclonal antibody (IgG1) that selectively binds to and decreases serum levels of free human IgE. It also downregulates the number of high-affinity IgE receptors on mast cells, basophils and dendritic cells[146,147]. These two mechanisms limit the release of inflammatory mediators and (via effects on dendritic cells) decrease antigen presentation to T cells.

Indications

Omalizumab is FDA-approved for the treatment of adults and adolescents (ages ≥12 years) with asthma. A recent randomized controlled trial found omalizumab to be effective in the treatment of chronic urticaria[147a], and it may have utility in the treatment of atopic dermatitis[148].

Dosages

Omalizumab is administered as a 150 to 375 mg subcutaneous injection every 2–4 weeks. Doses are determined by the baseline serum total IgE level and body weight.

Contraindications

There are no contraindications other than previous hypersensitivity to omalizumab.

Major Side Effects

The most common serious adverse events seen in clinical trials with omalizumab were anaphylaxis (0.1%; 3 of 3507 patients) and malignancy (0.5% vs 0.2% in placebo patients). Injection site reactions occurred in 12% of patients treated with omalizumab, compared to 9% of those who received placebo.

Interactions

No specific interactions with other medications have been noted.

Use in Pregnancy

Omalizumab is pregnancy category B. It is excreted into the breast milk of monkeys, and caution is advised when administering it to nursing women.

TARGETED IMMUNE MODULATORS UNDER INVESTIGATION

Development of other targeted immune modulators for use in dermatology continues. Table 128.10 is a partial listing of the drugs that are currently under investigation for psoriasis. Additional drugs that are being developed for non-cutaneous inflammatory diseases might be effective for skin disorders or associated with adverse cutaneous effects.

INTRAVENOUS IMMUNE GLOBULIN (IVIg)

Key features

- IVIg is useful for inflammatory disorders, including some cutaneous diseases
- Doses for inflammatory disorders are empiric, but have generally been 2 g/kg/month for chronic diseases, and 3 g/kg total for acute conditions
- There are only a few skin disorders for which there is a high level of evidence indicating effectiveness of IVIg

INTRODUCTION

IVIg is a sterile solution of globulins extracted from pooled plasma donated by 100 000–200 000 individuals per production cycle. Processing results in a product that is predominantly IgG, having eliminated all but trace amounts of IgA and other soluble immunologically active particles. It has a half-life of 3 to 5 weeks.

IVIg is currently used in the treatment of immunodeficiency syndromes, inflammatory disorders and infectious diseases[149]. It is occasionally administered as prophylaxis to susceptible individuals exposed to particular infectious agents (e.g. non-immune, immunocompromised patients exposed to varicella zoster virus). Clinical studies, most of which were uncontrolled, and anecdotal reports suggest that IVIg is useful for some cutaneous conditions (Table 128.11), but randomized clinical trials, barring those for dermatomyositis, are lacking. IVIg offers hope for the treatment of many severe dermatologic conditions, including toxic epidermal necrolysis/Stevens–Johnson syndrome[150], dermatomyositis[151] and chronic autoimmune blistering diseases[152].

MECHANISM OF ACTION

The immunomodulatory effects of IVIg may be exerted through one or more of the following mechanisms: 1) functional blockade of Fc receptors; 2) inhibition of complement-mediated damage; 3) alteration of cytokine and cytokine antagonist profiles; 4) reduction of circulating antibodies via anti-idiotype antibodies; and 5) neutralization of toxins that trigger autoantibody production[149,153]. In toxic epidermal

USES OF IVIg IN DERMATOLOGY			
Indication	**Summary of evidence**	**Dosing**	**Comments**
Dermatomyositis	Benefit established	2 g/kg (over 2 days) Initially given every month, maintenance schedule individualized	Beneficial in patients intolerant of prednisone or immunosuppressives
Kawasaki disease	Benefit established	2 g/kg (over 6–12 hours)	
Toxic epidermal necrolysis	Case series, anecdotal evidence	1 g/kg/day for 3 days	
Pemphigus variants	Case series, anecdotal evidence	2 g/kg (over 2–3 days) Initially given every month, maintenance schedule individualized	Adjunctive or second-line therapy
Bullous pemphigoid	Case series, anecdotal evidence	2 g/kg (over 2–3 days) Initially given every month, maintenance schedule individualized	Adjunctive or second-line therapy
Mucous membrane (cicatricial) pemphigoid	Case series, anecdotal evidence	2–3 g/kg (over 3 days) Initially given every 2–6 weeks, maintenance schedule individualized	Adjunctive or second-line therapy
Epidermolysis bullosa acquisita	Anecdotal evidence	2 g/kg (over 2–3 days) Initially given every month, maintenance schedule individualized	Adjunctive or second-line therapy
Necrotizing fasciitis	Uncertain benefit	2 g/kg (over 6–12 hours); repeat 1–2 g/kg in 2–5 days if disease progresses	Adjunctive for progressive disease
Pyoderma gangrenosum	Uncertain benefit	2 g/kg (over 2 days) Initially given every month, maintenance schedule individualized	May be considered
Atopic dermatitis	Uncertain benefit (inconsistent results in controlled studies)	2 g/kg (over 1–2 days) Monthly	

Table 128.11 Uses of IVIg in dermatology. *Adapted from Mydlarski PR, Mittman N, Shear NH: Intravenous immunoglobulin: use in dermatology. Skin Therapy Lett. 2004;9:1–6.*

SOME PREPARATIONS OF IVIg THAT ARE AVAILABLE IN THE US				
	Gammagard S/D	**Privigen**	**Gamunex**	**Carimune NF**
Manufacturer	Baxter	CSL Behring	Talecris	CSL Behring
Form	Lyophilized	Liquid	Liquid	Lyophilized
Concentration	5% (also 10%)	10%	10%	3–12%
Maximum infusion rate	4.0 ml/kg/h	4.8 ml/kg/h	4.8 ml/kg/h	2.5 ml/kg/h
Time to infuse 70 g	5.3 h	2 h	2 h	6.6 h
pH	6.8	4.8	4.25	6.4–6.8
Osmolarity (mOsm/l)	636	320	260	192–1074
Sugar content	2% glucose	None	None	1.67 g sucrose/g of protein
Sodium content	0.85%	Trace	Trace	<20 mg/g of protein
IgA (mcg/ml)	<2.2	<25	46	720

Table 128.12 Some preparations of IVIg that are available in the US.

necrolysis, IVIg is believed to block Fas (CD95)-mediated keratinocyte death by inhibiting Fas–Fas ligand interactions (see Ch. 20).

INDICATIONS

IVIg is approved for treatment of primary and secondary immunodeficiency diseases. Table 128.11 lists dermatologic disorders for which IVIg represents a therapeutic option.

DOSAGES

At least nine different preparations of IVIg are available in the US[154]. The products differ in their sugar content, sodium content, osmolarity, pH and IgA levels (Table 128.12). The doses recommended vary depending upon the disease state being treated (see Table 128.11).

CONTRAINDICATIONS

Preparations containing IgA are contraindicated in patients with a history of hypersensitivity to IVIg, the presence of anti-IgA antibodies or a profound IgA deficiency (which may be associated with the development of anti-IgA antibodies and a risk of anaphylaxis).

MAJOR SIDE EFFECTS

Major toxicity includes the potential for anaphylaxis, aseptic meningitis, renal failure (particularly with sucrose-containing products, which can lead to "osmotic nephrosis"), thromboembolic events, hyperviscosity syndromes, dyshidrotic eczema (pompholyx), cardiac collapse and pulmonary edema. These risks vary with the preparation selected and the patient being treated. Pretreatment with acetaminophen and diphenhydramine may lessen infusion reactions, and decreasing the rapidity of the infusion lessens the risk of thromboembolic events, aseptic meningitis, and renal and cardiovascular events.

INTERACTIONS

Individuals receiving IVIg may have a suboptimal response to vaccination with live viruses.

USE IN PREGNANCY

IVIg is in pregnancy category C. There does not appear to be an excessive risk in pregnancy or lactation associated with the use of IVIg.

OTHER TARGETED ("BIOLOGIC") AGENTS CURRENTLY USED IN MEDICINE		
Drug (Trade name®)	**Target**	**FDA-approved indications/non-approved dermatologically relevant uses**
Abatacept (Orencia)	B7–1 (CD80)	Rheumatoid arthritis/psoriasis (historical) (see Fig. 128.8E)
Abciximab (ReoPro)	Glycoprotein IIb/IIIa	Cardiovascular disease
Alemtuzumab (Campath)	CD52	B-cell CLL/mycosis fungoides, ATLL
Basiliximab (Simulect)	IL2Rα (CD25)	Solid organ transplantation/GVHD
Belimumab (Benlysta)	B-lymphocyte stimulator	Systemic lupus erythematosus
Bevacizumab (Avastin)	VEGF	Colorectal cancer
Brentuximab vedotin (Adcetris)	CD30	Anaplastic large cell and Hodgkin lymphomas
Canakinumab (Ilaris)	Interleukin-1β	Cryopyrin-associated periodic syndrome
Cetuximab (Erbitux; IgG1)*,†	EGFR	Head and neck SCC, colorectal cancer
Daclizumab (Zenapax)	IL2Rα (CD25)	Solid organ transplantation/GVHD
Denileukin diftitox (Ontak)	Interleukin-2 receptor	Cutaneous T-cell lymphoma
Denosumab (Prolia, Xgeva)	RANK ligand	Osteoporosis, bone metastases
Eculizumab (Sorilis)	Complement component 5	Paroxysmal nocturnal hemoglobinuria/dermatomyositis
Gemtuzumab (Mylotarg)‡	CD33	AML
Ibritumomab tiuxetan (Zevalin)§	CD20	Non-Hodgkin lymphoma
Ipilimumab (Yervoy)	CTLA-4 (CD152)	Unresectable or metastatic melanoma (Fig. 128.8E)
Muromonab (Orthoclone OKT3)	CD3	Acute allograft rejection (renal, cardiac, hepatic)
Natalizumab (Tysabri; previously Antegren)	α-4 integrin	Multiple sclerosis, Crohn's disease
Ofatumumab (Arzerra)	CD20	B-cell CLL
Palivizumab (Synagis)	Respiratory syncytial virus (RSV)	RSV infections
Panitumumab (Vectibix; IgG2)*,†	EGFR	Metastatic colorectal cancer
Ranibizumab (Lucentis; intravitreal agent)	VEGF	Age-related macular degeneration
Rilonacept (Arcalyst)	Interleukin-1	Cryopyrin-associated periodic syndrome
Tocilizumab (atlizumab; Actemra)	Interleukin-6 receptor	Rheumatoid arthritis
Tositumonomab (Bexxar)§	CD20	Non-Hodgkin lymphoma
Trastuzumab (Herceptin)	HER2/neu	Breast cancer
TYROSINE KINASE INHIBITORS*		
Crizotinib (Xalkori)	ALK	ALK+ non-small cell lung cancer
Dasatinib (Sprycel)	c-KIT, c-Abl	CML, Philadelphia chromosome-positive ALL
Erlotinib (Tarceva)†	EGFR	Non-small cell lung and pancreatic cancer
Gefitinib (Iressa)†	EGFR	Non-small cell lung cancer
Imatinib (Gleevec, Glivec)	c-KIT, c-Abl, PDGFR	CML, GIST, DFSP (see Ch. 116), systemic mastocytosis (see Ch. 118), hypereosinophilic syndrome (see Fig. 25.8), sclerodermatous conditions (e.g. morphea, chronic GVHD)
Lapatinib (Tykerb, Tycerb)†	EGFR, HER2/neu	Metastatic breast cancer
Nilotinib (Tasigna)	c-KIT, c-Abl, PDGFR	CML
Pazopanib (Votrient)	VEGFR1,2&3, PDGFR, c-KIT	Renal cell carcinoma
Ruxolitinib (Jakafi)	Janus kinases 1&2 (JAK1/2)	Myelofibrosis
Sorafenib (Nexavar)	VEGFR1&2, PDGFR, BRAF	Renal cell carcinoma/melanoma
Sunitinib (Sutent)	VEGFR1&2, PDGFR, c-KIT, FLT3	Renal cell carcinoma, GIST
Vandetanib (Caprelsa)†	VEGFR, EGFR, RET	Metastatic medullary thyroid cancer
Vemurafenib (Zelboraf)	BRAF (a serine/threonine kinase) with the V600E mutation	Unresectable or metastatic melanoma with the $BRAF^{V600E}$ mutation
HEDGEHOG PATHWAY INHIBITOR		
Vismodegib (Erivedge)	Smoothened receptor	Unresectable or metastatic basal cell carcinoma

*See Table 21.14.
†See Chapter 36.
‡Withdrawn from the market.
§Radioactive forms are used, with ibritumomab tiuxetan conjugated to yttrium-90 or indium-111 and tositumomab conjugated to iodine-131.

Table 128.13 Other targeted ("biologic") agents currently used in medicine. Additional agents with cutaneous applications that are not yet FDA-approved include epratuzumab (anti-CD20; B-cell lymphomas, systemic lupus erythematosus) and mepolizumab (anti-interleukin-5; hypereosinophilic syndrome). ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; ATLL, adult T-cell leukemia-lymphoma; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CTLA-4, cytotoxic T-lymphocyte antigen-4; DFSP, dermatofibrosarcoma protuberans; EGFR, epidermal growth factor receptor; FLT3, FMS-like tyrosine kinase 3; GIST, gastrointestinal stromal tumors; GVHD, graft-versus-host disease; IL2Rα, interleukin-2 receptor α; PDGFR, platelet-derived growth factor receptor; RANK, receptor activator of nuclear factor κB; SCC, squamous cell carcinoma; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor.

OTHER AGENTS

Many other targeted immune modulators are used in other areas of medicine (Table 128.13). There are frequent cutaneous adverse reactions with some of these agents (e.g. the epidermal growth factor inhibitors used to treat solid tumors) (see Tables 21.14 and 128.8). Additionally, some of these agents might have benefit for dermatologic conditions (e.g. ipilimumab and vemurafenib for melanoma; imatinib for fibrosing conditions including scleroderma, mastocytosis and dermatofibrosarcoma protuberans)[155].

Chapter Contents

General principles of topical therapy 2153
Anesthetics 2156
Antipruritic agents 2156
Keratolytic agents 2157
Skin-lightening agents 2158
Agents that affect hair growth 2159
Chemotherapeutic agents 2159
Vitamin D analogues 2160
Miscellaneous agents 2161

Key features

- Absorption of topical medications depends upon several factors, including cutaneous barrier function, the anatomic site, the active agent, and characteristics of the vehicle
- In neonates, there is a greater risk of systemic toxicity with use of topical medications
- Combination or rotational therapy using topical agents may result in increased efficacy and decreased risk of side effects

INTRODUCTION

Topical medications are fundamental in the armamentarium of dermatologic therapeutics, offering the ability to deliver treatment directly to the skin while limiting systemic side effects. However, topical therapy can be time-consuming and messy, and it may not be practical for generalized skin disorders or effective for conditions with deeper involvement. Choosing an appropriate topical regimen requires consideration of the disease process and involved site(s) as well as the vehicle, application strategy and duration of use of the selected agent. This chapter reviews general principles of topical therapy and topical medications not discussed elsewhere in the textbook. Table 129.1 lists topical medications covered in other chapters.

GENERAL PRINCIPLES OF TOPICAL THERAPY

Topical formulations consist of an active ingredient in a non-active base (vehicle). To be effective, topical medications must gain entry into the skin and reach the desired target site (e.g. the epidermis below the stratum corneum or the dermis) in adequate concentrations. Successful topical therapy therefore requires percutaneous absorption, which depends upon factors related to the skin being treated as well as the agent and its vehicle (Table 129.2). The role of the stratum corneum in skin barrier function, including percutaneous absorption of medications, is discussed in Chapter 124.

Quantity of Application

In general, topical medications should be applied to the skin as a layer measuring approximately 0.05 to 0.1 mm in thickness (or sometimes less). A thicker layer of medication does not result in enhanced penetration or additional therapeutic benefit. It is estimated that 1 g of cream covers a 10 cm × 10 cm area of skin; 1 g of ointment spreads approximately 10% further than the same amount of cream.

A practical guide to quantifying the amount of ointment necessary to treat different areas of the body was developed by Long and Finlay[1]. They defined the "fingertip unit" (FTU) as the amount of ointment (dispensed from a 5 mm-diameter nozzle) that stretches from the distal

TOPICAL MEDICATIONS DISCUSSED IN OTHER CHAPTERS	
Topical medications	**Chapter(s)**
CHAPTERS ON MEDICAL THERAPY OR COSMETICS

Table 129.1 Topical medications discussed in other chapters.

FACTORS THAT AFFECT PERCUTANEOUS ABSORPTION
CHARACTERISTICS OF THE PATIENT/SKIN
• Patient age – Suboptimal skin barrier function in neonates, especially if premature (see Table 129.7)
• Diseases, physical injuries or chemical exposures that disrupt skin barrier function (e.g. Netherton syndrome)
• A thicker stratum corneum decreases absorption
• Skin hydration and/or occlusion increase absorption (e.g. in a skin fold)
• Anatomic location (approximate ratio of absorption compared to the forearm) – *Higher absorption:* scrotum (40), face (10), axilla (4), scalp (3) – *Intermediate absorption*: trunk (1.5), arm (1) – *Lower absorption*: palm (0.8), ankle (0.4), sole (0.1)
PROPERTIES OF THE MEDICATION/ITS APPLICATION
• Drug/prodrug properties that increase absorption – Smaller molecular size and/or lower frictional coefficient – Increased lipophilicity – Increased concentration and/or solubility
• Vehicle composition
• Application under occlusion increases absorption (e.g. ointment, occlusive dressing)

Table 129.2 Factors that affect percutaneous absorption.

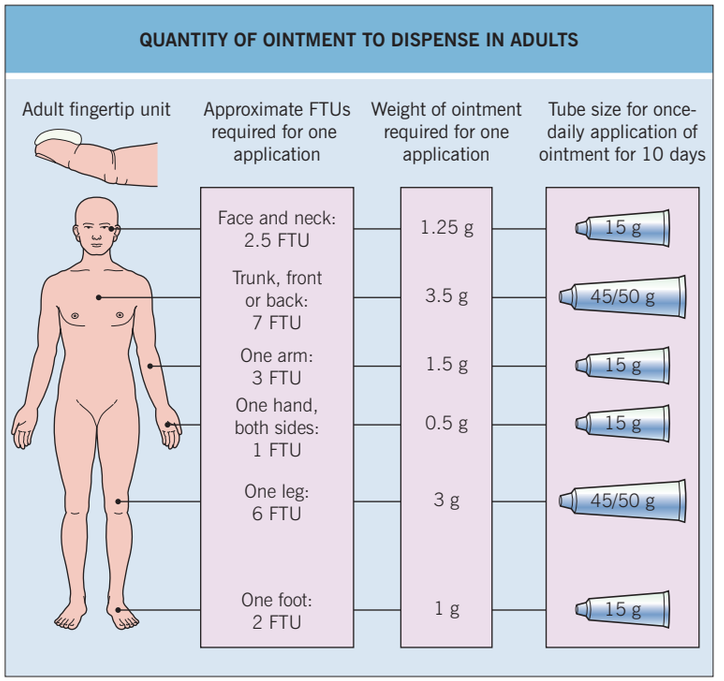

Fig. 129.1 Quantity of ointment to dispense in adults. FTU, fingertip unit.
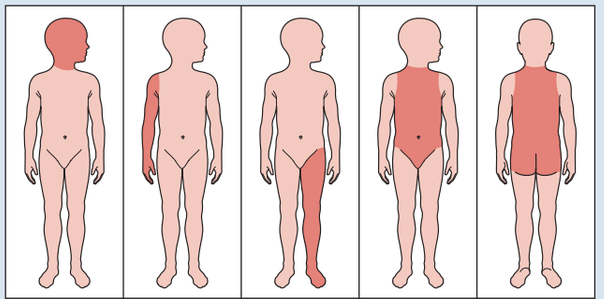
Redrawn from Long CC, Finlay AY. The finger-tip unit – a new practical measure. Clin Exp Dermatol. 1991;16:444–7.

QUANTITY OF OINTMENT TO DISPENSE IN CHILDREN ACCORDING TO AGE



Age	Face & Neck	Arm & Hand	Leg & Foot	Trunk (Front)	Trunk (Back) inc. Buttocks
	Number of FTUs				
3–11 mos	1	1	1½	1	1½
1–2 y	1½	1½	2	2	3
3–5 y	1½	2	3	3	3½
6–10 y	2	2½	4½	3½	5

Fig. 129.2 Quantity of ointment to dispense in children, according to age. FTU, fingertip unit (in an adult). *Redrawn from Long CC, Mills CM, Finlay AY. A practical guide to topical therapy in children. Br J Dermatol. 1998; 138:293–6.*

crease to the tip of the index finger in an adult. One FTU is equal to approximately 0.5 g. The numbers of FTUs/grams that are needed to treat various areas of the body in adults and children are presented in Figures 129.1 and 129.2. Approximately 20 g are necessary to treat the entire body of an adult man, requiring ~250 g per week if applied twice daily. Approximately 0.5 FTU (0.25 g) is utilized for the area of one side of an extended ("flat") hand, and estimating the number of "flat hand areas" of affected skin can help to determine the amount of medication needed (e.g. four "flat hand areas" would require 1 g per application and ~15 g per week if applied twice daily).

CLASSIFICATION OF EXTERNAL PREPARATIONS
LIQUID
• Monophasic solutions – Pure aqueous: lotions, gels – Alcoholic, alcoholic-aqueous: paints – Oily: oils • Emulsions – Oil in water (O/W; can be washed off with water) – Water in oil (W/O; cannot be washed off with water) • Suspensions • Aerosols (solutions with pressurized gaseous propellants) – Foam – Spray
SEMISOLID
• Water-free: ointments • Water-containing – Monophasic: hydrogels – Multiphasic: emulsions, creams (O/W or W/O) • Highly concentrated suspensions: pastes
SOLID
• Powders (e.g. zinc oxide, titanium dioxide, talc)

Table 129.3 Classification of external preparations. Vehicles can also contain preservatives, emulsifiers, absorption promoters, and fragrances.

FACTORS IN THE CHOICE OF FORMULATION AND VEHICLE FOR TOPICAL MEDICATIONS
NATURE OF THE DERMATOSIS
• Wet dermatoses (e.g. oozing) – water-based formulations, drying pastes • Dry dermatoses (e.g. scaling) – ointments and other oil-based formulations • Highly inflamed or crusted dermatoses – ointment or cream following or combined with wet compresses (e.g. open wet dressings, wet wraps) or soaks • Fissured or eroded skin – avoid formulations containing alcohol or salicylates, which can lead to stinging and burning
LOCATION OF THE DERMATOSIS
• Glabrous skin – ointment, cream or emulsion • Skin folds – lotion or O/W cream; avoid occlusive ointments and W/O formulations • Hairy areas – lotion, gel, foam or oil

Table 129.4 Factors in the choice of formulation and vehicle for topical medications. O/W, oil in water; W/O, water in oil.

Formulations and Vehicles

A classification of topical formulations is provided in Table 129.3, and clinical guidelines for vehicle selection are presented in Table 129.4. A discussion of how vehicles affect drug delivery is found in Chapter 124.

Topical Therapy During Pregnancy and Lactation

When treating a woman of childbearing age, it is important to be aware of recommendations regarding the use of specific drugs during pregnancy and lactation. The decision to use topical medications during pregnancy should be based on the potential risk of the medication and the extent to which the condition affects the health of the woman. For example, use of the following topical medications during pregnancy (not a comprehensive list) is generally contraindicated: podophyllin, anthralin, lindane, chemotherapeutics (e.g. carmustine, mechlorethamine hydrochloride [nitrogen mustard], 5-fluorouracil), tazarotene, and peels with phenol or salicylic acid. Table 129.5 presents the US Food and Drug Administration (FDA) classification system of pharmaceutical pregnancy categories. Table 129.6 provides lists of topical medications with minimal risk during pregnancy and lactation.

Topical Therapy in Neonates

In full-term newborns, the stratum corneum (which represents the main barrier to percutaneous absorption) is fully developed and similar

FDA CLASSIFICATION SYSTEM OF PHARMACEUTICAL PREGNANCY CATEGORIES	
Category	**Description**
A	Controlled studies show no risk. Adequate well-controlled studies in pregnant women have failed to demonstrate risk to the fetus.
B	No evidence of risk in humans. Either animal studies show risk, but human studies do not; or, if no adequate human studies have been done, animal findings are negative.
C	Risk cannot be ruled out. Human studies are lacking, and animal studies are either positive for fetal risk or lacking as well. However, potential benefits may justify the potential risk.
D	Positive evidence for risk. Human studies, or investigational or post-marketing data, show risk to fetus. Nevertheless, potential benefits may outweigh potential risk.
X	Contraindicated in pregnancy. Studies in animals or humans, or investigational or post-marketing reports, have shown fetal risk, which clearly outweighs any possible benefit to the patient.

Table 129.5 FDA classification system of pharmaceutical pregnancy categories. FDA, Food and Drug Administration.

TOPICAL MEDICATIONS WITH MINIMAL RISK DURING PREGNANCY AND LACTATION		
Pregnancy	**FDA category (see Table 129.5)**	**Lactation**
Azelaic acid	B	Acyclovir
Ciclopirox	B	Bacitracin
Clindamycin	B	Benzoyl peroxide
Clotrimazole	B	Butoconazole
Erythromycin	B	Calcipotriene
Metronidazole*	B	Ciclopirox
Mupirocin	B	Clotrimazole
Naftifine	B	Erythromycin
Nystatin†	A (pastilles)	Hydroquinone
Oxiconazole	B	Ketoconazole
Permethrin	B	Metronidazole
Retapamulin	B	Mupirocin
Terbinafine	B	Nystatin
		Oxiconazole
		Terbinafine
		Tretinoin

*Avoidance of oral metronidazole during the first trimester is often recommended.
†Intravaginal topical application not advised close to term because of risk of contamination if membranes have ruptured.

Table 129.6 Topical medications with minimal risk during pregnancy and lactation. Minimal risk defined here as FDA pregnancy category B.

FACTORS THAT INCREASE THE RISK OF SYSTEMIC TOXICITY FROM TOPICAL MEDICATIONS IN NEONATES
Increased ratio of surface area to body weight (fourfold greater than in adults)
Suboptimal epidermal barrier function due to the higher pH of neonatal stratum corneum (neutral instead of acidic)
Decreased hepatic metabolism of drugs
Decreased renal excretion of drugs
Increased distribution of drug, including the CNS due to a more permeable blood–brain barrier
Decreased plasma protein binding

Table 129.7 Factors that increase the risk of systemic toxicity from topical medications in neonates.

POTENTIAL SYSTEMIC SIDE EFFECTS OF TOPICAL MEDICATIONS	
Medication	**Systemic side effect**
Androgens	Virilization in women and male fetuses
Boric acid	Generalized erythema, fever, vomiting, mental status change
Calcipotriene (calcipotriol)	Hypercalcemia, hypercalciuria
Carmustine (BCNU)	Bone marrow suppression
Chlorhexidine	Nausea, signs of ethanol intoxication
Clindamycin	Diarrhea, pseudomembranous colitis (controversial)
Corticosteroids	Iatrogenic Cushing's syndrome, inhibition of hypothalamic–pituitary axis
Dimethylsulfoxide	Nausea, abdominal pain
Epinephrine (adrenaline)	Tachycardia
Estrogens	Pseudoprecocious puberty, gynecomastia, hypogonadism in men
Gentamicin	Ototoxicity
Hexachlorophene	Neurotoxicity, coma, death
Iodine	Hypothyroidism
Lidocaine and other topical anesthetics	With overdose (>5 mg/kg of lidocaine absorbed): *early/lower levels* – paresthesias (e.g. perioral tingling), tinnitus, dysgeusia (e.g. metallic taste), lightheadedness, tremors; *late/higher levels* – seizures, hypotension, arrhythmias, cardiopulmonary arrest (see Ch. 143)
Lindane	CNS toxicity
Malathion	CNS toxicity, hyperglycemia
Mechlorethamine (nitrogen mustard)	Myelosuppression
Mercury	CNS and renal toxicity, acrodynia
Minoxidil	Cardiac toxicity, death
Neomycin	Ototoxicity, nephrotoxicity
Phenol	Cardiac arrhythmia, death
Podophyllin	Gastrointestinal (nausea, vomiting), neurologic (mental status changes, peripheral polyneuropathy) and hematologic (thrombocytopenia, leukopenia) effects
Prilocaine–lidocaine (EMLA®)	Methemoglobinemia (perioral/acral cyanosis, vascular "mottling") related to prilocaine; see lidocaine above
Propylene glycol	Hyperosmolality, with or without lactic acidosis
Salicylic acid	Tinnitus (early sign), gastrointestinal symptoms (e.g. nausea, vomiting), CNS toxicity (e.g. confusion, delirium, seizures), metabolic acidosis with respiratory compensation (i.e. tachypnea), hypoglycemia, coma, death
Silver (silver nitrate, silver sulfadiazine)	Leukopenia, argyria

Table 129.8 Potential systemic side effects of topical medications. For most, the risk of these side effects is either theoretical or exists only in instances where the medication is applied to neonates or in quantities greatly exceeding normal exposure. CNS, central nervous system.

in thickness to that of adults (see Ch. 2). However, several factors result in an increased risk of systemic toxicity from topically applied medications during the neonatal period (defined as the first 30 days of life) (Table 129.7). Systemic toxicity (Table 129.8) has been reported in neonates exposed to topical corticosteroids, salicylic acid, lindane, hexachlorophene, chlorhexidine and propylene glycol.

Combination and Rotational Topical Therapy

The advantages of using a single topical agent include improved compliance and (in most instances) lower cost. However, combination or rotational therapy is sometimes employed to provide additive/synergistic effects (via using medications with different mechanisms of action) or to decrease potential side effects by reducing exposure to one or both

agents (especially if they have different adverse-effect profiles). Examples of this strategy for topical therapy include various combinations of benzoyl peroxide, retinoids and antibiotics to treat acne; use of a corticosteroid together with a vitamin D analogue or tazarotene to treat psoriasis; and rotating use of a corticosteroid and calcineurin inhibitor to treat atopic dermatitis.

ANESTHETICS

Indications and general principles

Topical agents can provide a moderate degree of local anesthesia without the anxiety and discomfort associated with injections. Products containing several different anesthetics or combinations of anesthetics are available for use on intact skin (see Ch. 143). These agents can be utilized prior to a wide range of dermatologic procedures, including laser therapy, curettage (e.g. of molluscum contagiosum), cryotherapy and soft tissue augmentation, as well as preceding injection of anesthesia for skin biopsies and excisions. Topical anesthetics may also be administered for postherpetic neuralgia and painful ulcers. Treatment sites should be cleansed before application of topical anesthetics, as skin contaminants and other topical medications can alter absorption and effectiveness[2].

APPLICATION OF TOPICAL ANESTHETICS TO INTACT SKIN IN CHILDREN				
Age	**Body weight (kg)**	**Maximum dose (g)**	**Maximum application area (cm²)**	**Maximum application time (hours)**
EMLA® CREAM				
<3 months	<5	1	10	1
3–12 months	5–10	2	20	4
1–6 years	10–20	10	100	4
7–12 years	>20	20	200	4
LIDOCAINE 4% LIPOSOMAL CREAM				
<12 months	<10	NA	100	1
1–6 years	10–20	NA	200	2
7–12 years	>20	NA	600	2

Table 129.9 Application of topical anesthetics to intact skin in children. Topical lidocaine is absorbed at rates of 0.045 mg/cm²/h for 2.5% cream and 0.072 mg/cm²/h for 4% liposomal cream when applied to intact skin; the maximum recommended absorbed lidocaine dose is 5 mg/kg. EMLA, eutectic mixture of lidocaine (2.5%) and prilocaine (2.5%); NA, information not available.

EMLA® (Eutectic Mixture of Lidocaine and Prilocaine)

Introduction and mechanism of action

EMLA® is a eutectic mixture of lidocaine (2.5%) and prilocaine (2.5%), both sodium channel-blocking amide anesthetics (see Ch. 143).

Dosages and application

EMLA® is available as an oil-in-water emulsion cream and a disc (which itself provides occlusion). It is typically applied under occlusion 1 to 1.5 hours prior to a procedure; dermal anesthesia is achieved after application under occlusion for 2 to 3 hours[3]. The effectiveness and application time required vary depending on the location of treatment. On the palms and soles (with a thick stratum corneum), anesthesia is difficult to achieve even with prolonged application[4], while on mucosal surfaces (with no stratum corneum), analgesia develops in as little as 5 to 15 minutes[5]. The duration of anesthesia is approximately 1 hour.

Side effects

Application of EMLA® commonly causes transient blanching (vasoconstriction) or erythema at the application site; burning and irritation occasionally occur, and chemical injury to the eye has been described[4]. An uncommon petechial or purpuric reaction is thought to result from an idiosyncratic toxic effect on blood vessels[6]. Contact urticaria or allergic contact dermatitis, most often due to the prilocaine component, have also been reported. There is substantial systemic absorption when EMLA® is applied to mucosal surfaces[4]. Methemoglobinemia represents a potential complication of systemic exposure to prilocaine, and the surface area of application should be limited, especially in infants and children (Table 129.9). Symptoms of systemic toxicity (including methemoglobinemia) are listed in Table 129.8.

Contraindications

EMLA® should not be used in patients at increased risk for methemoglobinemia. This includes premature neonates with a gestational age <37 weeks (due to their immature reductase pathways) and individuals with pre-existing methemoglobinemia or glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Interactions

EMLA® should not be used in young children (especially those <1 year of age) receiving medications that may increase the risk of methemoglobinemia (e.g. acetaminophen, antimalarials, dapsone, nitrofurantoin, nitroglycerin, phenobarbital, phenytoin, sulfonamides)[4]. Caution is also advised for older children and adults receiving these medications.

Lidocaine

Several other lidocaine-containing topical anesthetic formulations are available (see Ch. 143), including a lidocaine–tetracaine patch that is applied for 10–20 minutes (e.g. Synera®) and needle-free powder or jet-injection lidocaine delivery systems (e.g. Zingo®, J-tip®). Lidocaine 4% or 5% in a liposomal cream (e.g. LMX®) is often used for cutaneous anesthesia, with application times of 30 to 60 minutes; occlusion is not required (but may be utilized). Prospective studies have shown that LMX® and EMLA® are equally effective in reducing needle-insertion pain. The amount of lidocaine that is systemically absorbed following topical application is directly related to the surface area to which it is applied and the duration of application; care should be taken when applying to large surface areas, and guidelines for pediatric patients are presented in Table 129.9. Signs and symptoms of systemic lidocaine toxicity (see Table 129.8) are uncommon and usually remit quickly upon removal of the medication from the skin[7].

Benzocaine

Topical benzocaine is an ester anesthetic that is found in a variety of over-the-counter topical preparations used for temporary amelioration of pain on the skin and mucous membranes. It is a potent contact sensitizer, and a recent analysis of patch testing data from the North American Contact Dermatitis Group demonstrated that half of all positive patch test reactions to local anesthetics were due to benzocaine[8].

ANTIPRURITIC AGENTS

Pruritus involves multiple components of the nervous system, including skin surface receptors, peripheral (especially unmyelinated C fibers) and central nerves, and specific brain regions (see Ch. 5). Treatment of the underlying dermatologic (e.g. with application of topical corticosteroids to inflamed skin and lubrication of dry skin) or systemic condition remains the most effective method of alleviating the sensation of itch. Topical antipruritic agents may help to reduce the urge to scratch, potentially improving the efficacy of skin disease-specific therapies. Mechanisms of topical antipruritics include substituting a different sensation for itching, anesthetizing cutaneous nerve endings and blocking molecular mediators of pruritus[9]. Unfortunately, a relative lack of comparative studies has made antipruritics difficult to evaluate. Commonly used agents are outlined in Table 129.10 (also see Table 5.5).

TOPICAL AGENTS USED TO ALLEVIATE PRURITUS			
Agent	**Classification/ derivation**	**Mechanism of action**	**Uses and side effects**
Pramoxine 1% (gel; in combination with 0.5–2.5% hydrocortisone in lotion, cream, ointment or foam)	Ester anesthetic	Blocks transmission of sensory nerve impulses; hypoalgesic effect on cold pain, but not warmth or heat pain[10]; duration of effect is 2–4 hours	• Beneficial for uremic pruritus[11] and histamine-induced itch; uses include pruritus ani, notalgia paresthetica and nonspecific mild pruritus • Allergic contact dermatitis is extremely uncommon
Menthol (up to 16% in a variety of lotions, creams, ointments and gels)	Cyclic terpene alcohol derived from plants in the *Mentha* genus	Activates TRPM8 cation channels, which also respond to cold thermal stimuli[12,13]; possible central itch modulation via Aδ fiber and/or κ-opioid receptor activation[14]	• Provides a cooling sensation • Inconsistent antipruritic results in controlled studies • Irritation, especially of inflamed or eroded skin; rare allergic contact dermatitis
Phenol	Originally a distillation product of coal tar	Thought to act directly on cold receptors	• Cooling and antipruritic effects; found in throat sprays and lozenges • Should not be used in pregnant women or infants <6 months of age • Irritation, especially of inflamed or eroded skin
Camphor (0.25–0.5%; various preparations)	Ketone originally derived from the camphor laurel tree (*Cinnamomum camphora*)	Local anesthetic effect	• Cooling sensation may relieve mild pruritus • Irritation, especially of inflamed or eroded skin
Capsaicin (0.025–0.075% cream, lotion, gel or stick; 8% patch)	Natural alkaloid; derived from Solanaceae family members, including hot chili peppers of the *Capsicum* genus	Activates the TRPV1 vanilloid receptor, which also responds to temperatures >43°C (109°F); repeated release of substance P from C neurons eventually leads to depletion of this neuropeptide (and reduced transmission of heat, pain and itch)[15]	• Applied three to five times daily or via a single 1-hour patch application • Initially evokes a sensation of warmth/ burning[16], with onset of the therapeutic effect ~1 week after initiation • Transdermal patch is FDA-approved for treatment of postherpetic neuralgia • Uses include notalgia paresthetica, brachioradial pruritus, renal pruritus, prurigo nodularis, psoriatic pruritus, and itch associated with a burning sensation • Burning, stinging and/or erythema at the application site occur in >50% of patients[17] • Hand washing after application helps to prevent contact with (and irritation of) other skin, the eyes and mucosal surfaces • Pregnancy category C
Doxepin 5% cream	Tricyclic compound	Potent histamine antagonist (H_1 and H_2); sedation via anticholinergic properties	• Applied four times daily for up to 7 days • Shown to relieve pruritus in patients with atopic dermatitis, lichen simplex chronicus and nummular eczema[18,19] • Drowsiness due to systemic absorption in ~25% of patients[20] • Occasionally irritant or (less often) allergic contact dermatitis; systemic contact dermatitis with subsequent administration of oral doxepin has been described • Contraindicated in patients with untreated narrow angle glaucoma or urinary retention and those receiving MAO inhibitors • Pregnancy category B; use during lactation is not recommended
Diphenhydramine (2% cream, lotion, gel or spray)	Antihistamine	H_1 histamine antagonist; localized anesthetic effect via blockage of sodium channels	• Use is *not recommended* due to lack of efficacy as an antipruritic agent and potency as topical sensitizer, which can lead to allergic contact dermatitis

Table 129.10 Topical agents used to alleviate pruritus. Calamine lotion is listed in Table 129.14. FDA, US Food and Drug Administration; MAO, monoamine oxidase; TRPM8, transient receptor potential melastatin 8; TRPV1, transient receptor potential vanilloid 1.

KERATOLYTIC AGENTS

Keratolytic agents reduce the thickness of the stratum corneum via elimination of squames. This can be beneficial in diseases characterized by reduced desquamation or accelerated epidermal proliferation. Use of these agents in cosmeceutical products and chemical peels is discussed in Chapters 153 and 154.

Urea

Introduction, dosages and indications

Topical urea, first synthesized in 1828 by the German chemist Frederich Wohler, has several applications in dermatology, including use as a humectant and mild keratolytic at low concentrations (10–25%) and as a hygroscopic keratolytic at higher (40–50%) concentrations. It

is occasionally employed to improve the penetration of other topical medications or for chemical nail avulsion[21]. Topical urea is available in a variety of formulations, including over-the-counter and prescription creams, lotions, gels, solutions and foams.

Mechanism of action

Urea enhances the water-binding capacity of protein. When applied topically, it incorporates itself into the stratum corneum and absorbs water from the atmosphere, which enhances barrier function by decreasing transepidermal water loss, increasing skin hydration and decreasing sensitizing effects of topical irritants[22]. The keratolytic mechanism of urea is thought to be related to its hygroscopic character, with absorption of water leading to physical alteration of the epidermis and desquamation of corneocytes[23].

Side effects

Although it is generally well tolerated, urea can cause irritation and/or burning at sites of application, especially on inflamed or eroded/fissured skin.

Use in pregnancy

Urea is pregnancy category B.

Salicylic Acid

Introduction, dosages and indications

Derived from the bark of the willow tree *Salix alba*, this β-hydroxy acid is used in the treatment of a variety of dermatologic diseases. Topical formulations containing salicylic acid include creams, lotions, ointments, gels, foams, solutions, shampoos, cleansers, pads and plasters, many of which can be obtained without a prescription. Lower concentrations (1–6%) are utilized for hyperkeratotic dermatoses, while higher concentrations (10–40%) are applied to corns, calluses, warts and focal hyperkeratosis. Low concentrations (0.5–2%) are also used for comedolytic effects in patients with acne.

Mechanism of action

Salicylic acid alters corneocyte adhesion[24], possibly by disrupting or extracting desmosomal proteins[25]. This can result in increased penetration of other topical agents. Salicylic acid may also have antimicrobial and mild anti-inflammatory effects.

Side effects

Depending upon the site and concentration, topical application of salicylic acid can result in irritation, peeling or even erosions; allergic contact dermatitis is uncommon but has been described[24]. Systemic absorption may result from extensive application, especially in neonates and infants; this can lead to salicylism, with gastrointestinal and neurologic toxicity[21,24] (see Table 129.8).

Use in pregnancy

Salicylic acid is pregnancy category C, and premature closure of the ductus arteriosus in the fetus (with subsequent pulmonary hypertension in the neonatal period) has been reported with extensive use in late pregnancy.

Alpha-hydroxy Acids

Introduction, dosages and indications

Alpha-hydroxy acids (AHAs) include glycolic, lactic, mandelic, tartaric, malic and citric acids (see Ch. 153). Lactic and glycolic acids are most commonly used in dermatologic therapy and are found at various concentrations and pH levels in a myriad of formulations, including cleansers, shampoos, lotions, creams, gels, masks and peeling agents. AHAs were first noted to have effects on corneocyte adhesion when their therapeutic role in the management of ichthyoses was described in 1974[26]. Other dermatologic conditions for which AHAs are utilized include xerosis, acne vulgaris, rosacea and photoaging.

Mechanism of action

AHAs diminish the strength of intercellular bonding, thereby weakening corneocyte cohesion and leading to exfoliation[27]. Unlike other "true" keratolytics, which cause disaggregation of corneocytes high in the stratum corneum, AHAs tend to influence corneocyte cohesion at lower, newly forming levels of the cornified layer[27]. Higher concentrations of AHAs may have dermal (e.g. increased thickness) as well as epidermal effects[28].

Side effects

Topical AHAs are generally well tolerated but can cause irritation and/or burning at sites of application (especially on inflamed or eroded/fissured skin).

Propylene Glycol

Propylene glycol is a sweet, viscous fluid that is soluble in water. It is used as a keratolytic agent at a concentration of 10–20%. Irritation is marked at higher concentrations. Propylene glycol is also employed as a preservative and a penetration enhancer.

SKIN-LIGHTENING AGENTS

Hydroquinone

Introduction, dosages and indications

Hydroquinone (1,4-dihydroxybenzene) is used for treatment for melasma and other disorders of hyperpigmentation[29] (see Ch. 67). In the US, 2% formulations are available over-the-counter, while 3% solution and 4% cream or gel require a prescription. Twice-daily application to affected areas is commonly recommended. Other products contain hydroquinone in combination with a sunscreen or with tretinoin (0.05–0.1%) and a class 5–7 corticosteroid[30].

Mechanism of action

Hydroquinone works as a bleaching agent by competing with tyrosine as a substrate for tyrosinase (the initial enzyme in melanin biosynthesis; see Ch. 65) and via selective damage to melanosomes and melanocytes by production of highly reactive oxygen radicals[29].

Side effects

Irritant or (less often) allergic contact dermatitis can develop. Exogenous ochronosis occasionally occurs with prolonged use of higher concentrations of hydroquinone. A variety of neoplasms have been noted to develop in rodents that received large systemic doses of the medication, but the relevance to topical therapy in humans has not been determined[29]. Concern regarding potential adverse effects related to misuse of hydroquinone led to its removal from Japanese and European markets.

Use in pregnancy

Hydroquinone is pregnancy category C.

Monobenzyl Ether of Hydroquinone

Monobenzyl ether of hydroquinone (MBEH) is infrequently used to depigment remaining normal skin in patients with extensive vitiligo in order to achieve a uniform appearance (see Ch. 66). MBEH was shown in 1951 to have an inhibitory effect on the tyrosine–tyrosinase reaction, thereby preventing melanin formation[31]. It is thought to act via competitive inhibition of tyrosinase and free-radical-mediated damage of melanocytes. Depigmentation is typically long-lasting, but repigmentation (especially in a perifollicular distribution) can reappear following intense sun exposure. Irritant and allergic contact dermatitis represent possible side effects[32].

Mequinol

Mequinol (4-hydroxyanisole) is a skin-lightening agent; a solution composed of mequinol 2% and tretinoin 0.01% is FDA-approved for the treatment of solar lentigines. Mequinol is a substrate of tyrosinase

and may serve as a competitive inhibitor of melanin biosynthesis[29]. The mequinol–tretinoin combination product is pregnancy category X.

AGENTS THAT AFFECT HAIR GROWTH

Both unwanted excessive hair and hair loss are common dermatologic complaints, and the underlying disorders may respond to topical therapy. Minoxidil and eflornithine are reviewed here, and a protocol for topical immunotherapy with diphencyprone (DPCP) or squaric acid dibutyl ester (SADBE) for alopecia areata is presented in Table 69.5.

Minoxidil

Introduction, dosages and indications

Originally developed as an antihypertensive agent, minoxidil has been known for decades to promote hair growth. Available in 2% and 5% solutions and a 5% foam, topical minoxidil is FDA-approved for the treatment of androgenetic alopecia in both men and women (see Ch. 69). It is also used for other forms of hair loss, including alopecia areata. Minoxidil is typically applied twice daily to the scalp[33].

Mechanism of action

Minoxidil causes premature termination of the telogen phase, lengthens the anagen phase and can increase follicle size (particularly of miniaturized follicles)[33,34]. Stimulation of vascular endothelial growth factor and prostaglandin synthesis may also play a role[34]. Although oral minoxidil relaxes vascular smooth muscle by opening ATP-dependent potassium channels, this mechanism has not been definitively linked to stimulation of hair growth[34].

Side effects

While generally well-tolerated, minoxidil can cause dryness, irritation and (uncommonly) allergic contact dermatitis. It may also result in unwanted hair growth at sites inadvertently exposed to the medication (e.g. the face or ears). Systemic side effects such as headache and peripheral edema are occasionally observed.

Use in pregnancy

Minoxidil is pregnancy category C.

Eflornithine

Eflornithine 13.9% cream is a prescription treatment for excessive and unwanted facial hair in women. It irreversibly inhibits ornithine decarboxylase in the skin, leading to decreased polyamine synthesis and arrest of follicular matrix cell proliferation[35]. Twice-daily application for 24 weeks has been shown to significantly decrease facial hair[35], and use of eflornithine together with laser hair removal may result in more rapid and complete reduction in facial hair than laser treatment alone[36]. Eflornithine is usually well tolerated, with occasional burning or acneiform eruptions at sites of application[35]; it is pregnancy category C.

CHEMOTHERAPEUTIC AGENTS

5-Fluorouracil

Mechanism of action

5-Fluorouracil (5-FU) is a pyrimidine analogue that interferes with DNA synthesis by irreversibly inhibiting thymidylate synthetase, which prevents cellular proliferation and results in cell death (preferentially affecting rapidly dividing cells)[37]. It is also incorporated into DNA and RNA, leading to DNA breakage and decreased protein synthesis, and it disrupts the exosome complex that degrades RNA.

Indications and dosages

The primary dermatologic use of topical 5-FU is the treatment of actinic keratoses (AKs; see Ch. 108)[38]. 5-FU is particularly helpful in treating numerous AKs and sites of severe actinic damage without clinically evident lesions. It is less effective for hypertrophic AKs owing to decreased percutaneous absorption through the thickened stratum corneum. Additional dermatologic applications of topical 5-FU include the treatment of actinic cheilitis, squamous cell carcinoma *in situ* (Bowen's disease), superficial basal cell carcinoma, cutaneous and genital warts, porokeratoses, nail psoriasis and extramammary Paget's disease[38]. It can also improve the appearance of photoaged skin via epidermal injury and subsequent dermal remodeling (similar to that seen following laser therapy)[39].

5-FU is available in both cream (0.5%, 1% and 5%) and solution (2% and 5%) formulations. Regimens vary depending on the concentration and vehicle as well as the indication and anatomic location (requiring a longer duration on the extremities than the face). 5-FU is typically applied once or twice daily for 2 to 6 weeks. Pretreatment with a topical retinoid for 2 weeks can increase efficacy on the extremities and trunk.

Side effects

During treatment of AKs, the skin progresses through stages of erythema (sometimes painful and associated with edema), crusted erosions and re-epithelialization. The principal side effects are related to this localized inflammatory response (Fig. 129.3), which is occasionally

Fig. 129.3 Reactions to topical 5-fluorouracil. A Inflammation with erythema and crusting at site of actinic keratoses on the forehead. **B** Large red–purple patches at sites of application on the upper chest in a patient with severe photodamage. **C** Erythema and crusting of photodamaged skin on the dorsal forearm. *B, C, Courtesy, Jean L Bolognia, MD.*

followed by residual pigmentary changes. A mid-potency topical corticosteroid can be applied for symptomatic relief once peak inflammation has been attained. Systemic adverse events are extremely rare, and absorption studies show that systemic levels of 5-FU after topical application are very low[38].

Contraindications and use in pregnancy

Use of 5-FU is contraindicated in patients with a history of hypersensitivity to this agent and those with dihydropyrimidine dehydrogenase deficiency. 5-FU is potentially teratogenic and is classified as pregnancy category X; use during pregnancy and lactation is contraindicated.

Mechlorethamine Hydrochloride

Introduction, dosages and indications

Mechlorethamine hydrochloride (HCl) (a form of nitrogen mustard) was introduced in 1959 and is used in the treatment of limited or generalized patch/plaque-stage mycosis fungoides (MF). Concentrations ranging from 10 to 40 mg/dl (0.01–0.04% w/w) are compounded in an ointment or (less often) aqueous solution. This is typically applied daily to affected areas or the entire body (sparingly to the skin folds and excluding genitalia) until clearance is achieved, which typically takes 6–12 months with ointment and 1–4 months with aqueous solution. A complete response occurs in approximately 65–75% of patients with patch/plaque-stage MF[40].

Mechanism of action

Mechlorethamine HCl is an alkylating agent (i.e. donates alkyl groups to DNA), with cytotoxicity that preferentially affects rapidly dividing cells. Immunostimulatory effects have also been postulated to have a role in the treatment of patients with MF[40].

Side effects

Irritant and/or allergic contact dermatitis occurs in approximately half of patients and may result in interruption of treatment. However, irritant reactions often improve with continued use, and patients can be desensitized if necessary. Other potential side effects include pruritus, xerosis, hyperpigmentation, urticaria, anaphylaxis and (with prolonged use) development of squamous cell carcinoma[40].

Use in pregnancy

Mechlorethamine HCl is pregnancy category D; use during pregnancy or lactation is contraindicated.

Carmustine

Introduction, dosages and indications

Topical nitrosoureas have been utilized in the treatment of MF since 1972[41]. Carmustine (1,3-bis [2-chloroethyl]-1-nitrosourea; BCNU) currently represents a second- or third-line therapeutic option for MF, due to the potential for hematologic complications secondary to systemic absorption. Like mechlorethamine HCl, it is available in an aqueous solution and ointment. Carmustine is applied once or twice daily until clearance of the treated areas occurs, which typically requires 1 to 4 months when the aqueous solution is used and 6 to 12 months with the ointment. A complete response is achieved in 85% of patients with limited patch/plaque-type disease (T1) and nearly 50% of those with generalized patch/plaque-type disease (T2)[40,42].

Mechanism of action

Carmustine is a nitrosourea alkylating agent that produces alkylation and subsequent cross-linking of DNA, thereby disrupting DNA synthesis and resulting in cytotoxicity that preferentially affects dividing cells[40].

Side effects

Erythema, tenderness, bullae and persistent telangiectasias can develop at application sites[40]. Allergic contact dermatitis occurs less frequently than with mechlorethamine HCl. However, higher levels of systemic absorption (5–30% of the administered dose) can lead to side effects such as mild to moderate myelosuppression[43].

Use in pregnancy

Carmustine is pregnancy category D; use during pregnancy or lactation is contraindicated.

VITAMIN D ANALOGUES

Mechanism of action

The skin serves as both a site of vitamin D biosynthesis (see Fig. 51.10) and a target organ for its ultimate activity. The cutaneous effects of 1,25-dihydroxyvitamin D_3 (calcitriol, the active form of vitamin D; Fig. 129.4) include inhibiting proliferation and promoting differentiation of keratinocytes as well as immunomodulatory actions such as decreasing production of inflammatory mediators (e.g. interleukin [IL]-2, IL-6, IL-8, interferon-γ and chemokines)[44]. Vitamin D exerts its regulatory functions by binding to vitamin D receptors (VDRs) on keratinocytes, melanocytes, Langerhans cells, macrophages, T cells and fibroblasts.

Topical agents and their indications

Several vitamin D analogues are available for clinical use: calcipotriene (calcipotriol) (Fig. 129.5), calcitriol, tacalcitol and maxacalcitol; their formulations and dosing are presented in Table 129.11. The primary indication for these agents is the treatment of psoriasis[45–49], and they are occasionally used for other skin conditions such as vitiligo, morphea, ichthyoses and Hailey–Hailey disease. Application of a vitamin D analogue in combination with a high-potency or superpotent topical corticosteroid in patients with psoriasis can have greater efficacy and a more rapid onset of action than either agent alone, as well as less irritation than the vitamin D analogue alone[46]. Additive benefits can also occur when vitamin D analogues are used together with acitretin, cyclosporine or phototherapy (narrowband or broadband UVB, psoralen plus UVA; applied after phototherapy

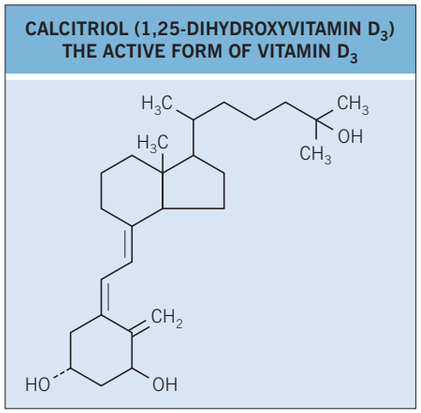


Fig. 129.4 Calcitriol (1,25-dihydroxyvitamin D_3), the active form of vitamin D_3.

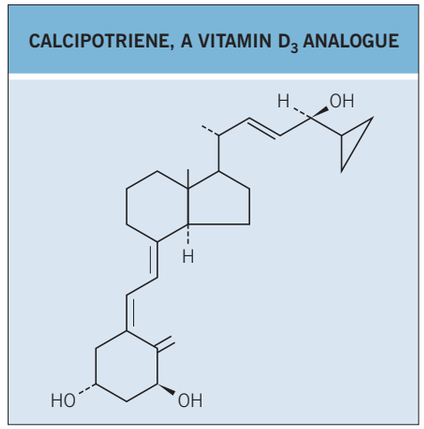

Fig. 129.5 Calcipotriene (calcipotriol), a vitamin D_3 analogue.

TOPICAL VITAMIN D_3 AND ITS ANALOGUES		
Agent	**Available formulations**	**Maximum weekly dose**
Calcipotriene (calcipotriol) 0.005% (50 microg/g)	Cream, ointment, solution; combined with betamethasone dipropionate 0.064% in an ointment and suspension	100 g
Calcitriol [1,25$(OH)_2D_3$] 3 microg/g	Ointment	200 g
Tacalcitol [1,24$(OH)_2D_3$] 4 microg/g*	Ointment, lotion	70 g
Maxacalcitol 25 microg/g*	Ointment, lotion	70 g
*Not available in the US.		

Table 129.11 Topical vitamin D_3 and its analogues. These agents are typically applied twice daily. In general, treatment of >30% of the body surface area is not recommended. Calcipotriene is the US Adopted Name (USAN) and calcipotriol is the International Nonproprietary Name (INN).

SAMPLE PROTOCOL FOR SHORT-CONTACT ANTHRALIN THERAPY FOR ALOPECIA AREATA
• Anthralin 0.5% cream is applied sparingly to affected areas of the scalp daily, followed by washing with shampoo/soap and water • An initial application time of 10 minutes is increased in 10-minute increments every 4–5 days until slight irritation (e.g. erythema, scaling, pruritus) occurs • If excessive irritation develops, treatment is withheld for several days and resumed at the last tolerated application time • If there is no irritation with a 60-minute contact time, 1% anthralin is applied for 10 minutes and application times increased as above • If there is no irritation with 1% anthralin applied for 60 minutes, overnight application is considered • Initial responses are typically seen within 12 weeks; cosmetically acceptable responses require a mean of 24 weeks
ADDITIONAL INFORMATION
• Brownish staining of treated areas of the scalp and hair is expected • To prevent staining of clothing, bedding and furniture, patients should wash their hands thoroughly after applying anthralin and avoid touching fabrics with their scalp until it has been washed off • Avoid getting anthralin into the eyes; do not apply to eyelids or eyelashes • Special care should be taken in sensitive areas (areas of scalp near the ears, eyebrows)

Table 129.12 Sample protocol for short-contact anthralin therapy for alopecia areata. *Courtesy, Julie V Schaffer, MD, and Jean L Bolognia, MD.*

sessions to avoid degradation by UV light) in the treatment of psoriasis and (for phototherapy) vitiligo.

Side effects

The most common side effect is irritation, burning and stinging at the application site, which limits the use of vitamin D analogues on the face and in intertriginous areas. Allergic contact dermatitis has been described with calcipotriene. The systemic effects of vitamin D and its analogues include releasing calcium from the bone, increasing renal tubular reabsorption and intestinal absorption of calcium, and decreasing parathyroid hormone release. Use of excessive amounts (see Table 129.11) of topical vitamin D analogues can lead to hypercalcemia and hypercalciuria. Parathyroid hormone levels should be monitored if use of these medications exceeds the recommended amounts. Patients with renal disease and those receiving medications that can increase the serum calcium level (e.g. thiazide diuretics, high doses of oral vitamin D) may be at increased risk of developing hypercalcemia.

Use in pregnancy

Calcipotriene and calcitriol are pregnancy category C.

MISCELLANEOUS AGENTS

Tar

Introduction and indications

Topical tar has served as a skin-directed therapy for over 2000 years, since the Greek physician Dioscorides applied "asphalt" to manage several cutaneous diseases[50]. Among the various types of tar (e.g. wood, bituminous [shale], petroleum, coal), coal tar is most often used as a dermatologic treatment. Currently, tar is utilized primarily in the management of psoriasis and several forms of dermatitis (e.g. seborrheic, nummular, atopic), most commonly in conjunction with other therapeutic modalities. For example, the classic Goeckerman regimen employs topical tar in combination with UVB radiation for the treatment of psoriasis[51].

Dosages

Coal tar in concentrations of 0.5% to 10% is available (or can be compounded) in a broad array of vehicles, including ointment, lotion, gel, foam, solution, oil, shampoo and soap. Liquor carbonis detergens is a distillate of crude car tar that is typically used in concentrations of 3% to 10%.

Mechanism of action

Coal tar is thought to suppress DNA synthesis, which may lead to normalization of epidermal differentiation in conditions such as psoriasis[50]. It appears to have anti-inflammatory, antimicrobial and antipruritic effects. In animal studies, tar has been found to decrease sebum secretion. Coal tar (but not other forms of tar) also has a photosensitizing effect in the 330–550 nm range of the UVA and visible light spectra[50].

Side effects

The unpleasant odor, messiness and staining potential of topical tar limit its use. Acneiform eruptions, folliculitis and irritant contact dermatitis (including pustules within plaques of psoriasis) may occur at application sites, and "tar smarts" can develop following exposure to UVA radiation. Ever since Sir Percival Pott described an increased risk of scrotal cancer in chimney sweepers in 1775, tar has been implicated as a potential carcinogen[50]. However, the evidence that topical tar formulations used in the treatment of skin disease result in an increased risk of skin cancer is inconclusive.

Use in pregnancy

Coal tar is pregnancy category C.

Anthralin

Introduction, dosages and indications

Anthralin, the synthetic form of chrysarobin (a substance found in the bark of the South American araroba tree), has been used in the treatment of dermatologic conditions for more than 80 years[52]. It is currently available in 0.5% and 1% creams. Although no longer commonly used for psoriasis, short-contact anthralin therapy (with gradual increases in the application time ± concentration) continues to be employed to treat alopecia areata via induction of an irritant effect (Table 129.12)[52].

Mechanism of action

Anthralin induces a brisk inflammatory response at sites of application, which may result from the generation of extracellular oxygen free radicals[52]. Inhibition of mitochondrial respiration and cell growth are thought to reduce keratinocyte proliferation and lead to antipsoriatic effects.

Side effects

Use of anthralin is limited by irritation at application sites (which depends on the concentration and contact time) and staining of skin, clothing, and household items (e.g. bed sheets, furniture). Staining and irritation can be ameliorated by the application of triethanolamine 10% cream to treatment sites after removal of the anthralin-containing product.

Use in pregnancy

Anthralin is pregnancy category C.

Podophyllin and Podophyllotoxin

Introduction, dosages and indications

Podophyllin resin is a crude extract from the May apple plant (*Podophyllum peltatum* or *Podophyllum emodi*) that has been employed for decades to treat condyloma acuminata. However, the concentration of its most active ingredient is not standardized in the 10–25% solutions that are applied in the physician's office weekly and washed off 1 to 4 hours later[53]. In contrast, podophyllotoxin is available in a stable and standardized 0.5% solution and gel as well as a 0.15% cream. These compounds lack the mutagens that are found in podophyllin and can be applied by the patient, usually twice daily for three consecutive days each week for 4 to 6 weeks. Reported clearance rates for condyloma acuminata range from 30% to 60% with podophyllin and from 45% to 75% with podophyllotoxin[53].

Mechanism of action

Podophyllin and podophyllotoxin act by arresting mitosis through reversible binding to tubulin.

Side effects

Common adverse effects associated with both podophyllin and podophyllotoxin include burning, erythema and skin breakdown at application sites. The extent of irritation may be reduced by application of petrolatum to the unaffected skin surrounding the warts that are treated. Because of its percutaneous absorption, application of large amounts of podophyllin can result in systemic toxicity (see Table 129.8).

Use in pregnancy

Use of podophyllin during pregnancy is contraindicated due to its teratogenic effects. However, podophyllotoxin is pregnancy category C.

SAMPLE PROTOCOL FOR TOPICAL IMMUNOTHERAPY WITH SQUARIC ACID DIBUTYL ESTER FOR CUTANEOUS WARTS
• Sensitize with a 2% SADBE solution in acetone applied to a small (e.g. 2 cm × 2 cm) area on the inner aspect of the upper arm; cover with a dressing and do not wash for 24 hours • After 1 week (2 weeks if the initial reaction was severe), apply 0.2% SADBE solution to non-facial warts; cover with a light dressing and wash after 12–24 hours • Apply approximately twice weekly to warts; can increase or decrease the length of time between treatments depending on the duration of the reaction (e.g. repeat application once the erythematous/eczematous reaction has subsided) • If there is no inflammation or response of the warts after 2–4 weeks, increase the concentration to 0.5% (and subsequently to 1% and 2% as needed); decrease concentration (e.g. from 0.2% to 0.1%) and/or amount applied if excessive inflammation (e.g. more than mild erythema and pruritus) • Responses are usually seen within 3 months, with complete clearance in 60–80% of patients after a mean of 6–8 weeks
ADDITIONAL INFORMATION
• The acetone solution should be applied using a cotton-tip applicator • SADBE should be refrigerated and protected from light • Side effects include severe or widespread eczematous reactions (which can be treated with topical or, if required, systemic corticosteroids), lymphadenopathy and postinflammatory pigment alterations (especially in patients with darkly pigmented skin)

Table 129.13 Sample protocol for topical immunotherapy with squaric acid dibutyl ester (SADBE) for cutaneous warts. This is not an FDA-approved medication.

Cantharidin

Introduction, dosages and indications

Cantharidin is a vesicant derived from "blister beetles" in the Coleoptera order and Meloidae family. It has been used since the 1950s for the treatment of warts and molluscum contagiosum. Although cantharidin met the safety requirements outlined by the Food, Drug and Cosmetic Act of 1938, it lost its FDA approval in 1962 when its manufacturers failed to submit required efficacy data[54]. A 0.7% concentration of cantharidin is currently available in a film-forming collodion vehicle; another formulation (primarily used for warts) combines 1% cantharidin with 2% podophyllin and 30% salicylic acid.

A thin film of cantharidin is typically applied to lesions in the office. After drying, occlusion may be used. The residual film is washed off

TRADITIONAL TOPICAL MEDICATIONS		
Agent	**Components**	**Classic uses**
1-2-3 paste	Burow's solution, petrolatum, zinc oxide	Hand eczema, erosions, ulcerations
Aqueous silver nitrate 10% solution*	Silver nitrate	Small recalcitrant ulcerations
Black cat*	Acetone, collodion, crude coal tar	Psoriasis, lichen simplex chronicus, nummular eczema, hypertrophic lichen planus
Burow's solution	Aluminum acetate	Weeping, macerated and/or (super)infected skin conditions, especially in intertriginous and acral sites (e.g. tinea pedis/cruris, candidiasis)
Calamine lotion	Zinc oxide, ferric oxide, glycerin, bentonite magma, calcium hydroxide solution (lime water)	Acute and subacute pruritic dermatoses
Castellani's paint (carbol fuchsin)	Phenol, resorcinol, basic fuchsin (without the latter in colorless version)	Cutaneous candidiasis, tinea pedis/cruris, pustular dermatoses of the hands and feet
Chrysarobin*	Chrysarobin, chloroform	Chronic paronychia
Fluffy tannic acid powder*	Fluffy tannic acid, bentonite, kaolin	Hyperhidrosis, contact dermatitis of the hands/feet
Gentian violet solution	Gentian violet	Candidiasis, tinea pedis/cruris
P&S® liquid	Mineral oil, glycerin, phenol	Psoriasis/sebopsoriasis with excessive hyperkeratosis (especially of the scalp)
Potassium permanganate	$KMnO_4$	Weeping, macerated and/or (super)infected skin conditions, especially in intertriginous and acral sites (e.g. tinea cruris/pedis, candidiasis)
Schamberg's lotion*	Menthol, phenol, zinc oxide, calcium hydroxide solution, olive oil	Acute and subacute pruritic dermatoses
Whitfield's ointment	Benzoic acid (6%), salicylic acid (3%)	Tinea pedis

*Primarily of historical interest.

Table 129.14 Traditional topical medications.

NEWER PRESCRIPTION BARRIER-REPAIR/MOISTURIZING AGENTS	
Agent	**Active ingredients**
Atopiclair®/Pruclair™ cream	Glycyrrhetinic acid (licorice root), *Vitis vinifera* (grape vine) extract, *Butyrospermum parkii* (shea butter), hyaluronic acid, telmesteine
Eletone® cream	70% oil (mineral oil, white petrolatum) dispersed in 30% water
EpiCeram emulsion	3:1:1 molar ratio of ceramide, cholesterol and free fatty acids (e.g. capric, linoleic, palmitic acids)
Hylatopic® (Plus) emollient foam	*Theobroma grandiflorum* seed butter, hyaluronic acid, ceramide (latter in "Plus" version)
MimyX®/PruMyx™ cream	Palmitamide monoethanolamine, palm glycerides, hydrogenated lecithin, squalane, olive oil
Neosalus™ foam	Dimethicone, stearic acid
Promiseb™ cream	Glycyrrhetinic acid, *Vitis vinifera* extract, *Butyrospermum parkii*, piroctone olamine, hydrogenated castor oil, telmesteine
Tetrix™ cream	Aluminum magnesium hydroxide stearate, cyclomethicone, dimethicone, hexyl laurate

Table 129.15 Newer prescription barrier-repair/moisturizing agents. These agents are FDA-approved as "medical devices" and available by prescription. Over-the-counter barrier-repair moisturizers containing ceramides (e.g. CeraVe® cream or lotion) or "pseudoceramides" and filaggrin breakdown products (Cetaphil®, Restoraderm® moisturizer) are also available.

thoroughly with soap and water or rubbing alcohol by the patient (or a parent) 2 to 6 hours after application. Blisters typically form during the next 24 hours, followed by superficial erosions; healing of treated areas (with temporary residual erythema) occurs over a period of 4 to 7 days[54]. Benefits of cantharidin use include painless application (particularly advantageous in young children) and a lack of scarring.

Mechanism of action

Cantharidin acts via release of neutral serine proteases that cause desmosomal plaque degeneration, leading to detachment of desmosomes from tonofilaments; resultant acantholysis is intraepidermal and therefore non-scarring[54].

Side effects

The blisters and erosions that form after cantharidin treatment can be painful or pruritic, and postinflammatory hypopigmentation may take several months to resolve. Use of cantharidin to treat warts occasionally results in a "doughnut wart" due to clearance in the center but not at the periphery of the lesion. Cantharidin poisoning has been described following ingestion, with potential sequelae including blistering and erosions in the mouth and gastrointestinal tract as well as dysuria, hematuria and renal failure. Standard in-office application of cantharidin, however, does not generally cause systemic effects.

Sulfur

Introduction

Sulfur, a yellow non-metallic element, has long been employed as a treatment for dermatologic conditions such as seborrheic dermatitis, rosacea, acne, pityriasis versicolor and scabies. Sulfur is typically used in concentrations ranging from 2% to 10%, often in combination with a second agent, e.g. 2% sulfur plus 2% salicylic acid in shampoos (used for seborrheic dermatitis) or 5% sulfur plus 10% sodium sulfacetamide in a cream, suspension or gel (used for rosacea, acne and seborrheic dermatitis; see Ch. 127).

Mechanism of action

Sulfur has antibacterial, antifungal and keratolytic properties.

Side effects

An offensive odor similar to that of rotten eggs (due to elaboration of H_2S) limits the use of sulfur in the absence of masking fragrances. Side effects are generally mild and include dryness and pruritus.

Contraindications

Topical sulfur is contraindicated in patients with a sensitivity to sulfur.

Use in pregnancy

Topical sulfur (5–10%) has been used to treat scabies in pregnant and lactating women, but precise safety data are lacking.

Azelaic Acid

Introduction and indications

Azelaic acid, a naturally occurring dicarboxylic acid, is used in the treatment of rosacea, acne vulgaris, melasma and postinflammatory hyperpigmentation.

Mechanism of action

Azelaic acid inhibits the production of free radical oxygen by neutrophils. This reduces oxidative tissue injury at sites of inflammation and decreases melanin production. Studies have also demonstrated selective cytotoxic and antiproliferative effects on hyperactive and abnormally proliferating melanocytes, with little effect on normal melanocytes. In addition, azelaic acid has antimicrobial activity against *Propionibacterium acnes* and *Staphylococcus epidermidis* as well as moderate anti-comedogenic properties via modification of epidermal keratinization.

Dosages

Azelaic acid, available in a 20% cream and 15% gel, is applied twice daily.

Side effects

Azelaic acid may cause mild to moderate irritant contact dermatitis (e.g. dryness, peeling, erythema), which often subsides after 2 to 4 weeks of treatment.

Use in pregnancy

Azelaic acid is pregnancy category B.

Diclofenac Sodium

Diclofenac sodium 3% in a gel vehicle containing hyaluronic acid is FDA-approved for the treatment of AKs. This nonsteroidal anti-inflammatory drug (NSAID) inhibits cyclooxygenase (COX)-2 and (to a lesser degree) COX-1. Its mechanism of action against AKs is thought to involve induction of apoptosis, alteration of cellular proliferation and inhibition of angiogenesis. Twice-daily application for 60 to 90 days results in AK clearance rates of up to 30–50%, with potential side effects including irritant, allergic and photoallergic contact dermatitis. Diclofenac is pregnancy category B.

Topical Immunotherapy

A sample protocol for topical immunotherapy with squaric acid dibutyl ester (SADBE) for cutaneous warts is outlined in Table 129.13, and a protocol for SADBE or diphencyprone for alopecia areata is presented in Table 69.6.

The Old and the New

Topical agents of historical interest are presented in Table 129.14. Many newer barrier-repair creams and moisturizers have purported benefit in the management of various dermatoses, such as atopic dermatitis and irritant contact dermatitis; these agents and their active ingredients are listed in Table 129.15.

INTRODUCTION

This chapter is designed to be a broad overview of a variety of systemic therapies for dermatologic diseases. It provides an historical perspective for each drug, a discussion of its mechanism of action and side effects, and then touches briefly on indications and clinical use. This information should serve as a starting point, allowing the reader to readily compare and contrast various treatment options. It is not a substitute for the in-depth knowledge and experience necessary to implement these systemic therapies, nor is it a complete library of systemic drugs used in dermatology. A number of systemic medications have been reviewed in other chapters (Table 130.1) and therefore will not be discussed here.

Systemic drugs used in dermatology may be subdivided into broad categories, such as immunosuppressive, cytotoxic and antiproliferative (Table 130.2). Drugs in a single category act in a relatively similar fashion and generally have similar important side effects. For example, immunosuppressive drugs suppress the body's ability to recognize or eliminate infections and neoplastic cells. Patients may be at increased risk for opportunistic infections and selected lymphoproliferative malignancies as well as squamous cell carcinomas. Given this increased risk for opportunistic infections, patients with either an active infection or one that may reactivate (such as tuberculosis) should be given these drugs with caution.

Among the drugs discussed are several older drugs which have been reformulated either into a prodrug that is more tolerable from a side-effect standpoint (e.g. mycophenolate mofetil) or into a more readily absorbed formulation such as Neoral® and Gengraf® (cyclosporine). Others represent older drugs that have found new uses in dermatology. Most lack Food and Drug Administration (FDA) approval for the diseases for which dermatologists use them. This is not an incrimination of the practice, but is rather due to a lack of pharmaceutical company enthusiasm for putting drugs through lengthy, expensive approval processes for diseases that are relatively uncommon. When choosing therapy for an individual patient, certain broad general principles always apply. First, the physician should be aware of all the common therapeutic modalities available and become very familiar with the drugs most frequently used and most likely to yield optimal results. Certain systemic medications will not be utilized frequently enough for a given clinician to become comfortable with their use; therefore, patients requiring more specialized drugs should be referred to colleagues more experienced with their use. Patients should be advised of all the reasonable therapeutic choices as well as the risk–benefit profile of each modality. Non-compliance is a relative contraindication for all of the medications discussed in this chapter.

Part of every initial prescription should be a complete history and physical examination, with specific emphasis on the organ systems that may be affected by the particular drug. Tuberculin skin testing and/or QuantiFERON-TB Gold test should be performed prior to using some of the immunosuppressive medications, specifically corticosteroids (particularly when a prolonged course is anticipated) and tumor necrosis factor (TNF) inhibitors (FDA-required). Consultation with appropriate generalists or specialists in selected situations may be required prior to initiating therapy as well as for periodic screening for complications of therapy. Table 130.3 outlines suggested monitoring guidelines for the systemic medications discussed in this chapter. These tests may need to be performed more frequently in high-risk patients or in patients with abnormal results. Additionally, each outpatient visit should include an appropriate review of systems and physical examination.

The use of each drug during pregnancy and lactation is reviewed. Wherever possible, this has been referenced with the eighth edition of *Drugs in Pregnancy and Lactation* by Briggs and colleagues. In general, one should be very circumspect in prescribing systemic medications to women of childbearing potential. It is not adequate to merely ask the patient if she is utilizing birth control before prescribing most of the medications discussed in this chapter; the patient must be made acutely aware of the risks associated with using the medication during pregnancy and the risks of continuing therapy if pregnancy does occur. The prescribing physician also needs to be aware that birth defects have sometimes been ascribed to systemic medications despite the lack of scientific evidence. Family planning consultation and communication with the patient's obstetrician or primary care physician can prove particularly helpful.

Several drugs discussed herein have parenteral formulations. Clinicians who administer parenteral medications in the office setting should be current in their Advanced Cardiac Life Support (ACLS) training and keep emergency resuscitation supplies readily available.

ANTIMALARIALS

Quinine and its derivatives have been used since the 1600s for the treatment of malaria. Quinine is derived from the bark of the cinchona tree in South America and was first used in dermatology by Payne in 1894 to treat discoid lesions in patients with lupus erythematosus (LE). The most common antimalarials are hydroxychloroquine (Plaquenil®), chloroquine (Aralen®) and quinacrine; the latter, which can lead to yellow discoloration of the skin, is only available in the US via compounding pharmacies and it will not be covered in detail here.

The antimalarials are absorbed extensively into tissues and slowly released, leading to a half-life of 40–50 days. A steady state is achieved slowly and it may take 3–4 months to see an adequate clinical effect. Hydroxychloroquine is catabolized into two metabolites, desethylhydroxychloroquine and desethylchloroquine. Chloroquine is metabolized only into the latter. The initial metabolites then undergo further

CATEGORIES OF SYSTEMIC DRUGS USED IN DERMATOLOGY BASED UPON MECHANISM OF ACTION			
Immunosuppressive/ Anti-inflammatory	**Cytotoxic**	**Antiproliferative**	**Miscellaneous**
Azathioprine Mycophenolate mofetil Cyclosporine Tacrolimus (FK506) Thalidomide	Cyclophosphamide Bleomycin	Methotrexate Hydroxyurea	Dapsone Antimalarials Saturated solution of potassium iodide (SSKI)

Table 130.2 Categories of systemic drugs used in dermatology based upon mechanism of action.

change into the primary amine form. Overall, 50% of each drug undergoes renal excretion[1].

Mechanism of Action

The mechanisms of action of the antimalarials are complex and incompletely understood. Known endpoints include the following: stabilization of lysosomes within injured cells; inhibition of antigen presentation, cell-mediated immunity and the synthesis of proinflammatory cytokines; and antithrombotic/antiplatelet effects[2]. The photoprotective effect attributed to the antimalarials may result from their anti-inflammatory properties[2].

Dosages

Most conditions will respond to dosages between 200 and 400 mg per day of hydroxychloroquine or 250 mg per day of chloroquine, with a maximum safe dose (from an ocular standpoint) being 6.5 mg/kg/day and 4.0 mg/kg/day, respectively. After a suitable therapeutic response has been achieved, the response may be maintained with hydroxychloroquine 100–200 mg daily. If available, quinacrine (100 mg/day) can be added to 200 mg twice daily of hydroxychloroquine, to maximize the clinical benefit without an increased risk of ocular toxicity. Lower doses of chloroquine (125 mg twice weekly) or hydroxychloroquine (100 mg three times weekly) must be used in patients with porphyria cutanea tarda, in order to minimize the risk of a toxic reaction (e.g. hepatotoxicity) in addition to a marked increase in urinary uroporphyrin output.

If no response is noted after 3–4 months, the specific antimalarial has failed and should be discontinued; however, a different antimalarial can be tried. In patients with porphyria cutanea tarda, the antimalarial can slowly be increased to daily dosing if necessary and if laboratory monitoring of transaminases allows.

Monitoring guidelines are outlined in Table 130.3. Because of the risk of dose-related ocular toxicity, a referral to an ophthalmologist is necessary for examination at baseline and then every 6 to 12 months[1].

Major Side Effects

Antimalarials are highly concentrated in the iris and choroid, reaching levels 480 000 times that of plasma[3]. Irreversible retinopathy may rarely occur and patients must be monitored by an ophthalmologist experienced with the ocular effects of antimalarials (see Table 130.4). Of note, the risk of retinopathy is much less with hydroxychloroquine as compared with chloroquine.

Up to one-third of patients who receive antimalarials for over 4 months will develop a blue–gray to black hyperpigmentation on their shins (Fig. 130.1), face, palate and/or nail beds. The discoloration fades after cessation of therapy, but may take months to resolve completely. Reversible bleaching of the hair roots (achromotrichia) occurs in up to 10% of patients, presumably due to interference with melanosomal function. Another 10–20% may develop an exanthem, ranging from urticaria to lichenoid reactions (Fig. 130.2) to exfoliative erythroderma. Of interest, morbilliform and urticarial exanthems have been observed with greater frequency in individuals with dermatomyositis as compared to in those with LE.

Antimalarials have been reported to worsen psoriasis in some patients, even though in the past they were commonly used to treat psoriatic arthritis. Psoriatic patients traveling to malaria-endemic areas may take these drugs prophylactically.

Laboratory abnormalities do not commonly occur, but it is the practice of the authors to monitor patients as outlined in Table 130.3. An overdose of antimalarials can be fatal, and although pediatric usage is safe and effective, patients should be warned to keep the drug out of the reach of small children.

Indications

The most common dermatologic use of antimalarials is as second-line therapy for cutaneous LE, after topical or intralesional corticosteroids. Antimalarials are especially useful in patients with widespread discoid lesions and in those with the annular or papulosquamous lesions of subacute cutaneous LE (SCLE). Antimalarial use has also been credited with fewer thromboembolic events in patients with systemic LE (SLE)[2]. In addition to the diseases listed in Table 130.5, other cutaneous disorders that may respond to antimalarial therapy include dermatomyositis and lichen planus[4].

Contraindications

The only true contraindication is hypersensitivity to the drug. Caution should be used in patients with severe blood dyscrasias or hepatic disorders, because hepatitis and bone marrow suppression can occasionally occur. Ophthalmologic changes of pre-maculopathy call for discontinuation of the drug. Ocular changes at this stage are potentially reversible, but could progress if the drug were continued.

Use in Pregnancy and Lactation

Chloroquine is thought to be safe for treatment and prophylaxis of malaria during pregnancy; however, there have been anecdotal reports of an increase in birth defects in pregnant women being treated for SLE. Hydroxychloroquine is thought to be safer during pregnancy, even with its much longer half-life.

Although excreted into breast milk, standard doses of either drug are not harmful to breastfed infants and are approved by the American Academy of Pediatrics for use during lactation[5].

Drug Interactions

Cimetidine may increase circulating levels of antimalarials, and antimalarials may increase digoxin levels. Kaolin and magnesium trisilicate, over-the-counter gastrointestinal drugs, decrease absorption of antimalarials. The most significant potential interaction is the additive

MONITORING GUIDELINES FOR SYSTEMIC MEDICATIONS			
Drug	**Initial screening**	**Follow-up monitoring**	**Special considerations**
Antimalarials	Ocular: Slit lamp and fundoscopic examination: assessment of visual acuity and visual field testing Laboratory: CBC CMP G6PD (selected cases)	Ocular: Repeat testing every 6 months for 1 year and then yearly Laboratory: CBC monthly for 3 months, then every 4–6 months CMP after 1 and 3 months, then every 4–6 months	G6PD testing before antimalarial therapy is controversial and is probably most important with the use of primaquine Urine or serum porphyrins should be measured when porphyria is clinically suspected Retinopathy risk is greatest for those on treatment for at least 5 years (especially with chloroquine) and if maximum daily safe dose has been exceeded
Azathioprine	CBC with PLT count CMP UA Consider pregnancy test for women of childbearing potential TPMT level, if available Tuberculin skin testing (should be considered depending on clinical situation)	CBC with PLT count every 2 weeks for 2 months, then every 2–3 months if stable AST/ALT every 2 weeks for 2 months, then every 2–3 months if stable	25% dose reduction is necessary if GFR 10–50 ml/min; 50% dose reduction if GFR <10 ml/min Frequency of laboratory studies is based on baseline TPMT determination (see Table 130.6); if TPMT is not known, hematologic parameters should be more closely monitored Discontinue therapy if WBC declines to <4000–4500 cells/mm^3 or if hemoglobin <10 g/dl Yearly skin examination and age-appropriate cancer screening, including yearly gynecologic examination in women
Cyclophosphamide	CBC with PLT count CMP UA Pregnancy test for women of childbearing potential	CBC with PLT count every week for 2–3 months, then every 2 weeks if stable. After 3–6 months, may decrease to every 3 months if stable UA every week for 2–3 months, then every 2 weeks if stable. After 3–6 months may decrease to every 3 months if stable CMP monthly for 3–6 months, then every 3 months if stable	Discontinue or lower dose if WBC declines to <4000–4500 cells/mm^3 or PLT count to <100 000 cells/mm^3 Stop treatment if red blood cells appear in urine; refer to urologist if hematuria persists Urine cytology after a cumulative dose of 50 g or after an episode of hemorrhagic cystitis; consider repeating yearly and/or after each 50 g Yearly physical examination and CBC as well as age-appropriate cancer screening
Cyclosporine	At least 2 baseline blood pressure readings At least 2 baseline serum creatinine levels CMP (must include BUN, magnesium, potassium and uric acid) CBC with PLT count UA with microscopic examination Fasting lipid profile (TG, cholesterol, HDL)	CBC with PLT count at 1 month, then every 2–4 months CMP (must include BUN, creatinine, uric acid, potassium, magnesium) every 2 weeks for 1–2 months, then monthly UA with microscopic examination every month if abnormal; otherwise yearly Fasting lipid panel every 2–4 weeks for 1–2 months, then monthly	Blood pressure must be monitored every 2 weeks for first 3 months and then monthly if stable Lower dose by 25–50% if serum creatinine remains elevated (over 2 weeks) by >25% of baseline Lower dose by 25–50%, or discontinue, if at any time serum creatinine is elevated by ≥50% of baseline Consider creatinine clearance if >6 months of therapy Skin examination at least yearly and age-appropriate cancer screening Consider trough whole drug cyclosporine level if non-compliance, poor absorption or drug interactions are suspected
Dapsone	CBC with PLT count CMP UA G6PD level	CBC with PLT count every week for 1 month, then every 2 weeks for 2 months, then every 3–4 months Reticulocyte count if anemia develops CMP every 3–4 months UA every 3–4 months	Each visit should include an assessment of peripheral motor function and an assessment for the signs and symptoms of methemoglobinemia and peripheral neuropathy (e.g. paresthesias, motor strength, reflexes) Methemoglobin level if clinically indicated Increase monitoring frequency when dose is increased

Table 130.3 Monitoring guidelines for systemic medications, as recommended by the authors (i.e. not necessarily standards of care). Before using any of these medications, the risk–benefit profiles and adverse effects should be thoroughly discussed with each patient. More frequent monitoring is needed in high-risk patients, when results are abnormal or when increasing doses. ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count with differential; CMP, comprehensive metabolic panel (includes liver function tests); G6PD, glucose-6-phosphate dehydrogenase; GFR, glomerular filtration rate; HDL, high-density lipoproteins; IM, intramuscular; PLT, platelet; TG, triglycerides; TPMT, thiopurine methyltransferase; TSH, thyroid-stimulating hormone; UA, urinalysis; WBC, white blood count.

Continued

MONITORING GUIDELINES FOR SYSTEMIC MEDICATIONS			
Drug	**Initial screening**	**Follow-up monitoring**	**Special considerations**
Hydroxyurea	CBC with PLT count CMP UA Pregnancy test for women of childbearing potential	CBC with PLT count weekly for at least 1 month until stable, then monthly CMP and UA monthly until stable, then every 3–6 months	A drop in hemoglobin of 1–2 g should be expected. Discontinue or decrease dose if the hemoglobin declines by more than 3 g or the WBC to <4000–4500 cells/mm^3 or the PLT count to <100 000/mm^3
Methotrexate	CBC with PLT count CMP Pregnancy test for women of childbearing potential Serologic tests for hepatitis A, B, C HIV testing if indicated	CBC with PLT and AST/ALT after initial 5–10 mg test dose CBC with PLT and AST/ALT every week for 2–4 weeks and after each dose escalation, then monthly for 2–4 months, and then every 3–4 months, if stable BUN and serum creatinine every 6–12 months	Per recent psoriasis treatment guidelines (2009)*, for patients without risk factors for hepatic fibrosis, liver biopsies may not be indicated or the frequency of liver biopsies may be markedly reduced (as compared to previous recommendations for liver biopsies baseline and then after every 1.5–2 g in low-risk patients). For high-risk patients, liver biopsies are done baseline and then after every 1 g, and in those with grade IIIA liver biopsy changes, every 6 months or as recommended by hepatologist Consider creatinine clearance, especially in elderly patients
Mycophenolate mofetil	CBC with PLT count CMP Pregnancy test for women of childbearing potential	CBC with PLT count every 2 weeks for 2–3 months, then monthly for first year CMP after 1 month and then every 3–4 months	Discontinue or decrease dose if WBC declines to <3500–4000 cells/mm^3
Saturated solution of potassium iodide (SSKI)	Thyroid function testing, including TSH, T_4 Pregnancy test for women of childbearing potential	TSH after 1 month of therapy	Consider antithyroglobulin and antimicrosomal antibodies in those with a history of thyroid disease
Tacrolimus	At least 2 baseline blood pressure readings At least 2 baseline serum creatinine levels CMP (must include BUN, magnesium, potassium and uric acid) CBC with PLT count UA with microscopic examination Fasting lipid profile (TG, cholesterol, HDL)	CBC with PLT count at 1 month, then every 2–4 months CMP (must include BUN, creatinine, uric acid, potassium, magnesium) every 2 weeks for 1–2 months, then monthly UA with microscopic examination every month if abnormal; otherwise yearly Fasting lipid panel every 2–4 weeks for 1–2 months, then monthly	The risk of diabetes mellitus post-transplant is higher with tacrolimus than with cyclosporine Blood pressure must be monitored every visit Lower dose or discontinue treatment if serum creatinine rises by >30% of baseline Consider creatinine clearance if >6 months of therapy Skin examination at least yearly and age-appropriate cancer screening Consider trough whole drug tacrolimus level if response is inadequate or if drug interactions are suspected
Thalidomide	CBC with PLT count CMP Pregnancy test in women of childbearing potential Subjective review of sensory and motor neurologic function and neurologic examination	Consider CBC with PLT count and AST/ALT every 2–3 months Pregnancy test every week for 4 weeks, then monthly for women of childbearing potential with regular menses, or every 2 weeks for those with irregular menses and as clinically indicated Neurologic examination monthly for 3 months, then every 1–6 months	Measurements of sensory nerve action potential amplitudes (SNAP), if indicated by history prior to therapy Consider SNAP measurements every 6 months, or as indicated

Table 130.3 Monitoring guidelines for systemic medications, as recommended by the authors (i.e. not necessarily standards of care) (cont'd). Before using any of these medications, the risk–benefit profiles and adverse effects should be thoroughly discussed with each patient. More frequent monitoring is needed in high-risk patients, when results are abnormal or when increasing doses. ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count with differential; CMP, comprehensive metabolic panel (includes liver function tests); G6PD, glucose-6-phosphate dehydrogenase; GFR, glomerular filtration rate; HDL, high-density lipoproteins; IM, intramuscular; PLT, platelet; TG, triglycerides; TPMT, thiopurine methyltransferase; TSH, thyroid-stimulating hormone; UA, urinalysis; WBC, white blood count.

SIDE EFFECTS OF SYSTEMIC DRUGS USED IN DERMATOLOGY			
Drug	**Common**	**Uncommon**	**Rare**
Antimalarials	***Derm***: blue–gray to black discoloration; yellowing from quinacrine	***Derm***: bleaching of hair roots, exanthem (e.g. urticarial, lichenoid) ***GI***: nausea, vomiting, elevated liver enzymes ***Neuro***: irritability, nervousness	***Heme***: pancytopenia, hemolysis (G6PD-deficient, primarily with non-dermatologic antimalarials) ***Ophtho***: reversible (early) and irreversible retinopathy, vision changes
Azathioprine	***Derm***: non-melanoma skin cancers ***Heme***: leukopenia, thrombocytopenia, immunosuppression	***GI***: nausea, vomiting ***ID***: opportunistic infections	***Heme***: pancytopenia ***GI***: pancreatitis, hepatitis ***Malignancy***: lymphoma, cutaneous and gynecologic SCC Hypersensitivity syndrome
Cyclophosphamide	***GI***: nausea, vomiting ***GU***: sterility (higher doses or long-term administration) ***Heme***: leukopenia	***Derm***: diffuse hyperpigmentation, alopecia ***GU***: dysuria, hemorrhagic cystitis, amenorrhea, azoospermia, sterility (with lower doses) ***Heme***: anemia, thrombocytopenia ***ID***: opportunistic infections	***GI***: hemorrhagic colitis, hepatotoxicity ***Heme***: aplastic anemia ***Malignancy***: bladder (esp. chronic oral), lymphoma, acute leukemia ***Pulmonary***: pneumonitis, interstitial fibrosis Anaphylaxis
Cyclosporine	***Cardiac***: hypertension ***Derm***: non-melanoma skin cancers (NMSC) ***GU***: renal dysfunction* ***Metabolic***: hyperlipidemia ***Neuro***: headache, tremor	***Derm***: hypertrichosis, gingival hyperplasia, sebaceous hyperplasia ***GI***: nausea, diarrhea ***Neuro***: paresthesia, hyperesthesia ***Metabolic***: hyperkalemia†, hypomagnesemia, hyperuricemia	***Derm***: trichodysplasia spinulosa ***ID***: infections (unless combined with other immunosuppressives) ***Musculoskeletal***: myalgias, myositis ***GI***: hepatotoxicity ***Malignancy***: lymphoma ***Pulmonary***: dyspnea, bronchospasm
Dapsone	***Heme***: hemolysis, methemoglobinemia	***GI***: dyspepsia, anorexia	***Heme***: agranulocytosis ***Neuro***: peripheral neuropathy Sulfone syndrome
Hydroxyurea	***Heme***: anemia, megaloblastic changes	***Derm***: leg ulcers, alopecia ***Heme***: leukopenia	***Derm***: hyperpigmentation, dermatomyositis-like lesions, NMSC ***GI***: hepatitis ***GU***: renal dysfunction ***Heme***: thrombocytopenia ***Malignancies***: acute leukemia
Methotrexate	***Heme***: leukopenia	***Derm***: photosensitivity, alopecia, oral ulcers ***GI***: elevated liver enzymes, nausea, vomiting, anorexia, cirrhosis ***Heme***: thrombocytopenia	***Derm***: necrosis of psoriatic plaques, accelerated rheumatoid (cutaneous) nodulosis ***Heme***: pancytopenia, lymphoproliferative disorder (primarily in patients with RA) ***ID***: infections ***Pulmonary***: pneumonitis, fibrosis
Mycophenolate mofetil	***GI***: diarrhea, cramps, nausea, vomiting	***Heme***: anemia, leukopenia, thrombocytopenia ***ID***: opportunistic infections	***GU***: dysuria, sterile pyuria ***Neuro***: insomnia, dizziness, tinnitus
Saturated solution of potassium iodide (SSKI)	***Derm***: acneiform eruption ***GI***: nausea, vomiting, diarrhea, abdominal pain ***Metabolic***: reversible hypothyroidism	***Derm***: iododerma ***Metabolic***: hyperkalemia	***Cardiac***: CHF, pulmonary edema ***Derm***: flare of dermatitis herpetiformis ***GI***: salivary gland enlargement ***Metabolic***: hyperthyroidism, goiter, "iodism" (see text) Hypersensitivity reactions (see Ch. 100)
Tacrolimus	***Cardiac***: hypertension ***Derm***: non-melanoma skin cancers ***GU***: renal dysfunction* ***Neuro***: paresthesias	***ID***: infections ***Metabolic***: hyperkalemia†, hypomagnesemia	***Metabolic***: diabetes mellitus, hyperuricemia ***Malignancy***: lymphoma
Thalidomide	***Derm***: xerosis, pruritus ***GI***: constipation ***Neuro***: peripheral neuropathy, sedation ***Ob/Gyn***: fetal abnormalities, amenorrhea	***Cardiac***: peripheral edema ***GI***: xerostomia, increased appetite ***Gyn***: primary ovarian failure ***Heme***: thromboses ***Psych***: headache, mood changes	***Derm***: exfoliative erythroderma, TEN ***Heme***: leukopenia Hypersensitivity reaction (in HIV+)

*Not permanent during short-term treatment if guidelines are followed.
†Especially when used in conjunction with ACE inhibitors.

Table 130.4 Side effects of systemic drugs used in dermatology. CHF, congestive heart failure; Derm, dermatologic; G6PD, glucose-6-phosphate dehydrogenase; GI, gastrointestinal; GU, genitourinary; Gyn, gynecologic; Heme, hematologic; ID, infectious diseases; Neuro, neurologic; Ob/Gyn, obstetrical/gynecologic; Ophtho, ophthalmologic; Psych, psychiatric; RA, rheumatoid arthritis; SCC, squamous cell carcinoma; TEN, toxic epidermal necrolysis.

risk of retinal toxicity when chloroquine and hydroxychloroquine are used concomitantly. Combined therapy consisting of chloroquine or hydroxychloroquine plus quinacrine is acceptable.

In patients with LE, cigarette smoking has been associated with decreased efficacy of antimalarials. Whether this represents a "drug–drug" interaction or decreased compliance (as a manifestation of high-risk behavior) is not known.

AZATHIOPRINE

Azathioprine was developed in 1959 from its parent drug 6-mercaptopurine (6-MP). After its anti-inflammatory and immunosuppressive effects were noted, dermatologists began to utilize azathioprine for the treatment of inflammatory diseases. With its moderately potent immunosuppressive and anti-inflammatory effects,

azathioprine has a reasonable risk–benefit profile. However, it should be reserved for more serious, life-threatening or recalcitrant dermatoses after other therapies have failed.

Azathioprine (Imuran®, Azasan®, Azamun™) has an 88% bioavailability. Immediately after absorption, it is converted to 6-MP and subsequently processed through three different and competing pathways (Fig. 130.3). When 6-MP is catabolized via two of these metabolic pathways, by either xanthine oxidase or thiopurine methyltransferase (TPMT), inactive metabolites result. Active metabolites, such as the purine analogue thioguanine monophosphate and others, are produced from the third and only anabolic pathway via hypoxanthine-guanine phosphoribosyl transferase (HGPRT)[6]. Should either the xanthine oxidase or TPMT catabolic pathway be blocked, more 6-MP will be shunted through the anabolic HGPRT pathway, leading to more active metabolites; excessive immunosuppression and pancytopenia may result[6].

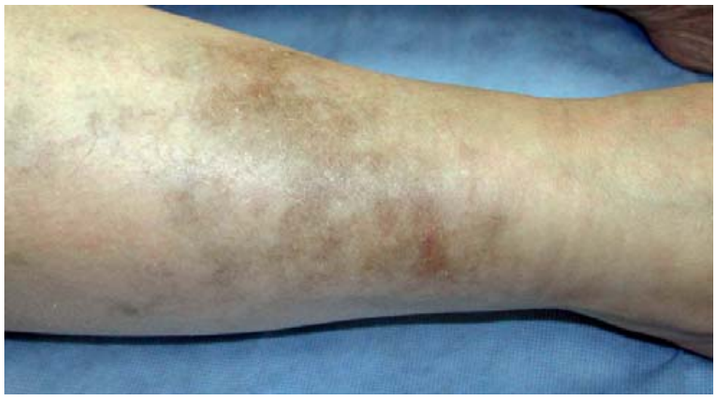

Fig. 130.1 Areas of blue–gray discoloration due to chloroquine.

Fig. 130.2 Generalized lichenoid drug eruption due to hydroxychloroquine. There is significant postinflammatory hyperpigmentation.

The TPMT pathway is interesting because the enzyme can have variable activity based upon genetic polymorphisms. Three distinct phenotypes exist and ethnicity may be a factor in the frequency of certain alleles. Encoded at the 6p22.3 locus, the TPMT activity trait is inherited in an autosomal co-dominant manner. Overall, 89% of Caucasians are homozygous for the high-activity allele and have relatively elevated levels, 11% are heterozygotes and have moderate activity, and 1/300 is homozygous for one of the seven low-activity alleles and has low TPMT activity. Red blood cell (RBC) TPMT activity mirrors systemic activity and a test for RBC TPMT activity has been developed. Although TPMT activity may vary somewhat between different laboratories and within different batches of the same test kit, knowledge of the baseline TPMT activity is clinically useful in the majority of patients who will receive azathioprine. However, vigilance in monitoring for pancytopenia will also identify those with low TMPT activity who will require dose reduction. Likewise, patients with high TMPT activity may need higher doses.

Decreased xanthine oxidase activity is rarely genetic in nature, but this enzyme is inhibited by allopurinol (see Fig. 130.3). Azathioprine dosage should be decreased by 75% in patients receiving allopurinol.

Mechanism of Action

6–Thioguanine, the active metabolite of azathioprine, is a purine analogue similar in structure to both adenine and guanine. Instead of an amino or hydroxyl group, it contains a thiol moiety. Incorporation of 6-thioguanine into DNA and RNA inhibits purine metabolism and cell division. 6–Thioguanine has other activities which are not well understood, such as suppression of T-cell function and B-cell antibody production[7]. It also decreases the number of Langerhans cells in the skin and inhibits their ability to present antigens[8].

Dosages

Available in 25, 50, 75 and 100 mg tablets, *empiric* dosing is generally started at 50 mg/day and increased to a maximum of 2.5 mg/kg/day according to clinical efficacy and careful monitoring. Maximum doses based on baseline TPMT determination are outlined in Table 130.6. In either case, doses must be reduced in the setting of renal insufficiency (see Table 130.3). Baseline evaluation should include a complete

CUTANEOUS DISORDERS THAT CAN BE TREATED WITH SPECIFIC SYSTEMIC DRUGS

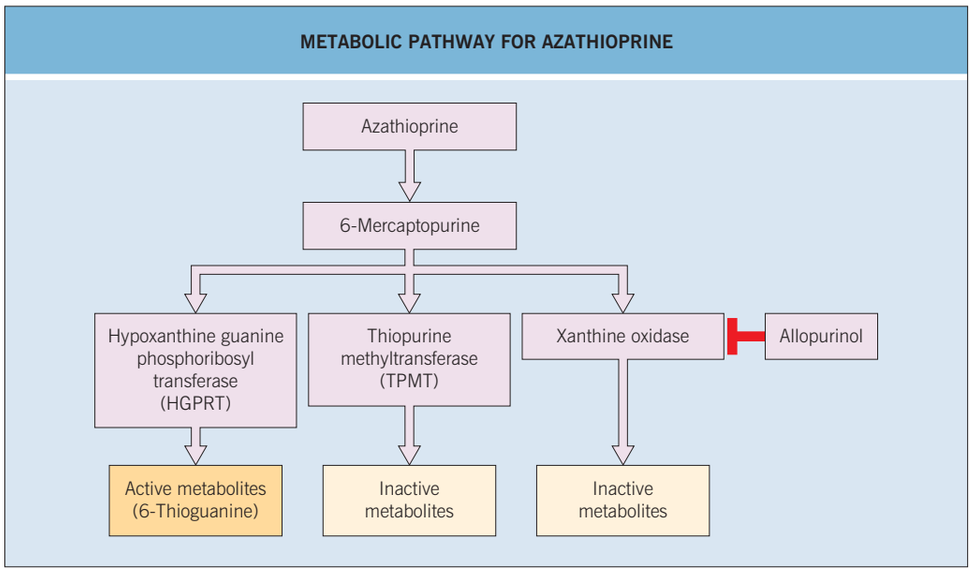

Fig. 130.3 Metabolic pathway for azathioprine. Either decreased activity of TPMT or inhibition of xanthine oxidase by allopurinol can lead to shunting of 6-mercaptopurine to the HGPRT pathway. As a result of this shunting, there is an increase in active metabolites and an increased risk of toxicity. Febuxostat also inhibits xanthine oxidase. *Adapted from Wolverton SE. Comprehensive Dermatologic Drug Therapy, 2nd edn. Philadelphia: Saunders, 2007.*

MAXIMUM DOSE OF AZATHIOPRINE AS DETERMINED BY BASELINE TPMT ACTIVITY

TPMT level	Maximum dose of AZA
<5 U	AZA contraindicated
5–13.7 U	Up to 0.5 mg/kg/day
13.7–19 U	Up to 1.5 mg/kg/day
>19 U	Up to 2.5 mg/kg/day

Table 130.6 Maximum dose of azathioprine as determined by baseline TPMT activity. AZA, azathioprine; TPMT, thiopurine methyltransferase; U, units.

medication history because of adverse effects when azathioprine is used concomitantly with allopurinol, febuxostat, captopril or warfarin (see below). Monitoring guidelines are outlined in Table 130.3.

Major Side Effects

Major side effects are related to the immunosuppressive effects of azathioprine (see Table 130.4). Pancytopenia occurs rarely, particularly when doses are based on TPMT activity. Patients may be at increased risk for malignancies, especially lymphoproliferative disorders and squamous cell carcinomas of the skin and female genitourinary tract, and patients should be monitored accordingly. Factors influencing a patient's malignancy risk include degree and duration of immunosuppression, ethnicity, and existing comorbidities.

Azathioprine may rarely cause a life-threatening hypersensitivity reaction, which most commonly develops during the first month of therapy and when the drug is used in combination with cyclosporine or methotrexate. The cutaneous eruption is typically morbilliform with areas of confluence (Fig. 130.4). Other components of the syndrome include fever, respiratory and gastrointestinal distress, hepatotoxicity and the possibility of cardiovascular collapse.

Indications

Although azathioprine has FDA approval for non-dermatologic uses only, dermatologists have been using this drug for over 35 years to treat severe dermatologic conditions, most often as a corticosteroid-sparing agent in the treatment of immunobullous diseases and various subtypes of cutaneous vasculitis (Table 130.5)[7,9]. It is inexpensive and has moderate immunosuppressive and anti-inflammatory effects. Clinical benefit of the drug may not be apparent until it has been administered for at least 4 to 6 weeks.

Fig. 130.4 Azathioprine hypersensitivity reaction. Pink to red macules, papules and areas of confluence are seen. *Courtesy, Kalman Watsky, MD.*

Contraindications

Absolute contraindications to azathioprine therapy include the history of a hypersensitivity reaction, as re-challenge may prove fatal. Active serious infection and pregnancy are relative contraindications. Concomitant use of allopurinol or febuxostat requires dose reduction of azathioprine (see above).

Use in Pregnancy and Lactation

Azathioprine is pregnancy prescribing category D. Even though it is considered relatively safe for use in transplant patients who become pregnant, for dermatologic purposes it should not be prescribed during pregnancy[5]. No information is available regarding the risk to breastfed infants.

Drug Interactions

Allopurinol or febuxostat inhibition of xanthine oxidase (see Fig. 130.3) increases the risk of pancytopenia in azathioprine-treated patients. Captopril may increase the risk of leukopenia. Azathioprine can decrease the effectiveness of warfarin and pancuronium, necessitating larger doses of these drugs. Since azathioprine may decrease the effectiveness of intrauterine contraceptive devices, alternative birth control methods should be employed.

BLEOMYCIN

The dosage, uses and side effects are outlined in Table 130.7.

CLOFAZIMINE

The dosage, uses and side effects are outlined in Table 130.8.

COLCHICINE

The dosage, uses and side effects are outlined in Table 130.9.

CYCLOPHOSPHAMIDE

Cyclophosphamide (Cytoxan®) was derived from nitrogen mustard in 1958; the latter was combined with phosphoric acid in an effort to make an inert drug capable of entering and releasing active nitrogen mustard within target cells[10]. It has approximately 75% oral bioavailability, peaks in the plasma at about 1 hour, and crosses the blood–brain barrier. Cyclophosphamide itself is inactive, but it is metabolized by cytochrome P450 (CYP) enzymes into the active metabolite 4-hydroxycyclophosphamide (nornitrogen mustard, $t_{1/2}$ 3.3 hours), which may then be converted into the other active metabolite phosphoramide mustard ($t_{1/2}$ 9 hours). Metabolites are excreted primarily via the kidney (50%). The inactive metabolite acrolein is believed to cause hemorrhagic cystitis and associated transitional cell carcinoma of the bladder[11].

BLEOMYCIN
Source: *Streptomyces verticillus* **Mechanism of action**: inhibits DNA synthesis in infected keratinocytes, but no direct effect on the human papillomavirus **Dermatologic use**: intralesional treatment of therapy-resistant verrucae vulgaris; 65–80% of lesions clear after 1 to 2 injections **Dosage**: 0.1 to 0.3 ml of 1 U/ml (of saline) injected into targeted lesions, with maximum total dose per treatment = 2 ml; repeated every 3 to 6 weeks until resolution; given its rapid degradation and expense, newly constituted solution should be divided into glass vials and stored at 20°C **Side effects**: injection is extremely painful (local or regional anesthesia may be required); pain and burning postinjection for 2–3 days; Raynaud's phenomenon occasionally; nail dystrophy; no systemic toxicity with recommended total dose **Contraindications**: pregnancy, immunosuppression, vascular compromise **Pregnancy and lactation**: not recommended; pregnancy prescribing category D

Table 130.7 Bleomycin.

CLOFAZIMINE
Drug properties: riminophenazine dye (red color) **Mechanism of action**: disrupts cell membranes (activation of phospholipase A_2 leads to generation of membrane-destabilizing lysophospholipids); enhances superoxide production; inhibits neutrophil motility and lymphocyte proliferation **Dermatologic use**: treatment of multibacillary leprosy, other infections (mycobacterial, malacoplakia, rhinoscleroma) and inflammatory skin diseases including neutrophilic dermatoses (pyoderma gangrenosum, Sweet's syndrome), granuloma faciale, orofacial granulomatosis, erythema dyschromicum perstans and discoid LE **Dosage**: 50–400 mg orally daily*; avoid long-term administration of >200 mg daily; see Table 75.4 for leprosy regimens **Side effects**: discoloration of skin† (red to red–brown diffusely, bluish to violet–brown in lesional sites), cornea/conjunctiva and body fluids (urine, sweat, tears); xerosis/ichthyosis; gastrointestinal symptoms (abdominal pain, nausea, vomiting, diarrhea); ocular irritation; elevated hepatic enzymes; crystal deposition-related enteropathy (rarely); cardiac arrhythmias (rarely; associated with electrolyte disturbances) **Contraindications**: prior hypersensitivity reaction **Pregnancy and lactation**: for dermatologic disorders, should be avoided during pregnancy (category C) and lactation (concentrated in breast milk)
*Larger doses are usually divided into two to four times daily. †Due to deposits of drug within fat and macrophages.

Table 130.8 Clofazimine. LE, lupus erythematosus.

Mechanism of Action

Cyclophosphamide is an alkylating agent that functions in a cell cycle-independent fashion. Although its major effect is suppression of B-cell function, it also suppresses that of T cells (especially regulatory T cells). Clearly, the T-cell effects are greatest if the drug is given prior to antigen presentation. Cyclophosphamide crosses the nuclear membrane, covalently binds with DNA, and inhibits the synthesis of guanine, cytosine and adenine. Cytotoxicity occurs by several mechanisms: (1) DNA cross-linking with various proteins or other DNA strands; (2) G-C → A-T substitution; and (3) depurination resulting in chain scission. These mechanisms can overwhelm the DNA repair mechanisms, inducing cell death[10].

Dosages

Cyclophosphamide is available in 25 and 50 mg tablets. Doses range from 1 to 3 mg/kg/day, either as a single morning dose or in equally divided doses. Dermatologic diseases seldom require more than 2 to 2.5 mg/kg/day of cyclophosphamide. Dose reduction is necessary in patients with hepatic or renal dysfunction. Because of the risk of hemorrhagic cystitis, patients should be advised to consume plenty of fluids on a daily basis. A monthly intravenous infusion (pulse) of 500 to 1000 mg has been used to treat a number of rheumatologic disorders, including severe SLE.

Prior to prescribing cyclophosphamide, patients should have documentation of a white blood count (WBC) of >4500/mm^3 and a granulocyte count of >1500/mm^3. Laboratory monitoring guidelines are outlined in Table 130.3. Of note, it is not necessary to induce significant myelosuppression in order to achieve immunosuppression[11].

Major Side Effects

The most common side effects from cyclophosphamide treatment are hematologic and gastrointestinal (see Table 130.4). Dermatologic side effects include anagen effluvium (5–30%, which is typically reversible), pigmented bands of the teeth (irreversible), diffuse hyperpigmentation, transverse ridging of nails, acral erythema, and, rarely, Stevens–Johnson syndrome. Up to 40% of patients have hemorrhagic cystitis, presumably from the acrolein metabolite, which is associated with a 10-fold increase in the risk for transitional cell carcinoma of the bladder. This risk is greater in patients who receive chronic "low-dose" cyclophosphamide (as given for dermatologic diseases) than in those exposed to brief courses of high-dose pulse therapy (as given for systemic lymphomas and SLE). Immunosuppression is significant, especially in patients concomitantly receiving systemic corticosteroid therapy. Infection and malignancy risks are real, and appropriate monitoring is suggested.

COLCHICINE
Source: alkaloid from *Colchicum autumnale* (autumn crocus) **Mechanism of action**: prevents microtubule assembly, resulting in mitotic arrest at metaphase and inhibiting cellular motility; decreases neutrophil chemotaxis, adhesion and degranulation **Dermatologic use**: treatment of neutrophilic dermatoses (Behçet's disease, Sweet's syndrome), small vessel vasculitis, neutrophil-rich autoimmune bullous diseases (EBA, linear IgA bullous dermatosis) and aphthous stomatitis **Dosage**: 0.5 or 0.6 mg orally two to three times daily; drug must be shielded from light (degraded by UVR) **Side effects**: commonly, gastrointestinal symptoms (diarrhea, abdominal pain, nausea, vomiting; dose-related); occasionally, alopecia, peripheral neuropathy, myopathy and bone marrow suppression (with prolonged therapy*); multiorgan failure with acute overdose† **Contraindications**: prior hypersensitivity reaction; severe renal, hepatic, gastrointestinal or cardiac disease; blood dyscrasias **Pregnancy and lactation**: for dermatologic disorders, should be avoided during pregnancy (category C); excreted in breast milk, but use during lactation allowed per AAP recommendations
*Particularly in patients with renal insufficiency. †A toxic epidermal necrolysis-like reaction has been described.

Table 130.9 Colchicine. In patients with renal or hepatic impairment on colchicine, P-glycoprotein and strong CYP3A4 inhibitors should be avoided. AAP, American Academy of Pediatrics; EBA, epidermolysis bullosa acquisita; UVR, ultraviolet radiation.

Long-term or high-dose therapy may be associated with infertility in either sex[7].

Indications

Although cyclophosphamide is only FDA-approved for use in advanced mycosis fungoides and hematopoietic malignancies, it can be extremely useful in treating a number of severe cutaneous diseases. Cyclophosphamide is a major component of treatment regimens for systemic vasculitides, especially Wegener's granulomatosis and Churg–Strauss syndrome[11]. It can also be used as a steroid-sparing agent in a variety of cutaneous diseases or as monotherapy after corticosteroids are discontinued.

Contraindications

Absolute contraindications are pregnancy, lactation, depressed bone marrow function, and hypersensitivity to the drug. Cyclophosphamide-allergic patients may have cross-reactions with chlorambucil or mechlorethamine (nitrogen mustard). Relative contraindications include active infections and significantly impaired hepatic or renal function.

Use in Pregnancy and Lactation

Cyclophosphamide is a first-trimester teratogen and is immunosuppressive in breastfed infants. It is pregnancy prescribing category D and should not be used during pregnancy or lactation[5].

Drug Interactions

Allopurinol, cimetidine and chloramphenicol may elevate cyclophosphamide drug levels and produce toxicity (via CYP450 interactions), whereas barbiturates may enhance conversion to inactive metabolites. Digoxin absorption may be decreased. Cyclophosphamide may enhance the effect of succinylcholine, increase the cardiotoxicity of doxorubicin, and cause additive immunosuppressive and carcinogenic effects with other immunosuppressive drugs. Unpredictable effects can be seen when used with the inhalation anesthetics halothane and nitrous oxide.

CYCLOSPORINE

Cyclosporine, a cyclic peptide of 11 amino acids, was isolated from the soil fungus *Tolypocladium inflatum* in 1970 and was found to have clinical immunosuppressive effects in 1976. In 1979, during a rheumatoid arthritis trial, it was discovered that cyclosporine improved cutaneous psoriasis in patients with psoriatic arthritis. Two forms are available, the original preparation (Sandimmune®) and a predigested microemulsion (Neoral®) that is more completely and consistently absorbed. The latter is available as capsules (25 mg, 100 mg) or as an oral solution (100 mg/ml)[1,2]. The solution can be mixed in orange juice or apple juice, but grapefruit juice should be avoided because it alters cyclosporine's metabolism (see Ch. 131).

Bioavailability of the microemulsion is not known, but it yields 40–106% higher peak blood levels than the original formulation. Cyclosporine is metabolized by the CYP3A4 pathway, and primary excretion is via bile and feces. Only 6% of cyclosporine is excreted unchanged in the urine. Monitoring blood levels of cyclosporine is not routinely necessary since levels correlate poorly with efficacy or toxicity; determination of drug levels (11-hour trough) is primarily of value when drug–drug interactions or non-compliance are a concern.

Mechanism of Action

T-cell receptor activation causes release of intracellular calcium that in turn binds to calmodulin and activates calcineurin (see Ch. 128). This calcineurin complex dephosphorylates the nuclear factor of activated T cells ($NFAT_c$) which is present within the cytoplasm, allowing it to migrate into the nucleus and bind with its intranuclear counterpart $NFAT_n$. This complex is a transcription factor for inflammatory cytokines such as interleukin (IL)-2. IL-2 receptors are also upregulated as a result of this process.

Cyclosporine binds to cyclophilin, a member of the family of intracytoplasmic proteins called immunophilins. This complex blocks the dephosphorylation of $NFAT_c$ and the subsequent upregulation of IL-2 and IL-2 receptors, resulting in a decrease in the number of $CD4^+$ and $CD8^+$ (cytotoxic) T cells in the epidermis[7,12].

Dosages

Cyclosporine is best used on a short-term basis (<6–12 months) to control flares of psoriasis and to provide an alternative to the patient's current regimen (see Ch. 8). However, safety has been documented in psoriasis patients receiving therapy for up to 2 years[13]. It is reasonable to use cyclosporine as sequential therapy with acitretin, methotrexate, or other systemic therapies such as TNF-α inhibitors. After psoriasis clearance has been initiated by cyclosporine, the alternative medicine may be started and advanced to the therapeutic dose. At the same time, cyclosporine may be weaned by 1 mg/kg/day each month until the patient is receiving acitretin or methotrexate alone. Historically, the maximum dermatologic dose for cyclosporine is 5 mg/kg/day, although a maximum dose of 4 mg/kg/day of the microemulsion formulation should be considered, given the greater bioavailability of this formulation. The dose for obese patients is based on ideal body weight.

For psoriasis patients with a severe flare or recalcitrant disease, cyclosporine may be initiated at the maximum dosage until significant disease resolution occurs. The dose is then tapered by 1 mg/kg/day every 2 weeks until the minimum effective maintenance dose is determined. For most patients with more moderate disease, therapy should be initiated at 2.5 mg/kg/day and increased by 0.5 to 1 mg/kg/day every other week until clinical improvement is seen or the maximum dose of 4–5 mg/kg/day (depending upon the formulation) is reached. If no improvement is observed after 3 months at the maximum dose, therapy has failed and should be discontinued[14].

Patients must be adequately monitored for the development of hypertension and laboratory abnormalities as outlined in Table 130.3. If the serum creatinine rises by >25% over baseline, the value should be rechecked within 2 weeks. If it returns to <25% over baseline, therapy can be continued at the current dose. However, if the elevation persists at that level, the dose should be decreased by 25–50% for 1 month and then the serum creatinine rechecked. If it is still >25% above baseline, therapy should be discontinued until the serum creatinine is within 10% of the baseline value. At that time, restarting therapy may be considered, but at a lower dose.

Major Side Effects

Cyclosporine is associated with a wide variety of adverse effects, including hypertension, renal dysfunction, hyperlipidemia, hyperkalemia, hypertrichosis and gingival hyperplasia (see Table 130.4). Most of the side effects associated with short-term therapy are reversible upon discontinuation of the drug. A quarter of all psoriasis patients on cyclosporine will develop hypertension, which is usually mild and manageable. A direct vasoconstrictive effect of cyclosporine on the kidney vasculature is responsible for the development of hypertension short-term[15]. Hypertension due to cyclosporine is both time- and dose-related.

Modern, conservative dosing guidelines have prevented significant kidney damage in the vast majority of patients on short-term therapy. However, renal interstitial fibrosis has been demonstrated histologically even in the absence of abnormal laboratory tests in patients on appropriate dosing and monitoring regimens. Renal biopsy specimens from patients on long-term treatment demonstrate irreversible changes including renal tubular atrophy, arteriolar hyalinosis, glomerular obsolescence and interstitial fibrosis[16,17]. In fact, all patients on cyclosporine for >2 years were shown to have some of these abnormalities.

Although transplant recipients on high doses and prolonged courses of cyclosporine have an increased risk of certain malignancies (e.g. cutaneous squamous cell carcinoma and lymphomas), patients with skin diseases on cyclosporine for less than 2 years and on lower "dermatologic" doses have not been observed to have a similar risk.

Indications

Cyclosporine can be beneficial for patients with psoriasis who have failed or cannot tolerate other therapies and for those with widespread, inflammatory disease (see Ch. 8). In fact, cyclosporine has FDA approval for three "types" of psoriasis: (1) severe; (2) recalcitrant; and (3) disabling. Patients with plaque-type psoriasis may also benefit from cyclosporine in rotating or sequential regimens with other modalities.

The use of cyclosporine in atopic dermatitis has been examined and a high percentage of patients improve with therapy; unfortunately, most relapse within 4 weeks of its discontinuation. Cyclosporine efficacy has been established in patients with severe pyoderma gangrenosum; however, some clinicians prefer cyclosporine for idiopathic pyoderma gangrenosum only, arguing that when there is a known underlying cause, therapy is best aimed at the latter (e.g. inflammatory bowel disease, myelodysplasia). Most other uses of cyclosporine are based upon anecdotal evidence[18].

Contraindications

Absolute contraindications include significant renal impairment, uncontrolled hypertension, and hypersensitivity to cyclosporine. Relative contraindications include age <18 years or >64 years, controlled hypertension, and medication usage that may interfere with cyclosporine metabolism or worsen renal function. Significant caution is necessary if used in patients with significant infections, recent live-virus vaccinations (see Table 128.9), or immunodeficiency syndromes, or in combination with methotrexate, phototherapy or other immunosuppressive drugs.

Use in Pregnancy and Lactation

Cyclosporine is not teratogenic, and it is classified as a pregnancy prescribing category C drug. Use during pregnancy should be considered only in exceptional patients for whom the potential benefits of cyclosporine therapy dramatically outweigh the risks. Cyclosporine is excreted into breast milk and should not be used during lactation, due to risks of immunosuppression and possible carcinogenesis in the breastfed infant[5].

Drug Interactions

Drugs that interact with cyclosporine are discussed in Chapter 131. The clinician should review the patient's medication list for potential interactions using the following guidelines. In general, drugs that inhibit the CYP3A4 pathway will increase cyclosporine levels, while inducers of the 3A4 pathway will decrease the effectiveness of cyclosporine, due to lower serum levels. Some drugs will potentiate renal toxicity, such as nonsteroidal anti-inflammatory drugs (NSAIDs), aminoglycosides, amphotericin B and miscellaneous antibiotics (vancomycin, trimethoprim–sulfamethoxazole). Cyclosporine will reduce the renal clearance of digoxin, lovastatin and prednisolone. Increased risk of hyperkalemia occurs with concurrent use of angiotensin-converting enzyme (ACE) inhibitors, potassium supplements and potassium-sparing diuretics.

DAPSONE

Dapsone is a sulfone drug, and sulfones are related to the sulfonamide family (see Ch. 21). Sulfonamides were initially derived from coal tar in the early 1900s for use as fabric dyes. Medically, they were first demonstrated to be effective against streptococcal infections. Synthesized in 1908, dapsone was shown to be effective against tuberculosis and leprosy. During the first half of the twentieth century, the related drugs sulfapyridine and sulfoxone were used to treat dermatitis herpetiformis (DH). However, since 1953, dapsone (the parent compound of sulfoxone) has been the mainstay of treatment for DH. Due to its activity in neutrophil-mediated dermatoses, dapsone has also proven useful in the treatment of several forms of autoimmune bullous diseases and vasculitis syndromes.

Dapsone is 80% orally bioavailable, peaks in the serum between 2 and 6 hours post-administration, and has a half-life of 24–30 hours. Being highly lipophilic, it has excellent cell penetration. Dapsone and its major metabolite monoacetyldapsone are strongly protein-bound and undergo enterohepatic recirculation. Thus, dapsone may be found in the bloodstream up to 1 month following a single dose[19].

Dapsone is metabolized by *N*-acetylation and *N*-hydroxylation in the liver[19,20]. Acetylation yields monoacetyldapsone, which is then de-acetylated to dapsone, yielding an equilibrium between dapsone and monoacetyldapsone. Hydroxylation via CYP enzymes produces *N*-hydroxy-dapsone, the metabolite which is believed to be responsible for the majority of dapsone side effects. Both dapsone and *N*-hydroxy-dapsone undergo glucuronidation in the liver, which results in more water-soluble compounds that are rapidly excreted in the urine[19].

Mechanism of Action

Dapsone is clinically most useful in the treatment of dermatologic diseases involving neutrophilic infiltrates. Researchers have demonstrated that dapsone inhibits neutrophil myeloperoxidase, thus reducing damage from the neutrophil respiratory burst mediated by this enzyme. Furthermore, dapsone has been shown to inhibit neutrophil chemotaxis to *N*-formyl-methionyl-leucyl-phenylalanine and to interfere with the CD11b/CD18-mediated neutrophil binding that induces chemoattractant signal transduction. IgA adherence is also inhibited. It is of clinical interest that dapsone also inhibits eosinophil myeloperoxidase activity, and thus may be efficacious in diseases in which eosinophils have a central role in pathogenesis, such as eosinophilic cellulitis[20].

Dosages

Dapsone is available in 25 mg and 100 mg tablets. The initial dose is often 50 mg/day in a single dose. Most conditions require 50–200 mg/day for adequate control of symptoms; rarely are dosages up to 300 mg/day required. In those with DH who respond to dapsone, rapid resolution of symptoms (within 48 hours) is usually noted; conversely, symptoms flare relatively rapidly after discontinuing therapy. Patients must be strictly warned against self-adjustment of the dosage, due to the various side effects that are dose-dependent.

Because of potential adverse effects, any cardiopulmonary or neurologic symptoms should be assessed prior to therapy. Documentation of peripheral motor nerve function may occasionally be necessary before or during therapy. Table 130.3 outlines monitoring guidelines for therapy. The clinician must be aware of all signs and symptoms associated with methemoglobinemia and peripheral neuropathy to ensure proper monitoring.

Major Side Effects

Serious systemic side effects of dapsone may be idiosyncratic or pharmacologic. The pharmacologic and dose-dependent adverse effects include methemoglobinemia and hemolytic anemia (see Table 130.4). Agranulocytosis, peripheral neuropathy and dapsone hypersensitivity are idiosyncratic reactions; however, patients on higher daily doses or long-term therapy may be more likely to develop a peripheral neuropathy. Although rare, dapsone hypersensitivity syndrome may be fatal. Patients present with fever, hepatitis and a generalized cutaneous eruption. Cutaneous reactions range from a exanthematous eruption to toxic epidermal necrolysis (TEN). Liver failure has occurred in patients with the dapsone hypersensitivity syndrome[21], and hypothyroidism may develop following resolution of the acute eruption.

Indications

Dapsone works well in a number of neutrophilic dermatoses and immunobullous diseases. Although only FDA-approved for DH, dapsone is very useful in linear IgA bullous dermatosis, bullous eruption of SLE, and erythema elevatum diutinum[19,20]. It is also a key component of combination therapy for leprosy.

Contraindications

The absolute contraindication to dapsone therapy is prior hypersensitivity to dapsone. Relative contraindications include a low glucose-6-phosphate dehydrogenase (G6PD) level, significant cardiopulmonary disease, and an allergy to sulfonamide antibiotics (because of the possibility of cross-reactivity). Patients with low G6PD levels are at an increased risk of the oxidative stress of the dapsone metabolites on RBCs. Those with significant cardiopulmonary disease may not tolerate the methemoglobinemia and hemolysis induced by dapsone.

Use in Pregnancy and Lactation

Dapsone does not appear to present a major risk to the fetus; however, it remains a pregnancy prescribing category C drug and should only be used during pregnancy if the benefits clearly outweigh the risks. There have been published papers reporting its use in pregnant patients with

Fig. 130.5 Postinflammatory hyperpigmentation secondary to gold eruption. There were features of both a lichenoid drug eruption and a pityriasis rosea-like drug eruption.

leprosy. Dapsone is found in breast milk and can cause hemolytic anemia in breastfed infants; however, it is approved by the American Academy of Pediatrics for use during lactation when required, as in patients with leprosy[5].

Drug Interactions

Drugs that may increase dapsone levels (and side effects) are probenecid (via decreased renal clearance), trimethoprim and other folate antagonists. Sulfonamides and hydroxychloroquine increase the oxidative stress on RBCs and may worsen hemolysis. Dapsone levels may be reduced by activated charcoal, para-aminobenzoic acid (PABA) and rifampin. Although cimetidine can increase absolute levels of dapsone, the former leads to a reduction in the more toxic hydroxylamine metabolite and thus the end result is a lower level of methemoglobin.

GOLD

The dosage, uses and side effects (Fig. 130.5) are outlined in Table 130.10.

GOLD THERAPY (CHRYSOTHERAPY)
Formulations: *Parenteral (IM)*: aurothioglucose (Solganal®); aurothiomalate (Myochrysine®, Myocrisin®) with 70% renal excretion and half-life of 6 days *Oral*: auranofin (Ridaura®) with primarily hepatobiliary elimination, 25% bioavailability, and half-life of 21 days **Mechanism of action**: inhibits chemotactic and phagocytic responses of neutrophils and macrophages *in vitro*; inhibits lysosomal enzymes and interferes with prostaglandin synthesis **Dermatologic use**: treatment of autoimmune bullous diseases (pemphigus vulgaris, mucous membrane [cicatricial] pemphigoid, EBA) and connective tissue diseases (discoid LE, systemic LE) **Dosage**: *IM*: 10 mg, followed in 1 week by 25 mg, then 50 mg biweekly in adults*; for maintenance, taper dose or increase interval *Oral*: 3 mg two to three times daily with maintenance dose of 3 mg daily; because of delayed onset, should be continued for up to 6 months **Side effects**: • Mucocutaneous (40% IM; 30% oral) – lichenoid and pityriasis rosea-like eruptions (Fig. 130.5), erythroderma, cheilitis, stomatitis; may persist for weeks after discontinuing drug • Diarrhea (35–40%) • Hematologic (1–2%) – leukopenia†, thrombocytopenia, eosinophilia [follow CBC with PLT count] • Proteinuria (2–10%) [follow creatinine & urinalysis] • Nitritoid reaction (IM) – dizziness, metallic taste, hypotension, syncope • Pulmonary fibrosis (rarely) • Anaphylaxis **Contraindications**: prior significant reactions to gold (e.g. anaphylaxis, erythroderma, severe hematologic abnormalities, necrotizing enterocolitis, pulmonary fibrosis) **Pregnancy and lactation**: for dermatologic disorders, should be avoided during pregnancy (category C); experts disagree regarding lactation (excreted in breast milk) but allowed per AAP recommendations
*In children, eventual dose is 1 mg/kg/week. †Rarely, aplastic anemia with auranofin.

Table 130.10 Gold therapy (chrysotherapy). AAP, American Academy of Pediatrics; CBC, complete blood count; EBA, epidermolysis bullosa acquisita; IM, intramuscular; LE, lupus erythematosus; PLT, platelet count.

HYDROXYUREA

Although hydroxyurea (Hydrea®) was first synthesized in 1869, its beneficial effect in psoriasis was not discovered until 100 years later. Being 100% bioavailable, hydroxyurea is very well absorbed. Peak levels are seen in 2 hours, its half-life is 5.5 hours, and 80% is excreted via the kidneys. Hydroxyurea is not highly protein-bound and can cross the blood–brain barrier. Metabolic mechanisms are poorly understood, but hydroxyurea is noted to accumulate in greater concentrations in leukocytes than in erythrocytes. With about 60% of patients noticing no side effects, hydroxyurea is typically well tolerated[22]. The macrocytic anemia that commonly occurs is the primary factor limiting hydroxyurea therapy.

Mechanism of Action

Hydroxyurea inhibits the M_2 subunit of ribonucleotide reductase, thus blocking DNA synthesis. Accumulation of DNA precursors may lead to DNA damage and strand scission. Cells are arrested in the G_2 phase and thus are unable to repair UV and ionizing radiation-induced damage. Hydroxyurea also causes hypomethylation of genes, inducing differentiation and normalization of psoriatic skin. Resistance may arise via increased levels of ribonucleotide reductase or by alteration of the enzyme leading to decreased susceptibility[11].

Dosages

The usual dosage is 20–30 mg/kg/day in divided doses, with a maximum of 2 g/day. Doses ranging from 1 to 2 g/day are commonly used[11]. Hydroxyurea is available in 200, 250, 300, 400 and 500 mg tablets. Monitoring guidelines are outlined in Table 130.3. A decrease in dosage (or discontinuation of therapy) is warranted if evidence develops of any type of significant cytopenia, concomitant infection, or other organ system involvement (see Table 130.4).

Major Side Effects

All patients on hydroxyurea develop megaloblastosis; however, only 10–35% develop anemia (see Table 130.4). Leukopenia is seen in 7% and thrombocytopenia in 2–3%. These changes may occur as soon as 48 hours after initiation of therapy, but typically resolve promptly with discontinuation of the drug. Transient, reversible hepatitis occurs occasionally and is associated with an acute "flu-like" syndrome. Sporadic elevations of blood urea nitrogen (BUN) and serum creatinine have been reported, but frank renal failure is rare.

Rare cutaneous side effects include diffuse hyperpigmentation (including the buccal mucosa and tongue) and leg and foot ulcers that resolve on discontinuation of the drug (Fig. 130.6). A characteristic dermatomyositis-like eruption on the dorsum of the hands has been reported. A wide variety of relatively minor side effects are well documented in the package insert.

Indications

Hydroxyurea is typically ineffective as monotherapy for clearing psoriasis, but it is quite effective as maintenance therapy following control of the disease by another modality, either phototherapy or another systemic medication. More commonly used throughout the 1970s, it

Fig. 130.6 Hydroxyurea-induced lower extremity ulcers.

is rarely prescribed in the current era of immunomodulating agents. Hydroxyurea is ineffective in psoriatic arthritis. Other uses include lymphocytic hypereosinophilic syndrome unresponsive to corticosteroids, chronic myeloproliferative disorders, and prophylaxis against sickle cell anemia crises.

Contraindications

Absolute contraindications include pregnancy, lactation, and hypersensitivity to hydroxyurea. Relative contraindications include concomitant use of cytarabine, blood dyscrasias, infection, cardiac, renal or pulmonary disease, and unstable or fulminant psoriasis.

Use in Pregnancy and Lactation

Hydroxyurea is a teratogen and should not be used in pregnancy or lactation. It is pregnancy prescribing category D[5].

Drug Interactions

Hydroxyurea has no significant drug interactions.

LEUKOTRIENE INHIBITORS

Leukotrienes, initially identified as the slow-reacting substance of anaphylaxis, play a key role in systemic and cutaneous inflammatory reactions[23]. Originating from arachidonic acid, leukotriene A_4 (LTA_4) is metabolized by divergent pathways to either LTB_4 or to the cysteinyl leukotrienes LTC_4, LTD_4 and LTE_4 (Fig. 130.7). LTB_4 mediates its effect through the BLT receptor(s), triggering chemotaxis of neutrophils, eosinophils and monocytes. By binding with cysteinyl leukotriene receptors, LTC_4, LTD_4 and LTE_4 cause bronchoconstriction, increased vascular permeability, smooth muscle contraction, mucus secretion and edema[23]. Leukotrienes and leukotriene receptors are widely distributed throughout the body, but their concentration and relative importance are organ- and cell type-specific. Leukotriene inhibitors abrogate the biologic effects of these mediators (Table 130.11).

METHOTREXATE

The effectiveness of the folic acid analogue methotrexate (MTX) in psoriasis was noted in the early 1950s, but remained without FDA approval until the 1960s. MTX is not difficult to use and oral administration achieves reliable blood levels unaffected by food intake. MTX is widely distributed throughout the body, but penetrates the blood–brain barrier poorly.

Within 1 hour of ingestion, distribution and active cellular uptake is complete. Plasma MTX is 50% protein-bound, and irreversibly bound to dihydrofolate reductase, the enzyme it inhibits. By 4 hours, the kidneys have excreted the plasma portion of the drug[24]. Over the next 10–27 hours, the drug is slowly released from body tissues.

Mechanism of Action

Dihydrofolate reductase (DHFR) converts dihydrofolate to tetrahydrofolate (fully reduced folic acid; see Ch. 127), which is a necessary cofactor in the synthesis of thymidylate and purine nucleotides, which, in turn, are required for DNA/RNA synthesis. MTX competitively inhibits DHFR, although this inhibition can be at least partially reduced by concomitant folic acid administration. MTX also exerts partially reversible inhibition downstream on thymidylate synthetase, inhibiting cell division in the S phase[7].

Although originally believed to suppress keratinocyte proliferation, it is more likely that MTX inhibits DNA synthesis in immunologically active cells. MTX decreases inflammation through other mechanisms as well. By inhibiting aminoimidocarboxyamido-ribonucleotide transformylase, MTX increases local tissue concentrations of the potent anti-inflammatory mediator adenosine. By inhibiting methionine synthase, MTX reduces production of the proinflammatory mediator S-adenyl methionine[25] .

Dosages

MTX is administered as a once-weekly dose of up to 30 mg for dermatologic and rheumatologic diseases. Oncologists may prescribe 20–40 mg/m^2 every 1 to 4 weeks with folinic acid rescue. Historically, MTX was administered in three doses over 24 hours (8 a.m. and 8 p.m. day 1, and 8 a.m. day 2). There were theoretical advantages for the divided dosing regimen from a cell cycle kinetics standpoint. However, since the clinical result is the same, a single dose, which is easier and less confusing (for the patient and the pharmacist), is currently recommended. The patient should be admonished to adhere to the dosing schedule religiously, as more frequent dosing invariably causes major hematologic complications and potentially an increased risk of liver fibrosis. Parenteral administration (intramuscular or subcutaneous) is available for patients who cannot tolerate oral MTX and has also been advocated by some clinicians for use in erythrodermic patients who may have decreased gastrointestinal absorption or when compliance is an issue.

Available in 2.5 mg tablets, therapy should begin with a test dose of 2.5–7.5 mg followed 5–6 days later with a complete blood count with differential (CBC), platelet count and hepatic profile. The dose may be gradually increased by 2.5 to 5 mg every 2–4 weeks until satisfactory results are obtained with minimal toxicity. Once disease control has been attained for at least 1–2 months, the MTX can be tapered by 2.5 mg every 1–2 weeks to the lowest dose that still maintains disease control. The usual weekly dose for psoriasis is 10–15 mg, although doses up to 25 mg per week are not uncommonly used, except in patients with renal insufficiency. In the past, rheumatologic and dermatologic monitoring regimens differed significantly, in that liver biopsies were not routinely recommended by rheumatologists. However, per recent psoriasis treatment guidelines (2009), for patients without risk factors for hepatic fibrosis, liver biopsies may not be indicated, or the frequency of liver biopsies may be markedly reduced, as compared to previous recommendations (see Table 130.3)[26]. In general, dosing and duration of therapy may be higher and longer for psoriasis patients than for those with rheumatologic diseases.

Major Side Effects

The most important side effects of MTX include pancytopenia and hepatotoxicity (see Table 130.4). Pancytopenia typically develops early, compared to hepatic fibrosis and cirrhosis, which take years to develop. There is considerable debate over the risk of hepatotoxicity in psoriasis patients on long-term MTX. Suffice it to say that the higher the cumulative dose of MTX, the greater the risk of significant liver damage (Table 130.12). Compounding risk factors for hepatic impairment include: previous or current excessive alcohol intake, persistent abnormal liver chemistries, a history of liver disease (including hepatitis B and C viral infections), family history of inheritable liver disease, diabetes mellitus, obesity, and a history of significant exposure to hepatotoxic drugs or chemicals. References discussing this issue in detail[24] should be consulted before prescribing MTX and referral to a hepatologist can be considered.

Elevated levels of procollagen III aminopeptide have been observed to be a serologic marker of fibrosis, and, in the future, this (or a similar) assay may help to determine which patients should be sent for liver

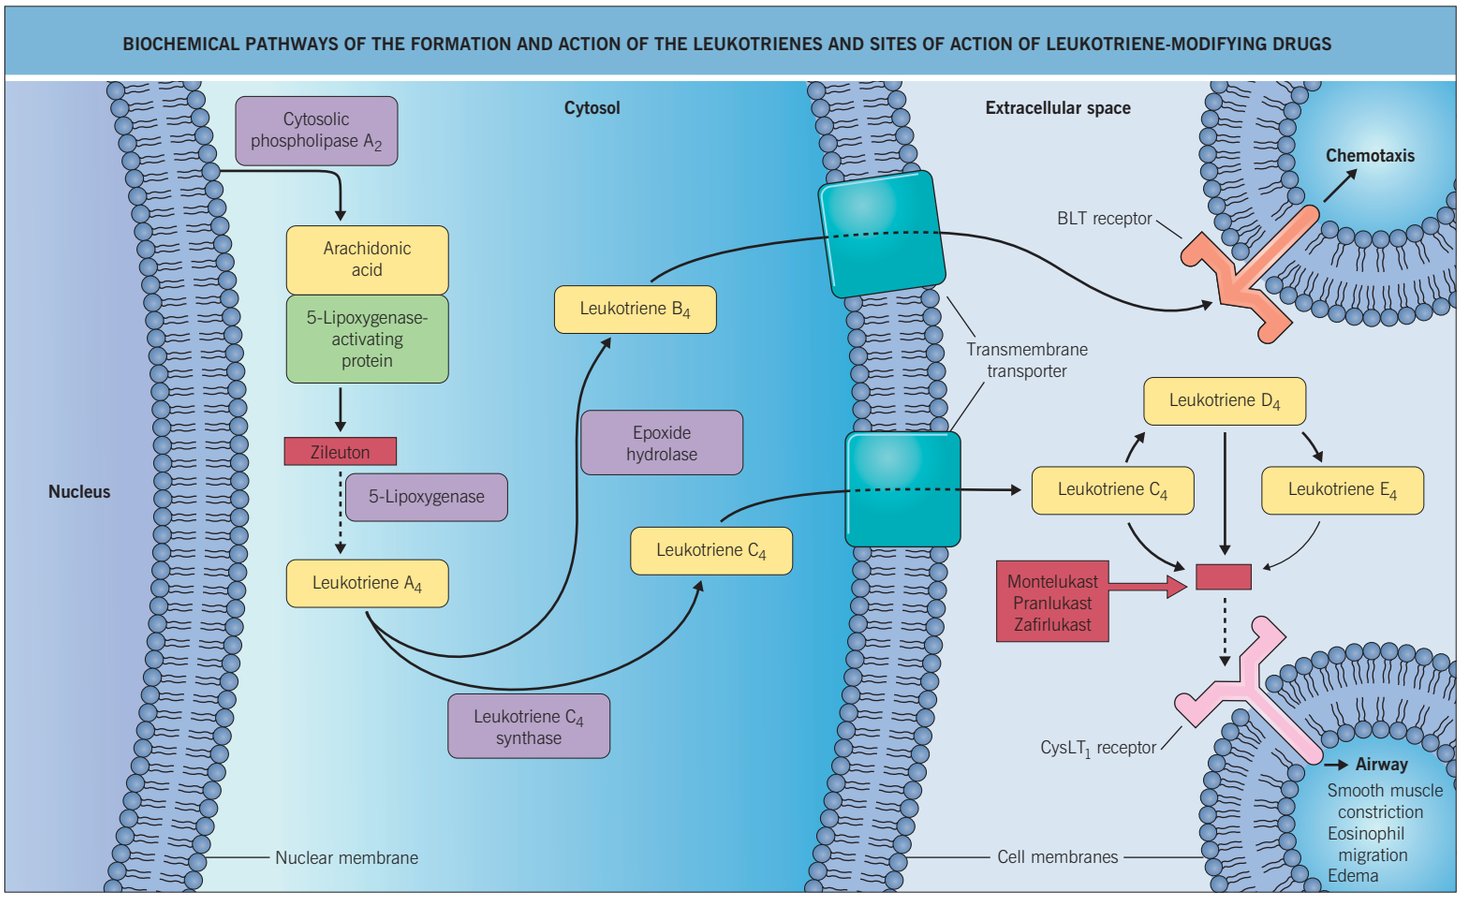

Fig 130.7 Biochemical pathways of the formation and action of the leukotrienes and sites of action of leukotriene-modifying drugs. Enzymes are shown in purple, products in yellow, essential cofactor in green, and drugs in red. Although the synthesis of leukotrienes B_4 and C_4 probably takes place in close proximity to the nuclear membrane, for clarity they are shown throughout the cytosol. An individual cell may produce the cysteinyl leukotrienes, leukotriene B_4, or, in rare cases, both. BLT, B leukotriene receptor. *From Drazen JM, Israel E, O'Byrne PM. Treatment of asthma with drugs modifying the leukotriene pathway. N Engl J Med. 1999;340:197–206.*

LEUKOTRIENE INHIBITORS

Mechanisms of action: antagonists of cysteinyl leukotriene receptors (block LTC_4, LTD_4 & LTE_4 binding) – montelukast (Singulair®), zafirlukast (Accolate®), pranlukast; inhibitor of 5-lipoxygenase – zileuton (Zyflo CR®); see Fig. 130.7
Dermatologic uses: limited evidence for atopic dermatitis, autoimmune bullous diseases, urticaria, Sjögren-Larsson syndrome; primary use is asthma
Dosages*: montelukast – 10 mg [adults], 5 mg [children 6–16 years]; zafirlukast 20 mg BID [adults & adolescents], 10 mg BID [5–11 years] on empty stomach; zileuton 1200 mg BID [adults & adolescents] with meals
Side effects: indigestion, nausea, myalgias, headaches, hepatitis; montelukast and zafirlukast have been associated with the development of eosinophilia and Churg–Strauss syndrome, usually in the setting of a taper of corticosteroids
Contraindications: prior hypersensitivity reaction to drug; significant liver disease
Pregnancy and lactation: montelukast and zafirlukast (pregnancy category B); zileuton (pregnancy category C); limited data
Drug interactions: zileuton may increase circulating levels of propranolol, theophylline, terfenadine or warfarin; zafirlukast may increase circulating levels of warfarin; aspirin or erythromycin may decrease plasma level of zafirlukast; phenobarbital may reduce levels of montelukast

*Oral.

Table 130.11 Leukotriene inhibitors.

CLASSIFICATION OF HISTOLOGIC FINDINGS IN LIVER BIOPSIES

Grade	Histologic findings	Methotrexate
I	Essentially normal liver	Continue
II	Moderate to severe fatty infiltration, nuclear variability, portal tract expansion, portal tract inflammation and necrosis	Continue; repeat biopsy after additional 1.5 g, or as recommended by hepatologist
IIIA	Mild fibrosis; fibrotic septae which extend into the lobules	Repeat biopsy in 6 months or as recommended by hepatologist
IIIB	Moderate to severe fibrosis	Discontinue
IV	Cirrhosis	

Table 130.12 Classification of histologic findings in liver biopsies. *Adapted from Roenigk H, Auerbach R, Maibach HI, et al. Methotrexate in psoriasis: revised guidelines. J Am Acad Dermatol. 1988;19:145–56.*

biopsy. In addition, based upon studies of patients with chronic hepatitis C viral infection, an index that incorporates circulating levels of a2-macroglobulin, tissue inhibitor of metalloproteinase-1 (TIMP-1), and hyaluronic acid has been developed. This index (e.g. FIBROSpect II) is commercially available and provides estimated risks of various degrees of hepatic fibrosis.

Photosensitivity may occur and patients should take appropriate sun precautions (see Ch. 21)[7]. Gastrointestinal intolerance is often abated with concomitant folic acid therapy (1–5 mg orally daily, based on symptoms). Other MTX-induced side effects include accelerated rheumatoid (cutaneous) nodulosis and reversible lymphoproliferative disorders. When used in very high doses, MTX may cause reversible oligospermia[24]. Family counseling is outlined in Table 130.13.

Drug Indications

MTX has FDA approval for use in psoriasis (see Ch. 8); however, it is used for those individuals with severe, debilitating or recalcitrant disease. In a recent randomized trial comparing methotrexate and adalimumab, 40 of 103 patients assigned to MTX (and who completed the study) had PASI 50 responses at 8 weeks at a dose of 15 mg weekly (dosage reached at week 4 from a baseline of 7.5 mg weekly). Of the

METHOTREXATE – COUNSELING FOR PATIENTS OF CHILDBEARING POTENTIAL
WOMEN
• Should not become pregnant while receiving MTX • MTX can cause birth defects and abortions • Must use highly effective means of contraception (e.g. OCPs; IUD; condom + spermicide) • After discontinuing MTX, wait at least one ovulatory cycle before attempting to become pregnant
MEN
• May lead to low sperm counts • Drug is present in semen • Must use highly effective means of contraception (e.g. OCPs; IUD [female partner]; condom + spermicide) • After discontinuing MTX, wait 3 months before attempting to have partner become pregnant

Table 130.13 Methotrexate – counseling for patients of childbearing potential. This drug is pregnancy category X. IUD, intrauterine device; MTX, methotrexate; OCPs, oral contraceptive pills.

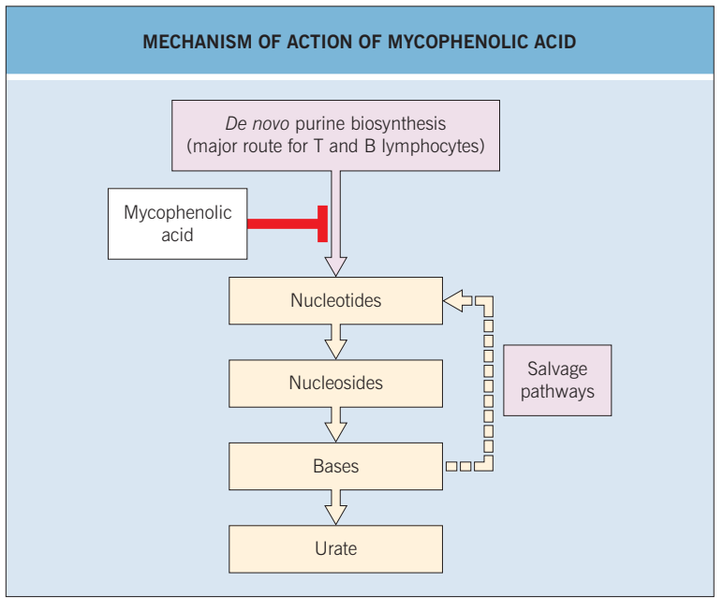

Fig. 130.8 Mechanism of action of mycophenolic acid. While most nucleated cells utilize salvage pathways, T and B lymphocytes must rely primarily on the *de novo* pathway for purine biosynthesis. Mycophenolic acid, the active drug form of the prodrug mycophenolate mofetil, inhibits inosine monophosphate dehydrogenase, an enzyme in the *de novo* pathway of purine biosynthesis.
Adapted from Wolverton SE. Comprehensive Dermatologic Drug Therapy, 2nd edn. Philadelphia: Saunders, 2007.

additional 63 patients, 22 achieved PASI 50 responses by week 12 after an increase to 20 mg weekly (at 8 weeks)[27]. This compares to PASI 75 rates of 60% at 16 weeks in patients treated with 15 mg weekly of MTX from the outset[28].

Other disorders (e.g. dermatomyositis) that respond to MTX are listed in Table 130.5. Of note, pityriasis rubra pilaris commonly requires up to twice the typical psoriasis dose, whereas PLEVA often responds to small MTX doses (2.5–5 mg/week). Methotrexate can also be used as a steroid-sparing agent, and in the elderly, monotherapy with weekly MTX is an option for the treatment of bullous pemphigoid.

Contraindications

Absolute contraindications to MTX use are pregnancy and lactation. Relative contraindications include significant liver disease or elevated liver enzymes and excessive alcohol intake. The presence of active infection or immunodeficiency, and the desire for imminent pregnancy are relative contraindications to MTX therapy (see Table 130.13). Caution is indicated and a dose reduction necessary if used in the setting of decreased renal function. In the elderly, serum creatinine levels may be deceptively low and may not reflect true renal function.

Use in Pregnancy and Lactation

MTX is an abortifacient and teratogen and should not be used during pregnancy. The American Academy of Pediatrics considers MTX to be contraindicated in breastfeeding owing to concerns of immune suppression, growth retardation and carcinogenesis[5].

Drug Interactions

Drugs that elevate MTX blood levels include NSAIDs, salicylates, sulfonamides, chloramphenicol, phenothiazines, phenytoin and tetracyclines. Dipyridamole and probenecid increase intracellular accumulation of MTX. Trimethoprim, sulfonamides and dapsone also inhibit the folate metabolic pathway (see Ch. 127) and markedly increase the risk for pancytopenia with concomitant use. Systemic retinoids and alcohol may cause synergistic liver damage in combination with MTX.

MYCOPHENOLATE MOFETIL

Mycophenolic acid (MPA) has been used in various forms for the treatment of psoriasis since the 1970s. Its use declined until the early 1990s, when a more bioavailable and safer formulation, mycophenolate mofetil (Cellcept®), became commercially available. Initially inactivated during first-pass glucuronidation in the liver (into the phenolic glucuronide of MPA, MPAG), MPA is then reactivated in the epidermis and gastrointestinal tract by β-glucuronidase (see Fig. 131.1). Mycophenolate mofetil has greater bioavailability than MPA, undergoes complete presystemic conversion to MPA after ingestion, and then follows the same inactivation/activation cycle[29]. Mycophenolate mofetil is 94% bioavailable. MPA is 97% and MPAG 82% albumin-bound. Over 90% of the drug is excreted in the urine, mainly as MPAG. Renal insufficiency can increase plasma concentrations up to sixfold[11].

Mechanism of Action

MPA selectively and non-competitively inhibits the enzyme inosine monophosphate dehydrogenase (IMPDH), preventing conversion of inosine- and xanthine-5-phosphate to guanosine-5-phosphate. This blocks *de novo* synthesis of guanine nucleotides and their subsequent incorporation into DNA (Fig. 130.8). DNA synthesis in T and B lymphocytes is preferentially inhibited because these cells lack the purine salvage pathway and are dependent on *de novo* purine synthesis. MPA decreases immunoglobulin levels and delayed-type hypersensitivity responses by inhibiting proliferative responses to mitogenic and allospecific stimulation; MPA also suppresses antibody formation by B lymphocytes.

Dosages

Mycophenolate mofetil is available in 250 mg capsules and 500 mg tablets. For dermatologic diseases, the best results are obtained with doses of 2000 mg daily. Selected patients may require doses carefully titrated up to 3000 mg daily.

Major Side Effects

The most common side effects of mycophenolate mofetil are gastrointestinal and include nausea, vomiting, diarrhea, abdominal cramps and tenderness (see Table 130.4). Significant hematologic and hepatic toxicity occur uncommonly. In 2008, the FDA released a safety report regarding a potential association (in transplant patients) between mycophenolate mofetil and the development of progressive multifocal leukoencephalopathy. Although a rare event, and cause-and-effect remains speculative, patients should be monitored accordingly[30]. Monitoring guidelines are outlined in Table 130.3. The dosage should be reduced or therapy discontinued for a WBC <3500–4000 cells/mm^3.

Indications

Mycophenolate mofetil is currently FDA-approved for renal allograft rejection only. However, it is quite useful in the treatment of autoimmune bullous diseases, severe forms of atopic dermatitis or cutaneous lupus, and refractory pyoderma gangrenosum. Mycophenolate

mofetil is generally used in conjunction with other immunosuppressive drugs, most commonly as a steroid-sparing agent.

Contraindications

Absolute contraindications to mycophenolate mofetil use are pregnancy and allergy to MPA. Relative contraindications include lactation, as MPA is partially excreted in breast milk. Peptic ulcer disease and hepatic, renal or cardiopulmonary disease are also relative contraindications. As noted previously, renal insufficiency can increase plasma concentrations up to sixfold[11].

Use in Pregnancy and Lactation

Mycophenolate mofetil is currently rated as a pregnancy prescribing category D medication[5]. Recent human data suggest that mycophenolate mofetil may cause birth defects, with a characteristic phenotype consisting of cleft lip and palate, microtia with atresia of the external auditory canal, micrognathia and hypertelorism[31]. Additional data suggest that defect severity may be dependent on the dose and duration of therapy as well as timing during pregnancy[32]. Mycophenolate mofetil is contraindicated during lactation, due to potential immunosuppression.

Drug Interactions

Drugs that alter the enterohepatic recirculation or gastrointestinal absorption of mycophenolate mofetil, such as cholestyramine, iron or aluminum and magnesium hydroxides, may decrease the effectiveness of mycophenolate mofetil (see Ch. 131). Plasma levels of acyclovir and mycophenolate mofetil are both elevated when used concomitantly.

SATURATED SOLUTION OF POTASSIUM IODIDE (SSKI)

Mechanism of Action

First discovered in seaweed in the 1800s, iodine was soon used medically for a variety of conditions, such as thyroid disease, syphilis, psoriasis and atopic dermatitis[33]. To this day, it remains an important tool in the treatment of sporotrichosis and a variety of inflammatory conditions, especially panniculitis. Most conveniently administered as a saturated solution of potassium iodide (SSKI), it is rapidly absorbed, widely distributed into the thyroid and salivary glands, choroid plexus and placenta, and then excreted primarily through the kidneys. Although its mechanism of action with regard to inflammatory diseases is speculative, it is thought to exert its effects via immune modulation. Similar to dapsone, SSKI appears to be effective in suppressing neutrophil migration and toxicity. The mechanism through which it eradicates sporotrichosis is unknown[33].

Dosages

SSKI is most commonly available in a solution with a concentration of 1000 mg/ml (see Ch. 100). The accompanying dropper has markings at 0.3 ml (300 mg) and 0.6 ml (600 mg); when lower doses are prescribed, drops (gt) are counted. The initial dose to treat inflammatory skin conditions is generally 150–300 mg three times daily, increased weekly as tolerated[34]. Improvement is generally seen within days to weeks. The dose for sporotrichosis is usually higher, beginning at 600 mg three times daily, with a maximum dose of 6 g, if tolerated[33]. The course of treatment for sporotrichosis is approximately 6–10 weeks.

Major Side Effects

Gastrointestinal side effects are common (see Table 130.4) and may be ameliorated by slow dose escalation. Long-term use can be associated with the development of "iodism", manifested by a burning mouth, a metallic taste, soreness of the teeth and gums, and a severe headache. Acneiform eruptions and iododerma can also occur, especially at higher dosages. Fortunately, symptoms abate quickly with cessation of therapy. SSKI may also alter thyroid metabolism, resulting in either hypo- or hyperthyroidism, with reversible hypothyroidism being relatively common. While hyperkalemia can occur, other side effects are rare.

Indications

Although SSKI is not FDA-approved for any cutaneous disease, it is a highly effective treatment for cutaneous and lymphocutaneous sporotrichosis. However, for systemic sporotrichosis, other drugs should be prescribed (see Ch. 77). SSKI has also been used successfully for a variety of neutrophilic disorders and granulomatous diseases as well as several types of panniculitis.

Contraindications

The only absolute contraindication is a hypersensitivity reaction to iodides. Relative contraindications include thyroid or cardiac disease, renal insufficiency and Addison's disease[35]. The latter are due to the risk of hyperkalemia.

Use in Pregnancy and Lactation

Iodide crosses the placenta and is considered pregnancy prescribing category D; fetal goiter and hypothyroidism have been described. Although it is present in breast milk, the American Academy of Pediatrics considers its use to be compatible with breastfeeding[5].

Drug Interactions

Concurrent use with other medications such as ACE inhibitors, potassium-sparing diuretics and potassium-containing medications may result in significant hyperkalemia. Hypothyroidism may result when used in combination with amiodarone, lithium, phenazone, and, possibly, sulfones[33].

TACROLIMUS

The dosage, uses and side effects are outlined in Table 130.14.

THALIDOMIDE

Few drugs have garnered such notoriety as has thalidomide. Originally introduced in Europe during the 1950s as a sedative/hypnotic, it was commonly used to control morning sickness during pregnancy. Thus, it was prescribed to thousands of pregnant women, with tragic results. By 1961, thalidomide was withdrawn from the market worldwide after being linked to thousands of babies born with phocomelia (severe underdevelopment of the extremities)[36]. At the time of worldwide withdrawal, thalidomide had never received FDA approval for use in the US. Renewed interest in the drug ensued in the mid-1960s with reports that thalidomide provided significant relief from the symptoms of erythema nodosum leprosum (ENL). Thalidomide received FDA approval for treatment of ENL in 1997.

In the US, both the prescribing physician and the dispensing pharmacist must be enrolled in the *S*ystem for *T*halidomide *E*ducation and *P*rescribing *S*afety (STEPS) program administered by the FDA and the Celgene Corporation (1–888–4–CELGEN[E] to enroll). Standardized

TACROLIMUS
Drug properties: macrolide lactone **Mechanism of action**: calcineurin inhibitor (see Ch. 128); inhibits production of cytokines such as IL-8 **Dermatologic use**: GVHD – prophylaxis, acute and chronic; pyoderma gangrenosum; recalcitrant psoriasis **Dosage**: 1–2 mg orally twice daily (blood level 5–10 ng/ml) **Side effects**: immunosuppression, renal dysfunction, hypertension, hyperkalemia (esp. in conjunction with ACE inhibitors), diabetes mellitus **Contraindications**: uncontrolled hypertension, significant renal impairment, prior hypersensitivity reaction to drug or, for parenteral administration, allergy to HCO-60 (polyoxyl 60 hydrogenated castor oil that is used as a surfactant); see contraindications for cyclosporine **Pregnancy and lactation**: for dermatologic disorders, should be avoided during pregnancy (category C) and lactation (concentrated in breast milk) **Drug interactions**: Other renal-toxic drugs; drugs that inhibit or induce CYP3A4 (see Ch. 131)

Table 130.14 Tacrolimus (Prograf®). Also known as FK506. There is significantly less hypertrichosis as compared to cyclosporine.

informed consent forms, patient education packets, and monitoring requirements are included in the program.

Thalidomide (Thalomid®) is a lipophilic, non-polar piperidine-dione that is poorly absorbed and highly protein-bound. Peak plasma levels are attained 2–6 hours after ingestion and absorption is not affected by food intake. The half-life of thalidomide is 9 hours. Although the major degradative pathway is non-enzymatic hydrolysis, the drug is also metabolized by the CYP enzymes. The precise method of excretion is not known, but it is non-renal[35].

Mechanism of Action

The precise mechanisms of action of thalidomide are unknown. However, its anti-inflammatory and immunomodulatory effects on dermatologic diseases are thought to be largely through inhibition of TNF-α release and activity.

Dosages

A major emphasis of the STEPS program is pregnancy prevention. Prior to therapy, women of childbearing potential must be on birth control for 1 month and have a negative serum pregnancy test within 24 hours of the first dose. If the initial history or physical examination indicates peripheral nervous system disease, neurologic consultation should be sought. Monitoring guidelines are listed in Table 130.3. Thalidomide is available in 50, 100, 150 and 200 mg capsules. Dosing regimens will vary according to the particular disease and its severity. Used in combination with anti-leprosy chemotherapy, the dose for ENL ranges from 100 to 400 mg per day (see package insert for details). Dosages for HIV-associated oral aphthae and neutrophilic dermatoses are generally 100 mg per day. The most common dose-limiting side effect is sedation.

Patients with recalcitrant discoid or SCLE lesions (Fig. 130.9) have 75–90% clearance rates with thalidomide. The initial dose of 50–100 mg/day is subsequently tapered to 25–50 mg/day after a clinical effect is seen, usually within 2 weeks. Acute cutaneous lesions of SLE have up to a 90% resolution rate, but require higher doses and a longer treatment period before results are noted. For some patients, intermittent courses of thalidomide (for 2–3 months) can be used to clear lesions, with antimalarials given concomitantly and as maintenance therapy.

Major Side Effects

A single dose of thalidomide during the first 21–36 days of gestation yields a 100% incidence of birth defects (see Table 130.4). Sedation is by far the most common adverse side effect and may necessitate nighttime dosing and a gradual titration of the thalidomide dose. Constipation is also relatively common. Permanent nerve damage (primarily sensory neuropathy) can develop and is more common with long-term therapy. Measurements of sensory nerve action potential amplitudes (SNAP) may be indicated before and/or during therapy. Amenorrhea and primary ovarian failure may occur.

Severe leukopenia, exfoliative erythroderma and TEN are rare, but severe, consequences of thalidomide treatment. A hypersensitivity reaction specific to HIV-positive patients has been described. Common dermatologic side effects include brittle fingernails, xerosis, pruritus and red palms. Peripheral edema can develop occasionally. Vascular thromboses are unusual unless the patient is receiving concomitant corticosteroids.

Indications

Thalidomide is FDA-approved and 99% effective for ENL (type II leprosy reaction). It has no effect on type I leprosy reactions. A variety of off-label uses of thalidomide have emerged over the years (Table 130.5)[37]. Although HIV-associated mucosal ulceration, as well as aphthae associated with neutrophilic dermatoses (including Behçet's disease), respond rapidly to thalidomide, ulcerations relapse quickly when the drug is discontinued. Curiously, the highest rate of peripheral neuropathy has been observed in prurigo nodularis patients[37].

Contraindications

Absolute contraindications to thalidomide therapy include sensitivity to thalidomide, pregnancy and a pre-existing peripheral neuropathy.

Fig. 130.9 Effect of thalidomide on subacute cutaneous lupus erythematosus. **A** The patient's disease was not controlled despite prednisone (60 mg/day), hydroxychloroquine (600 mg/day) and isotretinoin (60 mg/day), all for at least 2 months. **B** Thalidomide (50–100 mg/day) was begun and the lesions resolved over 6 to 8 weeks. *Courtesy, Jean L Bolognia, MD.*

Women of childbearing potential must agree to use highly effective methods of birth control (e.g. two reliable forms of contraception simultaneously). Men taking thalidomide who have female partners of childbearing potential must wear condoms (even if they have had a vasectomy) while their partners use an additional form of birth control (either oral or barrier). Relative contraindications include significant hepatic or renal disease, a history of neurologic disease, congestive heart failure, hypertension, constipation and hypothyroidism. In patients with a predisposing condition (e.g. antiphospholipid antibodies, myeloma), there can be an increased risk of thromboses. Individuals receiving antimalarials should continue to do so, because these drugs have been reported to inhibit platelet aggregation and adhesion.

Use in Pregnancy and Lactation

Thalidomide is pregnancy prescribing category X and should not be used in pregnant women[5]. It is wise to avoid thalidomide in nursing mothers.

Drug Interactions

Thalidomide may amplify the sedative effects of alcohol, barbiturates, chlorpromazine and reserpine. Any drug that significantly induces the CYP3A4 enzymes may decrease the effectiveness of hormonal contraception, increasing the potential of pregnancy and, thus, teratogenicity.

How to minimize the risk of drug–drug interactions 2189

INTRODUCTION

There are two concerns in drug safety: drug reactions and drug interactions. When multiple medications are prescribed, drug interactions become an important safety and efficacy consideration for patients and physicians alike[1]. Non-prescription drugs, as well as herbal or alternative medicines and foods (such as grapefruit juice), may also be implicated in interactions with drug therapy.

It is difficult to obtain precise rates of incidence and prevalence, as specific diagnostic codes for drug interactions are lacking[2]. Drug interactions are known to be responsible for up to 2.8% of hospital admissions[3,4]. It has been estimated that adverse drug outcomes occur about once every 100 patient days[3,5]. Although it is impossible to remember all potential drug interactions, knowledge of the interactive properties of drugs can help reduce the risk of serious adverse outcomes. Moreover, it is the responsibility of physicians to counsel patients regarding drug interactions[6]. Unfortunately, even when serious new drug interactions are recognized and reported, physicians, pharmacists and patients are often unaware that there is a risk[7].

PUTTING INTERACTIONS INTO PERSPECTIVE

Prescribing drugs with the potential for a deleterious interaction increases the risk of, but need not lead to, an adverse outcome. Many drug–drug interactions are susceptible to control by dose adjustment. Some interactions can even be exploited for a therapeutic advantage, e.g. coadministration of erythromycin to increase cyclosporine levels as a means of reducing costs associated with the latter.

While most drugs are associated with interactions, many do not produce significant outcomes[8]. In fact, not all listed or reported drug interactions are actually clinically significant. Whereas some have little clinical relevance, others are clearly defined as contraindications on the basis of substantiation of risk, potential severity and frequency of occurrence. Still others can be successfully managed by dosage adjustment and monitoring. In one study that examined the occurrence of drug interactions, based upon adverse events reported during large clinical trials[9], the authors concluded that serious adverse drug reactions (ADRs) secondary to drug–drug interactions were infrequent; however, drug–drug interactions that involved selected drugs with a narrow therapeutic index (which elicited life-threatening undesired effects) did occur. Serious ADRs secondary to drug–drug interactions were most frequently observed in elderly patients, with polypharmacy in the psychiatric patient population, and in the presence of inappropriate prescriptions or multiple prescribers. Thus, for most drug interactions, it is necessary to assess each patient situation individually.

ASSESSMENT OF RISK IN THE CLINICAL OUTCOME OF DRUG INTERACTIONS

The clinical importance of specific drug interactions is often either over- or underestimated, as these assessments are largely based on clinical experience in using a particular drug combination[10]. The clinical outcome of most drug interactions is highly situational, as most patients who receive drugs with the potential for interactions do not develop adverse effects. Emphasis should be placed on those factors that increase or decrease the risk to a given patient.

In order to prevent or detect drug interactions, the physician needs to identify risk factors in each individual patient. That said, some patient groups are more likely than others to develop adverse events caused by drug interactions. Identified risk factors are listed in Table 131.1 and are grouped by category[12].

The elderly frequently experience drug interactions because of the physiologic changes that accompany the aging process and the types of drugs that older patients tend to receive[11]. Polypharmacy, which is common in the elderly, makes them particularly susceptible. In addition, medications may impair pathways of drug elimination by interfering with drug metabolism, thereby increasing the likelihood of adverse drug reactions. Alterations due to advanced age, including changes in drug–protein binding and drug distribution within tissue, may also promote drug interactions. Of note, most adverse metabolic drug interactions occur when an inhibitor or inducer is begun in a patient who previously had stable levels of a substrate drug.

Patients with AIDS also have a high rate of adverse drug reactions[13]. In some instances, this may relate to phenotypic changes in drug metabolism, which can vary with progression of the underlying HIV infection[14]. The latter can alter enzyme function, with resultant changes in drug metabolism and a higher rate of adverse reactions in these patients.

A major source of interindividual differences in drug metabolism is genetic polymorphisms, which are inherited and can result in significant variations in the activity of drug-metabolizing enzymes. For example, the genes encoding cytochrome P450 (CYP) isoforms are highly polymorphic (see Table 131.13). In some cases, it is actually possible to determine an individual's genotype[15]. Further details on genetic polymorphisms are discussed later in the chapter.

Interactions with other drugs can predispose a patient to the development of certain types of ADR. For example, coadministration of valproic acid increases the risk of severe cutaneous adverse reactions to lamotrigine[16], and allopurinol increases the risk of exanthematous eruptions to antibiotics such as amoxicillin. A disease state itself may directly affect the likelihood of an ADR. For example, active infection with Epstein–Barr virus or cytomegalovirus also increases the risk of exanthematous eruptions to amoxicillin. The basis of these interactions is unknown but may represent a combination of factors, including alterations in drug metabolism, drug detoxification, antioxidant defenses and immune reactivity[17]. The disease state may also dictate the way in which a drug is prescribed, and this will subsequently affect the outcome. When a drug has more than one therapeutic action, an interacting drug may affect the action of the first drug when it is used to treat one disease but not when it is used to treat the first disease. This is known as pharmacologic selectivity.

An example of intrinsic effects of disease states would be when epinephrine (adrenaline) is given to patients receiving non-cardioselective

PATIENT RISK FACTORS FOR DRUG INTERACTIONS
• Multiple medications – polypharmacy
• Demographic risk factors
– Female gender
– Extremes of age (very young and elderly)
• Major organ dysfunction (especially when multiple medical problems)
– Liver dysfunction
– Renal insufficiency*
– Congestive heart failure
• Metabolic and endocrine risk factors
– Obesity
– Hypothyroidism
– Hypoproteinemia
• Pharmacogenetic risk factors
– Slow acetylator phenotype
– Reduced thiopurine methyltransferase (TPMT) activity
– Other genetic polymorphisms (see text and Table 131.13)
• Other medical issues
– Hypothermia
– Hypotension
– Dehydration
*May be underestimated in elderly patients.

Table 131.1 Patient risk factors for drug interactions[11].

β-adrenergic blockers (but who do not have anaphylaxis) and this results in hypertension. In contrast, the same β-blockers inhibit the pressor response to epinephrine[18] when the latter is given to patients with anaphylaxis.

An example of a dose-dependent drug interaction is the concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs) and methotrexate. Available evidence indicates that the risk of this combination is considerably greater in patients receiving high-dose methotrexate for cancer than it is in patients receiving lower weekly dosages for psoriasis[19]. This is because the distribution of the drug is not very important mechanistically in determining drug interactions, but changes in drug elimination are. When larger doses of methotrexate (as used in cancer therapy) are given in combination with an NSAID, reduced drug elimination becomes an important issue, increasing the risk of methotrexate toxicity.

Gender-related differences in pharmacokinetics may cause variations in drug absorption, gastric emptying and distribution based on percentage of adipose tissue[20]. Gender-related differences in receptor density and sensitivity, enzyme activity (CYP2D6) and underlying disease activities also contribute to pharmacokinetic variation. The effect of obesity on metabolism is cytochrome-specific. For example, obesity decreases the activity of CYP3A4 and increases the activity of CYP2E1.

Certain medications are clearly more likely to be involved in drug interactions. More specifically, clinically significant interactions occur more frequently with drugs that have a narrow margin of safety, i.e. a narrow therapeutic window. Drugs with the potential for such serious interactions include warfarin and cyclosporine. When prescribing a new medication that could potentially interact with warfarin, it is prudent to have the patient's international normalized ratio (INR) measured within 2–3 days of administration of the new drug.

Medication-related factors that contribute to clinical risk include the dose, route of administration and duration of administration of the *precipitant drug* (the drug that causes the interaction) as well as the sequence of administration of the interacting drugs. Most metabolic drug interactions are dose-related. That is, as the dose of the precipitant drug is increased, the magnitude of its effect on the *object drug* tends to increase. Thus, the dose of the precipitant drug is often an important determinant of risk. However, the dose of the object drug may also affect the risk of an adverse drug interaction. For example, a patient who takes small doses of an object drug with serum concentrations at the lower end of the target range is at a lesser risk when an enzyme-inhibiting precipitant drug is added than would be a patient taking large doses of the same object drug. Lastly, the bioavailability of either drug may have an impact.

The route of administration is an important risk factor for some non-metabolic drug interactions, such as when one drug binds to another in the gastrointestinal (GI) tract. However, the route of administration can also be important for metabolic drug interactions, especially when the drug undergoes extensive first-pass metabolism in the gut wall and liver by CYP3A4 or P-glycoprotein. Most drug interactions also have a typical time course over which the effects develop. For example, giving rifampin, a typical inducer of CYP3A4, for only a few days is unlikely to have much effect on substrates of CYP3A4, as induction of an enzyme takes weeks to occur.

In summary, there is pharmacodynamic and pharmacokinetic variability between people, as well as host variability in terms of disease state. Overall, this variability contributes to confusion, as tables and lists that outline potentially interacting medications vary amongst different sources. One reason is that various levels of evidence exist for many of these drugs in terms of their ability to contribute to/cause drug interactions. This is outlined in more detail in the next section.

LEVELS OF EVIDENCE

Drug interaction literature is often confusing due to poorly substantiated claims[21]. This confusion occurs as a result of inaccurate or cursory evaluations of published cases or inappropriate extrapolations from the literature. Metabolic drug interactions are a major source of potential clinical problems, but their investigation during drug development is often incomplete. *In vitro* studies give very accurate data on the interactions of drugs with selective CYP isozymes, but their interpretation in the clinical context is difficult. Although *in vitro* systems have been developed to test the effects of certain drugs on the metabolism of other drugs, these systems may not accurately predict the effect in patients receiving drugs with complex metabolism. Also, problems with the detection of adverse events after a drug has been released arise mainly because such events are rare. It takes a surveillance system with a high degree of sensitivity to detect such problems[22].

Furthermore, most *in vivo* and *in vitro* studies of drug interactions evaluate two-drug regimens, and the results may not apply to the multidrug regimens used clinically. This is especially true for a regimen consisting of three or more drugs with opposing effects on CYP3A4 metabolism. The lack of studies of multiple drug interactions provides little assistance to the prescribing physician, who is left to rely on adverse events or treatment failure to demonstrate whether an interaction has occurred. In addition, the design of *in vivo* studies is sometimes poor (choice of prototype substrate, doses, schedule of administration, number of volunteers), with the risk of minimizing the real potential for interaction. To link *in vitro* and *in vivo* studies, several authors have suggested using extrapolation techniques, based on the comparison of *in vitro* inhibition data with the active *in vivo* concentrations of the inhibitor. However, the lack of knowledge with regard to one or several important parameters, such as the role of metabolites and intrahepatocyte accumulation, often limits the ability to make safe and accurate predictions.

The uncertainty and inaccuracy of predicting the extent and duration of *in vivo* drug interactions currently stems from a lack of definitive models by which to assess likely substrate and inhibitor concentrations at the active site of metabolism. Additional issues contributing to the uncertainty of predicting drug interactions include assumptions of the contribution of presystemic drug extraction and the effect of inhibitors on the processes involved. As a consequence, these methods are useful for complementing *in vivo* studies and helping to design clinically relevant *in vivo* studies, but in the foreseeable future they will not totally replace *in vivo* investigations.

ABSORPTION

Interactions that alter the absorption of drugs often lead to dramatic changes in plasma drug concentrations. Drug interactions within the GI tract can result in decreased absorption. This reduces the bioavailability or the amount of drug available to the systemic circulation and results in subtherapeutic serum concentrations. The underlying mechanisms of most drug interactions that alter GI absorption involve: (1) the formation of drug complexes that reduce absorption; (2) alterations in gastric pH; and/or (3) changes in GI motility that alter transit time[23].

Common drugs that form complexes with other drugs include antacids, sucralfate, and bile acid-binding resins used to lower cholesterol

levels (e.g. cholestyramine) (Table 131.2). A significant interaction occurs between multivalent cations – such as calcium, aluminum, iron and magnesium – and tetracyclines or fluoroquinolone antibiotics. For example, there is an 85% reduction in the absorption of ciprofloxacin when ingested 5–10 minutes after a dose of an aluminum hydroxide/magnesium hydroxide antacid[24]. These interactions can be easily avoided by administering the fluoroquinolone at least 2 hours before or 6 hours after the antacid. Alendronate, as well as other bisphosphonates prescribed for the prevention and treatment of osteoporosis, forms complexes with cations and several other drugs, thereby further decreasing their already low oral absorption. Once-weekly dosing reduces the opportunity for bisphosphonate-related interactions. When mycophenolate mofetil and iron preparations were administered concomitantly, a significant decrease in mycophenolate mofetil absorption was observed (Fig. 131.1)[25].

Drugs that increase gastric pH, such as proton pump inhibitors, antacids and H_2 antihistamines, may reduce the absorption of drugs such as ketoconazole and itraconazole, which are best absorbed in an acidic environment[26]. Although itraconazole is best absorbed when the gastric pH is low, its administration with food is more important for achieving high plasma concentrations[27]. The absorption of fluconazole is unaffected by variations in gastric pH. Drugs that affect GI motility, such as anticholinergic agents, may decrease the rate of absorption but not the extent of absorption. An overall reduction in drug absorption has more clinical significance[28].

Some drugs may interfere with the enterohepatic recirculation of a substrate drug. When the substrate is excreted into the GI tract, a second drug can bind to it and prevent its reabsorption back into the systemic circulation. The bound substrate drug is excreted in the feces, thereby effectively shortening its half-life. An example of this is the concurrent administration of warfarin and cholestyramine, in which the half-life of warfarin is shortened by oral cholestyramine.

DRUG INTERACTIONS THAT REDUCE THE EFFICACY OF SUBSTRATES

Mechanism	Substrate/ parent drug	Concomitant drugs	Time course
Reduced GI absorption	Itraconazole Ketoconazole	Antacids* Didanosine H_2 antihistamines Proton pump inhibitors Sucralfate	Rapid
	Fluoroquinolones	Antacids* Iron Sucralfate	
	Tetracycline	Divalent cations Calcium Magnesium Iron	
	Dapsone Mycophenolate mofetil	Didanosine Iron	
Induction of CYP3A4†	Calcineurin inhibitors Cyclosporine Tacrolimus Oral contraceptives Prednisone Warfarin	Anticonvulsants Carbamazepine Phenytoin Phenobarbital Antituberculous agents Isoniazid Rifampin Dexamethasone Griseofulvin	1–2 weeks
Antagonistic effects	Epinephrine Cyproheptadine	β-Blockers SSRI antidepressants Fluoxetine Paroxetine	

*Often contain aluminum hydroxide, magnesium hydroxide and/or calcium carbonate.
†Also A5, A7.

Table 131.2 Drug interactions that reduce the efficacy of substrates. In addition, bile acid-binding resins (e.g. cholestyramine, colestipol) dramatically reduce GI absorption of furosemide and thiazide diuretics and absorption of bisphosphonates is reduced by divalent cations. GI, gastrointestinal; SSRI, selective serotonin reuptake inhibitors.

P-glycoprotein (PGP)

Membrane-bound transport systems may also determine drug disposition[29]. PGP is an ATP-dependent plasma membrane glycoprotein (Fig. 131.2) belonging to the superfamily of ATP-binding cassette transporters[30]. In humans, the multidrug resistance (MDR) genes, including *MDR1*, encode membrane glycoproteins that function as drug transporters and hence affect both drug absorption and elimination. High levels of PGP are found in superficial columnar epithelial cells of the small intestine, the apical surface of epithelial cells in the proximal tubules of the kidney, and in the biliary canalicular membrane of hepatocytes. PGP is also detected in high concentrations in the endothelial cells of the capillaries of the blood–brain barrier, testes, uterus and placenta. An understanding of the physiologic regulation of these transporter proteins is key to designing strategies for improving the therapeutic efficacy of drugs that serve as their substrates (Table 131.3).

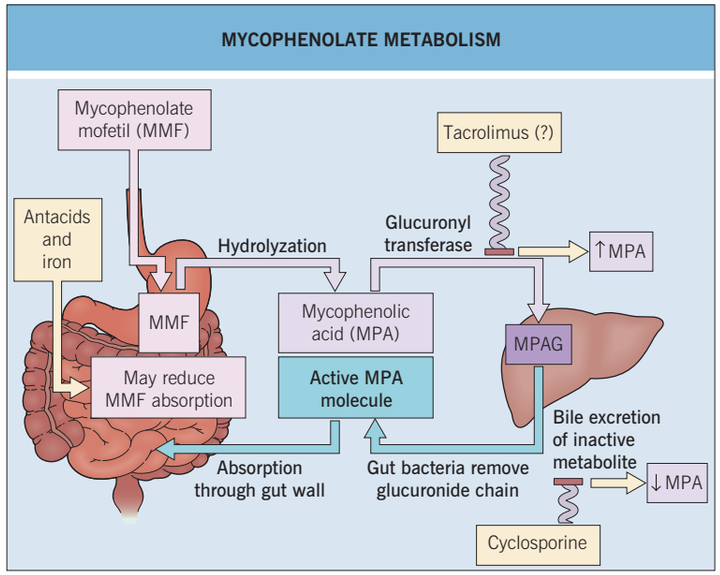

Fig. 131.1 Mycophenolate metabolism. Mycophenolate is hydrolyzed to mycophenolic acid (MPA). Following glucuronidation in the liver, inactive MPA glucuronide (MPAG) is excreted into the gut via bile acid secretion. In the gut, bacteria remove the glucuronide chain to produce MPA, the active molecule, which is then reabsorbed through the gut wall. Cyclosporine impairs MPA enterohepatic recirculation by inhibiting biliary excretion of MPAG (thereby *decreasing* MPA levels), whereas tacrolimus may inhibit UDP-glucuronyl transferase (thereby *increasing* MPA levels).

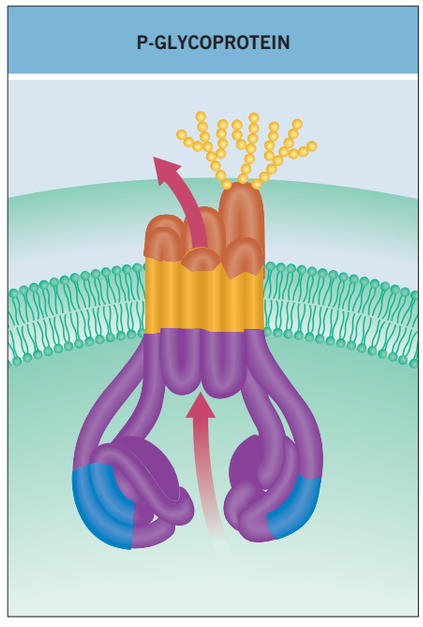

Fig. 131.2 P-Glycoprotein. This is an ATP-dependent plasma membrane glycoprotein that functions as a drug transporter and hence affects both drug absorption and elimination. *Adapted from Kartner N, Ling V. Scientific American 1989;260:44–51.*

P-GLYCOPROTEIN SUBSTRATES		
ANTIMICROBIALS	**HIV PROTEASE INHIBITORS**	**CARDIAC AGENTS**
Ciprofloxacin	Indinavir	Amiodarone
Erythromycin	Nelfinavir	Atorvastatin
Ivermectin	Ritonavir	Digoxin
Other quinolones	Saquinavir	Diltiazem
Rifampin		Lovastatin
	ANTIEMETICS	Nadolol
ANTICANCER AGENTS	Domperidone	Pravastatin
Actinomycin D	Ondansetron	Propranolol
Daunorubicin		Quinidine
Docetaxel	**RHEUMATOLOGIC AGENTS**	Timolol
Doxorubicin	Colchicine	Verapamil
Etoposide	Methotrexate	
Mitomycin C	Quinine	**MISCELLANEOUS**
Paclitaxel		Cimetidine
Vinblastine	**IMMUNOSUPPRESSIVES**	Lidocaine
Vincristine	Cyclosporine	Loperamide
	Tacrolimus	Terfenadine*

*Historical.

INHIBITORS OF P-GLYCOPROTEIN		
ANTIMICROBIALS	**PSYCHOTROPIC AGENTS**	**CARDIAC AGENTS**
Clarithromycin	Amitriptyline	Amiodarone
Erythromycin	Chlorpromazine	Carvedilol
Itraconazole	Desipramine	Diltiazem
Ivermectin	Disulfiram	Dipyridamole
Ketoconazole	Doxepin	Felodipine
Mefloquine	Fluphenazine	Nicardipine
Ofloxacin	Haloperidol	Nifedipine
Rifampin	Imipramine	Propranolol
Voriconazole		Propafenone
	STEROID HORMONES	Verapamil
IMMUNOSUPPRESSIVES	Progesterone	
Cyclosporine	Testosterone	**MISCELLANEOUS**
Tacrolimus		Grapefruit juice
		Orange juice isoflavones
		Ritonavir
		Tamoxifen

Table 131.4 Inhibitors of P-glycoprotein.

These membrane-bound transport systems appear to have developed as a mechanism for protecting the body from harmful substances. It appears that PGP acts as a pump whereby the efflux of drugs from the cell membrane or cytoplasm is powered by the energy from ATP hydrolysis. For example, the aminoglycoside antibiotics amikacin and tobramycin are not effectively delivered orally, perhaps because of active efflux from the brush border cells of the small intestine by the PGP pump. The most remarkable property of PGP is its ability to transport a diverse array of compounds that do not appear to share obvious structural characteristics. The range of substrates, inhibitors and inducers of PGP is vast and expanding (Tables 131.3 & 131.4).

Because PGP blocks absorption in the gut, these glycoproteins should be considered part of the "first-pass effect". In fact, PGP can "set up" or act as "gatekeepers" for later cytochrome P450 actions. Although the inhibition and induction of intestinal CYP3A enzymes from metabolic processes result in direct changes in drug absorption, the inhibition and induction of PGP primarily affects the rate of drug absorption[31]. If one drug is a substrate of both PGP and CYP3A4 (which are found in close proximity in the intestinal wall), and a second drug is added that is an inhibitor of both PGP and CYP3A4 (e.g. ketoconazole, erythromycin), then a greater amount of the first drug will be absorbed. Because CYP3A4 is inhibited, higher levels of *unmetabolized* drug will enter the blood. The effect of PGP blockade is to "open the gates" so that the later actions of CYP3A4 inhibition will be increased.

PGP is an important component of the blood–brain barrier and an active PGP will prevent drugs from entering the brain. It has been suggested that the reason newer antihistamines do not cause sedation is that PGP activity acts as a barrier to CNS penetration. This would suggest that PGP inhibitors (see Table 131.4) could interact with and allow increased cerebral concentrations of these antihistamines, with an attendant increase in sedation[32].

Evidence also suggests that intestinal PGP plays a significant role in the first-pass elimination of cyclosporine, probably by being a rate-limiting step in absorption. Intestinal CYP3A4 is thought to play a lesser role[33]. However, the overlap of tissue distribution and substrate specificity of CYP3A4 and PGP in the intestinal wall makes it difficult to define the precise mechanisms of some drug interactions and to predict the plasma concentrations of certain drug combinations. Moreover, the involvement of CYP3A4 and PGP in drug interactions is not always complementary.

DISTRIBUTION

Drugs that are highly protein bound (>90%) may cause interactions based on alterations in distribution. When one drug displaces another from plasma protein-binding sites, the free serum concentration of the displaced drug is increased and its pharmacologic effect increases. However, the unbound fraction of the drug is not only more available to sites of action but is also more readily eliminated. Any enhanced pharmacologic effect occurs only transiently because of a compensatory increase in elimination, and the *effect of displacement interactions is then negligible*. Therefore, interactions involving drug displacement from binding proteins tend to be self-limiting[34]. Typically, the pharmacologic activity of the displaced drug is increased for a few days. This is followed by a return of the pharmacologic response back to the previous unbound serum concentration, even if the concomitant therapy is continued. Therefore, it is safe to say that if a patient does not manifest an adverse event from the combination therapy in the first week or so of administration, an adverse event probably will not occur.

In practice, protein-binding displacement interactions do not produce clinically important changes in drug response unless the drug also has a limited distribution in the body, is slowly eliminated, or has a low therapeutic index[28]. For this reason, protein-binding displacement interactions may assume greater importance when the displacing drug also reduces the elimination of the substrate drug. A good example of this principle involves interactions between NSAIDs and methotrexate (Table 131.5).

Medications that are most susceptible to interactions based on changes in drug distribution involving displacement from binding proteins include warfarin, sulfonamides and phenytoin[11].

DRUG BIOTRANSFORMATION

Cytochrome P450 Enzymes

After their administration, drugs are metabolized through a series of reactions to enhance their hydrophilicity and to facilitate excretion. These drug biotransformation reactions are broadly grouped into two phases, I and II. Phase I reactions involve intramolecular changes such as oxidation, reduction and hydrolysis that make the drug more polar and therefore more readily eliminated. Phase II reactions are conjugation reactions in which an endogenous substance combines with the functional group derived from phase I reactions to produce a highly polar drug conjugate that can be even more readily eliminated. These reactions involve glucuronidation and sulfation.

The cytochrome P450 (CYP) enzymes are the major drug-metabolizing enzymes (Fig. 131.3). They are present in the endoplasmic reticulum of many cells but the their highest concentrations are found in hepatocytes[35]. CYP enzymes are also present in the crypt cells of the GI tract, with the highest concentrations found in the enterocytes at the tips of the villi; their presence accounts for the first-pass metabolism of many drugs. These heme-containing proteins are encoded by a gene superfamily, with the encoded isoforms exhibiting distinct but overlapping substrate specificities and isoform-specific regulatory and pharmacogenetic properties[36]. The nomenclature employs a three-tier classification consisting of the family (40% homology in amino acid

sequence), the subfamily (77% homology) and the individual protein (e.g. CYP2D6).

An increased understanding of CYP drug metabolism has solved much of the mystery behind drug interactions. While there are approximately 60 genes that encode CYP isoforms, over 90% of drug oxidation can be attributed to six main cytochromes: CYP1A2, 2C9, 2C19, 2D6, 2E1 and 3A4[37]. The metabolism of a drug by a specific isoenzyme indicates that it is a substrate for that enzyme. *Whether enzyme inhibition or induction occurs is an entirely separate issue*. Many drugs serve only as substrates and produce no significant enzyme inhibition or induction. It is entirely possible for a drug to be a substrate for one enzyme and inhibit or induce another enzyme that is not involved with its own metabolism. Therefore, drug interactions are more aptly termed drug–protein–drug (food) interactions. These are affected by genetics (polymorphic genes cause particular enzymes to be less effective, 2D6 being an example), drugs (a drug may inhibit or induce a cytochrome, or interfere in the chemical pathway of another drug, e.g. ketoconazole reduces cyclosporine metabolism by inhibiting CYP3A4), chemicals (dioxin is an inducer of CYP3A4 while a food such as grapefruit juice is an inhibitor of CYP3A4) and the environment (cigarette smoke is an inducer of CYP1A2). Deciding what is clinically relevant is a challenging, relatively new field of investigation.

Drug metabolism is investigated even before human exposure. With recombinant human CYP enzymes, it is possible to determine the metabolic pathways, potential genetic polymorphisms, ability to induce or inhibit drug metabolism, and possible drug interactions. Although there are limitations to the information gleaned from *in vitro* studies, nonetheless this information can be used to guide more expensive *in vivo* studies.

However, using *in vitro* tests that focus on cytochrome enzymes alone to predict clinical interactions may not always be reliable for a variety of reasons. First, it is not always possible to know the therapeutic concentration of a new drug and its primary metabolites in specific tissues[29]. Second, there are a large number of pathways and interactions, and it is impossible to test them all even in an *in vitro* system. Third, the demonstration of an *in vitro* effect does not tell physicians whether that effect is likely to occur in clinical practice, i.e. the clinical significance of an *in vitro* interaction is unknown. Fourth, the underlying disease state may contribute to the development of a drug interaction and this would be unaccounted for by *in vitro* studies alone. Until clinical data demonstrate the presence or absence of a clinically significant interaction, dosage adjustments are premature[38].

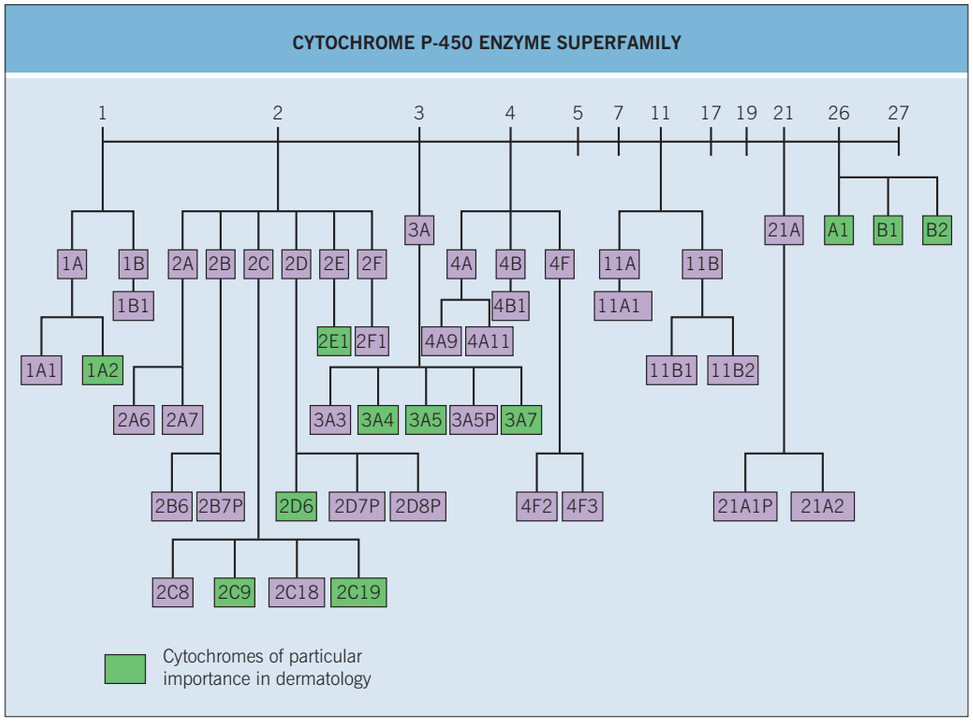

Fig. 131.3 Cytochrome P450 enzyme superfamily.

THE CONFUSING WORLD OF DRUG INTERACTIONS

Why does it take so long to learn about interactions? Some drugs come to market and their various interactions are not realized for several years. One reason is that drugs are prescribed on the basis of indications that may have their own adverse effects on patient outcome. Also, studies in healthy volunteers are not sufficient to determine the contribution of underlying diseases to the development of interactions. The latter are affected by genetics, drugs, chemicals, the underlying health status of the patient, the therapeutic index of the drug affected by the interaction, dose-related factors, the duration of coadministration, the time course of the interaction, whether active metabolites are involved, and the environment (Table 131.6). In addition, the multiple metabolic pathways of some drugs can make it difficult to predict the outcome of drug interactions.

Metabolism

The most clinically relevant drug interactions are those caused by alterations in drug metabolism, and CYP isoenzymes are the key players in drug metabolism. Members of the CYP3A subfamily are the most abundant of the human hepatic cytochromes and account for up to 70% of GI cytochromes. This subfamily contains the major metabolizing isoforms for many of the drugs prescribed by dermatologists (Tables 131.2, 131.5, 131.7 & 131.8; Fig. 131.4). CYP3A4 in particular has a pivotal role in xenobiotic metabolism and has been estimated to be involved in the metabolism of approximately 50% of the drugs in clinical use[1]. Although the most important isoform is 3A4, there is close structural homology to 3A5 and 3A7 and so these three isoforms are grouped together. Of note, CYP3A4 is also located in the placenta, uterus, kidney, lung and fetus.

INFLUENCES ON CYTOCHROME P450 ACTIVITY

	Cytochrome P450 activity				
	1A2	2C	2D6	2E1	3A4

Smoking	↑				
Alcohol				↑	
Drugs	↑ or ↓	↑ or ↓	↑ or ↓		↑ or ↓
Environmental factors	↑			↑	↑
Genetics		↑ or ↓	+		

Table 131.6 Influences on cytochrome P450 activity.

There is significant interindividual variability in the metabolic activity of CYP3A4. The extent of variability may be as much as 20-fold and the individual level of CYP3A4 activity probably has clinical relevance. Obesity also plays a role in drug metabolism in an enzyme-specific way[39] as it decreases isoform 3A4 metabolism (see Table 131.6), and 33% of Americans are obese.

The successful application of information regarding CYP to prevent drug interactions and improve the therapeutic risk:benefit ratio can occur only if we know which enzyme is responsible for the metabolism of a particular drug. Drug interactions are also made more predictable by determining which compounds induce and inhibit which specific P450 enzymes. While knowing all of the major enzyme substrates, inhibitors and inducers is a formidable task, Tables 131.7 to 131.10 are intended to summarize large amounts of this information.

Cytochrome induction

Many enzymes involved in drug biotransformation, including CYPs, are able to increase in amount and activity in response to substances known as inducers. The onset and offset of enzyme induction is *gradual* because the induction phase depends on the accumulation of the particular inducing agent and the subsequent synthesis of new enzyme. The offset depends on elimination of the inducer and decay of the increased enzyme levels.

Inducers may enhance parent drug metabolism, so that therapeutic efficacy is actually reduced if the parent drug is the active moiety (Fig. 131.5). Alternatively, inducers may enhance the metabolism of a substrate to active metabolites, with the potential for exaggerated toxicity. For example, the alkylating agent cyclophosphamide is a prodrug that requires metabolic activation to phosphoramide mustards for its therapeutic effect. Unfortunately, metabolic activation also leads to the formation of acrolein, which causes the bladder toxicity seen with this medication[42].

Cytochrome inhibition

Inhibition of drug metabolism is the most important mechanism for drug interactions because it can lead to an increase in plasma drug concentration, enhanced drug response, and toxicity. In contrast to the time course seen with enzyme induction, inhibition of drug metabolism begins within the first one or two doses of the inhibitor and is maximal when a steady-state concentration of the inhibitor is achieved. Therefore, the time course for inhibitory actions is usually in terms of *days* not weeks.

Inhibitory interactions can be either competitive or non-competitive. An example of *competitive* inhibition involves the tight binding of inhibitors such as ketoconazole, cimetidine and macrolides to the heme moiety of the cytochrome P450 isozyme. As long as the inhibitor occupies this specific site of the CYP, the substrate cannot be biotransformed[43]. As the concentration of the inhibiting drug increases, the degree of saturation of the isoenzyme increases. When the enzyme

system is saturated, further metabolic activity by that enzyme system is limited. At that point, a patient becomes the equivalent of a poor metabolizer and concentrations of co-prescribed medications begin to rise. The extent of inhibition of one drug by another depends on the affinity each compound has for the CYP isoform. In addition to the concentration of substrate required to saturate the system and the half-life of the inhibitor drug, competitive inhibition clearly depends on the affinity of the substrate for the enzyme being inhibited. The onset and offset of enzyme inhibition are dependent on the half-life and time to steady state of the inhibitor.

The significance of an elevated plasma level of a particular drug is determined largely by the therapeutic margin of the drug. Therefore, when considering the potential clinical relevance of an interaction, one must exercise more caution with drugs that have a narrow therapeutic range. Non-competitive inhibition is less common and occurs when the enzyme is destroyed, inactivated, or changed by the inhibitor such that it can no longer metabolize the original substrate.

HOW TO MINIMIZE THE RISK OF DRUG–DRUG INTERACTIONS

One commonly perpetuated myth is that all drugs in a given class are equally susceptible or contributory to drug interactions. Understanding the differences between drugs in a particular class with regard to potential for drug interactions is clinically relevant. Specific drugs, from a given class of drugs associated with interactions, may have little or no clinical potential for drug interactions and are therefore safer choices (Table 131.11).

Various drug classes commonly encountered by dermatologists will be discussed, with emphasis on important interactions and ways to minimize risks by appropriate drug choices within a given drug class.

Allylamine Antifungals

Terbinafine is an orally active allylamine antifungal used in the treatment of dermatophytoses. Reports suggest some degree of significant inhibition of CYP2D6 and CYP1A2 by terbinafine[44]. There are three principal levels of activity of CYP2D6 in the general population: poor metabolizers (PM), extensive metabolizers (EM) and ultrarapid metabolizers. The EM status is by far the most common and is considered "normal". Approximately 7.5% of Caucasians and <2% of Asians and African-Americans are poor metabolizers. Inhibition of CYP2D6 by terbinafine would make individuals who have active enzyme (extensive metabolizers) into poor metabolizers, and this effect could possibly last for weeks after discontinuing terbinafine. This can cause two problems: there may be an accumulation of the parent drug (substrate), and this can result in dose-dependent drug toxicity, or there can be reduced formation of active metabolites, and this can result in loss of efficacy (see Fig. 131.5)[45].

For now, terbinafine appears to be a potent inhibitor of CYP2D6, and so clinicians should be aware of potential interactions (see Table 131.10). The area of greatest concern, because of possible severity and common use, would be bradycardia from excess *β-blockade* (e.g. propranolol) or from the accumulation of *donepezil* (used to treat Alzheimer's disease)[46]. Codeine could lose its analgesic effect, as the active metabolite, morphine, is not formed when CYP2D6 activity is low[47].

DRUG-METABOLIZING ENZYMES CYP1A2, 2C9 AND 2C19: SELECTED SUBSTRATES, INHIBITORS AND INDUCERS

Table 131.10 Substrates and inhibitors of CYP2D6[40,41]. Drugs in bold italics are particularly potent inhibitors.

Azole Antifungals

The imidazole ketoconazole and the triazole itraconazole require an acid milieu for absorption; therefore, concomitant *antacids, H_2 blockers, proton pump inhibitors, sucralfate* and *didanosine* significantly reduce absorption (see Table 131.2). The administration of these agents with carbonated cola beverages will acidify (pH <3) the stomach, thereby improving absorption of the antifungal drug. Fluconazole and voriconazole are alternatives for patients in whom drugs that reduce gastric acidity are required, as these antifungal medications do not rely on an acid milieu for absorption.

Among the systemic azole antifungals, ketoconazole has been shown *in vitro* to be the strongest inhibitor of CYP3A4. Many substrates are metabolized via these enzymes (see Tables 131.2, 131.5, 131.7), and moderate to severe drug interactions have been observed with several substrates, including *cyclosporine*, *warfarin* and *phenytoin*. Itraconazole is contraindicated when the patient is also receiving the following CYP3A substrate drugs: *triazolam*, *oral midazolam*, *lovastatin*, *simvastatin*, *quinidine*, *pimozide* or astemizole (historical). Caution has been suggested with *warfarin, cyclosporine, digoxin* and atorvastatin. Significant effects on the metabolism of fluvastatin or pravastatin by itraconazole do not appear to occur[48] (see Table 131.11). Fluconazole inhibition of CYP3A4 is dose-related: 100 mg/day usually has little effect on CYP3A4, but inhibition can occur at daily doses of 200–400 mg (or more), depending upon the substrate.

When the azole antifungals are administered with cyclosporine, the concentrations of the latter are increased, requiring careful monitoring of cyclosporine levels. Similarly, frequent monitoring of the INR is required for patients on warfarin who require therapy with an azole antifungal. The azole antifungals reportedly increase the anticoagulant effects of warfarin by two- to threefold. In one study, *phenytoin* concentrations were significantly increased 48 hours after fluconazole administration (400 mg daily), owing to a 33% decrease in the clearance of phenytoin[49].

Azole antifungals also interfere with the metabolism of benzodiazepines such as triazolam and midazolam, leading to increased levels and sedation. There is also decreased metabolism of some of the HMG-CoA reductase inhibitors, e.g. lovastatin and simvastatin, leading to increased levels, as well as to rhabdomyolysis. Additional drugs whose metabolism is decreased by azoles include *tacrolimus, indinavir* and *calcium channel blockers*. Peripheral edema due to an interaction between nifedipine and itraconazole has been reported. It was suspected that itraconazole inhibited the metabolism of this calcium channel blocker, resulting in an increased serum nifedipine concentration and leg edema. This hypothesis was confirmed by obtaining serum levels of nifedipine, itraconazole and hydroxyitraconazole (the active metabolite of itraconazole) before and after the administration of itraconazole[50]. The authors recommended that patients receiving both azole or triazole antifungals and calcium channel blockers be monitored for side effects such as leg edema and, more importantly, hypotension, because of the increased serum concentration of the calcium channel blocker.

Fluconazole, but not itraconazole, interacts with *losartan*, an angiotensin II receptor antagonist antihypertensive. Fluconazole inhibits losartan's metabolism to the active metabolite E-3174[51]. The clinical significance of this interaction remains unclear, but the possibility of a reduced therapeutic effect of losartan should be borne in mind. Phenytoin is also a CYP2C9 substrate, and concurrent fluconazole use at bedtime has resulted in several cases of phenytoin toxicity[52].

In contrast to the azole antifungals, terbinafine is an allylamine that does not inhibit CYP3A4[53]. This antifungal may be a viable therapeutic option in patients on concomitant therapy with a high likelihood of drug interactions with the azoles.

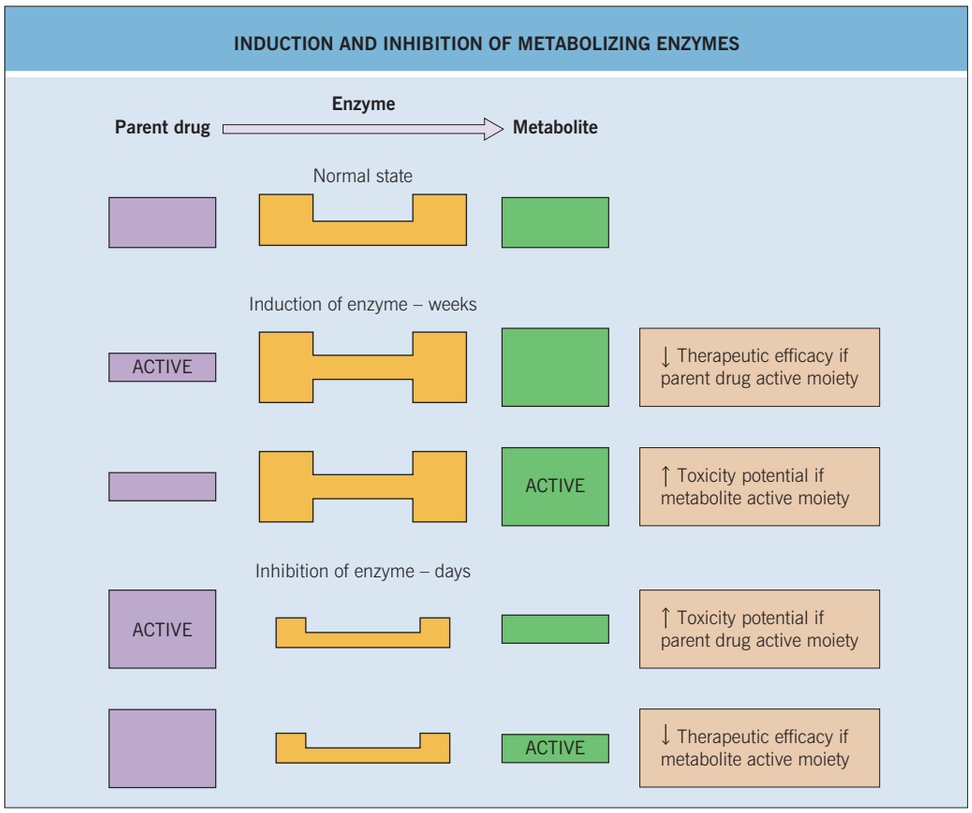

Fig. 131.5 Induction and inhibition of metabolizing enzymes.

DRUGS AND FOODS WITH DIFFERING POTENTIAL FOR DRUG–DRUG INTERACTIONS BASED ON METABOLISM

Drug/food class	More potential for interaction	Less potential for interaction
ACE inhibitors and angiotensin II receptor blockers (ARBs)	NSAIDs	Acetaminophen Celecoxib
Antifungals	Azoles and triazoles (CYP3A4 inhibition)	Terbinafine
Calcium channel blockers	Diltiazem Nicardipine Verapamil	Amlodipine Nifedipine
Macrolides	Clarithromycin Erythromycin	Azithromycin
Quinolones	Ciprofloxacin Enoxacin	Levofloxacin Lomefloxacin Ofloxacin
H_2 blockers	Cimetidine	Famotidine Nizatidine Ranitidine
Protease inhibitors	Ritonavir (most potent) Indinavir	Saquinavir Nelfinavir
HMG-CoA reductase inhibitors	Simvastatin Lovastatin Cerivastatin	Pravastatin Fluvastatin Rosuvastatin
Citrus fruit juice	Grapefruit juice	Orange juice

Table 131.11 Drugs and foods with differing potential for drug–drug interactions based on metabolism. ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

Azathioprine

Azathioprine is metabolized to 6-mercaptopurine (6-MP) and there are three subsequent pathways for the metabolism of 6-MP. Both thiopurine methyltransferase (TPMT) and xanthine oxidase metabolize 6-MP to inactive metabolites, whereas hypoxanthine-guanine phosphoribosyltransferase (HGPRT) metabolizes 6-MP to active purine analogues, in particular 6-thioguanine (see Fig. 130.3). *Allopurinol* and *febuxostat* inhibit the metabolism of 6-MP via xanthine oxidase; this leads to increased levels of 6-MP (plus active purine analogues via HGPRT) and, as a result, increased antimetabolite effects and associated toxicity. Combining either azathioprine or 6-MP with allopurinol or febuxostat should be avoided. If the latter must be used, an alternate immunosuppressant should be selected.

Colchicine

Colchicine is a substrate of PGP and concurrent use of PGP inhibitors has resulted in severe colchicine toxicity. It is also a substrate for CYP3A4, so inhibitors of this enzyme may result in increased plasma concentrations of colchicine. Given the possibility of fatal colchicine toxicity, few situations would warrant the concomitant use of colchicine with a *CYP3A4 or PGP inhibitor*. However, if this combination must be prescribed, careful monitoring for colchicine toxicity (diarrhea, abdominal pain, fever, muscle pain or weakness, paresthesias) should be performed. If toxicity is suspected, both drugs must be discontinued immediately. Of note, grapefruit juice is an inhibitor of both PGP and CYP3A4 and colchicine toxicity has been reported with the intake of large amounts of grapefruit juice.

Cyclosporine/Sirolimus/Tacrolimus

Numerous drug interactions with cyclosporine have surfaced that are associated with its metabolism and presystemic metabolism (both by the CYP3A4 enzyme and by PGP), in the liver and intestine, respectively. It is thought that this GI tract metabolism may explain its erratic absorption. In fact, potent 3A4 inhibitors have been administered intentionally to improve cyclosporine's bioavailability, thereby reducing dosing requirements and lowering overall drug costs. *Ketoconazole* (200–400 mg/day) can decrease the required daily dose of cyclosporine by 60–80%[54].

Diltiazem can decrease cyclosporine dosing by as much as 30%[55], while effects with *grapefruit juice* have been variable. Other drugs that alter cyclosporine concentrations via cytochrome 3A4 inhibition include other calcium channel inhibitors (*verapamil*, *nifedipine*), triazoles and imidazoles (*fluconazole*, *itraconazole*, *ketoconazole*), macrolides (*erythromycin*, *clarithromycin*) and *tacrolimus*. Conversely, isoform 3A4 inducers, such as *rifampin*, *phenytoin*, *carbamazepine* and *phenobarbital*, decrease cyclosporine concentrations. More recently, decreased

cyclosporine levels have been observed with coadministration of *troglitazone* or *ticlopidine*[56]. Cyclosporine trough levels, as well as signs of toxicity versus adequate immunosuppressive response, should be monitored when any of these drugs are combined with cyclosporine.

Grapefruit Juice

Grapefruit juice interactions are of potential clinical relevance for a wide range of drugs. The mechanisms of grapefruit juice interactions are exclusively pharmacokinetic in nature. The effect is mediated mainly by the suppression of CYP3A4 and PGP in the small intestinal wall by either fresh or frozen grapefruit juice[57] (see Fig. 131.4). This results in a diminished first-pass metabolism, with higher bioavailability and increased maximal plasma concentrations of substrates of this transporter and/or enzyme. The effect is most pronounced in drugs with high first-pass degradation, such as *felodipine*, *nifedipine*, *saquinavir*, *cyclosporine*, *midazolam*, *triazolam*, *terazosin*, *ethinylestradiol*, *17β-estradiol*, *prednisone*, and the HMG-CoA reductase inhibitors *lovastatin* and *simvastatin*[58,59].

It is not yet clear which component in grapefruit juice is to blame. Psoralen, mainly a bergamottin compound, is thought to be the major inhibitor, with a minor role attributable to flavonoids such as naringenin and quercetin[60]. Even a change in the brand or batch of grapefruit juice may influence the grapefruit juice/drug interaction to an unpredictable degree, as grapefruit juice is a natural product that is not standardized in composition. Similar interactions have not been seen with other citrus fruit juices, such as orange juice. Lack of 6,7-dihydroxybergamottin in orange juice probably accounts for the absence of inhibitory effects[61]. However, isoflavones in orange juice may mediate this food's inhibitory effect on PGP.

The idea of using grapefruit juice as a cost-cutting measure has been used in patients on concomitant cyclosporine therapy[62]. It was thought that because grapefruit juice can inhibit the metabolism of cyclosporine, combining the two would lower the required daily dose of cyclosporine, thereby reducing drug costs. However, the difficulty is that grapefruit juice is not a standardized product. More recent studies have also demonstrated that grapefruit juice increases the bioavailability of saquinavir without affecting its clearance, suggesting that inhibition of intestinal CYP3A4 may represent a way to enhance effectiveness without increasing the dose[63].

However, in general, it is recommended that patients refrain from ingesting grapefruit juice when taking a drug that is extensively metabolized, unless a lack of interaction has been documented. Many hospital cafeterias now place warnings of the potential for drug interactions in areas where grapefruit juice is sold. Orange juice is a good alternative (see Table 131.11).

Herbal Remedies

Herbal medicines (see Ch. 133) have become a popular form of therapy. They are perceived to be "natural" by the public and thus harmless. Although many current therapeutic agents (including digitalis, atropine, vincristine and narcotic derivatives) have been derived from plants, little is known about the relative safety of current herbal therapies compared with prescription drugs, and even less is known when the two are co-consumed. Because of under-reporting, our present knowledge represents the tip of the iceberg. It is estimated that 80% of the world's population relies primarily on traditional medicines utilizing plant extracts or their active ingredients.

The interactions of phytomedicines with prescription medications are under-researched[64]. Because herbs are not sold as drugs, no proof of efficacy or warnings about side effects are required. When a drug is prescribed, the dosage and quality of the substance are assured. No such standardization or quality control exists for herbal preparations. Contamination, mislabeling and misidentification of herbs are also problems. Some patients do not know what they are taking, as they may purchase a product whose ingredients are listed in a foreign language only.

A study in 12 healthy volunteers examined the effect of the ingestion of *St John's wort* on cytochrome activity[65]. Short-term administration (less than 2 weeks) of St John's wort had no effect on CYP activity, whereas long-term St John's wort administration resulted in a significant and selective induction of CYP3A activity in the intestinal wall. St John's wort did not alter the activity of CYP2C9, CYP1A2 or CYP2D6. Reduced therapeutic efficacy of drugs metabolized by CYP3A should be anticipated during long-term administration of St John's wort.

When taking a history regarding medications, it is important to ask specifically about prescription, non-prescription and herbal therapies. Patients should tell their physician if they are using herbal remedies, in order to improve monitoring of side effects and potential interactions. See Table 131.12 for some important drug interactions between herbal medicines and dermatologic therapies.

HMG-CoA Reductase Inhibitors

Although dermatologists may not prescribe these lipid-lowering agents, their use by family physicians and specialists is so widespread that it is fairly common to encounter patients who are taking this class of drugs. To date, all reports of significantly increased rates of myalgias from combination therapy with a "statin" plus certain other drugs involve simvastatin or lovastatin. Notably, these are the statins with the highest known metabolic dependency on the CYP3A4 pathway for elimination[68]. Fluvastatin is metabolized via CYP2C9 and therefore is not expected to interact with CYP3A4 inhibitors, but may interact with 2C9 inhibitors. Pravastatin is not metabolized by CYP3A4, nor is it cleared by PGP to a clinically significant degree[69].

Macrolide Antibiotics

When a macrolide is required in a patient who is receiving systemic tacrolimus, azithromycin should be used (rather than erythromycin or clarithromycin) because this does not produce significant inhibition of CYP3A4[70]. When erythromycin is prescribed to a patient on long-term *warfarin*, there is a risk of increased plasma warfarin levels, with increased anticoagulation and hemorrhage. This occurs because *tacrolimus* and warfarin are CYP3A4 substrates and erythromycin is a

HERBAL REMEDIES/PRESCRIPTION DRUG INTERACTIONS

Herbal remedy	Side effects	Drug interaction
Zemaphyte (Chinese herbal therapy)	Diarrhea, transaminitis, reversible dilated cardiomyopathy, reversible acute hepatitis, fatal hepatic necrosis, worsening of atopic dermatitis, acute urticaria	Methotrexate
Coenzyme Q10[3]	Reduced efficacy of warfarin	Warfarin
Ginseng[66]	Can reduce the anticoagulant response of warfarin	Warfarin
Kava	CNS depressant	Alcohol, barbiturates, benzodiazepines, opiates
Licorice (*Glycyrrhiza glabra* or *uralensis*)	Contraindicated if hypertension, diabetes mellitus, hypokalemia, hepatic or renal disease	Cyclosporine, digoxin, prednisone, thiazides
Purple coneflower (*Echinacea angustifolia* or *purpurea*)	Recurrent erythema nodosum Caution in patients with HIV, autoimmune CTD, TB, MS, or ragweed/sunflower allergies	Immunomodulators and cyclosporine, methotrexate, corticosteroids
Ginkgo (*Ginkgo biloba*), garlic, ginger[67]	Can cause spontaneous bleeding	Can potentiate aspirin, digoxin, NSAIDs, warfarin, heparin
St. John's wort[3] (oral) (inducer of CYP2C19, CYP3A4 & P-glycoprotein)	Photosensitivity Erectile dysfunction	Cyclosporine, digoxin, nevirapine, oral contraceptives, erlotinib, imatinib, voriconazole

Table 131.12 Herbal remedies/prescription drug interactions. CNS, central nervous system; CTD, connective tissue disease; MS, multiple sclerosis; TB, tuberculosis.

potent inhibitor. As with azole antifungals, historically the coadministration of erythromycin and astemizole or terfenadine was associated with a risk of cardiotoxicity (prolongation of the QT interval, torsades de pointes).

Erythromycin also inhibits the metabolism of *sildenafil*, resulting in a significant increase in serum levels of sildenafil[71]. If concurrent administration is unavoidable, reduced doses of sildenafil and tadalafil are recommended. In addition, an interaction between erythromycin and *carbamazepine* has been well established[72]. Erythromycin significantly inhibits hepatic metabolism of carbamazepine; the interaction is highly predictable, develops with rapid onset, and may also occur with clarithromycin or troleandomycin[72]. Concurrent use should therefore be avoided.

Quinolone Antibiotics

In the GI tract, all fluoroquinolones interact with multivalent cation-containing products, and the bioavailability of the quinolone can be reduced by up to 50% when coadministered with *iron* compounds (ciprofloxacin and moxifloxacin are more affected than levofloxacin or gemifloxacin). There is also a significant decrease in the bioavailability of quinolones when given with *sucralfate*[72], and antibiotic treatment failure has been documented. If sucralfate cannot be discontinued, the quinolone should be taken 2–6 hours before the sucralfate. Similar decreases in bioavailability occur when a quinolone is given concurrently with an *antacid*[72]. The antacid should therefore be taken 6 hours prior to or 2 hours after the antibiotic.

Sparfloxacin is associated with cardiac manifestations in the form of QTc prolongation and has a high phototoxicity potential. While moxifloxacin can prolong the QT interval, it does not alter the QT dispersion (QT dispersion is thought to be a more sensitive predictor of the risk of torsades de pointes). As such, the increased risk of torsades de pointes attributable to moxifloxacin is questionable[73]. Levofloxacin has no QT prolongation and a very low phototoxic potential, making it one of the safest fluoroquinolones[74]. An enhanced anticoagulant effect of *warfarin* has been reported after coadministration with norfloxacin, ciprofloxacin, ofloxacin or enoxacin[56].

Pimozide

Pimozide is a neuroleptic that may be used for psychogenic dermatologic problems such as delusions of parasitosis. While newer drugs may replace pimozide (see Ch. 7), as long as it is still being prescribed, dermatologists must be aware of its drug–drug interactions. Case reports suggest that pimozide prolongs the cardiac QT interval and may lead to arrhythmias. Pimozide is oxidized by two CYP isoforms, CYP3A4 and CYP1A2, with the former being the responsible isoform at therapeutically relevant pimozide concentrations[75]. Pimozide is also an inhibitor of CYP2D6 without being a substrate of this isoform. Therefore, a greater risk of adverse effects is expected when pimozide is co-prescribed with metabolic inhibitors.

The risk of concomitant administration of CYP3A inhibitors with pimozide is highlighted by a report of fatal cardiac arrhythmias in patients taking pimozide plus clarithromycin[76]. To examine the latter interaction, investigators gave a single oral dose of pimozide with and without clarithromycin to 12 healthy subjects who were documented as either extensive or poor metabolizers with regard to CYP2D6[77]. Pimozide itself was capable of prolonging QT intervals, and pimozide concentrations were increased in the presence of clarithromycin; the average QT prolongation was longer when both drugs were taken. CYP2D6 activity, however, was not a factor.

In summary, patients who are at risk of ventricular arrhythmias because of prolonged QT intervals or electrolyte disturbances, or who take other drugs that affect QT intervals, should use pimozide with caution. Adding a CYP3A4 inhibitor such as *clarithromycin*, *erythromycin* or an *azole antifungal* may increase the risk of toxicity. A baseline assessment of the QT interval and reassessment 6 hours after a pimozide dose may be helpful in patients at risk who require pimozide.

Pharmacogenetics – Role of Polymorphisms

Cytochrome P450 enzymes

The genes encoding the CYP isoenzymes are highly polymorphic, and, as a result, the individuals within a general population have different levels of enzyme activity due to the presence of variant alleles. People with genetically determined low levels of activity are referred to as poor metabolizers. Those who have a functional enzyme are known as extensive metabolizers. There are yet others who have more than the usual complement of functional genes and more than the usual amounts of certain enzymes, and they are referred to as ultrarapid metabolizers. Still others have partially functional enzymes and are slower metabolizers than normal. Poor metabolizers may have a larger response and be at greater risk of toxicity than extensive metabolizers for drugs that are highly dependent on clearance to an inactive metabolite by the particular isoform[78]. On the other hand, ultrarapid metabolizers might not reach therapeutically active plasma concentrations of certain drugs, thereby not achieving the anticipated desired effect.

CYP enzymes that exhibit genetic polymorphisms include CYP1A2, CYP2C9, CYP2C19, CYP2D6 and CYP2E1 (Table 131.13). However, provocation tests are not routinely employed in clinical practice and unfortunately there are no clinical parameters that are useful in predicting the metabolizing status of a given individual. Molecular analysis of the genes that encode the key CYP isoenzymes can be performed, i.e. testing is commercially available, but this is also not routinely done.

Other drug-metabolizing enzymes

Pharmacogenetic variation can also occur in other drug-metabolizing enzymes. Pertinent to dermatologists, the enzyme thiopurine methyltransferase (TPMT) is important in the metabolism of azathioprine and 6-mercaptopurine to non-toxic metabolites. There is a 0.3% rate of homozygous deficiency of this enzyme, putting these patients at great risk for toxicity, especially myelosuppression[79]. Conversely, 88% of the population is homozygous for the active TPMT enzyme and may therefore require doses greater than the recommended daily dose of azathioprine (1–2 mg/kg/day) to achieve therapeutic success. Determination of the patient's TPMT level provides *a priori* information that allows the individualization of azathioprine dosing, thereby minimizing toxicity and maximizing efficacy.

Drug–Cytokine Interactions

Cytochrome P450 drug metabolism can be altered by certain proinflammatory cytokines, such as interleukin (IL)-6, IL-1 and tumor necrosis factor (TNF)-α[80]. These cytokines can cause a reduction in CYP3A function and they are released during periods of stress, trauma or infection, as well as administered as immunomodulators, in particular IL-2[81].

Drug–HIV Interactions

A recent review presents current information regarding drug interactions in patients with HIV infection[14]. For example, the coadministration of pimozide with most of the protease inhibitors or

PHARMACOGENETICS – IMPACT OF POLYMORPHISMS ON DRUG METABOLISM

Cytochrome P450 (CYP) isoenzyme	Frequency of poor metabolizers	Examples of drugs affected
CYP2C9	6–8%	Glyburide, warfarin, phenytoin
CYP2C19	3–5% of Caucasians 12–23% of Asians	Diazepam, omeprazole, pantoprazole
CYP2D6	6–10% of Caucasians 3–6% of Mexican-Americans 2–5% of African-Americans 1% of Asians	Codeine, imipramine, propafenone, metoprolol
CYP3A4	Under study	Numerous (probably 50% of drugs are metabolized by CYP3A4/5)

Table 131.13 Pharmacogenetics – impact of polymorphisms on drug metabolism.

delavirdine is contraindicated because of the risk of inducing ventricular arrhythmias. In addition, there are reports of adrenal suppression and iatrogenic Cushing's syndrome when patients on ritonavir-based antiretroviral therapy received inhaled, intra-articular and even topical corticosteroids[81a].

CONCLUSION

Dealing with drug interactions is a challenge in clinical practice. Although no one can be expected to know all drug interactions, good resources are available. One of the best pocket reference guides is *The Top 100 Drug Interactions* by Hansten and Horn (www.hanstenandhorn.com)[82]. This handbook is concise, up-to-date and, unlike most desk references, it is not limited by class-related statements that may falsely and unnecessarily restrict therapeutic options.

More research during the early stages of drug development is required to identify new interactions, define mechanisms of older interactions, and examine the safety of new drugs from classes that are known to cause interactions. We also need more sensitive post-marketing surveillance tools to identify important drug interactions that become evident over time in diseased hosts and that were not seen in pre-marketing studies of healthy volunteers. Physicians need better tools, but, in the meantime, understanding the nuances of the cytochrome P450s will help take the fright out of prescribing.

Because the best evidence for clinically relevant drug interactions comes from case reports, prescribing physicians can have a major impact. Observations of drug interactions should be confirmed, if possible, by serum drug concentrations. Then they should be reported to regulatory bodies and submitted to journals. By understanding the mechanisms behind drug interactions and staying alert for toxicities, we can help make drug therapy safer and reduce the fear of drug interactions.

Sunscreen regulation 2197
Mechanisms of sunscreen action 2199
Active ingredients in sunscreens 2199
Sunscreen efficacy 2201
Sunscreen safety 2203
Sunscreen recommendations 2203

Key features

- Modern sunscreens were first developed during the 1940s with the primary aim of preventing sunburn: today, sunscreens are also used to prevent other aspects of photodamage, including carcinogenesis and photoaging
- The active ingredients in sunscreens include inorganic agents (i.e. physical blockers) and organic compounds (i.e. chemical absorbers). The latter are further classified as UVB and/or UVA absorbers
- The ability of sunscreens to prevent cutaneous squamous cell carcinoma has been demonstrated in human studies. Their ability to prevent basal cell carcinoma and cutaneous melanoma remains controversial, although evidence supports efficacy in this regard
- Side effects from sunscreens include irritation (which is common) and allergy (which is rare)
- Sunscreen usage and sun avoidance may lead to a decrease in vitamin D levels in some individuals; optimum vitamin D levels can be achieved with a healthy diet and supplements

INTRODUCTION AND HISTORY

Sun Exposure

Evidence exists that even ancient civilizations sought protection from the damaging effects of the sun. The concept of excessive sun exposure as unhealthy or at least cosmetically unacceptable eventually spread to Northern Europe, especially among the aristocracy, and continued into the nineteenth century, until the period of the Industrial Revolution. In 1890, Palm noted that children in urban slums of England had rickets whereas those in similar housing conditions in sunny India did not, and linked the lack of sun to the development of rickets[1]. Physicians then began to treat such children with artificial UV radiation. At the same time, Finsen began to treat a number of other diseases, including tuberculosis and, interestingly, lupus erythematosus, with artificial light. He was awarded the Nobel Prize for his work in 1903. At the turn of the twentieth century, the image of tanned skin as aesthetically pleasing began to emerge. The French fashion designer Coco Chanel is often credited with developing the concept of tanned skin as beautiful that still persists today. However, the twentieth century also saw the recognition of sunburn as an effect of UVB, the discovery of UVC- and UVB-induced DNA mutations, and establishment of UVB as a complete carcinogen.

During the 1990s, dermatologists and other healthcare professionals made serious efforts to educate consumers regarding the damaging effects of excessive sun exposure as well as exposure to artificial tanning devices. Despite these efforts, recent studies show that while understanding of the adverse effects of exposure has increased, there has been very little positive change in behavior. This is especially true for adolescents, who continue to suffer sunburns and who continue to seek a tan through natural and artificial exposure. Over 20 million Americans go to tanning salons every year and sunscreen usage has actually been declining in some studies[2–4]. Achieving better compliance with sun protection will depend on a better understanding of behavior modification and techniques of disseminating the right message to consumers in an effective manner.

Sunscreens

Sunscreens are pharmaceutical preparations that attenuate UV wavelengths that would otherwise interact with molecules in the skin (chromophores) to generate photochemical reactions, leading to photobiologic change. These preparations are usually combinations of active agents or ingredients which absorb or scatter incident radiation, and they are dispersed in a variety of bases. The active ingredients are not absorbed in any large quantity into the living epidermis and dermis or the general circulation.

The first modern sunscreen was a product containing benzyl salicylate and benzyl cinnamate, which was introduced in the US in 1928. However, widespread use of sunscreens did not occur until World War II, when the US Military provided preparations containing red petrolatum to prevent sunburn in troops stationed in sunny areas. After the war, there was an increased interest in UV-absorbing chemicals, and para-aminobenzoic acid (PABA), patented in 1943, was the first of these to gain widespread usage. It was not until the mid-1970s that sunscreens gained a degree of consumer acceptance.

The initial sunscreens were produced primarily to prevent sunburn and therefore contained primarily UVB-absorbing agents. As scientific evidence grew documenting the deleterious effects of longer-wavelength UVA radiation and as manufacturers strove to develop higher levels of protection against burning, agents with absorption in the longer wavelengths (e.g. benzophenones) were combined with UVB absorbers. The physical blocking sunscreens (e.g. titanium dioxide) were used from the early days of sunscreen manufacturing, but, because of large particle size, were not cosmetically acceptable in high concentrations. Newer technology allowed for micronization of such particles, with an increase in transparency and therefore greater cosmetic acceptability. More recently, chemical agents with greater UVA absorption have been introduced (see below) and are gaining in popularity.

In addition to sunscreens for "beach" use, manufacturers also began to develop various cosmetics for daily use which contained sunscreen agents. Today, a wide array of sunscreen-containing preparations, including foundations, moisturizers and lipsticks, are commercially available. Another improvement in sunscreen products has been the development of agents with increased substantivity. Such agents, usually marketed as "sports" products, have bases which persist on the stratum corneum for longer than do the usual bases, allowing for vigorous outdoor activity and even swimming with retained photoprotection.

SUNSCREEN REGULATION

Since sunscreens alter the structure or function of skin, they are considered over-the-counter drugs in the US and are regulated by the Food and Drug Administration (FDA). Regulations include the maximum concentration of active ingredients, safety labeling, and the method for determining the sun protection factor (SPF).

Sun Protection Factor

The measure of efficacy of sunscreens is designated the sun protection factor (SPF), and the SPF is determined as outlined in Table 132.1. If

DETERMINATION OF THE SUN PROTECTION FACTOR (SPF)
• 10 human subjects • Skin type I or II • Instrumentation: light source which mimics solar spectrum • Procedure: determine minimal erythema dose (MED) in protected* and unprotected skin • $SPF = \frac{MED\ protected}{MED\ unprotected}$ • To test substantivity – *after application and before MED testing*: Water resistant (40): 2 × 20-min water immersions (whirlpool bath)† Water resistant (80): 4 × 20-min water immersions (whirlpool bath)†
*Sunscreen product applied at 2 mg/cm^2. †Air drying in between immersions.

Table 132.1 Determination of the sun protection factor (SPF).

RELATIONSHIP OF THE SUN PROTECTION FACTOR (SPF) TO BLOCKAGE OF ERYTHEMAL RADIATION	
SPF	**Blockage of erythemal radiation (%)**
10	90
15	92.5
20	95
40	97.5

Table 132.2 Relationship of the sun protection factor (SPF) to blockage of erythemal radiation.

LABELING OF SUNSCREENS – ULTRAVIOLET B (UVB) AND ULTRAVIOLET A (UVA) PROTECTION (2011)
ULTRAVIOLET B (UVB) PROTECTION
• Sun protection factor (SPF): up to 50+
ULTRAVIOLET A (UVA) PROTECTION
• Either no label or BROAD SPECTRUM • BROAD SPECTRUM can be used if the critical wavelength is ≥ 370 nm
SUBSTANTIVITY
• WATER RESISTANT (40 minutes) or WATER RESISTANT (80 minutes) • No use of the following designations: "WATERPROOF", "SUNBLOCK", "ALL DAY PROTECTION", or "SWEAT PROOF"
ADDITIONAL LABELING
• If a sunscreen has an SPF ≥ 15 *and* is BROAD SPECTRUM, then can state that the product can help to reduce the risk of skin cancer and the risk of early skin aging, when used regularly and as directed in combination with other sun protection measures • If the SPF of the sunscreen is < 15 *or* it is not BROAD SPECTRUM, then it must have the following Skin Cancer/Skin Aging Alert: "Spending time in the sun increases your risk of skin cancer and early skin aging. This product has been shown only to help prevent sunburn, not skin cancer or early skin aging."

Table 132.3 Labeling of sunscreens – ultraviolet B (UVB) and ultraviolet A (UVA) protection (2011). Based upon the 2011 FDA Final Rule for "Labeling and Effectiveness Testing; Sunscreen Drug Products for Over-the-Counter Human Use". For an explanation of critical wavelength, see text. SPF is also referred to as sunburn protection factor.

properly tested and applied, a product with an SPF of 10 would allow 10 times as much time in the sun with the same resultant level of erythema as without the product in a given individual. An SPF 20 similarly would allow 20 times as much exposure with the same result. As shown in Table 132.2, this does not mean that the SPF 20 product absorbs twice as much radiation as the SPF 10 product.

Testing for UVA Protection

Since scientists became aware of the damage that can be caused by photons of wavelengths longer than 320 nm, many attempts have been made to develop a standard method of testing for protection against long-wave or UVA radiation. Because there is no easily reproducible and biologically relevant endpoint for UVA radiation (as erythema is for the UVB range), investigators have suggested a number of assays, including both *in vitro* and *in vivo* methodology (see below). Some researchers have suggested that erythema produced by UVA sources could be utilized, but the irradiation times for such wavelengths are too long to make such an assay practical. Others have utilized psoralen-sensitized human skin plus UVA, with delayed erythema as the endpoint. Such an assay, however, has the shortcoming of measuring protection from only the photons responsible for psoralen photosensitivity.

The most commonly utilized human-skin-based assays include immediate pigment darkening and persistent (delayed) pigment darkening, both with endpoints that measure the skin's overall tanning response to UVA radiation. The former, as discussed in Chapter 86, is dependent upon radiation-induced darkening of pre-formed melanin, while the latter is a more complex response which includes increased production and transfer of melanin as well as proliferation of melanocytes. Both endpoints can be produced with relatively small amounts of UVA radiation, making them reasonable for human assays. In Japan, the assay for persistent pigment darkening is favored[5].

The most commonly accepted *in vitro* method for assaying UVA protection is the critical wavelength determination, which is utilized in some countries in the European Union and in Australia. This is a relatively simple assay in which the sunscreen is dissolved in solvent and the absorption spectrum is determined in a spectrophotometer. The critical wavelength for the product is determined as the wavelength at which 90% of solar-simulated radiation above 320 nm is absorbed[6].

In 1999, the FDA regulations regarding sunscreens were published. They included a labeling cap of 30+ for the SPF and the term *waterproof* was changed to *very water resistant*. However, methods for testing and labeling for long-wave range protection were not addressed and manufacturers had to limit claims of efficacy (in labeling or marketing) to protection from sunburn. In response to the 1999 regulations, a consensus conference was held[7]. One recommendation was that there be no cap on the SPF; it was thought that such a cap would discourage manufacturers from producing more protective sunscreens, since without labeling there would be no way for clinicians and consumers to identify such products. A second recommendation was to standardize testing and labeling for long-wave range protection; both critical wavelength determination (see above) and an *in vivo* human assay such as persistent pigment darkening could be utilized and the level of UVA protection of a product should be included on the label (along with the standard SPF value). A third recommendation was for the UVA protection afforded by a product be proportional to its level of UVB protection, so that products that were highly protective in the UVB range would have comparable protection in the UVA range. Lastly, assessments of sunscreen efficacy should go beyond protection against sunburn, since additional benefits would increase consumer awareness of other harmful effects of sun exposure and hopefully lead to greater usage of sunscreens.

In August 2007, the FDA released proposed regulations for sunscreen labeling (The Final Rule) that included several changes (Table 132.3): (1) the SPF claim could be increased from 30+ to 50+; (2) the SPF would still be measured in the same manner but would be renamed the *sunburn* protection factor; (3) a descriptor of the level of UVB protection would be required on the label (in addition to the SPF number); (4) a rating system for UVA protection would consist of 1 to 4 stars (low, medium, high, highest); and (5) the UVA protection rating would be based upon an *in vivo* (persistent pigment darkening) and an *in vitro* assay and would consist of the lower of the two results. The *in vitro* assay for assessing UVA protection would be based upon the breadth of reduction of UVA penetrance and results expressed as a ratio of UVA1 absorption to total UV absorption.

After considering the many responses received regarding this very complex testing and labeling system, the FDA published its Final Rule for "Labeling and Effectiveness Testing; Sunscreen Drug Products for Over-the-Counter Human Use" in June 2011. The latter represents a much simpler system. The major label on each product consists of the SPF number and, if efficacy in the UVA range is deemed sufficient, the term "Broad Spectrum". Testing is limited to an *in vitro* critical wavelength (CW) determination (see above), with a CW ≥ 370 nm meriting the Broad Spectrum claim. Substantivity ratings are limited to "Water Resistant (40)" and "Water Resistant (80)". The SPF is capped at 50+,

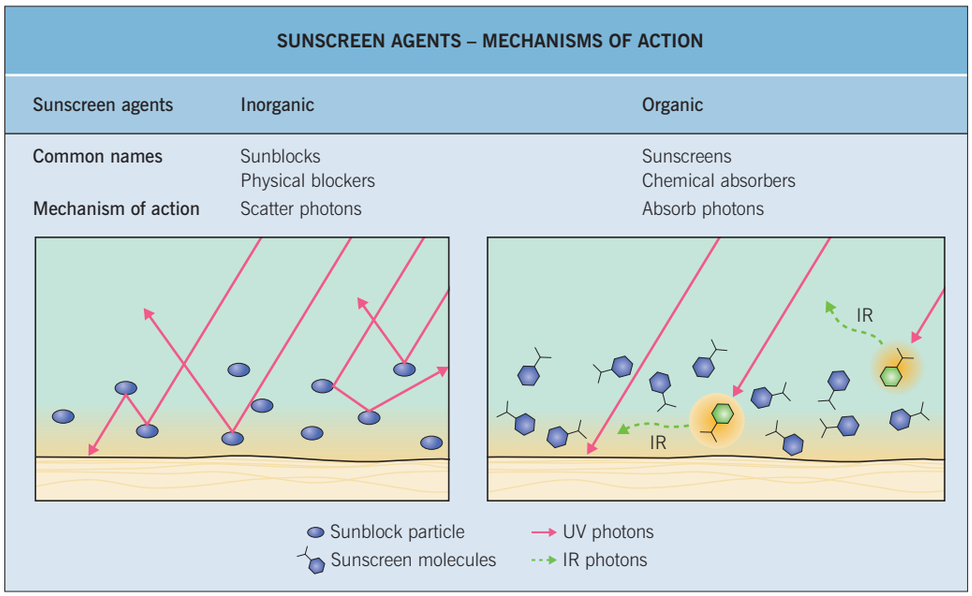

Fig. 132.1 Sunscreen agents – mechanisms of action. IR, infrared. *Courtesy, Mark Naylor, MD.*

although the FDA has stated that it will consider higher ratings if the data support sufficient increased efficacy of such products.

MECHANISMS OF SUNSCREEN ACTION

Sunscreens, when applied properly, form a film or coating on the surface of the stratum corneum and attenuate radiation that would otherwise reach the living epidermis and dermis. The active agents in sunscreen products do this by either absorbing or scattering the photons reaching the skin (Fig. 132.1). Agents that scatter radiation are opaque particles of inorganic materials and are referred to as physical agents or sunblockers. Agents that absorb radiation are organic compounds, referred to as chemical agents or sunscreens. Scattering of radiation by inorganics is based on particle size, while chemical absorption is related to chemical structure. The photons scattered by the inorganic screens are reflected back out of the skin, whereas the energy absorbed by the organic agents is converted to non-damaging energy and dissipated primarily as heat. Many sunscreen products today contain combinations of both types of agents.

Because of the large particle size of the original preparations of inorganic agents, they were not deemed cosmetically acceptable, owing to their opaque appearance on the skin. Nowadays, these agents are formulated as micronized particles, resulting in products that are more cosmetically acceptable. However, such micronized inorganics actually act more like organic sunscreens, scattering as well as absorbing radiation to some extent.

Currently, most sunscreens contain a combination of two or more agents created to offer high levels of protection against both UVB and longer-wavelength radiation.

ACTIVE INGREDIENTS IN SUNSCREENS

Figure 132.2 lists, according to type of activity and spectrum of protection, the active agents currently used in sunscreens[8].

Organic Screens

Para-aminobenzoic acid and derivatives

Padimate O (or octyl dimethyl PABA) is a PABA ester and one of the most common UVB absorbers found in sunscreens today. Both padimate O and its parent compound, PABA, are highly effective UVB absorbers. However, the latter causes staining of clothing and today is utilized infrequently.

Cinnamates

Octyl methoxycinnamate is a good UVB absorber but is not as potent as PABA and its esters. Presently, it is the most common sunscreen ingredient in the US. Although an approved agent, cinoxate is currently not used in any sunscreens in the US.

Salicylates

The salicylates are relatively weak UVB absorbers but do have the ability to stabilize other agents, thereby preventing photodegradation. Consequently, they are used in combination with other organics. This group includes octisalate, homosalate and trolamine salicylate.

Benzophenones

Benzophenones are good UVA absorbers, although their effectiveness is primarily in the UVA2 range. Oxybenzone is the most commonly used agent in this group and actually affords both UVB and UVA protection. Sulisobenzone and dioxybenzone have similar protective spectra but are infrequently utilized.

Other organic screens

Octocrylene is a commonly used UVB filter which is primarily employed to stabilize photolabile agents. Ensulizole is likewise a photostable UVB absorber. Avobenzone is an excellent UVA filter with absorption well into the UVA1 range, but is very photolabile. It is combined with other agents which assist in stabilizing its protective ability. Menthyl anthranilate is a UVA filter with a maximum absorption in the UVA2 range, but its efficacy is relatively weak.

Agents recently approved by the FDA (i.e. added to the Monograph) or awaiting FDA approval include ecamsule (UVA absorption; maximum absorption 345 nm), drometrizole trisiloxane (UVB and UVA; 344 nm), bisoctrizole (UVB and UVA; 358 nm) and bemotrizinol (UVA; see Fig. 132.2).

A process for approval of new sunscreens agents, termed the Time and Extent Application (TEA), is now available to manufacturers interested in utilizing newer agents, and studies of efficacy and safety generated outside of the US are accepted in the applications. Additional agents awaiting approval under this process include enzacamene (4-methyl-benzylidene camphor [4-MBC], Neo Heliopan® MBC, Eusolex 6300; UVB), ethylhexyl triazone (Uvinul® T 150; UVB), diethylamino hydroxybenzoyl hexyl benzoate (Uvinul® A Plus; UVA), bisdisulizole (Neo Heliopan® AP; UVA), and iscotrizinol (Uvasorb® HEB; UVB and UVA) (see Fig. 132.2).

Inorganic Screens

The two major inorganic screens are titanium dioxide and zinc oxide. There are a few so-called "chemical-free" products that contain only inorganics, but usually these agents are combined with organic screens. The activity of the inorganic agents depends upon particle size. Agents with large particle size like those on the market in the 1970s offered protection well into the UVA1 and even visible ranges, but because of

SUNSCREEN AGENTS

		Absorption

their opaque appearance they were not acceptable to many consumers. More cosmetically acceptable agents were developed with smaller particle size (i.e. micronized), but at the expense of shifting the protection toward the shorter UVA2 range. Micronized zinc oxide appears to have better activity in the UVA1 range than does titanium dioxide at comparable concentrations[9]. With the advent of nanotechnology, smaller particles of inorganic agents can be incorporated into sunscreen products.

Other Agents

Dihydroxyacetone is the compound most commonly used in sunless tanners. This agent, which when applied is colorless, binds to the stratum corneum and colors the skin to produce a tanned appearance. Although it has a very low SPF, it does offer protection from long-wave radiation (even into the visible range). Iron oxide offers protection across the UV spectrum and into the visible range, and is used as a colorant in some products[10].

Other "active" ingredients have been added to sunscreens, with claims of increasing efficacy of the finished products[8]. The most popular of these are antioxidants, including vitamins E and C and green tea polyphenols, some of which have decreased UV-induced damage in *in vitro* and *in vivo* assays. However, factors including chemical structure, concentration and stability in a finished product cannot be determined from package labels, so at this point it is impossible for the clinician and the consumer to judge efficacy.

In addition, sunscreen manufacturers are beginning to incorporate "boosters" into their products. Although these agents are not UV filters, they serve to increase the protective nature of sunscreens by boosting the SPF and UVA protection (but without the addition of or increased concentrations of active agents). Examples include tiny spheres that scatter incoming radiation and agents that increase the spread of the sunscreen on the skin, leading to greater protection.

SUNSCREEN EFFICACY

A good modern sunscreen should protect against sunburn, carcinogenesis, photoaging, photoimmune suppression and photosensitivity. Efficacy of a given sunscreen product is usually assumed if the combined absorption spectra of the agents in a product match the action spectrum of a given adverse event.

The action spectra for the adverse effects of sun exposure are listed in Table 132.4. There is abundant evidence that sunburn, nonmelanoma skin cancer induction, photoimmune suppression and photoaging are all most efficiently produced by UVB radiation. However, studies have shown that for some of these events, UVA also plays a greater or lesser role. For example, UVB is about 1000 times as effective at inducing erythema in human skin as is UVA. On the other hand, photoaging was originally thought to be primarily due to UVB radiation, but UVA penetrates more deeply into the dermis and is likely to have an important role in this process. Similarly, although most studies (in a number of model systems) show that the maximal effective radiation for producing photoimmune suppression is in the UVB range, sunscreens with only UVB protective agents are not totally effective in blocking this effect[11].

With regard to cutaneous squamous cell carcinoma (SCC), epidemiologic and animal studies, combined with the identification of UVB and UVA "signature" mutations in human SCCs, strongly support causation primarily by UVB, but UVA may also play a role[12]. Most evidence also supports the role of UVB in basal cell carcinoma (BCC) induction, but a great deal of controversy exists as to the action spectrum for melanoma. Still, UVB seems the most likely culprit. For example, in transgenic mice in which melanocytes are aberrantly located in the epidermis, a single erythemal (burning) dose to neonatal mice greatly enhanced melanoma formation[13]. Additional models for melanoma are currently under investigation and may provide further insights.

It must also be remembered that even though UVA may be less effective at inducing a given event in the skin when compared to UVB, there is 10 to 20 times as much UVA as UVB in sunlight (Fig. 132.3). This ratio is even higher in the skin of an individual wearing a UVB-protective sunscreen (especially if the SPF is ≥8), which might allow him or her to stay in the sun longer and obtain larger amounts of UVA radiation[14]. Therefore, the use of broad-spectrum sunscreens should be a goal of any photoprotection strategy.

Although the effectiveness of the protection of a given product might be predicted from a comparison of the action spectrum (see Table 132.4) versus the absorption spectrum (see Fig. 132.2), the most valid measures of efficacy are prospective studies in human subjects. However, in the case of skin cancer and photoaging, these studies are difficult to conduct because the photobiologic processes have such a long latency period. Animal models can be utilized, and this has often been done for photoaging and SCC induction, but has been quite limited for BCC (e.g. mice with only one normal allele for *Ptch*) and melanoma (e.g. opossums). Another approach has been to employ assays that measure the effect of sunscreens on biologic endpoints known to be important precursors in a pathologic process (but before the development of a recognizable lesion). Examples would be studying the effects of sunscreens on the development of actinic keratoses or assaying for DNA damage or mutated genes in human skin[14]

Much of the information on sunscreen efficacy is based on retrospective case-controlled studies. Because of the lower level of validity of such studies and because of variability of study design and especially the inherent recall bias, many such studies arrive at conflicting results. In addition, prospective trials are limited by the ability to blind subjects (to control vehicle vs active ingredients) in the setting of sun exposure.

ACTION SPECTRA FOR PHOTODAMAGE

Effect	Spectrum of light			Type of evidence
	UVB	UVA	Visible	
Sunburn	++++	+		1
Photoaging	++++	++	?	3,4
Squamous cell carcinoma	++++	+		2,3,4
Basal cell carcinoma	+++	?		2,4
Cutaneous melanoma	++	+		3,4
Photoimmune suppression	++++	++		1,3,4
Photosensitivity	+	+++	+	1 (varies with disease)

Table 132.4 Action spectra for photodamage (relative values). 1, human studies; 2, epidemiologic studies; 3, animal studies; 4, *in vitro* studies of associated biologic endpoints.

Sunburn

Tens of thousands of unpublished SPF studies performed in the premarketing testing of sunscreens attest to their ability to prevent sunburn. Controlled human studies in "real world" settings have found, however, that sunscreen usage does not always prevent sunburn[15]. The major reason for this dichotomy is that individuals do not apply sunscreens at the same concentrations as are utilized in controlled SPF testing – that is, 2 mg/cm^2. Some studies have shown that most sunscreen users apply only 25–75% of that quantity[16]. This means that the SPF is similarly reduced, i.e. applying only one-half of the standard amount of an SPF 15 product will result in protection comparable to a product with an SPF of 7.5. The proper quantity of sunscreen to cover the skin of an adult is approximately 30 ml or two tablespoons. Strategies to improve compliance include applying the product twice to gain the proper concentration, which also reduces the occurrence of "skip" areas (Fig. 132.4), or to use a product with twice the SPF as desired[17,18].

Photoaging

There are numerous animal studies demonstrating that sunscreen usage prevents clinical and histologic changes of photoaging and such usage can actually help reduce some of the damage that has already occurred. In addition, Boyd et al.[19] noted a significant reduction in dermal elastosis with daily sunscreen use over a 2-year period during an actinic keratosis study. A shorter-term study found that sunscreens with broad spectral coverage (extending significantly into the UVA spectrum) prevented many biochemical measures of sun damage (from solar-simulated radiation) in human volunteers[20].

Photoimmune Suppression

Immune suppression by UV radiation was first reported in animal studies that showed that mice could no longer reject UV-induced skin tumors if they had been irradiated with non-tumorigenic doses of UV before transplantation of the tumors. This immunosuppressive effect of UV has been shown to affect delayed-type hypersensitivity and contact sensitivity as well as tumor rejection and has been shown to be active in humans as well as animals[21,22]. While the responsible action spectrum has been shown to be predominantly in the UVB range, in experimental studies UVB sunscreens have not always afforded protection against immune suppression[23]. In an elegantly designed study in a large number of human volunteers, Kelly and colleagues[24] reported that sunscreen did offer some protection against immune suppression but the level of protection was not as great as its protection against sunburn. The researchers utilized a measure of photoprotection against suppression, designated the immune protective factor (IPF), and compared it with the erythema protection factor (EPF), a measure similar to SPF. In their study, the IPF was only 4.9, while the EPF was 14.2. The authors postulated that this difference was due to UVA radiation not blocked by the applied sunscreen[24]. Some investigators concerned about the effect of photoimmune suppression on various aspects of human health have suggested that sunscreens should be tested and labeled for IPF as well as SPF.

Non-melanoma Skin Cancer

Because of the long latency period for the development of SCC and BCC, the first two prospective studies in humans examining the effect of sunscreen on cancer prevention used actinic keratoses, precursors of SCC, as surrogates for SCC development. Naylor et al.[25] studied the daily application of an SPF 29 sunscreen applied over a 2-year period in a group of 53 individuals with a previous history of actinic keratoses. The sunscreen-treated group had significantly fewer actinic keratoses over the 2-year period compared with the placebo group. The difference between the two groups with regard to skin cancers was not significant, probably due to the relatively short duration of the trial.

Thompson et al.[26] studied the effects of an SPF 17 sunscreen applied daily in 588 individuals (>40 years of age) during a single Australian summer. This study also found a significant reduction in the number of actinic keratoses in the sunscreen-treated group.

Later, Green et al.[27] undertook a prospective study of the daily use of an SPF 17 sunscreen in Australians. This study compared an active intervention group, in which sunscreen was supplied and its use encouraged, against the background rate of sunscreen use in the general population. The number of SCCs was found to be significantly less in the sunscreen-treated group, but there was no difference in the number of BCCs between the two groups. From clinical observations regarding anatomic distribution, the relationship between UV radiation and BCC is known to be more complex than with SCC.

In a prospective trial involving 120 solid organ transplant recipients (all of whom received education regarding sun protection), 60 individuals were given free broad-spectrum sunscreen to apply daily to the head and neck, forearms and hands[28]. Over a period of 24 months in which an average of 5.6 applications per week was recorded, significantly fewer new actinic keratoses and SCCs developed in the sunscreen group as compared to the control group. While the baseline actinic keratosis count was equal in the two groups, there was an overall reduction in the number of actinic keratoses in the sunscreen group.

Cutaneous Melanoma

Developing sunscreen efficacy studies for decreasing the risk of melanoma is difficult and some might not consider them to be ethical. As with SCC and actinic keratoses, a number of researchers have used the development of melanocytic nevi in children as a marker for melanoma risk. The number of nevi has been related to sun exposure in children and the former has also been linked to risk for melanoma[29]. In several retrospective epidemiologic studies, researchers have actually reported that children who used sunscreens had an increased number of nevi[30]. However, in the only prospective controlled study published to date, Gallagher et al.[31] demonstrated that sunscreens could suppress the development of nevi. The study was conducted over a 3-year period with an SPF 30 sunscreen in a total of 485 schoolchildren 6 to 9 years of age.

Retrospective case-controlled studies of melanoma patients have produced conflicting results with regard to sunscreen usage and the risk of developing melanoma. Some of these studies showed a decreased risk, while others actually showed an increased risk. Meta-analyses of the published studies by two different groups concluded that sunscreen usage did not increase the risk of developing melanoma, but the analyses could not confirm a protective effect from using sunscreen[32,33].

This dichotomy of results has led to a significant controversy concerning the use of sunscreens. The controversy is based on two different but related lines of reasoning. The first relates to the action spectrum for induction of melanoma. If in fact the action spectrum for melanoma is in the UVA range (as suggested by studies in fish), then wearing sunscreens with UVB protection will allow individuals to stay in the sun longer and receive larger doses of UVA, thereby increasing their risk of developing melanoma. However, several animal models suggest that the action spectrum is probably predominantly in the UVB range (see above). The second theory is based on the concept that sunscreen usage decreases vitamin D levels in humans. Because vitamin D has

CLASSIFICATION AND ACTION SPECTRA OF PHOTOSENSITIVE SKIN DISEASES

Table 132.5 Classification and action spectra of photosensitive skin diseases (relative values).

been shown to reduce proliferation and increase differentiation of various normal and tumor cells, low vitamin D levels might increase the risk of developing some cancers, including melanoma[34].

However, in a recently reported study, 1621 Australians (ages 25–75 years) were randomly assigned to daily or discretionary sunscreen application to the head and arms (in combination with 30 mg β-carotene or placebo supplements) for a period of 4 years[35]. They were then followed for another 10 years, and over that time period, 11 new primary cutaneous melanomas were identified in the daily sunscreen group and 22 in the discretionary group. This represented a reduction in the observed rate in the former group (hazard ratio [HR], 0.50; 95% CI, 0.24 to 1.02; p = 0.05); the reduction in invasive melanomas was more substantial (3 in the daily group versus 11 in the discretionary group).

Photosensitivity Disorders (see Ch. 87)

The action spectra of the more common photosensitivity disorders are listed in Table 132.5. Some of these reactions are caused by UVB radiation, but the majority of affected individuals react to UVA and/or visible light. Therefore they require photoprotection with agents that absorb or reflect longer wavelengths; a small number of studies have confirmed the efficacy of such agents[34]. Currently, the most protective formulations appear to be avobenzone- and ecamsule-containing products[36]. Other useful agents include inorganic titanium and zinc oxides and benzophenones. The self-tanners containing dihydroxyacetone in combination with regular sunscreen usage may offer some benefit and iron oxide-containing products can also be helpful.

SUNSCREEN SAFETY

Sunscreens have been utilized for decades with an excellent safety record. While studies appear from time to time suggesting that some sunscreen agents are mutagenic or carcinogenic or have adverse hormonal effects in various *in vitro* and animal studies, there is no convincing evidence that such studies have relevance for humans[37].

The major adverse effects of sunscreens are minor skin irritation, which is common, and allergic contact dermatitis, which is rare. These reactions are usually due to ingredients in the base of the product, such as fragrance or preservatives. Presently, the organic compounds most often responsible for the rare instances of allergy or photoallergy are oxybenzone and padimate O, and, less commonly, avobenzone[38].

As noted previously, some researchers believe that sunscreens may actually be deleterious to health by blocking the production of vitamin D. The first step in the production of this important nutrient is the conversion within the epidermis of 7-dehydroxycholesterol to pro-vitamin D_3 by UVB radiation (see Ch. 51). Sunscreens that are effective at blocking UVB photons would therefore be expected to decrease levels of vitamin D, and studies have shown that this does in fact occur. However, the majority of human studies that measured serum vitamin D levels in sunscreen users (as compared to non-users) found that the levels, though reduced, were within the normal range[39]. In addition, studies have shown that dark-skinned individuals, women, and, during the wintertime, individuals who live in northerly climes all have reduced levels[40].

Recently, scientists in the fields of nutrition and bone metabolism have presented data suggesting that individuals who have serum vitamin D levels in the low normal range may actually have insufficient vitamin D for optimum health. Some of these studies suggest that not only do these low normal or "insufficient" levels of vitamin D adversely affect good musculoskeletal health, but that they may also increase the risk of other adverse events like cancer and decreased immune function[41]. One publication linked lower levels of sun exposure to decreased survival in melanoma patients and suggested that this was related to insufficient vitamin D[41,42].

Controversy has arisen because scientists cannot agree on what constitutes the "normal" range for serum 25-OH vitamin D levels and similarly cannot agree on the minimum suggested daily intake for the vitamin. Although vitamin D can be obtained from foods such as fish oils, in developed countries the more common sources are vitamin D-fortified milk and milk products, as well as vitamin supplements. In 2010, the Institute of Medicine issued a consensus statement regarding the recommended dietary allowance for vitamin D – 600 IU per day, except for those over 70 years of age in whom 800 IU per day was recommended (www.iom.edu). Unfortunately, the tanning salon industry has "fanned the flames" by suggesting that UV light exposure and tanning represent the optimum way to assure healthy vitamin D metabolism[43].

This area of medicine is evolving, and, as specialists in skin health and disease, we should not simply deny any merit to the controversy. We should continue to evaluate studies from our colleagues in other fields. Notably, it does not mean that we should change our message about sun avoidance and sunscreen usage; we simply have to suggest that all individuals maintain adequate vitamin D intake via diet and supplements.

SUNSCREEN RECOMMENDATIONS

There is ever-increasing evidence that although the public is aware of the damaging effects of sun exposure, there does not seem to be a significant degree of alteration in behavior. In an effort to re-energize the medical community's need to try to change behavior, the American Academy of Dermatology has reformulated its message concerning protection (www.aad.org). While the importance of sunscreen is stressed, the recommendations are broader and more positive, and hopefully this and other improvements in consumer education will eventually lead to a decrease in photodamage in the world's population.

Botanicals, dietary supplements, and other biologically based practices 2205
Traditional Chinese medicine 2211
Homeopathy 2214
Aromatherapy 2215
Mind–body medicine 2216

Key features

- Globally, complementary and alternative medicine (CAM) is commonly utilized, and it is rising in popularity
- CAM encompasses a diverse group of therapies
- Among dermatology patients, the most popular forms of CAM include herbals, dietary supplements, homeopathy and acupuncture
- Scientific research regarding CAM has expanded significantly

INTRODUCTION

Complementary and alternative medicine (CAM) represents a diverse set of healthcare systems, practices and treatment modalities that are grouped together because they are not considered part of conventional medicine. Various classifications of CAM have been suggested, including one summarized in Table 133.1[1]. Integrative medicine combines the most efficacious CAM with conventional therapies.

An estimated 80% of the world's population uses CAM as their initial and perhaps only type of medical care[2]. The prevalence of CAM usage is higher in low-income countries, but is rising in high-income countries. In 2007, ~40% of adults and ~12% of children in the US used CAM[3]. Fifty percent of the US population takes dietary supplements, and ~20% of all prescription users take herbals or high-dose vitamins (megavitamins)[1]. CAM usage is also significant in Europe (10–50%), Australia (70%) and Japan (75%).

In the US, CAM usage tends to be more prevalent in women, adults 30 to 69 years of age, those with higher levels of education, and former smokers[3]. It is also associated with the number of health conditions, number of doctor visits over the past year, and hospitalization within the past year. Children whose parents used CAM were five times more likely to use CAM. When worry about cost delayed receipt of conventional care, both adults and children were more likely to use CAM. The overwhelming majority of CAM users in high-income countries, including those with dermatologic conditions, use CAM to complement conventional medicine rather than as a complete alternative[3].

Patients who report having skin "problems" are more likely to use CAM (UK: 39% vs 20% [general population]; US: 49% vs. 38% [general population]), and some use CAM specifically for dermatologic conditions (UK, 45%; US, 6%). An estimated 35% to 70% of dermatology patients use CAM during their lifetimes, most frequently herbals, dietary supplements, homeopathy and acupuncture[4].

BOTANICALS, DIETARY SUPPLEMENTS, AND OTHER BIOLOGICALLY BASED PRACTICES

Biologically based practices include herbs/botanicals, dietary supplements (e.g. animal-derived products, vitamins, minerals, fatty acids, amino acids, proteins, prebiotics/probiotics), diet-based therapies, chelation therapy and megavitamins (see Table 133.1).

Modern medicine has its roots in natural substances; however, biologically based practices and conventional medicine differ fundamentally. Conventional medicine takes a reductionist view of the body's functions, emphasizing a belief in science's ability to isolate the active molecules needed to treat specific diseases. In contrast, biologically based practices ideally take a holistic approach to health and emphasize disease prevention and health promotion by strengthening the body's own healing mechanisms.

Dermatologic Applications

Conventional dermatology uses many products of herbal origin, including podophyllin, psoralens, oatmeal and pyrethrins. Such accepted treatments are discussed elsewhere in this textbook; this chapter limits its discussion to herbals that are less well known but are commonly used. Examples are discussed below and are listed in Table 133.2.

Aloe vera

The gel from *Aloe vera* leaves is often used topically on wounds and burns. Aloe reduces burning, itching and scarring from radiation dermatitis, and it can be used for ulcers, postsurgical wounds, frostbite, pruritus and stasis dermatitis as well as for minor cutaneous infections (bacterial, fungal, herpes simplex). Double-blind, placebo-controlled studies of aloe have shown statistically significant improvement of psoriasis (83% vs 7%), seborrheic dermatitis (62% vs 25%), and irritant contact dermatitis.

Active components of aloe include: (1) salicylic acid, which decreases vasoconstriction and platelet aggregation and improves dermal perfusion via a decrease in thromboxane A_2, thromboxane B_2 and prostaglandin 2α; (2) carboxypeptidase, which inactivates bradykinin and decreases pain; (3) polysaccharides such as acemannan, which have anti-inflammatory, antimicrobial (bactericidal, viricidal, antifungal), and immune-stimulating actions; and (4) aloesin, which inhibits tyrosinase and suppresses UV-induced tanning by a third. Aloe also increases collagen biosynthesis and degradation within granulation tissue and it can cause allergic contact dermatitis[6]. If ingested, aloe can lead to hypoglycemia in diabetics on oral hypoglycemic drugs.

Honey

Randomized, controlled trials have shown that honey enhances healing of first-degree and superficial second-degree burns. The evidence is inconclusive with regard to acute wounds, postoperative wounds and pressure ulcers, and it is not effective for venous ulcers. One study suggested that honey may be more effective than topical acyclovir in the treatment of recurrent labial and genital herpes simplex[7].

Honey contains sugars, amino acids, vitamins, minerals and enzymes (e.g. catalase), which are thought to encourage debridement, promote granulation and epithelialization, and reduce edema. Antibacterial properties are related to peroxide activity and osmolarity. For example, manuka honey has antibacterial activity equivalent to that of phenolic acid. Contact dermatitis has rarely been reported[8].

Marigold

Marigold (*Calendula officinalis*) is an antiseptic and is commonly used for diaper dermatitis. *Calendula* is also used for wounds, ulcers, burns, furuncles, herpes zoster, varicose veins, eczema, and mouth and throat inflammation. There is evidence that marigold may be useful as prophylaxis for acute radiation dermatitis[9].

Marigold contains flavonoids, triterpene saponins and carotenoids. It has anti-inflammatory, antimicrobial and immunomodulating properties. Animal studies have demonstrated increased glycoproteins and

CLASSIFICATION OF COMPLEMENTARY AND ALTERNATIVE MEDICINE (CAM)		
Biologically based practices	Chelation therapy	
	Folk medicine	
	Herbs/botanicals	Non-vitamin, non-mineral, natural products
	Dietary supplements	Animal-derived extracts Vitamins Minerals Fatty acids Amino acids Proteins Prebiotics, probiotics
	Diet-based therapies	Vegetarian Macrobiotic Atkins Pritikin Ornish Zone South Beach
	Megavitamin therapy	
Alternative medical systems	Acupuncture/traditional Chinese medicine Ayurveda Homeopathic medicine Naturopathy	
	Other traditional healers	Curandero, Espiritista, Hierbero/Yerbera, Shaman, Botanica, Native American, Sobrador
Mind–body therapies	Biofeedback Meditation Guided imagery Progressive relaxation Deep breathing exercises Hypnosis Yoga Tai chi Qi gong Cognitive behavioral therapy Patient support groups Autogenic training Spirituality Prayer Mental healing	
	Therapies that use creative outlets	Music therapy Art therapy Dance therapy
Manipulative and body-based practices	Chiropractic manipulation Osteopathic manipulation Massage	
	Movement therapies	Feldenkrais method Alexander technique Pilates Trager psychophysical integration
	Bowen technique Craniosacral therapy Reflexology Rolfing	
Energy medicine	**Energy types**	**Energy therapies**
	Veritable energy:	
	Mechanical vibrations	Sound therapy
	Electromagnetic energy (light, magnetic fields, laser beams, infrared, direct and alternating current)	Light therapy Magnetic therapy Millimeter wave therapy Infrared therapy
	Putative energy:	
	Qi (Chinese)	Traditional Chinese medicine (acupuncture, qi gong)
	Ki (Japanese)	Reiki Johrei
	Dosha	Ayurvedic medicine
	Prana	Yoga
	Homeopathic resonance	Homeopathy
	Other energy types:	
	Ether (Greek) Fohat (Tibetian) Mana (Polynesian) Orgone, Odic force (European)	Therapeutic touch Vortex healing Polarity therapy Distant healing Intercessory prayer

Table 133.1 Classification of complementary and alternative medicine (CAM). Based upon classifications from the National Center for Complementary and Alternative Medicine (NIH) and the National Center for Health Statistics (CDC)[1].

collagen at wound sites treated with marigold. There are rare reports of contact dermatitis to *Calendula*[6].

Capsaicin

Capsaicin is found in hot peppers (*Capsicum*), and it is a mixture of vanillyl amides of isodecenoic acid. Topical capsaicin is used for post-herpetic neuralgia, notalgia paresthetica, diabetic neuropathy, reflex sympathetic dystrophy, and hemodialysis-related pruritus. By binding to the capsaicin vanilloid receptor-1 on pain fibers, capsaicin stimulates the release and eventually depletion of the neurotransmitter substance P. Prolonged exposure leads to death of these neurons, although they can regenerate over time.

Capsaicin also has antimicrobial properties and has been used for verrucae. It decreases scaling, thickness, erythema and pruritus in patients with psoriasis. A common side effect is temporary burning, both locally and at sites of unintended application, which may limit its use.

Arnica

Arnica (*Arnica montana*) is approved by the German Commission E for its anti-inflammatory effects[6]. It is used for treating myalgia, arthralgia, bruises, insect bites, furuncles, acne, gingivitis, hemorrhoids, seborrheic dermatitis and psoriasis. Active components include sesquiterpene lactones, which reduce inflammation by inhibiting the transcription factor NF-κB, an important regulator of inflammatory mediators. Arnica is toxic when ingested, unless given in homeopathic doses, and should only be used topically on intact skin. As a member of the Compositae (Asteraceae) family, contact dermatitis is a possible adverse effect. A single case report of Sweet's syndrome with pathergy to arnica occurred in a patient with leukemia.

Chamomile

Chamomile (*Matricaria recutita*, *Chamomilla recutita*) is used to treat inflammation of the skin and mucous membranes and to promote wound healing. It is traditionally used for dermatitis and may be ingested as a tea or applied topically. Studies have demonstrated that the anti-inflammatory effects of topical chamomile are 60% to 100% that of topical hydrocortisone 0.25%. One double-blind trial showed decreased wound surface area and healing time with chamomile. *In vitro*, chamomile has antimicrobial and antioxidant effects, while animal studies have demonstrated anti-inflammatory and antispasmodic effects.

Active components include α-bisabolol, bisabolol oxides A and B, levomenol, matricin, chamazulene, farnesene, and the flavonoids apigenin, luteolin, patuletin and quercetin. These substances inhibit cyclooxygenase and lipoxygenase, inhibit histamine release, and promote granulation tissue formation. Chamomile contains coumarins, and theoretically could increase the risk of bleeding.

BOTANICALS AND OTHER BIOLOGICALLY ACTIVE SUBSTANCES USED FOR DERMATOLOGIC CONDITIONS				
Common name	**Latin name and/or sources**	**Active components**	**Uses/properties**	**Known side effects**
PREVENTION OF BRUISING				
(Arnica is discussed in the text)				
Comfrey	*Symphytum officinale* L.	Allantoin, triterpene saponins, tannins	• Bruises, wounds, ulcers, burns, dermatitis, psoriasis • Arthritis, myalgia, acute back pain • Anti-inflammatory	• For *topical* use only; if ingested, hepatotoxic, mutagenic
Pineapple extract	*Ananas comosus*	Bromelain (a protease)	• Hematoma resorption, wound healing • Ingestion 1–2 h prior to meals enhances uptake by WBCs	• Hypersensitivity reaction, anaphylaxis
ANTIOXIDANTS USED FOR PREVENTING SKIN CANCER AND/OR PHOTOAGING				
Anapsos/calaguala/ kalawalla/golden serpent fern	*Polypodium leucotomos*	Flavonoids, alkaloids, lipids (including calaguline)	• Photoprotection, including against PUVA-induced phototoxicity, PMLE, vitiligo, psoriasis, atopic dermatitis • Commercially, may be combined with β-carotene and green tea extract • Antioxidant, immunomodulator, anti-inflammatory	• No known side effects, but a related fern, *P. vulgare*, causes hypotension, tachycardia, drowsiness
β-carotene	Sweet potatoes, carrots, kale, spinach, turnip greens, winter squash, collard greens	NA	• Photoprotection – EPP, PMLE, UV-induced erythema • Cataracts, chemotherapy-associated toxicities, COPD, immune enhancement • Antioxidant	• May increase risk of lung and prostate cancer, intracerebral hemorrhage, death from cardiovascular disease • Carotenoderma
Coffee berry	*Coffea arabica*	Polyphenols, including chlorogenic acid, quinic acid, ferulic acid, condensed proanthocyanidins	• Preventing photocarcinogenesis, photoaging • Antioxidant	• Caffeine-related: restlessness, insomnia, GI symptoms
Gingko biloba	*Gingko biloba*	Flavonoid glycosides, terpenoids (ginkgolides, bilobalides), urushiol (seed coat; see Ch. 17)	• Photoaging (*topically*), vitiligo, dementia, cardiovascular disease, multiple sclerosis • Blocks platelet-activating factor • Antioxidant	• Interactions: decreases clearance of MAO inhibitors and SSRIs • Increased risk of bleeding, GI upset, vomiting, headaches, dizziness, palpitations, restlessness
Ginseng	*Panax ginseng*, *P. quinquefolius*	Ginsenosides (triterpenoid saponin), fatty alcohols (falcarinol, panaxacol, panaxydol), polysaccharides	• Anti-aging (*topically*), immune enhancement, type II diabetes, hypertension, erectile dysfunction • Antioxidant, antineoplastic, antimicrobial	• Headache, insomnia, GI upset, hypoglycemia
Grape seed extract	*Vitis vinifera*, *V. coignetiae*	Proanthocyanidins including epicatechin and catechins, vitamin E, resveratrol	• Hyperpigmentation, reduction of photocarcinogenesis, varicose veins, chronic venous insufficiency, hypercholesterolemia, hypertension • Antioxidant, anti-inflammatory	• Interactions: inhibits hepatic clearance of some drugs • Mild stomach discomfort, nausea, headache, dizziness
Lycopene (a carotenoid)	Tomatoes, especially cooked tomato products	NA	• Photoprotection – SPF = 1.3 (oral) • Carcinoma (prostate, colon, breast, endometrial), macular degeneration • Antioxidant (*topical* and oral)	• Carotenoderma
Pine tree bark extract, from Mediterranean maritime pine tree	*Pinus pinaster* *P. pinaster* ssp. *atlantica* (French maritime pine tree)*	Pycnogenol®, proanthocyanidins including catechin, epicatechin, taxifolin	• Chronic venous insufficiency, hyperpigmentation, anti-aging (*topically*), diabetes • Binds and stabilizes collagen and elastin; increases endothelial nitric oxide • Antioxidant, anti-inflammatory	• Interactions: inhibits hepatic clearance of some drugs • Mild stomach discomfort, nausea, headache, dizziness • Possible allergen
Pomegranate	*Punica granatum* L.	Alkaloids, polyphenols, ellagic acid	• Photoaging, photoprotection, rheumatoid arthritis • Oral ellagic acid 5% increases sunscreen SPF by 25%; topical ellagic acid inhibits UVA-mediated activation of cellular pathways in keratinocytes • Antioxidant, antiviral, photoprotectant	
Resveratrol-containing plants	Grapes (skin and seeds), many berries (e.g. cranberries, blueberries, bilberries), fruits, and nuts (e.g. peanuts)	Resveratrol (polyphenol)	• Coronary artery disease, diabetes • *Topically*, decreases UVB-induced damage and carcinogen-induced skin cancers in mice • Anti-inflammatory, antineoplastic, antioxidant	• Interactions: inhibits cytochrome P450 3A4 • Phytoestrogen-like effects, slows wound healing (antiangiogenic), inhibits platelet aggregation
*Source of Pycnogenol®[5].				

Table 133.2 Botanicals and other biologically active substances used for dermatologic conditions. COPD, chronic obstructive pulmonary disease; EPP, erythropoietic protoporphyria; GI, gastrointestinal; h, hours; MAO, monoamine oxidase; NA, not applicable; PMLE, polymorphic light eruption; SPF, sun protection factor; WBCs, white blood cells.

Continued

BOTANICALS AND OTHER BIOLOGICALLY ACTIVE SUBSTANCES USED FOR DERMATOLOGIC CONDITIONS				
Common name	**Latin name and/or sources**	**Active components**	**Uses/properties**	**Known side effects**
Shiitake mushroom	*Lentinula* (*Lentinus*) *edodes*	Eritadenine, L-ergothioneine, active hexose correlated compound (AHCC), lentinan, vitamin D†	• Anti-aging, carcinomas (esp. gastric, colorectal) • Immunostimulant, antibacterial, antiviral	• Flagellate hyperpigmentation (if eaten raw or partially cooked)
Silymarin (milk thistle)	*Silybum marianum*	Silibinin (silybin), a flavonoid	• Anti-aging (*topically*), liver disease (e.g. hepatitis, cirrhosis), carcinomas (e.g. breast), type II diabetes, hypercholesterolemia • Antioxidant, hepatoprotectant, antineoplastic	• Interactions: inhibits cytochrome P450 • GI upset, diarrhea • Allergenic (Compositae [Asteraceae] family)
Soy	*Glycine max* L. Merr	Phospholipids (phosphatidylcholine), essential fatty acids (omega-3), vitamin E, isoflavones‡ (genistein, daidzein, glycitein), soybean trypsin inhibitor, Bowman Birk inhibitor	• Hyperpigmentation (*topically*), photoprotection (*topically*), photodamage (*topically*), reducing unwanted body hair (*topically*), hypercholesterolemia, osteoporosis prevention, cancer prevention • *Topically*, estrogenic effects (theoretical); soybean trypsin inhibitor is thought to inhibit activation of PAR-2 on keratinocytes, thereby reducing melanosome transfer • Antioxidant, anti-inflammatory, antineoplastic (esp. genistein), estrogenic and anti-estrogenic properties	• Mild indigestion • Potential food allergen • Conflicting data regarding breast cancer
Vitamin C (L-ascorbic acid)	Broccoli, bell peppers, kale, cauliflower, strawberries, lemons, mustard, turnip greens§	NA	• Photoprotection, photoaging, melasma, solar lentigines, acne, acne scarring • Promotes collagen synthesis, decreases collagen degradation • Antioxidant, anti-inflammatory	• Diarrhea, nausea, vomiting, flushing, insomnia (very large systemic doses) • *Topical* – mild ICD
Vitamin E (tocopherol)	Nuts, seeds, spinach, mustard greens, peppers, olive oil	NA	• Atopic dermatitis; prevention of age-related macular degeneration, cataracts and cognitive decline • Antioxidant	• Increased risk of cardiovascular disease, hemorrhagic stroke, possibly prostate cancer • *Topical*: rarely dermatitis
SUPPLEMENTS CONTAINING ANTI-INFLAMMATORY FREE FATTY ACIDS				
Acai berry	*Euterpe oleracea*	Oleic acid (omega-9; 60%), linoleic acid (omega-6; 12%), phytosterols, anthocyanins (flavonoid)	• Antioxidant	• Major food source for indigenous populations in Brazil
Black currant seed oil	*Ribes nigrum*	γ-linolenic acid (13%), α-linolenic acid (17%)	• Atopic dermatitis, rheumatoid arthritis, cardiovascular disease, premenstrual symptoms, • Reduces inflammatory cytokines IL-1 and TNF-α	• Few data available
Borage seed oil	*Borago officinalis*	γ-linolenic acid (GLA; 23%)	• Atopic dermatitis, infantile seborrheic dermatitis, rheumatoid arthritis • Richest plant-based source of GLA	• GI upset, nausea, headache
Evening primrose oil	*Oenothera biennis*	Linolenic acid (72%), γ-linolenic acid (10%)	• Atopic dermatitis, especially pruritus (oral and *topical*), hypercholesterolemia • Anti-inflammatory, antineoplastic	• Nausea, diarrhea, headache, thrombosis, immunosuppression with prolonged use (>1 year)
Fish oil (algae sources)	Tuna, salmon, sardines, herring, oysters, crab	Omega-3 fatty acids (eicosapentaenoic acid, docosahexaenoic acid)	• Psoriasis (conflicting data), cardiovascular disease, hypertriglyceridemia, rheumatoid arthritis, cell-protective during chemotherapy	• Diarrhea, anticoagulation, risk of methylmercury contamination (fish sources)
See also: olive oil (discussed in text)				
SUPPLEMENTS USED FOR PIGMENTARY DISORDERS				
Bearberry	*Arctostaphylos uva-ursi*	Arbutin, a glycosylated hydroquinone	• *Topical*: melasma, postinflammatory hyperpigmentation; suppresses UV-induced tanning, alone (43%) or with aloesin (63%) • Systemic: urinary tract infections, nephrolithiasis • Inhibits tyrosinase *in vitro*	• Systemic: nausea, vomiting, green urine, tinnitus
Chitin (insect and crustacean shell component)	Many	N-acetylglucosamine	• *Topical*: Hyperpigmentation • Inhibits tyrosinase activation	• Limited data

†Vitamin D activity is greater in dried shiitake mushrooms.
‡A class of phytoestrogens.
§Also Brussels sprouts, papaya, chard, cabbage, spinach, kiwis, snowpeas, cantaloupe, oranges, grapefruit, limes, tomatoes.

Table 133.2 Botanicals and other biologically active substances used for dermatologic conditions (cont'd). GI, gastrointestinal; ICD, irritant contact dermatitis; IL, interleukin; NA, not applicable; PAR-2, protease-activated receptor-2; TNF, tumornecrosis factor.

Continued

BOTANICALS AND OTHER BIOLOGICALLY ACTIVE SUBSTANCES USED FOR DERMATOLOGIC CONDITIONS				
Common name	**Latin name and/or sources**	**Active components**	**Uses/properties**	**Known side effects**
Paper mulberry	*Broussonetia papyrifera* L.	Root extract contains prenylated, polyhydroxylated mono- and bis-phenyl derivatives	• *Topical*: Melasma • Root extract (0.4%) inhibits tyrosinase by 50% (equivalent to hydroquinone 5.5% and kojic acid 10%)	• Limited data
Supplements that contain free fatty acids: nuts, seeds, vegetable oils (see previous section)	Many diverse plants and animals	α-linolenic, linoleic acid, γ-linolenic acid	• *Topical*: reduces UVB-induced hyperpigmentation, especially α-linolenic acid	• Variable, depending on particular supplement
Zengse pill	Proprietary Traditional Chinese medicine formula	Unknown	• Vitiligo • Immunomodulator: increases $CD4^+$ and decreases $CD8^+$ T cells	• Limited data
See also: soy, pine bark extract, grape seed extract, anapsos, persimmon leaf (listed in this table); licorice root (discussed in text), vitamins B_3 and C (Ch. 51).				
ASTRINGENTS USED TOPICALLY FOR TREATING ACNE				
English walnut leaf	*Juglans regia*	Tannins¶	• Acne, type I diabetes (very controversial)	• Unknown; limited data
St. John's wort	*Hypericum perforatum*	Naphthodianthrones (hypericin, pseudohypericin), tannins¶, flavonoids, phenolic acids, phloroglucinols, sesquiterpenes	• Acne, wounds, burns, insect bites • Most commonly used for depression, anxiety, insomnia	• Interactions: induces cytochrome P450 and P-glycoprotein • Systemic: photosensitivity, anxiety, sexual dysfunction
White oak bark	*Quercus alba*	Tannins¶	• Acne	
Witch hazel	*Hamamelis virginiana*	Tannins¶, gallic acid, catechins, proanthocyanins, flavonoids, polyphenols	• Acne, eczema, oral ulcers, bruises, edema, varicose veins, hemorrhoids • Vasoconstrictor, hemostatic, antioxidant	• Systemic: nausea, vomiting, hepatotoxic, nephrotoxic
Additional astringents that contain tannins¶ (with potential side effects) include: agrimony (urticaria), Labrador tea (muscle cramps, paralysis), goldenrod (contact dermatitis), Lady's mantle, rhubarb (nephrotoxicity due to oxalic acid), and yellowdock (diarrhea, metabolic diarrhea); lavender (*Lavendula* spp.) is also an astringent				
TREATMENT OF INFESTATIONS				
Anise seeds	*Pimpinella anisum*	Terpenoid anethole, phytoestrogens	• Infestations	• Contraindicated during pregnancy and breastfeeding
Chrysanthemums	Asteraceae (Compositae) family	Pyrethrins	• Scabies	• Allergic contact dermatitis, photosensitivity
Neem	*Azadirachta indica*	Nimbidin	• Infestations, psoriasis (better than placebo)	• Contraindicated during pregnancy and breastfeeding and in children
TREATMENT OF CHRONIC VENOUS INSUFFICIENCY				
(Horse chestnut seed extract is discussed in the text)				
Buckwheat	*Fagopyrum esculentum*	Rutin, D-chiro-inositol	• Chronic venous insufficiency, including decreasing leg edema, type 2 diabetes, PCOS	• Increased risk of bleeding
Butcher's broom	*Ruscus aculeatus*	Polyphenols, steroidal saponins	• Chronic venous insufficiency, hemorrhoids • Vasoconstrictor, diuretic, diaphoretic	• Nausea
Sweet clover (yellow)	*Melilotus officinalis*	Polyphenols, coumarins	• Chronic venous insufficiency, hypertension, insomnia, improvement of lymphatic drainage	• Increased risk of bleeding
TREATMENT OF CONDYLOMATA ACUMINATA AND VERRUCAE				
Bittersweet nightshade	*Solanum dulcamara*	Solanine (toxin)	• Condylomata, verrucae	• Contraindicated during pregnancy and breastfeeding
Calotropis	*Calotropis procera*	Calotropin (toxin)	• Condylomata, verrucae	• Contraindicated during pregnancy and breastfeeding
Greater celandine	*Chelidonium majus*	Coptisine, and other isoquinoline alkaloids (toxins)	• Condylomata, verrucae	• Contraindicated during pregnancy and breastfeeding
Wild oats (straw)	*Avena sativa*	Straw contains silica	• Condylomata, verrucae	• Few data
OTHER SUPPLEMENTS USED FOR DERMATOLOGIC CONDITIONS				
(Aloe vera, arnica, capsaicin, chamomile, fumaric acid esters, honey, horse chestnut seed extract, licorice root, marigold, olive oil/olive leaf extract, teas and tumeric are discussed in the text; see Ch. 153 for fruit acids; see Ch. 51 for vitamins B_3, B_6 and B_{12}, zinc, and selenium)				
Chaparral	*Larrea tridentate*	Nordihydroguaiaretic acid	• Native American remedy for actinic keratoses • Antioxidant, antibiotic	• Contact dermatitis • Renal and liver toxicity
¶Tannins coagulate cell surface proteins to form a protective barrier.				

Table 133.2 Botanicals and other biologically active substances used for dermatologic conditions (cont'd). BCC, basal cell carcinoma; PCOS, polycystic ovary syndrome.

Continued

BOTANICALS AND OTHER BIOLOGICALLY ACTIVE SUBSTANCES USED FOR DERMATOLOGIC CONDITIONS				
Common name	**Latin name and/or sources**	**Active components**	**Uses/properties**	**Known side effects**
Echinacea	*Echinacea purpurea*, *E. angustifolia*, *E. pallida*	Inulin	• Eczema, burns, herpes simplex, wound healing • Stimulates neutrophils & macrophages, antimicrobial, antihyaluronidase	• Hypersensitivity reaction; contraindicated in autoimmune diseases
False hellebore, corn lily	*Veratrum californicum* Durand	Cyclopamine	• Burns (roots), possibly BCC, psoriasis • Cyclopamine inhibits sonic hedgehog signaling pathway	• Contraindicated during pregnancy, breastfeeding
Feverfew	*Tanacetum (Chrysanthemum) parthenium*	Parthenolides vs parthenolide-free extract (PFE), melatonin	• Fevers – oral parthenolide • Anti-inflammatory – *topical* feverfew PFE (topical parthenolide produces ICD)	• GI upset, mouth ulcers, inhibits platelet aggregation; if withdrawal, headache, irritability, insomnia • Contraindicated during pregnancy
Garlic	*Allium sativum*	Allicin, allyl sulfides, ajoene, vinyldithiins	• Atherosclerosis, hypercholesterolemia, hypertriglyceridemia, occasionally verrucae, tinea pedis • Antibacterial, antiviral, antifungal	• Enhances anticoagulation by inhibiting platelet aggregation and increasing fibrinolysis • *Topically*, contact dermatitis
Gotu kola, luei gong gen	*Centella asiatica*	Triterpenoids	• Burns, scars, varicose veins, psoriatic arthritis, scleroderma • Stimulates collagen & fibronectin production; inhibits keratinocyte proliferation	• Absolute contraindication during pregnancy and breastfeeding
Jewelweed	*Impatiens biflora, I. capensis*	Tannins	• *Toxicodendron* dermatitis (conflicting data)	• Nausea, vomiting, diarrhea
Oregon grape root, barberry	*Mahonia aquifolium* (syn. *Berberis aquifolium*)	Berberine	• Psoriasis, chronic pustular eruptions • Antimicrobial, anti-inflammatory, antihistamine, antineoplastic; inhibits sebaceous gland lipogenesis	• Jaundice in infants; caution during pregnancy and breastfeeding
Pansy flower	Viola tricolor	Salicylic acid, saponins, mucilage	• Seborrheic dermatitis in infants	• Salicylate toxicity a *theoretical* risk
Persimmon leaf	*Diospyros kaki* folium	Polyphenols, catechins, vitamins C, B_1, K, β-carotene, flavonoids, tannins	• Eczema, acne • Antioxidant; inhibits tyrosinase, collagenase & elastase	
Propolis	Resinous substance collected by bees, esp. poplars & conifers	Flavonoids, phenolic acids, clerodane diterpenoid	• Aphthous ulcers, herpes simplex (comparable to topical antivirals) • Antimicrobial, anti-inflammatory, antioxidant, antitumorigenic	• Hypersensitivity reactions (see Fig 133.1); contraindicated if allergy to honey, bee products, conifers, poplars
Rosemary	*Rosmarinus officinalis*	Cineole, rosmarinic acid, carnosol	• Antibacterial, antioxidant, antineoplastic	• Contraindicated during pregnancy
Sarsaparilla	*Smilax* spp.	Saponins, sarsaponin, β-sitosterol	• Psoriasis, eczema, scleroderma; anti-inflammatory	• GI symptoms, renal dysfunction
Vitex	*Vitex agnus-castus*	Flavonoids, iridoid glycosides, terpenoids	• Acne related to menstrual cycle • Decreases stress-induced secretion of prolactin via dopaminergic effects; thought to decrease progesterone and increase estrogen levels	• Contraindicated during pregnancy, breastfeeding

Table 133.2 Botanicals and other biologically active substances used for dermatologic conditions (cont'd). GI, gastrointestinal; ICD, irritant contact dermatitis.

Allergic reactions to chamomile, a member of the Compositae (Asteraceae) family, include contact dermatitis and anaphylaxis[6,10].

Horse chestnut seed extract

Horse chestnut seed extract (HCSE) (*Aesculus hippocastanum* L.) is a remedy for chronic venous insufficiency. *Topical* HCSE can be used for varicose veins, phlebitis and hemorrhoids, while *oral* HCSE is effective for chronic venous insufficiency. Controlled studies have shown a decrease in leg volume, calf and ankle circumferences, and pain, with efficacy equivalent to that of grade II compression stockings.

HCSE contains escin (a triterpene saponin), which inhibits the release of elastase and hyaluronidase from leukocytes, thus preventing proteoglycan degradation and vascular leakage. Release of enzymes from activated leukocytes is considered one component of the pathophysiology of chronic venous insufficiency.

Natural horse chestnut seeds are poisonous and need to be processed to remove esculin, a toxic component. Side effects of esculin include hepatotoxicity, renal toxicity, anaphylaxis and possible potentiation of anticoagulation. There has been one case report of drug-induced lupus from a German HCSE-containing oral medication. Irritant contact dermatitis has also been reported[11]. Of note, drug interactions may limit the use of oral HCSE in patients receiving oral hypoglycemics, insulin, anticoagulants, aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), or other supplements that affect serum glucose levels.

Tea (white, green, oolong, black)

Tea (*Camellia sinensis*) has antioxidant, anti-inflammatory, anticarcinogenic, wound-healing, anti-aging and antimicrobial effects. Tea contains flavonoids, caffeine and fluoride. Flavonoid compounds are polyphenolic structures which serve as scavengers for reactive oxygen species[12]. Green tea polyphenols, especially (-)-epigallocatechin gallate (EGCG), also modulate gene transcription and signaling pathways. Although their antioxidant effects are commonly known, it is now thought that tea flavonoids act as anticarcinogens primarily via modulation of cell-signaling pathways.

Both topical and oral green tea can protect against inflammation, UVR-induced photodamage, chemical carcinogenesis and photocarcinogenesis. Green tea appears to have antitumor effects that include melanoma, basal cell carcinoma and squamous cell carcinoma. Because black tea is oxidized (oolong tea to a lesser extent) and this process destroys polyphenols (converting them into theaflavins and thearubigins), white and green teas have higher amounts of polyphenols than do black and oolong teas. Nonetheless, black tea has been shown to decrease UVB-induced damage and inhibit tumor proliferation.

Caffeine, present in teas, appears to have an independent protective effect against photocarcinogenesis[13].

A topical formulation of green tea, sinecatechins ointment 15% (Veregen®), is FDA-approved for treating condylomata acuminata. In addition, patients with atopic dermatitis experienced improvement when they drank oolong tea.

Tea is generally safe for adults; common side effects are caffeine-related (gastrointestinal symptoms, restlessness, insomnia). Liver damage has been reported with concentrated green tea extracts, and two cases of hypokalemia occurred in elderly individuals with extreme tea consumption (3–14 liters/day).

Licorice root

Licorice root (*Glycyrrhiza inflata*, *G. uralensis*, *G. glabra*) is used for its anti-inflammatory properties by both European and Chinese herbalists. It can be used, both topically and orally, for rosacea and eczematous dermatitis. Licorice contains flavonoids, chalcones (antioxidants), glycyrrhizin and liquiritin. Liquiritin cream has been used to treat melasma, with enhanced efficacy compared to placebo (70% vs 20%). Glycyrrhizin confers anticarcinogenic and antiviral effects, but it also inhibits 11β-hydroxysteroid dehydrogenase and can have mineralocorticoid-like effects. Excessive use of licorice root may lead to hypertension, edema, congestive heart failure and hypokalemia (i.e. syndrome of apparent mineralocorticoid excess)[6].

Fumaric acid esters

Fumarates represent breakdown products of the urea cycle, which then enter the Krebs cycle and produce energy. Good evidence exists for the use of an oral fumarate for severe psoriasis[14]; this is widely accepted in Europe. Fumaric acid esters inhibit epidermal cell turnover, lymphocyte proliferation and intercellular adhesion molecule expression, and they alter the cytokine profile in psoriatic plaques. Side effects are common and include gastrointestinal upset, cramping, diarrhea, skin flushing, lymphopenia and eosinophilia.

Olive oil and olive leaf extract

Olive oil and olive leaf extract (*Olea europaea*) can be used for hydration, for wound healing, and to stimulate blood flow[15]. The oil is used for scars, cleansing, calluses, brittle nails, onychomycosis, hair conditioning, sunburn and diaper dermatitis. Extra-virgin grade is preferred, produced by physical means only (without heat or chemicals for extraction). Both olive oil and olive leaf extract contain oleic and palmitic acids as well as a number of antioxidants, primarily secoiridoids (oleuropein), lignans, flavonoids, phenolic acids and alcohols.

Topical olive oil applied after UVB exposure decreases DNA damage (in the form of 8-hydroxy-2′-deoxyguanosine) and it protects against photocarcinogenesis in mice; this effect is not seen if the oil is applied *prior* to UVB exposure, implying photolability of the active component. Olive leaf extract administered orally decreased UVB-induced tumors in mice, presumably by inhibiting the expression of matrix metalloproteinases, VEGF and cyclooxygenase-2.

Turmeric

Turmeric (*Curcuma longa*) contains curcumin, which consists of tumerone, curcuminoids and heptanoids[15]. It is used both orally and topically to treat wounds, ulcers, dermatitis and pruritus. In general, turmeric is administered orally for radiation dermatitis and psoriasis. Curcumin has anti-inflammatory, antioxidant, anticarcinogenic and antimicrobial properties. It inhibits lipoxygenase and cyclooxygenase, thereby reducing levels of leukotrienes, thromboxanes and prostaglandins. Turmeric also reduces expression of interleukin-12, NF-κB and TNF-α as well as impairing induction of a Th-1 immune response. In addition, curcumin inhibits collagenase, elastase and hyaluronidase. The most common side effect is gastrointestinal upset; curcumin is contraindicated in patients with gallbladder disease.

Escharotics

Escharotics include zinc chloride, bloodroot (*Sanguinaria canadensis*) and goldenseal (*Hydrastis canadensis*)[16]. These agents are caustic and can produce necrotic crusts, pain and even scarring. In the past, escharotics were used topically to treat skin cancers, but they have since been replaced by more efficacious methods. Nowadays, patients may erroneously use them for this purpose.

Prebiotics and probiotics

Prebiotics are non-digestible sugars that encourage the growth of certain "good" types of bacteria within the intestine. Probiotics are live microorganisms that are ingested in an attempt to alter the gastrointestinal flora into a beneficial mix. Probiotics can be in tablets or food, especially yogurt, fermented and unfermented milk, miso, tempeh and soy beverages. The most commonly used probiotics are *Lactobacillus*, *Bifidobacterium* and *Saccharomyces boulardii*.

Patients with eczema have been shown to have different gastrointestinal flora (e.g. a reduced proportion of *Bifidobacteria* spp. in the feces of infants with eczema) and are thought to have more inflammation and permeability of their intestines. Probiotics decrease intestinal inflammation and permeability, and perhaps this may alter antigen presentation in a way that is beneficial for eczema. However, in trials, probiotics have led to a modest, if any, improvement in eczema, but additional subspecies have yet to be studied. Side effects usually consist of mild gastrointestinal symptoms, but there have been case reports of probiotic sepsis[17].

Diet-based therapies

Dietary modifications have been used to treat atopic dermatitis. Certain foods, thought to be allergenic, are excluded from the diet. Most commonly, the diet involves elimination of common allergens such as cow's milk and/or eggs, or elimination of a food associated with a proven food allergy. More extreme diets include the "few foods diet", in which only a few foods are permitted, and the "elemental diet", which is an all-liquid diet containing vitamins, minerals, amino acids, carbohydrates and fat (e.g. triglycerides); these diets can cause nutritional deficiencies. Kwashiorkor has even been observed in infants on the rice milk diet. Although several randomized, controlled trials support the use of an egg-free diet to treat atopic dermatitis in infants with IgE antibodies to eggs, there does not seem to be any benefit in restricting foods for patients without a known food allergy[18]. Exacerbation of acne by high glycemic load diets has been reported by several groups, and increased dairy ingestion appears to be weakly associated with acne.

Side Effects

Herbs are composed of organic and inorganic components that are biologically active, and as with any medication, may have serious side effects[19] and/or interact with other medications. Multiple herbal and dietary supplements can affect coagulation, as both procoagulants and anticoagulants (Table 133.3). Because patients often do not report use of CAM (up to 70%), it is recommended that preoperative assessments include specific questioning regarding dietary supplements (see Ch. 151).

A common misperception exists that herbs are "natural" and "safer" than prescription medications. Hematologic, nephrotoxic, cardiotoxic and hepatotoxic effects have been observed, as well as contact allergy (Fig. 133.1), phototoxicity (Fig. 133.2) and hypersensitivity reactions, including anaphylaxis, Stevens–Johnson syndrome and toxic epidermal necrolysis. Additionally, in most countries, herbal medicine is not subject to the same regulation as prescription medications. Some herbal supplements have been found to be contaminated with metals, prescription drugs (e.g. corticosteroids, NSAIDs), microorganisms and other substances.

Several challenges stem from the use of plants as therapeutics. These considerations include differences in: climate and soil; cultivars and species; growing, harvesting and storage conditions; methods of extraction; chemical standardization of products; and bioavailability of formulations[1].

TRADITIONAL CHINESE MEDICINE

Traditional Chinese medicine (TCM) is a system of healing that originated in China prior to 2000 BC. Unique versions then developed in Japan, Korea and other countries. TCM encompasses a myriad of treatment modalities, including herbal medicine, acupuncture, massage, exercise, and dietary and lifestyle modifications (Table 133.4). Herbal medicine represents approximately two-thirds of the TCM armamentarium, and acupuncture one-third.

TCM takes a holistic attitude towards health. For health to occur, balance and harmony must be achieved between two opposing and complementary forces, Yin and Yang. Central to Yin–Yang theory is the

DIETARY SUPPLEMENTS AND EFFECTS ON COAGULATION		
MOST COMMONLY USED DIETARY SUPPLEMENTS (US)		
Name	**Common uses**	**Effects on coagulation**
Fish oil, omega-3 fatty acids (eicosapentaenoic acid, docosahexaenoic acid)	Cardiovascular disease, hypertriglyceridemia, see Table 133.2	Inhibits platelet aggregation
Glucosamine sulfate	Osteoarthritis, chronic venous insufficiency	Increases INR, potentiates warfarin
Flaxseed, flaxseed oil	Constipation, menopausal symptoms (seed), arthritis, hypercholesterolemia	Theoretically, may potentiate anticoagulation
Ginseng	Mental and physical performance, see Table 133.2	Inhibits platelet aggregation, contains coumarins, decreases anticoagulant effect of warfarin (by inducing P450)
Ginkgo biloba	Dementia, cardiovascular disease, see Table 133.2	Inhibits platelet aggregation (blocks platelet-activating factor), decreases plasma viscosity
Chondroitin sulfate	Osteoarthritis	Antithrombotic
Garlic	Hypercholesterolemia, atherosclerosis, hypertension	Increases clotting time, inhibits platelet aggregation, increases fibrinolysis, decreases plasma viscosity
Coenzyme Q10	Hypertension, age-related macular degeneration, atherosclerosis, cardiomyopathy; slowing the progression of Parkinson's disease, dementia	Possible competitive inhibitor of vitamin K-dependent clotting factors; paradoxically, decreases the anticoagulant effect of warfarin
Fiber or psyllium	Constipation, diarrhea, irritable bowel syndrome, diverticulosis, hypercholesterolemia, colorectal carcinoma prevention	Psyllium may reduce absorption of warfarin
Green tea	Prevention of cardiovascular disease, cancer, kidney stones, see Table 133.2	Inhibits platelet aggregation, but contains vitamin K and decreases warfarin efficacy in large quantities
Cranberry (pills, gelcaps)	Urinary tract infections, *Helicobacter pylori* infection	May increase INR in patients taking warfarin
Saw palmetto	Benign prostatic hypertrophy	May increase effects of anticoagulants, antiplatelet medications, and NSAIDs
Soy or other isoflavones	Hypercholesterolemia, cancer prevention	May decrease efficacy of warfarin slightly
Melatonin	Jet lag, insomnia	Probably minimal; may increase efficacy of warfarin
Vitamin C	Prevention of URIs, urinary tract infections, cancer	Increases effects of aspirin, but conversely, very high doses may lower prothrombin time
Vitamin E	Antioxidant	Inhibits platelet adhesion and aggregation
Magnesium	Hypertension, cardiovascular disease, diabetes	Inhibits platelet adhesion and aggregation
ADDITIONAL SUPPLEMENTS		
Name	**Medicinal (other) uses**	**Effects on coagulation**
Alfalfa	Atherosclerosis, diabetes, hypercholesterolemia	Contains coumarins and vitamin K
Bilberry	Diabetes, retinopathy, diarrhea	Contains coumarins
Capsaicin	Dyspepsia, arthritis, postherpetic neuralgia	Contains coumarins, inhibits platelet aggregation
Celery	Arthritis, urinary tract infections	Contains coumarins
Chamomile	Dyspepsia, anxiety, dermatitis	Contains coumarins, inhibits P450
Dan shen	Cardiovascular disease, thrombosis	Inhibits platelet aggregation, antithrombin III-like activity
Dang gui (dong quai)	Menopausal symptoms, menstrual disorders	Contains coumarins
Fenugreek	Dyspepsia, diabetes, stimulation of breastmilk production (cooking)	None known, but contains coumarins
Feverfew	Migraines, arthritis, fever	Inhibits platelet aggregation
Ginger	Nausea, osteoarthritis, rheumatoid arthritis (cooking)	Inhibits platelet function, decreases platelet thromboxane production, vitamin K antagonist
Goldenseal	URIs, inflammation	Contains coumarins and berberine, a heparin antagonist
Horse chestnut seed extract	Chronic venous insufficiency, hemorrhoids	If raw or not processed well, contains esculin, a coumarin
Horseradish	Infection, inflammation	Contains coumarins
Huang qi	Immune system stimulant	Inhibits platelet aggregation and increases fibrinolysis (*in vitro*)
Kava kava	Anxiety, stress	Decreases platelet aggregation, can cause severe hepatotoxicity
Licorice	Cough, inflammation	Contains coumarins
Passion flower	Anxiety, insomnia	Contains coumarins
Red clover	Respiratory "problems", menopausal symptoms, psoriasis	Contains coumarins
St. John's wort	Depression	Induces hepatic cytochrome P450 and increases metabolism of warfarin

Table 133.3 Dietary supplements and effects on coagulation. List of most commonly used dietary supplements based upon data from the National Center for Health Statistics. Most commonly used supplements for which no effects on coagulation have been reported to date include echinacea, silymarin and lutein; minimal data are available for grape seed extract and methysulfonylmethane. **Sweet clover and buckwheat are reviewed in Table 133.2.** INR, international normalized ratio; NSAIDs, nonsteroidal anti-inflammatory drugs; URIs, upper respiratory tract infections. *Adapted with permission from Collins SC, Dufresne RG. Dietary supplements in the setting of Mohs surgery. Dermatol Surg. 2002;28:447–52.*

TRADITIONAL CHINESE MEDICINE (TCM) TREATMENT MODALITIES	
Modality	**Delivery methods/related modalities**
Herbal medicine	Decoctions – water is used to simmer herbs, then the decanted fluid is taken in divided doses
	Topical poultices
	Essential oils
	Lotions, creams, ointments
	Tablets, capsules
Acupuncture	Needles – stainless steel (most common), gold, silver
	Moxibustion
	Cupping, coining, rubbing
	Acupressure
	Electroacupuncture
	Auricular acupuncture
	Laser acupuncture
	Medicamentous acupuncture
	Magnet therapy
Therapeutic exercise	Tai ji (tai chi), qi gong (chi gong)
Massage therapy	Tui na, acupressure
Dietary modification	
Meditation	

Table 133.4 Traditional Chinese medicine (TCM) treatment modalities.

Fig. 133.2 Phototoxic reaction due to herbal tea. *Courtesy, Josef Smolle, MD.*

concept that no single part can be understood except in relation to the whole. Yin–Yang theory takes a dialectical view of health, which differs fundamentally from conventional medicine's reductionist view of disease. Normal flow patterns of Qi, or life-force (which is Yang), and Blood (which is Yin) are essential for health, and disruptions of flow cause pain and disease. Regulation of flow is the goal of therapy, and acupuncture, moxibustion and massage are thought to correct Qi/Blood flow and thus health.

TCM has been employed for most dermatologic conditions. While a complete discussion is beyond the scope of this chapter, the next section focuses on TCM treatments for atopic dermatitis and psoriasis.

TCM – Herbal Medicine

Atopic dermatitis

A Cochrane systematic review analyzed a number of studies involving the use of Chinese herbal preparations for atopic dermatitis, including three double-blind, randomized, controlled, crossover trials, all investigating a standardized mixture of 10 raw herbs (see below)[20]. In two of these trials, greater improvement was observed with the herb decoction (extraction of water-soluble components via boiling) than with placebo. For both adults and children, the 10-herb decoction led to greater reductions in erythema, surface area of involvement, and pruritus, as well as improved sleep quality. A third trial failed to demonstrate any difference between the 10-herb decoction and placebo. Hematologic cell counts, renal function, and liver function studies were performed in all three studies, and no changes were observed.

One-year follow-up observational studies were performed with both adult and pediatric patients who chose to continue the herbal decoction. There was a significant benefit as compared with patients who chose not to continue. During this 1-year study, two of 37 children experienced asymptomatic elevations in serum levels of aspartate aminotransferase which normalized after discontinuing the herbs; no adult patient experienced laboratory abnormalities.

By focusing on the 10 herbs present in the decoction (*Ledebouriella seseloides*, *Potentilla chinensis*, *Anebia clematidis*, *Rehmannia glutinosa*, *Paeonia lactiflora*, *Lophatherum gracile*, *Dictamnus dasycarpus*, *Tribulus terrestris*, *Glycyrrhiza uralensis* and *Schizonepeta tenuifolia*), multiple studies have sought to characterize possible mechanisms of action. For example, CD23, a low-affinity IgE receptor found on monocytes/macrophages in the peripheral blood and skin, is overexpressed in patients with atopic dermatitis, and these herbs can lead to a dose-dependent reduction in CD23 expression, and they may also reduce HLA-DR expression. Additionally, these herbs have antioxidant properties.

For pruritus associated with atopic dermatitis, two Japanese remedies (Sho-seiryu-to, Moku-boi-to) have antihistamine effects equal to that of diphenhydramine.

Psoriasis

TCM herbs with anti-inflammatory and immunosuppressive effects are used to treat psoriasis, including *Indigo naturalis*, *Tripterygium wilfordii* Hook, *Tripterygium hypoglaucum* Hutch and *Camptotheca acuminata*

Decne. A randomized, placebo-controlled trial of *Tripterygium wilfordii* Hook for rheumatoid arthritis showed a significant dose-dependent immunosuppressive response[21], and when compared to sulfasalazine, the herb extract was superior[22]. Side effects include gastrointestinal symptoms, myelosuppression and elevated liver enzymes.

In a study of 801 psoriatic patients, over half responded to a decoction of five herbs (*Rhizoma sparganii*, *Rhizoma zedoariae*, *Herba serissae*, *Resnia boswelliae* and *Myrrha*)[23]. Herbs that contain furocoumarins, such as *Radix angelicae dahuricae* and *Radix angelicae pubescentis*, can be used in conjunction with UVA phototherapy for a psoralen-like effect. Psoriasis clearance rates were similar for *Radix angelicae dahuricae* plus UVA versus PUVA (with 8-MOP), with fewer side effects.

Side effects

As with other botanicals, TCM herbs have biologically active components, and may have serious side effects. TCM should be administered under the supervision of a licensed practitioner.

TCM – Acupuncture

Acupuncture is considered less useful than herbal medicine for dermatologic conditions. There are case reports of using acupuncture for atopic dermatitis, neurodermatitis, lichen planus, psoriasis, alopecia areata, verrucae, herpes viral infection, postherpetic neuralgia, and urticaria[24]. One controlled trial of acupuncture for psoriasis failed to demonstrate any efficacy over placebo. More support exists for the use of acupuncture for symptoms associated with dermatologic conditions, e.g. pain, pruritus, stress, anxiety and depression.

Mechanism of action

Proposed mechanisms of action for acupuncture analgesia include: gate control, diffuse noxious inhibitory control, and stimulating release of neuroactive substances including endorphins and enkephalins[25]. By altering the release of neurotransmitters, acupuncture may exert anti-inflammatory and immunomodulatory effects. In addition, it has the potential for balancing the sympathetic (Yang) and parasympathetic (Yin) nervous systems. Acupuncture has also been shown to increase adrenal production of corticosterone and cortisol as well as production of β-endorphin and corticotropin by the pituitary.

The proposed mechanism of action of acupuncture for depression and anxiety incorporates the monoamine hypothesis for affective disorders. Both cerebral serotonin release and intracephalic blood flow are increased by specific acupuncture points.

Side effects

Fatigue is the most common side effect associated with acupuncture (<10% of patients), with a small minority of patients (<1%) experiencing cutaneous side effects such as pruritus, petechiae, ecchymoses, or subcutaneous hematomas. Infection and pneumothorax have also been reported. Infectious risks are minimized by using single-use needles, and the risk of pneumothorax is minimized by using traditional angles of insertion. Localized argyria (rare) can result from using subcutaneous permanent needles made of silver instead of stainless steel.

TCM – Moxibustion, Cupping and Other Treatment Modalities

Moxibustion is the practice of burning dried moxa (*Artemisia vulgaris*), placed in small cone-shaped piles, over acupuncture points. Moxibustion may be either direct, in which the moxa-cones are allowed to burn completely down to the skin surface, or indirect, in which the cones are removed prior to the burning fibers touching the skin. Side effects include first- and second-degree burns.

Cupping is another method used to stimulate acupuncture points. It is accomplished by igniting alcohol-soaked cotton, placing the burning cotton in a jar, and placing the jar on the skin. A vacuum is created, and circular areas of erythema and ecchymosis may result (Fig. 133.3).

Skin scraping, also known as coining or spooning, is commonly practiced in Southeast Asia to improve circulation. A tool is used to rub skin that has been treated with oil; symmetric, linear ecchymoses may result (Fig. 133.4).

Fig. 133.3 Cupping. Well-demarcated circular areas that are pink-purple and yellow in color and contain petechiae. *Courtesy, Donald J Baker, MD.*

Fig. 133.4 Linear ecchymoses on the back due to coining.

Any Asian patient with cutaneous lesions in patterns suggestive of external causes should be asked about traditional medicine before accusations of abuse arise. Ethiopians have similar practices of moxibustion and cupping.

HOMEOPATHY

Homeopathy is a system of healing founded by Samuel Hahnemann (1755–1843), a German physician. He hypothesized that one can select treatments based on the "principle of similars", which states that symptoms may be cured by giving a therapy that induces the same symptoms. A homeopathic therapy provides the additional stimulus needed for the body to recognize and fight an illness. Hahnemann studied remedies by giving repeated doses to healthy volunteers and then observing their physical symptoms, emotions and mental states[26].

Homeopathic remedies are given in dilutions; a second assumption of homeopathy, the "principle of infinitesimals", hypothesizes that the higher the dilution, the greater the effect. Some remedies are so highly diluted (one part in 10^{24} or higher) that not a single molecule of the substance remains, according to the laws of chemistry and Avogadro's number (6.023×10^{23}). In homeopathy, however, it is believed that the dilutant, usually alcohol and water, or sugar pellets, carries an "essence" of the original substance, which can be used to treat disease. This "essence" is thought to be an imprint of the electromagnetic frequency of the original substance, which then acts as an "energetic vaccine" to stimulate the body to heal itself.

Dermatologic Applications

Skin disease is one of the most common reasons why patients seek homeopathic treatment. At a British homeopathic hospital, eczema and psoriasis accounted for 13% of referrals[27]. Homeopathy is also used to treat seborrheic dermatitis, urticaria, acne, rosacea, alopecia areata, radiation-induced pruritus, verrucae and other infections. Unlike herbal remedies, the manufacture and sale of homeopathic remedies are regulated by the FDA, although the FDA does not endorse the use of homeopathy.

Mechanism of Action and Clinical Evidence

In general, evidence to support the use of homeopathy for dermatologic conditions is limited to anecdotal case reports. A few studies have tried to demonstrate the "essence" of water dilutant. A study published in *Nature* demonstrated degranulation of human basophils using very dilute antiserum against IgE[28], but this has not been replicated.

Meta-analyses of the literature have found conflicting evidence regarding the efficacy of homeopathy. Randomized, controlled trials of homeopathic treatment of warts have not found any efficacy beyond that of placebo[26].

Side Effects

Because homeopathic remedies are usually highly diluted, side effects, e.g. headache, fatigue, myalgia, arthralgia, diarrhea, are rare. Contact dermatitis has been reported[27]. Homeopathy should be used under the supervision of a licensed practitioner.

AROMATHERAPY

Aromatherapy is the therapeutic use of aromatic essential oils. Considered a subset of botanical medicine, aromatherapy may use any plant part, including leaves, stems, flowers, fruits, roots and wood resins. Essential oils are obtained via solvent extraction, steam distillation, cold-pressing or other methods.

The term "aromathérapie" was coined in 1927 by René-Maurice Gattefossé, a French chemist, whose interest began after a personal incident. After burning his hand in the laboratory, Gattefossé dipped it into a nearby vat of lavender oil. His hand healed rapidly, and he subsequently studied essential oils at military hospitals during World War I. Today, France is a leader in aromatherapy research.

Aromatherapy is used to treat a wide range of physical, mental and emotional states. Oils may be used externally or internally. External methods are more common and include inhalation, massage, compresses, gels/creams/pastes, sprays and baths. Internal routes include oral, otic, intrarectal and intravaginal[29].

Dermatologic Applications

Aromatherapy may be used directly to treat dermatologic conditions, or indirectly to treat the anxiety or other psychiatric symptoms associated with psychocutaneous disorders (Table 133.5). Indications for aromatherapy include: wound healing (burns, ulcers), acne, alopecia areata, pruritus, xerosis, psoriasis, contact dermatitis, radiation dermatitis, herpes viral infections, scarring and analgesia. Treatments often employ multiple oils, e.g. for psoriasis, lemon balm is used for associated xerosis and pruritus, chamomile for stress reduction, and lavender to promote relaxation[29].

Mechanism of Action and Clinical Evidence

Essential oils are mixtures of organic compounds including acids, alcohols, aldehydes, coumarins, esters, ethers, ketones, lactones, oxides, phenols and terpenes. Oils high in ketones are used for wound healing, while acids, aldehydes and alcohols have antimicrobial and immunostimulatory properties. Phenols, ethers and terpenes are antimicrobial, with terpenes also having antihistamine and cortisone-like effects. Of note, essential oils that are inhaled or applied topically have been shown to enter the bloodstream.

Because of its antimicrobial properties, tea tree oil (*Melaleuca alternifolia*) is one of the most commonly used aromatherapies for skin disorders. A single-blind trial in acne patients found similar efficacies for tea tree oil 5% gel and benzoyl peroxide 5% lotion; tea tree oil had a slower onset of action but fewer side effects. The efficacy profile of tea tree oil 100% for onychomycosis is similar to that of clotrimazole 1% solution. For tinea pedis, tea tree oil 10% cream helps ameliorate symptoms, but is no more effective than placebo in achieving mycologic cure. As tea tree oil contains terpinenes, it can cause allergic contact dermatitis[29].

In a randomized, controlled, double-blind trial in alopecia areata, aromatherapy (thyme, rosemary, lavender, cedarwood) led to significantly greater improvement than did the placebo (44% vs 15%)[30].

AROMATHERAPY: ESSENTIAL OILS USEFUL IN DERMATOLOGICAL CONDITIONS

Latin name	Common name	Actions/Indications
Boswellia carterii	Frankincense	Immunostimulant; wound healing
Citrus aurantium var. *amara*	Petitgrain	Infected acne
Citrus bergamia	Bergamot	Pruritus, psoriasis, HSV-1 infection, wound disinfection
Citrus sinensis	Sweet orange	Wound disinfection
Cymbopogon citratus	Lemongrass	Anti-inflammatory
Eucalyptus citriodora	Eucalyptus (lemon scented)	Anti-inflammatory, analgesic; herpes zoster, candidiasis
Eucalyptus radiata	Australian eucalyptus	Acne
Jasminum officinalis	Jasmine	Antiseptic, anti-inflammatory
Juniperus communis	Juniper berry	Anti-inflammatory, analgesic; skin "problems"
Juniperus communis	Juniper twig	Acne
Lavandula angustifolia	True lavender	Burns, wound healing, analgesic
Lavandula latifolia	Spike lavender (French)	First-degree burns, neuralgia
Lavandula stoechas	Stoechas lavender	Dermatitis
Melaleuca alternifolia	Tea tree	Antifungal, antiviral, antibacterial; acne, verrucae, radiation burn prevention
Melaleuca leucadendra	Cajeput	Genital herpes viral infection, radiation burn prevention
Melaleuca quinquenervia/ viridiflora	Nialouli	Dermatitis
Melissa officinalis	Lemon balm	Viral skin infections
Mentha x piperita	Peppermint	Dermatitis, herpes viral infections
Ocimum basilicum	Basil	Dermatitis
Pelargonium x asperum	Geranium	Acne, impetiginized dermatitis
Pinus sylvestrus	Scots pine	Allergy, inflammation
Piper nigrum	Black pepper	Analgesic
Pogostemon cablin	Patchouli	Anti-inflammatory, antiseptic, antimicrobial; acne, seborrhea, dermatitis (including weeping forms), scars, tinea pedis
Ravensara aromatica	Ravensara	Herpes zoster
Rosa damascena	Rose	Dermatitis
Rosmarinus officinalis	Rosemary (verbenone) CT verbenone	Antispasmodic
Satureja montana	Winter savory	Oil used for its antibacterial, antiparasitic, antiviral and antifungal properties; psoriasis, analgesia
Styrax benzoe	Benzoin	Skin infections, acne, dermatitis, psoriasis, ulcers

Table 133.5 Aromatherapy: essential oils useful in dermatological conditions. HSV, herpes simplex virus. *Reproduced with permission from Stevenson CJ. Aromatherapy in dermatology. Clin Dermatol. 1998;16:689–94.*

Lemon balm (*Melissa officinalis*) may be used for herpes labialis; it resulted in a decrease in lesion size and healing time in a double-blind, randomized, controlled trial. The active components are tannins, polyphenols, terpenes and sesquiterpenes, including citronella, citral-A and citral-B. Lastly, a number of essential oils, including lavender, have anxiolytic and sedative properties and may be useful for dermatologic disorders worsened by stress[31].

Additional potential uses of essential oils in dermatology include as antitumor agents, enhancers of transdermal drug delivery, and promoters of cutaneous blood flow.

Side Effects

Essential oils have biologically active components and may be toxic. For example, ketones can have neurotoxic effects, especially in patients with seizure disorders, pregnant women and children. Some compounds are potentially carcinogenic, including safrole in sassafras oil and β-asarone in calamus oil[29]. Cutaneous side effects include contact dermatitis and phytophotodermatitis.

MIND–BODY MEDICINE

Mind–body medicine encompasses a wide range of therapeutic interventions which emphasize the complex interactions involving the brain, mind, behavior, spirit and body. Mind–body interventions include meditation, relaxation, hypnosis, imagery, yoga, tai chi, qi gong, biofeedback, cognitive behavioral therapies, group therapy, breathing techniques, autogenic training, dance therapy, music therapy, spirituality and prayer (see Table 133.1). Excluding prayer, approximately 30% of the US population has used mind–body therapy, most commonly meditation, guided imagery and yoga. Prayer was used by more than 50%[1].

Western medicine acknowledges mind–body relationships such as the placebo effect, which accounts for 35% of the therapeutic response to any treatment[1]. However, the mental and spiritual aspects of health are challenging to study, and scientific and technologic advances have led to an emphasis on the physical aspects of medicine and a separation from the less tangible facets of healing.

Dermatologic Applications

Patients with psychocutaneous disorders are good candidates for mind–body interventions, including those with skin manifestations of primary psychiatric diagnoses (e.g. obsessive–compulsive disorder, body dysmorphic disorder); dual psychiatric/dermatologic diagnoses (e.g. neurotic excoriations, trichotillomania); and dermatologic conditions that can be worsened by emotional factors (e.g. acne, psoriasis, atopic dermatitis) (Table 133.6)[32].

Good evidence exists for the use of hypnosis for atopic dermatitis, alopecia areata, verrucae and psoriasis, as well as for relaxation during procedures. Patients who have higher levels of hypnotic susceptibility seem to benefit more. There are scattered case reports of its use in urticaria, hyperhidrosis, acne excoriée and vitiligo. For verrucae, hypnosis has response rates of 27% to 55%, and children respond better than adults[33]. In a study of 21 patients with severe alopecia areata refractory to standard therapy (nine with totalis or universalis), 12 (57%) showed hair regrowth of 75% to 100% after three to eight sessions of hypnotherapy; five patients had subsequent relapse.

There is preliminary evidence supporting the use of group therapy, biofeedback, psychotherapy and massage therapy for atopic dermatitis[34]. Controlled trials using cognitive behavioral therapy, meditation, hypnosis and/or stress-reduction audiotapes have shown promising results for psoriasis[35]. One study of trichotillomania found cognitive behavioral therapy to be better than fluoxetine, while a controlled trial of massage therapy for children with atopic dermatitis (as an adjunct following medication application) observed a greater decrease in redness, lichenification, excoriation, pruritus and anxiety levels in the massage therapy group (compared to medication alone). There are case reports of using biofeedback (e.g. for rosacea, acne, urticaria, Raynaud's phenomenon), guided imagery/relaxation therapy (e.g. acne excoriée, psoriasis, hyperhidrosis, neurotic excoriations), and cognitive behavioral therapy (e.g. acne excoriée, prurigo nodularis, onychotillomania, trichotillomania, body dysmorphic disorder)[36].

Mind–body interventions have been found to be useful in treating problems indirectly associated with dermatologic conditions. Nociception is readily altered by meditation and behavioral techniques, and in dermatologic surgery, there is the potential for improved wound healing and pain reduction.

DERMATOLOGICAL CONDITIONS ASSOCIATED WITH PSYCHO-EMOTIONAL FACTORS

DERMATOLOGICAL CONDITIONS WITH PSYCO-EMOTIONAL COMPONENT	
• Hyperhidrosis	• Telogen effluvium
• Dyshidrotic eczema	• Alopecia areata
• Pruritus sine materia	• Median nail dystrophy
• Urticaria	• Acne vulgaris
• Lichen simplex chronicus	• Rosacea
• Atopic dermatitis	• Perioral dermatitis
• Nummular dermatitis	• Warts
• Psoriasis	• Herpes simplex
• Seborrheic dermatitis	• Vitiligo
• Lichen planus	• Contact dermatitis
PSYCHOCUTANEOUS DISORDERS	
• Dermatitis artefacta	• Dermatologic phobias
• Neurotic excoriations	Venereophobia
• Trichotillomania	Oncophobia
• Onychotillomania	Dysmorphophobia (dermatologic non-disease)
• Delusions of parasitosis (Ekbom's syndrome)	Bromidrosiphobia
• Body dysmorphic syndrome	• Glossodynia/glossopyrosis*
• Hypochondriasis	• Vulvodynia/vulvopyrosis*

*Following exclusion of underlying medical etiologies.

Mechanism of Action and Clinical Evidence

Mind–body medicine is an active area of research. The hypothalamic–pituitary–adrenal (HPA) axis and autonomic nervous system (ANS) affect immunity and endocrine function via their regulation of glucocorticoid and catecholamine production, respectively. Therefore, psychological and behavioral interventions that affect the HPA and ANS activity have the potential to treat disease. Stress or different mood changes can slow wound healing, in part by altering the expression of matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) and by activating the HPA axis[1].

The skin itself produces enough hormones, neurotransmitters, neuropeptides and functional receptors to form complete, cutaneous neuroendocrine axes. These include cutaneous equivalents of: (1) the HPA axis; (2) the cholinergic system; (3) the catecholaminergic system; (4) the serotoninergic/melatoninergic system; (5) steroidogenic pathways; and (6) pituitary–thyroid axis elements. These local neuroendocrine systems are used by the skin to preserve homeostasis[37]. However, most of the research has focused on interactions just within the skin, rather than on interactions between the skin, central nervous system, and body.

One model is the "neuro-immuno-cutaneous-endocrine (NICE)" network, in which four physiologic systems interact via a complex amalgamation of neurotrophic substances, cytokines, hormones including glucocorticoids, and other molecules. For example, physical stimulation of the skin induces the release of neuropeptides, which can influence the CNS as well as having local effects. In particular, α-melanocyte stimulating hormone (α-MSH), which is produced by the skin and the pituitary gland, may play a key role. α-MSH inhibits experimentally induced cutaneous inflammation[38]. In addition, fibroblasts and melanocytes, but not keratinocytes, respond to corticotropin-releasing hormone in a manner analogous to the HPA axis, by releasing corticosterone (fibroblasts and melanocytes) and cortisol (melanocytes). Through this network, the mind can exert a myriad of physiologic effects on nociception, wound healing, immunity and other aspects of health.

Side Effects

Mind–body interventions have minimal side effects because physical agents are not used. Potential side effects include autonomic responses such as lightheadedness, nausea, vomiting or syncope.

CONCLUSION

Globally, CAM is increasing in popularity for all diseases, including many dermatologic disorders. It is important for dermatologists to recognize and acknowledge the use of CAM in their patients, both to better empathize with their patients as well as to recognize potential side effects. There are a few studies supporting the role of CAM modalities in dermatology, including herbal medicine, traditional Chinese medicine, homeopathy, aromatherapy and mind–body medicine. However, many of these studies are case series, or animal or *in vitro* studies, and there is a need for additional and better-designed studies.

Ultraviolet Therapy 134

Herbert Hönigsmann and Thomas Schwarz

Chapter Contents

Phototherapy with UVB 2219
Phototherapy with the 308 nm excimer laser 2223
Phototherapy with UVA1 2223
Phototherapy with psoralens (PUVA) 2224
Extracorporeal photochemotherapy (photophoresis) 2233

Key features

- Phototherapy denotes the use of ultraviolet (UV) light in the treatment of skin disease
- Currently, phototherapy encompasses irradiations with broadband UVB (290–320 nm), narrowband UVB (311–313 nm), 308 nm excimer laser, UVA1 (340–400 nm), UVA plus psoralens (PUVA), and extracorporeal photochemotherapy (photopheresis)
- Therapeutic success depends upon proper selection of the phototherapy modality for a given disease
- Proper dosimetry is required to avoid acute side effects such as a sunburn reaction, blistering, and burning sensations
- The risk of skin carcinogenesis represents the major long-term side effect of phototherapy. Except for PUVA, the magnitude of this risk is not yet clearly delineated

INTRODUCTION

Over the past 40 years, phototherapy has greatly influenced treatment concepts in dermatology. Studies focusing on the effects of electromagnetic radiation (Fig. 134.1) on the skin have induced fruitful collaborations between basic scientists and clinicians.

Although ultraviolet (UV) radiation had been used for decades in the management of common skin diseases such as psoriasis and atopic dermatitis, the introduction of PUVA in the mid-1970s sparked a whole new series of discoveries, including high-intensity UV sources and selective spectra in the UVB and UVA range, e.g. narrowband UVB (311–313 nm) and UVA1 (340–400 nm).

PHOTOTHERAPY WITH UVB

Historical Aspects

Phototherapy using artificial light sources has a tradition dating back more than 80 years. The combination of topical crude coal tar and subsequent UV irradiation for the treatment of psoriasis was introduced by Goeckerman in 1925 and became a standard therapy for psoriasis for half a century, particularly in the US. In the 1970s, it was observed that broadband UVB radiation alone, if given in doses that produce a slight erythema, could clear the milder forms of psoriasis, particularly the seborrheic and guttate types. A major advance was the development of fluorescent bulbs that emitted narrowband UVB radiation at 311–313 nm in the mid-1980s. This narrow spectrum is superior in clearing psoriasis and thus represents the most effective and most frequently used UVB phototherapy for psoriasis; it is also beneficial for a variety of other dermatoses that were previously treated with PUVA (see below).

Principles and Mechanisms

UVB phototherapy refers to the use of artificial UVB radiation without the addition of exogenous photosensitizers. The radiation is absorbed by endogenous chromophores, and photochemical reactions involving these UV-absorbing biomolecules mediate a variety of biologic effects, ultimately leading to the therapeutic effects. The most important chromophore for UVB is nuclear DNA. Absorption of UV by nucleotides causes the formation of DNA photoproducts, primarily pyrimidine dimers (see Ch. 86)[1].

UVB exposure reduces DNA synthesis and thus is used to suppress the accelerated DNA synthesis found in psoriatic epidermal cells. UVB also induces the expression of the tumor suppressor gene *p53*, and this can lead to either cell cycle arrest (allowing time for DNA repair) or apoptosis of keratinocytes ("sunburn cells") if the DNA damage is too severe to be repaired. Through these mechanisms, *p53* prevents photocarcinogenesis.

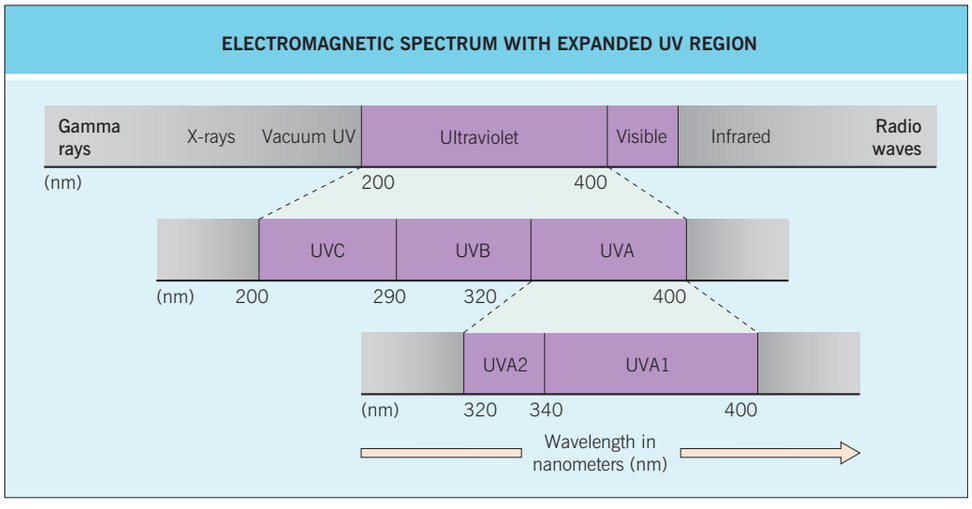

Fig. 134.1 Electromagnetic spectrum with expanded UV region.

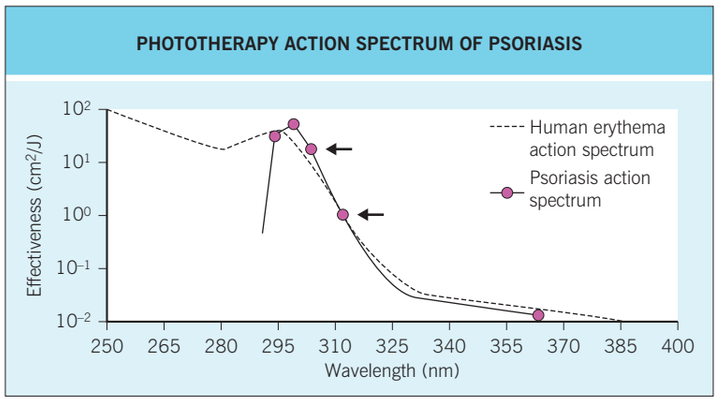

Fig. 134.2 Phototherapy action spectrum of psoriasis. The phototherapy action spectrum of psoriasis is plotted as the reciprocal of the lowest effective daily dose to clearing versus wavelength. The dashed line shows the human erythema action spectrum. The solid line is the action spectrum of psoriasis. Circles represent the reciprocal of the lowest effective daily dose for wavelengths that cleared psoriasis (295, 300, 304, 313, 365 nm); the arrows point to the wavelengths that were optimally effective (304, 313 nm). Presently, narrowband UVB sources that emit wavelengths between 311 and 313 nm are available. *Adapted from Parrish JA, Jaenicke KF. Action spectrum for phototherapy of psoriasis. J Invest Dermatol. 1981;76:359–62.*

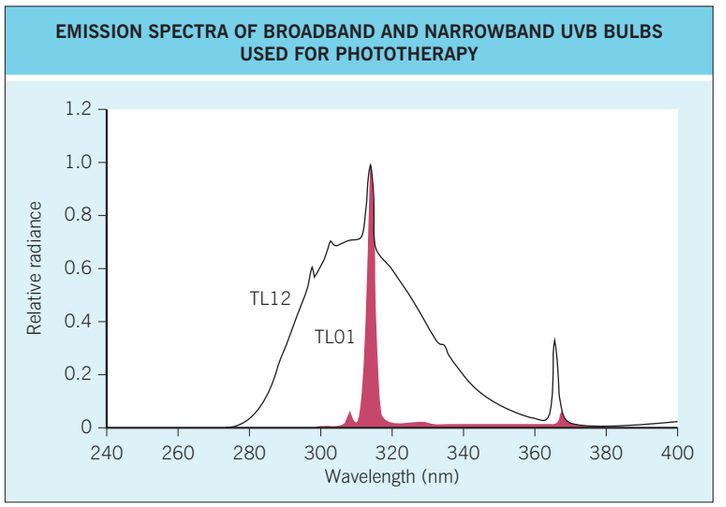

Fig. 134.3 Emission spectra of broadband and narrowband UVB bulbs used for phototherapy. Philips TL12, broadband UVB bulb; Philips TL01, narrowband UVB bulb.

In addition to its effect on the cell cycle, UV induces the release of prostaglandins and cytokines. Interleukin (IL)-6 and IL-1, for example, seem to play important roles in producing the systemic symptoms of UV phototoxicity (sunburn) and immune suppression, respectively[1]. These responses may, however, prove to be equally important for therapeutic effectiveness.

There is also increasing evidence that UV radiation can affect, in addition to DNA, extranuclear molecular targets located in the cytoplasm and cell membrane. These targets include cell surface receptors, kinases, phosphatases and transcription factors. It was has been shown that nuclear and cytoplasmic/membrane effects are not mutually exclusive, rather they independently contribute to the various biologic effects of UVB.

Many of the therapeutic effects of UVB may be due to its immunosuppressive properties which have been linked to the formation of pyrimidine dimers. UV radiation suppresses contact allergy, delayed-type hypersensitivity and immune surveillance against UV-induced non-melanoma skin cancers in mice. Of note, Langerhans cells are very sensitive to UVB, which alters their antigen-presenting function. Keratinocytes also secrete soluble mediators such as IL-1 and IL-6, prostaglandin E_2 and TNF-α in response to UVB, which by themselves can alter the immune response. Therapeutic UVB suppresses the type 1 (proinflammatory) axis as defined by IL-12, interferon-γ and IL-8, and can selectively reduce proinflammatory cytokine production by individual T cells[1].

The interplay of the various photobiological pathways is far from being completely understood. In psoriasis, both epidermal keratinocytes and cutaneous lymphocytes may be targeted by UVB. Immune suppression, alteration of cytokine expression, and cell cycle arrest may all contribute to the suppression of disease activity in psoriatic plaques[2]. In addition, a subset of T cells, Th17 cells, which seem to play a central role in the immunopathogenesis of psoriasis, are also down-regulated by UVB[3]. Recently, evidence was presented that keratinocyte apoptosis may be a key mechanism in the clearance of psoriatic plaques[3a].

EXPOSURE DOSES FOR MED ASSESSMENT WITH BROADBAND AND NARROWBAND UVB SOURCES (mJ/cm²)						
Broadband UVB	20	40	60	80	100	120
Narrowband UVB	200	400	600	800	1000	1200

*1 joule (J) of energy/second = one watt (W); irradiation (dose) is measured in J/cm² (UVA) or mJ/cm² (UVB).

Table 134.1 Exposure doses for minimal erythema dose (MED) assessment with broadband and narrowband UVB sources (mJ/cm²)*. Physical doses as measured with an integrated UV meter (Waldmann, Schwenningen, Germany).

Action Spectrum and Radiation Sources

Parrish and Jaenicke[4] demonstrated that for antipsoriatic activity, 304 and 313 nm were the optimally effective wavelengths (Fig. 134.2), even at suberythemogenic doses. Erythemogenic UVA doses are also therapeutically effective, but 1000 times higher fluences are needed (as compared with UVB), and, on a practical level, this is not feasible. The addition of UVA also does not enhance the therapeutic efficacy of UVB in psoriasis (unlike atopic dermatitis). The Philips TL01 fluorescent lamp that emits narrowband UVB (311–313 nm) was introduced to optimally meet the requirements for antipsoriatic activity (Fig. 134.3).

Treatment Protocols

Before starting phototherapy, determination of the patient's UV sensitivity via phototesting is recommended, since skin typing alone does not always reflect the actual sensitivity of a particular individual. However, phototesting is not mandatory for the experienced therapist and, for practical reasons, is often not done. Testing is performed by exposing four to six small template areas (e.g. 1 cm diameter circles) of usually non-sun-exposed skin (lower back, buttocks) to an incremental series of UVB irradiations. Increases are made by fixed values (e.g. 10 or 20 mJ/cm²) or by a fraction of the last dose (e.g. 40%). An example is given in Table 134.1. Note that these doses strongly depend on the photometer used. Narrowband UVB is much less erythemogenic with regard to physical units (mJ/cm²) than broadband UVB.

The minimal erythema dose (MED) is defined as the lowest dose that causes a minimally perceptible erythema reaction at 24 hours after irradiation. Sunbathing or exposure to "sunlamps" should be avoided before phototesting. It is crucial to document the type of lamp used for the MED determination, since the values obtained with broadband and narrowband sources differ tremendously (see Table 134.1).

Despite continued discussion as to whether visual assessment of the MED is the optimal method for establishing a reference value for dosimetry, it is an easily performed procedure that does not require any specialized equipment. An initial therapeutic UVB dose equal to 70% of the MED is recommended. Treatments are given two to five times weekly. Since UVB erythema peaks within 24 hours after exposure, doses may be increased with each successive treatment. However, if treatments are given five times weekly, the doses should be increased every other treatment. The rate of increase depends on treatment frequency and the outcome of the preceding UVB exposure. The objective of the dose increments is to achieve a minimally perceptible erythema

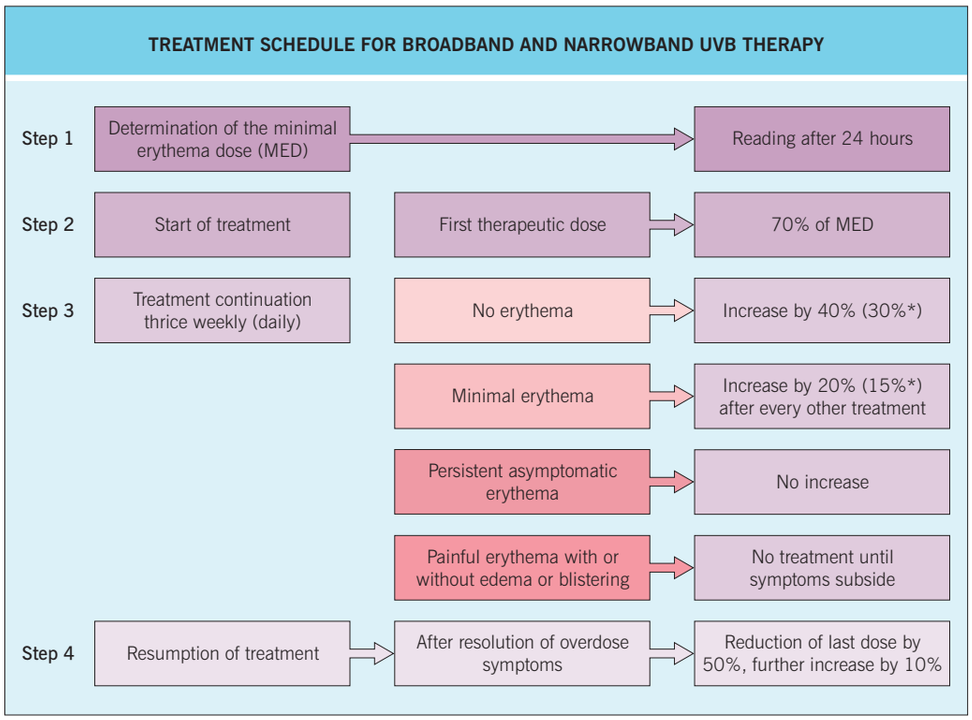

Fig. 134.4 Treatment schedule for broadband and narrowband UVB therapy. *If treatments are given five times per week or daily.

as a clinical indicator of optimal dosimetry. For example, with thrice-weekly exposures, doses are increased by 40% if no erythema appears, and by 20% upon development of slight erythema. If mild erythema persists, the dose should be maintained. With daily exposures, these rates are no more than 30%, 15% and 0%, respectively. If more intensive or painful erythema develops, irradiations are stopped until the symptoms disappear. Treatment is then continued until complete remission is achieved or no further improvement can be obtained with continued phototherapy (Fig. 134.4).

Whether maintenance treatment leads to a more prolonged remission time is still a matter of debate, since minimal precise data are available. In cutaneous T-cell lymphoma (CTCL), most therapists perform maintenance treatment for several months to a year. For psoriasis, some centers use a 2-month maintenance phase with twice-weekly exposures for 1 month and once-weekly exposures for another month. The last effective UVB dose is given throughout the maintenance phase. If relapses occur during the maintenance phase, treatment frequency and UVB dose are increased again until clearing. Of note, there was some evidence in a recent study that maintenance narrowband UVB may lead to longer remission times in plaque-type psoriasis[5].

Excellent guidelines for use of narrowband UVB have been prepared by the British Photodermatology Group. They present evidence-based guidance for treatment of patients with a variety of dermatoses and photodermatoses, with identification of the strength of evidence available at the time of preparation[6].

Phototherapy for Psoriasis

Guttate and seborrheic (minimally elevated) forms of psoriasis respond most favorably and rapidly to broadband UVB, while chronic, plaque-type psoriasis is more resistant. Despite its proven efficacy, broadband UVB is certainly inferior to PUVA, both in terms of clearing efficiency and duration of remission.

However, narrowband UVB phototherapy is superior to conventional broadband UVB with respect to both clearing and remission times. In many countries, narrowband UVB has mostly replaced conventional UVB phototherapy. Based on our own studies and other publications, we regard narrowband UVB phototherapy to be less effective than PUVA[7].

In addition to the treatment protocols mentioned above, other regimens may be used. Some schedules utilize skin type-dependent starting doses and fixed increments regardless of skin reaction. Sometimes, the patient's extremities (in particular the lower extremities) are exposed to higher doses than the trunk.

Adjunctive topical agents and combination therapies are often tried in order to improve efficacy and to reduce the cumulative UVB dose, with the ultimate aim of minimizing the risk of long-term side effects. Narrowband UVB has been successfully combined with therapies such as anthralin and calcipotriol. The use of bland emollients before UVB treatment is laborious and time-consuming. In our experience, it does not dramatically increase treatment efficacy. The concurrent use of topical corticosteroids may reduce remission times and thus is discouraged[8].

Systemic drugs such as retinoids increase efficacy, particularly in patients with chronic plaque-type psoriasis[9]. In addition, retinoids may reduce the carcinogenic potential of UVB phototherapy. There have been open-label studies and small comparison studies regarding the efficacy of combining UVB phototherapy and biologic agents[10,10a]. To date, there have been no large-scale studies, and long-term data, including remission times, are unavailable.

Phototherapy for Cutaneous T-Cell Lymphoma, in particular Mycosis Fungoides

For early stages (IA, IB and IIA) of mycosis fungoides (MF), conventional treatment strategies include topical corticosteroids, UV radiation, and topical cytotoxic agents such as nitrogen mustard (mechlorethamine). More advanced stages are treated with total body electron beam radiation therapy (see Ch. 139), X-irradiation, systemic retinoids, systemic chemotherapy and biologic therapies (e.g. IFN), but none of these regimens has been demonstrated to induce permanent remission.

Lesions of MF frequently occur in non-sun-exposed areas of the body, and patients with early stage MF often benefit from exposure to natural sunlight. In one study with long-term follow-up, 74% of patients treated with broadband UVB remained in complete remission after a median treatment period of 5 months[11]. Response to phototherapy was related to the type (i.e. patch stage MF did better than the plaque type) but not the extent of skin involvement. In a more recent study, prolonged maintenance therapy (up to 30 months) resulted in a relapse-free period of 26 ± 10 months[12].

The proposed mechanisms for UVB phototherapy of MF include impairment of epidermal Langerhans cell function and alterations in cytokine production and adhesion molecule expression by keratinocytes[13]. Moreover, it was noted that narrowband UVB induces apoptosis of T lymphocytes, which may contribute particularly to the beneficial effect of this light source[14].

UVB phototherapy is clearly less efficient than PUVA, and the duration of treatment in the clearing and maintenance phases is longer and thus requires higher patient compliance. Whether patients would benefit from adding UVA, as is sometimes recommended, remains questionable. Likewise, narrowband UVB and broadband UVB therapy have not been compared in MF. It is possible that combining a systemic retinoid (e.g. bexarotene) with narrowband UVB may increase efficacy. Lastly, a pilot study documented the efficacy of medium- to high-dose UVA1 therapy (see below) in patients with stage IA and IB MF. However, there is no evidence that UVA1 is superior to PUVA and no long-term follow-up is available.

Phototherapy for Vitiligo

Many patients observe follicular repigmentation in areas of vitiligo following sun exposure. Because of seasonal and weather-dependent variations in sunlight intensity in moderate climates, exposure to natural sunlight is often not a practical option for inducing complete repigmentation. In the past, PUVA was most frequently used for the treatment of vitiligo, but exposure to artificial UVB irradiation, in particular narrowband UVB, can also provide an acceptable therapeutic effect, if given for a sufficiently long period. Although the action spectrum for phototherapy of vitiligo is not known, narrowband UVB has clearly become quite popular in recent years. In comparison studies of narrowband UVB with PUVA, narrowband UVB was as effective as PUVA but had fewer side effects (Fig. 134.5). Also, in a recent randomized double-blind trial of non-segmental vitiligo, narrowband UVB therapy was superior to oral PUVA therapy and the color match of repigmented skin was considered to be better in the patients treated with narrowband UVB[15]. UVA alone is of limited benefit.

Since intense erythema may induce the Koebner phenomenon and worsening of the disease, it is necessary to stay within a dose range that induces minimally perceptible erythema. Therefore, initial assessment of the MED in a vitiliginous area that is normally not sun-exposed (e.g. buttocks, lower back or abdomen) is recommended. The UVB doses have to be increased more carefully than in other disorders, because of the increased photosensitivity.

The initial exposure is 70% of the MED in *lesional* skin, and subsequent doses are chosen according to the response in vitiligo areas, i.e. the goal is to induce a barely perceptible erythema. This minimal erythema is the only useful parameter for determining dosage increments. The dose should not be increased more than once weekly by 10–20% of the preceding dose. Despite the lack of pigment, vitiliginous skin does develop some tolerance, probably as a result of epidermal hyperplasia and thickening of the stratum corneum. Usually, a maximum dose will be reached during the first couple of months which is used throughout the entire treatment period. Most commonly, two to three treatments per week are given. However, too few controlled studies are available for any particular phototherapy regimen to be preferred over another.

Fig. 134.5 Narrowband phototherapy for vitiligo. A Before treatment. **B** After 10 months of treatment (twice weekly). Note the persistence of depigmentation of the areolae, an area which is particularly resistant to treatment.

Phototherapy for Atopic Dermatitis

Broadband UVB phototherapy

Based on the empirical experience that sun exposure was beneficial for patients with atopic dermatitis, broadband UVB has been used to treat atopic dermatitis since the end of the 1970s.

UVA/UVB phototherapy

More recent studies suggest that a combination of UVA plus UVB irradiation (UVA/UVB therapy) is superior to conventional broadband UVB, conventional UVA, or low-dose UVA1 therapy in the management of chronic, moderate atopic dermatitis. A paired-comparison study demonstrated statistically significant differences in favor of UVA/UVB therapy, compared with broadband UVB therapy[16].

Narrowband UVB phototherapy

George et al.[17] first used an air-conditioned narrowband UVB irradiation unit to treat atopic dermatitis. It not only improved the total clinical score, but also substantially reduced the need for potent topical corticosteroids. These beneficial effects were still present in the majority of patients 6 months after cessation of phototherapy. A randomized controlled trial has shown similar results[18]. Narrowband UVB therapy has been used successfully in conjunction with UVA1 therapy.

Phototherapy for Graft-versus-Host Disease

Experience with UVB therapy of GVHD is very limited, since it has been used only in selected patients. It is still unclear whether irradiation of the skin shortly after transplantation is of benefit in the prevention of human cutaneous GVHD[19]. Currently, PUVA represents the mainstay for phototherapy of GVHD.

Phototherapy for Pityriasis Lichenoides and Lymphomatoid Papulosis

Both pityriasis lichenoides acuta and chronica can have a prolonged course and be rather resistant to therapy. As sunlight may lead to some improvement, UVB phototherapy has also been associated with some success. However, PUVA seems to be more effective (see below), especially in the acute form of the disease (perhaps because of the deeper extension of the dermal inflammatory infiltrate). Although Honig et al.[20] have recommended PUVA as the treatment of choice for the acute form, PUVA may be reserved for cases of pityriasis lichenoides chronica that are UVB-resistant.

Phototherapy for Seborrheic Dermatitis

Seborrheic dermatitis generally improves during the summer and "sunny" vacations. Accordingly, UV radiation also seems to have a beneficial effect on this condition. However, flares of dermatitis may occasionally occur. In an open prospective study, narrowband UVB was found to be an effective treatment in severe cases[21].

Phototherapy for Pruritus

Both narrowband and broadband UVB therapy can be beneficial in various forms of pruritus, particularly those associated with diabetes

Fig. 134.6 Target-like appearance of psoriatic lesions secondary to phototoxicity due to UVB. Annular erythema is separated from the psoriatic plaques by Woronoff's ring.

and hepatic disorders or those that are idiopathic in nature. Remissions in hepatic disease, however, are relatively short-lived. In a case series, narrowband UVB led to improvement of uremic pruritus[22].

Side Effects of Phototherapy with UVB

Short-term side effects include erythema (Fig. 134.6), xerosis accompanied by pruritus, occasional blistering, and an increased frequency of recurrent herpes simplex viral infections. Painful erythema resulting from overexposure is treated with topical corticosteroids. Systemic nonsteroidal anti-inflammatory drugs and corticosteroids can prove useful in severe cases, if administered early.

Long-term side effects include photoaging and carcinogenesis. Although UVB is a known carcinogen, its carcinogenic potential seems to be lower than that of PUVA. A 16-center study conducted by Stern and Laird[23] did not detect a relationship between UVB phototherapy and non-melanoma skin cancer. In a recent British study comprised of 3867 patients treated with narrowband UVB, no significant association between narrowband UVB treatment and basal cell carcinoma (BCC), squamous cell carcinoma (SCC) or melanoma was found[24]. There was a small increase in BCCs amongst those patients who also had been previously treated with PUVA. To determine the true carcinogenic risk of narrowband UVB phototherapy, additional longitudinal studies are essential.

Because narrowband UVB has been in use for just over two decades, its long-term side effects are not yet known. Compared with broadband UVB, up to 10-fold higher physical doses of narrowband UVB are required to produce erythema, edema and sunburn cell formation. Using single-cell gel electrophoresis (the comet assay), therapeutically equivalent doses from these two radiation sources produced minimal differences in the amount of DNA damage[25]. As narrowband UVB is clinically more effective than broadband UVB, the former requires less MED-equivalents to achieve a therapeutic response, implying that narrowband UVB will be less carcinogenic than broadband UVB[26].

PHOTOTHERAPY WITH THE 308 NM EXCIMER LASER

The use of the 308 nm excimer laser represents an enhancement of narrowband UVB delivery. The clinical use of this laser for plaque-type psoriasis was first reported in 1997[27]. Subsequent reports[28] showed that in some patients, high multiples of the MED, such as 4 and 6 MEDs, could induce a longer duration of remission than achieved with conventional narrowband therapy. Other advantages of the use of the excimer laser for psoriasis are the lower number of treatments that may be necessary to induce clearing and the ability to treat exclusively the affected skin and with a reduced cumulative dose, thus perhaps reducing the long-term risk of carcinogenicity[29]. However, widespread psoriasis generally cannot be treated with this modality because the spot size is less than 2 cm^2. Clearly, the excimer laser will be most suitable for patients with stubborn plaques unresponsive to other treatments and/or those with difficult-to-treat localized areas such as the palms, soles, knees and elbows. The excimer laser is now approved by the Food and Drug Administration (FDA) for the treatment of psoriasis. Whether it really represents a therapeutic advancement still remains to be determined by larger and longer-term studies, particularly in view of the high costs of the laser treatment. However, the newer excimer *lamps* are less expensive and appear to be similarly effective[29].

Based upon case series, targeted phototherapy with the excimer laser may also serve as a new treatment modality for the management of stable vitiligo[30] and for a variety of chronic inflammatory localized dermatoses such as granuloma annulare, lichen planus, lichen simplex chronicus and alopecia areata[31].

PHOTOTHERAPY WITH UVA1

The UVA spectrum (320–400 nm) has been arbitrarily subdivided into two parts: UVA1 (340–400 nm) and UVA2 (320–340 nm) (see Fig. 134.1). The main reason for this subdivision was the observation that UVA2 resembled UVB in its ability to cause erythema as well as immunomodulation and photocarcinogenesis. Because of its longer mean wavelength, UVA1 radiation penetrates more deeply into the skin than UVA2 (see Ch. 86), and thus affects not only epidermal structures, but also mid and deep dermal components, especially blood vessels. Since the skin is a large organ, exposure of circulating immune cells to UVA1 irradiation may have significant systemic ramifications. In particular, its ability to induce T-lymphocyte apoptosis is likely to be relevant in the treatment of atopic dermatitis and possibly of MF. It may reduce the number of Langerhans cells and mast cells in the dermis in atopic dermatitis, and in cutaneous mastocytosis. In addition, it has been shown that increased collagenase expression in treated lesions of localized scleroderma accompanies improvement with UVA1 irradiation. Perhaps the efficacy of UVA1 in localized scleroderma, and in other sclerosing conditions, is in part due to this action.

UVA1 phototherapy is currently being investigated as a safer alternative to PUVA for treating chronic conditions. To date, most of the UVA1 studies have been performed in Europe, where efficient sources of UVA1 radiation are more widely available (Fig. 134.7).

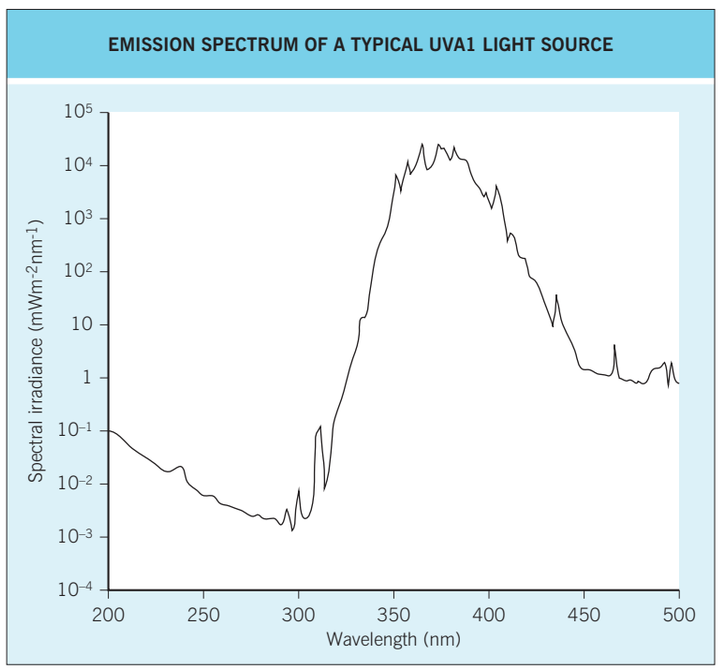

Fig. 134.7 Emission spectrum of a typical UVA1 light source (filtered metal halide lamp).

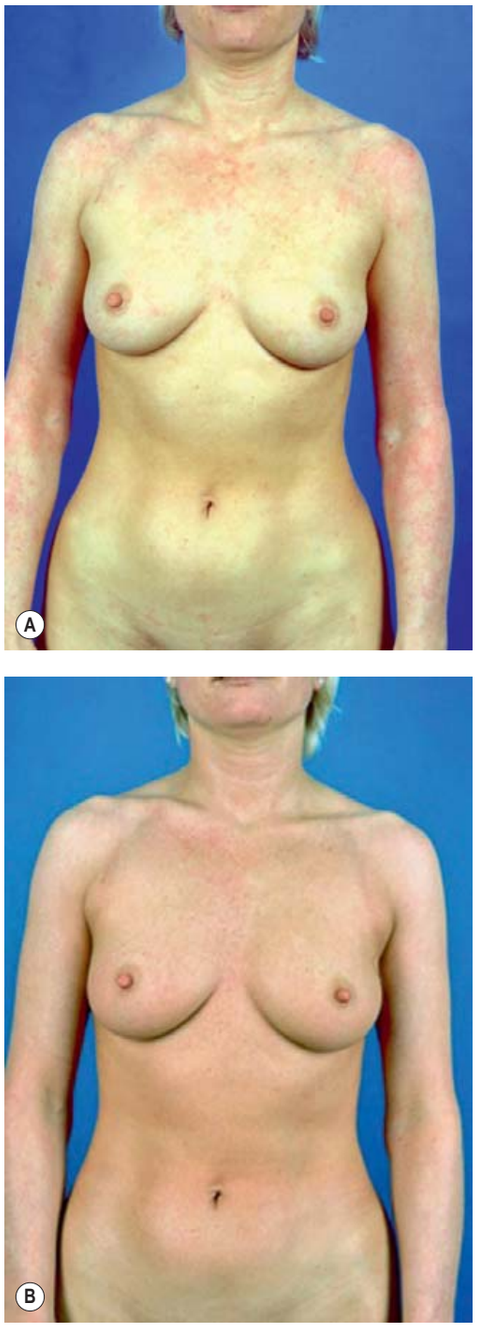

Fig. 134.8 UVA1 phototherapy of atopic dermatitis (split-body comparison). A Before treatment. **B** After treatment (15 exposures) with high-dose (130 J/cm^2, left side) *versus* medium-dose (65 J/cm^2, right side) UVA1 phototherapy. Note that there is no difference in the therapeutic result.

UVA1 can have a therapeutic effect on atopic dermatitis[32,33] (Fig. 134.8). It seems to be more effective than UVA/UVB therapy, at least for severe exacerbations of atopic dermatitis. If used as a monotherapy, medium and high daily doses are better than low doses. When UVA1 and narrowband UVB were compared for the treatment of atopic dermatitis, they seemed to be equally effective[34].

UVA1 therapy has been reported to be beneficial in several other dermatoses[35], including localized scleroderma[36], acute and chronic sclerodermoid GVHD[37,38], urticaria pigmentosa[35] and MF[39]. However, the latter indication in particular requires confirmation in larger patient series. Clearly, this area of phototherapy is still under evaluation.

Side Effects of Phototherapy with UVA1

The adverse effects of UVA1 are less severe than those of UVB and UVA2. Until more is known about UVA1 therapy, its use (especially with high doses such as 130 J/cm^2) should be limited to treating diseases with periods of severe, acute exacerbations, and, in general, one treatment cycle should not exceed 10–15 successively administered exposures and should not be repeated more than once a year. A European prospective longitudinal study has been initiated to monitor patients treated with UVA1 phototherapy for the development of skin cancer and photoaging. An increased expression of *p53* and a slight increase in Bcl-2 protein expression in keratinocytes were found in human skin after UVA1 irradiation (even with suberythemogenic doses), suggesting that UVA1 may cause DNA damage[40]. In addition, UVA1 induced promutagenic cyclobutane pyrimidine dimers and oxidative DNA damage (at both the genomic and nucleotide resolution level) in normal human skin fibroblasts[41]. Of note, in the years since the widespread use of UVA1 phototherapy in Europe began in 1992, no serious negative side effects in humans have been reported.

PHOTOCHEMOTHERAPY WITH PSORALENS (PUVA)

Psoralen photochemotherapy (PUVA) combines the use of psoralens (P) and long-wave UV radiation (UVA). This combination results in a therapeutically beneficial phototoxic effect, which is not produced by either of the components alone. Psoralens can be administered orally or applied topically in the form of solutions, creams or baths, with subsequent UVA exposure.

Historical Aspects

Topical exposure to extracts, seeds or parts of plants (e.g. *Ammi majus*, *Psoralea corylifolia*) that contain natural psoralens, followed by exposure to sunlight, was used as a remedy for vitiligo for thousands of years in ancient Egypt and India[42]. In 1974, it was shown that the oral ingestion of 8-methoxypsoralen (8-MOP) and subsequent exposure to a new, high-intensity, artificial UVA radiation source was highly effective for the treatment of psoriasis[43]. This was followed by a recognition of its therapeutic effect for multiple skin disorders (Table 134.2)[17].

Psoralens

Psoralens are naturally occurring linear furocoumarins that are found in a large number of plants, and there are several synthetic psoralen compounds. For oral and topical (bath, cream) PUVA, 8-MOP (methoxsalen) is used primarily; it is of plant origin but also available as a

synthetic drug. The synthetic compound, 4,5′,8-trimethylpsoralen (TMP, trioxsalen), is less phototoxic than 8-MOP after oral administration, but more phototoxic when bath-water-delivered. TMP is used primarily in Scandinavia for bath PUVA. 5-Methoxypsoralen (5-MOP, bergapten) is also therapeutically effective when given orally; it is less erythemogenic and is not associated with gastrointestinal intolerance (Fig. 134.9). In Europe (where available) it is now used for routine PUVA. Oral preparations of 8-MOP and 5-MOP contain either crystals, micronized crystals or solubilized psoralens in a gel matrix. The liquid preparation induces earlier, higher and more reproducible peak plasma levels than the crystalline preparations.

The steps between the ingestion of a psoralen and its arrival in the skin include disintegration and dissolution of the drug, absorption, first-pass effect, blood transportation, and tissue distribution. The absorption rate of a psoralen from the gut depends on the physicochemical properties of the molecule, the rate of dissolution, the galenic characteristics of the preparation, and the fat content of concomitantly ingested food. 5-MOP is less water-soluble than 8-MOP and its absorption rate is approximately 25% of that of 8-MOP. Like 8-MOP, liquid preparations of 5-MOP give higher and earlier peak serum levels than do crystalline formulations. In addition, peak serum levels are achieved by liquid preparations after a relatively reproducible time interval, whereas wide time variability occurs with crystalline formulations. Before reaching the skin via the circulation, psoralens are metabolized during their passage through the liver. Plasma levels of 8-MOP administered orally at different doses show a strong non-linearity, indicating a saturable first-pass effect. Thus, small differences in the ingested doses and absorption rates of psoralens lead to large differences in plasma levels. As a practical consequence, small amounts of the drug are almost completely metabolized by the liver during the first pass and therefore may be therapeutically inactive.

8-MOP and 5-MOP serum levels show a wide range of inter-individual differences. Even on different occasions in the same patient, serum levels may differ; however, the levels are usually sufficiently constant to provide for relatively reproducible therapeutic results. This unpredictable pharmacokinetic behavior is probably due to inter- and intra-individual variations in intestinal absorption, first-pass effect, blood distribution in the body, and metabolism and elimination of the drug.

In a particular individual, serum levels of 8-MOP correspond fairly well with skin reactivity, with the peak of skin phototoxicity coinciding with peak serum levels. A correlation between 8-MOP and 5-MOP serum levels and epidermal concentrations does exist. Whether there is a significant correlation between maximum psoralen blood concentrations and the minimal phototoxicity dose (MPD) remains equivocal.

The pharmacokinetics of topical 8-MOP depend on the mode of application. 8-MOP administered topically as a 0.15% emulsion or solution has been shown to result in plasma levels comparable to those obtained by oral delivery, when large areas of the body are treated. In contrast, due to the much lower concentrations that are used, plasma levels following bath-PUVA treatment of almost the entire body surface are very low. Bath-water-delivered psoralens are readily absorbed into the skin, but are promptly eliminated without cutaneous accumulation[2].

Psoralen photochemistry

Psoralens react with DNA in three steps. First, in the absence of UV radiation, the psoralen intercalates into the DNA double strand. Absorption of photons in the UVA range results in the formation of a 3,4- or 4′,5′-cyclobutane monoadduct with pyrimidine bases of native DNA. The 4′,5′ monoadducts can absorb a second photon and this reaction leads to the formation of an interstrand cross-link of the double helix with the 5,6 double bond of the pyrimidine base of the opposite strand (Fig. 134.10).

Excited psoralens can also react with molecular oxygen. The reactive oxygen species formed by this reaction cause cell membrane damage by lipid peroxidation and may activate the cyclooxygenase and arachidonic acid metabolic pathways.

The cross-linking of psoralens with epidermal DNA inhibits DNA replication and causes cell cycle arrest. Although not proven, it is generally assumed that this effect may be the therapeutic mechanism in psoriasis. Psoralen photosensitization also causes an alteration in the expression of cytokines and cytokine receptors. However, DNA cross-linking does not appear to be a prerequisite for all the therapeutic effects of PUVA, and the successful treatment of other skin diseases is unlikely to be due directly to this molecular reaction. Psoralens also interact with RNA, proteins and other cellular components and indirectly modify proteins and lipids via singlet oxygen-mediated reactions or by generating free radicals[44,45].

PUVA can reverse the pathologically altered patterns of keratinocyte differentiation markers and reduce the number of proliferating epidermal cells. Infiltrating lymphocytes are strongly suppressed by PUVA, with variable effects on different T-cell subsets. PUVA is far more potent in inducing apoptosis in lymphocytes than in keratinocytes[1], which may explain its efficacy in CTCL as well as in inflammatory skin diseases. Although much is known about pathways and mechanisms in psoralen photosensitization, the interactions and relative contributions to the clearing of a specific disease are not well understood.

Psoralens also stimulate melanogenesis. This involves the photoconjugation of psoralens to DNA in melanocytes, followed by mitosis and subsequent proliferation of melanocytes, increased formation and melanization of melanosomes, enhanced transfer of melanosomes to keratinocytes, and increased synthesis of tyrosinase via stimulation of cAMP activity.

Action Spectrum and Light Sources

The action spectrum for 8-MOP-induced delayed erythema has its maximum activity in the 330–335 nm range and the antipsoriatic activity of 8-MOP (plus UVA) appears to parallel its erythema action spectrum[46]. Conventional therapeutic UVA fluorescent tubes and broad-spectrum metal halide lamps, which are filtered in the UVB and UVC range, cover well the psoralen action spectrum. The typical fluorescent UVA lamp used for PUVA therapy peaks at 352 nm and emits approximately 0.5% in the UVB range (Fig. 134.11). Major advantages of mercury halide units are the stability of output and their high irradiance, enabling short treatment times.

UVA doses are given in J/cm^2, instead of mJ/cm^2 used for UVB, and usually measured with a photometer with a maximum sensitivity at 350–360 nm. Within the treatment system, the irradiance must be relatively uniform so that the dose does not vary at different anatomic sites. UVB emission should be kept low enough to avoid erythemogenic UVB doses before sufficient UVA is absorbed to produce the psoralen photosensitivity reaction.

Photosensitivity Effects of PUVA

PUVA treatment produces an inflammatory response that manifests as delayed phototoxic erythema. The reaction depends on the dose of drug,

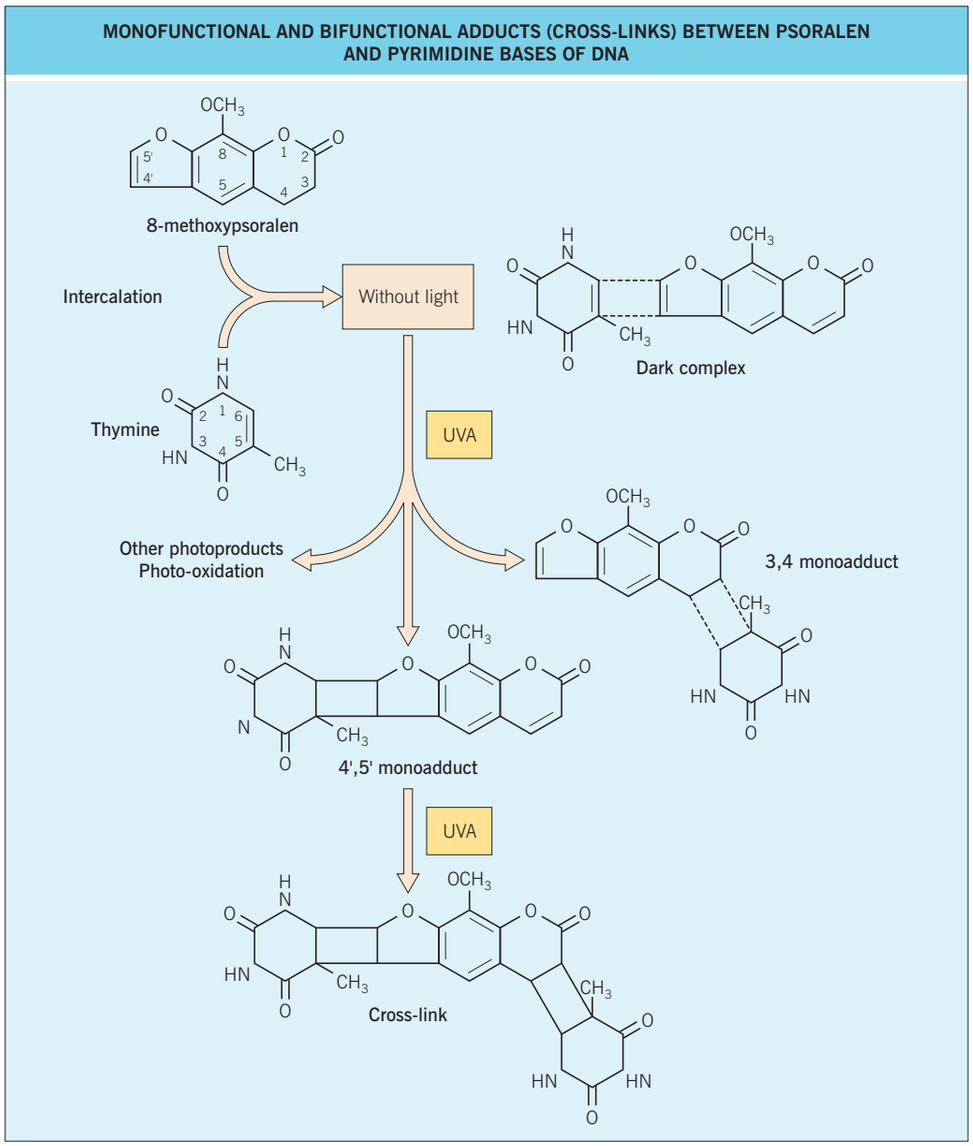

Fig. 134.10 Monofunctional and bifunctional adducts (cross-links) between psoralen and pyrimidine bases of DNA.

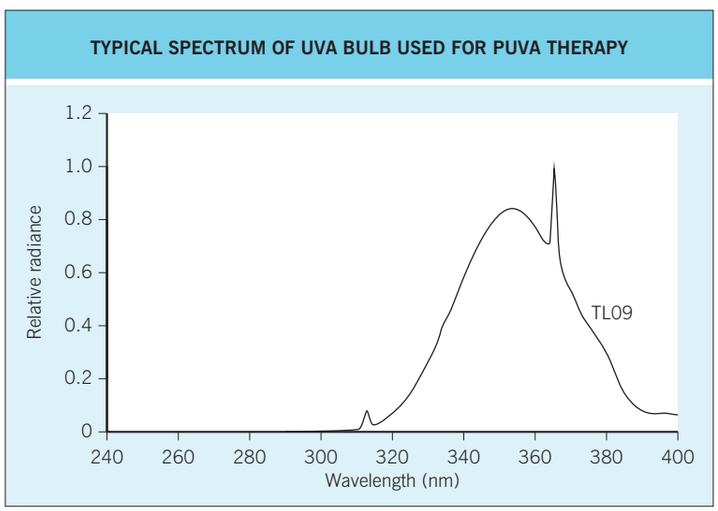

Fig. 134.11 Typical spectrum of a UVA bulb (Philips TL09) used for PUVA therapy.

the dose of UVA, and the individual's sensitivity (skin type). Recently, it was shown that changes in 8-MOP dose had no detectable effect on the maximum slope of the PUVA erythema dose–response curve. Thus, 8-MOP dose changes within individuals, over a narrow but clinically relevant range, appear to significantly alter the threshold response to PUVA erythema but not the rate of increase in erythema with increasing UVA dose[47].

PUVA erythema differs remarkably from the sunburn or UVB erythema that appears after 4–6 hours and peaks 12–24 hours after exposure to UVB. PUVA erythema does not occur before 24–36 hours and it peaks at 72–96 hours or even later after exposure. It has a shallower dose–response curve than UVB erythema (by a factor of approximately 2) and this difference is maintained even at the time of maximum erythema[48]. PUVA erythema persists for longer periods of time (lasting up to more than 1 week) and it consists of a deeper red, even a violaceous, hue. Severe reactions may lead to blistering and to superficial skin necrosis. Overdoses of PUVA are frequently followed by edema, intense pruritus and sometimes by a peculiar stinging sensation in the affected skin area. At present, erythema is the only available parameter that allows an assessment of the magnitude of the PUVA reaction and thus represents an important factor for determining UVA dose adjustments[2].

Pigmentation, the second important effect of PUVA, may develop without clinically evident erythema, especially when oral 5-MOP or TMP is used; this is of particular importance in the treatment of vitiligo and for the preventive treatment of some photodermatoses. In normal skin, PUVA pigmentation peaks about 7 days after exposure and may last from several weeks to months. As with sun-induced tanning, the individual's ability to tan is genetically determined, but the dose–response curve is much steeper. A few PUVA exposures result in a much deeper tan than that produced by multiple exposures to solar radiation. One goal of phototherapy of inflammatory and neoplastic disorders

SKIN PHOTOTYPES AND INITIAL DOSE OF UVA FOR PUVA THERAPY		
Skin phototype*	**Skin reaction**	**Recommended initial dose (J/cm²)**
I†	Always burns, never tans	0.5
II	Always burns, but sometimes tans	1.0
III	Sometimes burns, but always tans	1.5
IV	Never burns, always tans	2.0
V‡	Moderately pigmented skin	2.5
VI	Darkly pigmented skin	3.0

*Types I–IV are determined by history; types V and VI by physical examination (racial descent).
†Patients with erythrodermic psoriasis are to be classified as skin phototype I for determination of UVA dosage.
‡Patients with this phototype should be classified into a lower skin phototype category if the sunburning history so indicates.

Table 134.3 Skin phototypes and initial dose of UVA for PUVA therapy. These irradiation doses are based upon an oral 8-MOP dose of 0.6–0.8 mg/kg.

is to produce a clinical response prior to the induction of significant pigmentation.

Treatment Protocols

Oral PUVA

The general principle of oral PUVA is to keep the dose of psoralen, as well as the interval between drug intake and UVA exposure, constant, and to vary the UVA dose according to the patient's sensitivity. A dosage of 8-MOP of 0.6 to 0.8 mg/kg is administered orally 1–3 hours before exposure, depending on the absorption characteristics of the particular drug brand. For example, liquid drug preparations are absorbed faster and yield higher and more reproducible serum levels than do microcrystalline forms. For 5-MOP, the usual dosage is 1.2–1.8 mg/kg.

The initial UVA doses are selected either by skin typing[9,49] or by determining the minimal phototoxicity dose (MPD)[50]. In the US, skin reactivity to solar radiation is evaluated and patients are classified based on a skin phototype scheme according to their sunburn history. Therapeutic doses of UVA are then given according to an empirical scheme based on this classification[9,47] (Table 134.3). In Europe, the most widely used approach consists of MPD determination analogous to MED determination. The MPD is defined as the minimal dose of UVA (following psoralen ingestion) that produces a barely perceptible, but well-defined, erythema. The doses range from 0.5 to 5 J/cm² if 8-MOP is used and 1 to 10 J/cm² if 5-MOP is used. Erythema readings are performed 72 (not later than 96) hours after irradiation, when the phototoxicity reaction usually peaks. As with the MED, the MPD should be determined on previously non-sun-exposed skin (lower back or buttocks). This will yield lower values than on previously exposed skin and thus contributes to a safer initial dosimetry. Although performing an MPD is more time-consuming than phototyping, it should be done whenever possible, since it allows for far more accurate and higher UVA doses during the initial treatment phase. As with UVB therapy, some experienced therapists do not consider phototesting to be mandatory.

Oral PUVA should not be used in patients with hepatitis, because slower metabolization of psoralens may prolong photosensitivity. Also, impaired renal function may slow down psoralen excretion.

Bath PUVA

Bath-water delivery of psoralens is becoming increasingly popular because it provides a uniform drug distribution over the skin surface, very low psoralen plasma levels, and a quick elimination of free psoralens from the skin, thereby reducing the period of photosensitivity. Due to the absence of systemic photosensitization, bath-water delivery of 8-MOP circumvents gastrointestinal side effects and potential ocular effects. Skin psoralen levels are highly reproducible and photosensitivity lasts no more than 2 hours. The higher incidence of unwanted phototoxicity can be prevented by a lower starting dose (30% of the initial MPD) and more cautious dosimetry during the initial treatment phase.

Originally, bath PUVA was performed with TMP, but 8-MOP and 5-MOP are now being used as well. Bath PUVA consists of 15–20 minutes of whole body (or hand and foot) immersion in solutions of 0.5–5.0 mg of 8-MOP per liter of bath water. Irradiation has to be performed immediately thereafter, as photosensitivity decreases rather rapidly. TMP is more phototoxic after topical application and thus is used at lower concentrations than 8-MOP. MPD testing for bath PUVA must take into account that, unlike with oral PUVA, the phototoxic threshold declines during the early treatment phase. In our experience, when the MPD is determined on a consecutive daily basis, the fourth MPD is approximately 50% of the first MPD (this may be due to persistent psoralen adducts)[2].

Topical PUVA

Application of 8-MOP (0.1–0.01%) in creams, ointments or lotions, followed by UVA irradiation, is effective but has several disadvantages. The non-uniform distribution on the skin surface may produce unpredictable phototoxic erythema reactions, and inadvertent application to surrounding uninvolved skin can lead to cosmetically unacceptable hyperpigmentation; this is a particular problem in patients with vitiligo. Furthermore, if numerous lesions are present, the application is laborious and time-consuming, and the treatment does not prevent the development of new active lesions in previously unaffected, untreated areas. Finally, extensive application ("paint" PUVA) of a 0.15% 8-MOP emulsion was found to cause plasma levels comparable to those detected with oral ingestion. Therefore, topical PUVA utilizing psoralen creams, ointments or lotions is now reserved primarily for psoriasis of the palms and soles and limited stable vitiligo.

Guidelines for bath, local immersion and other forms of topical PUVA have been published by the British Photodermatology Group. These recommendations are based, where possible, on the results of controlled studies; otherwise they represent a consensus view on current practice[51].

Initial Treatment (Clearing) Phase

The initial treatment phase is defined as the treatment period until clearing of the disease is achieved; repeated exposures are required, with gradual dose increments as pigmentation develops. Doses that are too low frequently result in failure of treatment, except in those diseases in which induction of pigmentation is the desired objective. In most dermatoses amenable to PUVA, the frequency of treatments should be reduced after satisfactory control of the disease.

Treatment should not be started until the end of the 72-hour period after MPD testing. A safe initial therapeutic dose for oral PUVA is 70% of the MPD (recent studies have shown that 50% is often sufficient for the effective treatment of psoriasis). For bath PUVA, it is advisable to start at only 30% of the MPD, because photosensitivity is up to 10 times higher than with oral PUVA (Fig. 134.12).

Irradiations are given two to four times weekly. Dose increments are performed no more often than twice a week (at least 72 hours apart) and never during the first week of treatment (if initial dose is based on MPD), in order to avoid accumulation of delayed cutaneous phototoxicity. Although not necessary for therapeutic success, a minimally perceptible erythema is considered a clinical indicator of adequate dosimetry. There exists no rigid scheme for dose increments; the major parameter for dose adjustments should be the clinical response of the disease. It is essential to note that with bath PUVA, the MPD can even decrease during the first days after initiation of treatment by up to 50%, but then increases at later stages. This may be due to persistent psoralen adducts which are converted into cross-links upon subsequent exposures.

In the absence of erythema, the UVA dose can be increased safely by 30% in both oral PUVA and bath PUVA (see Fig. 134.12). However, some patients will not need dose adjustments over prolonged periods of time, because of erythema formation (e.g. vitiligo) and/or adequate treatment response.

Maintenance Phase

The purpose of maintenance therapy is to achieve a longer remission. In the European regimen, maintenance therapy consists of one month of twice-weekly treatments utilizing the final UVA dose administered during the clearing phase, followed by another month of once-weekly

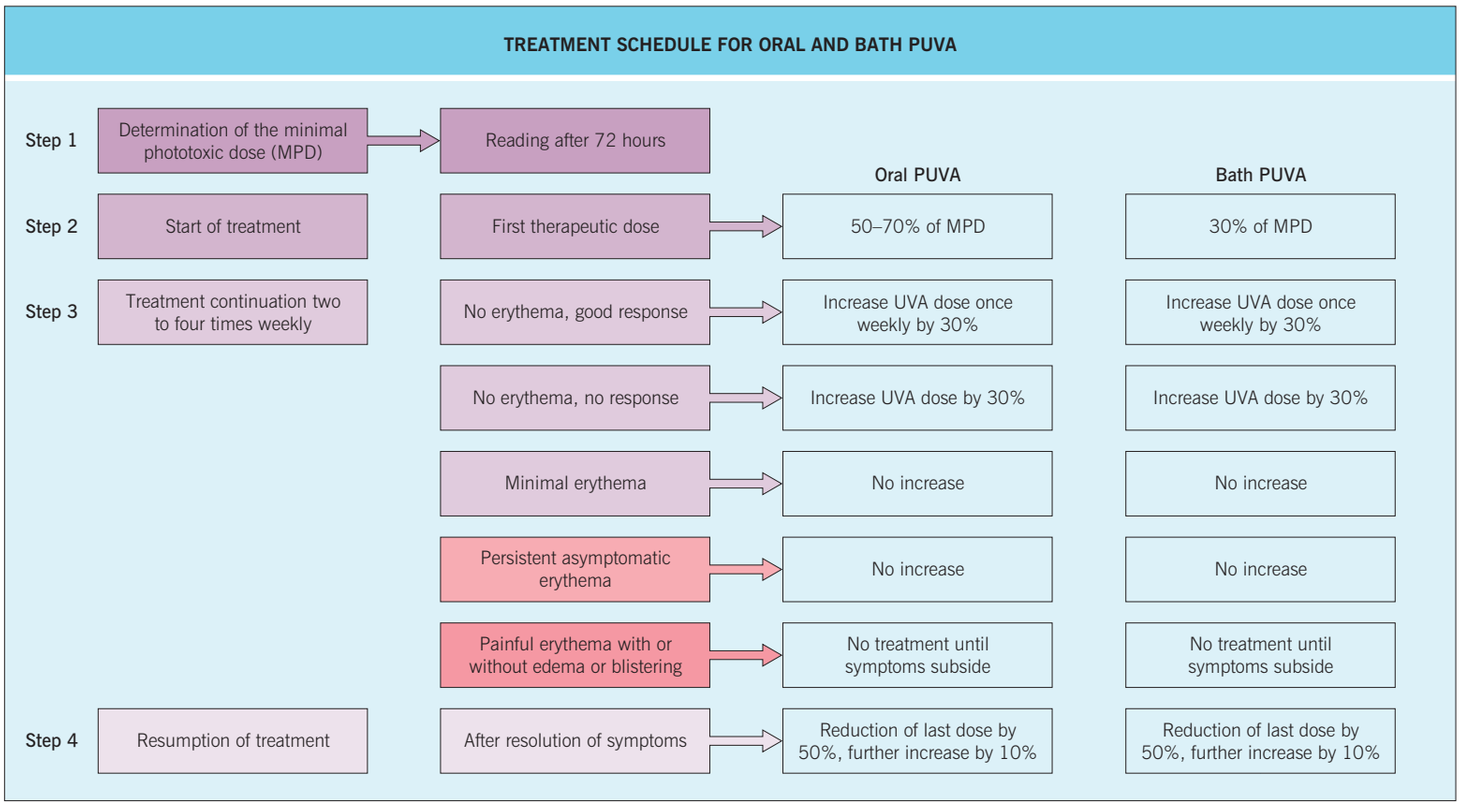

Fig. 134.12 Treatment schedule for oral and bath PUVA.

exposures. However, results of a recent study indicated that short-term maintenance therapy was not effective in preventing early relapses of psoriasis[52]. For MF, many institutions recommend some form of permanent maintenance therapy. However, due to the lack of prospective studies, no valid recommendation can be given. Perhaps a once-monthly treatment would be a feasible compromise.

Mild relapses during the maintenance phase are handled by temporarily increasing the frequency of treatments; in the case of a severe relapse, the original clearing phase schedule must be resumed until clearing is once again achieved. A disadvantage of maintenance therapy for patients in remission is the potential to overtreat the patient and to increase the potential for long-term toxicity that is related to the total cumulative dose of the PUVA.

PUVA for Psoriasis

Basically, all types of psoriasis respond to PUVA, although the management of erythrodermic or generalized pustular psoriasis is more difficult[2]. Both the US and the European regimens have proven to be highly efficient and therefore have remained in use, although with the advent of bioengineered immunomodulators (see Ch. 128), phototherapy of all types has lessened. Table 134.4 lists the differences between these two methods of administering oral 8-MOP PUVA[49,50].

Three studies have compared bath-water delivery of 8-MOP with oral administration[53–55]. In two reports, initial doses were determined by skin typing and treatments were given two to three times weekly. Dosage increments were done with every treatment in the first study[53], whereas smaller increments were performed every third treatment in the second[54]. Patients in the third study were treated according to the guidelines of the standard European regimen for oral PUVA; this group had the lowest incidence of treatment failures and overdose episodes[55]. Relative to the results obtained with oral PUVA, bath PUVA showed equal clearing rates with lower numbers of exposures. The greater therapeutic efficacy could be due to a higher penetration of psoralens through the abnormal stratum corneum overlying psoriatic plaques as compared with healthy perilesional skin where phototoxicity is monitored during the therapy. The incidence of erythema and pruritus was similar or lower with bath PUVA as compared to oral therapy. In all the investigations, episodes of systemic intolerance such as nausea and vomiting were recorded only with oral PUVA[2].

DIFFERENCES BETWEEN THE US AND EUROPEAN PROTOCOLS FOR PUVA THERAPY

	US	Europe
UVA dosimetry	Predetermined dose according to skin phototype	Individualized dose according to MPD determination
Frequency of treatment	Two to three times per week	Four times per week
Dose increments	Predetermined	Individualized
Principle of approach	Rigid, cautious	Flexible, aggressive
Goal	To clear without ponderous testing and acute side effects	To clear rapidly before maximum pigmentation develops

Table 134.4 Differences between the US and European protocols for PUVA therapy. MPD, minimal phototoxicity dose.

Oral 5-MOP PUVA represents another alternative to 8-MOP PUVA. Psoriatic lesions clear with a comparable number of exposures, but 5-MOP requires significantly higher cumulative UVA doses (Fig. 134.13). This is due to the lower phototoxic potential of 5-MOP and to its greater tanning activity. Nevertheless, 5-MOP PUVA therapy seems particularly valuable because of the absence of nausea and vomiting, and the lower incidence of pruritus and severe phototoxic skin reactions.

PUVA alone can produce a definite remission in many cases of psoriasis, but a considerable number of patients require combination therapy (see below).

Combination Treatments

Topical combination

As with UVB phototherapy, PUVA can be combined with other treatment modalities to improve efficacy and to reduce potential side effects[2]. Topical adjuvant therapies include corticosteroids, anthralin and tar, and, more recently, calcipotriol and tazarotene (see Chs 125, 126 &

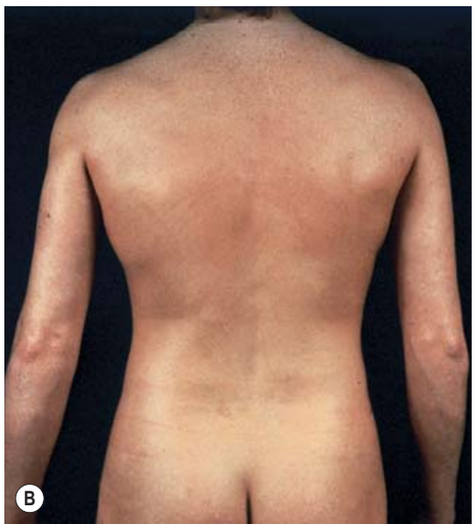

Fig. 134.13 PUVA treatment for psoriasis (5-MOP; four times weekly). A Before treatment. **B** After 6 weeks of treatment.

129). However, some patients are reluctant to "retry" topical agents that previously proved unsuccessful when used alone.

Methotrexate, cyclosporine, bioengineered immunomodulators

The combination of PUVA and methotrexate (MTX) during the clearing phase reduces the duration of treatment, number of exposures, and cumulative UVA dose, and is also effective in clearing patients unresponsive to PUVA or UVB alone[56]. If used for long-term treatment, this combination might be potentially hazardous because PUVA and MTX could act synergistically in the development of skin cancers[23]. However, to date, no increased risk of non-melanoma skin cancer has been reported for this combination. In contrast, cyclosporine plus PUVA has been clearly shown to dramatically enhance skin carcinogenesis. Thus, this combination should be categorically discouraged[57], including the use of cyclosporine subsequent to PUVA therapy. Presently, there are no studies evaluating the safety and efficacy of the combination of any bioengineered immunomodulators ("biologics") with PUVA.

Retinoids

The combination of PUVA with systemic retinoids (RePUVA) is one of the most potent therapeutic regimens for psoriasis. The therapeutic efficacy of PUVA therapy is significantly enhanced upon daily combination with oral retinoids (acitretin, isotretinoin) (0.75–1 mg/kg for etretinate and isotretinoin, 0.5–0.75 mg/kg for acitretin) administered for 5–10 days before PUVA is started, with the combination continued throughout the clearing phase. RePUVA reportedly can reduce the number of exposures by one-third and the total cumulative UVA dose by more than one-half. RePUVA can also clear "poor PUVA responders"[2].

The underlying mechanism of the synergistic action of retinoids plus PUVA may be a reduction in the inflammatory infiltrate and an accelerated desquamation of the psoriatic plaques, thereby optimizing the optical properties of the skin. In theory, retinoids may also reduce the long-term carcinogenic risk of PUVA by reducing the number of exposures and providing chemoprevention against skin cancers. Some evidence for this was presented in a study where patients with psoriasis treated with PUVA in combination with systemic retinoids showed a reduced risk of SCC but not a significantly altered incidence of BCC[58].

Short-term side effects of retinoids are completely reversible upon discontinuation, and long-term toxicity is not relevant because of the limited duration of their use (until clear). The potential teratogenicity of retinoids represents a serious concern. For women of childbearing age, the use of isotretinoin is an option, because contraception is only necessary for 1–2 months after discontinuation of therapy, as opposed to acitretin, which requires at least 2 years of contraception[2].

PUVA for Cutaneous T-Cell Lymphoma, in particular Mycosis Fungoides

Based on the empirical beneficial effect of natural sunlight on early stage MF, Gilchrest et al.[59] first reported the successful use of PUVA for MF. Patients with unsatisfactory responses to other therapies and histologically confirmed plaque or tumor stage MF or the erythrodermic form of CTCL were subjected to PUVA. Complete clearing was observed, except in those areas that were shielded from UVA exposures, thus excluding the possibility of spontaneous remission. This also indicated that the therapeutic effect of PUVA was local rather than systemic.

Numerous studies followed which addressed the rates of initial response and average duration of remission in relation to the stage of MF, the efficacy of PUVA compared with other established treatment options, the efficacy of combination treatments, the mechanisms responsible for the therapeutic effects, and the risk of short- and long-term side effects[2].

Treatment schedules and dosimetry in the photochemotherapy of MF are essentially the same as for psoriasis, consisting of three phases – clearing, maintenance and follow-up. Some authors suggest that remission should be confirmed by histologic examination of previously involved areas. In some institutions, maintenance therapy includes two exposures per week for one month and one exposure per week for another month. If still in remission, therapy is discontinued and the patient is monitored monthly and then bimonthly. If a relapse occurs, the patient is again treated with three or four PUVA exposures per week until complete clearing. However, some investigators advocate permanent maintenance treatment consisting of treatments once monthly or every other month, as it appears that PUVA treatment is not curative. Since the course of MF varies considerably from patient to patient, the final answer remains to be determined. Clinical experience indicates that patients benefit most from individualized schedules.

Several studies involving large patient cohorts have provided information on the initial response rates of PUVA treatment in relation to disease stage. Overall, the best initial complete response rates were obtained for stages IA (~90%), IB (~76%) and IIA (~78%), as compared to stages IIB and III (~60%). There was some heterogeneity in results and the use of different treatment protocols, psoralen preparations and light sources may have contributed to this finding. Only a few patients with stage IV disease have been treated with PUVA monotherapy, because, in this stage, PUVA is generally considered to be only a palliative or adjunctive therapy.

The long-term outcome is strictly dependent on the relapse rates and the mean disease-free intervals. In the first follow-up study of 44 PUVA-treated patients, 56% (5/9) with stage IA disease and 39% (10/26) with stage IB disease remained in remission during a mean follow-up period of 44 months[60]. Patients who experienced relapses had mean disease-free intervals of 20 months for stage IA and 17 months for stage IB. All patients (7/7) with stage IIB disease had multiple recurrences[60]. In a second study of 82 patients with a median follow-up period of 43 months, 53% in stage IA, 37% in stage IB, 50% in stage IIA, and the only one in stage IVA did not develop recurrences after complete

Fig. 134.14 PUVA treatment for cutaneous T-cell lymphoma (mycosis fungoides) (8-MOP; four times weekly). A Before treatment. **B** After 12 weeks of treatment.

clearing. One stage IIB patient and two of six stage III patients initially cleared, but they all eventually relapsed[61].

Relapses usually respond to PUVA in the same manner as the initial response. Clinical remissions appear to be directly related to phototoxic destruction of the malignant infiltrate. Thus, complete clearing may be induced when the cells are confined to the epidermis and the superficial dermis and do not exceed the depth of UVA penetration into the skin. Patients with tumor stage MF exhibit a high rate of early recurrences, which require permanent maintenance treatment; often only the combination of PUVA with local radiotherapy and/or systemic chemo-immunotherapy can result in complete tumor resolution[60].

In summary, the data thus far indicate that PUVA is an excellent treatment option for early stage (IA–IIA) CTCL (Fig. 134.14). High rates of complete clearing can be achieved and a substantial percentage of patients remain free of disease for many years. In advanced stages (IIB–IVB), PUVA is not sufficient as monotherapy, but as adjunctive treatment it can reduce the tumor burden in the skin and can improve the quality of life for patients. Presently, no therapeutic regimen is known to arrest eventual progression of advanced stages of MF to tumor formation, dissemination and fatal outcome. Prolonged remissions have been observed with combinations of PUVA with first- or second-generation retinoids, bexarotene[62] or interferon-α-2a[63,64]. Possible long-term side effects related to frequent PUVA treatments are probably less meaningful for patients with CTCL compared with patients with benign conditions.

While PUVA therapy is very effective in inducing remission as long as the lymphoma is confined to the skin, the impact of this therapy on the natural course of CTCL and on patient survival is not yet determined. However, data from Sweden have shown a significant drop in the death rates of CTCL patients since the introduction of PUVA[65].

PUVA for Vitiligo

As mentioned above, vitiligo was the first disease treated with an ancient form of psoralen photochemotherapy in India and Egypt. PUVA in its modern form stimulates melanogenesis, melanocyte proliferation and migration, and reconstitutes the normal skin color in more than 50% of vitiligo patients.

Treatment protocols and results

Oral 8-MOP and TMP are the photosensitizers most frequently used, followed by exposure to sunlight or artificial UVA radiation. A large, controlled clinical trial by the Harvard group provided detailed information regarding different treatment schedules. Also, 5-MOP was used in a large trial in India and is used in Europe, where available, with good success[2]. To induce repigmentation, patients need constant long-term therapy. It is crucial that the patient understands that PUVA, like other vitiligo therapies, may require months or even years to achieve a satisfactory result. All too optimistic prognoses regarding therapeutic efficacy and length of time to produce adequate repigmentation should be avoided. The patients must also be aware that the treatments stimulate the pigmentation of normal skin, which will intensify the contrast between normal and vitiliginous skin.

Because of weaker phototoxicity, oral TMP is preferred to 8-MOP for treatment with sunlight as the radiation source. Treatments should be given at least twice a week, but not more than three times, with at least one day between treatments. If there is no response after 4–5 months or approximately 30–40 treatments, PUVA should be terminated. Responsiveness is defined as development of multiple perifollicular macules of repigmentation, or, in the case of small (<2 cm) lesions, contraction in size. If treatment is discontinued, reversal of acquired repigmentation may occur unless the lesion has completely repigmented. Completely repigmented areas can be stable for a decade or more without relapse[66].

Another photochemotherapeutic regimen for vitiligo consists of khellin (a furanochromone) as the photosensitizer and UVA irradiation (KUVA). Khellin is not phototoxic and exhibits substantially lower mutagenic activity than psoralens. Its efficacy and failure rate in vitiligo are comparable with PUVA[67]. The major advantage of khellin is that, given its lack of phototoxicity, it can be considered safe for home treatment or treatment with natural sunlight. The treatment schedule is the same as for PUVA; khellin is administered orally at a dose of 100 mg 2 hours before treatment or applied topically as a 5% cream. Khellin is not available in the US. With oral khellin, approximately 30% of vitiligo patients develop reversible increases in liver transaminases that remain to be explained[67]. Under special circumstances, KUVA may be considered an alternative to conventional photochemotherapy. However, the efficacy of topical KUVA in comparison with oral PUVA or other therapeutic modalities has not been established.

Photochemotherapy with topical 8-MOP can be used in patients with small lesions (less than 5% total body surface area) or in children in whom one may hesitate to use systemic PUVA. The therapy must be done in an office setting, since home treatment involves a high risk of severe phototoxic side effects. Topical 8-MOP preparations (0.01% or 0.1% 8-MOP in a cream or ointment base) are applied evenly on the treatment area 30 minutes prior to irradiation. Exposure times (beginning at ≤0.25 J/cm^2) are increased weekly in increments of 0.25 J/cm^2 unless marked erythema occurs. Once- to twice-weekly treatments are recommended. TMP and 5-MOP can also be used for topical PUVA but

are more phototoxic than 8-MOP. For topical application, the vehicle plays a major role in delivery and resulting cutaneous psoralen levels. Solutions should be avoided as they can "run", producing hyperpigmented streaks. Application of sunscreen to the surrounding uninvolved skin prior to application of the topical psoralen can reduce hyperpigmented rims.

Patient selection appears to be critically important in vitiligo treatment. For oral PUVA, the patients should be ages 10–12 years or older, and for all forms, they must be available for 12–24 months of continuous therapy. Lips, distal dorsal hands, fingers and toes, palms, soles and nipples are very refractory to treatment, as are large areas with only white hairs. Patients need to be made aware of this fact.

Stable disease, e.g. segmental vitiligo present for at least a year, is usually easier to treat. On average, a complete treatment course consists of at least 150 exposures. However, because of the different response rates in different body areas, total repigmentation is only rarely achieved, and approximately 30% of patients do not respond at all, despite months of therapy. As mentioned above, in a recent trial of non-segmental vitiligo, narrowband UVB therapy resulted in a better color match as compared to oral PUVA[15].

The mechanisms by which PUVA induces repigmentation in vitiligo remain mostly speculative. Bearing in mind the immunomodulating effect of UV radiation, one might postulate a hypothetical suppressor cell population generated by PUVA that suppresses the stimulus for melanocyte destruction.

PUVA for Atopic Dermatitis (see Ch. 12)

Many patients with moderate, severe and even erythrodermic forms of atopic eczema can benefit from PUVA therapy[56]. The treatment guidelines are essentially the same as for psoriasis. However, as compared to psoriasis, atopic dermatitis is more difficult to treat; quite often, a higher number of treatments is required. Although atopic eczema may be cleared by PUVA, recurrence rates are high and rapid, requiring frequent maintenance exposures. Due to the average patient's young age, however, long-term maintenance therapy should be avoided. A combination of PUVA with topical corticosteroids appears to be superior to PUVA alone in maintaining remissions, and in a recent study involving patients with severe atopic dermatitis, PUVA provided better short- and long-term responses than did medium-dose UVA1[68]. The mechanism of action of photochemotherapy in atopic dermatitis is unclear; current concepts support an alteration of lymphocyte function in the dermal infiltrate.

PUVA for Lichen Planus (see Ch. 11)

The beneficial effect of PUVA in lichen planus was first reported shortly after its introduction. In generalized lichen planus, PUVA can provide an effective alternative to systemic corticosteroids. Later studies pointed to an overall response rate between 50% and 90%, suggesting that lichen planus was less responsive than psoriasis to PUVA. In addition, more treatment sessions and higher cumulative UVA doses were generally necessary for complete remission and not all patients responded satisfactorily. Marked postinflammatory hyperpigmentation may impair the final cosmetic result. An exacerbation during PUVA treatment has been reported in a few patients. Bath PUVA also works in lichen planus. A combined RePUVA regimen (as is used for psoriasis) may accelerate clearing in disseminated and particularly keratotic forms of lichen planus. Compared to narrowband UVB, oral PUVA led to a better initial clinical response rate, but both were effective treatments and produced similar long-term outcomes[69]. Thus, overall, PUVA is an effective therapeutic option for extensive lichen planus; however, this disease is usually more resistant than psoriasis.

PUVA for Graft-versus-Host Disease

An indication of increasing importance may be acute and chronic cutaneous GVHD. Due to clinical and histologic similarities between idiopathic lichen planus and lichenoid GVHD, PUVA treatment was evaluated for the latter[70]. Beneficial effects were observed in patients who had not responded to conventional immunosuppressive therapy alone. PUVA can also improve acute GVHD[71]. Results of PUVA therapy for scleroderma-like variants of cutaneous GVHD are controversial. In our experience, the more localized and circumscribed morpheaform lesions appear to respond to PUVA fairly rapidly, concomitantly with softening of the associated sclerosis. However, the more advanced and widespread sclerodermoid form hardly responds to PUVA.

As opposed to other conditions, PUVA may exert not only local, but also systemic, effects, since improvement of mucosal erosions was observed during treatment of chronic lichenoid GVHD with PUVA, but this could also be mere coincidence. Apparently, there is no improvement of GVHD of other organs, e.g. liver and gut. Of note, deterioration of liver GVHD has not been reported thus far. This is important, since psoralens are metabolized by the liver.

The therapeutic regimen used for the treatment of chronic GVHD is basically the same as for psoriasis. UVA doses should not be increased too aggressively, in order to avoid erythema and possible (re)activation of GVHD. The UVA dosage is increased by no more than 0.5 J/cm^2 every second to fourth exposure, and patients are treated three to four times weekly. After clearing of skin lesions, exposures are reduced according to the maintenance schedule outlined for psoriasis.

There may be a slight overall increased risk of cutaneous malignancies in all hematopoietic stem cell recipients, but much less than in solid organ transplant patients who receive long-term immunosuppression. If patients are receiving long-term prophylactic treatment with voriconazole, switching to posaconazole should be considered in order to reduce possible enhancement of SCC formation. Serial cutaneous examinations are recommended, especially in those who have received PUVA and are of fair complexion.

PUVA for Urticaria Pigmentosa (see Ch. 118)

PUVA causes a temporary involution of cutaneous mastocytosis[72,73]. The treatment results in loss of Darier's sign, relief of itching, and flattening and sometimes even complete disappearance of cutaneous macules and papules. Surprisingly, even systemic symptoms such as histamine-induced migraines and flushing fade gradually as treatment is continued[72]. In most patients, the manifestations of the disease recur several months after discontinuation of PUVA. The recurrences respond as well as the original lesions, and complete clearing of signs and symptoms can again be achieved. In children, PUVA is also often helpful, and appears to be justified in widespread, disabling mastocytosis. To avoid sudden mediator release from mast cells, a PUVA regimen of gradually increasing doses, especially during the initial phase, seems advisable, although the therapy should otherwise be undertaken according to the usual guidelines.

PUVA for Miscellaneous Dermatoses

Both acute and chronic *pityriasis lichenoides*[20] respond to photochemotherapy and favorable results have been reported for *lymphomatoid papulosis*[20,74]. Nevertheless, the experience with these conditions is limited to a few anecdotal cases. In *pityriasis rubra pilaris*, the results are quite inconsistent. Some patients seem to respond well[20], while others may flare and some require combination treatment with retinoids or methotrexate. Generalized *granuloma annulare* has been reported to clear completely, but long-term maintenance treatment was required to maintain remissions[75]. Regrowth of hair was described in *alopecia areata* (with either topical or systemic PUVA) in which exposures were localized to the alopecia areas. There was a great variation in the number of treatments required for regrowth, and circumscribed lesions responded better than did total alopecia. However, follow-up studies of larger patient groups concluded that PUVA is generally not effective in alopecia areata[76,77], which is in accordance with our own experience. *Localized scleroderma* and *pansclerotic morphea* have been successfully treated with bath PUVA and oral PUVA[78,79].

PUVA for Photodermatoses

Tolerance to sunlight can be induced in several photodermatoses with PUVA[80]. In *polymorphic light eruption* (PMLE), the most common photodermatosis, PUVA is a very effective preventive treatment (via hardening)[81]. In approximately 70% of patients with this condition, a 3- to 4-week course of PUVA suffices to suppress the disease upon subsequent exposure to sunlight. The initial exposure and dose increments should be performed according to the guidelines outlined for psoriasis. PUVA induces pigmentation rapidly and intensively at relatively low (suberythemogenic) UVA doses that usually remain well below the threshold doses for eliciting the PMLE. About 10% of the patients develop typical lesions during the initial phase of PUVA.

Interruption of treatment or reduction in the UVA dose is rarely required in such cases. Usually, brief symptomatic treatment with topical corticosteroids suffices.

PUVA hardening is indicated in selected patients with severe PMLE whose disease cannot be prevented with the use of sunscreens or UVB phototherapy. Treatment is given three times weekly over a period of 4 weeks in the early spring. Both 8-MOP and 5-MOP can be used as photosensitizers; however, 5-MOP is preferable because of better tolerability and higher pigment potential. The PUVA therapy protects only temporarily, and regularly repeated sun exposures are subsequently required to maintain protection. However, a considerable number of patients remain protected for 2 to 3 months, even after pigmentation has faded.

The mechanisms by which phototherapy induces tolerance to sunlight are not clear. Hyperpigmentation and thickening of the stratum corneum may be important factors for this protective effect. However, other mechanisms may also be involved, since PMLE does occur in darkly pigmented individuals and even patients with skin type I who do not tan profit from hardening. Modulation of cutaneous immune functions is a possible explanation.

The therapeutic value of preventive photochemotherapy for PMLE has to be balanced against its potential long-term side effects. Given the fact that very few treatments and low cumulative UVA doses (ranging from 15 to 40 J/cm^2 per treatment course, depending on skin type and photosensitizer) are required for photoprotection and that PMLE can severely impair patients in their outdoor activities, PUVA treatment of PMLE is justified when other preventive measures (e.g. antimalarials) fail[81].

There is also some experience with PUVA prophylaxis of other photodermatoses. In *solar urticaria*, PUVA therapy appears to be the most effective preventive treatment available and it is certainly better than antihistamines[82]. Tolerance to sunlight can be increased 10-fold or more after a single treatment course. The suppressive effect may last throughout the summer, depending on regularly repeated sunlight exposures. Problems may occur during the first several PUVA exposures, since in some patients the urticaria threshold dose appears to be lower than their MPD. In these cases, stepwise UVA irradiation of single quadrants of the body a few hours before each PUVA treatment has proven useful[82]. PUVA is then administered during the refractory period.

Successful photochemotherapy has also been reported in occasional patients with *chronic actinic dermatitis*[83] and *hydroa vacciniforme*[84]. Limited experience in patients with *erythropoietic protoporphyria* indicates that, with a very cautious approach and in combination with β-carotene, PUVA may increase light tolerance considerably[85].

Side Effects and Long-Term Hazards of PUVA

As discussed above, oral 8-MOP has a high incidence of nausea (30% of patients) and vomiting (10% of patients), and this may occasionally require discontinuation of the treatment. These side effects are more common with liquid than with crystalline preparations, probably because of higher psoralen serum levels. With 5-MOP, nausea is nearly absent, even with doses up to 1.8 mg/kg, and this is the major reason for increased usage of this compound.

The short-term side effects of the combined action of psoralens plus UVA radiation consist of redness, swelling, and occasionally blister formation as can be seen with excessive sunburns. Generalized pruritus or tingling sensations may herald phototoxic side effects. When large areas of skin are affected, systemic symptoms of excess phototoxicity such as fever and general malaise may occur. Nonsteroidal anti-inflammatory drugs and topical and systemic corticosteroids may be required to alleviate the symptoms, but have to be given early. Such overdosage phenomena are more common after topical psoralen application, because of high epidermal psoralen concentrations. Accumulation of phototoxic effects after several consecutive UVA exposures is also more common with topical PUVA.

Some patients experience persistent pruritus during PUVA treatment, particularly after slight UVA overdosage, and, in rare cases, a stinging pain may develop in circumscribed areas. PUVA-induced skin pain unrelated to actual phototoxic burns occurs rarely, but it may necessitate discontinuation of treatment. The mechanism is unknown and the symptoms are unresponsive to antihistamines. Usually, these complaints subside slowly upon continuation of treatment.

Ophthalmologic effects

Eye protection is mandatory during UVA exposure, and UVA-opaque glasses are required for ambient exposure until the evening of the treatment day. UVA penetrates into the ocular lens and potentially could induce cataracts by forming psoralen-protein photoproducts. The higher permeability of the ocular lens at a younger age led to the relative contraindication of oral PUVA in children younger than 12 years of age. Despite the experimental data indicating a risk of premature cataract formation, clinical evaluation has shown no increase in lens opacities even in patients who neglected careful eye protection[86]. Obviously, there is no risk with topical or bath PUVA.

Laboratory data

Because psoralens can cause liver damage in laboratory animals when given in excessive doses, concern was expressed in the past regarding possible hepatotoxic effects in humans. Several large-scale studies demonstrated no significant abnormal laboratory findings in patients receiving PUVA over prolonged periods of time[49,50,87]. In particular, serial laboratory examinations performed over a period of several years have not revealed any substantial evidence for an impairment of hepatic function. Liver biopsies after 1 year of therapy did not show signs of hepatotoxicity. Anecdotal case reports of hepatitis during PUVA treatment were most likely unrelated to therapy. Several large-scale studies have negated a possible relationship between PUVA therapy and the occurrence of antinuclear antibodies[88].

Potential long-term risks of PUVA

Repeated phototoxic injury to the skin can be expected to result in cumulative actinic damage regardless of whether it is induced by sunlight, artificial UV radiation or PUVA. Although the precise action spectrum of actinic damage has not been determined, epidermal changes are attributed to UVB and dermal changes more to UVA, because the latter penetrates more deeply into the skin. Thus, chronic exposure to PUVA may produce changes in the skin that generally resemble those known as dermatoheliosis and may add to the injury induced by sunlight. High cumulative doses of whole body UVB or PUVA result in pigmentary changes, xerosis, loss of elasticity, wrinkle formation and actinic keratoses. Additionally, PUVA may induce profuse formation of dark stellate lentigines (Fig. 134.15), termed PUVA lentiginosis[50]. These lentigines result from repeated and prolonged treatment and are commonly associated with high cumulative doses of UVA and a high number of treatments. So far, no increased risk of cutaneous melanoma associated with these lentigines has been recorded, but the cosmetic effect may be quite disturbing.

The major concern with prolonged and repeated phototherapeutic regimens is photocarcinogenesis. Therefore, from the onset, PUVA-treated patients were carefully monitored for the development of precursors and malignant skin tumors. Almost all data were obtained from psoriatics, since they represent the largest group of patients receiving PUVA.

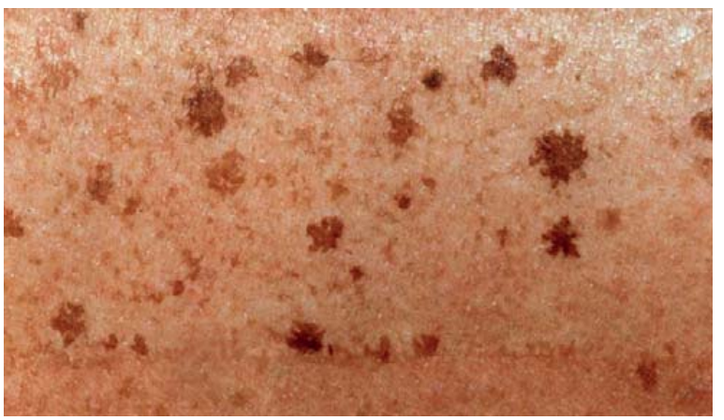

Fig. 134.15 PUVA lentigines. These develop after repeated PUVA treatments over several years.

The risk is certainly related to DNA damage, but PUVA-induced immunosuppression may play a role as well. In PUVA patients, the risk of SCC, but not of BCC, is significantly increased in comparison with matched controls, and the magnitude of the increase appears to be dose-dependent[23,89]. However, there is uncertainty regarding PUVA being the sole factor; many of the affected patients had previous exposure to excessive sunlight and to treatments with carcinogenic potential, including arsenic, UVB and antimetabolite therapy[90]. Particularly, high levels of UVB exposure appear to increase the risk of non-melanoma skin cancer in PUVA-treated patients[91]. In non-Caucasians who received long-term oral PUVA therapy, an increased risk of skin cancers was not observed[92].

According to a single study, the genitalia of male patients previously treated with tar and UVB appeared to be particularly susceptible to the carcinogenic stimuli of PUVA[93], but the risk seemed not to be increased if only PUVA were used[94]. In a retrospective study from France comprised of 5400 patients treated between 1978 and 1998, no case of genital skin cancer was found, despite the fact that the genital area had not been protected during UVA exposure, and this raises the question whether genital shielding is absolutely necessary[95]. Interestingly, no increased risk of skin carcinoma has so far been reported for patients treated with PUVA for vitiligo.

The carcinogenicity of 5-MOP PUVA is unknown, but in *in vitro* photomutagenicity and photocarcinogenicity studies in mice, the activity of 5-MOP was similar to that of 8-MOP.

Only a few anecdotal cases of cutaneous melanoma have been described in long-term PUVA-treated psoriatics, and, to date, with one exception, no increased risk of melanoma has been observed in any reported large-scale study. However, Stern et al.[96] reported on the cohort of 1380 patients enrolled in the PUVA Follow-up Study (16-center study), and, since 1975, 23 patients had developed 26 invasive or *in situ* cutaneous melanomas. Beginning 15 years after the initial exposure to PUVA, an increased risk of melanoma was observed in their cohort of PUVA-treated patients. However, the lead author concluded that perhaps PUVA has been treated unfairly. Its long-term risks have been subject to much greater scrutiny than the risks of other therapies utilized for severe psoriasis, such as methotrexate and particularly immunosuppressive therapies such as cyclosporine (CSA). Of note, several other US studies, as well as European studies, have not observed an increased risk of melanoma in patients treated with PUVA[97,98].

An increased risk of cutaneous SCC has been observed in patients with solid organ transplants who have received long-term CSA and in patients who have received CSA subsequent to PUVA therapy[57]. UVA-sparing, aggressive regimens without prolonged maintenance therapy may be safer than continuous non-aggressive regimens[99] (see Table 134.4).

In a study of 944 Swedish and Finnish patients[100], bath PUVA with TMP appeared to have no relevant risk of carcinogenesis. In addition, no association between cutaneous carcinoma and 8-MOP bath PUVA was found in 158 Finnish psoriatic patients[101]. Perhaps related to lower cumulative UVA doses, these data on the long-term safety of bath PUVA are encouraging, but no premature conclusions should be drawn. The risk/benefit ratio still seems very favorable for PUVA[102], and, so far, no single therapy, except perhaps narrowband UVB, has been accepted as equally safe and efficient.

UVB and PUVA in HIV-Infected Patients

Treatment of psoriasis with oral PUVA has not induced progression of HIV disease nor was there an increase in side effects. The conclusion is that PUVA may be safe for HIV-infected patients with psoriasis. Theoretical modeling of UVB- and PUVA-induced HIV promoter activation in human skin indicated that UVB was more likely than PUVA to activate viral transcription *in vivo*. Although further studies will be needed to unequivocally establish the safety of both UVB and PUVA phototherapy in HIV-associated psoriasis, the benefits are considerable, particularly in those with severe psoriasis[103].

EXTRACORPOREAL PHOTOCHEMOTHERAPY (PHOTOPHERESIS)

Extracorporeal photochemotherapy (photopheresis, ECP) was introduced in the early 1980s for the palliative treatment of erythrodermic CTCL[104]. Efficacy was observed in several uncontrolled clinical trials, and it was FDA-approved as a device in 1988 for the treatment of this disease. In 1994, at the International Consensus Conference on Staging and Treatment Recommendations for CTCL, ECP was recommended as the first line of treatment for patients with erythrodermic CTCL[105]. However, not all authorities agree (see Ch. 120).

Attempts to better characterize those CTCL patients who are more likely to respond to ECP revealed the following:

- There seems to be a significant linear association between response and CD4:CD8 ratio. Patients with a ratio <10 are more likely to respond than are patients with a ratio >10.
- There is a marginally significant linear association between response and LDH level. Patients whose LDH is not elevated at the start of treatment tend to have a better response to ECP compared to patients with an elevated LDH[106].

ECP has also been advocated for the treatment of chronic cutaneous GVHD as well as acute GVHD[107], in addition to acute allograft rejection in solid organ transplant recipients[108].

Treatment Protocols

The ECP procedure involves the oral administration of 8-MOP followed by passage of blood fractions from one arm vein through a photopheresis machine and then back. A discontinuous flow cell separator harvests mononuclear cells (PBMC) within a buffy coat collection. The red cell fraction is returned to the patient without further treatment. 8-MOP can also be administered directly into the collection of the PBMC, thereby avoiding 8-MOP-induced nausea. The collection of PBMC is then exposed to 2 J/cm^2 of UVA and reinfused into the patient. This treatment is typically repeated on two successive days with 2- to 4-week intervals.

Mechanism of Action

Despite the fact that ECP has been in use for almost 20 years, the mode of action still remains enigmatic. It was postulated that the response of CTCL to ECP is due to the induction of an immune response against the malignant cells. Recent experimental results suggest that infusion of autologous haptenated cells, in which apoptosis was induced by 8-MOP/UVA, induces immunologic tolerance. The nature of this tolerance is due primarily to regulatory T cells, because transfer in an animal model conferred similar protection. The demonstration of the induction of regulatory T cells may explain why, in humans, ECP exerts a beneficial effect in a wide variety of diseases which would be amenable to such activity. The generation of antigen-specific regulatory T cells may explain why generalized immunosuppression has not been noted with ECP[109,110]. Monocyte-derived immature dendritic cells may play a role.

Side Effects

Side effects of ECP are uncommon and consist of transient nausea after oral ingestion of 8-MOP and episodes of hypotension and vasovagal reflex due to volume shifts during treatments; the latter usually do not interfere with the treatment.

Other Indications

A number of studies have been performed in order to evaluate the efficacy of ECP in inflammatory diseases other than CTCL and chronic GVHD where autoreactive T cells play a key role. Uncontrolled clinical trials have revealed variable success in selected entities such as atopic dermatitis, systemic sclerosis, pemphigus vulgaris, and systemic lupus erythematosus[111,112].

Future directions 2249

Synonym: ■ Photoradiation therapy

Key features

- Over the past two decades, photodynamic therapy (PDT) has evolved into a practical and effective therapeutic option, especially for actinic keratoses and superficial non-melanoma skin cancer, with an expanding range of applications including acne, photoaging, cutaneous infections, and vascular anomalies
- The photodynamic effect is due to a photochemical reaction which requires the presence of a photosensitizing molecule, photoactivating wavelengths of light, and tissue oxygen to generate singlet oxygen
- Singlet oxygen is highly reactive and initiates a series of reactions that culminate in necrosis, apoptosis and antimicrobial death
- Target cells may undergo either apoptosis due to photosensitizer-induced membrane damage or ischemic necrosis due to vascular injury from photosensitizers concentrated within endothelial cells, or both; host immunologic responses may also contribute to the overall clinical effect
- Photosensitizers may be applied topically as pro-photosensitizers (e.g. aminolevulinic acid) that are metabolized *in situ* to photoactive porphyrins or administered systemically as intact porphyrins (e.g. verteporfin)
- An incubation period is required after drug administration to allow photosensitizer production as well as its partitioning into targeted tissue and cellular compartments
- Red or blue light is typically used to illuminate the skin and energize the photosensitizer

INTRODUCTION

Photodynamic therapy (PDT) involves the administration of a photosensitizing agent followed by its photoactivation by light which then generates singlet oxygen within biologic tissues (Fig. 135.1). Singlet oxygen is a highly reactive form of oxygen that can induce necrosis and/or apoptosis and modulates a variety of other biologic processes. During the latter part of the twentieth century, PDT was synonymous with the use of *systemic* photosensitizers in combination with red *laser* light in order to treat cancers. Although there are a number of clinical variations, nowadays for dermatologists PDT consists primarily of applying a topical photosensitizer precursor to the skin and then illuminating the treatment site with blue or red light.

HISTORY AND DEVELOPMENT

The photodynamic effect was originally studied in the early 1900s by a German medical student, Oscar Raab, who noted that cultures of *Paramecium* would die only if exposed to both an organic dye (acridine) and visible light. His professor, Dr Von Tappeiner, discovered the oxygen-dependence of this effect and coined the term "photodynamic action" to describe the phenomenon. In humans, hematoporphyrin was shown by Meyer Betz to induce profound and persistent generalized photosensitivity, beginning with when he self-injected this agent. By capitalizing on its fluorescent properties when illuminated with a Wood's lamp (365 nm), hematoporphyrin was shown in animals to localize to neoplastic tissue. Hematoporphyrin was also noted to induce tumor involution when exposed to visible light. *Hematoporphyrin derivative* was subsequently developed by Schwartz in an attempt to improve upon the tumor-localizing properties of hematoporphyrin, and then utilized by his colleague Lipson in animal models[1].
